Sustainable Food Production

Selected entries from the Encyclopedia of Sustainability Science and Technology

Springer Reference

Sustainable Food Production

This volume collects selected topical entries from the *Encyclopedia of Sustainability Science and Technology* (ESST). ESST addresses the grand challenges for science and engineering today. It provides unprecedented, peer-reviewed coverage of sustainability science and technology with contributions from nearly 1,000 of the world's leading scientists and engineers, who write on more than 600 separate topics in 38 sections. ESST establishes a foundation for the research, engineering, and economics supporting the many sustainability and policy evaluations being performed in institutions worldwide.

Sections

Animal Breeding and Genetics
Editor: Ignacy Misztal

Animal Breeding and Genetics, Introduction
Animal Breeding Methods and Sustainability
Animal Breeding, Foundations of
Animal Breeding, Long-Term Challenges
Animal Breeding, Modeling in
Animal Genetic in Environment Interaction
Animal Molecular Genetics from Major Genes to Genomics
Breeding in Beef Cattle
Breeding in Developing Countries and Tropics
Breeding in Horses
Dairy Cattle Breeding
Pig Breeding for Increased Sustainability
Poultry Breeding
Socially Affected Traits, Inheritance and Genetic Improvement

Crop Science and Technology
Editors: Paul Christou and Roxana Savin

Abiotic Stress Tolerant Crops: Genes, Pathways and Bottlenecks
Agroecological Basis for Managing Biotic Constraints
Agronomic Interactions with CO2 Sequestration
Biomass Crops for Biofuels and Bio-based Products
Biotechnology and Nutritional Improvement of Crops
Commercialisation of GM Crops: Comparison of Regulatory Frameworks
Crop Breeding for Sustainable Agriculture, Genomics Interventions in
Crop Development Related to Temperature and Photoperiod
Crop Diseases, Management and Control of
Crop Plants Transformation Methods
Crop Radiation Capture and Use Efficiency
Crop Responses to Available Soil Water
Crop Responses to Nitrogen
Crop Science and Technology, Introduction
Crop Traits: Gene Isolation
Crop Yields Around the World: Closing the Gap and Raising the Potential
Cropping Systems: Shaping Nature

Abiotic Stress Tolerant Crops: Genes, Pathways and Bottlenecks

Korneel Vandenbroucke, Michael Metzlaff
Bayer BioScience N.V, Ghent, Belgium

Article Outline

Glossary

Abiotic stress Any negative impact on a living organism caused by a nonliving factor in the environment in which the organism is present.

Biological modeling *In silico* description of a biological process to generate predictions for experimental validation.

Conventional breeding Development of new plant varieties by selection after natural reproduction.

Epigenetics The study of inherited changes in phenotype or gene expression caused by mechanisms other than changes in the DNA sequence.

Genetic engineering Development of a new plant variety through genetic modification by using recombinant DNA technology.

Phenotype Observable trait or characteristic (i.e., appearance) of an organism in a specific environment.

Phenome Collection of phenotypes of an organism in all possible environments.

Phenotyping Process of studying the phenotype.

Plant productivity Ability of a plant to produce a certain amount of biomass, either as green tissue and/or as seeds (yield).

Quantitative trait locus (QTL) Stretches of DNA that are closely linked to the genes that underlie the trait in question.

Regulon biotechnology Genetic engineering by targeting genes encoding proteins with regulatory function, often transcription factors.

Trait Characteristic of an object.

Definition of the Subject

World food and feed security is increasingly dependent on continuous crop improvement and, in particular, the development of crops with increased resistance to abiotic stresses. This economical and social challenge has attracted the global community of plant breeders and scientists and many potential solutions have been put forward. Our understanding of the response of plants to abiotic stress has significantly improved over the last year. However, abiotic stress tolerance is a complex trait that can be affected by many external factors. Abiotic stress tolerance involves many processes that are not yet completely understood and several limitations still need to be overcome. Recent advances in many areas of plant research, including phenotyping, make scientists optimistic that valuable solutions will be found to allow deployment/commercialization of plants better able to tolerate abiotic stresses.

Introduction

A growing world population with increased living standards combined with the urgent need for a more sustainable agriculture demands the development of crop varieties which are able to cope with fluctuating and adverse environmental conditions limiting plant growth and productivity, referred to as abiotic stresses [1]. Further global warming is expected to aggravate the negative impact of abiotic stresses. Low water availability (drought stress), high salinity (salt stress), and high temperatures (heat stress) are considered to be among the most threatening abiotic stresses, which can compromise up to 80% of the attainable yield [2]. New technologies for plant improvement that aim to overcome the negative impact of these stresses therefore need to be urgently identified and implemented. Abiotic stresses and their effects on plant productivity have attracted academic scientists as well as large and small Ag biotech companies. This is reflected by increasingly more publications in peer-reviewed journals (including recent issues in plant physiology

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

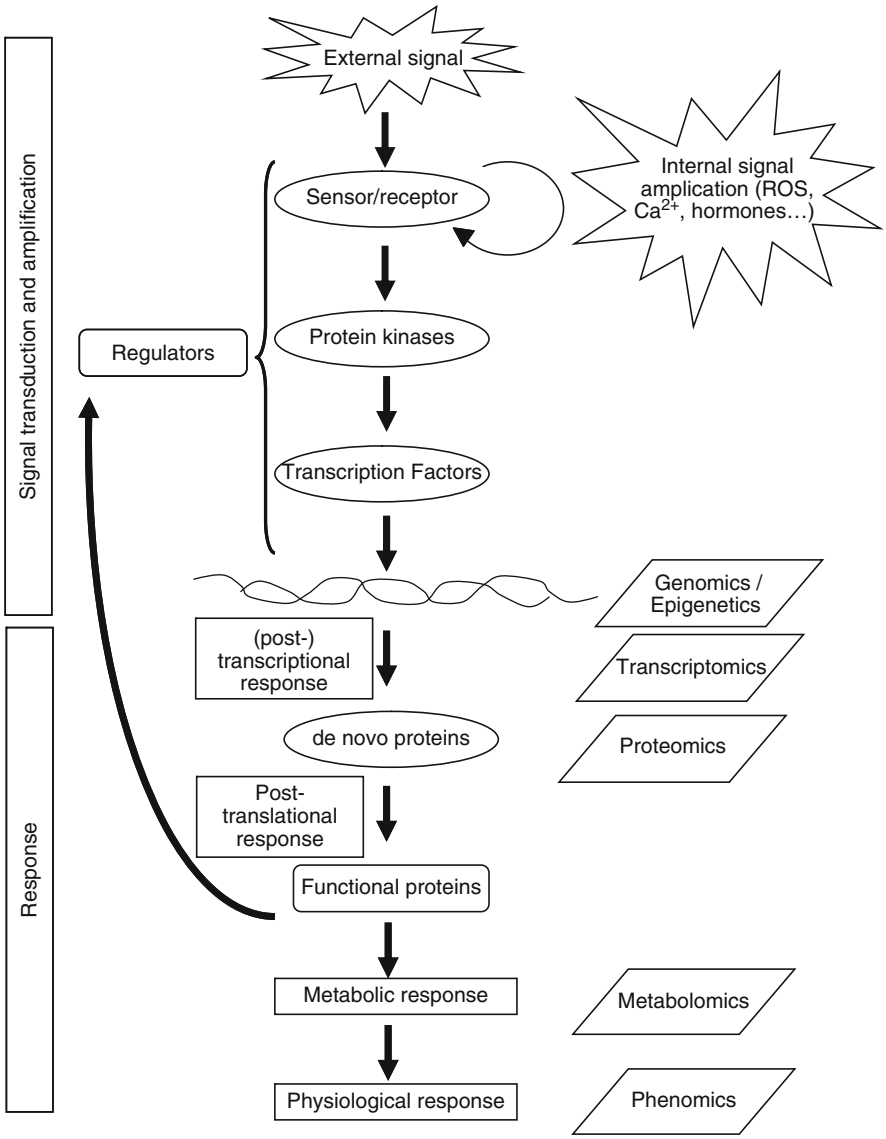
and functional plant biology dedicated to abiotic stress), online centralization of relevant information (www.plantstress.com; www.yieldbooster.org) and numerous patent applications protecting potential new solutions (Fig. 1).

Plants respond to abiotic stresses at different levels in an avoidance-tolerance mode, which includes physiological and molecular changes (Fig. 2). An important interest of plant biologists aims not only to better understand the adaptive response of plants to abiotic stress, but also to exploit this knowledge for the production of varieties that are better protected against the detrimental effects. Before the genomics era, classical or conventional breeding of plants with improved physiological characteristics was the only way to improve crop productivity. In the last 20 years, mapping of quantitative trait loci (QTL), genetic engineering, and their implementation in marker-assistant (molecular) breeding have become increasingly important [3–5]. Such genomics-based approaches rely on the identification of genes (gene discovery) that may be valuable candidates for crop improvement and were empowered by the advent of state-of-the-art molecular tools, such as DNA sequencing and expression profiling [6].

In this entry, some of the recent genomics-based advances in engineering stress-tolerant crops are summarized, existing limitations associated with these approaches are described, and some emerging trends facilitating better evaluation of crop performance in the greenhouse and in the field are outlined.

Abiotic Stress-Tolerant Crops

Plants protect themselves from the detrimental effects of abiotic stresses by increasing the expression of defense or stress tolerance genes. Plant varieties that evolved to have constitutive or high(er) expressed levels of such genes are better adapted to abiotic stress conditions. Genes with potential value for genetic engineering of stress tolerance have been ever more discovered either indirectly by genetic dissection of identified QTLs in stress-tolerant varieties, or directly through their changed expression in plants exposed to stress. Introduction of selected genes seems to be the favored way to improve plants in the future [1]. Plant



Abiotic Stress Tolerant Crops: Genes, Pathways and Bottlenecks. Figure 2
Signal transduction and response of plants to abiotic stress with the corresponding evaluation platforms

biotechnologists have been reporting genetically engineered plants with increased stress tolerance for almost 2 decades. Many genes have already been directly employed to improve stress tolerance of higher plants using a wide variety of approaches [7].

One attractive approach for engineering stress tolerance in crops has been the constitutive overexpression of stress genes from bacteria, yeast, or model plant species, such as *Arabidopsis thaliana (Arabidopsis)*. Such a heterologous gene approach worked particularly well when the genes encode proteins with single biological functions that are often absent or only expressed at low levels in the target plant. Such genes are often referred to as functional genes and can encode molecular protectants, detoxifying proteins, or ion transporters. A second group is comprised of regulatory proteins with often multiple biological functions, including enzymes involved in (phospho)lipid signaling, protein kinases, protein phosphatases, calcium/calmodulin-binding proteins,

and various transcription factors (TFs) [8]. With the emergence of large-scale genome sequencing in crops, several crop orthologues of stress genes could be identified and increasingly be used to engineer stress tolerance in crops. Here some of the approaches for engineering stress tolerance using genes involved in different cellular processes or pathways are summarized, including detoxification, protein stabilization, osmoregulation, transport, lipid metabolism, transcription and signaling, and posttranscriptional, and (post-) translational regulation. However, genetic engineering for stress tolerance in crops is not limited to these gene classes as recently shown for mustard annexin Bj1, a gene encoding a calcium-dependent phospholipid and cytoskeleton binding protein that is involved in golgi-mediated secretion, which resulted in stress tolerance when expressed in cotton [9].

Detoxifying Genes

Most, if not all, abiotic stresses induce the accumulation of reactive oxygen species (ROS), which in turn cause oxidative stress [10, 11]. ROS are extremely reactive, and therefore can undergo uncontrollable and damaging reactions with cellular components, including DNA, lipids, and proteins. This can aggravate the detrimental effects of the initial stress and can even lead to cell death [12, 13]. To protect against oxidative stress, plant cells possess an extensive ROS scavenging network, which involves nonenzymatic antioxidants, including vitamin C, vitamin E, glutathione, carotenoids, and flavonoids, as well as numerous enzymatic mechanisms such as multiple superoxide dismutases (SOD), catalases (CAT), ascorbate peroxidases (APX), glutathione peroxidases (GPX), glutathione-S-transferases (GST), alternative oxidases, and peroxiredoxines [12]. It was hypothesized that alleviation of oxidative damage by the use of ROS scavengers would enhance plant resistance. This was confirmed by a number of transgene transfers using this detoxification strategy. Stress tolerance could be improved by either direct scavenging of ROS or by enhanced removal of oxidative damaged and hazardous components accumulating in the cell. Since the accumulation of ROS and derivatives thereof is a common theme during most, if not all, abiotic stresses, the detoxification strategy enabled the generation of transgenic plants with simultaneous tolerance to multiple stresses [14–22].

In crops, enhanced stress tolerance was achieved by increasing the level of typical scavenging enzymes such as GST, different SOD isoforms, APX, and CAT [23–28]. Overexpression of a GST enzyme in rice resulted in increased protection against salt, low temperature, and oxidative stress [23]. SOD catalyzes the dismutation of superoxide into oxygen and hydrogen peroxide (H_2O_2). Transgenic rice plants expressing a manganese SOD from pea were more tolerant to drought stress [26]. Similarly, transgenic oilseed plants ectopically expressing a wheat manganese SOD were tolerant to oxidative and heavy metal stress [15]. A copper/zinc SOD was shown to be effective to protect rice plants against drought, salt, and oxidative stress [28]. Excess H_2O_2, produced either as by-product of superoxide detoxification by SOD or directly by metabolic processes, can be removed by APX, which catalyzes the reduction of H_2O_2 to water. Cotton plants with high levels of an APX isolated from pea were tolerant to low temperature stress [24]. Because of their complementary functions (i.e., removal of superoxide and H_2O_2), also the combination of SOD and APX resulted in enhanced stress tolerance [27]. As APX, also CAT protects plants from toxic H_2O_2 molecules. Hence, expression of a wheat CAT enzyme in rice protected these plants against low temperature stress by reducing the levels of H_2O_2 [25].

Engineering tolerance to oxidative stress is not limited to the use of the traditional ROS detoxifying enzymes. Significant improvement of stress tolerance in tobacco plants was achieved by overexpressing a stress-responsive aldehyde dehydrogenase gene from maize [29]. Recently, it was also shown that ectopic expression of the cotton stress-responsive MT3a gene in tobacco increased tolerance to salt, drought, and low temperature [30]. MT3a belongs to the metallothionein family that has numerous cellular functions including the regulation of metal homeostasis and oxidative stress. Another gene that can protect plants from abiotic stress-induced ROS is the mitochondrial alternative oxidase (AOX), the terminal oxidase in the alternative respiratory pathway of plants [31]. For example, tobacco AOX1a is necessary

for survival against oxidative stress when the cytochrome pathway is dysfunctional [32].

Protein Stabilization by Molecular Chaperones

One major detrimental effect of abiotic stresses is that they usually cause protein dysfunction through denaturation and aggregation of nonfunctional or aberrant proteins. Maintaining proteins in their functional conformation is therefore important for cell survival under stress. This can be accomplished, for example, through transcriptional induction of genes encoding heat shock proteins (HSPs, [33]). HSPs control the correct folding and conformation of both structural (e.g., cell membrane) and functional (e.g., enzymes) proteins. This important function has prompted researches to create transgenic lines with increased HSP levels. Studies on HSP proteins in plants have mostly focused on heat stress [34–42]. Although most of the evidence is limited to *Arabidopsis*, the protective capacities of HSP proteins and their potential economical value for crop engineering for heat stress tolerance was proven in tomato [42]. Recently, it was demonstrated that constitutive expression of a cotton HSP, GHSP26, enhanced drought tolerance in transgenic cotton plants [43].

In addition to HSPs, also LEA-type proteins can confer molecular protection of cellular components during abiotic stress [44]. LEA-type proteins are encoded by RD (responsive to dehydration), ERD (early responsive to dehydration), KIN (cold inducible), COR (cold regulated), and RAB (responsive to abscisic acid) genes in different plant species [45, 46]. As HSPs are typically induced by high temperatures, LEA proteins accumulate in response to dehydration (drought, osmotic, and/or cold stress). The actual functions of these proteins remain however largely unknown. Their hydrophilic nature suggest that LEA proteins act as water-binding proteins, but additional functions, including ion sequestration and protein and membrane stability, have also been proposed [47, 48]. Few examples for the use of LEA proteins to engineer stress tolerance in crop exist. Increasing the levels of endogenous LEA3 through genetic engineering of rice made these plants more tolerant to drought stress [47]. Ectopic expression of barley HVA1 in oat resulted in enhanced salt and osmotic stress tolerance [49].

Osmoregulation and Protection by Genes Involved in Metabolite Biosynthesis

Plants respond to drought stress by producing organic compounds to avoid water loss from cells (dehydration) and damage to essential components (osmotic stress). Therefore, one of the earliest approaches for genetic engineering of stress tolerance in plants (reports dating from the early 1990s) consists in enhanced synthesis of such metabolites, called osmoprotectants [50, 51]. Osmoprotectants include sugars and sugar alcohols (e.g., mannitol, trehalose, and galactinol), amines (e.g., polyamines and glycine betaine), and amino acids (e.g., proline) [52, 53]. These molecules normally do not interfere with cellular functions and are therefore often referred to as compatible solutes. Many plant species lack the ability to synthesize the special osmoprotectants that naturally accumulate in stress-tolerant species. Therefore, several transgenic approaches to increase the synthesis of osmoprotectants used bacterial biosynthetic genes, such as CodA and BetA (glycine betaine), MtlD (mannitol), and genes from the ectoine or trehalose biosynthesis operon [54–59]. Alternatively, key biosynthetic genes, including betaine aldehyde dehydrogenase and choline monooxygenase (glycine betaine biosynthesis), and pyrroline carboxylate synthase (proline synthesis), were isolated from specific plant species, such as *Vigna aconitifolia* and *Spinacia oleracea* and used to induce drought and salt tolerance in wheat and rice respectively [60, 61]. Although the accumulation of compatible solutes during stress is mainly important for osmoregulation and for maintaining correct protein structures, this may also be important for reducing or preventing the damaging effects of ROS [62, 63].

Transport Proteins

Ion transport proteins are involved in reestablishing ionic homeostasis after salt stress either by increasing ion storage in the vacuole, or by improving ion excretion from the cells [64]. Different types of ion transporters, depending on their localization and selectivity, have been the target of genetic engineering. These include both vacuolar and membrane Na^+/H^+ antiporters, vacuolar Ca^{2+}/H^+ antiporter, and Mg^{2+}, Na^+/K^+, and Ca^{2+} transporters [43, 64]. Known salt stress tolerance genes encoding ion transporters

isolated from crops include NHX1 (rice), KAT1 (rice), and HKT1 (wheat) [65–67]. Plasma membrane cation/proton antiporters cause alkalinization of the apoplast, thereby changing the activity and conformation of membrane proteins, which might serve as a signal to mediate gene regulation and induce a general stress response [68]. Besides using ion transporters to induce tolerance to salt stress, tolerance to osmotic stresses was engineered by increasing the levels of proteins involved in water transport [69]. Tolerance to heavy metal stress was achieved by constitutive expression of heavy metal transport proteins, including wheat ALMT1 [70–72].

Lipid Metabolism

Adaptation of living cells to low temperatures involves alterations in the membrane lipid composition, for example, by decreasing membrane fluidity through fatty acid unsaturation. It was demonstrated that increasing the number of unsaturated fatty acids by genetic engineering could improve stress tolerance in plants [73–77]. Overexpression of a spinach glycerol-3-phosphate acyltransferase (GPAT) in rice increased tolerance to low temperature whereas downregulation of a fatty acid desaturase in rice increased tolerance to high temperatures [73, 78]. Upon overexpression, tomato GPAT also increased the tolerance of tomato plants to low temperature stress [76].

Stress Sensing and Signal Transduction

The first and probably most important step in the response of plants to abiotic stress is the sensing or detection of the external stimuli by receptors, typically located in the cellular membranes. The identification of important stress receptors has been a difficult challenge and until recently, there was no report on their use in engineering stress tolerance. Overexpression of *Arabidopsis* membrane-bound receptor-like protein kinase 1 and a membrane located calcium/calmodulin-binding receptor-like kinase from soybean in transgenic *Arabidopsis* resulted in enhanced plant tolerance to drought and salt stress, respectively [79, 80]. In rice, overexpression of SIK1 resulted in higher tolerance to salt and drought stresses [81]. Other receptors operate in the cytosol and react to internal stimuli that amplify abiotic stress signals, such as calcium and ROS, as well as various hormones and other small molecules. The best-studied stress hormone is abscisic acid (ABA), which is involved in stomatal closure and plays a crucial role in tolerance against drought stress by preventing transpiration and water loss from stomata [82]. ABA also has an essential role in activating signal transduction pathways involved in tolerance to drought, cold, and salt stress. Recently, an important ABA receptor protein family has been identified [83, 84].

Stress receptors or sensors transduce external and internal signals into an intracellular response, for example, through phosphorylation and dephosphorylation cascades controlled by protein kinases and phosphatases. Genes encoding protein kinases were successfully exploited to engineer stress-tolerant crops. Modification of normal endogenous levels of GSK1, SAPK4, CDPK7, CIPK03, CIPK12, and CIPK15 in rice protected the plants against various abiotic stresses, including drought, salt, and low temperature stress [85–88]. Expression of tobacco mitogen-activated protein kinase, NPK1, in maize resulted in drought and low temperature stress tolerance [89]. Constitutive overexpression of a stress-inducible small GTP-binding protein PgRAB7 from *Pennisetum glaucum* enhances abiotic stress tolerance in transgenic tobacco [90].

Transcriptional Regulation

In the last decade, the most widely used and probably most important strategy for engineering abiotic stress tolerance in plants relied on the expression of genes that are involved in signaling and regulatory pathways [91, 92]. The use of TFs for tailoring stress tolerance is often referred to as regulon biotechnology because it affects the expression of many target genes in parallel [93, 94]. One of the reasons for their popularity is that TFs are believed to mediate durable tolerance to multiple stresses. Most TFs that control stress tolerance in plants belong to (large) protein families based on the presence of common DNA binding motifs and selectivity toward certain cis-regulatory elements in the promoters of target genes. These families include APETALA2/ ethylene responsive element binding proteins (AP2/EREBP) such as ethylene responsive factors (ERF), the DREB/CBF (drought-responsive element binding/cold-responsive element binding factor) proteins, basic domain leucine-zipper (bZIP) proteins

such as ABFs (abscisic acid (ABA)-responsive element binding factor), basic helix-loop-helix proteins (including MYC proteins), NAC (petunia NAM *Arabidopsis* ATAF1/2, and CUC2-domain) proteins, MYB-related proteins, as well as different families of zinc-fingers domain-containing proteins, such as WRKY binding factors, C_3H- and C_2H_2-type TFs. In recent years, many excellent reviews have been published on the role and use of TFs for engineering of stress tolerance in plants [48, 93–96].

Many AP2/EREBP–type TFs, the best studied being DREB/CBF proteins, have been used to engineer stress-tolerant crops. Transgenic rice plants with higher levels of CBF1/DREB1B and CBF3/DREB1A were more resistant to drought, salt, and low temperature stress [97]. A similar approach with CBF15 and CBF17 in oilseed and NF-YB2 in maize resulted in increased tolerance to low temperature and drought stress, respectively [98, 99]. Potato plants with increased levels of endogenous EREBP1 were more tolerant to salt stress and low temperatures [100]. Ectopic expression of the soybean ERF3 gene in transgenic tobacco plants gave tolerance to drought and salt stress [101]. Similarly, ectopic expression of an *Arabidopsis* AP2/ERF TF, HARDY, in rice also induced tolerance to drought and salt [102]. Expression of TERF1 in rice regulates expression of stress-responsive genes and enhances tolerance to drought and high salinity [103].

However, not only the AP2/EREBP-type TFs have been exploited to engineer stress-tolerant crops. For example, in rice, it was shown that constitutive expression of proteins from various other TF types, including bZIP23, zinc-finger protein 245, TIFY11, MYB3R-2, IRO2, NAC6, SNAC1, and PF1 TFs, could induce tolerance to drought, salt, low temperature, and nutrient deficiency [104–111], and the rice dst mutant, DST encoding a novel C_2H_2-type TF, showed increased tolerance to drought and salt [112]. In tomato, ectopic expression of rice MYB4 and pepper PIF1 induced low temperature and drought stress tolerance, respectively [113, 114]. Also in tomato, constitutive expression of SlAREB, a bZIP TF with affinity for ABA-responsive elements, increased tolerance to drought and salt stress [115]. Ectopic expression of cotton ZFP1, encoding a CCCH-type zinc-finger protein, and rice ZFP177, an A20/AN1-type zinc finger, enhanced stress tolerance in tobacco [116, 117].

Posttranscriptional and (Post-)Translational Regulation

Posttranscriptional control of stress gene expression is mediated by proteins that are involved in splicing, export, and degradation of gene transcripts, which contributes to correct function of the encoded proteins. In the last years, it has become evident that nonprotein coding RNA molecules, including microRNA and other small RNA molecules, play a very important role in posttranscriptional regulation of plant stress responses [118]. miRNA-mediated posttranscriptional control of antioxidant gene expression seems very important in plants, as shown for APX during programmed cell death and drought stress, and for Cu/Zn SOD during tolerance against oxidative stress [21, 119, 120]. ROS-induced stabilization of SOS1 mRNA transcripts is essential for SOS1-dependent salt tolerance [68].

Several genes that encode proteins involved in RNA processing were discovered to be involved in stress tolerance processes [121–125]. In addition, also proteins that control translation (deoxyhypusine synthase, DHS), posttranslational modification (peptide methionine sulfoxide reductase, PMSR4), and protein degradation (SDIR1) are interesting candidates for engineering stress tolerance in plants [126–128]. However, the above examples resulted only from *Arabidopsis* research and much less information on the importance of such processes is available for crops. Recently, it was shown that transgenic rice plants with increased levels of methione sulfoxide reductases, MSRA and MSRB, are more tolerant to salt stress [129]. Two other approaches were reported to work in both *Arabidopsis* and oilseeds. Wang and coworkers (2005) reported that loss-of-function of farnesyl transferase (FTA and FTB) increased tolerance to drought stress [130]. Similarly, reduction of poly-ADP-ribose polymerase (PARP) activity improved drought tolerance by increasing energy use efficiency [131]. PARP is involved in the modification of nuclear genes, such as histones. Downregulation of PARP resulted in the deregulation of the expression of genes in response to stress [132]. Processes that control stress tolerance and general fitness of plants in the field, such as energy use efficiency, can even be controlled by an epigenetic component [133]. By starting with an isogenic canola line,

Hauben and coworkers could separate in subsequently selfed generations "good" and "bad" performing plants, which only differed in epigenetic parameters but remained genetically identical.

All these examples show that the plant response to abiotic stress is not only dependent on transcriptional changes, but also on RNA processing, translation, post-translational processes, and epigenetics, which are nearly unexploited until today. The lack of understanding these processes is a limiting factor in engineering stress tolerance in crops.

Limitations of Genetic Engineering for Stress Tolerance

Because conventional breeding is a very time-consuming process, genetic engineering is now an important technology for many commercial applications aiming at plant improvement [1]. Today this mainly includes the production of plants with engineered herbicide or insect tolerance. However, it has been and still is extremely challenging to progress engineered plants with reported abiotic stress tolerance from research to field applications for farmers [134]. The main factors hampering the production of commercial solutions for the abiotic stress-related problems in agriculture are related to: (1) the availability of sequence information and transformation protocols, (2) the genetic diversity between model species and crop, (3) the multigenic character of stress tolerance, (4) the definition of stress tolerance and (5) the methods for the evaluation of stress tolerance [53, 135].

The first requirements for genetic engineering of plants include the availability of sequence information and transformation protocols. This important information is still lacking for many agricultural crops. For long time, this has limited (academic) research to model plant species. Although the use of model species such as *Arabidopsis* has proven its value, the genetic diversity within higher plants is the main factor that limits translatability of results obtained in model species into commercial crops. Even in those cases where the research is conducted in a more closely related model crop, it remains to be a challenge to translate the results into genetically diverse elite varieties used for commercialization.

Another factor limiting translatability from model species to crops is the complex, multigenic character of stress tolerance mechanisms. Despite the use of single genes for engineering stress tolerance, efficient and sustainable stress tolerance requires the cooperative action of many genes that are involved in various cellular processes that are not completely understood. Due to the initial success of transcriptomics, it has been accepted for long time that responses to abiotic stresses were almost exclusively regulated at the transcriptional level by a small set of core transcription factors. However, it is now clear that many other regulatory processes such as posttranscriptional control, translation, posttranslational, and epigenetic effects play an important role. In addition, some of these processes might not always be evolutionarily conserved but rather genetically diverse.

The early availability of the full genome sequence and many molecular analysis tools has turned *Arabidopsis* into the primary model species of choice for academic research in general, and for studying the response of plants to abiotic stresses in particular. However, the methods for evaluation of stress tolerance using *Arabidopsis* plants grown in a laboratory environment and agricultural crops in the field can be quite diverse. From an agronomic point of view, it is more relevant to study the effects of abiotic stresses on plant growth and yield over longer periods which cover the life span of a crop under field conditions. Appropriate field tests are therefore highly important because they allow studying plants in their natural environment in which they are exposed to combination of multiple stresses or cycles of the same stress [136]. In contrast to the field situation for crops, most studies on abiotic stress in *Arabidopsis* focus on short-term and strong stress treatments. Therefore, evaluation of stress tolerance is often focused on survival which is easier to screen. In contrast, yield-related traits are more difficult to measure but much more important for crops. Abiotic stress tolerance of crops should therefore be defined as the potential to produce high yields when exposed to mild(er), multiple stresses instead of the ability to survive a single, lethal stress.

Another limiting factor for successful field applications of plants with engineered protection against stress is the seemingly mutual exclusive characteristic of high

yield under normal conditions and high stress tolerance. Most reported experiments focused either on abiotic stress tolerance or on yield rather than including detailed analysis of both traits. More in-depth analysis of stress-tolerant plants under "normal" conditions often revealed a negative effect on growth, development, and yield traits. On the other hand, engineered plant with improved growth features, for example, by boosting a metabolic process, can be less adapted to maintain growth under abiotic stress conditions. Negative effects, often referred to as yield penalty, can be (at least partially) circumvented by temporally and spatially controlled expression of the target gene [137]. However, the availability of suitable promoters is still limited. Improved sequencing and bioinformatic tools for identification and construction of promoters allowing the expression of genes in a spatially and temporally controlled manner can overcome this bottleneck.

Phenotyping experiments with a set of genetically defined plants are often difficult to repeat because plants are largely influenced by the environment in which they grow. In fact, growth and yield (i.e., performance) of a plant under normal or stress conditions is the output of all integrated physiological processes in the plant. It is therefore not surprising that different laboratories often obtain different results for plant performance [138]. More effort is needed to describe and standardize the design of the experiments, of protocols for measuring traits, and of the growing conditions. Different methods to evaluate stress tolerance in *Arabidopsis* and a conceptual framework for phenotyping during breeding for drought tolerance have already been proposed, including defining the minimal information needed for carrying out a drought stress experiment [139, 140]. Improved and systematic phenotyping of plants will greatly contribute to overcome the limitations associated with the methods to evaluate stress tolerance.

Systematic Phenotyping of Plants

In the last decades, it has become clear that there is a substantial need for automation of research processes [141]. Automation not only allows increasing throughput, but also ameliorates standardization, reproducibility, and therefore the overall quality of an experiment. Automation increases the research value and also reduces "cost to practice" for companies aiming to apply the research findings toward the development of a superior and sustainable product. It can therefore be assumed that automation will help to improve the translation of research findings into valuable products for the customer.

Plant research has already embraced the development of high-throughput screening experiments that were used for drug or herbicide discovery. Such experiments focused on assessment of certain molecular function. Next to these screens, also high-content screening protocols were developed to asses such molecules in a biological assay. Although these technologies have proven value for single trait discovery, the efficient development of plants with complex, multifactorial traits such as increased tolerance to abiotic stresses is fully dependent on protocols and methods to automatically phenotype at the plant level. The performance of whole plants is assessed by studying their physiology or phenotype in tissue culture, environmentally controlled growth chambers, greenhouse, or the field. Various methods for automated phenotyping of plants or plant parts in well-defined environments have been published [141]. After the establishment of genomics, transcriptomics, proteomics, and metabolomics in plant sciences, which all greatly contributed to gene or lead discovery in the field of abiotic stress, plant phenomics needs to be developed and implemented [142–144].

Plant phenomics is expected to enable the efficient and reliable evaluation of a new trait solution and thereby enhance breeding for stress-tolerant varieties. Large, dedicated plant phenotyping centers such as the ACPFG in Adelaide (Plant Accelator™; http://www.plantaccelerator.org.au/), the CSIRO Plant Industry in Canberra (High Resolution Plant Phenomics Centre; http://www.plantphenomics.org.au/HRPPC), or the Research Centre in Jülich (Jülich Phenomics Centre; http://www.fz-juelich.de/icg/icg-3/jppc/) have been created. These research institutions can act as service providers for academia and industry by centralizing both high-tech infrastructure and highly skilled researchers with different background, including engineering, mathematics, computer science, and plant physiology/biology. An important biological question that probably can be answered by automated

phenomics studies is which phenotypes or combination of multiple phenotypes need or do not need to be collected in order to be able to correctly evaluate plant performance in the environment of interest. Moreover, parallel phenotyping of plants in one or multiple environments allows detection of associations between traits [145]. Identification of redundant information from (highly) associated phenotypes will help to reduce complexity and focus on essential phenotypes.

Well-described examples of automated platforms from academia or private companies to study the phenotype of model plants or crops include phenopsis, phenodyn, GROWSCREEN, TraitMill^{TM}, PlaRoM, and various LemnaTec products. Phenopsis is a phenotying platform for *Arabidopsis* that allows measuring multiple parameters, including plant growth, water use, and transpiration rates, which are associated to plant performance under normal and drought stress conditions [146]. Phenodyn was specifically constructed to perform similar experiments with monocots such as maize and rice [147]. GROWSCREEN is an automated method for growth analysis of a limited set of small seedlings [148]. TraitMill^{TM}, one of the first automated phenotyping systems, was developed to study traits in rice [149]. LemnaTec offers commercialized phenotyping systems for different purposes and has customers from both academia and industry all over the world (http://www.lemnatec.com). Although most phenotyping platforms focus on the shoot of the plant, several systems for root phenotyping were also developed [150, 151]. By using large field scanners, it is even possible to use similar approaches during field trials.

One common feature of all automated phenotyping systems is the use of digital cameras for imaging. The use of digital imaging has many advantages over traditional plant phenotyping efforts. While traditional experiments were often dependent on subjective visual scoring of plant traits or on labor-intensive, often destructive manual sampling, for example, for fresh and dry weight measurements, automated phenotyping by digital imaging is nondestructive, and therefore allows following the development of a single plant over time [152]. Another important advantage of digital imaging is that the raw data (digital images) can be easily stored and accessed later on for reanalysis, providing there is a good database in place. Obviously, adequate image analysis software is an essential feature in the concept of automated phenotyping. Several (semi-automated) image analysis tools are based on the free-ware ImageJ software, but other, more sophisticated software, for 2D or 3D analysis, were designed for measurement of leaf shape (LAMINA, [153]), root growth (GROWSCREEN_ROOT, [154]; ROOTEDGE, [155]; RHIZOSCAN, [156]; [157]; EZ-Rhizo, [158]); and hypocotyl growth and shape (HYPOTrace, [159]). The challenge is to find the most appropriate software that can extract the information relevant for the biological questions driving the experiment. Depending on the type of digital camera and the image analysis software, different types of information that describe the phenotype of the plant can be extracted: morphological or physiological and quantitative or qualitative. For example, conventional imaging can be used to measure color, shape, length, width, and size. Video imaging or consecutive imaging of the same plant or plant part over time even allows calculating plant growth. Thermal imaging (infrared thermography) is used to measure temperature and transpiration, while fluorescence and reflectance imaging allows measuring photosynthetic activity of a plant leaf or canopy. Leaf density in the canopy can be analyzed using light detection and ranging imaging that is based on laser scanning. It is now also possible to use typical clinical imaging applications, for example, magnetic resonance imaging (MRI, alternatively called nuclear magnetic resonance) for studying plant hydraulics (water or sap flow) and carbon biomass production [160]. X-ray computed tomography and a combined analysis using MRI and positron emission tomography allow the nondestructive analysis of root growth in soil environments [154]. All these types of image-derived information can be relevant to study abiotic stress tolerance mechanisms, but temperature and photosynthetic activity of leaves are among the most widely studied phenotypes in the response to abiotic stresses.

Imaging is particularly useful for the rapid, early-stage detection of abiotic stress in a plant because it allows detecting changes in the plant performance beyond the naked eye. It is therefore a unique way to diagnose plants. Understanding how plants sense stresses can be considered as a prerequisite for engineering stress tolerance. It can be assumed that plants

that have reduced stress-sensing capacities will continue to grow in mild stress conditions for longer time and thereby produce higher yields. In contrast, when subjected to severe or lethal stresses, the same plants could have a disadvantage because the investment into energy-demanding processes such as growth is high and tolerance mechanisms may be induced only late. Therefore, when exposed to severe stress conditions, plants ideally should be able to increase their stress-sensing ability.

Future Directions

Increased protection of plants against abiotic stresses involves a complex regulatory network controlling morphological, physiological, biochemical, and molecular changes. Understanding such changes has been of key importance in breeding. Breeding crop varieties with improved performance under suboptimal growing conditions is now one of the ambitious, but crucial objectives in modern plant biotechnology. Despite the great progress in the last decade, it is now apparent that abiotic stress tolerance is a complex trait involving genes with different biological functions. However, the number of genes that were actually successfully used to improve crop performance in the field is still low. Although many types of genes or processes have been the target of genetic engineering, certain areas are still unexplored. Interesting developments were recently made in the field of miRNA regulation and epigenetics [161]. Another unexplored field is that of small peptides and their role during abiotic stress signaling.

It is very unlikely that there will be one or a few solutions for current agronomic challenges caused by abiotic stresses, but rather specific solutions for specific cases. Most of the current findings originate from work in model plant species, but much more work is needed to translate such basic research findings to crops. Because of the complex nature of abiotic stress tolerance in plants, it appears that modifying one gene to induce stress tolerance will be in many cases not sufficient. Hence, the approach of using regulon biotechnology for crop improvement, modifying a functional process or even multiple interconnected functional processes instead of one single function, appears to be the way forward. However, this approach is often limited by the lack of knowledge on the network of molecular mechanisms underpinning stress tolerance. Conventional approaches were also hampered by experimental limitations, which can now (partially) be overcome by the advent of automated phenotyping platforms for both model and crop species. Based on the efforts made for phenotyping of *Arabidopsis* plants, it can be anticipated that this small weed will remain the primary model system of choice for academic/basic research in near future. However, "omics" platforms for crop species are becoming available and it will not take too long before research in model crop species will become intensified. Validation of results obtained in *Arabidopsis* in (model) crops will increase the value of the lead technologies and justify the large investments for field trials.

After the development of high-throughput, automated platforms to study plant phenotypes in various environments, it will be essential to combine the data obtained from the various "omics" platforms to intensify biological modeling. Modeling has proven to be useful to study specific processes, such as root growth and flowering. Efforts are now being made to model abiotic stress tolerance in plants [162]. Improved phenotyping technologies will not only allow better experimental validation of predictions drawn from such biological models, but also to improve existing models by including knowledge on the impact of external factors such as abiotic stresses. By including modeling in biological studies, our understanding of the plants' response to abiotic stress will reach a systems biology level, a new quality in plant sciences, which will accelerate the breeding process toward abiotic stress tolerance in all our major crops.

Article Outline

Glossary

Abiotic factor A nonliving component of the environment, such as soil, nutrients, light, fire, or moisture.

Adaptation (1) Any aspect of an organism or its parts that is of value in allowing the organism to withstand the conditions of the environment. (2) The evolutionary process by which a species' genome and phenotypic characteristics change over time in response to changes in the environment.

Agroecology The science of applying ecological concepts and principles to the design and management of sustainable agroecosystems.

Agroecosystem An agricultural system understood as an ecosystem.

Agroforestry The practice of including trees in crop- or animal-production agroecosystems.

Allelopathy An interference interaction in which a plant releases into the environment a compound that inhibits or stimulates the growth or development of other plants.

Beneficial insects – arthropods Beneficial insects are predators, parasites, or competitors of insect pests, helping to regulate pest populations without harm to crops.

Biomass The mass of all the organic matter in a given system at a given point in time.

Biotic factor An aspect of the environment related to organisms or their interactions.

Competition An interaction in which two organisms remove from the environment a limited resource that both require, and both organisms are harmed in the process. Competition can occur between members of the same species and between members of different species.

Consumer An organism that ingests other organisms (or their parts or products) to obtain its food energy.

Decomposer A fungal or bacterial organism that obtains its nutrients and food energy by breaking down dead organic and fecal matter and absorbing some of its nutrient content.

Disturbance An event or short-term process that alters a community or ecosystem by changing the relative population levels of at least some of the component species.

Diversity (1) The number or variety of species in a location, community, ecosystem, or agroecosystem. (2) The degree of heterogeneity of the biotic components of an ecosystem or agroecosystem (*see ecological diversity*).

Domestication The process of altering, through directed selection, the genetic makeup of a species so as to increase the species' usefulness to humans.

Dominant species The species with the greatest impact on both the biotic and abiotic components of its community.

Ecosystem A functional system of complementary relations between living organisms and their environment within a certain physical area.

Generalist A species that tolerates a broad range of environmental conditions; a generalist has a broad ecological niche.

Habitat The particular environment, characterized by a specific set of environmental conditions, in which a given species occurs.

Herbaceous Nonwoody.

Herbivore An animal that feeds exclusively or mainly on plants. Herbivores convert plant biomass into animal biomass.

Host An organism that provides food or shelter for another organism.

Intercropping Planting more than one crop in a field using a regular pattern that interleaves each crop in some pattern. A form of polyculture.

Integrated pest management Pest control using an array of complementary approaches including natural predators, parasites, pest-resistant varieties, pesticides, and other biological and environmental control practices.

Legume A plant in the Leguminosae (Fabaceae) family. Most species in this family can fix nitrogen.

Microclimate The environmental conditions in the immediate vicinity of an organism.

Multi-trophic relationships The organization of feeding and energy-transfer relationships that determine the path of energy flow through a community or ecosystem that involves organisms of different levels.

Mycorrhizae Symbiotic fungal connections with plant roots through which a fungal organism provides water and nutrients to a plant and the plant provides sugars to the fungi.

Organic matter Material containing molecules based on Carbon, usually referring to soil organic matter.

Parasite An organism that uses another organism for food and thus harms the other organism.

Parasitism An interaction in which one organism feeds on another organism, harming (but generally not killing) it.

Parasitoid A parasite that feeds on predators or other parasites.

Patchiness A measurement of the diversity of successional stages present in a specific area.

Patchy landscape A landscape with a diversity of successional stages or habitat types.

Phenotype The physical expression of the genotype; an organism's physical characteristics. Phenology is the study of periodic plant and animal life-cycle events and how these are influenced by seasonal and interannual variations in climate.

Polyculture Cropping systems in which different crop species are grown in mixtures in the same field at the same time.

Predation An interaction in which one organism kills and consumes another.

Predator An animal that consumes other animals to satisfy its nutritive requirements.

Primary production The amount of light energy converted into plant biomass in a system.

Productivity The ecological processes and structures in an agroecosystem that enable production.

Seed bank The total seed presence in the soil.

Shifting agriculture Farming systems that alternate periods of annual cropping with extended fallow periods. "Slash and burn" systems of shifting cultivation use fire to clear fallow areas for cropping.

Species richness The number of different species in a community or ecosystem.

Successional stages A condition characterized by a particular community of a succession, which is the process by which one community gives way to another.

Definition of the Subject

Agroecology provides guidelines to develop diversified agroecosystems that take advantage of the effects of the integration of plant and animal biodiversity. From a management perspective, the agroecological objective is to provide balanced environments, sustained yields, biologically mediated soil fertility, and natural pest regulation through the design of diversified agroecosystems and the use of low-input technologies.

Introduction

Constraints to agricultural production may be classified into four basic categories: abiotic, biotic, socioeconomic, and those related to crop management. The origin and importance of each constraint, their associated losses, and opportunities to alleviate them will vary for the crop, the input and management levels employed, and the environmental and socioeconomic characteristics of the broader farming system in which the crop is grown. Agronomists and plant protectionists usually address production constraints by focusing on management and input issues to alleviate yield losses caused by particular biotic factors (weed, pest, or disease) that are frequently overestimated, and when added up, exceed crops' yield potential. Moreover, plant breeders, especially with the recent addition of bioengineering and biotechnological tools, have assumed that better varieties alone are able to alleviate the impact of factors curtailing production. From an appreciation of constraints and losses, solutions or

opportunities have been proposed, prioritized, and placed into an agenda for action involving technology experimentation, training, socioeconomic and policy support, among other types of intervention. However, there is a need for broader more holistic integration that would jointly assess four broad categories of constraint: biotic, abiotic, management, and socioeconomic. In addition, it is important to focus on how, or through which process constraints to production are generated.

A concern with constraints studies that attempt to average out problems and losses over farms, villages, watersheds, or farming systems is the spatial variation encountered in the types and severity of constraints, in their associated losses, and achieved yields. Variation is often substantial and at a small scale (e.g., parts of the same small field and across field types on a farm). This is especially evident for smallholder farming systems that frequently exhibit historically variable and targeted inputs (e.g., fertilizers) and management superimposed on variability in biophysical factors such as soil types, water availability, weed and pest distribution [1].

Agroecology provides the basic ecological principles needed for studying, designing, and managing agroecosystems that are both productive and that are culturally sensitive, socially just, and economically viable. Instead of focusing on one particular component of the agroecosystem, agroecology emphasizes the interrelatedness of all of its components and the complex dynamics of ecological processes including all environmental and human elements. This approach is based on enhancing the habitat both aboveground and in the soil to produce strong and healthy plants by promoting beneficial organisms while adversely affecting crop pests (weeds, insects, diseases, and nematodes). From a management perspective, the agroecological objective is to provide balanced environments, sustained yields, biologically mediated soil fertility, and natural pest regulation through the design of diversified agroecosystems and the use of low-input technologies [2, 3].

Agroecologists recognize that intercropping, agroforestry, and other diversification methods mimic natural ecological processes, and that the sustainability of complex agroecosystems lies in the ecological models they follow. By designing farming systems that mimic nature, optimal use can be made of sunlight, soil nutrients, and rainfall [4]. The assumption is that by assembling a functional biodiversity, it is possible to subsidize key processes in the agroecosystem that impact on ecological services, such as the activation of soil biology, the recycling of nutrients, the enhancement of beneficial arthropods and antagonists (Table 1) [5]. Altieri [6] argues that there is evidence supporting that promotion of biodiversity within agricultural systems is the cornerstone strategy of system redesign, since: (1) higher diversity (genetic, taxonomic, structural, and resource) within the cropping system leads to higher diversity in associated biota, (2) increased biodiversity leads to more effective pest control and pollination, and (3) increased biodiversity leads to tighter nutrient cycling.

Agroecological Basis for Managing Biotic Constraints.

Table 1 Ecological processes to optimize in agroecosystems

• Strengthen natural pest-control system
• Decrease toxicity through elimination of agrochemicals
• Optimize metabolic function (organic matter decomposition and nutrient cycling)
• Balance regulatory systems (nutrient cycles, water balance, energy flow, population regulation, etc.)
• Enhance conservation and regeneration of soil-water resources and biodiversity
• Increase and sustain long-term productivity

There is evidence that agroecological diversified agrosystems improve their adaptive capacity and reduces vulnerability to natural disasters, climate change impacts, and new and emerging environmental and economic system stresses and shocks. This ability of withstanding the impact of factors that may reduce agroecosystem sustainability (systems resilience) can be accomplished through physical, biological, sociocultural, and political means. Aspects such as habitat and crop diversification, in situ conservation of local/indigenous seed and germplasm diversity, maintenance of natural enemies' species diversity, increased carbon sequestration, improved water capture and retention, etc., and diversification of farming systems and local economies; technical, legal, and social support networks for small-scale farmers, rural

communities, and indigenous people that reduce socioeconomic vulnerability and strengthen adaptive knowledge processes, etc., can be listed as means to increase sustainability. A study of 208 agroecologically based projects and/or initiatives throughout the developing world documented clear increases in food production over some 29 million hectares, with nearly 9 million households benefiting from increased food diversity and security. Promoted sustainable agriculture practices led to 50–100% increases in per hectare food production (about 1.71 t per year per household) in rain-fed areas typical of small farmers living in marginal environments; that is an area of about 3.58 million hectares, cultivated by about 4.42 million farmers. Such yield enhancements are a true breakthrough for achieving food security among farmers isolated from mainstream agricultural institutions [7].

Crop rotations, polyculture cover crops; intercropping, crop/livestock mixtures are some of the strategies that have been recognized as useful to restore agricultural diversity in both time and space. These strategies exhibit ecological features that have been recognized by different studies. For example, crop rotations incorporate temporal diversity into cropping systems, providing crop nutrients and breaking the life cycles of several insect pests, diseases, and weed life cycles [8]. Polycultures are complex cropping systems in which more than two crop species are planted within sufficient spatial proximity to result in competition or complementation, thus enhancing yields [9, 10]. Intercropping may include trees and animals creating agroforestry systems or mixed crop/livestock mixtures resulting in enhanced complementary relations between components increasing multiple use of the agroecosystem [11]. Moreover, animal integration in agroecosystems aids in achieving high biomass output and optimal recycling [12]. Cover crops based on the use of pure or mixed stands of legumes or other annual plant species under fruit trees improve soil fertility, enhance biological control of pests, and modify the orchard microclimate [13]. Altieri and Rosset [14] argue that including these, strategies in farming provide for diversified forms of agroecosystems that share the following features:

(a) Maintain vegetative cover as an effective soil and water conserving measure
(b) Provide a regular supply of organic matter adding manure, compost, and promotion of soil biotic activity
(c) Enhance nutrient recycling mechanisms with livestock systems based on legumes, etc.
(d) Promote pest regulation enhancing the activity of biological control agents achieved by introducing and/or conserving natural enemies and antagonists

Agroecosystems and Biological Constraints to Production

Plant and animal domestication and technological innovation processes, occurring at different rates depending on ecological and social factors during the expansion of agricultural land use, resulted in the development of sophisticated agricultural systems, which included various types of fallow-crop rotation farming, irrigation, land terracing, soil amendment and fertilizing [15, 16]. In these man-made systems tuned in novel ecosystems, farming became increasingly dependent on labor and capital (technological developments) as intensification maintained or even increased outputs. The population density of domestic animals and humans (slaves and peasants) available to satisfy production needs, such as planting, harvesting, and controlling weeds, became an important factor limiting yields and an important destination for agricultural products. Therefore food and fiber demands were not only driven by the nonagricultural fraction of the society, but were also increasingly demanded as labor populations grew to intensify land production. The social structural changes together with modern technological developments, such as steam and internal combustion engines that occurred since the beginning of industrialization made possible the replacement of animal and human labor by machinery and traditional by scientific agriculture. Mechanization of farming reduced the time needed to perform activities and was the means for augmenting the loads of energy inputs to the agricultural system in a way that increased productivity as never seen before. Postindustrial intensification that occurred during the twentieth century in most of the more developed countries, known as "The Green Revolution," became so efficient that the continuous increase in demands for food and fiber by the world's

population could be satisfied despite that during the century's last decades agricultural land shrank [16].

Food supply and human population growth are related, therefore farming intensification process can be seen as following predator prey pattern of change over time, in which population grows following the increase in food supply, and food supply follows labor/energy inputs to the agroecosystem. However, studies on agricultural development have shown that as society builds up its knowledge base through science and other methods to produce technological innovations, they may further increase yield through intensification of farming practices, even when food demands were well below supply, so intensive farming can be pushed just by technological developments [16]. Paradoxically, once expansion of agriculture stops and technological developments give way to intensification of production, technology innovation may at the same time reestablish the expansion model for agricultural production.

This traditional expansion–intensification model has typified agricultural production systems for the first 75 years of the last century. Gain of agricultural land to the sea by means of polders and drainage systems, the use of river damming to build irrigation oasis into desert lands, transformation of tropical rain forests into coffee, tea, sugar cane, and soybean areas, wetland drainage to produce annual crops are all examples on how technology expanded cropped lands. Perhaps the most interesting example on how technology may help in reestablishing the expansion model is the development of improved cultivars by means of plant breeding programs aimed at increasing crop tolerance to stress factors such as high or low temperatures, drought, pests, and disease and soil salinity. Once these characteristics are bread into crops, there is an expansion in the environmental ranges in which the crops are planted. Shifting agriculture and expansion of agricultural frontiers enabled the incorporation of highly fertile lands into production. These activities molded self-designed novel ecosystems [17, 18], the agroecosystems, which compensated and many times overcompensated the yield reductions due to soil erosion and increase in problems related to biotic constraints to production (weeds, pests, and diseases) that appeared in sites with longer agricultural histories [19, 20]. When settlements became fixed and expansion rate was reduced, intensification originally depended on the generation of spontaneous technological developments. Later, and especially in modern farming, agricultural and agronomy schools became nodal institutions integrating different and somehow related disciplines to generate the technological solutions to the continually emerging problems for agricultural production. Technological approaches tend to engineer and construct new systems, which use practices, like soil plowing, to destroy the natural vegetation and weeds creating the conditions for crop establishment and growth.

As discussed before, these new systems induced important modifications in the human social and economical structures. Individual and collective reactions to these changes repeatedly appeared in different sites and historical times, sometimes sustained on religious dogmas, others on philosophical views, as naturalism, or on scientific disciplines, such as ecology, that became important for modern societies. Integrated pest management (IPM) and agroecology originated as a reaction challenging the modern industrial farming practices. It emerged as a scientific-based philosophical view that questions the modern expansion–intensification agricultural model and its associated dogma of production at any cost. In the last decades, hundreds of research projects and technological development attempts, aimed at environmentally prone management, have taken place delivering significant information. However, the thrust is still highly technological, and focus is on alleviation or suppression of limiting factors or the symptoms disregarding malfunction of the agroecosystem.

Biotic constraints to agricultural production are broadly identified as weeds (plants), pests (animals), and diseases (fungi and bacteria), and their related biological interactions (namely, competition, herbivory, and predation and parasitism), which cause reductions in physical yields or yield quality. The prevalent philosophy is that pests, nutrient deficiencies, or other factors are the cause of low productivity, as opposed to the view that pests or nutrients only become limiting if conditions in the agroecosystem are not balanced [21]. This understanding of how production is sustained has diverted agriculturists from realizing that limiting factors only represent symptoms of a more systemic disease inherent to unbalances within the agroecosystem

and from an appreciation of the context and complexity of agroecological processes thus underestimating the root causes of agricultural limitations [6].

Pest, disease, and weed problems are strong site- and time-specific imposing a biotic constraint on a crop dimensions. The crop-loss impacts of one organism growing in a location may be entirely different from the losses incurred by the same organism on the same crop in other locales. Further, organism population dynamics, migration, invasion, and damage are driven by local conditions, such as temperature and rainfall, but also by the ecosystem and community complexities. Recognition of the systemic dimensions of biological constraints to production is needed to understand how climate–soil interactions, topography, natural, ecological, and land-use complexity, agricultural history, and cropping practices may determine their occurrence, importance, and frequency [22].

Agroecosystems that have evolved in tropical and subtropical climates have high levels of complexity, including many organisms and multi-trophic interactions. Those that have evolved under temperate or Mediterranean climates may also show complexity, but frequently are structurally simpler and may show strong seasonal variation caused by changes in resource availability during the cold/dry season that stops primary productivity. Topography may cause environmental gradients or patchiness adding complexity at regional and landscape scales. Agricultural land-use history, however, at both regional and landscape scales are important drivers of the agroecosystem complexity and organization of the communities that occur in the different crops. Agriculture in many regions of Europe, Middle-East, Asia, Andean regions in South America, and Central America has been practiced in the same sites through millennia, while in others, covering large extensions of Australia, South and North America, expansion of agriculture has occurred within the last centuries. During the last decades, land under agriculture in some of these regions with relatively new agroecosystems has shrunk, and intensification occurred in those areas that remained under cropping. In other regions, such as those in the Mato Grosso, Cerrado, and Chaco from Brasil, Paraguay, and Argentina, natural systems have been turned into cropland recently, and this transformation is still happening. These differences in agricultural histories are related to important differences in the organization of the biotic interactions in the agroecosystem. Different selection pressures occurring in agroecosystems select for different adaptations, which include coevolution of crops and organisms that challenge them as well as cropping practices [23]. Therefore, arable land complex communities have evolved in regions with long agricultural histories. These communities have strong interactions among organisms. Communities that were assembled in apparently homogeneous agroecosystems under long periods of monocultures can reach high levels of complexity. For example, Javanese rice fields, which are cropped as simple rice monocultures, can support large numbers of arthropods summed by 765 species that are important for biocontrol [24]. Vegetationally simple cropping systems in the UK have been shown to develop complex belowground biodiversity that may include 100 species of bacteria, 350 species of protozoa, 140 species of nematodes, and 24 distinct types of arbuscular mycorrhizae [25].

Size and variability in the above- and belowground community structures that functionally support the agroecosytem is important to discuss biotic constraints to production and the agroecological basis for managing them. The more complex and diverse ecosystems may sustain greater productivity and stability in ecosystem functions since they are supported by more than one species, and are then less vulnerable to changes in the populations of a particular species due to environmental stress or pest attack. However, complex biotic systems may also deliver more organisms, which may challenge the crop increasing the importance and stability of biotic constraints [26]. There are numerous studies showing that increased plant diversity enhances biological pest control [27, 28], but counter examples also exist where pests or disease levels increase due to the provision of highly palatable species or changes in canopy microclimate [27–30].

Many of the species originated in regions with long histories of agriculture, and even whole communities have migrated into regions in which crops and agroecosystems have recently expanded. In this way, the flora and fauna of the new agricultural areas of the world such as those in the Argentinean Pampas are dominated by species from the Mediterranean-European agricultural communities. In these new

areas, arable land communities may show instability due to the continuous introduction of new organisms and species shifts [18, 31, 32]. Changes in trading systems, land use, and cropping practices, experienced by many regions with long agricultural history, are enhancing instability of biotic communities caused by addition of organisms (*biotic invasions*), extinctions, and species shifts due to change in landscape [33]. The impacts of biotic complexity have significance, especially when cropping systems are simplified to monocultures, as many organisms would impose biotic limitations to production. Diverse cropping systems are typical of many traditional agricultural systems found around the world, particularly in risk-prone environments, but also with long histories of agricultural production [6]. It is also in these regions, primarily in the developing world, where the greatest emphasis on improving diverse production systems through intercropping and agroforestry is found. It is clear that there are trade-offs with more diverse agricultural systems, and that the kind of diversity matters greatly, but the question is how to design diverse systems that can meet multiple goals in an acceptable way [22].

System Management

As discussed previously, cultural and technological changes that took place during the second half of the twentieth century impacted on land-use patterns and agroecosystem design especially driven by the adoption of industrialized production technologies and reliance on increasing input loads of agrochemicals to alleviate agricultural production constraints. Despite the success in achieving significant increases in global food and fiber yields and yield stability, paradoxically, increasing environmental damage, loss of biodiversity, and associated traditional knowledge were often experienced in the new agroecosystems. In high-external input agriculture intensification of production due to technological development has increased by augmenting input levels that resulted in increased (biomass) production per unit of land and uniformity of the produce. In many cases, this intensification led to reductions in output stability and resource-use efficiency, and has enhanced overexploitation of natural resource base, and consequently reduced sustainability of agroecosystems [34]. There are many examples of reduction in sustainability by the elimination of growth limitations and of yield reduction factors that induced environmental homogenization and a decrease in genetic variation. Noteworthy are the studies showing that application of biocides to reduce biotic constraints to production impact negatively on organisms that are directly or indirectly beneficial for crop growth [34, 35] and, due to their effects on natural enemies of pests and diseases, further increase the need for biocides control [1].

Agroecological bases for reducing biological constraints to crop production depends on the possibility of managing diversity and disturbance at multiple spatial and temporal scales to use biotic interactions to provide desired agroecosystem service.

Arable Land Biotic Community Constraints

Small Scale Soil disturbance caused by plows and other cultivating devices have been used for centuries in different parts of the world to reduce weed competition as well as for reduction of some pests and diseases. Particular traits are selected by cultural practices in many organisms that survive and reproduce in arable lands and show functional patterns that can be identified [36]. Selection pressures imposed by agricultural practices may be sufficiently strong over extended periods of time so that weed populations can evolve into more competitive populations better adapted to agricultural field conditions than populations from nonagricultural areas [37] or populations from agricultural areas submitted to other type of management. In recent times, management approaches that include reduced tillage have strong impacts on the soil biota of plowed soils. It favors fungal food webs, increases abundance and diversity of predators that can reduce soils weed seed banks, and increases control of pests and diseases. It also changes the environmental conditions reducing germination of seed of many weeds or changing ontogenic processes and phenology of pests and diseases adapted to plowed-cultivated soil conditions. These effects may alleviate biotic constraints especially caused by weeds; its effects are not stable, and shifts in species happen after this practice is adopted for some time. The design and management of the agroecosystems complexity requires an understanding of general system behavior combined with species- and site-specific knowledge.

The performance of agroecological management could be improved since crops were selected in the ecological conditions likely to occur in the low-input farming. Adaptation to these conditions in which biotic interactions are expected to occur and characteristics such as increased competitiveness to weeds, disease, and pest resistance, enhanced ability to support beneficial rhizosphere microorganisms, and improved capacity to access soil nutrients could all potentially benefit crop growth. Noteworthy is that selecting for such traits and acquiring the necessary knowledge to understand the structure of particular agroecosystem structure dynamics can only be accomplished with long agricultural history to provide for coevolution and the existence of relatively strong interactions. In addition to this, if such a mix of characteristics can be identified, selecting it would be difficult and time consuming. Probably a more practical alternative to adaptation of a single crop to a complex biotic system would be the use of mixtures of cultivars within a field to improve crop production and disease management [38, 39].

Cropping systems may include crop sequences to favor beneficial biotic interactions, such as the use of crops that enhance the populations of beneficial rhizobacteria that reduce diseases and nematodes [40], accompanied by soil cultivation, fallow, and residue management practices aimed at maintaining soil cover and organic matter as well as arbuscular michorrhiza populations [41] and weed suppression [42]. Competitive crops species or mixtures may be used to reduce the impact of weeds on crop yields. However, holistic management approaches aimed at reducing weeds may integrate the use of other strategies such as manipulating crop seeding density and spatial arrangement, tillage, intercropping, use of allelopathic residues and suppressive mulches, and targeted use of biocontrol agents that reduce weed growth and fecundity during the growth cycle may be integrated in holistic weed management approaches. Also, various soil management techniques aimed at reducing weed seed survival such as reduced tillage, residue management, and organic matter inputs can be used and integrated with the use of weed-suppressive crop rotations that may also impact on seed survival due to enhanced seed predation or infection by pathogens [39].

In agricultural systems, species are selected to obtain yields but can also be used to manage diversity aiming at encouraging beneficial interactions and minimizing undesired ones [43]. For intercropping systems, species are usually chosen considering species or varieties that differ in rooting patterns, canopy types, phenology, etc., to avoid or reduce negative interference or that have positive interactions such as with the introduction of a legume. Well-designed intercrops can increase overall productivity [10, 44] and potentially reduce risk to farmers. A regional-scale field experiment with rice production in China shows how even a small increase in diversity can have a large impact on system function. In that experiment, simply interplanting two varieties of rice, rather than planting them in separate fields, led to a dramatic reduction in pest problems and pesticide use [45].

Large Scale As scale increases, so does the relative importance of species richness because greater numbers of species are needed for the maintenance of ecosystem functions [26]. Loss of diversity in agricultural landscapes has been linked to the disruption of ecological functions such as pest management, pollination services, resistance to plant invasion [46]. Spatial scale is particularly important for both occurrence of pest-related yield constraints to production and for management, because landscape features affect species interactions, microclimates, and weather patterns [24, 46–48]. Landscape structure and dynamics can have notable effects on pests by changing habitat patterns and immigration rates [46, 49–53]. In many regions of the world, agriculture shares space with other land uses forming structural mosaic of habitats with insects and other mobile organisms moving between them [33]. The development of multi-trophic arthropod communities depends on spatial processes (dispersal and foraging) that occur at larger scales than the farm, as well as temporal processes such as overwintering and reproduction. Habitat fragmentation caused by farming can disrupt both types of process and isolate small natural enemy populations from one another, increasing local extinctions [54].

Several biotic constraints to production could be alleviated if biological control maintained following several strategies that help to enhance indigenous populations of beneficial insects by providing food

resources (host prey, pollen and nectar, alternate prey) and shelter for overwintering. Habitat management involves vegetation diversification at multiple scales [55]. Use of insectary plantings or leaving strips of unharvested plants are examples of infield strategies, whereas wildflower borders, grassy buffer strips, windbreaks, and hedgerows are examples of field margin diversification techniques. Larger-scale distribution and connectivity of landscape features such as hedgerows, habitat fragments, and riparian vegetation can also impact levels of biological control as well as provide biodiversity conservation benefits [56]. Interplanting crops with flowering herbaceous plants is promoted as a farmscaping technique since pollen and nectar are essential to the fecundity and longevity of several natural enemy species [57, 58]. Planting of multispecies hedgerows along the edges of farm fields can provide stable habitat and resources for beneficials while fields are bare or crops are young. Biological control may not be enhanced by hedgerows if the availability of pollen and nectar is so high within the hedgerows so that natural enemies do not disperse into adjacent agricultural fields to feed on crop pests [59]; or if the hedgerow attracts new pests, non-pest prey that natural enemies prefer over the crop pest; or top predators that prey on the natural enemies of interest [60–63].

Natural enemy dispersal ranges, which can vary from a few meters to over a kilometer for some parasitoid species [64], will determine the effectiveness of various habitat patterns at enhancing biological control. Blackberry and prune trees provide habitat for alternative hosts of the parasitic wasp, *Anagros epos*, which later preys upon the vineyard leafhopper pest, *Erythroneura elegantula* [65, 66], but connecting border plantings to infield floral corridors may encourage greater natural enemy movement and biological control in vineyards [63]. Successful conservation biological control relies upon matching vegetational scale and pattern to the movement range of desired natural enemies in relation to their primary food sources. This requires an expansion beyond habitat management at the field level to incorporate larger landscape patterns and processes, a still relatively unexplored area. In addition to the size and distance between habitat patches, the "matrix" between patches is important for insect movement [67]. Many species that live in habitat patches also utilize resources outside the habitat patch, which is a desirable attribute for biological control allowing for natural enemies to migrate into agricultural fields. Structurally complex landscapes have been found to lead to higher levels of parasitism and lower crop damage [68, 69]; but this is not always the case even within the same region if parasitism rates also depend upon the presence of particular species or plant communities [70, 71].

Various strategies for increasing vegetation diversity within crop fields, including tolerating low levels of weed infestation and intercropping, have been exploited to reduce the density of herbivores attacking crops. Crops within diverse assemblages can be "harder to find and easier to lose" by herbivores, and better protected by natural enemies [72]. Diversified vegetation in field margins and mosaic patches across landscapes can support natural enemies that move into crop fields and provide biocontrol of pest herbivores [71]. Vegetation diversity may also affect management of phytopathogens.

Weed consumption by herbivores could be increased by reducing chemical pesticides to control agricultural pest and weeds, and then adopting resistant or repellent crops to generalist consumers found in agroecosystems. This management practice has been successful with some crop species toxic or deterrent to insects, negatively impacting weeds mainly consumed by herbivores [73]. This also is a good example on how food webs may be reorganized in response to human intervention. Native species of insects, rodents, birds, and other organisms can consume large numbers of weed seeds and promote reductions in requirements for chemical control tactics [74]. Interspersed strips of diverse, phenologically dissimilar crops may better conserve populations of weed seed consumers than crop monocultures [75]. Specialist pathogens have been used to suppress several weed species in pasture and rangelands, but in annual crops, the difficulty of maintaining appropriate environmental conditions for host infection and the need to achieve rapid weed suppression in a narrow time window has impeded the use of this approach [76].

Meadow strips enhanced pollinator diversity and plant reproductive success in adjacent fields in Switzerland [77]. Similarly, in Costa Rica, proximity to forested areas increased pollination and yield in coffee orchards [78]. Weeds in crop fields supply food for

many bird species [79], and hedgerows and other forms of field margin vegetation supply both habitat and food for wildlife species [80].

Timing and intensity of agricultural management such as the way in which soil cropping or irrigating activities are designed may alter habitat distribution and connectivity across the landscape that are very important for maintaining viable populations of different organisms [59, 61, 81]. For example, asynchronous tillage is important for maintaining beetle populations in arable cropland [82] as well as asynchronous flooding is important for sustaining natural enemy populations in rice fields [24]. Initial studies also found that creating a mosaic of crop fields and wetlands in different successional stages had great promise as a strategy for improving waterfowl habitat and sustaining crop production in a multiuse landscape [83]. Interestingly, maintaining rice fields flooded through the winter for waterfowl foraging habitat also provided beneficial agronomic impacts by increasing decomposition of rice straw and reducing grassy weed biomass [84]. Further, numerous studies have shown the interactive effects of landscape complexity and the impacts of agricultural management practices, with more benign practices (such as organic farming) having the greatest effects on increased biodiversity in simple landscapes [46, 85, 86].

Conclusions

Our understanding of biotic interactions taking place in agroecosystems and how they relate to production constraints is growing rapidly, aided by agroecological approaches and the integration of ecological methodologies and ecologists into agricultural research. Numerous studies provide data allowing for the characterization of agrosystems that reduce the importance of biological constraints to production. They include great spatiotemporal diversity of crops, discontinuity in monoculture (rotations, early varieties, etc.), a mosaic of small fields to ensure the juxtaposition of cultivated and noncultivated land, the presence of a dominant perennial crop (especially orchards), crops grown with high sowing density to limit weed populations, great genetic diversity in the crops (varieties grown in mixed or alternate rows of crops). Based on them, recommendations can be made concerning the management of cultivated plants and the choice of cropping techniques that consider the spatiotemporal dimension of cropping lands, the composition and abundance of the indigenous flora in and around the fields, soil type, the nature of the environment, and the type of farm.

Future Directions

It is clear that agroecosystems are self-designed, and their outputs are controlled and depend on the biotic interactions that evolve as they exist. If managing biotic constraints for crop production is to be sustained on agroecological bases, there is a need to understand how agricultural communities are structured taking into consideration the effects of diversity, species composition, and food web structure on ecosystem processes; the impacts of timing, frequency, and intensity of disturbance (at different complexity levels, i.e., whole ecosystem, community, population); and the importance of multi-trophic interactions. All of these aspects have to be observed and explicitly integrated at multiple spatial and temporal scales. The potential for a greater use of agroecological management approaches is high. However, given the variability of biological phenomena, the implementation of the agroecological strategy requires a planned spatiotemporal farm management. However, owing to the nature of these self-assembled ecosystems, there is some inherent unpredictability about responses to different management interventions. Effective synthesis of complex and often apparently contradictory information is still needed. Field-based research that includes monitoring of species performance, along with social learning mediated by farmer-researcher collaborations may help in this task.

Agronomic Interactions with CO_2 Sequestration

Rattan Lal
OARDC/FAES Kottman Hall, Carbon Management and Sequestration Center, The Ohio State University, Columbus, OH, USA

Article Outline

Glossary

Carbon sequestration Transfer of atmospheric CO_2 into long-lived reservoirs

Mean residence time The duration during which CO_2-C resides in a specific pool (pool)

Soil quality Capacity of a soil to perform ecosystem services

Definition of the Subject

Atmospheric concentration of carbon dioxide (CO_2) can be stabilized, if not reduced, by reducing anthropogenic emissions, sequestering emissions, or both. Emission reduction implies identifying and using no-carbon (C) or low-C energy sources such as alternatives to fossil fuel including wind, solar, hydro, geo-thermal, biofuels, etc. Reductions in gaseous emissions can also be achieved by enhancing the energy use efficiency. In agronomic systems, involving practices to raise crops and livestock, enhancing energy efficiency implies a range of practices which increase agricultural productivity per unit input of energy-based resources (i.e., fertilizers, pesticides, irrigation). Another strategy is elimination or reduction in frequency and intensity of tillage operations and converting plow-based tillage to no-till farming or conservation agriculture. Use of solar and wind energy for grain drying, water pumping, and heating buildings can also reduce emissions.

Agricultural soils and ecosystems can also be used for sequestration of atmospheric CO_2 by enhancing photosynthesis, increasing net primary productivity (NPP), and converting some of the NPP into stable biomass (forest products) and the soil C pool. The biomass in forest, with a long mean residence time (MRT), has two distinct but related components: the above-ground biomass and the below-ground biomass. The above-ground biomass can be alive or the detritus material. The photosynthates transferred deep into the subsoil through a tap root system have a long MRT. Agroforestry systems, growing crops and raising livestock in combination with perennials (tree species), can enhance the ecosystem C pool by increasing both biomass-C and soil-C components.

Sequestering C in soil entails increasing soil organic C (SOC) pool and also the soil inorganic C (SIC) pool. The SOC pool has three related components: labile/active pool, intermediate pool, and the passive/recalcitrant pool with MRT of $<$ year, $<$decades to a century, and several millennia, respectively. The goal is to transfer the labile pool into intermediate and preferably passive pools through conversion to conversion tillage, use of manure/compost and other biosolids (biochar), and complex cropping/farming systems. Sequestration of SIC occurs through formation of secondary carbonates. In irrigated systems, however, leaching of bicarbonates is also an important mechanism of SIC transfer into the groundwater. Agronomic practices strongly interact with strategies of reducing emissions and sequestrating CO_2 in soils and biota. Therefore, the strategy of agronomic management is to identify the interactive agronomic practices which enhance ecosystem (biotic and pedologic) C pools.

Introduction

Limiting global warming to 2°C necessitates identification and adoption of diverse strategies which reduce

the net anthropogenic emissions of greenhouse gases (GHGs). Agriculture, hitherto a major source of GHGs, is an important industry which can be made more energy-efficient. Importance of improving agricultural production, by as much as 70% between 2010 and 2050, cannot be overemphasized in view of the need to reduce hunger, malnutrition, and poverty. Although a major challenge, making agriculture emission-neutral is a prudent long-term strategy. It is in this context that understanding of the agronomic interactions with CO_2 sequestration in soil is important.

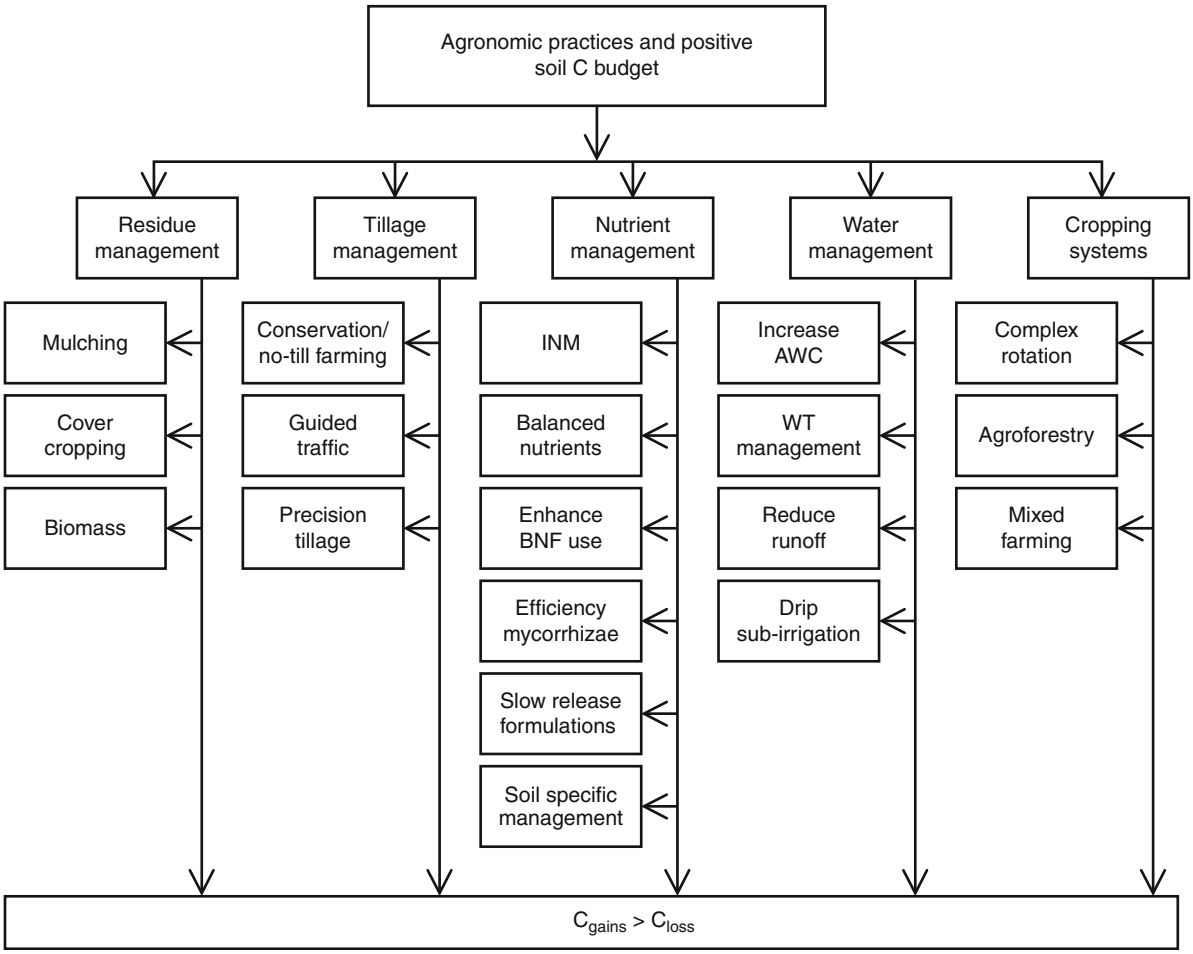
Agronomic systems are defined as site-specific management of soils and crops on the basis of eco-regional and physiographic characteristics, and in the context of socioeconomic and policy environments. These systems are strong determinants of agricultural production, sustainable use of resources, and their environmental impact. Pertinent examples of the environmental impacts of agronomic systems include accelerated soil erosion, nonpoint source pollution, emission of GHGs, and alterations in ecosystem and soil C pools. Most soils of agricultural ecosystems (i.e., croplands, grazing lands) are depleted of their SOC pool. In comparison with the natural/climax vegetation, the remaining SOC pool in agricultural soils may be 20–50% of the antecedent pool under undisturbed conditions [1]. The magnitude of loss is large in soils characterized by high than low antecedent pool, coarse than fine texture, in warm than cold climates, and in degraded/eroded than favorable quality. Furthermore, the magnitude of loss is more from soils managed by extractive farming than of intensive/science-based agriculture. The historic loss is also equivalent to the potential soil C sink capacity, a part of which can be realized through conversion to a restorative land use and adoption of recommended management practices (RMPs).

Sequestration of CO_2 in agroecosystems implies transfer of atmospheric CO_2 into biota and soils through photosynthesis and NPP in a manner such that the biomass-C is neither readily nor immediately returned back to the atmosphere. The strategy is to enhance the MRT of C in biota and soils. Principal determinants of MRT comprise of a wide range of factors including soil processes and plant/biomass characteristics. Important among soil processes are formation of: (1) stable micro-aggregates, (2) organo-mineral complexes including absorption on clay surfaces, and (3) recalcitrant organic polymers involving physical, chemical, and biological protection of soil organic matter (SOM). Another process of physical protection is transfer of SOM into the subsoil by illuviation as dissolved organic (DOC) such that it is away from the surface layer prone to accelerated erosion, intense mineralization, and other natural and anthropogenic perturbations. Important among plant characteristics which increase MRT are: (1) a deep root system and (2) a high concentration of recalcitrant compounds. This chapter is aimed at describing the processes and practices which moderate the agronomic interactions with CO_2 sequestration in soil as a recalcitrant humus of a long MRT.

Soil Carbon Budget

The strategy is to create a positive SOC budget so that input of biomass-C exceeds the losses. Important among agronomic practices which create a positive C budget (Fig. 1) are mulch farming, no-till/conservation agriculture, integrated nutrient management (INM) including slow release formulation of chemical fertilizers and biofertilizers, conservation and management of soil water to reduce losses by surface runoff and evaporation and increase soil-water storage, and use of complex cropping/farming systems including agroforestry and mixed farming systems. The strategy is to replace extractive farming practices, which deplete soil fertility and SOC pool, by science-based agriculture involving the widespread adoption of RMPs. Some RMPs outlined in Fig. 1 are generic, and no one practice is universally applicable because of the extreme diversity of soil types, ecoregions, and the human dimensions related to socioeconomic and political consideration. Site/soil-specific validation and adaption through fine-tuning of RMPs is essential.

While increasing the input of biomass-C, it is equally important to reduce its losses. Agronomic/soil processes which deplete the SOC pool are outlined in Fig. 2. The SOC pool is strongly depleted by accelerated soil erosion. The preferential/selective removal of SOC by runoff and erosion, as indicated by an enrichment

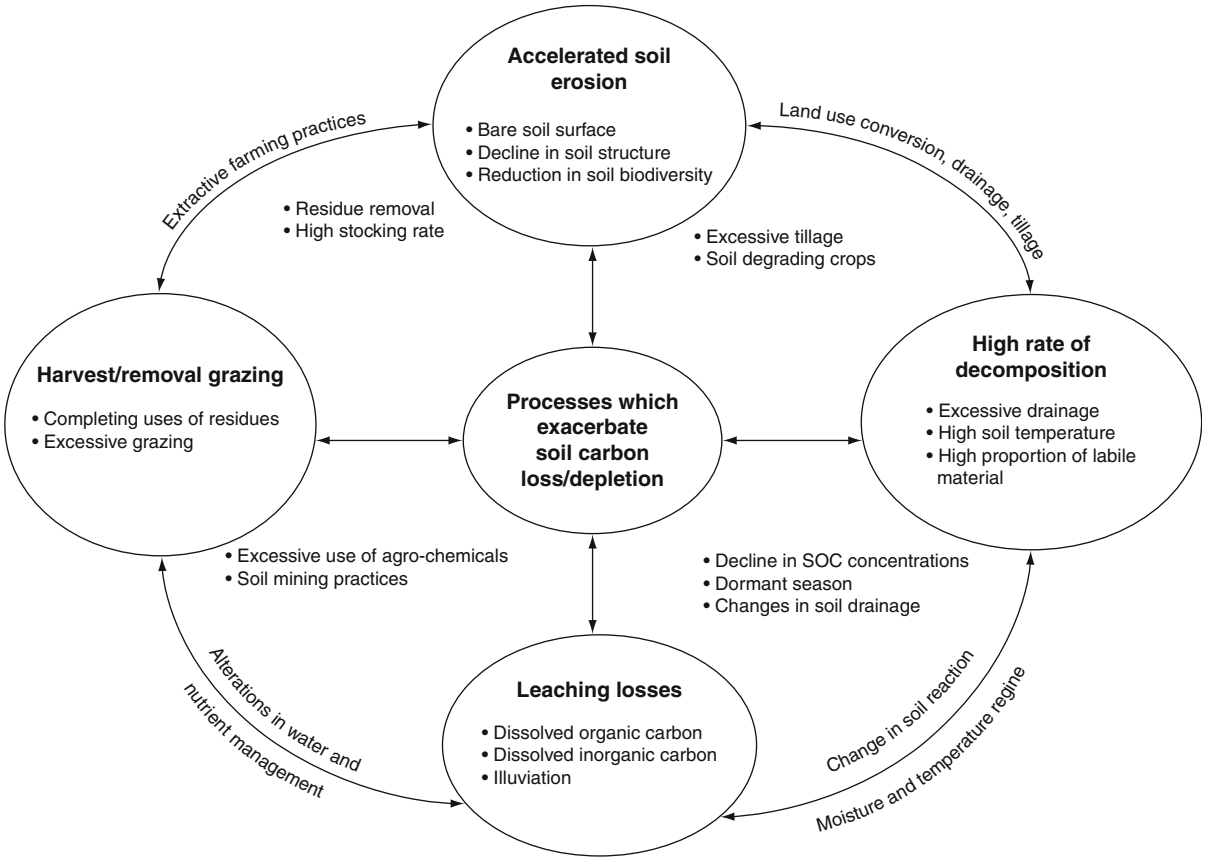


Agronomic Interactions with CO_2 Sequestration. Figure 1

Agronomic interactions which cause positive carbon budget (*INM* integrated nutrient management, *AWC* available water capacity, *WT* water table, *BNF* biological nitrogen fixation)

ratio of C in sediments ranging from 5 to 30 depending on soil/land and climate, is attributed to: (1) low density of SOC, (2) high concentration (stratification) in the surface layer, and (3) absorption on clay and thus removal along with the clay particles. Soil erosion is exacerbated by plowing, residue removal, uncontrolled and excessive grazing, and management practices which degrade soil structure and accentuate its vulnerability to climatic erosivity.

The SOC pool is also depleted by increase in the rate of mineralization. The latter increases with increase in soil temperature and changes in soil moisture regime. Conversion of natural to managed/agricultural ecosystems alters both the soil temperature and moisture regimes and accentuates the rate of mineralization. The latter, being a biochemical reaction, is approximately doubled with every 10°C increase in temperature (Vant Hoff rule). There is an optimal soil moisture regime for the mineralization/decomposition. Water table management and drainage of excessively wet soils increase the rate of mineralization. Excessive wetness increases methanogenesis and denitrification with an attendant increase in emissions of CH_4 and N_2O. In contrast, supplemental irrigation in arid and semi-arid climates can also accentuate mineralization and denitrification. In general, therefore, emissions of GHGs may be more from agricultural soils than those under natural ecosystems.



Agronomic Interactions with CO_2 Sequestration. Figure 2
Agronomic soil processes which deplete the soil carbon pool

Hidden Carbon Costs

Most agronomic inputs, especially in intensively managed systems, are based on use of fossil fuel combustion. Important among these are tillage operations, harvesting, drying, application of fertilizers, and other chemicals (pesticides) and irrigation. The hidden C cost (HCC) of these inputs are listed in Table 1. Agronomic practices with a significant input of HCC are tillage systems, and agricultural chemicals. Thus, a complete Life Cycle Analysis (LCA) is needed to determine the ecosystem C budget and assess the net C gains. The latter can be described by Eq. 1:

$$\text{Net C gain} = C_{input} - (C_{loss} + HCC) \quad (1)$$

C_{input} includes biomass addition such as shoot, leaves, detritus materials, roots, compost, manure, deposition through wind and water, etc. C_{loss} occurs mainly through erosion, decomposition, and leaching. Principal components of HCC are the energy-based inputs. Quantification of each of these components is essential to conducting LCA for specific soil, crop, ecoregion, and other site-specific factors.

It is often argued that HCC should not be deducted from the gross C gains because agronomic inputs (i.e., fertilizers, tillage, pesticides, manure, irrigation, and harvesting) are not used for C sequestration but for achieving food security to meet the food and other demands (i.e., feed, fiber, and raw materials) of the growing population. If HCCs are also considered, land managers/farmers are not adequately rewarded by payments through C trading.

Agronomic Interactions with CO_2 Sequestration.

Table 1 Hidden carbon costs of agronomic practices (Adapted from [2])

Agronomic practice		Carbon cost
I.	*Tillage (kg CE/ha)*	
	Moldboard plowing	15.2 ± 4.1
	Chisel plowing	7.9 ± 2.3
	Disking	8.3 ± 2.5
	Cultivation	4.0 ± 1.9
	Rotary hoeing	2.0 ± 0.9
II.	*Fertilizers (kg CE/kg)*	
	Nitrogen	1.3 ± 0.3
	Phosphorus	0.2 ± 0.06
	Potassium	0.15 ± 0.06
	Lime	0.16 ± 0.11
III.	*Pesticides (kg CE/kg)*	
	Herbicides	6.3 ± 2.7
	Insecticides	5.1 ± 3.0
	Fungicides	3.9 ± 2.2
IV.	*Irrigation (kg CE/ha/year)*	
	Surface	9.4–24.6
	Sprinkler	16.3–121.3
	Trickle	84.9

Farming Carbon

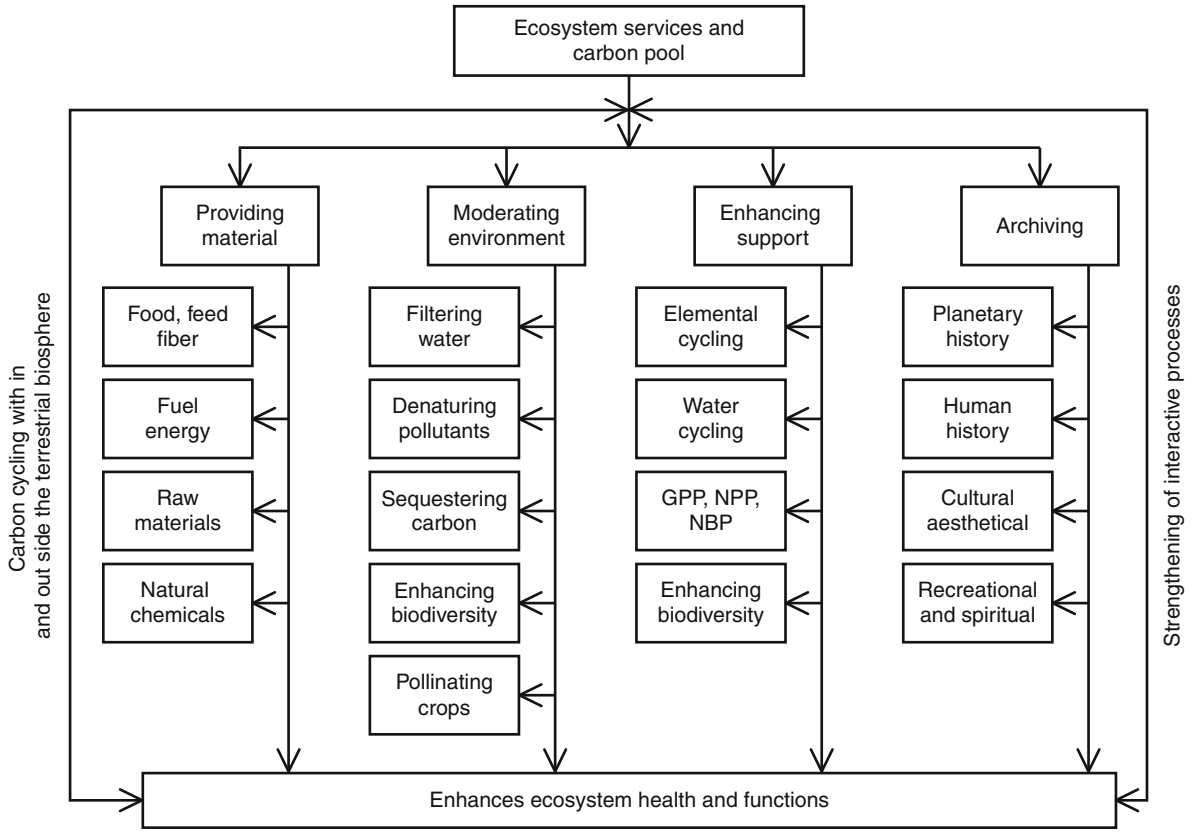
The term "farming carbon" implies growing/increasing C pool in soils and biota (trees) of managed ecosystems (agriculture, forestry, urban lands, wetlands) so that any increase in the ecosystem C pool can be traded in the market as a farm produce. Agronomic interactions, practices which enhance soil and the biotic C pools, are strong determinants of the C gains (or losses) from the ecosystem. Changes in the ecosystem C pool must be monitored by a standardized procedure so that the data are credible, reproducible, and verifiable by other procedures. A protocol for measurement, monitoring, and verification (MMV) is essential to implement C trading.

Ecosystem Services and Soil Carbon Sequestration

Sequestration of C in soils and biota generates and enhances numerous ecosystem services (Fig. 3). Important among these are: (1) providing materials of use to human (i.e., food), (2) moderating the environment (i.e., climate), (3) enhancing support, and (4) archiving human and planetary history [3, 4]. Soil and the ecosystem C pools are strong determinants of these services directly and indirectly. For example, quantity and quality of the SOC pool affect soil functions through (1) increasing soil aggregation and improving soil tilth, (2) increasing nutrient retention and availability, (3) moderating water retention and availability, (4) improving infiltration and reducing water runoff, (5) reducing soil erosion and nonpoint source pollution, (6) providing energy source and food to soil biota, (7) enhancing nutrient/elemental cycling, (8) accentuating use efficiency of input, (9) enhancing rhizospheric processes and micro-climatic environment, and (10) improving GPP and NPP.

Carbon Sequestration and Agronomic Production

It is because of numerous positive effects of organic carbon concentration in the root zone on soil quality that it is a strong determinant of the use efficiency of agronomic input and of crop growth and yield. Depending upon soil type and crop characteristics, there is a threshold value of 15–20 g/kg of SOC concentration in the root zone [5]. Crop growth and yield are strongly reduced when SOC concentration is below the threshold level (Fig. 4, [6, 7]). The yield response to SOC concentration in the root zone also depends on the management. The crop response (i.e., growth and yield) is generally stronger in agronomic practices based on low than high external inputs such as fertilizers, manure/compost, irrigation, etc. Indeed, the yield potential of elite varieties cannot be realized unless soil quality and the related agronomic interactions are optimized. Therefore, enhancing SOC concentration to above the threshold level is essential to improving agronomic yield in depleted/degraded soils of sub-Saharan Africa, South and Central Asia, and elsewhere in regions with low crop yields.



Agronomic Interactions with CO_2 Sequestration. Figure 3
Ecosystem services enhanced by soil carbon sequestration (*GPP* gross primary productivity, *NPP* net primary productivity, *NBP* net biome productivity)

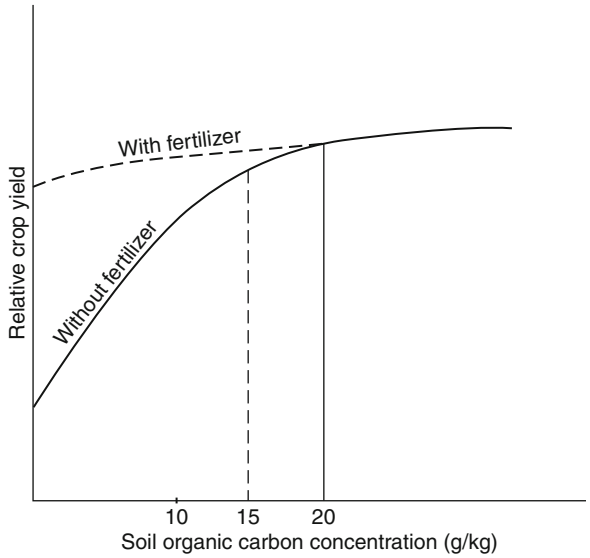
Future Directions

There is a strong need to understand the following:

- Soil processes and agronomic practices which create a positive C budget for diverse ecoregions
- Rate of C sequestration in relation to soil type, climate, and management
- Relationship between soil C pool/concentration and soil quality parameters, and agronomic yield
- Process, factors, and causes which enhance the mean residence time of C in soil
- Threshold value of C concentration for predominant soil type and crops
- Policy interventions to promote "carbon farming"

Conclusions

Creating a positive budget of C (and N) is important to C sequestration in the soil. Agronomic practices to create a positive C budget are those which enhance the inputs of biomass-C. Important among these are conservation/no-till agriculture, mulch farming, cover cropping, integrated nutrient management, harvesting/recycling of water, complex farming systems, and perennial culture. Restoration of eroded/degraded soils and ecosystems is important to C sequestration in the soil. Energy-based inputs (i.e., fertilizers, pesticides, and tillage) have high hidden



Agronomic Interactions with CO_2 Sequestration. Figure 4

A generalized response curve of agronomic yield response of crops to concentration of soil organic matter in the root zone

C costs. The strategy is to minimize losses of these inputs by erosion, leaching, volatilization, etc. Increase in soil organic C pool above the threshold level can enhance crop yield. Improvement in soil quality through increase in SOC pool is essential to increasing crop yields and agronomic production of soils in African, Asian, Caribbean, and the Andean regions.

Animal Breeding and Genetics, Introduction

Ignacy Misztal
Department of Animal and Dairy Science Breeding and Genetics, University of Georgia, Athens, GA, USA

Informal animal breeding started thousands of years ago when hunter-gatherers started domesticating animals. Out of thousands of species available only few were domesticated as the requirements for domestication were numerous: plant diet, fast growth rate, ability to breed in captivity, good disposition, little tendency to panic, and ability to function well in groups [1]. An ancient farmer/herder took special care of well-behaving animals that provided good growth, or plenty of milk, or reliable draft, or lots of wool, etc., while eliminating the troublesome ones. The domestication greatly increased the nutritional output per unit of land although it also brought new problems, e.g., new diseases and wars. These problems were smaller than the benefits of the domestication as hunter-gatherers mostly disappeared. Some of the benefits could be due to a positive effect of animal products on IQ [2].

The natural selection maximizes survival under the natural conditions. Under domestication, the selection maximizes utility of a specie for a farmer while deemphasizing and thus reducing energy expenditure for characteristics less important or unimportant under domestication, e.g., fighting ability to select a mate or defend against predators, ability to cover long distances, etc. [3]. The degree of economically beneficial selection is environment dependent because some traits (e.g., resistance to harsh conditions) may be necessary in some environments while they are redundant in other environments. In the end, the improved animals have a smaller environmental imprint [4].

In ► Animal Breeding Methods and Sustainability, Agustin Blasco provides a historical perspective to animal breeding including the creation of breeds. Although the breeding has been practiced for many millennia, the science behind it is relatively recent. With new breeding tools, the genetic improvement accelerated resulting in much higher productivity per animal with lower cost per unit of animal product. High productivity of a few improved breeds raises a question of survival and consequently conservation of less improved breeds. Also, highly improved breeds may not be optimal in more demanding environments.

In "► Animal Breeding, Foundations of," Guilherme Rosa focuses on theories that made modern animal breeding possible. These are population genetics, quantitative genetics, mixed models, and related issues. He examines the infinitesimal genetic model where it is assumed that a trait is controlled by a large number of independent loci, and he mentions models involving quantitative trait loci (QTL) or major genes. Selection can be for a single trait with possibly undesirable response for some of the remaining traits, or it can be multitrait, where weights on traits are economically derived for a more balanced breeding.

The selection in animal breeding depends on models and often sophisticated computing to estimate parameters of those models. In "► Animal Breeding, Modeling in," Lawrence Schaeffer presents mixed models that are commonly used to analyze many traits in small and large populations. In particular, an animal model considers all phenotypes and pedigrees to provide best unbiased linear predictions of animals' breeding values (EBV). While the basic animal model may be sufficient for fairly accurate predictions, sometimes additional features are necessary to better reflect the complexity of data. Large differences in variability within the environments require a model that accounts for heterogeneous variances per environment, categorical traits are best analyzed by a threshold model; special models are needed to analyze data censored, e.g., by time.

While most of the progress in animal breeding was based on the infinitesimal model, the availability of genetic markers raised hopes of finding major genes. Subsequently, marker-assisted selection (MAS) would allow determining EBV for young animals without waiting for phenotypes. In his entry "► Animal Molecular Genetics from major genes to genomics," Asko Mäki-Tanila describes theories for finding markers or QTL and applications of MAS. While several large QTLs have been found, in general, the estimated values for large QTL seem to be inflated while many QTLs are below the detection level. Thus, the total contribution of large QTLs seems to be small for most traits.

Currently, individuals can be genotyped inexpensively for a large number of SNP markers. The use of these markers for breeding is called the genomic selection. The genomic selection is successful in populations with small effective population sizes where the genomic information provides more accurate relationships.

A selection is usually performed in a specific environment, which is defined as a combination of climate, nutrition, management, and stability. Animals excelling in one environment may perform poorly in another environment and vice versa, or show a genotype by environment interaction (GxE). In "► Animal Genetic in Environment Interaction," Erling Strandberg describes terms useful for quantification of GxE such as plasticity and homeostasis. GxE can be analyzed by reaction norms. We are interested in GxE only when genotypes rank differently in different environments.

The traditional selection is by selecting the "best" individuals. However, these individuals may indirectly be selected for poor group performance, e.g., aggression, and such animals may inhibit the growth of the other animals. In "► Socially affected traits, Inheritance and genetic improvement," Peter Bijma presents cases where the group performance is more important than the individual performance, proposes models that can be used to breed "socially adapted" animals, and describes results of experiments with such breeding. The social performance is most important for animals bred in cages such as poultry and pigs where the aggression can result in physical harm or even death. An intuitively obvious solution to aggression of allowing more space per animal in fact increases fighting and subsequently causes economic losses, as extra space allows for more fighting.

The next few entries are devoted to breeding for specific species.

In the entry ► Poultry Breeding, Yoav Eitan and Morris Soller document how, over the past 100 years, the chicken meat changed from being one of the most expensive to the least expensive. Such a progress required a good choice of initial breeds, intensive selection, and diligent research to discover sources of new problems and their mitigation, and constantly adapting management to address these problems. The success with chicken is possible only when the environment can be tightly controlled as highly adapted animals retain minimal flexibility to handle less than the optimal conditions. An important issue in chicken is animal welfare. While some stresses are unavoidable, like in nature, reducing the avoidable distress can be good economics.

In the entry ► Pig breeding for increased sustainability, Pieter Knapp examines broader issues in breeding using pigs as an example. The first issue is diversity. Should different breeds be preserved or is it unimportant? What is the optimal size of the breeding population to sustain genetic variability and maximize the genetic progress over the long run? Pigs have been singled out as causing environment pollutions. Can breeding minimize the pollution? One way to minimize pollution and environmental damage is to breed efficient animals with good feed conversion ratio (FCR). Can one radically improve FCR? Is animal welfare a liability or an asset? The entry by Pieter Knapp contains extensive references.

Filippo Miglior, Sarah Locker, and Roger Shanks take a look into dairy breeding in their entry ► Dairy Cattle Breeding. An intensive selection for milk made Holsteins the highest producing and the most popular dairy breed in temperate countries. Most of the progress in Holsteins, and to a lesser intent, in other breeds, is through the extensive use of highly select sires through artificial insemination. The selection of sires is in fact global because national sire evaluation from some 30 countries are now pooled together by an international agency "Interbull," and semen of bulls ranked by this agency are available worldwide. Strong selection for production had an undesirable effect on fitness, including reduced fertility and survival. This side effect is remedied now by increased emphasis on fertility and survival in the selection index, and by crossbreeding. Lately, genomic selection greatly changed the breeding scheme in dairy.

Matthew Spangler describes beef breeding in the USA in his entry ► Breeding in Beef Cattle. As opposed to dairy, the beef population consists of many breeds, and most animals sold for beef are crossbreds. Beef is initially raised in ranches and later brought to feedlots for a short time for accelerated growth. Animals are genetically evaluated based on growth at a few age points, for carcass characteristics and for fertility. Important issues in beef evaluation are heterosis and recombination loss in crosses. FCR in beef is much lower than in poultry or pigs; however, beef can utilize land unsuitable for crops.

Thorvadur Árnason, in his entry ► Breeding in Horses, presents issues in breeding horses, predominantly for racing. Such breeding is successful as the trend for maximum speed is positive. As only selected individuals are run in races, breeding for speed requires accounting for censoring, i.e., lack of records for an important part of the population. This is done by treating as phenotype a categorical variable of "has" or "does not have" records. An issue specific for horses is increased inbreeding due to very intensive selection and small populations. Large increase in inbreeding has negative effects on many traits and also increases the chances of propagating a recessive gene.

SWP Cloete looks at aspects of ► breeding in developing countries and tropics. Increased production due to the animal breeding and limited population growth was successful in developing countries in creating surpluses of animal products. In developing countries, the animal breeding was less successful while the population exploded, resulting in shortages of animal products. The breeding was less successful because of specific challenges in developing countries and especially the tropics, and much smaller R&D. Traits especially important in the tropics are disease resistance (including tick and trypanosome), draft resistance, and ability to produce under periodic feed shortages. Subsequently, animals bred in the developed world may not survive in the tropics; however, their crosses sometimes do well. This entry contains a large number of references.

Even though the animal breeding is successful, there is a question whether the current pace of progress can be maintained. For example, FCR cannot be decreased below some 1.5 kg feed/1 kg of meat, unless the extra selection results in increased water content. Also, increased milk production at a cost of reduced fitness (less fertility, lower survival, more susceptibility to diseases) can at one point decrease overall profitability. Peer Berg ponders long-term challenges in animal breeding in his entry titled ► Animal Breeding, Long-term Challenges. Low effective population sizes make whole populations less biosecure. Too optimized genotypes may require huge facilities that could destroy the environment and rural life. Also, new requirements for welfare may require changing breeding goals. However, most long-term challenges are not well known.

Animal Breeding Methods and Sustainability

Agustin Blasco
Institute of Animal Science and Technology, Universidad Politécnica de Valencia, Valencia, Spain

Article Outline

Glossary

Breed A population of animals with common morphological characteristics that is recognized as a breed by the administration, by a breeders association, or by other groups of people.

Best linear unbiased prediction (BLUP) It is the most common statistical method used in breeding evaluation.

Quantitative trait locus (QTL) A gene having influence in a quantitative trait.

Markers Fragments of the DNA molecule for which their position is known.

Response to selection Genetic progress.

Definition of the Subject

After domestication, animals were selected in different environments and for different traits leading to the modern breeds. Long before the appearance of the science called now as "Genetics," animal breeding had been practiced by humans following intuitive criteria, less efficient than the scientific ones, but criteria that had provided success along many generations of selection [1]. The lack of a theory explaining inheritance slowed down animal breeding for many years, but with the rediscovery of Mendel's rules at the beginning of the twentieth century and the development of quantitative genetics in the 1920s and 1930s animal breeding had the tools needed for its development. Animal breeding methods were developed in the 1930s and 1940s, and the first animal breeding companies and cooperatives started in using scientific methods for animal selection [2]. The development of artificial insemination in cattle in the 1940s and frozen semen in the 1950s led to the modern schemes of progeny test, in which bulls are proved with a high number of daughters, and semen of the best bulls is available worldwide. Large companies of animal breeding were created in the 1960s for poultry and pigs, and nowadays they dominate the market of reproducers, particularly in the avian case. In 1953 the structure of the DNA was published, leading to a quick development of all molecular genetics techniques. Today, DNA information is widely used as a complementary tool to the statistical methods based on data from records, to estimate the genetic values of the candidates to selection [3]. Although the commerce of genes is now extended worldwide, there is a recent interest in conserving breeds in danger of extinction due to this globalization. These breeds are a genes reserve for ensuring possible changes in the future market. Besides, some breeds can be helpful for developing sustainable systems in areas in which modern developed animals cannot be bred because of the lack of resources, climate, or other reasons [4].

Introduction

Long before the appearance of the science that is now called "Genetics," animal breeding had been practiced by humans following intuitive criteria, less efficient than the scientific ones, but criteria that had provided success along many generations of selection. Darwin himself was impressed by the achievements of farmers, and artificial selection was a source of inspiration for his theory of evolution [5].

> We cannot suppose that all the breeds were suddenly produced as perfect and as useful as we see now them; indeed, in several cases, we know that this has not been their history. The key is man's power of accumulative selection: nature gives successive variations; man adds them up in certain directions useful to him. In this sense he may be said to make for himself useful breeds.

Animal breeding starts with domestication. Although there are several theories about the domestication process, it is generally admitted that selective breeding led to modern domestic animals, a hypothesis corroborated by the experiment of domestication of wild silver foxes started by Dimitri Belyaev in 1959 and still continued. After 40 years of selection for quiet temperament, silver foxes, which are aggressive to humans in the wild, became as friendly as dogs [6]. As a correlated response, some physical appearance also changed, and some bones of the skull were modified in the same direction as dogs when compared with wolves [7]. Modern molecular techniques permit to reconstruct the history of domestication [8]. After domestication, animals were selected in different environments and for different traits, leading to the modern breeds. References to animal breeding can be found in ancient Greek and Roman authors' works [9]; however, modern breeding practices start with the self-taught work of Robert Bakewell (1725–1795), who produced new breeds and had a high reputation as breeder [1]. He focused his work in the performances of his cattle and sheep, hiring rams, recording the offspring and keeping the sons of the best males. He fixed few and clear breeding objectives mating the best females with the best males. However, he disregarded the damaging effects of inbreeding and due to this, he had fertility troubles with his new breeds, but he is still considered as the first farmer practicing modern animal breeding.

The lack of a theory explaining inheritance slowed down animal breeding for many years. The theory of blending inheritance, sustaining that offspring was intermediate between parents, could not explain the persistence of genetic variability. Some hybrid breeders had noticed that crossing hybrids they can recover discrete traits that were present in the parental population [10], but Gregor Mendel (1822–1884) was the first in calculating the frequencies in which the observed traits were transmitted, allowing him to propose the first rules of genetic inheritance [11]. Although Mendel was conscious of the importance of his research, his work, published in a context of hybrid plant production, was largely ignored until it was rediscovered at the beginning of the twentieth century, and it was widely used to explain the inheritance of discrete observable traits. Mendel's rules worked well for discrete traits like yellow or green color, but many traits like milk production or body weight showed a continuous variation and seemed to follow different inheritance rules. The biometrician school, founded by Karl Pearson (1857–1936), was using and developing statistical methods, and rejected Mendel's rules, considering them as a special case of inheritance for some discrete characters [12]. Mendel was aware about the fact that the simple rules he discovered could not be applied to continuous variation, but he suggested that in these cases many inheritance factors might act simultaneously producing all intermediate indistinguishable classes. After some exam of this possibility, it was disregarded by the biometricians, and a bitter dispute about the mechanisms of inheritance started until Fisher (1890–1962), in a seminal paper [13], used statistical methods to reconcile Mendel's laws on inheritance with the continuous variation observed by biometricians. (For a history of early development of genetics and this dispute, see [12].)

The work of Fisher in this and subsequent papers started both modern statistics and modern quantitative genetics, but the methods of this new science had still to be applied to animal breeding. This task was accomplished by Lush (1896–1982), who harmonized breeding practices with the knowledge provided by the new discipline. Lush defined concepts like heritability, and proposed methods of selection including the information of relatives, weighed according to the genetic contribution predicted by Mendel's rules and quantitative genetics. The several editions of his book "Animal breeding plans" contributed to spread the new knowledge among scientists, technicians, and breeders [14]. Modern indexes of selection for several traits were developed for plants by Fairfield Smith [15] closely following some indications given by Fisher, and Hazel [16] applied them to animal breeding allowing on one side to use family information and on the other side to weigh all traits of economic interest according to the predicted benefits that the offspring would give.

The development of artificial insemination permitted having offspring of the same sires in many farms (see [17] for a history of its development). As environmental effects were different depending on the farm circumstances, data had to be corrected in order to evaluate the animals properly. Corrections for environmental effects like parity, season, length of lactation, etc., had been made before, but then the problem was

more complex. Several methods were developed to pre-correct the data before genetic analysis was made, but it was Henderson (1911–1989), who proposed a method for integrating the genetic values and the environmental ones in the same statistical model. This allowed the prediction of genetic values at the same time that corrections for environmental values were made [18]. The development of computers allowed using all relatives in the evaluation, and some computing difficulties derived from the use of all relatives were solved by Henderson himself [19]. Nowadays his method called best linear unbiased prediction (BLUP) is the standard method in animal breeding evaluation. BLUP needs the variance components (genetic and environmental) for predicting the genetic values. To estimate them is a difficult task, because data come from different farms and different environments and they should be corrected as before. Paterson and Thompson [20] showed how to correct for the environmental effects and how to estimate the genetic variance components at the same time. Their method is called REML (Residual or Restricted Maximum Likelihood) and it is a standard for variance component estimation.

Animal breeding was dominated by REML and BLUP – and they are still the most common methods – until the development of modern computers allowed the use of Bayesian methods. These methods use probabilities for inferences, which give them several advantages and permit to express the uncertainty about the unknowns in a natural way. For example, it is easier to understand that the probability of a breed having a higher growth rate than another is 93% than to understand that when estimating the difference in growth rate between breeds, in an infinite number of repetitions of the experiment, new samples will be higher than the actual sample in a 7% of the cases (which is the definition of a *P*-value of 7%). A review of Bayesian methods compared with classical statistical methods in animal breeding can be found in [21]. Bayesian methods were introduced by Daniel Gianola in the 1980s [22], but they lead to complicated integrals that could not be solved even by approximate methods. The rediscovery of a numerical method called Monte Carlo Markov Chains permitted to overcome this problem and to use Bayesian methods, leading to a high development and extension of them in animal breeding (see [23] for a detailed exposition of the methods).

With the arrival of DNA analysis techniques, a new field was open for research. Transgenesis looked as a promising area, but its real usefulness in animal breeding has been discussed [24]. Molecular markers, however, have been widely used in animal breeding as a complementary tool in genetic programs. They have been also used for capturing major genes; unfortunately, most traits are not controlled by major genes and molecular markers have had a limited success in this area [25]. Recently, simple molecular markers consisting in a single nucleotide substitution in the DNA chain (SNP) have been made easy and cheap to detect. This permits to use several thousand markers in each individual, thus all genes controlling a trait can potentially be associated to SNPs [26]. A main problem of this procedure is that these associations between SNPs and genes are lost after few generations of selection [27], but new associations can be reestimated. Nowadays genomics is being examined as a promising tool for many genetic programs, particularly in species like dairy cattle in which there is a continuous recording, the trait is expressed only in females, and generation intervals are large. In this case, genomics can be used for a better evaluation of young bulls that still have no offspring. Other uses of genomics will appear in the forthcoming years and it will be probably established as a useful complementary tool to current genetic programs.

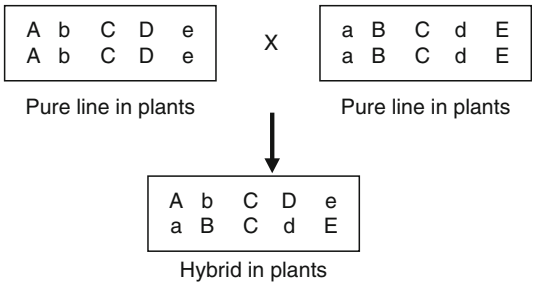
Animal Breeding and Sustainability

Animal breeding consists essentially in selecting animals kept in close reproduction systems, often accompanied with crosses between these groups of animals [2]. Historically, the groups of animals kept in close reproduction were breeds, although modern intensive meat production of prolific species is now based in selection of synthetic lines. These lines are called "synthetic" because they do not correspond to traditional breeds, but have been generated by crossing animals from different breeds or crossing commercial "hybrids" (which are not hybrids in a genetic sense, as it will be seen later). This procedure allows obtaining a large genetic variability available for selection on productive traits. The relevance of breeds for sustainability lies in that some breeds can be particularly well adapted to local conditions, although this does not mean that local breeds are always better for local conditions than

foreign breeds. A foreign breed can be better adapted or can be economically more interesting than a local breed. This is common mainly in species like poultry, pigs, or rabbits, which are usually kept in better environmental conditions than beef, sheep, or goats, but it also happens in ruminants. For example, Nelore cattle, a foreign breed in Brazil, has had a high success and now it is extensively implanted there [28].

Definition of Breed

There is no consensus about the definition of what a breed is. Many definitions of breed have been compared [29–31], and the only common requirement to all of them is the genetic homogeneity, which applies essentially to external traits. It can be said that *a breed is a group of animals with some common external characteristics defined by some people who consider this group of animals to be a breed*. A breed requires some people who decide the external characteristics used to define the breed; often they also attribute some "average performances" to the breed. The problem with this definition is that it depends too much on external characteristics that may be very useful for dog or ornamental animals, but not necessarily for animals producing meat or milk in an efficient way. Some breeds were historically selected for improving some traits and they have been established as the most productive ones in intensive production systems; Leghorn hens for white eggs, Friesian cows for dairy cattle and Landrace and Large white in pig production are now widely established. However, the word "Leghorn" or "Landrace" only define the external appearance of the breeds; there are many types of Landrace in the world, depending on the traits for which they have been selected, and the few multinational companies that control the eggs market use specific highly productive Leghorn lines, therefore the concept of "breed" is often of little utility. Other words used in animal breeding that can lead to confusion are "pure breed" and "hybrid." In plants, a hybrid is the cross of two pure lines. A pure line is homozygous for all its genes, and all individuals have the same genotype, all hybrids have also the same genetic composition, and the cross of two plant hybrids produces very different plants due to the segregation of all the alleles (Fig. 1).



Animal Breeding Methods and Sustainability. Figure 1 Pure lines and hybrids in plants. Couples of letters indicate genes; capital letters indicate one allele of a gene and small letters another allele of the same gene

There are no "pure lines" in animals in the same sense as in plants. Pure lines in plants have been produced by self-fertilization or by fertilization of close relatives, something that is not possible in animals. Some attempts of creating highly inbred lines in pigs and poultry were done in the 1940s and 1950s, without positive results, because inbreeding produces infertility and abnormalities to a degree that prevents its use in animal breeding [2]. "Pure lines" in animals are only groups of animals in closed reproduction that will not be homozygous for all their genes, therefore animal "hybrids" will be crosses between lines or breeds with no genetic homogeneity. Moreover, it is a frequent practice in animal breeding to open the lines to some animals from other commercial lines in order to reduce inbreeding. This practice is also useful to capture genes that would be in lower frequency in the recipient line and that may be in higher frequency in the imported animals [32]. As "animal hybrids" are only crossed animals, they can be used to produce new "animal pure lines" with high genetic variability available for selection; for example, several rabbit breeds used for commercial purposes were originated by crossing commercial "hybrids" [33].

Breeds were created by humans after domestication by selecting traits they particularly liked. New breeds can be created nowadays. Apart from pets, many companies of pigs, rabbits, and poultry now use synthetic breeds without giving special importance to external characteristics, with the exception of the functional ones.

Breed Conservation

Some breeds, local or not, can perform better than some intensively selected lines in systems in which food is less rich in protein or energy, or less balanced than in intensive systems. Some breeds can also perform better in some areas in which climate or breeding conditions are very different from the ones of current intensive production systems. There are more reasons for conserving breeds [34]: keeping genes that may be useful in the future, supporting sustainable animal production systems for food security, maintaining genetic variability for further use, conserving cultural heritage, etc. However, when a breed is useful, it does not normally need special aids for conservation, since it produces some profit and then it is kept for obtaining benefits. Help is needed especially for breeds that are not profitable, but there are reasons for inferring that they have genes that may be useful in the future. A question then would be whether the object of conservation should be breeds or genes, that is, whether it can be created as synthetic breeds having the genes of interest instead of spending funds in several programs for conserving several breeds. Although focusing the problem in keeping genes seems to be simpler, this can produce some problems. A first problem is that creating synthetic breeds may lead to undesirable gene interactions, difficult to manage for both the survival of the breed and the transmission of the interesting genes. Another problem would be the difficulties in integrating new synthetic breeds in areas in which farmers would not be prepared or accustomed to manage [35].

One of the main objectives of breed conservation, keeping genes for the future, has been discussed [35]. This objective is too vague unless the concrete purpose for using these genes in the future is envisaged. When a breed is a tool for making meat, milk, or eggs, conservation should be focused on whether this tool works now or whether there are expectations for using this tool in the future. This is an important point, because the extinction of a breed is completely different from the extinction of species. Breeds extinction, which can be created, transformed, or recovered, should not be compared with losing unrecoverable species created by natural evolution and forming part of a peculiar ecosystem.

The more concrete objective of maintaining genetic variability can be attractive for two reasons. First, genetic variability is needed for selection. Second, genetic variability implies a gene reserve that may also be useful when a rapid change in selection objectives is needed, for example, the current fertility problem of Holstein, partially caused by the increasing levels of inbreeding, can be managed by crossing Holstein with more fertile breeds [36, 37]. We should, however, notice that the genes of interest in animal breeding control economically relevant traits, thus keeping genetic variability is not an objective if the trait is near its optimum (100% of survival, for example). Genetic variability can be divided in between breeds variability and variability within breeds. It is important to know how much of the total existing genetic variability can be found between and within breeds, because if most of the genetic variability is contained within breeds, there is no genetic reason for conserving many breeds. For example, measuring the number of SNPs per kb in chicken, the International Chicken Genome Sequencing Consortium [38] detected "surprisingly little difference in diversity in comparisons between red jungle fowl and domestic lines, between different domestic lines, and within domestic lines." For productive traits, it is generally admitted that about 50% of genetic variability is between breeds and 50% within breeds [39, 40]. Some methods of measuring genetic variability, like estimating genetic distances between breeds by molecular markers, have among other problems that they do not consider within breed genetic variability. The core of the argument for maintaining between breeds genetic variability is that some breeds have genes that other breeds do not have or have in low frequency, and these genes may be useful in the future. It is a type of "insurance argument": insurance against changes in market or environmental conditions, and safeguard against potential emerging disasters as emergent diseases [4]. There is nothing wrong in keeping every breed in danger when having an unlimited amount of financial resources, but when resources are scarce, for example, in developing countries, a precise analysis of the foreseen benefits is needed.

Breeds and Sustainable Systems

By animal breeding sustainable systems, it is generally understood that farming systems are capable of maintaining their productivity indefinitely without damaging the environment [41]. This definition does not prevent having intensive systems with highly productive animals integrated in an industrial food chain, but sustainability is often associated to some kind of traditional farming at small scale in which waste is recycled, local breeds and local sources of food used and a rather high amount of hand labor is needed. Local breeds have a key role in this second type of sustainable systems, particularly when the environmental conditions are harsh or the food resources are not particularly good. This second type of sustainable systems is in general much less efficient for producing meat or animal products than intensive systems. There are, however, some reasons for establishing them:

1. *There are harsh environments in which no other systems will work properly.* A common example is cattle in swamp tropical areas. This applies essentially to cattle, sheep, and goats, and not necessarily to pigs, rabbits, or poultry, which have been kept in much better conditions traditionally.
2. *Using these systems in poor areas avoids land abandoning and migration of people to urban areas, avoiding desertification.* If life in these areas is hard for humans, this type of sustainable system should be considered as a temporary solution, because people living there deserve a better life.
3. *Sustainable systems are more environmentally friendly and produce a better animal welfare.* Although this reason is frequently invoked, this may or may not happen, and each case should be critically examined. Intensive industrial egg production can use enriched cages and manure process ensuring both welfare and sustainability. Moreover, animals in intensive systems arrive to commercial slaughter weight much earlier, thus they can produce less CO_2 and pollutants *per unit of product* than animals bred in extensive production systems, including pollution producing for transport, machinery, etc. A report ordered by the British government to the University of Cranfield [42] shows how this happens in poultry meat production, being organic chickens more contaminant *per kg of meat produced*, although results are more variable in pig production (for most pollutants, organic pigs contaminate less per kg of product). The same can be said about welfare: free-range hens are not necessarily happier than hens in enriched cages [43]. Looking for better animal welfare is not a particular task of industrial systems; it affects non-intensive systems as well.
4. *Some of these systems provide farmers an independence from big multinational companies.* This may be true, but is not necessarily good. Feeding people is a priority of poor countries, and the cheapest way may be to buy the genes to multinational companies. Genetics is very cheap; the genetic cost of 1 kg of pork, chicken, or rabbit meat is less than a 1% of the total cost of the meat as it will be seen in next section, and the same can be said about the genetics of 1 l of milk. Few companies provide the cheapest animal protein in the world (eggs and poultry meat and, up to a certain extent, pork meat), and genetics of dairy cattle is now managed in what is a world nucleus in practice. Poor countries need efficient genetic material for meat production even if this does not ensure genetic independence from multinational companies; this happens in industrial products and in other sectors (cars, industrial products, energy, etc.), and there is no reason for not accepting this in animal breeding.
5. *Some breeds are better adapted to local environment.* As said before, some breeds can be particularly well adapted to local conditions, although this does not mean that local breeds are better for local conditions than foreign breeds. There are spectacular examples of foreign breeds particularly well adapted, as Nelore cattle in Brazil. Besides, adaptation is a bigger problem in some species than in others. Poultry, pigs, and rabbits have been raised in better environments than sheep or goats, thus intensive commercial breeds have less adaptation problems than in other species. Local food sources are often of lower quality than the usual food provided for highly productive breeds, and it has been said that local breeds can take a better profit of it. This is highly speculative, since the available

Animal Breeding Methods and Sustainability. Table 1 Sow reproductive performance of PIC pigs in Philippines [44]

	Ave total born per litter	Ave born alive per litter	Ave weaned pigs per litter	Ave birth weight (kg)	Ave 30 day weight (kg)

Small farm sector	11.9	11.4	11.1	1.5	8.8

Source: From Gibson et al. [44]

information for these local breeds is normally scarce or null. Moreover, highly productive breeds of pigs, poultry, or rabbits can be bred with success in developing countries, even by small farmers [44]. Table 1 shows that small farms in rural conditions can obtain a similar profit as better farms using the same genetic material of a big multinational company (PIC). Local breeds of cattle, sheep, and goats may be better adapted in some harsh environments, although it is important to check whether this is true and when it is true.

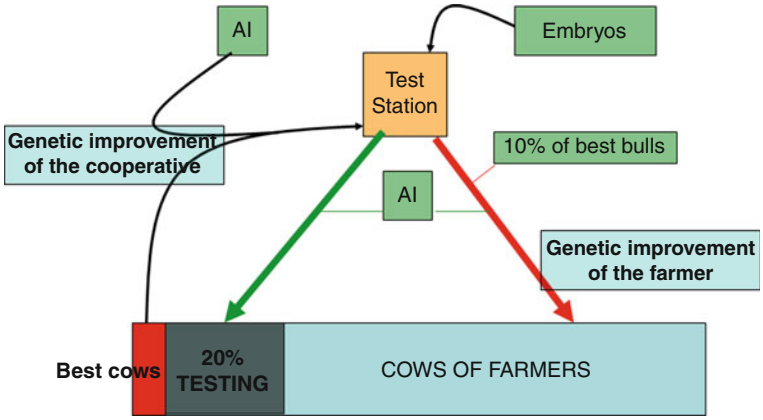
6. *Local breeds produce better quality products.* The question is too general to give a simple answer. It is rather obvious that an Iberian pig (local breed) produces a much better cured ham than a Large White pig. Production of high quality products is one among several reasons for keeping breeds that are less efficient in producing meat or meat products. It is nevertheless convenient to check whether this better quality is detectable by the consumer. Some products like fresh cheese are not easy to differentiate, and local breeds sometime only show an external appearance of the animals different from the main breeds used for cheese production. It is also important, as St. Clair Taylor has stressed many times [45], that comparisons between breeds are performed at the same stage of maturity. As breeds have often different adult size and growth rate, if they are slaughtered at the same commercial weight, they can be compared at different stage of maturity, thus differences between them can be due to the fact that one breed is younger, in physiological terms, than the other. For example, a breed can have a better meat quality than another only because at the same commercial weight it is slaughtered at a more mature stage.

Animal Breeding Methods and Schemes

Breeding Companies: Organization and Diffusion of Genetic Progress

Animal breeding can be practiced at small scale by farmers or small farmers associations, but this affects only the local breeds and its efficiency is low [21]. Nowadays animal breeding is generally in the hands of multinational companies or large cooperatives, although there are still medium sized ones performing animal breeding at a smaller scale. There are two types of schemes, based on recording data on farm or concentrating on all animal improvement in a small nucleus and diffusing later the genetic progress. The first scheme applies mainly to dairy cattle, and the second one to pigs, poultry, and rabbits.

The standard example of the first scheme is dairy cattle. A 20% of the cows of a cooperative are inseminated with semen of young bulls that are going to be tested. The daughters are then inseminated with semen from other bulls in order to have lactation. Milk, protein, fat and cell count of the milk, and sometimes longevity, are recorded for each of the daughters, and these data are used to decide which 10% of the bulls being tested will pass to the catalogue of the cooperative (Fig. 2), to be used by the farmers to inseminate their cows in order to replace their stock. Each bull being tested provides semen for 1,000 cows in order to be sure that most of them will have at least 100 daughters, in order to achieve a high precision in the estimation of their breeding value [46]. This implies that an association created for bulls testing should have at least 100,000 cows in order to include a couple of bulls per year in their catalogue. Nowadays there are many practices: big cooperatives test their bulls; some associations test few bulls that are available



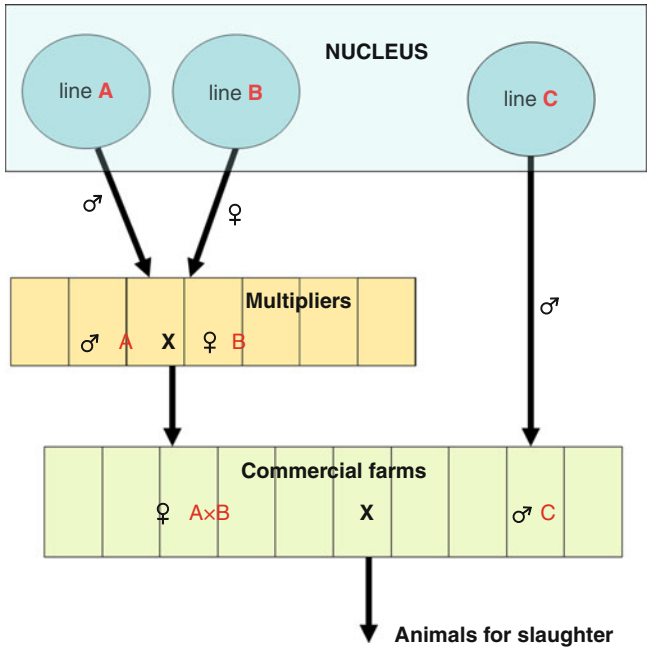
Animal Breeding Methods and Sustainability. Figure 2
Schemes of genetic evaluation and gene diffusion for dairy cattle

in their catalogue after having 60 or 70 daughters, and import semen and embryos making them available to the members; some companies test bulls and then commercialize the semen; etc. In a global society in which frozen semen can be bought worldwide and records are collected in different countries, a global genetic evaluation has been established by an association called Interbull that publish their world evaluation for all sires of different countries.

Selection is made from the records, but since a bull being tested will inseminate 1,000 cows, a previous strong selection is made when deciding which bulls will go to the test station to be proved. To do this, the best cows of the association are inseminated with the best semen available to produce the bulls to be proven. Nowadays it is also possible to buy embryos from the best cows evaluated in the world and the best semen available. Genomics is used here to help in the evaluation of these bulls that will arrive to the station. A particularity of the system is that individual farmers can make their own genetic improvement. Catalogues contain an accurate prediction of the genetic value of bulls for many traits, thus a farmer having particular problems with protein content of the milk, functional conformation, or other trait, can buy semen from bulls particularly well evaluated for these traits, improving the genetic level of his farm in the aspects he particularly needs.

The other scheme commonly used in animal breeding is the nucleus-multiplier scheme [47, 48]. Here all improvement is concentrated in a farm, from which it is spread to commercial farms through multiplication steps. This is the typical scheme for pigs, poultry, and rabbits (Fig. 3). Usually two lines are selected in closed reproduction, and males of one of the lines and females from the other are sent to farms called "multiplication units," in which both are crossed to produce the crossed female sent to the farmers. Typically, these lines are selected for prolificacy and they may be selected for other traits. A third line is selected to produce the males that the farmers will use (called "terminal sires"); in this case, the line is not selected for prolificacy because this is a trait attributed to the dam, in which males seem to have little influence. Commonly, there is only one nucleus of selection in each company, and multipliers are spread in several countries. Multipliers act usually under a contract with the company; they buy parental stock for multiplication and they are in charge of providing facilities for breeding and commercializing the product: This system has allowed a rapid development of the business. There are some variations of the scheme; terminal sires are sometimes the product of a cross between two lines C and D, and sometimes there is a multiplication step more, in which other multipliers receive females A $\times$ B to be crossed by a male from other line E to produce females (A $\times$ B) $\times$ E for the commercial farmers.

Multiplication permits to reduce the cost of selection, for example, in pigs, a female coming from one



Animal Breeding Methods and Sustainability. Figure 3
Scheme of selection and gene diffusion in pigs, poultry, and rabbits

of the lines of the nucleus and entering a multiplier can cost 600 € from which 500 € is the cost of the genetics and the rest is the cost of producing a pig. This female will produce about 15 crossbred females for production farms during her life, the rest of them being culled for various reasons (leg problems, diseases, etc.). This means that the 500 € of the genetic cost should be divided by the 15 females, giving 33 € of genetic cost for the farmer. If each female produces an average of 50 pigs for slaughter during his life, the cost of genetics for slaughtered pig is about 67 cents per pig, less than 1 cent for kg. These figures are extreme in poultry production, in which each female of the nucleus can produce nearly 100 females for the multiplication step, and each female of a multiplier can provide about the same quantity for commercial farms.

Statistical Methods of Selection

Statistical methods used in animal breeding are essentially based in the infinitesimal model [49]. In this model, traits are determined by many genes independently distributed, having each one a small effect on the trait. A first consequence of the model is that genetically good animals can produce by chance some genetically poor sons, since by chance a son can inherit most of the alleles producing poor performances, whereas other sons can be genetically better than the parents if they get good versions of the alleles. As an average, all possible offspring of a parent will define how good this parent for breeding is. This is known as "breeding value" or additive value of the parent. The genetic value of an animal is not exactly this because genes can interact between them or among them producing better or worse individuals than the sum of their individual effects. These interactions are known as "dominance" when they appear between the two alleles of one gene or "epitasis" when they appear between alleles of different genes. Interactions can also occur between genotypes and environment, when the best genotypes in an environment (e.g., in the farm where the animals are selected) are not the best in other environments (e.g., in commercial farms). The development of artificial insemination in cattle and the prominent situation in the market of large

companies selling parent stock along the world has made the interactions between genotype and environment an important area of research in modern animal breeding [50].

Another consequence of the infinitesimal model is that it permits to invoke a theorem of statistics known as the *central limit theorem*, which permits considering the traits genetically distributed according to multivariate normal distributions. The multivariate normality has many advantages, for example, zero correlation implies independence between variables (which does not occur in other distributions), variables are determined by few parameters, and all relationships between variables are linear. Statistical methods in animal breeding are based thus in linear regression techniques. The most common models applied in animal breeding are called "mixed models" because they estimate simultaneously the breeding values, considered as random effects, and the environmental values, considered as fixed effects.

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Zu} + \mathbf{e}$$

where $\mathbf{y}$ is a vector with the data, $\mathbf{b}$ is a vector containing the environmental effects (season, herd, parity, etc.), $\mathbf{u}$ is a vector with the breeding values, and $\mathbf{e}$ is a vector with the residuals. $\mathbf{X}$ and $\mathbf{Z}$ are known design matrixes containing 1s and 0s indicating the presence or absence of the effects. Fixed effects remain when repeating the experiment, and random effects change each repetition. Due to this, random effects are not usually estimated in classical statistical theory, but geneticists are interested in the value of these random effects, because they are the breeding values that, *as an average*, will be transmitted to the offspring; thus the best animals can be selected by taking offspring only from the ones with better predicted breeding values. The covariance structure of the breeding values is known due to our knowledge of Mendel's rules for gene transmission. For example, half brothers share *as an average* half of the genetic information of their father. This allows calculating the genetic covariance matrix between random effects $\mathbf{G}$ after knowing which part of the observed variance is due to the genes and which part to the environment. The most common method to estimate these variance components, correcting at the same time for the environmental effects, and using the same model as for estimating breeding values, is called REML (Restricted or residual Maximum Likelihood) [20].

The data need not be normally distributed; in these cases, the model gives the best linear solution. Directly solving this model for many individuals, for example, several thousands or millions of data in dairy cattle, would not be possible, but an equivalent system of equations allows finding the solutions easily [18]. This system is known as Mixed Model equations, and the solution is known as the best linear unbiased prediction (BLUP) of the random genetic values.

$$\begin{bmatrix} \mathbf{X'X} & \mathbf{X'Z} \\ \mathbf{Z'X} & \mathbf{Z'Z} + \mathbf{G}^{-1} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{u}} \end{bmatrix} = \begin{bmatrix} \mathbf{X'y} \\ \mathbf{Z'y} \end{bmatrix}$$

There is a technical difficulty in solving the mixed model equations, because inverting a large matrix as $\mathbf{G}$ is difficult. However, there is an easy way for directly calculating $\mathbf{G}^{-1}$, allowing a general use of these equations in animal breeding programs [19]. The model can be complicated adding repeated data, effects corresponding to single genes, and many other possibilities. It can also be used for many traits simultaneously. When several traits are used, the random effects are correlated not only due to the relationships between individuals, but also due to the genetic correlations between traits, originated when some genes have influence not in one trait but in several ones. Multitrait genetic variances and covariances can be estimated by REML as before, but Bayesian techniques, using a numerical procedure known as Markov Chain Monte Carlo (MCMC), have been particularly useful in complex situations, for example, when some traits have repeated data and other traits not and consequently the design matrixes X, Z are not the same for both traits. Bayesian methods also permit to transform multivariate problems in series of unvaried estimations. Bayesian techniques with MCMC have been rapidly developed in the field of animal breeding, mainly for complex models, for example, when traits have different distributions, for censored data, for robust models, etc. (see [21] for a scope of their use and a comparison with classical methods and [23] for detailed description of Bayesian procedures).

In the case of using many traits, the objective is maximizing the economical benefit, which is obtained weighing each trait by economic weights. These weights can be calculated with more or less sophisticated

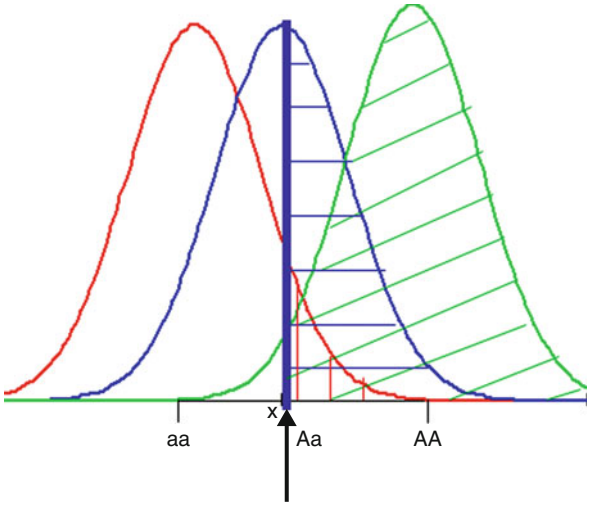
models [51, 52], but in essence they represent the amount of benefits, measured in economical units, obtained by improving one unity of the trait, for example, the number of euros of benefit for producing 1 kg of milk.

The Use of Molecular Genetics in Animal Breeding

Molecular genetics has influenced modern genetic programs. Two different aspects, will be commented here, transgenic animals and molecular markers, including in the late genomic selection. A critical review and discussion about the uses of transgenesis and cloning in animal breeding, with references to markers, can be found in [24]. Genomic selection is very recent and its possibilities and development are still under discussion.

Transgenesis The first transgenic mice growing twice than normal created an enormous expectation about what could be done with transgenic animals [53], particularly in the field of animal production. However, few transgenic animals are now available, and the economical advantage of transgenic animals is small [24]. Although apparently it is economically viable to produce transgenic products useful for human health, the application of transgenic animals in medicine will not be considered here.

To apply transgenesis in animal production, genes with major effects are needed, but unfortunately, most economically interesting traits are determined by many genes of small effects. Sometimes there are genes with major effects for some traits, for example, for fat deposition in pigs, but classical selection has fixed yet the favorable alleles in commercial populations, thus they are not particularly useful now. When a trait of an economic interest has a major gene segregating in the population of study, this gene can be easily captured by selection. This can be shown by computer simulation [54, 55] but a simple example can help in understanding this. In Fig. 4, it can be seen the phenotypical distribution of a trait is controlled by a single gene. When selecting the best 50% of the animals, copies of the allele "A" are selected with preference. Therefore, in few generations of selection the gene will be in high frequencies or will get fixed. If the frequency of the favorable allele is low, the process takes more



Animal Breeding Methods and Sustainability. Figure 4 Phenotypic distribution of a trait determined by a major gene with a high additive effect. Selection of the best 50% individuals

generations, but in general, it hardly will compensate to use transgenesis to capture it. Marker-assisted selection can be used for augmenting more rapidly the frequency of such genes of major effects, as it will be commented in next section.

Some major genes that are present in a breed or a line but not in other can be easily introduced by introgression without requiring transgenesis. The breed with the gene of interest G is crossed with the breed objective O, and then backcross is made by crossing O with the animals of the G × O cross that carry the gene of interest. After several backcrosses, the gene is introgressed. An example of gene introgression is often performed with the Boorola gene in sheep that augments litter size, due to the high prolificacy of the carriers that permit an easy identification. When the carriers do not clearly show the gene of interest, genetic markers can be used to help the introgression [56].

The process of transgenesis is extremely inefficient. Genes are placed at random, thus the gene can be inserted in an inappropriate tissue or it can happen that genes around the inserted gene modify the expression of it. Transgenes are not always expressed and they are not always transmitted to descents. Moreover, many animals are needed for obtaining a viable embryo expressing the genes

transferred. For example, 36,500 embryos were needed to obtain 18 transgenic calves expressing the trait, and the cost of each transgenic cow was higher than 500,000 dollars [57]. Lentivirus vectors can produce transgenic animals more efficiently in some species and at a lower cost, but they still suffer the former problems [58].

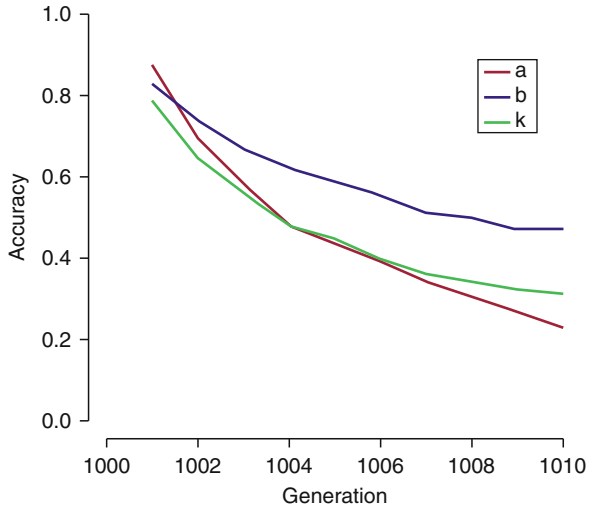
Transgenic animals should be tested to prove that they are commercially viable [24]. They should be tested for the trait that is the object of transgenesis, because it should be proved that the transgene is expressed in the animal and in the offspring for several generations. They should be also tested for commercial traits, since a transgenic line might be good for a trait but might have a poor productivity for other economic traits. The overall productivity should be evaluated. Transgenic animals may have poor fitness, sensitivity to diseases for which non-transgenic animals are resistant and poor performances in other traits that might affect longevity; it is also frequent that transgenic animals have reproductive problems.

Once the major gene has been transferred in an animal, a whole population or line having this gene has to be constituted. In the nucleus-multiplier scheme, inbreeding depression will increase when creating the transgenic nucleus, since mating with relatives during several generations are needed to spread the gene [59]. The process of evaluation of transgenic animals, and the diffusion of the transgene in a line, increases the genetic lag between the transgenic line and the commercial lines, due to the genetic improvement made during this time by its competitors. Diffusion of a transgenic animal in dairy cattle, in which a world nucleus of selection is much higher than in prolific species, and generation interval is large due to progeny testing (6 years), has also been studied. It has been calculated that in a population of 10,000,000 cows, three generations later after the introduction of the transgenic founder (18 years later), the presence of the gene in the population would be between 1% and 4% [60]. The genetic lag produced, the fact that a transgenic animal may be genetically inferior for other traits not controlled by the gene transferred, the complications of the processes and the scarce number of gene candidates for being transferred, makes transgenesis little attractive, even if it would be a less expensive and more successful technique [24].

Genetic Markers and Genomic Selection Genetic markers are parts of the DNA molecule that can be identified in individuals. They may be close to a gene of interest, so they can be used to select the favorable version of a gene affecting a quantitative trait. Genes controlling a quantitative trait are called QTL (quantitative trait loci), and occasionally they can have a large effect and can be selected with the help of a marker. However, generally quantitative traits are controlled by many genes with small effects, thus the effectiveness of markers has been rather limited [25]. The situation has dramatically changed since it has been possible to obtain a large number of markers at low cost and since they can be associated to many of the genes controlling traits even having small effects. There are several types of markers; the simplest one is the Single Nucleotide Polymorphism (SNP), which marks a place in the genome in which there is variability in a single nucleotide. Nowadays there are microchips allowing detection of about 50,000 SNPs in a genome; the number of SNPs that can be easily detected is increasing to 500,000 and soon it will be possible to genotype the whole genome of livestock species at reasonable prices. Prediction equations can be fitted, in which a set of SNPs will be used for predicting breeding values. Taking data from 1,000 to 4,000 animals (calling this *training population*), the model to be fitted can be

$$y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + \cdots + b_{50,000}\,x_{50,000}$$

where $x_1, x_2, \ldots, x_{50,000}$ are the variables indicating the presence of one polymorphism (AA, Aa, aa) of each SNP (usually indicated by 1, 0, −1, or by 0, 1, 2), and $b_1, b_2, \ldots, b_{50,000}$ are the regression coefficients to be estimated. These equations cannot be solved by least squares given the high number of SNPS in relation to the data available for the prediction, and Bayesian techniques should be used. The use of prior information allows solving these big equation systems, and depending on how prior information is included, the Bayesian methods differ [61]. This method can also be used for several traits [27]. Many of these SNPs are noninformative, and there are some techniques to select only informative SNPs [61, 62]. There is now a promising research area for selecting informative SNPs for prediction, often using nonparametric statistics [62].



Animal Breeding Methods and Sustainability. Figure 5 Loss of accuracy of genomic selection on parameters a, b, and k of Gompertz growth curve. Selection acts on trait a, and the loss of accuracy of traits b and k are due to genetic correlations with trait a (From Blasco and Ibáñez-Escriche [27])

Genomic selection has been proposed for traits that are difficult or expensive to measure (e.g., adult weight [24], index of conversion [63], mortality [64]). It has also been proposed in dairy cattle, in which the traits of interest are expressed in dams but selection acts mainly in sires, and the generation interval is very long [65]. It may be useful for other traits like litter size, difficult to select due to their low heritability, but studies are needed to determine its usefulness in these cases, because very low heritabilities will give poor prediction equations since the records will then be determined mainly by the environment.

A main problem of genomics is that the association of SNPs with the genes responsible of the trait quickly disappears in few generations of selection, thus the prediction equations have to be reestimated and new training populations are needed. Figure 5 shows an example of the loss in accuracy of the prediction of genetic values. It can be observed that accuracy is practically halved in four generations of selection.

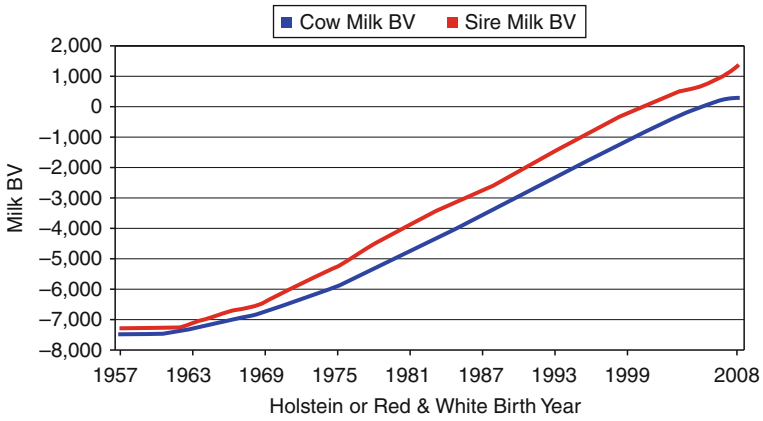
This limits the use of genomic selection in current programs, because in some species the generation interval is short (6–9 months in rabbits or hens, 1 year in pigs), and a continuous reestimation can be difficult or expensive. Finding when and how genomics can be included in current genetic programs is one of the most important research areas nowadays.

Future Directions

The Future Evolution of Methods and Schemes

Prediction of breeding values from records seems to be well established with the methods briefly exposed in section "Statistical Methods of Selection" and it does not seem that dramatic changes will occur in the future at short or medium term. The revolution in methods for estimating breeding values is in the area of genomics. The possibility of having information from several thousands of markers at a reasonable price, now from several hundred thousands and in the near future from the whole genome, has brought the problem of how to manage all these data, and prediction methods are examined from other areas of knowledge as artificial intelligence, using nonparametric or semiparametric methods, Bayesian methods, etc.

Schemes of selection are also changing due to the globalization of the market of genes. Today the best cows of the world are not dedicated to produce milk but embryos that are sexed, frozen, and commercialized. Some of the deficiencies of current dairy cattle programs such as long generation intervals can be partially solved by using genomic selection and having a quicker and better evaluation of the bulls being tested. Larry Schaeffer suggested that genomic evaluation can substitute progeny test, dramatically shortening generation intervals [66], but it is doubtful that farmers will accept genomics evaluation as they accept now tests mainly based in offspring records [65]. It can also happen that private companies will compete with others or that breeders can organize brands in which semen is not identified, like in pigs, as Maurice Bichard suggests [67], but it looks unlikely, since farmers like to perform their own genetic improvement at farm level by buying semen from accurately tested sires. Poultry genetics is now in the hands of two large holdings, and the only change envisaged in their structure is related to possible troubles with laws about competence. Pig companies tend also to be bigger, but they will probably coexist with nucleuses of smaller companies well established in local markets, and with large pig production companies producing parental stock for



Animal Breeding Methods and Sustainability. Figure 6
Genetic values of sires and cows in USA in the last 50 years (From USDA http://aipl.arsusda.gov/eval/summary/trend.cfm)

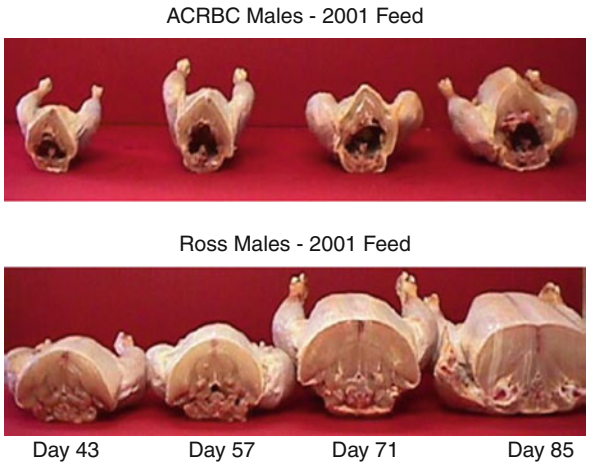
themselves. Both pigs and poultry companies will introduce genomics in their programs not only as a complementary tool for selection but also as a commercial strategy, using modern methodologies as an added value to their products. The interest in meat quality traits and quality of animal products will probably increase. Companies will also stress the sustainability of their productions and the good welfare of their animals, thus there will probably be an increasing interest in traits like robustness and disease resistance. The new emphasis in sustainability will give importance to breed conservation programs, which will receive more attention and will get substantial public funds. Nevertheless, no dramatic changes in objectives are envisaged in the near future. Changes in genetic objectives are slow and the product of the selection arrives with delay to the market, thus this prevents short-term selection policies.

The Limits to Genetic Progress

The theory of selection limits was developed by Alan Robertson (1920–1989) [68]. Classic quantitative genetics theory predicts the extinction of genetic variability by selection, and consequently the end of genetic progress. Frequencies of favorable genes increase with selection until they are close to 100%, and the genetic response is necessarily low, or genes are fixed by genetic drift, which occurs more likely when they are at high or low frequencies and when the selected population is small. Mutation can introduce new genetic variability, but useful mutations are rare and they were disregarded in the classical theory of limits of selection. A decline in genetic response is thus expected until genetic variability is exhausted, and some experiments arrived to a plateau after showing response to selection along 20 or 30 generations in drosophila [69] and mice [70]. However, there is little evidence of any loss of genetic variability in commercial populations [71, 72]. Heritability of milk production in dairy cattle is not decreasing with time but augmenting! [73] and this is not only due to a better control of environmental variance or methods of correction, but also to the continuously maintained response to selection in the last 50 years (Fig. 6).

Long-term genetic responses have been observed in both plants and animals, and there are several examples of continuous genetic progress in all livestock species. A part of the success of the phenotypic trends observed in animals is due to improvements in nutrition, but when comparing chicken broilers fed with food as prepared in 1957 and as prepared in 2001, most of the observed differences are due to genetic improvement [74]. Figure 7 shows carcasses of poultry from an unselected line and a selected line of the same company, fed with modern food.

Broilers show a continuous growth, egg mass production continuously increases, pigs' lean growth selection has dramatically decreased the amount of fat of the carcasses, and in general all selection programs



Animal Breeding Methods and Sustainability. Figure 7 Carcasses of 1957 and 2001 of an unselected and a selected line of poultry fed with the same food [75]

continue having success [72]. The reasons for this apparent non-limits to selection are selection pressure on genes produced by mutation (which has a heritability of about 0.1% [72, 76]) or epistatic interactions, but even when epistatic interactions are important, additive variance typically accounts for over half, and often close to 100%, of the total genetic variance [77]. Bill Hill moved further the classical theory of limits of selection showing how new mutations with selective advantage can increase genetic variability [78]. An experiment corroborating the theory showed how totally homozygous lines produced artificially in drosophila melanogaster could recover genetic variability by selection [79].

Are there limits to the genetic progress? Some traits have biological limits but still genetic progress can be obtained acting on related traits, for example, it is not possible to produce more than one egg per day, but it is possible to increase the laying period, and most of the new response to artificial selection in egg mass comes from this [72]. Highly productive animals can increase the incidence of pathological problems like ascites in broiler chicken or fertility in dairy cattle, but selection on these unfavorable traits [80] or crossbreeding [36] can be performed to continue the progress. Selection including traits different from strictly productive ones should be considered to avoid undesirable consequences of the continuous genetic progress [81]. Apart from some obvious limits (e.g., traits measured in percentage, like survival, cannot surpass 100%), it seems that genetic response can be directed to overcome the biological limits presented when selection acts only in one or few productive traits.

Article Outline

Glossary

Bayesian inference Statistical inference approach based on the combination of prior information and evidence (i.e., observations) for estimation or hypothesis testing. In Bayesian analysis the prior information is updated with the experimental data to generate the posterior distribution of unknowns, such as model parameters. The name "Bayesian" comes from the use of the Bayes' theorem in the updating process.

Breeding value A measure of the genetic merit of an individual for breeding purposes.

Genetic correlation The correlation between traits that is caused by genetic as opposed to environmental factors. Genetic correlations can be caused by pleiotropy (genes that affect multiple traits simultaneously) or by linkage disequilibrium between genes affecting the different traits.

Genomic selection Genomic selection is a form of marker-assisted selection in which genetic markers covering the whole genome are used such that all quantitative trait loci (QTL) are in linkage disequilibrium with at least one marker.

Heritability (narrow sense) The fraction of the phenotypic variance that is due to additive genetic effects.

Infinitesimal genetic model A genetic model that assumes that a trait is influenced by a very large (effectively infinite) number of loci, each with infinitesimal effect.

Linkage disequilibrium Nonrandom association of alleles at two or more loci, leading to combinations of alleles (haplotypes) that are more or less frequent in a population than would be expected from a random formation of haplotypes from alleles based on their frequencies.

Mixed models A mixed-effects model (or simply mixed model) is a statistical model containing both fixed and random effects. Such models are useful in a wide variety of disciplines in the physical, biological, and social sciences, especially for the analysis of data with repeated measurements on each statistical unit or with measurements taken on clusters of related statistical units.

Population genetics The study of allele frequency distribution and change under the influence of the four main evolutionary processes: selection, genetic drift, mutation, and migration.

Quantitative genetics The study of complex traits (e.g., production and reproductive traits, disease resistance) and their underlying genetic mechanisms. It is effectively an extension of simple Mendelian inheritance in that the combined effect of the many underlying genes results in a continuous distribution of phenotypic values or of some underlying scale or liability thereof.

Definition of the Subject

The term *Animal Breeding* refers to the human-guided genetic improvement of phenotypic traits in domestic animals such as livestock and companion species [1]. Animal breeding is based on principles of *Quantitative Genetics* [2–4] and aims to increase the frequency of favorable alleles and allelic combinations in the population, which is achieved through selection of superior individuals and specific mating systems strategies. Selection methods and mating strategies are developed by combining principles of quantitative and population genetics with sophisticated statistical methods and computational algorithms for integrating phenotypic, pedigree, and genomic information, along with the utilization of reproductive technologies that allow for

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

larger progeny cohorts from superior animals as well as shorter generation intervals.

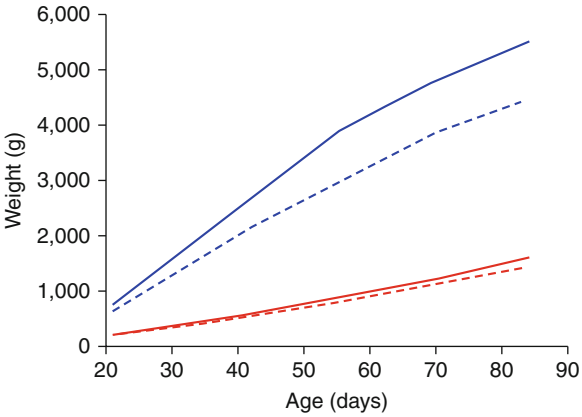
Through selection and mating of superior animals the frequency of favorable alleles is increased, so the overall additive genetic merit of a population is increased through successive generations [5]. Selection can be regarded as the most important tool for the improvement of lines or breeds within a specific species in terms of additive genetic effects. Such lines or breeds can be then intermated such that nonadditive genetic effects such as dominance and epistasis can be exploited through specific inter- and intralocus allelic combinations [1–4].

The theoretical foundations of population and quantitative genetics can be traced back to the work of R. A. Fisher, J. B. S. Haldane, and S. Wright. The rational animal breeding has its origins in the work of J. L. Lush, who made substantial contributions to animal genetics and biometrics research and is generally referred to as the father of modern scientific animal breeding [1].

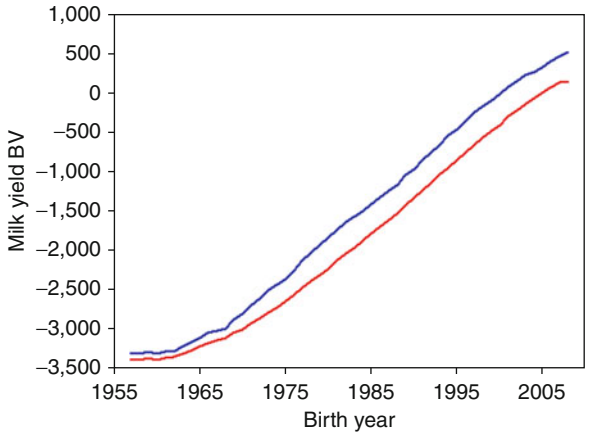
More recent theoretical developments in population and quantitative genetics have been fostered by researchers such as C. C. Cockerham, C. W. Cotterman, J. F. Crow, W. J. Ewens, W. G. Hill, M. Kimura, G. Malécot, T. Nagylaki, and B. S. Weir, among others. A landmark in the area of animal breeding and genetics is the development of mixed model methodology, first proposed by C. R. Henderson, which has been used extensively in many applications in the field, ranging from breeding value prediction under the infinitesimal assumption to gene mapping and segregation analysis. Most recently, Bayesian methods, Monte Carlo, and resampling techniques have been employed to fit and evaluate complex models in different contexts, including nonlinear systems, generalized models, survival analysis, and situations in which the number of parameters or covariates surpasses the number of observations, such as in association analysis and whole-genome marker-assisted selection using high density panels of single nucleotide polymorphism (SNP) markers.

Introduction

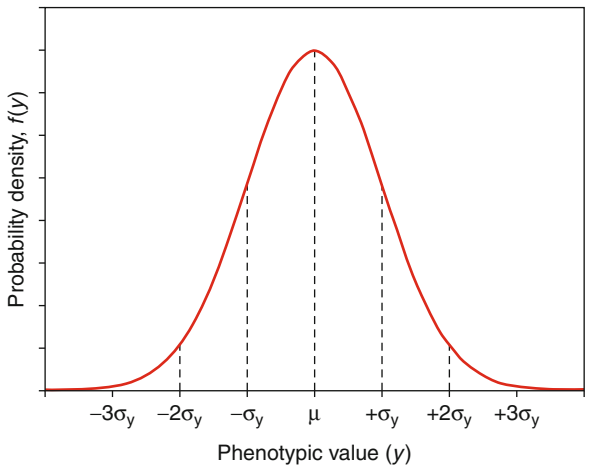
Since domestication, artificial selection has greatly changed the shape, size, and production and reproduction performance of livestock and companion animal species. For example, there is an incredible diversity of canine breeds – and between dogs and their wolf ancestors – from differences in overall appearance to behavior and their ability to perform specific tasks. Although to a lesser degree, the same can be observed in many other companion animal species, such as cats and horses. With livestock species, tremendous genetic changes have been accomplished as well, markedly in the last 50 years or so. For example, Fig. 1 depicts the average growth curves of broilers from selected and control populations. These results refer to a population of birds selected for over 40 years for increased growth rate and another population kept without artificial selection, with both groups derived from the same base population, starting in 1957 [6]. In the experiment presented in Fig. 1, the two groups of birds were fed diets typical of 1957 and 2001, such that the interaction between genetics and feed, as well as the genetic contribution to the phenotypic differences observed, could be assessed. It is seen that the 2001 genetics group presented an average body weight of about 4 kg at 56 days of age, while its 1957 counterpart weighed only 800 g or so. Moreover, it is shown that 85–90% of this fivefold improvement is accounted for by genetics with the remaining 10–15% to nutrition.



Animal Breeding, Foundations of. Figure 1
Average growth curves of commercial broilers. *Blue* and *red lines* represent birds with "2001" and "1957" genetics, respectively. *Solid* and *dashed lines* represent birds fed diets typical of 2001 or 1957, respectively (Adapted from [6])



Animal Breeding, Foundations of. Figure 2
Genetic trend for milk yield in the US Holstein and Red and White populations. Males and females average breeding values are in *blue* and *red*, respectively; genetic base refers to cows born in year 2005 (*Source*: AIPL – USDA; http://www.aipl.arsusda.gov/)



Animal Breeding, Foundations of. Figure 3
Probability density function of a normally distributed trait with mean $\mu = E[y_i]$ and variance $\sigma_y^2 = \mathrm{Var}[y_i]$, i.e., $y_i \sim N(\mu, \sigma_y^2)$

Similar levels of genetic improvement can also be observed in many other species, such as swine, beef and dairy cattle, and some species of fish. For example, as illustrated in Fig. 2, the average breeding value for milk yield in the US Holstein, and Red and White populations has increased over 3,500 kg in the last 50 years.

Such genetic improvements have been accomplished mostly through the selection and breeding of superior animals, which can be chosen using specific statistical methods such as those discussed on the following sections. In this chapter, the discussion will focus on methods developed for normally distributed (Gaussian) traits, under the infinitesimal assumption, i.e., that traits are affected by a large (virtually infinite) number of genes of small effects [2–4], although this assumption is somewhat alleviated in marker- assisted selection, which is discussed later.

Principles of Selection

Basic Genetic Model for Quantitative Traits

The basic genetic model can be expressed as [2, 3, 7]:

$$y_i = \mu + g_i + e_i \qquad (1)$$

where y_i is the phenotypic value of animal i (i.e., the animal's performance for a specific trait); μ is the population mean (average performance of the animals); g_i is the genotypic value of the animal, expressed as a deviation from the mean; and e_i is a term representing environmental factors affecting the animal's performance, also expressed as a deviation from the mean. Hence, it is assumed that $E[g_i] = 0$ and $E[e_i] = 0$, such that $E[y_i] = \mu$, where $E[.]$ represents the expectation function. Moreover, the variance of y_i is given by $\mathrm{Var}[y_i] = \sigma_y^2 = \sigma_g^2 + \sigma_e^2$, where $\sigma_g^2 = \mathrm{Var}[g_i]$ and $\sigma_e^2 = \mathrm{Var}[e_i]$ are the genetic and environmental variances, respectively. Normally distributed traits, i.e., phenotypic traits with a bell-shaped distribution, are generally represented as $y_i \sim N\left(\mu, \sigma_y^2\right)$. Such distribution has a probability density function that can be described as [2, 4]:

$$f(y_i) = \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left\{-\frac{1}{2\sigma_y^2}(y_i - \mu)^2\right\},$$

for $-\infty < y_i < \infty$, $-\infty < \mu < \infty$, and $\sigma_y^2 > 0$, which can be represented as in Fig. 3. To simplify the notation used throughout the text, it is noted that either random variables or their realizations will be represented with lower case letters. However, the context should make it clear to the reader when a letter represents one or the other.

The genetic component g_i of Model (1) can be partitioned into additive (a_i) and nonadditive (c_i) genetic effects, i.e., $g_i = a_i + c_i$, where a_i is also called "breeding value," and c_i refers to the "gene combination value," which encompasses interaction effects between alleles within each locus (i.e., dominance effects) or between alleles in different loci (i.e., epistatic effects).

Hence, Model (1) can be expressed as:

$$y_i = \mu + a_i + c_i + e_i \tag{2}$$

where $a_i \sim N(0, \sigma_a^2)$, $c_i \sim N(0, \sigma_c^2)$, and $e_i \sim N(0, \sigma_e^2)$, with all these terms assumed independent from each other. The phenotypic variance can be then expressed as $\text{Var}[y_i] = \sigma_y^2 = \sigma_a^2 + \sigma_c^2 + \sigma_e^2$, from which two important definitions are derived. The first one is called broad sense heritability, given by $\text{H}^2 = \sigma_g^2/\sigma_y^2$, where $\sigma_g^2 = \sigma_a^2 + \sigma_c^2$, which gives the proportion of the phenotypic variance that is due to genetic effects. The second, called narrow sense heritability, refers to the specific contribution of additive genetic effects to the phenotypic variance, i.e., $h^2 = \sigma_a^2/\sigma_y^2$. These two quantities, particularly narrow sense heritability, will be further discussed and used in the next sections.

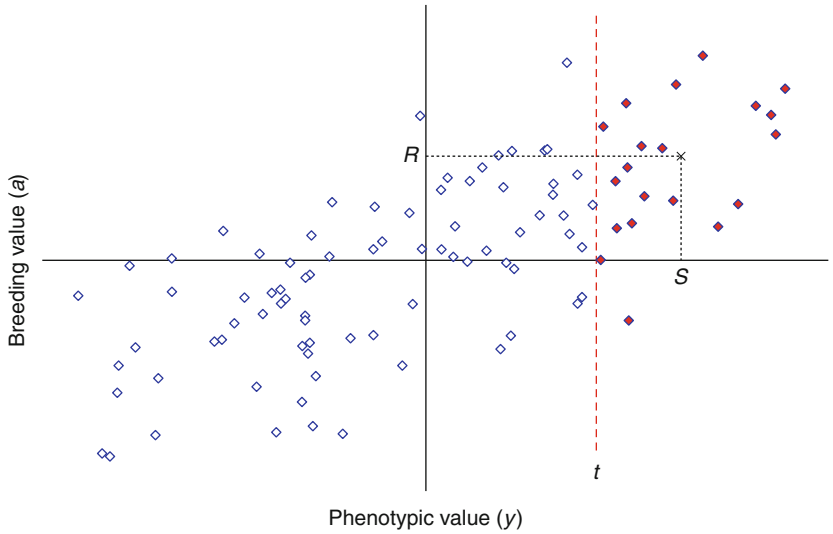
The breeding value of an individual (a_i) is equal to the sum of additive effects of individual alleles within and across loci, and it is sometimes called "additive genetic deviation" or "additive genetic effect." Because individual alleles, and therefore independent allele effects, are passed from parent to offspring, the breeding value of an individual is important for predicting its progeny's performance and so it is central to selection of superior animals [1, 3]. The gene combination value (c_i) is the difference between the genetic merit (g_i) of an animal and its breeding value, i.e., $c_i = g_i - a_i$, so it is often called "nonadditive genetic deviation." Because the component c_i involves interactions between alleles (both within and between loci), and only a single allele (as opposed to a pair of alleles) in each locus is transmitted from parents to offspring, nonadditive effects are not transmitted in a predictable manner. Hence, while average breeding value in a population can be changed through selection of superior animals, the gene combination value should be explored through specific mating systems. Here, the discussion will focus on selection approaches and the genetic improvement of a population in terms of additive genetic effects only. For a discussion on mating systems, such as inbreeding and outbreeding strategies, see for example, [1, 7, 8]. Additional discussion on inbreeding depression and heterosis (or hybrid vigor) can be found in [3, 4].

As discussed previously, the breeding value of an individual is equal to the sum of its independent allele effects. Because a parent passes a random sample of half of its alleles to its progeny, an animal's breeding value is twice what is often called "transmitting ability" or "expected progeny difference" [1, 5]. The expected breeding value of an offspring (a_o) is then equal to the average of its parents' breeding values (the same as the sum of its parents' transmitting abilities), i.e., $E[a_o|a_s, a_d] = \frac{a_s + a_d}{2}$, where a_s and a_d represent the (realized) breeding values of the offspring's sire and dam, respectively. However, there will be variability in terms of breeding values within a full-sib family because of the random sampling of parents' alleles that each offspring receives, the so-called Mendelian sampling [4].

The breeding value of an individual can be expressed as a function of its parents' breeding values as $a_o = 0.5a_s + 0.5a_d + \delta$, where δ refers to the Mendelian sampling component. It is interesting to notice that the variance of breeding values in a specific generation is equal to $\text{Var}[a_o] = 0.25\text{Var}[a_s] + 0.25\text{Var}[a_d] + \text{Var}[\delta]$. Assuming the same additive genetic variance across generations and for both sexes (i.e., $\text{Var}[a_o] = \text{Var}[a_s] = \text{Var}[a_d] = \sigma_a^2$), it is shown that the Mendelian sampling variance is equal to half the additive genetic variance, i.e., $\text{Var}[\delta] = \sigma_a^2/2$.

Phenotypic Selection

The most traditional approach of genetic improvement of livestock (and more generally any domestic animal or plant species) is based on selection of animals with the best performance, or "phenotypic selection" [1–4]. Accordingly, given a group of animals supposedly reared in similar environmental conditions, only those with the highest performance are allowed to breed to produce the next generation. As discussed previously (Model 2), the performance of each animal is a combination of its breeding value and all other nonadditive genetic effects and



Animal Breeding, Foundations of. Figure 4
Scatter plot of breeding values versus phenotypic values. Each dot represents a specific animal and those colored in *red* are selected animals with performance (i.e., phenotypic value) above a specified threshold (*t*). *S* and *R* represent the average phenotypic and breeding values of the selected (*top*) animals, respectively

environmental factors, such that a superior performance does not always represent superior breeding value. Nonetheless, whenever $\sigma_a^2 > 0$, there will be a positive correlation between performance and breeding value, and the effectiveness of phenotypic selection (i.e., selection response) will increase with such correlation.

To illustrate this concept consider Fig. 4, in which a scatter plot of breeding values and phenotypes (centered on zero, i.e., $y_i - \mu$) for a few fictitious animals is presented. As indicated before, in this chapter the discussion will be focused on selection approaches and the genetic improvement of a population in terms of additive genetic effects only, such that Model (2) can be conveniently reexpressed as:

$$y_i = \mu + a_i + \varepsilon_i \qquad (3)$$

where $\varepsilon_i = c_i + e_i$ represents all nonadditive genetic and environmental effects affecting the phenotypic value y_i, assumed $\varepsilon_i \sim N(0, \sigma_\varepsilon^2)$.

Assuming that each effect in Model (3) is independent from each other, the covariance between phenotype and breeding value is given by:

$$\mathrm{Cov}[y_i, a_i] = \mathrm{Cov}[\mu + a_i + \varepsilon_i, a_i] = \mathrm{Var}[a_i] = \sigma_a^2,$$

such that the correlation between phenotype and breeding value is:

$$r_{y_i,a_i} = \frac{\mathrm{Cov}[y_i, a_i]}{\sqrt{\mathrm{Var}[y_i]\mathrm{Var}[a_i]}} = \frac{\sigma_a^2}{\sigma_y \sigma_a} = \frac{\sigma_a}{\sigma_y} = \sqrt{h^2},$$

i.e., the square root of the (narrow sense) heritability.

As the breeding values of animals are unknown in practice, what phenotypic selection does is to predict (or estimate) the animals' breeding values based on their own performance. The prediction is based on the regression of breeding values on phenotypes, and the regression coefficient (slope) is given by:

$$b_{a_i \bullet y_i} = \frac{\mathrm{Cov}[y_i, a_i]}{\mathrm{Var}[y_i]} = \frac{\sigma_a^2}{\sigma_y^2} = h^2.$$

This means that an animal's estimated breeding value (EBV) based solely on its performance (and with a single measurement only) can be expressed as:

$$\hat{a}_i = h^2(y_i - \mu).$$

The correlation between such EBV (which is a linear transformation of y_i) and the true breeding value (a_i) is $r_{\hat{a}_i,a_i} = \frac{\mathrm{Cov}[\hat{a}_i,a_i]}{\sqrt{\mathrm{Var}[\hat{a}_i]\mathrm{Var}[a_i]}} = \frac{h^2\sigma_a^2}{\sqrt{h^4\sigma_y^2\sigma_a^2}} = h$, which

is generally referred to as "prediction accuracy" in the animal breeding literature [5]. The square of the accuracy in this case is equal to the heritability of the trait and is often called "prediction reliability." The prediction accuracy (and consequently the reliability) can be increased by using additional sources of information on an animal (such as repeated measurements of the trait or performance of progeny and other relatives) when estimating its breeding value. An example is with selection indexes and mixed model methodology, which will be discussed later in this chapter.

As indicated in Fig. 4, the selected animals (i.e., the best performing animals) will have an average phenotypic value equal to S and an average breeding value equal to *R*. The expected average breeding value (and also the expected phenotypic performance) of the progeny of the selected animals is also *R*, as illustrated in Fig. 5, and the ratio R/S is equal to the heritability (h^2) of the trait under selection. The genetic progress after one generation of selection is then given by:

$$R = h^2 S,$$

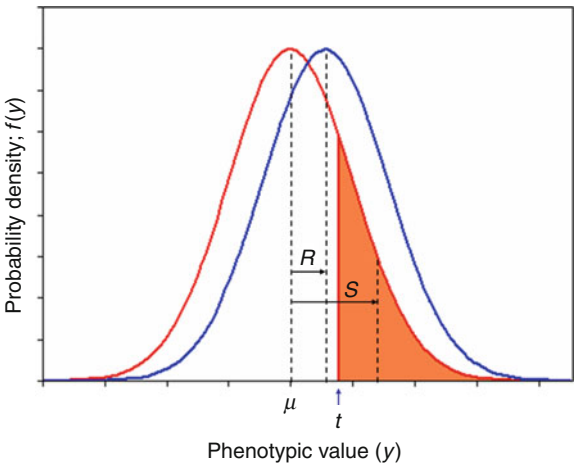
where $R = \mu_P - \mu$ and $S = \mu_S - \mu$, with μ_P, μ_S, and μ representing the average phenotypic performance of the progeny (generation 1), of the selected animals, and of the selection candidate (generation 0) populations, respectively.

The selection differential (S) can also be expressed as $S = i\sigma_y$, where $i = \frac{\mu_S - \mu}{\sigma_y}$ is called "selection intensity," and represents the selection differential in terms of phenotypic standard deviations. In addition, as *R* represents the genetic progress expected in a single generation of selection, the genetic improvement per unit of time is then given by $R^* = R/L$, where *L* is the generation interval. Hence, the expected genetic progress when phenotypic selection on a single trait is employed is [1, 3]:

$$R^* = \frac{h^2 i \sigma_y}{L},$$

which, given that $\sigma_y = \sigma_a / h$, can be expressed also as:

$$R^* = \frac{h i \sigma_a}{L}.$$



Animal Breeding, Foundations of. Figure 5
Probability density of the distribution of phenotypic values in the candidates-for-selection (*red*) and the progeny (*blue*) populations. The candidates-for-selection group represents the parental population (or generation 0), from which the top performing animals (above the threshold *t*) are selected and mated to produce the next generation, or progeny (generation 1). The difference between the phenotypic average of the selected animals and that of the generation 0 is called selection differential (represented by *S*), and the difference between the phenotypic mean of the progeny and that of the generation 0 is called genetic progress, or genetic response (represented by *R*)

This equation is a special form of the so-called "breeder's equation" (or "key equation"), for the case of phenotypic selection. In its general form, the breeder's equation is expressed as [5]:

$$R^* = \frac{\text{Accuracy} \times \text{Intensity} \times \text{Variation}}{\text{Generation interval}},$$

meaning that the genetic progress per unit of time is proportional to the accuracy of breeding values prediction, to the selection intensity, and to the genetic variation, and inversely proportional to the generation interval.

Hence, to increase the genetic progress in a population (e.g., breed or line) through selection, animal breeders (and similarly plant breeders) work to improve the four components of the equation above. As the genetic variability is a natural characteristic of a population and cannot be easily changed, genetic

progress is generally incremented by improving prediction accuracy (e.g., by using specific statistical techniques to combine different sources of information regarding the animals' genetic merit), by increasing the selection intensity, and by shortening the generation interval, which can be accomplished using molecular genetics techniques (e.g., the use of marker-assisted selection) and biotechnology approaches (e.g., artificial insemination).

It is important to mention that the breeder's equation discussed here can be extended for more complex scenarios, such as when males and females contribute differently for some components of the equation [5]. For example, prediction accuracies and selection intensity are generally higher for males if artificial insemination is used. Another important issue to mention here is that selection not only shifts the mean of the breeding values in a population but also changes the genetic variance (and heritability). A primary cause of the change in genetic variance is due to the fact that selected parents represent one tail of the phenotypic distribution, therefore their phenotypic variance is smaller than that of the whole candidates-for-selection population. This leads to a reduction in both the phenotypic and additive genetic variances in the progeny population, which is known as the "Bulmer effect" [2]. In addition, as selection modifies allele frequencies toward the fixation of favorable alleles, selection in one direction over many generations is also expected to reduce the genetic variation. Additional discussion on effects of selection on variance and other short-term and long-term consequences of artificial selection can be found, for example, in [2, 3].

In the remainder of this chapter specific statistical techniques (such as the selection index, BLUP, and genomic selection) for the improvement of accuracy, intensity, and generation interval, and consequently the increase of genetic progress from artificial selection, will be discussed.

Correlated Response and Indirect Selection

If two traits x and y are genetically correlated, direct selection on one of the traits (say y) will also cause a genetic change in the other trait (trait x), which is called "correlated response" [3]. Correlated response to selection ($R_{x\bullet y}$), that is, genetic change in trait x as a consequence of direct selection on trait y, can be predicted by:

$$R_{x\bullet y} = b_{x\bullet y} R_y,$$

where R_y is the genetic progress of trait y through direct selection on itself, and $b_{x\bullet y}$ is the genetic regression coefficient, given by:

$$b_{x\bullet y} = \frac{\mathrm{Cov}(a_x, a_y)}{\sigma^2_{a_y}},$$

where $\mathrm{Cov}(a_x, a_y)$ is the genetic covariance between traits x and y.

The genetic correlation between two traits x and y is given by:

$$\rho_{a_x,a_y} = \frac{\mathrm{Cov}(a_x, a_y)}{\sigma_{a_x}\sigma_{a_y}},$$

such that $\mathrm{Cov}(a_x, a_y) = \rho_{a_x,a_y}\sigma_{a_x}\sigma_{a_y}$ and the genetic regression can be expressed as:

$$b_{x\bullet y} = \frac{\rho_{a_x,a_y}\sigma_{a_x}\sigma_{a_y}}{\sigma^2_{a_y}} = \rho_{a_x,a_y}\frac{\sigma_{a_x}}{\sigma_{a_y}}.$$

Using this term, and recalling the selection response formula discussed before, given by $R_y = h_y i_y \sigma_{a_y}$, the correlated response can then be expressed as:

$$R_{x\bullet y} = \rho_{a_x,a_y}\frac{\sigma_{a_x}}{\sigma_{a_y}} h_y i_y \sigma_{a_y} = \rho_{a_x,a_y}\sigma_{a_x} h_y i_y,$$

or, given that $\sigma_{a_x} = h_x \sigma_{y_x}$, it can be finally written as:

$$R_{x\bullet y} = \rho_{a_x,a_y} h_x h_y i_y \sigma_{y_x}.$$

Such an equation can be used either to monitor potential genetic changes in correlated traits when performing direct selection on a specific trait of economic importance or, alternatively, to explore indirect selection strategies using indicator traits [5]. The latter use may be of interest when a trait of economic importance (e.g., trait x) is difficult or expensive to measure, or it is expressed later in an animal's life, so it may be advantageous to select on a correlated trait (e.g., trait y), which would be the indicator trait. To assess the effectiveness of indirect selection relative to direct selection, one may look at

the ratio of expected genetic progress per unit of time in each scenario, i.e.,

$$\frac{R_{x\bullet y}}{R_x} = \frac{\rho_{a_x,a_y}\sigma_{a_x}h_y i_y/L_y}{h_x i_x \sigma_{a_x}/L_x} = \frac{\rho_{a_x,a_y}h_y i_y L_x}{h_x i_x L_y} = \rho_{a_x,a_y}\frac{h_y}{h_x}\frac{i_y}{i_x}\frac{L_x}{L_y}.$$

So, it can be seen that this ratio can be higher than 1 (meaning that the indirect selection is more effective than the direct selection) depending on the genetic correlation between the economic and the indicator traits, the ratios of their heritabilities, and their potential selection intensities and generation intervals.

Selection Index

In section "Phenotypic Selection," selection based on a single measurement on each animal was discussed. However, it is not always possible to observe the phenotype for all animals, such as traits that are expressed in only one sex or that require the sacrifice of animals to be measured, etc. In addition, even when it is possible to measure the phenotypic trait in each animal, information from relatives can be used to obtain earlier or more reliable predictions of breeding values. In this section, the prediction of breeding values using different sources of information (e.g., multiple measurements of the trait in each animal and progeny performance) will be discussed and a methodology (the selection index) that combines multiple sources of information into a single prediction for each animal will be presented.

When multiple measurements of the same trait are recorded (e.g., milk yield in multiple lactations), breeding values can be predicted using the average of observations ($\bar{y}_i$) from each animal as $\hat{a}_i = b_{a_i\bullet\bar{y}_i}(\bar{y}_i - \mu)$. However, to derive the genetic regression of breeding value on average phenotypic value, Model (3) must be expanded to include an additional term, which is discussed next.

It can be shown empirically that the covariance (or resemblance) between repeated measurements on the same animal is larger than σ_a^2, which is what would be expected under the assumptions of Model (3). This additional source of covariance between records for the same animal refers to environmental factors that affect all records similarly, the so-called "permanent environmental effects" [1, 4]. Under these circumstances, the Model (3) can be extended to:

$$y_{ij} = \mu + a_i + p_i + \varepsilon_{ij} \tag{4}$$

where y_{ij} represents the observation j ($j = 1, \ldots, n_i$) on animal i, with n_i being the total number of records on animal i; μ and $a_i \sim N(0, \sigma_a^2)$ are as defined previously; p_i refers to the permanent environmental effects affecting records on animal i, assumed $p_i \sim N(0, \sigma_p^2)$; and $\varepsilon_{ij} \sim N(0, \sigma_\varepsilon^2)$ represent residual effects (nonadditive genetic and temporary environmental effects) associated with observation y_{ij}. In addition, it is assumed that all random terms in Model (4) are independent from each other, i.e., $\mathrm{Cov}(a_i, p_i) = \mathrm{Cov}(a_i, \varepsilon_{ij}) = \mathrm{Cov}(p_i, \varepsilon_{ij}) = \mathrm{Cov}(\varepsilon_{ij}, \varepsilon_{ij'}) = 0$ for any i, j, and j' ($j \neq j'$).

Under these settings, the average phenotypic value of an animal is given by $\bar{y}_{ij} = \mu + a_i + p_i + \bar{\varepsilon}_{ij}$, where $\bar{\varepsilon}_i = \frac{1}{n_i}\sum_{j=1}^{n_i}\varepsilon_{ij}$, such that its variance is given by $\mathrm{Var}[\bar{y}_i] = \sigma_a^2 + \sigma_p^2 + \sigma_\varepsilon^2/n_i$, and the covariance between a_i and $\bar{y}_i$ is $\mathrm{Cov}(a_i, \bar{y}_i) = \sigma_a^2$. In this case, the regression of breeding values on phenotypic means is given by:

$$b_{a_i\bullet\bar{y}_i} = \frac{\mathrm{Cov}[a_i, \bar{y}_i]}{\mathrm{Var}[\bar{y}_i]} = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_p^2 + \sigma_\varepsilon^2/n_i}.$$

An important definition related to repeated measurements refers to repeatability (r), which is given by the intraclass correlation, i.e., the ratio of the within-individual (or between repeated measurements) to the phenotypic variances [1, 4]:

$$r = \frac{\sigma_a^2 + \sigma_p^2}{\sigma_y^2} = \frac{\sigma_a^2 + \sigma_p^2}{\sigma_a^2 + \sigma_p^2 + \sigma_\varepsilon^2},$$

and measures the correlation between records on the same animal.

Noting that $r = 1 - \frac{\sigma_\varepsilon^2}{\sigma_a^2+\sigma_p^2+\sigma_\varepsilon^2}$, the variance of the average phenotypic value of an animal can be expressed as a function of the repeatability as $\mathrm{Var}[\bar{y}_i] = [r + (1-r)/n_i]\sigma_y^2$, such that the genetic regression becomes:

$$b_{a_i\bullet\bar{y}_i} = \frac{\sigma_a^2}{[r + (1-r)/n_i]\sigma_y^2} = \frac{n_i h^2}{1 + (n_i - 1)/r}.$$

The prediction accuracy in this case, i.e., the correlation between an animal's estimated breeding

value using repeated records and its true breeding value is given by:

$$r_{\hat{a}_i,a_i} = r_{\bar{y}_i,a_i} = \frac{\mathrm{Cov}(\bar{y}_i, a_i)}{\sqrt{\mathrm{Var}(\bar{y}_i)\mathrm{Var}(a_i)}} = \frac{\sigma_a^2}{\sqrt{r + (1-r)/n_i}\sigma_y\sigma_a} = h\sqrt{\frac{n_i}{1+(n_i-1)r}} = \sqrt{b_{a_i\bullet\bar{y}_i}}.$$

Hence, it can be seen that compared with single record phenotypic selection, there is a gain in accuracy when predictions are based on repeated records and that the gain will depend on the values of r and n_i; higher gain in accuracy is obtained when r is low and when n_i is high.

Another alternative to predict breeding values is to use progeny performance, which is often employed for predicting breeding values of males for traits where records can be obtained only on females, such as milk yield. For example, let $\bar{y}_i$ be the average of single records on n_i progeny of sire i, and assume that the sire was mated to a random sample of females not related to him. In this case, each progeny record can be expressed as:

$$y_{ij} = \mu + \frac{1}{2}a_i + \frac{1}{2}d_{ij} + \delta_{ij} + \varepsilon_{ij},$$

where a_i is the breeding value of a specific sire i; d_{ij} is the breeding value of dam j ($j = 1, \ldots, n_i$) mated with sire i; and δ_{ij} and ε_{ij} refer to the Mendelian sampling and residual (environmental) components associated with the observation y_{ij}. Using this notation, the following model can be used to describe the progeny average of sire i:

$$\bar{y}_i = \mu + \frac{1}{2}a_i + \frac{1}{2}\bar{d}_i + \bar{\delta}_i + \bar{\varepsilon}_i \qquad (5)$$

where $\bar{y}_i = \frac{1}{n_i}\sum_{i=1}^{n_i} y_{ij}$, $\bar{d}_i = \frac{1}{n_i}\sum_{i=1}^{n_i} d_{ij}$, $\bar{\delta}_i = \frac{1}{n_i}\sum_{i=1}^{n_i} \delta_{ij}$, and $\bar{\varepsilon}_i = \frac{1}{n_i}\sum_{i=1}^{n_i} \varepsilon_{ij}$. Given that $E[\bar{d}_i] = 0$ and $E[\bar{\delta}_i] = 0$, the breeding value of sire i can be then predicted by $\hat{a}_i = b_{a_i\bullet\bar{y}_i}(\bar{y}_i - \mu)$, where $b_{a_i\bullet\bar{y}_i} = \mathrm{Cov}[a_i, \bar{y}_i]/\mathrm{Var}[\bar{y}_i]$. It is shown that:

$$\mathrm{Cov}(a_i, \bar{y}_i) = \mathrm{Cov}(a_i, a_i/2) = \sigma_a^2/2$$

and

$$\mathrm{Var}[\bar{y}_i] = \mathrm{Var}\left[\frac{1}{2}a_i + \frac{1}{2}\bar{d}_i + \bar{\delta}_i + \bar{\varepsilon}_i\right] = \frac{1}{4}\sigma_a^2 + \frac{1}{4}\frac{\sigma_a^2}{n_i} + \frac{\sigma_a^2}{2n_i} + \frac{\sigma_\varepsilon^2}{n_i} = \frac{(n_i+3)\sigma_a^2 + 4\sigma_\varepsilon^2}{4n_i} = \frac{(n_i+3)h^2 + 4(1-h^2)}{4n_i}\sigma_y^2 = \left[k + \frac{1-k}{n_i}\right]\sigma_y^2,$$

where $k = h^2/4$ is the intraclass correlation between half-sibs, such that the genetic regression coefficient is given by:

$$b_{a_i\bullet\bar{y}_i} = \frac{\sigma_a^2/2}{[k + (1-k)/n_i]\sigma_y^2} = \frac{h^2\sigma_y^2/2}{[h^2/4 + (1-h^2/4)/n_i]\sigma_y^2} = \frac{2n_ih^2}{4 + (n_i-1)h^2},$$

and the prediction accuracy by:

$$r_{a_i,\bar{y}_i} = \frac{\mathrm{Cov}[a_i, \bar{y}_i]}{\sqrt{\mathrm{Var}[a_i]\mathrm{Var}[\bar{y}_i]}} = \frac{h^2\sigma_y^2/2}{\sqrt{h^2\sigma_y^2[k+(1-k)/n_i]\sigma_y^2}} = \sqrt{\frac{n_ih^2/4}{1+(n_i-1)k}} = \sqrt{\frac{n_ih^2}{4+(n_i-1)h^2}} = \sqrt{b_{a_i\bullet\bar{y}_i}/2},$$

which approaches unity (one) as the number of progeny records increases.

Up to this point, it has been discussed how breeding values can be predicted using different sources of information, such as an animal's own performance (either a single record or multiple measurements) or progeny performance. Other sources of information that could also be used are the performance of parents, sibling, or other kinds of relatives. However, what generally happens is that multiple sources of information are available simultaneously, so the question becomes how to best combine all the information in order to improve prediction accuracy. Here, a classical approach will be discussed, the "selection index," and later on in this

chapter a more general and modern alternative, based on mixed model methodology, will be presented.

Consider, for example, that there are three sources of information available on animal i (represented here as y_{i1}, y_{i2}, and y_{i3}, and expressed as deviations from their means), so the goal is to predict the animal's breeding value with a linear combination of such information, i.e.,

$$\hat{a}_i = b_{i1}y_{i1} + b_{i2}y_{i2} + b_{i3}y_{i3},$$

such that the prediction accuracy (i.e., correlation between predicted and true breeding value) is maximized.

Maximization of $r_{\hat{a}_i,a_i}$ is equivalent to the maximization of $\log(r_{\hat{a}_i,a_i})$, which is generally easier to accomplish. The log correlation can be expressed as (here, to simplify the notation, the index i indicating the animal is dropped):

$$\log(r_{\hat{a},a}) = \log\left[\frac{\sigma_{\hat{a},a}}{\sqrt{\sigma^2_{\hat{a}}\sigma^2_a}}\right] = \log(\sigma_{\hat{a},a}) - \frac{1}{2}\sigma^2_{\hat{a}} - \frac{1}{2}\sigma^2_a,$$

where the covariance between $\hat{a}$ and a, and the variance of $\hat{a}$ are given respectively by:

$$\sigma_{\hat{a},a} = b_1\sigma_{y_1,a} + b_2\sigma_{y_2,a} + b_3\sigma_{y_3,a}$$

and

$$\begin{aligned}\sigma^2_{\hat{a}} =& b_1^2\sigma^2_{y_1} + 2b_1b_2\sigma_{y_1,y_2} + 2b_1b_3\sigma_{y_1,y_3} \\ &+ b_2^2\sigma^2_{y_2} + 2b_2b_3\sigma_{y_2,y_3} + b_3^2\sigma^2_{y_3}.\end{aligned}$$

Substituting these expressions into $\log(r_{\hat{a},a})$, taking the partial derivatives of $\log(r_{\hat{a},a})$ with respect to each of the regression coefficients b_j $(j = 1, 2, 3)$, and setting them to zero, gives the following set of equations:

$$\begin{cases} \dfrac{\partial\log(r_{\hat{a},a})}{\partial b_1} = \dfrac{\sigma_{y_1,a}}{\sigma_{\hat{a},a}} - \dfrac{b_1\sigma^2_{y_1} + b_2\sigma_{y_1,y_2} + b_3\sigma_{y_1,y_3}}{\sigma^2_{\hat{a}}} \\ \dfrac{\partial\log(r_{\hat{a},a})}{\partial b_2} = \dfrac{\sigma_{y_2,a}}{\sigma_{\hat{a},a}} - \dfrac{b_1\sigma_{y_1,y_2} + b_2\sigma^2_{y_2} + b_3\sigma_{y_2,y_3}}{\sigma^2_{\hat{a}}} \\ \dfrac{\partial\log(r_{\hat{a},a})}{\partial b_3} = \dfrac{\sigma_{y_3,a}}{\sigma_{\hat{a},a}} - \dfrac{b_1\sigma_{y_1,y_3} + b_2\sigma_{y_2,y_3} + b_3\sigma^2_{y_3}}{\sigma^2_{\hat{a}}} \end{cases}$$

which can be rearranged as:

$$\begin{cases} b_1\sigma^2_{y_1} + b_2\sigma_{y_1,y_2} + b_3\sigma_{y_1,y_3} = k\sigma_{y_1,a} \\ b_1\sigma_{y_1,y_2} + b_2\sigma^2_{y_2} + b_3\sigma_{y_2,y_3} = k\sigma_{y_2,a} \\ b_1\sigma_{y_1,y_3} + b_2\sigma_{y_2,y_3} + b_3\sigma^2_{y_3} = k\sigma_{y_3,a} \end{cases}$$

where $k = \sigma^2_{\hat{a}}/\sigma_{\hat{a},a}$.

Extending the system for any number m of components (i.e., sources of information), these equations can be expressed in matrix notation as:

$$\mathbf{Pb} = \mathrm{k}\mathbf{c},$$

where $\mathbf{P} = \begin{bmatrix} \sigma^2_{y_1} & \sigma_{y_1,y_2} & \cdots & \sigma_{y_1,y_m} \\ \sigma_{y_1,y_2} & \sigma^2_{y_2} & \cdots & \sigma_{y_2,y_m} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{y_1,y_m} & \sigma_{y_2,y_m} & \cdots & \sigma^2_{y_m} \end{bmatrix}$ is the covariance matrix of the vector $\mathbf{y} = [y_1, y_2, \ldots, y_m]'$, $\mathbf{b} = [b_1, b_2, \ldots, b_m]'$ is the vector of regression coefficients (weights) of each source of information, and $\mathbf{c} = [\sigma_{y_1,a}, \sigma_{y_2,a}, \ldots, \sigma_{y_m,a}]'$ is the vector of covariances between each piece of information and the breeding value of the animal, such that the weights $\mathbf{b}$ of the index $\hat{a} = \mathbf{b}'\mathbf{y}$ are given by $\mathbf{b} = k\mathbf{P}^{-1}\mathbf{c}$.

It should be noted that the constant k does not change the relative size of the regression coefficients $\mathbf{b}$ or the value of $r_{\hat{a},a}$, so it can be set to 1. In fact, if instead of maximizing $r_{\hat{a},a}$, the average square prediction error $E[\hat{a} - a]^2$ is minimized, then $\sigma^2_{\hat{a}} = \sigma_{\hat{a},a}$ and the system (usually called selection index equations) becomes:

$$\mathbf{b} = \mathbf{P}^{-1}\mathbf{c}.$$

The correlation between the index and the true breeding value is given by $r_{\hat{a},a} = \sigma_{\hat{a},a}/\sqrt{\sigma^2_{\hat{a}}\sigma^2_a} = \sqrt{\sigma_{\hat{a},a}/\sigma^2_a} = \sqrt{\frac{1}{\sigma^2_a}\sum_{j=1}^{m} b_j\sigma_{y_j,a}}$.

Multiple-Trait Selection

Usually more than one trait is considered in a selection program, as multiple traits may be economically important in a production system (e.g., [9]). There are many strategies for multi-trait selection, including the tandem approach (which selects rotationally one trait at a time) and the independent culling levels strategy (which sets minimum performance levels for each of the traits of interest), but they are generally suboptimal.

Here, the selection of a combination of multiple traits evaluated in economic terms will be discussed. Such a combination of traits is generally called "aggregate breeding value" or "breeding objective," and can be expressed as [3]:

$$T = \mathbf{w}'\mathbf{a} = w_1a_1 + w_2a_2 + \ldots + w_ka_k,$$

where $\mathbf{w} = (w_1, w_2, \ldots, w_k)'$ is the vector of economic weights (expressed as net economic value per unit of trait) for k traits of linear economic value, and $\mathbf{a} = (a_1, a_2, \ldots, a_k)'$ is a vector of breeding values relative to the k traits defining T. Here again, to simplify the notation, a subscript indexing the animal is suppressed.

Suppose records are available for m traits, which may or may not be included in the k traits describing the breeding objective. The goal then is to predict T based on the m traits observed, using the so-called economic selection index. The theory of selection index was introduced in the previous subsection as a means of combining multiple sources of information to predict breeding values for a specific trait. Here, similar methodology will be considered, but will be used to combine information from multiple traits to predict an overall economic merit for each animal, i.e.,

$$\hat{T} = I = \mathbf{v}'\mathbf{y} = v_1 y_1 + v_2 y_2 + \ldots + v_m y_m,$$

where $\hat{T}$ is the predicted overall economic merit of an animal, $\mathbf{v} = (v_1, v_2, \ldots, v_m)'$ is the vector of weighting factors, and $\mathbf{y} = (y_1, y_2, \ldots, y_m)'$ is the vector of phenotypic measurements.

An alternative for determining the weights $\mathbf{v} = (v_1, v_2, \ldots, v_m)'$ is to first predict separately the breeding values a_j, $j = 1, 2, \ldots, k$, for each trait involved in the breeding objective, using information from all the traits with measurements, $\mathbf{y} = (y_1, y_2, \ldots, y_m)'$. Afterward, such predictions are substituted for the true breeding values in the breeding objective equation, and then coefficients are grouped accordingly.

The breeding values a_j for each trait can be predicted by $\hat{a}_j = b_{j1} y_1 + b_{j2} y_2 + \ldots + b_{jm} y_m$, in which the weights are obtained as usual, to maximize $r_{\hat{a}_j, a_j}$ or minimize $E[\hat{a}_j - a_j]^2$. The equations which define the weights for the prediction of a_j are then given by:

$$\begin{cases} b_{j1}\sigma^2_{y_1} + b_{j2}\sigma_{y_1,y_2} + \ldots + b_{jm}\sigma_{y_1,y_m} = \sigma_{y_1,a_j} \\ b_{j1}\sigma_{y_1,y_2} + b_{j2}\sigma^2_{y_2} + \ldots + b_{jm}\sigma_{y_2,y_m} = \sigma_{y_2,a_j} \\ \quad\vdots \qquad\quad \vdots \qquad\qquad \vdots \qquad\quad \vdots \\ b_{j1}\sigma_{y_1,y_m} + b_{j2}\sigma_{y_2,y_m} + \ldots + b_{jm}\sigma^2_{y_m} = \sigma_{y_m,a_j} \end{cases}$$

This procedure is repeated for all k traits in the breeding objective, and the predictions $\hat{\mathbf{a}} = (\hat{a}_1, \hat{a}_2, \ldots, \hat{a}_k)'$ are then substituted for the true values $\mathbf{a} = (a_1, a_2, \ldots, a_k)'$ in the aggregate breeding value, i.e.,

$$\hat{T} = w_1\hat{a}_1 + w_2\hat{a}_2 + \ldots + w_k\hat{a}_k.$$

This overall index estimating T can be rewritten as $I = v_1 y_1 + v_2 y_2 + \ldots + v_m y_m$, by using appropriate multiplications and grouping of coefficients. It is shown that each coefficient v_i is given by $v_i = w_1 b_{1i} + w_2 b_{2i} + \ldots + w_k b_{ki}$, with $i = 1, 2, \ldots, m$.

Another way of deriving the weights $\mathbf{v} = (v_1, v_2, \ldots, v_m)'$ defining the economic selection index $I = \mathbf{v}'\mathbf{y}$ is to maximize the correlation $r_{T,I}$, which will generate the following equations:

$$\begin{cases} v_1\sigma^2_{y_1} + v_2\sigma_{y_1,y_2} + \ldots + v_m\sigma_{y_1,y_m} = \sigma_{y_1,T} \\ v_1\sigma_{y_1,y_2} + v_2\sigma^2_{y_2} + \ldots + v_m\sigma_{y_2,y_m} = \sigma_{y_2,T} \\ \quad\vdots \qquad\quad \vdots \qquad\qquad \vdots \qquad\quad \vdots \\ v_1\sigma_{y_1,y_m} + v_2\sigma_{y_2,y_m} + \ldots + v_m\sigma^2_{y_m} = \sigma_{y_m,T} \end{cases}$$

where $\sigma_{y_i,T}$ is the covariance between each measured trait i $(i = 1, 2, \ldots, m)$ and the linear function $T = \mathbf{w}'\mathbf{a}$, i.e., the aggregate breeding value. It can be shown that both approaches for determining the weights $\mathbf{v} = (v_1, v_2, \ldots, v_m)'$ are equivalent.

Mixed Model Methodology

Introduction

Many statistical methods for analysis of genetic data are specific (or more appropriate) for phenotypic measurements obtained from planned experimental designs with balanced data sets. While such situations may be possible within laboratory or greenhouse experimental settings, data from natural populations and agricultural species are generally highly unbalanced and fragmented by numerous kinds of relationships. Culling of data to accommodate conventional statistical techniques (such as those discussed to this point) may introduce bias and/or lead to a substantial loss of information. The mixed model methodology, on the other hand, allows efficient estimation of genetic parameters (such as variance components and heritability) and breeding values while accommodating extended pedigrees, unequal family sizes, overlapping generations, sex-limited traits, assortative mating, and natural or artificial selection.

The single trait prediction methods discussed in the previous section use only a single source of information or, when multiple sources of information are available, they require them to be split into independent subgroups, i.e., specific groups of relatives such as half-sibs, full-sibs, progeny, etc. However, in practice the data may be extremely complex due to the intricate pedigree structure commonly found in livestock species, e.g., beef and dairy cattle populations. Other drawbacks of the selection index include an inability to account for genetic trend over time and that the phenotypes must be pre-adjusted for environmental effects, which can be done, for example, using the average of contemporary groups of animals. However, contemporary group effects can be inferred only under the unrealistic assumption that they are genetically equal. Hence, a selection index can be reliably applied only to individual animals within same herd and born in same year.

In view of such limitations, linear mixed models (models including both fixed and random effects) and best linear unbiased predictions (BLUP) of breeding values were developed [10–12]. The BLUP methodology uses performance information from all known relatives to estimate breeding values, can be applied to whole herds or large populations using data from many years, and can also accommodate genetic differences between contemporary groups. Presently, mixed models are widely used in many fields of science as a flexible tool for the analysis of data where responses are clustered around some random effects, such that there is a natural dependence between observations in the same cluster. Examples of applications of mixed models in genetics and genomics include gene mapping and association analysis (e.g., [13, 14]), and gene expression assays using microarrays [15, 16] or RT-PCR [17], to name a few.

In some applications of mixed models the central objective is the estimation and hypothesis testing regarding fixed effects (e.g., treatment effects in an experimental study), in which case the random effects (e.g., block effects) are nuisance effects. In animal breeding, however, the main goal is the prediction of realized values of random effects (breeding values of animals), and the fixed effects are generally environmental factors that should be taken into account to adjust the observed phenotypic values. A third application or goal of mixed models is the estimation of variance components, such as genetic and environmental variances, or functions of them, such as heritability and repeatability.

In this section some basics regarding mixed models are briefly reviewed, with some emphasis toward the prediction of random effects, and subsequently some specific applications of the mixed model methodology in animal breeding and genetics are presented.

A linear mixed-effects model is defined as:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon} \tag{6}$$

where $\mathbf{y}$ is the vector of responses (observations), $\boldsymbol{\beta}$ is a vector of fixed effects, $\mathbf{u}$ is a vector of random effects, $\mathbf{X}$ and $\mathbf{Z}$ are known incidence matrices relate $\mathbf{y}$ to the vectors $\boldsymbol{\beta}$ and $\mathbf{u}$, respectively, and ε is a vector of residual terms. Generally, it is assumed that $\mathbf{u}$ and ε are independent from each other and normally distributed with zero-mean vectors and variance–covariance matrices $\mathbf{G}$ and $\boldsymbol{\Sigma}$, respectively.

As mentioned before, in animal breeding a central goal refers to the prediction of random effects (breeding values). In linear (Gaussian) models as in (6) such predictions are given by the conditional expectation of $\mathbf{u}$ given the data, i.e., $E[\mathbf{u}|\mathbf{y}]$. Given the model specifications above, the joint distribution of $\mathbf{y}$ and $\mathbf{u}$ is:

$$\begin{bmatrix}\mathbf{y}\\ \mathbf{u}\end{bmatrix} \sim \mathrm{MVN}\left(\begin{bmatrix}\mathbf{X}\boldsymbol{\beta}\\ \mathbf{0}\end{bmatrix}, \begin{bmatrix}\mathbf{V} & \mathbf{ZG}\\ \mathbf{GZ}' & \mathbf{G}\end{bmatrix}\right),$$

where $\mathbf{V} = \mathbf{ZGZ}' + \boldsymbol{\Sigma}$.

From the properties of multivariate normal distributions, $E[\mathbf{u}|\mathbf{y}]$ is given by:

$$E[\mathbf{u}|\mathbf{y}] = E[\mathbf{u}] + \mathrm{Cov}[\mathbf{u}, \mathbf{y}']\mathrm{Var}^{-1}[\mathbf{y}](\mathbf{y} - E[\mathbf{y}]),$$

such that in this case:

$$\begin{aligned} E[\mathbf{u}|\mathbf{y}] &= \mathbf{GZ}'\mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) \\ &= \mathbf{GZ}'(\mathbf{ZGZ}' + \boldsymbol{\Sigma})^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}). \end{aligned}$$

This expression, however, depends on the fixed effects values $\boldsymbol{\beta}$, which also need to be inferred from the data. The fixed effects are then typically replaced by their estimates, such that predictions are made based on the following expression:

$$\hat{\mathbf{u}} = \mathbf{GZ}'\mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}).$$

To estimate the fixed effects $\boldsymbol{\beta}$, all random effects in Model (6) can be combined into a single vector,

$\boldsymbol{\xi} = \mathbf{Zu} + \boldsymbol{\varepsilon}$, such that the following fixed effects model is obtained: $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\xi}$. It is shown that the expectation of the ξ term is $E[\boldsymbol{\xi}] = E[\mathbf{Zu} + \boldsymbol{\varepsilon}] = \mathbf{Z}E[\mathbf{u}] + E[\boldsymbol{\varepsilon}] = \mathbf{0}$, and that its variance is $\mathrm{Var}[\boldsymbol{\xi}] = \mathrm{Var}[\mathbf{Zu} + \boldsymbol{\varepsilon}] = \mathbf{Z}\mathrm{Var}[\mathbf{u}]\mathbf{Z}' + \mathrm{Var}[\boldsymbol{\varepsilon}] = \mathbf{ZGZ}' + \boldsymbol{\Sigma} = \mathbf{V}$. Under these settings, the distribution of $\mathbf{y}$ is multivariate normal with mean vector $\mathbf{X}\boldsymbol{\beta}$ and covariance matrix $\mathbf{V}$, i.e., $\mathbf{y} \sim MVN(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$, and the maximum likelihood estimator of β can be shown to be:

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y},$$

which is distributed as $\hat{\boldsymbol{\beta}} \sim MVN(\boldsymbol{\beta}, (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1})$. If the design matrix $\mathbf{X}$ is not full column rank, a generalized inverse of $\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}$ must be used to obtain a solution $\boldsymbol{\beta}^{\boldsymbol{0}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$ of the system, from which estimable functions $\boldsymbol{\theta} = \mathbf{L}\boldsymbol{\beta}$ are estimated as $\hat{\boldsymbol{\theta}} = \mathbf{L}\boldsymbol{\beta}^{\boldsymbol{0}}$.

The solutions $\hat{\boldsymbol{\beta}}$ and $\hat{\mathbf{u}}$ discussed before require $\mathbf{V}^{-1}$. As $\mathbf{V}$ can be of huge dimensions, especially in animal breeding applications, its inverse is generally computationally demanding if not unfeasible. However, Henderson [18] presented the mixed model equations (MME) to estimate $\boldsymbol{\beta}$ and $\mathbf{u}$ simultaneously, without the need for computing $\mathbf{V}^{-1}$. The MME were derived by maximizing (for $\boldsymbol{\beta}$ and $\mathbf{u}$) the joint density of $\mathbf{y}$ and $\mathbf{u}$, expressed as:

$$p(\mathbf{y}, \mathbf{u}) \propto |\boldsymbol{\Sigma}|^{-1/2}|\mathbf{G}|^{-1/2} \exp\left\{-\frac{1}{2}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Zu})' \boldsymbol{\Sigma}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Zu}) - \frac{1}{2}\mathbf{u}'\mathbf{G}^{-1}\mathbf{u}\right\}.$$

The logarithm of this function is:

$$\begin{aligned}\ell &= \log[p(\mathbf{y}, \mathbf{u})] \propto |\boldsymbol{\Sigma}| + |\mathbf{G}| + (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Zu})'\boldsymbol{\Sigma}^{-1} \\ &\quad (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Zu}) + \mathbf{u}'\mathbf{G}^{-1}\mathbf{u} \\ &= |\boldsymbol{\Sigma}| + |\mathbf{G}| + \mathbf{y}'\boldsymbol{\Sigma}^{-1}\mathbf{y} - 2\mathbf{y}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\boldsymbol{\beta} - 2\mathbf{y}'\boldsymbol{\Sigma}^{-1}\mathbf{Zu} \\ &\quad + \boldsymbol{\beta}'\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\boldsymbol{\beta} + 2\boldsymbol{\beta}'\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Zu} \\ &\quad + \mathbf{u}'\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Zu} + \mathbf{u}'\mathbf{G}^{-1}\mathbf{u}.\end{aligned}$$

The derivatives regarding $\boldsymbol{\beta}$ and $\mathbf{u}$ are:

$$\begin{bmatrix}\frac{\partial \ell}{\partial \boldsymbol{\beta}} \\ \frac{\partial \ell}{\partial \mathbf{u}}\end{bmatrix} = \begin{bmatrix}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{y} - \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} - \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}\hat{\mathbf{u}} \\ \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{y} - \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} - \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}\hat{\mathbf{u}} - \mathbf{G}^{-1}\hat{\mathbf{u}}\end{bmatrix}.$$

Equating them to zero gives the following system:

$$\begin{bmatrix}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}\hat{\mathbf{u}} \\ \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}\hat{\mathbf{u}} + \mathbf{G}^{-1}\hat{\mathbf{u}}\end{bmatrix} = \begin{bmatrix}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{y} \\ \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{y}\end{bmatrix},$$

which can be expressed as:

$$\begin{bmatrix}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X} & \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} \\ \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{X} & \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1}\end{bmatrix}\begin{bmatrix}\hat{\boldsymbol{\beta}} \\ \hat{\mathbf{u}}\end{bmatrix} = \begin{bmatrix}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{y} \\ \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{y}\end{bmatrix},$$

known as the mixed model equations (MME).

Using the second part of the MME,

$$\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} + (\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1})\hat{\mathbf{u}} = \mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{y},$$

such that

$$\hat{\mathbf{u}} = (\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1})^{-1}\mathbf{Z}'\boldsymbol{\Sigma}^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}).$$

It can be shown that this expression is equivalent to $\hat{\mathbf{u}} = \mathbf{GZ}'(\mathbf{ZGZ}' + \boldsymbol{\Sigma})^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})$ and, more importantly, that $\hat{\mathbf{u}}$ is the best linear unbiased predictor (BLUP) of $\mathbf{u}$. Using this result into the first part of the MME,

$$\begin{aligned}&\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}\hat{\mathbf{u}} = \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{y} \\ &\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1})^{-1} \\ &\qquad \mathbf{Z}'\boldsymbol{\Sigma}^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) = \mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{y} \\ &\hat{\boldsymbol{\beta}} = \{\mathbf{X}'[\boldsymbol{\Sigma}^{-1} - \boldsymbol{\Sigma}^{-1}\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1})^{-1}\mathbf{Z}'\boldsymbol{\Sigma}^{-1}]\mathbf{X}\}^{-1} \\ &\qquad \mathbf{X}'[\boldsymbol{\Sigma}^{-1} - \boldsymbol{\Sigma}^{-1}\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Sigma}^{-1}\mathbf{Z} + \mathbf{G}^{-1})^{-1}\mathbf{Z}'\boldsymbol{\Sigma}^{-1}]\mathbf{y}\end{aligned}.$$

Similarly, it is shown that this expression is equivalent to $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$, which is the best linear unbiased estimator (BLUE) of $\boldsymbol{\beta}$.

It is important to note that $\hat{\boldsymbol{\beta}}$ and $\hat{\mathbf{u}}$ require knowledge of $\mathbf{G}$ and $\boldsymbol{\Sigma}$, or at least some function of them. As these matrices are rarely known, the practical approach is to replace $\mathbf{G}$ and $\boldsymbol{\Sigma}$ by some sort of point estimates $\hat{\mathbf{G}}$ and $\hat{\boldsymbol{\Sigma}}$ into the MME.

Many methods have been proposed to estimate variance components in mixed-effects models. The simplest is the analysis of variance (ANOVA) method, which works well for simple models (such as a one-way structure) or balanced data (such as data from designed experiments with no missing data), but they are not indicated for more complex models and data structures such as those generally found in the animal breeding context.

Alternative methods proposed for estimating variance components in more complex scenarios include

the expected mean squares approach of Henderson [19] and the minimum norm quadratic unbiased estimation [20]. However, maximum likelihood-based methods are currently the most popular (see, for example, [21]), especially the restricted (or residual) maximum likelihood (REML) approach [22], which attempts to correct for the well-known bias in the classical maximum likelihood (ML) estimation of variance components. Additional literature on variance component estimation and mixed model methodology can be found, for example, in [23–27].

The Animal Model

The advent of mixed-effects models has undoubtedly revolutionized the animal breeding field, and today they are widely used in the genetic improvement of many livestock and companion animal species. In this subsection some of the applications of mixed models for the genetic evaluation of populations using phenotypic and pedigree information will be presented. In the following section applications incorporating molecular marker information will be discussed as well.

As a first application of mixed models in animal breeding, the so-called "animal model" is considered here for the specific situation of a single trait and a single phenotypic observation (including missing values) per animal. The animal model can be described as:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \boldsymbol{\varepsilon},$$

where $\mathbf{y}$ is an $(n \times 1)$ vector of observations (phenotypic scores), $\boldsymbol{\beta}$ is a $(p \times 1)$ vector of fixed effects (e.g., herd-year-season effects in cattle evaluations), and $\boldsymbol{\varepsilon}$ represents residual effects, assumed $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ as before. In most applications of animal models, however, residuals are assumed independent across animals, such that the residual covariance structure can be expressed as $\mathbf{R} = \mathbf{I}\sigma^2_{\boldsymbol{\varepsilon}}$, where $\mathbf{I}$ is an identity matrix of appropriate order, and $\sigma^2_{\boldsymbol{\varepsilon}}$ is the residual variance. In the case of animal models, the random effects $\mathbf{u}$ represent the breeding values, i.e., $\mathbf{u} = \mathbf{a}$, assumed to be $\mathbf{a} \sim N(\mathbf{0}, \mathbf{G})$. The vector $\mathbf{a}$, of dimension $(q \times 1)$, may include breeding values of all animals with record or in the pedigree file, such that q is generally bigger than n.

The matrix $\mathbf{G}$, which in this case describes the covariances among the breeding values, follows from standard results for the covariances between relatives. It is seen that the additive genetic covariance between two relatives i and i' is given by $2\theta_{ii'}\sigma^2_a$, where $\theta_{ii'}$ is the coefficient of coancestry between individuals i and i', and σ^2_a is the additive genetic variance in the base population [28]. Hence, under the animal model, $\mathbf{G} = \mathbf{A}\sigma^2_a$, where $\mathbf{A}$ is the "additive genetic (or numerator) relationship matrix," having elements given by $a_{ii'} = 2\theta_{ii'}$.

As mentioned earlier, in animal breeding the usual main interest is prediction of breeding values – for selection of superior individuals – and on estimation of variance components. The fixed effects are, in some sense, nuisance factors with no central interest in terms of inferences, but which need to be taken into account (i.e., they need to be corrected for when inferring breeding values).

Because under the animal model $\mathbf{G}^{-1} = \mathbf{A}^{-1}\sigma^{-2}_a$ and $\mathbf{R}^{-1} = \mathbf{I}\sigma^{-2}_{\boldsymbol{\varepsilon}}$, the mixed model equations reduce to:

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \lambda\mathbf{A}^{-1} \end{bmatrix} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix},$$

where $\lambda = \dfrac{\sigma^2_{\boldsymbol{\varepsilon}}}{\sigma^2_a} = \dfrac{1-h^2}{h^2}$, such that:

$$\begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \lambda\mathbf{A}^{-1} \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix}.$$

It is worth mentioning that $\mathbf{A}^{-1}$ can be obtained directly from the pedigree, without setting up $\mathbf{A}$ [29, 30], which is computationally very convenient.

Conditional on the variance components ratio λ, the BLUP of the breeding values are given then by $\hat{\mathbf{a}} = (\mathbf{Z}'\mathbf{Z} + \lambda\mathbf{A}^{-1})^{-1}\mathbf{Z}'(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})$, which are the estimated breeding values (EBV). Alternatively, some breeders' associations express their results as predicted transmitting abilities (PTA) or expected progeny differences (EPD), which are equal to half the EBV, representing the portion of an animal's breeding values that is passed to its offspring.

The amount of information contained in an animal's genetic evaluation depends on the availability of its own record, and of phenotypic information from its relatives (including how many and how closely related to it). As a measure of amount of information in livestock genetic evaluations, EBV are typically reported with their associated accuracies, i.e. the correlation between true and estimated breeding values, $r_i = r_{\hat{a}_i, a_i}$. Instead of accuracy, some livestock species

genetic evaluations use reliability, which is the accuracy squared (r_i^2).

The calculation of r_i requires the diagonal elements of the inverse of the MME coefficient matrix, represented as:

$$\mathbf{C} = \begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \lambda\mathbf{A}^{-1} \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{C}^{\beta\beta} & \mathbf{C}^{\beta a} \\ \mathbf{C}^{a\beta} & \mathbf{C}^{aa} \end{bmatrix}.$$

It is shown that the prediction error variance (PEV) of EBV $\hat{a}_i$ is given by:

$$\text{PEV} = \text{Var}(\hat{a}_i - a_i) = c_i^{aa}\sigma_\varepsilon^2,$$

where c_i^{aa} is the ith diagonal element of $\mathbf{C}^{aa}$, relative to animal i. The PEV can be interpreted as the fraction of additive genetic variance not accounted for by the prediction. Therefore, PEV can also be expressed as:

$$\text{PEV} = (1 - r_i^2)\sigma_a^2,$$

such that $c_i^{aa}\sigma_\varepsilon^2 = (1 - r_i^2)\sigma_a^2$, from which the reliability is obtained as $r_i^2 = 1 - c_i^{aa}\sigma_\varepsilon^2/\sigma_a^2 = 1 - \lambda c_i^{aa}$.

Extensions and Variations of the Animal Model

The animal model discussed above can be extended also to multiple (correlated) traits [31, 32]. For instance, consider as an example the analysis of k traits, in which the model for each trait is expressed as:

$$\mathbf{y}_j = \mathbf{X}_j\boldsymbol{\beta}_j + \mathbf{Z}_j\mathbf{a}_j + \boldsymbol{\varepsilon}_j,$$

where $\mathbf{y}_j$, $\mathbf{X}_j$, $\boldsymbol{\beta}_j$, $\mathbf{Z}_j$, $\mathbf{a}_j$, and $\boldsymbol{\varepsilon}_j$ are defined as before, but here have an additional index to indicate the trait ($j = 1, 2, \ldots, k$).

For a joint analysis of the k traits, the single trait models can be combined as:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \boldsymbol{\varepsilon},$$

where $\mathbf{y} = [\mathbf{y}_1'\ \mathbf{y}_2'\ \ldots\ \mathbf{y}_k']'$, $\boldsymbol{\beta} = [\boldsymbol{\beta}_1'\ \boldsymbol{\beta}_2'\ \ldots\ \boldsymbol{\beta}_k']'$, $\mathbf{a} = [\mathbf{a}_1'\ \mathbf{a}_2'\ \ldots\ \mathbf{a}_k']'$, and $\boldsymbol{\varepsilon} = [\boldsymbol{\varepsilon}_1'\ \boldsymbol{\varepsilon}_2'\ \ldots\ \boldsymbol{\varepsilon}_k']'$, and the design matrices in this case are:

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{X}_k \end{bmatrix} \text{ and } \mathbf{Z} = \begin{bmatrix} \mathbf{Z}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{Z}_k \end{bmatrix}.$$

It is assumed that $\text{Var}\begin{bmatrix} \mathbf{a} \\ \boldsymbol{\varepsilon} \end{bmatrix} = \begin{bmatrix} \mathbf{G} \otimes \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma} \otimes \mathbf{I} \end{bmatrix}$,

where $\mathbf{G} = \begin{bmatrix} \sigma_{a_1}^2 & \sigma_{a_1a_2} & \cdots & \sigma_{a_1a_k} \\ \sigma_{a_1a_2} & \sigma_{a_2}^2 & \cdots & \sigma_{a_2a_2} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{a_1a_k} & \sigma_{a_2a_k} & \cdots & \sigma_{a_k}^2 \end{bmatrix}$ and $\boldsymbol{\Sigma} = \begin{bmatrix} \sigma_{\boldsymbol{\varepsilon}_1}^2 & \sigma_{\boldsymbol{\varepsilon}_1\boldsymbol{\varepsilon}_2} & \cdots & \sigma_{\boldsymbol{\varepsilon}_1\boldsymbol{\varepsilon}_k} \\ \sigma_{\boldsymbol{\varepsilon}_1\boldsymbol{\varepsilon}_2} & \sigma_{\boldsymbol{\varepsilon}_2}^2 & \cdots & \sigma_{\boldsymbol{\varepsilon}_2\boldsymbol{\varepsilon}_2} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{\boldsymbol{\varepsilon}_1\boldsymbol{\varepsilon}_k} & \sigma_{\boldsymbol{\varepsilon}_2\boldsymbol{\varepsilon}_2} & \cdots & \sigma_{\boldsymbol{\varepsilon}_k}^2 \end{bmatrix}$ are the genetic and residual variance–covariance matrices, respectively, $\mathbf{A}$ and $\mathbf{I}$ are the numerator relationship matrix and an identity matrix, and $\otimes$ represents the direct (Kronecker) product.

The MME for multi-trait analyses are of the same form as before, i.e.,

$$\begin{bmatrix} \mathbf{X}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{X} & \mathbf{X}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{Z} \\ \mathbf{Z}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{X} & \mathbf{Z}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{Z} + \mathbf{G}^{-1} \otimes \mathbf{A}^{-1} \end{bmatrix} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{y} \\ \mathbf{Z}'(\boldsymbol{\Sigma}^{-1} \otimes \mathbf{I})\mathbf{y} \end{bmatrix},$$

from which the BLUEs and BLUPs of $\boldsymbol{\beta}$ and $\mathbf{a}$ can be obtained, respectively.

The dimensionality of such multi-trait MME, however, can become a hurdle for solving it when more than two or three traits are considered. An alternative for the analysis of multiple traits is to use a canonical transformation of the traits [33–35], which consists of transforming the vectors of correlated traits into a new vector of uncorrelated variables. In such case, each transformed variable can be analyzed independently using standard single trait models, and subsequently the estimated breeding values are transformed back to the original scale of measurement.

Some other interesting applications of mixed models in animal breeding involve multiple random effects, as in the cases of repeated measurements of the same trait or traits with maternal effects. For the analysis of repeated measurements, as discussed in section "Selection Index" (Model 4), environmental effects can be partitioned into permanent and temporary effects. In this case, the mixed model, usually called "repeatability model," can be written as:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{W}\mathbf{p} + \boldsymbol{\varepsilon},$$

where all terms are as previously defined for a single trait animal model, and $\mathbf{p}$ is the vector of permanent

environmental effects, with each level pertaining to a common effect to all observations of each animal, and **W** is a known incidence matrix relating **y** to the vector **p**.

It is often assumed that $\mathbf{a} \sim N(\mathbf{0}, \mathbf{A}\sigma_a^2)$, $\mathbf{p} \sim N(\mathbf{0}, \mathbf{I}\sigma_p^2)$, and $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \mathbf{I}\sigma_{\boldsymbol{\varepsilon}}^2)$ are independent from each other. Under these assumptions, the MME becomes:

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} & \mathbf{X}'\mathbf{W} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z}+\lambda_a\mathbf{A}^{-1} & \mathbf{Z}'\mathbf{W} \\ \mathbf{W}'\mathbf{X} & \mathbf{W}'\mathbf{Z} & \mathbf{W}'\mathbf{W}+\lambda_p\mathbf{I} \end{bmatrix} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{p}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \\ \mathbf{W}'\mathbf{y} \end{bmatrix},$$

where $\lambda_a = \sigma_{\boldsymbol{\varepsilon}}^2/\sigma_a^2$ and $\lambda_p = \sigma_{\boldsymbol{\varepsilon}}^2/\sigma_p^2$.

There are some traits of interest in livestock, such as weaning weight in beef cattle, in which progeny performance is affected by the dam's ability to affect the calf's environment, such as in the form of nourishment through her milk production, the quantity and quality of which is in part genetically determined. In some cases, there can also be a paternally provided environmental component. In such cases, parents contribute to the performance of their progeny not only through the genes passed to the progeny (the "direct genetic effects") but also through their ability to provide a suitable environment (the "indirect genetic effects").

Here maternally influenced traits are considered, for which the mixed model can be written as [36]:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a} + \mathbf{K}\mathbf{m} + \mathbf{W}\mathbf{p} + \boldsymbol{\varepsilon},$$

where all terms are as before, except that the model now includes a vector **m** of random maternal genetic effects, and a vector **p** of random permanent environmental effects, with **K** and **W** as their respective incidence matrices. It is assumed that $\mathbf{a} \sim N(\mathbf{0}, \mathbf{A}\sigma_a^2)$, $\mathbf{m} \sim N(\mathbf{0}, \mathbf{A}\boldsymbol{\sigma}_{\boldsymbol{m}}^{\boldsymbol{2}})$, $\mathbf{p} \sim N(\mathbf{0}, \mathbf{I}\sigma_p^2)$, and $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \mathbf{I}\sigma_\varepsilon^2)$, and quite often a covariance structure between direct and maternal additive genetic effects is considered, assumed equal to $\mathbf{A}\sigma_{a,m}$.

Some other variations of the animal model, which are computationally convenient, include the "sire model" and the "reduced animal model" [37]. In the sire models, only sires are evaluated, using progeny records under the assumption of randomly selected mates. In the reduced animal model, instead of having equations set up for every animal (i.e., parents and progeny), it allows equations to be set up only for parents in the MME, making the dimensions of the system greatly reduced. The breeding values of the parents are estimated directly from the MME, and the progeny breeding values are then inferred by back solving from the predicted parental breeding values.

As a final note regarding the use of mixed models in animal breeding, it is important to mention that solving the MME does not necessary require the inversion of the coefficient matrix **C**. More computationally convenient alternatives for solving high dimensional systems of linear equations include methods based on iteration on the MME, such as the Jacobi or Gauss–Seidel iteration [38], and the "iteration on the data" strategy [39], which is a commonly used methodology in national genetic evaluations involving millions of records.

Marker-Assisted Selection

Introduction

The advent of molecular markers has created opportunities for a better understanding of genetic inheritance and for developing novel strategies for genetic improvement in agriculture. Molecular markers are used, for example, to study quantitative trait loci (QTL), which are defined as chromosomic regions contributing to variation in phenotypic traits. The location and effects of QTL can be inferred by combining information from marker genotypes and phenotypic scores of individuals and by exploring genetic linkage [40–43] and linkage disequilibrium [44, 45] information between marker loci and QTL, such as in experimental or mapping populations (e.g., backcross or F_2, or granddaughter designs) or in complex pedigrees in outbred populations. Information on markers associated with QTL can be used to enhance prediction of genetic merit of animals [46]. This is especially useful for low heritability traits, traits that are expensive or difficult to measure, or traits expressed in only one sex [47].

Classical Approaches with Few Markers

The application of molecular information for genetic improvement of animals and plants, or marker-assisted selection (MAS), requires that candidate-for-selection individuals are genotyped for specific markers. For MAS purposes, there are three types of genetic markers, and for each type there are specific statistical

approaches for incorporating their information into selection programs [47]. A first type of marker refers to situations in which the functional polymorphism itself can be genotyped. These markers are called "direct markers," as they indicate exactly the genotype an animal has at specific causative loci.

A second type of marker refers to those that are in population-wide linkage disequilibrium (LD) with the causative or functional mutations. In such cases, although the marker genotype of an animal does not unambiguously indicate the genotype at a specific functional locus, it still provide information regarding how likely an animal carries a specific allele or genotype at such a locus. Finally, a third kind of molecular marker refers to those loci that are in population linkage equilibrium with the functional mutations, which are often called "indirect markers." In such cases, although the marker information on a single animal in a population does not provide any information regarding the genetic merit of that animal, it still can be useful in exploring family (pedigree) structure when genotyped animals are related to each other.

While direct markers are the simplest and most efficient in MAS programs, their identification is much more difficult and generally involves a prescreening step using QTL mapping methods to identify promising chromosomic regions, followed by fine mapping (often using functional and positional candidate gene strategies), followed by validation (using some strategy such as a knock-out approach). On the other extreme, indirect markers are extensively available for most livestock species, but their use in MAS is more complex and the results are generally modest.

Statistical models to incorporate direct and/or LD markers in the genetic evaluations of animals are relatively straightforward. For example, a marker can be included into an animal model context with the following specification:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a}^* + \mathbf{M}\mathbf{g} + \boldsymbol{\varepsilon},$$

where all terms are as defined before, except that $\mathbf{a}^* \sim N(\mathbf{0}, \mathbf{A}\sigma^2_{a^*})$ represents now the random additive (nonmarked) polygenic effects, and $\mathbf{g}$ and $\mathbf{M}$ are the (fixed) QTL effects and an incidence matrix, respectively. In the case of direct markers, the matrix $\mathbf{M}$ represents the marker genotypes and is obtained directly from the genotyping of animals. In the case of LD markers, the incidence matrix $\mathbf{M}$ will represent genotype probabilities at each QTL locus, which can be derived using segregation analysis. The overall genetic merits of the animals are then given by the sum of their $\mathbf{a}^*$ and $\mathbf{g}$ components. Other strategies for combining the infinitesimal and the QTL components to increase long-term genetic gain have also been proposed (e.g., [48–50]); a review of MAS strategies can be found, for example, in [47].

In the case of indirect markers, however, the within-family LD between QTL and linked markers must be explored. One approach is to determine the marker effects or the marker-QTL linkage phases separately for each family. Alternatively, more general MAS models have been proposed to incorporate marker data in genetic evaluations for complex pedigrees [13, 51], which can be represented as:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{a}^* + \mathbf{M}\mathbf{q} + \boldsymbol{\varepsilon},$$

where the terms are as before, but here the QTL effects $\mathbf{q}$ are assumed random and normally distributed, such that:

$$\begin{bmatrix} \mathbf{a}^* \\ \mathbf{q} \end{bmatrix} \sim \mathrm{N}\left(\mathbf{0}, \begin{bmatrix} \mathbf{A}\sigma^2_{a^*} & \mathbf{0} \\ \mathbf{0} & \mathbf{G}_\lambda\sigma^2_q \end{bmatrix}\right),$$

where $\mathbf{G}_\lambda$ is the gametic relationship matrix for the QTL, and σ^2_q is the additive variance of the QTL allelic effects. The gametic relationship matrix gives the probabilities of identity between each of the two alleles in each individual, and it can be derived based on the QTL position λ and the marker information.

Genomic Selection

As most quantitative traits are influenced by many genes, tracking a small number of them using molecular markers (as in the MAS approaches discussed above) will explain only a small fraction of the total genetic variance. Moreover, individual genes are likely to have small effects and so a large amount of data is needed to accurately estimate their effects [52]. Genome-wide Marker-Assisted Selection (GWMAS), or simply Genomic Selection (GS), on the other hand, makes use of a very dense set of markers covering the entire genome, which potentially explain all genetic variance. In addition, given the LD between the dense markers and the QTL, estimated marker effects pertain across the population [53].

Meuwissen et al. [54] were the first to propose GS and suggested a model that can be described as:

$$\mathbf{y} = \mathbf{1}\mu + \sum_{j=1}^{p} \mathbf{M}_j \mathbf{q}_j + \boldsymbol{\varepsilon},$$

where μ is the overall mean, $\mathbf{q}_j$ represents the genetic effects of marked genes (j=1, 2, . . ., p), and $\mathbf{M}_j$ represents the design matrices (genotypes) relative to a large number (p) of biallelic markers (e.g., SNP loci), which present different levels of LD with QTL affecting the phenotypic trait of interest ($\mathbf{y}$). Here it is assumed that the QTL affecting the trait act additively, and that $\mathbf{q}_j$ refers to per-allele effects; nonadditive effects as well as effects relative to nonmarked QTL are lumped together into the residual term of the model.

Fitting such GS model using standard regression approaches is not trivial, as the number p of markers (and so the number of genetic effects to be estimated) may easily exceed the number n of individuals available. The "large p small n paradigm" is central in many applications of genomic technologies, including expression profiling and association analysis, and various statistical strategies have been proposed in the literature to overcome this problem, such as dimension-reduction techniques, stepwise fitting procedures, ridge regression [55], and least absolute selection and shrinkage operator – LASSO [56].

Specifically in GS, hierarchical modeling has become the methodology of choice, due to its flexibility and good statistical properties. Within this approach, the genetic effects $\mathbf{q}_j$ are assumed random effects and distributed according to some prespecified distribution [54]. For example, $\mathbf{q}_j$ may be assumed normally distributed with mean 0 and variance σ_j^2, and the hierarchy can be extended by assuming a prior distribution for the variances σ_j^2 [54, 57–59]. Alternative distributions can be adopted for the $\mathbf{q}_j$, such as double exponential or mixture distributions including a mass point at zero. It is interesting to note the connection between the ridge regression approach and a Bayesian model with normal priors with common variances $\sigma_j^2 = \sigma_0^2$, as well as the LASSO methodology and a Bayesian model with double exponential priors for the genetic effects [60].

The potential of GS to accelerate genetic progress has been demonstrated through many simulation studies (e.g., [54, 61, 62]), and confirmed by some real data applications. The first use of GS using thousands of markers in livestock has been in dairy cattle [63, 64], followed by some breeds of beef cattle and more recently in poultry. Table 1 shows some encouraging results on dairy cattle obtained by the USDA.

Animal Breeding, Foundations of. Table 1 Comparison of April 2010 genomic and traditional evaluations for bulls with an AI status of active or foreign

Trait	Average reliability (%)		
	Genomic	Traditional	Difference
Net merit	87	81	+6
Milk yield	93	91	+2
Fat yield	93	91	+2
Protein yield	93	91	+2
Productive life	81	71	+9
Somatic cell score	88	83	+5
Daughter pregnancy rate	79	69	+10
Final score	89	85	+4
Sire calving ease	90	84	+6
Daughter calving ease	80	67	+13

Future Directions

As shown here, the mixed model methodology is extremely flexible and can be used in a wide variety of applications. Other extensions of the methods discussed here include models with nonadditive genetic effects (e.g., [65, 66]), mixed models for the analysis of non-Gaussian traits such as binary and categorical (e.g., [67, 68]) or counting data (e.g., [69]), robust models [70, 71], survival traits [72], nonlinear models to study, for example, growth curves (e.g., [73, 74]), among others. However, such models can get extremely complex and asymptotic statistical methods are generally required. Alternatively, Bayesian analysis employing Markov Chain Monte Carlo (MCMC) methods can be used, given their exceptional

flexibility and the possibility of incorporating prior information regarding the model parameters [75]. Bayesian analysis has been increasingly used in many applications of genetics and animal breeding, and for a review the reader can refer, for example, to [76–78]. A comprehensive treatment of Bayesian MCMC approaches in animal breeding is presented in [23].

Bayesian hierarchical modeling has also been extensively used in genomic selection [54, 79–81]. In addition, nonparametric and semiparametric methods, and machine learning techniques based on artificial intelligence have been proposed and used for the analysis of high density marker panels in the context of animal breeding, such as in [82–86]. Moreover, some other recent methods aim to combine all available phenotypic, pedigree, and genomic information for prediction of genetic merit of animals [87].

As indicated in the beginning of this chapter, the genetic improvement observed in many livestock and companion animal species is truly remarkable. Most of this genetic progress has been accomplished through selection, using the methods discussed here. Two technological and methodological developments however must be mentioned as turning points in the genetic trends observed in some species; these are the advent of artificial insemination and the mixed models. Seemingly, the development of high density SNP panels and, more recently, next generation sequencing technologies and their application in genomic selection strategies promise to be the next turning point. This new era for animal breeding and genetics will require a different profile of animal breeders, requiring not only knowledge of population and quantitative genetics, classical statistical and computational methods, but also some more modern statistical and computational methods based on hierarchical modeling [23, 88], non- and semiparametric methods, and machine learning techniques [60, 89]. It is indeed a very exciting time to work in animal breeding!

Article Outline

Glossary

Animal breeding Intentional breeding for certain traits, or combination of traits, by selecting animals for breeding with superior genotypes in growth rate, egg, meat, milk, or wool production, or in other desirable traits.

Animal genetic resources Genetic diversity, either characterized or as yet uncharacterized, that is found in economically important animals.

Animal welfare Animal welfare is the viewpoint that some or all animals, especially those under human care, should be treated in such a way that they do not suffer unnecessarily.

Effective population size Is the size of an idealized population that would behave the same as an actual population. The ideal population is one in which there is random mating and no selection. The effective size of a population is typically smaller than its actual size.

Genetic trends Changes in the mean breeding value of a population over time for one or more traits.

Stakeholders Any party that has an interest ("stake") in a project or activity, which in the context of this chapter is animal breeding.

Definition of the Subject

A major long-term challenge of animal breeding is to ensure that animal breeding is sustainable, in order to contribute to a stable long-term contribution of food for the globe. The need to address sustainability in animal breeding schemes has increased as the development in the last decades has been toward larger demands for food, fewer breeds contributing to the production of animal products, low effective population sizes despite the actual populations being large, and a decreasing number of breeding schemes providing the majority of the genetics underlying production of animal products.

The FAO report on *The State of the World's Animal Genetic Resources for Food and Agriculture* [1] indicates that the vast majority of developing countries have not been successful in sustaining genetic improvement in their livestock populations. Among the breeds considered to be in active use, 77% are located in developing countries. Animal genetic resources for food and agriculture (AnGR) provide the biological capital on which livestock production systems and food security are built. Planning for sustainable livestock development should, from the outset, take account of genetic differences among the species, the breeds, and the animals considered for use, along with their adaptive fitness to the production environments in which they will be kept. The different ways in which animals are used in different production systems and communities should also be recognized [2].

Introduction

Animal production has significantly increased its productivity during the last 50 years. This has been a combined effect of improvements in the environment provided to the animals, for example, improved feeding and management, as well as efficient breeding schemes resulting in significant and cumulating genetic progress. These improvements are synergistic, as genetic improvements and management and feeding improvements stimulate each other. Examples of drastic changes in productivity include

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

- Manyfold increases in milk production of dairy cattle
- Improvements of growth, leanness, and litter size in pigs
- Manyfold increases of growth and egg production in broiler and layer hens, respectively

This trend in productivity is expected to continue for several reasons. In a competitive market for food production, genetic improvements are an essential parameter to ensure a profitable production. However, the demand for food is also expected to increase, and thus stimulates a larger and more efficient production. The World Bank has estimated that it will be necessary to increase meat production by about 80% between 2000 and 2030.

However, the improvements in productivity have also contributed to a global concentration on fewer breeds for the largest part of animal production. In dairy cattle, Holstein-Friesian is now the dominating breed of the world, with exchange of semen and embryos across countries resulting in a relatively low effective population size (∼40–70, [3, 4]). In poultry breeding, a few multinational companies now control the commercial genetic improvement and thus the genetics of the vast majority of eggs and poultry meat produced globally.

Recently, the effect of animal breeding has come under critical evaluations from an ethical point of view, reflecting public concerns on the effects of current and future animal breeding. Developments in biology, neuroscience, and genetics have resulted in changes in our perception of the world, and there is an increasing focus on the effects of animal breeding and the ethics of changing animals by selective breeding for our own good (e.g., [5, 6]). Ethical problems in animal production have historically focused on housing and husbandry, but more emphasis is now focused on the effect of animal breeding [7]. It is argued that the fact that selective breeding can introduce welfare problems places an ethical responsibility on the animal breeding industry [7].

The European animal breeders have realized that these powerful technologies to create genetic progress have generated public concern about the impact of animal breeding and the use of new technologies [8].

According to FAO [2]: *A strategic and logistical approach to sustainable livestock development is required. To appropriately address the use of available AnGR and the role of genetic improvement in sustainable development, from the outset, all policies, plans, and programs for the livestock sector must:*

- *Be based on soundly established and agreed livestock development objectives (LDOs) and well-integrated and realistic livestock development strategies (LDS) that are able to achieve the LDOs.*
- *Account for major environmental, structural, and socioeconomic differences among the production systems concerned.*
- *Ensure participation of the end users (the livestock keepers themselves). Both men and women should have access to relevant information, be involved in the formulation of policies and plans, and have ample opportunities to give their opinions.*
- *Be appropriately funded.*
- *Promote step-by-step development and the sustainability of the actions undertaken.*
- *Be based on well-documented approaches that are understood and agreed by all the stakeholders involved at each stage.*
- *Take fully into account the fundamental principles of genetic improvement and their technical implications.*

Thus, a major future challenge of animal breeding is to ensure a sustainable use of the animal genetic resources available and to implement sustainable breeding schemes in active populations.

The focus of this entry is the long-term challenges of animal breeding focusing on sustainability of animal breeding schemes. This is done by discussing the concept of sustainability in the context of animal breeding and then describing risk factors affecting sustainability. Then guidelines for developing sustainable and future directions to ensure sustainable are discussed.

Sustainability

Sustainability is a term that has a widespread use, and thus is often used in different meanings. It is often used in the sense of human sustainability on planet Earth and this has resulted in the most widely quoted definition of sustainability and sustainable development, that of the Brundtland Commission of the United Nations on March 20, 1987: "sustainable development is development that meets the needs of the present without

compromising the ability of future generations to meet their own needs" [9]. This definition is also relevant to animal breeding; it is, however, not very operational.

In order to define and address sustainability in the context of animal breeding, it is first necessary to identify the stakeholders of animal breeding schemes. These stakeholders all have interests in animal breeding, and some of their interests might be conflicting. Understanding the diverse interest in animal breeding is a prerequisite for developing sustainable breeding schemes.

Obvious stakeholders are the animal breeders, breeding companies, and breeding associations, which have the major responsibility for defining and running the breeding scheme. Additional stakeholders include producers, veterinarians, manufacturers and retail enterprises, and consumers. For some aspects, the society as a whole may be considered a stakeholder in itself. These stakeholders have different perceptions of the desired outcome of animal breeding schemes and thus sustainability, influenced by their role in production and utilization of animal products and their time horizon.

In the short term, objectives of different stakeholders can be very different. Animal breeders will typically focus on the factors limiting the profitability of the primary production. The interest of manufacturers and retail enterprises is on product quality, quantity, and possibilities of adding value to the primary product to ensure profitability of manufacturing and retail. Consumers will typically focus on product quality and price, product safety in addition to potentially cultural and political issues, such as environmental impact and animal welfare.

However, it can be expected that stakeholders will share many long-term interests in animal breeding schemes. Long-term interests of producers and manufacturers are likely to be more similar to the interests of consumers in the long-term, as they are the main actors determining quantity and quality demands. A thorough discussion of sustainability in the context of animal breeding is provided in [10], focusing on the need to address the interests of all stakeholders.

Interests of stakeholders include the following areas, which should be considered for defining sustainable animal breeding schemes for the future [11]:

- Food security, including
  - Quantity produced
  - Product quality
  - Food safety from both a biological and technical perspective
- Socioeconomic effects, including
  - Impacts of breeding schemes on rural economy, employment, and trade
  - Subsidies and their effects on objectives and methods used in animal breeding
  - Public (ethical) perception of the methods and technologies applied in animal breeding
- Environmental impact, including
  - The relationship between animal production and measures of environmental quality
  - Landscape management where animal production plays a major role
  - Interactions with biodiversity and ecosystems
- Health, welfare, and ethics including
  - Health management and biosecurity related to both the risk of zoonoses and contamination of products
  - Ethics of breeding and production

Sustainable Animal Breeding

Animal breeding is based on selecting animals with a superior genotype relative to the desired direction of selection, as reflected in the breeding objective. However, breeding values cannot be observed directly in animals, and they have to be predicted based on phenotypic records on the individuals themselves and their relatives and/or genetic markers. Thus, animal breeding is based on selecting the seemingly superior individuals given their predicted breeding values. Secondly, selected parents pass half of their genes to a given offspring, and each individual is thus a genetically unique individual. A direct result of this is that planning of animal breeding schemes is not an exact science. Genetic progress can be predicted but the realized response to selection can vary depending on a number of factors reflecting biological and economic uncertainty that influences the outcome of a breeding scheme. The breeding objective represents the desired direction of change of a population, most often expressed as the marginal economic value of changing a trait. The breeding objective should address

all aspects of animal production and the characteristics of the product.

Ignoring the interests of some stakeholders when defining breeding objectives might negatively affect the success of a breeding scheme. This can be addressed by considering the interests of all stakeholders. The large potential of animal breeding is the contribution of additive improvements toward a long-term objective. However, there are factors that are not necessarily stable over time, factors that can potentially also change the interests of stakeholders. Examples of such factors include market structure, fluctuations in prices, regulations of production systems, disease outbreaks, and variation in the response to selection, both in the traits directly selected for and in traits indirectly affected as a correlated effect of selection. In addition to these factors, uncertainty on the assumptions underlying the design of a breeding scheme contributes to the risk of this breeding scheme. The risk of a breeding scheme is related to the deviations of the realized effects of a breeding scheme relative to those planned. These factors have two effects: some contribute to a reduction of the realized outcomes of a breeding scheme (e.g., diseases) and others contribute to an increased variability of the outcome of a breeding scheme.

Thus, a sustainable animal breeding scheme should address the interests of all stakeholders and actively reduce the risks of the breeding scheme. This is in line with the SEFABAR project that produced a "Code of Good Practise for Farm Animal Breeding and Reproduction Organisations" [10, 12]. The code addresses issues of food safety and public health, product quality, genetic diversity, efficiency, environmental impact, animal health, animal welfare, and breeding and reproduction technologies. The code is based on the following six general statements:

- Breeding organizations must follow zootechnical, animal welfare, and animal health legislations and relevant regulations and practices.
- Breeding organizations must consult and collaborate with international, national, and regional authorities for the development and implementation of policies, practices, and regulations. These policies should assist the achievement of economic, environmental, and social sustainability of the animal breeding sector.
- Breeding organizations must use modern biosecurity methods to minimize disease transmission.
- Breeding organizations must ensure the health and welfare of the animals under their care.
- Breeding organizations must treat the animals under their care with respect.
- Breeding organizations must ensure that selection for production traits is balanced by appropriate attention to reproduction traits and health- and welfare-related traits.

The intention is that this should result in sustainable breeding programs by an economically viable balance of (a) food safety and public health, (b) product quality, (c) genetic diversity, (d) efficiency, (e) environmental impact, and (f) animal health and welfare.

Risks in Animal Breeding Schemes

The expected outcome of a breeding scheme might not be the same as the realized outcome for several reasons. These include

- Uncertainty on the genetic model assumed
- Uncertainty on the assumed genetic parameters (heritabilities, genetic correlations, etc.)
- Genetic drift resulting from finite population size
- Suboptimal decisions and implementation of the breeding scheme
- Breeding objectives that do not include all relevant costs and benefits of the production system targeted
- Changes in markets and consumer preferences

Some of these can contribute to both positive and negative deviations from the expected outcome, for example, deviations in genetic parameters from those assumed might either increase or decrease genetic gain relative to that expected.

However, most deviations are expected to result in a realized outcome of selection being lower than that expected, as the predictions assume that parameters are known and selection decisions are optimal. If the breeding objective does not reflect the true breeding objective, this will always result in selection decisions being suboptimal and response to selection being lower than expected. Likewise, changes in markets, consumer

preferences, or political regulations of the industry will result in suboptimal goals being targeted by the breeding scheme, and thus the realized outcome being inferior to that expected.

Thus, two groups of factors contributing to the risk of animal breeding schemes can be identified.

The first group is risks intrinsic to the breeding scheme. The response of a breeding scheme might deviate from expectations due to variability of response to selection for the traits considered in the breeding objective and in the selection index. This can be due to uncertainties about genetic parameters used for predicting breeding values, uncertainties in the breeding values predicted from phenotypic records and/or genetic markers, and genetic drift.

Genetic drift can also increase the frequency of deleterious (recessive) alleles. Examples include BLAD [13] and CVM [14] in dairy cattle and the halothane sensitivity locus in pigs [15]. These alleles increased in frequency either by directly having a positive impact on some of the traits selected for, or being linked to alleles with positive effects on the traits selected for. In general, all traits not directly selected for and not correlated with the traits in the selection criterion are most affected by genetic drift. In a closed population, genetic drift is highly related to the rate of inbreeding.

Unfavorable correlated responses to selection can appear if important traits are not included in the breeding objective and selection criterion. There is evidence of general negative effects of selection for increased production resulting in increased occurrence of behavioral, physiological, and immunological disorders [16]. A theory (resource allocation theory) has been proposed to explain the general negative correlated changes in fitness and health-related traits when selecting for production traits. The theory predicts that with limited resources available, selection for increased production results in less resources being allocated to, for example, health and reproductive traits [17]. In a mice model it was shown that a line selected for large litter size allocated more resources to lactation and mobilized body energy for a longer time period than a control line [18]. However, results suggest that not all aspects of immune response are decreased by selection for production. In a comparison of chicken lines from 1957 to 2001, it was concluded that the 2001 chickens selected for growth have a decreased adaptive immune response but a better cell-mediated immune response [19]. These examples highlight the need to consider the direct response to selection not only in the traits selected for, but also in other traits of relevance for production, animal health, and animal welfare.

Effective population size (which in a closed population is inversely proportional to rate of inbreeding) is the most important indicator of genetic risk in a breeding scheme, being inversely proportional to both genetic drift in a closed population and variation in selection response. Larger effective population size results in less genetic drift and less variability in the response to selection. Selection intensity, population size, and selection and mating criteria all influence the effective population size. It has been argued that the effective population size should be at least 50–100 individuals in order to avoid negative effects of genetic drift [20], but should be significantly larger in order to maintain mutations contributing to maintaining genetic variability.

The second group of risks is external to the breeding scheme. These include environmental risks due to changes in environmental factors unforeseen when planning the breeding scheme. Such risks are diseases, particularly epidemic diseases and diseases under national and international regulations (e.g., foot-and-mouth disease), and changed market and/or production regulations. These changes will most often result in the realized outcome of a breeding scheme being less than expected.

Guidelines for Developing Sustainable Breeding Schemes

Animal breeding schemes produce additive genetic improvement, and are thus most powerful when applied for a long-term improvement of a population. Thus, breeding objectives should reflect the future market for which production is aimed. The development of breeding objectives includes an assessment of the breed and its characteristics relative to the future market preferences. Traditionally, this includes an economic analysis aiming at estimating the marginal value of improving a trait. These marginal values are often the economic value of changing a trait given all other traits are constant. The breeding objective is then defined by the marginal values of the traits. However, this is not

necessarily sufficient as a breeding objective should also consider the risk and uncertainty of aiming at a particular market, including status and trends in consumer preferences, social attitude, political and economic regulations, and infrastructure.

The breeding objective should reflect the most profitable improvement of the population, conditional on the current and future market conditions. The derivation should include traits beyond those currently recorded or included in a selection criterion.

The expected genetic trends should also be evaluated to ensure the breeding objective is sustainable. Ethical evaluations and public perception of animal welfare might alter the relative weights used in the breeding objective. Including a trait in the breeding objective does not guarantee that that particular trait is improved. Traits with low heritability, traits negatively correlated to important traits in the breeding objective, and traits measured late in life are at risk of not being improved despite being in the breeding objective. Traits that fulfill all the above-mentioned criteria include health-related traits, such as mastitis and fertility in dairy cattle. It has been suggested that such traits should have a larger weight in the breeding objective, the larger weight reflecting a nonmarket value [21]. Such nonmarket values could reflect public concern on, for example, increased disease susceptibility resulting from the current breeding objective.

Ignoring important traits in deriving marginal (economic) values to be used in the breeding objective will bias the prediction of the economic outcome of the breeding scheme. For example, ignoring quality measures that are not considered in current market conditions but are important in distinguishing the product from other competing products might be harmful to the long-term competitive ability of the product.

Breeding objectives should not only be defined in terms of production, but should also include traits related to animal health and welfare resulting in robustness being part of the breeding objective [16].

Derivation of the marginal value of all important traits is crucial, in order to predict the effects of selection, not only on traits selected on, but also traits correlated to those traits. This is necessary to avoid unfavorable genetic changes in traits not selected for.

The expected outcome for a given breeding objective also depends on the recording scheme. Recording is often one of the most costly elements of a breeding scheme and should thus be an integral part of planning a breeding scheme. Generally, the objective of recording should be to allow for favorable genetic trends in the traits included in the breeding objective. This might be complicated by biological constraints of, for example, when a trait is realized and the number of individuals it can be recorded on. Examples are traits measured late in life (e.g., longevity), measured after slaughter (e.g., meat quality), or measured on one sex (e.g., female fertility), which poses challenges in defining efficient recording schemes. Modern technology allows for some remedies to this challenge. Genetic markers can be measured early in life, and in addition they can be used to predict the breeding value for traits not yet recorded [22].

In addition to the traits directly selected for, other important traits should also be recorded, in order to document the trend in these traits. Such traits include traits that are economically or ethically important, but they are not necessarily included in the breeding objective if they are at acceptable levels. However, correlated effects of selection might change these traits in undesired directions.

Two aspects of sensitivity to environmental factors should be considered. Chance events, such as disease epidemics have the potential to critically damage a breeding scheme, particularly if breeding animals are kept in a limited region or in a few herds. The foot-and-mouth disease outbreak is an example of a disease outbreak that has threatened breeding nuclei. Backup and safety procedures are necessary for safeguarding a breeding scheme. This can be done by implementation of techniques such as cryopreservation of embryos, eggs and semen, and segmentation of the breeding nucleus. This will naturally be very species specific, depending on the biological possibilities in the given species.

The second aspect of environmental sensitivity relates to environmental sensitivity, whether an individual's performance is sensitive to the environment in which it is kept. More specifically, this is an issue if genotypes and environment interact, such that an individual would be ranked differently in two environments relative to other individuals. A more realistic

example is offspring from two bulls having different relative merits in two environments. The implications of an interaction are multiple. First, prediction of the performance in an environment that differs from the environment in which selection was performed might be impossible. Second, genetic improvement in one environment might not result in similar genetic changes in another environment. As an example, in some breeding schemes, candidates for selection are housed individually in order to allow for individual recording of the traits of interest, whereas animals in commercial production are housed in groups, providing a significantly different environment to that selected in. In such cases, where the environment of the breeding nucleus and the production herds differ, then genetic trend should be recorded in the production environment to ensure that selection is in the direction desired. If genotype–environment interaction exists, genetic evaluations should take this into account. Also the breeding objective should be specific on which environment(s) genetic changes are optimized for. A specific type of genotype–environment interaction is the situation where environments describe a continuum of environmental effects, and thus cannot be grouped in classes of environmental effects. Reaction norm models describe such interactions, and a feature of these models is that they can model the sensitivity to the environment, and that this sensitivity is partly genetically determined. This has two implications. First, it is expected that environmental sensitivity will change as a correlated effect of selection on the mean, assuming nonzero correlations between mean performance and sensitivity. Second, it implies that environmental sensitivity can be selected for or against. The second implication also means that genetic changes will require changes in the environment to be fully expressed in all environments. This is an important outcome of a breeding scheme, and it has to be taken into consideration whether such environmental changes can be accommodated in commercial environments. There are many examples of highly improved breeds, selected in environments with a high level of management, that fail to express their genetic potential when transferred to environments characterized by lower management levels, for example, when highly selected breeds are transferred to tropical countries with lower input levels and other environmental characteristics. Thus, potential changes in environmental sensitivity have to be taken into account when predicting and evaluating the expected response to selection.

The optimum selection environment is not always equal to the environment in which the response is to be realized, but depends on the degree of genotype–environment interaction (determined by the ratio of variances in slope and level of a linear reaction norm), the correlation between level and slope, and the heritability of the trait [23].

In relation to breeding objectives, it was stressed that the market for which production is aiming should be defined. The reasoning is that this is a prerequisite to ensure that consumers will accept the product and its characteristics and that the product(s) addresses the preferences of the consumers. Consumer responses have been instrumental in changing egg production systems in European countries, and the use of gene transfer worldwide.

Measuring the success of a breeding scheme involves two components. First, expected response to selection should be predicted, as the measure against which to compare the operational and strategic outcome of the breeding scheme. To predict the expected response to selection estimates of genetic parameters, covariances between traits, generation intervals, recording scheme, and resulting accuracies of the predicted breeding values, selection intensities and the weights used in the breeding objective are required. Uncertainty about one or more of these should be taken into account when predicting response to selection. These predictions are based on a genetic model, on which there may also be uncertainty. Second, realized genetic trends should be compared to the predicted response to selection, both in order to evaluate the success of the breeding scheme, but also to modify it if required to better fulfill the overall objectives of the breeding scheme.

Most breeding schemes rely on genetic progress accumulating in a nucleus, representing the animals active in the breeding scheme. The genetic progress is then disseminated to production herds. This might involve several tiers, such as a breeding and multiplier level, in order to efficiently disseminate genetically superior individuals or semen to production herds. The time from genetic progress in the breeding nucleus

to the dissemination of this progress in production herds is termed genetic lag, and is a major indicator of the efficiency of utilizing genetic progress in production.

The outcome of a breeding scheme is realized in the years following the selection decisions and the majority of the costs. An economic evaluation of a breeding scheme thus requires that costs and revenues are discounted back to a common base. This should take into account that returns more distant in time are more uncertain than those occurring in the near future. This involves defining the time horizon for which revenues are discounted, reflecting the uncertainties about the market and production conditions. This reflects an economic time horizon of the breeding scheme.

Expected and realized response to selection should be compared at regular interval as an integral part of controlling and optimizing the breeding scheme. This should be done at intervals shorter than the economic time horizon.

Future Directions

Following is a discussion including potential impacts on the development of certain areas of science.

Animal breeding is a competitive business, and producers pursue genetic material that best suits their needs. This naturally means purchasing animals that are economically optimal in the specific production. This potentially limits the focus on animal welfare–related traits not directly related to productivity.

However, since animal breeding decisions for most species are made centrally and, increasingly, internationally it has been argued that international agreements are needed [7] to ensure sustainable breeding schemes that address all relevant traits.

There is evidence that breeding companies are addressing these challenges. Survival in poultry has been improved by, among other initiatives, selective breeding and current focus is on selection against feather pecking, cannibalism, leg disorders, and heart/lung disorders [24]. And more generally, breeding objectives now contain more traits, also related to animal health and costs of production. In many cases, inclusion of health- and welfare-related traits results in more profitable breeding schemes than selection on production alone [25].

It should, however, also be acknowledged that despite the well-documented negative effects that selection for production traits has had on welfare-related traits, modern genetic technologies also give possibilities of understanding the biology underlying animal welfare and actively select for improved welfare [26]. Welfare-related traits are likely to show genetic variation, and it is thus also possible to select for increased animal welfare [27].

New technologies have the potential to affect animal welfare in both positive and negative directions [28]. Positive examples are the use of sexed semen in dairy cattle, which can decrease the number of unwanted male offspring that are killed after birth in some breeds and result in easier birth of female offspring. An overall positive effect is conditional on no adverse effects of the technology on the calves and/or the mothers.

Genomic selection [22] is currently under implementation in the large dairy, pig, and poultry breeding schemes. Genomic selection is fundamentally different to previous selection strategies, which relied on phenotypic records being recorded on the candidates for selection and/or their relatives. With genomic selection, this is replaced by a two-step procedure where the association being genome wide, markers and phenotypes are established in a part of the population where both phenotypic recording and genotyping are performed. Secondly, breeding values can be predicted for individuals based on their genotype. This allows for accurate breeding values being available earlier in life. This is particularly useful for traits recorded late in life, traits with low heritability, and traits recorded in one sex, which are largely the characteristics of many traits related to animal health and welfare. Genomic selection thus improves efficiency of selection for traits that are currently difficult to improve genetically, and thus has the potential to contribute to more sustainable animal breeding schemes [29].

Effective population size is a measure of the risk of a breeding scheme. Constraining the rate of inbreeding has the potential to reduce the variance of response to selection, reduce the loss of genetic variance, and reduce genetic drift. Quadratic selection indices jointly maximizing response to selection while constraining rate of inbreeding have been developed [30]. This quadratic index optimizes the genetic contributions of

parents to the next generation, and the contribution of any parent depends on which other parents that are selected.

Acceptable rates of inbreeding are often described as being in the range of 0.5–1% per generation, equivalent to an effective population size of 50–100. More specifically, the acceptable level of inbreeding depends on the extent of inbreeding depression on fitness [20], and thus a sustainable breeding scheme ought to validate the acceptable level of inbreeding.

The implementation of sustainable breeding schemes requires, as described above, a thorough analysis based on an understanding of genetics, economics, and market characteristics. Training and education is a prerequisite for qualified personnel to contribute to the development and maintenance of sustainable breeding schemes.

Sustainability is a new measure in the context of animal breeding, but many elements contributing to sustainability are well known and have been taken into account previously. The aim of developing sustainable animal breeding schemes puts these elements into a coherent context, highlighting the need to take interests of all stakeholders into account, as well as the risks and uncertainties of assumptions and outcomes.

Article Outline

Glossary

Contemporary groups A group of animals of approximately the same age living in the same environment and being treated by the same management practices during the same interval of time.

Estimated breeding value An estimate of the total additive genetic merit of an individual, the effects that are directly passed to offspring.

Genotypes The particular set of alleles at all gene loci that influence the phenotypes.

Inbreeding coefficients The proportion of alleles at gene loci that are identical due to being inherited from a common ancestor.

Infinitesimal genetic model A genetic model that assumes there are an infinite number of gene loci affecting a trait each with a small and equal effect.

Mixed model equations Proposed by Henderson in 1949 for the estimation of breeding values and other nongenetic effects from phenotypes.

Phenotypes The observable characteristics of an animal that can be measured, scored, or recorded.

Definition of the Subject

Modeling in animal breeding involves describing the major factors that influence the performance ability or production level of animals in order to predict the genetic merit of future progeny for that ability. Successful modeling depends on good record collection systems, accurate pedigree records, and sophisticated statistical models. Models have evolved over time as computer technology has advanced. Genetic evaluation of dairy bulls began in the early 1930s using simple daughter averages for milk production in selection index procedures of Lush and his students [1]. Genetic evaluation systems spread to all livestock and to many countries due to Lush. Henderson [2] introduced best linear unbiased prediction (BLUP) around 1950, and this methodology is still widely used in animal breeding except that the models are more detailed and complex. Gianola and others [3, 4] taught animal breeders how to use Bayesian methods which are especially useful for non-normally distributed data.

All methods consider the total additive genetic merit of animals. Additive genetic effects are directly transmitted to progeny, assuming infinitely many gene loci, each with a small and equal effect on the trait of interest. Examples of traits are milk yields of dairy animals, growth rates of meat-producing animals, occurrence of health problems, ability to reproduce, and behavior.

Models to analyze traits differ depending on the nature of the traits being evaluated. Traits can be broadly grouped into production traits, growth traits, reproductive traits, health traits, and survival, and the models for each group are very specialized. In the 1930s, dairy bulls were selected almost solely for the ability of their daughters to produce milk. Over time, the success of that selection pressure for one trait caused negative correlated responses in reproduction potential and disease susceptibility. Genetic evaluation systems consider many traits simultaneously with a primary focus on efficiency of economic production and cost savings.

Introduction

Modeling in animal breeding began with the expression

$$\mathbf{p} = \mathbf{g} + \mathbf{e},$$

where **p** is the phenotype of an individual, **g** is the genetic source of variation or genotype in **p**, and **e** is the environmental source of variation, presented by Wilhelm Ludwig Johannsen in 1909 [5]. A phenotype is a measurement of an animal's performance for an economically important trait, such as daily milk yield of a dairy cow, goat, or sheep; a growth record on a beef animal, pig, or rabbit; or wool production of a sheep or llama. Current models are extensions of this basic equation.

Genetic Component

The **g** term of the model is partitioned as

$$\mathbf{g} = \mathbf{g}_a + \mathbf{g}_d + \mathbf{g}_i,$$

where

- $\mathbf{g}_a$ are additive genetic effects, the collective effects generated by individual alleles at every loci in the genome.
- $\mathbf{g}_d$ are the dominance genetic effects, the collective effects generated by combinations of alleles at every locus in the genome.
- $\mathbf{g}_i$ are the many interactions among loci throughout the genome, in a collective sense.

Animal breeders are primarily concerned with additive genetic effects because those effects are passed directly from parents to progeny. Dominance and interaction genetic effects occur depending on the combinations of alleles from the paternal and maternal sides of the pedigree, and cannot be predicted prior to making a mating of specific individuals.

Further, $\mathbf{g}_a$ is assumed to be the combined effects of an infinite number of loci, each with a small and equal effect, i.e.,

$$\mathbf{g}_a = \sum_{k=1}^{\infty} g_k.$$

The population is assumed to be very large and mating randomly. This is known as the *infinitesimal genetic model* upon which genetic evaluation systems are based. This is a reasonable model if you consider that there are roughly 30,000 loci (this estimate is continually changing), and if one assumes only two alleles at each locus, then there are three possible genotypes per locus, or $3^{30,000}$ possible genotype outcomes. This number is large enough to be nearly infinite for all practical purposes. The number of possible genotype outcomes is actually much bigger if you allow that there are more than two alleles for many loci.

Environmental Component

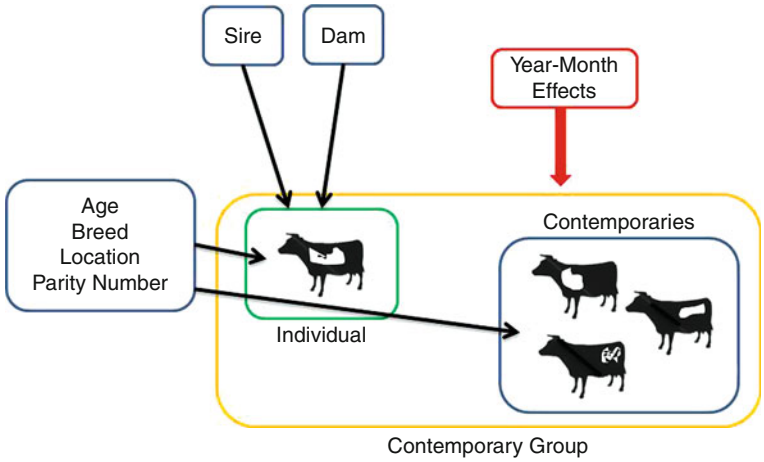
The **e** term can be split into identifiable factors that are known to have effects on the phenotypes. Some effects are shared with other animals in the same location at the same time, and some effects are specific to individuals.

Animal Model

The common model in animal breeding is called an *animal model*, based on the underlying infinitesimal genetic model, containing factors to account for time trends, contemporary groups, additive genetic effects, residual, and other factors, that depend on the species and trait of interest. Figure 1 depicts a typical animal model in a diagrammatic format. Each individual is affected by the additive genetic merits of its sire and dam, as well as year and month of birth or calving. Contemporaries are animals that share the same year and month effects as the individual because they exist in the same space and time. These effects include weather, location, herd owner, and herd management practices of feeding, breeding, and health care. Individual production is affected by breed, age, and parity number, and these effects are common to all animals of the same breed, age, and parity number.

Depending on the species and trait, other factors could be included in the diagram.

Models in animal breeding are conveniently presented in matrix notation. Models consist of three parts which are the equation, the expectations and distributions of random variables, and finally a list of assumptions and limitations. The three parts are briefly described.



Animal Breeding, Modeling in. Figure 1
Diagram of genetic and environmental factors affecting dairy cow milk production

The Equation

A linear statistical model is written generally (in matrix notation) as

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Zu} + \mathbf{e},$$

where

y is a vector of observations on the trait of interest from individual animals, either one or more per animal.

b is a vector of levels of factors that are known to affect the magnitude of the observations. These factors are fixed factors, in that they are constants and not random variables drawn from a particular distribution or population of effects. One factor that should always be included in an animal model is one that accounts for time, either year, or year-season. Seasons may be groups of months, individual months or weeks of the year. This time factor is meant to account for changes in average production over time due to changes in production technology, global warming, nutritional improvements, or financial impacts that affect the entire population. Other factors are effects of gender, breed, age of dam, and diet.

u is a vector of levels of random factors, which are random samples from a large population of levels of that effect. Animal additive genetic effects are one such random factor contained in **u**. Two random factors that should always be included in an animal model are the animal additive genetic effect, **a**, and the contemporary group effect, **c**, $(\mathbf{u}' = (\mathbf{a}' \ \mathbf{c}'))$. Contemporaries are animals that coexist in the same location and time space, and thus share the same management care and treatment during the time they are observed for a trait. Contemporary groups are commonly called herds, flocks, or tanks, and are nested within year or year-season effects. Contemporary groups are random because there are a large number of them, each contemporary group contains different individuals, and the effects during that one occurrence are random in nature.

e is a vector of random residual (environmental) effects specific to each observation, that cannot be accounted for by other factors in the model. The residual effects may be samples from different populations having different variances.

Expectations and Covariances

The model also describes the distributions of the random factors and indicates their expected values or means and covariance structures. That is,

$$\begin{aligned} \mathrm{Var}(\mathbf{u}) &= \mathbf{G} \\ \mathrm{Var}(\mathbf{e}) &= \mathbf{R}, \text{ and} \\ \mathrm{Cov}(\mathrm{u}, \mathbf{e}') &= 0, \end{aligned}$$

where Var() is a variance-covariance matrix, and Cov() is a covariance matrix.

Further, **G** can be partitioned into other matrices for each factor contained within **u**. Because **u** will contain animal additive genetic effects, **a**, and contemporary group effects, **c**, then both **a** and **c** are assumed to follow normal distributions with null means. The variance-covariance matrix of **a** is

$$Var(\mathbf{a}) = \mathbf{A}\sigma_a^2,$$

where **A** is the numerator additive genetic relationship matrix of Wright (2), and σ_a^2 is the additive genetic variance of the trait of interest. More will be given on the additive relationship matrix shortly.

Similarly,

$$\mathrm{Var}(\mathbf{c}) = \mathbf{I}\sigma_c^2,$$

where σ_c^2 is the contemporary group variance (variance of all contemporary group effects), and **I** is an identity matrix, which means the contemporary group effects are independent of each other. Finally,

$$\mathrm{Cov}(\mathbf{a}, \mathbf{c}') = 0,$$

additive genetic and contemporary group effects are independent.

The residual effects are assumed to be independent of all other random factors, meaning their covariances with other random factors are 0. If known, the ratios of residual variance to the additive genetic variance and to the contemporary group variance should be provided, or at least the values that are intended to be used.

Assumptions and Limitations

Limitations occur because of a lack of information in the data records. A factor that could be important is not included in the model because there is no information about that factor in the data files on animals. For example, an animal's record may or may not be affected by its health status. If the record was affected, then health status should be a factor in the linear model. However, health information may not be a part of the data files, and therefore, it cannot be included in the model. Consequently, an assumption is needed that animals were healthy when observations were taken. Depending on the trait and species, this assumption may or may not be critical.

A complete list of the explicit or implied assumptions should be a part of every model description, but often they are omitted. Readers of a scientific report may not be as familiar with the data files and production system as the authors, and may not be able to assess the assumptions that need to be made. The presence of this part of the model helps readers to judge the quality of an analysis.

Genetic Relationships

The animal model works best when pedigree information is complete and accurate. Preparing pedigree files can be tedious, depending on the species. Animals can be registered in different organizations with different identifications in each organization, both of which may be found in the data files. Efforts are needed to make sure that each animal has only one unique identification in both the data files and the pedigree file. Good identification systems include codes for breed of the animal and year of birth.

Next, pedigrees of animals need to be arranged in chronological order. Parents should appear in a list before (ahead of) their progeny. Ordering a pedigree is most easily accomplished by sorting animals by birthdate. Birthdates, however, can be incorrectly recorded, or for many individuals may not be available. One approach is to assume that all birthdates are incorrect. Assign all animals a generation number of 1. Then cycle through the pedigree file and modify the generation numbers so that the generation numbers of the sire and dam of an animal are at least one unit greater than the generation number of that animal. Iterate through the pedigree file as many times as needed until no further modifications are made to any generation numbers.

Inbreeding Coefficients

Genetic relationships among individuals were worked out by Wright [6] as correlation coefficients. Later, only the numerators of these correlation coefficients were needed in genetic evaluation, and were called Wright's numerator, additive genetic relationships. The dimensions of the additive genetic relationship matrix, **A**, equal the number of animals (N) in the pedigree. The pedigree file usually contains more individuals than are represented with records in the data file. If constructed,

the **A** matrix would be 95% full (nonzero numbers). For one million animals, the storage of these numbers would be an overwhelming problem computationally. Fortunately, during genetic evaluation, only the inverse of this matrix is needed. The inverse is typically very sparse by comparison, and the elements in the matrix can be generated as needed and do not ever need to be stored. For this to work, the inbreeding coefficients of every animal need to be determined.

Henderson [7] showed that the additive relationship matrix could be written as

$$\mathbf{A} = \mathbf{TBT}',$$

where **T** is a lower triangular matrix and **B** is a diagonal matrix. The diagonals of **B**, say b_{ii}, were shown to equal

$$b_{ii} = (0.5 - 0.25(F_s + F_d)),$$

where F_s and F_d are the inbreeding coefficients of the sire and dam, respectively, of the ith individual. If one parent is unknown, then

$$b_{ii} = (0.75 - 0.25F_p),$$

where F_p is the inbreeding coefficient of the parent that is known. Lastly, if neither parent is known, then $b_{ii} = 1$. An inbreeding coefficient indicates the proportion of alleles that are in common within an individual due to being inherited from common ancestors some generations back in the pedigree. This happens when related animals are mated together.

The key discovery of Henderson [7] was that

$$\mathbf{A}^{-1} = \mathbf{T}'^{-1}\mathbf{B}^{-1}\mathbf{T}^{-1},$$

and that each row of $\mathbf{T}^{-1}$ had a one on the diagonal and two negative one-halves on the off-diagonals corresponding to the locations of the sire and dam of that individual. Only two nonzero numbers that are always equal to 1 or $-\frac{1}{2}$. The elements of $\mathbf{B}^{-1}$ are equal to b_{ii}^{-1}. Every animal could have a different b_{ii}, so these would need to be stored.

Meuwissen and Luo [8] developed a very efficient algorithm to compute inbreeding coefficients, and from these come b_{ii}. The algorithm requires animals to be chronologically ordered and processed, so that inbreeding coefficients of an animal's ancestors are known before that animal is processed. Once the inbreeding coefficients are known, then b_{ii} are easily obtained. Having b_{ii} for each individual, then elements of $\mathbf{A}^{-1}$ can be calculated readily, as needed. Consult Meuwissen and Luo [8] for details of their algorithm.

Missing Parents

Animals with unknown parents are assumed to be animals from a large randomly mating population of unrelated, unselected individuals. This group of animals is known as the *base population*. In dairy cattle, the base population might be animals that were born in the 1950s. However, even today, there are animals in the data files and pedigree files that have unknown parentage. Clearly, these animals are genetically different from animals born 60 years earlier, and they should belong to a population different from the base population. For this reason, unknown parents are assigned to genetic groups based on the year of birth of their progeny, and whether the progeny was male or female [9, 10]. Suppose an animal was born in 2009 and was a male. If the male parent of this animal was unknown, then it would be assigned to a Sire of Males group for 2009, and if the female parent was unknown assignment would be to a Dam of Males group for 2009. The assumption made for assignments is that the selection intensity of each pathway differs so that the genetic means of these groups would be different. The other two pathways are Sires of Females and Dams of Females. These groups may be further subdivided, based on breeds or countries of origin.

Computationally, genetic groups are treated as though they were a separate individual, which requires simple modifications in the computation of elements of $\mathbf{A}^{-1}$. Genetic groups are essential in the animal model in order to obtain unbiased estimates of genetic trends, and accurate evaluations of all animals. There are always animals with unknown parents resulting from movement of animals between countries, but also between herds or flocks within a country.

Genetic Evaluation

Best linear unbiased prediction (or BLUP) has been used since 1970 when Henderson applied the method to genetic evaluation of dairy bulls in the northeastern United States even though the theory

had been available since 1950. BLUP requires setting up and solving a linear system of equations that is equal in size to the number of animals and number of levels of other effects that are in the model. The equations are known as the mixed model equations (MME). The solutions to these equations are usually obtained by iteration rather than through the direct inverse of the large coefficient matrix. Many various strategies have been devised to iterate solutions quickly.

Iteration is a technique where initial solutions begin at zero, and by going through one equation at a time, each solution is updated based on the values of the other solutions at that time. An updated solution causes all subsequent solutions to change during the updating process. Iterations continue until the changes are less than a certain value (like 1×10^{-9}), at which point the solutions have reached convergence.

Mixed Model Equations

The mixed model equations (MME) of Henderson [2] yield the BLUP predictors of the random effects of the linear model and generalized least squares estimators of the fixed effects. Following the notation for the linear model, the MME, generally, are written as

$$\begin{pmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z} \\ \mathbf{Z}'^{-1}\mathbf{X} & \mathbf{Z}'\mathbf{R}^{-1}\mathbf{Z} + \mathbf{G}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{u}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}'\mathbf{R}^{-1}\mathbf{y} \end{pmatrix}.$$

From one model to the next, **X**, **Z**, **R**, and **G** change in how they may be constructed, but the MME always have the same form. Computations also differ and may simplify in certain cases.

Estimation of Variances

Two methods of estimation of **G** and **R** are commonly used in animal breeding. First is Restricted (or Residual) Maximum Likelihood (REML) [11–13], of which there are four computational versions, and second is Bayesian Estimation using Gibbs Sampling as a tool to maximize the joint posterior distribution [14]. Both methods require major computing time, and consequently, smaller subsamples of the complete data file are chosen for estimating covariance matrices.

The main advantage of these two methods is that the estimated covariance matrices are positive definite matrices that can be used directly in MME. A covariance matrix must be positive definite like a variance must always be positive.

Another advantage of the methods is that the REML and Bayesian estimators are more accurate than other methods. The disadvantage is the increased computing demands necessitating the need to subsample the data into smaller sets.

Reliabilities

All estimates of breeding values of animals require information about the accuracy or reliability of that estimate. Theoretically, standard errors of prediction are derived from the inverse of the coefficient matrix of the MME. Given that solutions result from iteration techniques rather than inversion, the standard errors of prediction must be approximated. Standard errors of prediction are often converted into a percent reliability that goes from 0 to 100. There are many approximation methods in use.

Reliabilities depend on the number of progeny, the number of contemporaries of those progeny, the completeness of pedigree information, and the variance and covariance parameters. Depending on the reliability of an animal's Estimated Breeding Value, (EBV), the EBV may or may not be made officially public. Minimum standards are agreed upon by industry committees.

Genetic Trends

Genetic trends are estimated by averaging animal EBVs by year of birth, or by years in which they make records. In dairy cattle, for example, the EBVs of all cows that were born in a given year and which completed at least one lactation can be averaged. By plotting these averages by year of birth, the genetic trend in milk production can be quantified. Plotting the average EBVs of dairy bulls by their year of birth would give a different trend, reflecting how bulls were chosen to be in artificial insemination. The cow averages would reflect how those bulls were used in breeding programs, and would likely lag a couple of years behind the sire birth years. Graphs of genetic trends should have details of what the averages represent.

Single Record per Animal

The models presented in this and the following sections become progressively more complicated, due to the type of traits that are considered. First, a simple animal model is illustrated which covers traits that are observed only once in an animal's lifetime, such as age at first breeding. Next, the situation where animals can be observed more than once per lifetime, such as annual antler production in elk, wool production in sheep, or race results in horses. Then traits influenced by maternal effects, such as birth weights, weaning weights, and calving ease, are considered. Longitudinal data, traits observed over time, such as milk production or egg production, provide models that analyze the shapes of curves. Multiple trait models are applied to two or more traits at a time, and include genetic and environmental correlations among the traits. Threshold models for categorical data are described, and finally, a model for the analysis of survival data is presented.

Data

The case of a single record per animal is presented in some detail because this is the simplest model and illustrates the process of constructing mixed model equations, and what happens to the solutions to those equations. The models are presented in a generic fashion without reference to particular species.

Table 1 contains the pedigree information and data on 16 animals. The first four animals are base population animals without records and without known parents. The inbreeding coefficients are shown and

Animal Breeding, Modeling in. Table 1 Example data for simple animal model

Animal	Sire	Dam	F_i	b_{ii}	Year	CG	Record

11	5	8	0.12500	0.50000	1	2	109
12	7	6	0.12500	0.50000	1	2	94
13	1	6	0.00000	0.50000	1	2	103
14	3	8	0.00000	0.50000	2	3	78
15	5	4	0.00000	0.50000	2	3	69
16	7	8	0.00000	0.50000	2	3	44
17	9	6	0.25000	0.50000	2	3	12
18	11	10	0.18750	0.46875	2	4	54
19	11	12	0.06250	0.43750	2	4	89
20	9	8	0.12500	0.50000	2	4	82

the values of b_{ii} which come from the inbreeding coefficients. Records were made over 2 years, and there were two contemporary groups within each year. Assume that the residual variance is 600, the genetic variance is 300, and the variance of contemporary group effects is 100. Heritability (denoted as h^2) is defined as the genetic variance divided by the total phenotypic variance, which is the sum of the genetic, contemporary group, and residual variances. In this case, $h^2 = 0.3$.

Mixed Model Equations

The equation of the model is (in scalar form)

$$y_{ijk} = (YR)_i + (CG)_j + a_k + e_{ijk},$$

where

y_{ijk} are the observations on animal k, belonging to contemporary group, $(CG)_j$, born in year, $(YR)_i$,

$$\mathbf{y} = \{y_{ijk}\}.$$

$(YR)_i$ are the fixed, year effects,

$$\mathbf{b} = \{(YR)_i\}.$$

$(CG)_j$ are the random, contemporary group effects,

$$\mathbf{c} = \{(CG)_j\}.$$

a_k are the random, additive genetic effects of individual animals,

$$\mathbf{a} = \{a_k\}$$

e_{ijk} are random, residual effects.

Also,

$$\mathbf{u} = \begin{pmatrix} \mathbf{c} \\ \mathbf{a} \end{pmatrix},$$

and

$$\mathrm{Var}\begin{pmatrix} \mathbf{c} \\ \mathbf{a} \end{pmatrix} = \begin{pmatrix} \mathbf{I}_4\sigma_c^2 & 0 \\ 0 & \mathbf{A}\sigma_a^2 \end{pmatrix} = \mathbf{G}.$$

Finally,

$$\mathbf{R} = \mathbf{I}_{16}\sigma_e^2,$$

and $\mathbf{Z}$ can be partitioned into one matrix for contemporary groups, and one for animal additive genetic values, i.e.,

$$\mathbf{Z} = \begin{pmatrix} \mathbf{Z}_{cg} & \mathbf{Z}_a \end{pmatrix}.$$

Inverse of Relationship Matrix

Notice that the MME contain $\mathbf{G}^{-1}$, which equals

$$\mathbf{G}^{-1} = \begin{pmatrix} \mathbf{I}\frac{1}{\sigma_{cg}^2} & 0 \\ 0 & \mathbf{A}^{-1}\frac{1}{\sigma_a^2} \end{pmatrix}.$$

Thus, the inverse of the relationship matrix is needed. This matrix can be constructed readily following simple rules that Henderson [7] provided. For each animal with both parents known, 9 numbers are added into the inverse matrix. For an animal with only one parent known, 4 numbers are added, and for an animal with both parents unknown, 1 number is added. Start with a matrix of order 20 that is completely null. Then process the pedigree file, one animal at a time until all animals are included.

Step 1: For animal i, let $\delta = b_{ii}^{-1}$. For animal 1, $\delta = 1$; for animal 6, $\delta = 2$, and for animal 19, $\delta = 2.2857$.

Step 2: Add δ to the diagonal element for that animal. For animal 19, add *delta* to element (19,19) of $\mathbf{A}^{-1}$.

Step 3: If the male parent is known, subtract -0.5δ from elements (i, s) and (s, i), where i is the animal's number and s is the sire's number. For example, for animal 19, $i = 19$ and $s = 11$. Also add 0.25δ to element (s, s).

Step 4: If the female parent (denoted by d) is known, subtract -0.5δ from elements (i, d) and (d, i), and add 0.25δ to element (d, d).

Step 5: If both parents are known add 0.25δ to elements (s, d) and (d, s).

Numbers are accumulative as the pedigrees are processed. Many of the elements will stay null values, especially for animals that do not have progeny.

Solutions to Equations

The resulting mixed model equations have 26 rows and columns with 26 unknowns to be estimated (2 year effects, 4 contemporary groups, and 20 animal effects).

Even for this small example, to display the equations fully would take up too much space. The solutions to the MME were as follows:

Year 1	=	88.8
Year 2	=	61.6
CG 1	=	.015
CG 2	=	−.015
CG 3	=	−3.303
CG 4	=	3.303

Animal		EBV	Reliability
1	=	8.32	.13
2	=	1.06	.11
3	=	−5.68	.14
4	=	−3.69	.10
5	=	4.38	.23
6	=	−15.50	.25
7	=	−.95	.25
8	=	7.37	.23
9	=	−4.28	.20
10	=	−6.58	.18
11	=	9.49	.24
12	=	−3.79	.24
13	=	−.02	.17
14	=	4.61	.17
15	=	2.41	.18
16	=	−.30	.16
17	=	−17.17	.25
18	=	−.90	.21
19	=	6.66	.16
20	=	4.65	.18

The solutions for the animal additive genetic effects are known as *Estimated Breeding Values* or EBVs. Progeny are expected to inherit an average of the EBVs of its parents, on average. EBVs are sorted from highest to lowest, or best animal to poorest animal. Every animal in the pedigree file obtains a solution due to genetic relationships to progeny and other individuals. The EBV of an animal consists of combined information from the animal's parents, its progeny, and its own performance record. The BLUP methodology combines the information in an optimal manner to maximize the correlation of the EBV with the animal's true genetic merit. The reliability is obtained from the inverse of the MME coefficient matrix, and expressed as a correlation coefficient. The greater is the reliability, the more certainty in the ranking of the animals. The highest reliability was 0.25, for animals 6, 7, and 17. Note that animal 6 had 4 progeny, plus a record on itself, and both parents were known. Animal 7 had 3 progeny. Animal 17 had no progeny, but was an offspring of animal 6 and was inbred the most. Reliability also reflects the number of contemporaries that each animal has, but the differences in this example were not great. The reliabilities of all animals in this example are very small, but there were only 16 observations in total. Dairy bulls, for example, can have hundreds or thousands of progeny giving them reliabilities above 0.99. A minimum reliability level is chosen before EBVs are released to the public.

The solutions for the year effects were 88.8 and 61.6, respectively. Thus, performances were lower in year 2 compared to year 1. There is likely a reason for this difference, such as year 2 being hotter, or a shortage of good feed, or feed prices may have caused many animals to be removed from farms. The difference between years is not genetic.

Contemporary group effects were random in the model, and the solutions have an average of zero as a consequence of how they were included in the model. The CG solutions average zero within the year effects, due to the fact they were a factor nested within year effects.

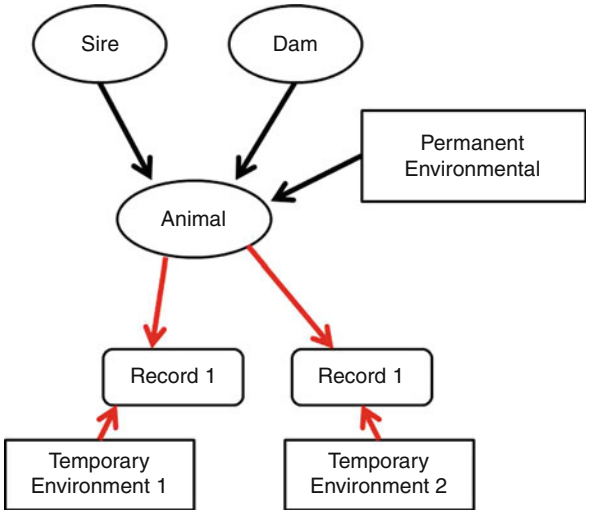
Genetic trends can be computed from the EBVs. Because animals have only one record each, the genetic averages for years 1 and 2 are the average EBVs of animals 5–13 for year 1, and animals 14–20 for year 2. These give −1.10 for year 1 and −0.01 for year 2. Thus, the animals in year 2 were slightly better than in year 1, genetically.

Repeated Records Animal Model

Animals are often observed more than once for some traits, such as

- Fleece weight of sheep in different years
- Calf records of a beef cow over time
- Test day records within a lactation for a dairy cow
- Litter size of sows over time
- Antler size of deer in different seasons
- Racing results of horses from several races

Animals are influenced by their environments, such as an athlete changes due to training and practice. These effects are called permanent environmental effects, and they accompany the animal every time the animal is observed for that trait as in Fig. 2. Permanent environmental effects are not genetic, in the sense that the animal does not transmit these effects to any of its



Animal Breeding, Modeling in. Figure 2
Diagram for an animal with repeated records including a permanent environmental effect

offspring. The following figure illustrates a model to describe permanent environmental effects. Only with repeated records can the permanent environmental and genetic effects be separated and estimated.

Data

In the example data of Table 2, animals have either one, two, or three records made in different years. The contemporaries for each year differ, but are confounded with the year effect in this example. If the animals could be assigned to different herds or management groups, then contemporary groups and years would not be confounded.

Normally performance of animals either improves or declines with the age of the animal, so that ages of animals should be known. The age of the animal in year 1 is given in the table, and so ages range from 1 to 4 years.

Mixed Model Equations

The equation of the model is (in scalar form)

$$y_{ijkl} = (YR)_i + (\text{Age})_j + a_k + p_k + e_{ijkl},$$

where

y_{ijkl} is observation l on animal k, belonging to age group j, born in year i.

Animal Breeding, Modeling in. Table 2 Example data for repeated records animal model

Animal	Sire	Dam	Age	Year 1	Year 2	Year 3
			Yr 1			
1			3	22	35	
2			3	31	46	
3			3	44	24	
4			3	53		
5			2	61	57	42
6			2	32		39
7	1	2	2	39	51	62
8	3	4	1	48	72	
9	5	6	1	71		96
10	1	4	1	37	56	47
11	3	6	1	66		86
12	1	2	1		46	38

$(YR)_i$ are fixed, year effects.
$(\text{Age})_j$ are fixed, age group effects.
a_k are random, additive genetic effects of individual animals.
p_k are random, permanent environmental effects of individual animals.
e_{ijk} are random, residual effects.

The covariance matrices of the random variables (animals, permanent environmental, and residual effects, respectively) are

$$\text{Var}\begin{pmatrix}\mathbf{a}\\ \mathbf{p}\\ \mathbf{e}\end{pmatrix} = \begin{pmatrix}\mathbf{A}\sigma_a^2 & 0 & 0\\ 0 & \mathbf{I}\sigma_p^2 & 0\\ 0 & 0 & \mathbf{I}\sigma_e^2\end{pmatrix}.$$

The total variance is

$$\sigma_y^2 = \sigma_a^2 + \sigma_p^2 + \sigma_e^2,$$

and the heritability is

$$h^2 = \frac{\sigma_a^2}{\sigma_y^2}.$$

Repeatability is a measure of the average similarity of repeated records on animals across the population (part genetic and part environmental), and is defined as a ratio of variances as

$$r = \frac{\sigma_a^2 + \sigma_p^2}{\sigma_y^2},$$

which is always going to be greater than or equal to heritability.

Let

Xb represent the fixed factors of years and ages
Za represent the random animal additive genetic effects
Wp represent the random animal permanent environmental effects

then the mixed model equations may be written as

$$\begin{pmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} & \mathbf{X}'\mathbf{W} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \mathbf{A}^{-1}k_a & \mathbf{Z}'\mathbf{W} \\ \mathbf{W}'\mathbf{X} & \mathbf{W}'\mathbf{Z} & \mathbf{W}'\mathbf{W} + \mathbf{I}k_p \end{pmatrix} \begin{pmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{p}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \\ \mathbf{W}'\mathbf{y} \end{pmatrix},$$

and let

$$k_a = \sigma_e^2 / \sigma_a^2 = 1.33333, \quad \text{and} \quad k_p = \sigma_e^2 / \sigma_p^2 = 3.$$

There are 26 observations in the example of Table 2, with 3 years and 4 age groups represented, plus 12 animal additive genetic effects and 12 permanent environmental effects giving a total of 31 equations. The **A** matrix is simple to construct because none of the animals are inbred. The resulting solutions are given in Table 3.

There are two possible uses of these solutions. First is to rank the animals for their genetic ability in order to plan future matings using the Estimated Breeding Values. Secondly, there is the decision about which animals to keep to make another record. The criterion for making this decision is the Most Probable Producing Ability, [1] which is the sum of the genetic and permanent environmental solutions (shown in the last column of Table 3). Thus, Animal 9 would likely make the best future performance of those 12 animals and would also likely generate the best future progeny.

Animal Breeding, Modeling in. Table 3 A set of solutions to the example data on repeated records model

Years		Ages		Animal			MPPA
				Genetic		Perm. Env.	
1	0.00	1	50.92	1	−8.37	−0.27	8.64
2	18.34	2	46.01	2	−1.50	0.98	−0.52
3	29.08	3	37.24	3	1.06	−1.84	−0.78
		4	19.50	4	3.14	3.16	6.30
				5	4.96	−0.84	4.12
				6	0.71	−5.00	−4.29
				7	−2.94	1.77	−1.17
				8	2.18	0.07	2.25
				9	9.68	6.08	15.76
				10	−6.66	−3.60	−10.26
				11	6.00	4.55	10.55
				12	−10.64	−5.07	−15.71

Comments

One could ask if permanent environmental effects are permanent. The answer is yes, but as an animal ages, it encounters new permanent environmental effects which accumulate with the previous effects. Hence, permanent environmental effects are cumulative over the life of an animal. This means permanent environmental effects are not constant throughout an animal's life. With the model as described in this section, the assumption is that permanent environmental effects are constant. Some of the cumulative parts, therefore, flow into the temporary environmental effects, and some are averaged with the previous permanent environmental effects.

Another assumption is that the genetic component of each record on an animal is the same. Genes are known to change in activity as an animal ages due to age, but also due to epigenetics (environmental effects that cause change to an animal's DNA). Thus, repeated records on one animal could have different genetic components. That means the genetic correlation between records is less than unity. A better model would be to assume that all records are genetically different (but correlated) traits. This would take into account both the different genetic effects associated with each record, and also the accumulation of permanent environmental effects with time.

Maternal Effects Animal Model

In mammalian species of livestock, such as beef cattle, sheep, or swine, the female provides an environment for its offspring to survive and grow in terms of protection and nourishment. Figure 3 illustrates how maternal effects can affect offspring records. Females vary in their ability to provide a suitable environment for their offspring, and this variability has a genetic basis. Offspring directly inherit an ability to grow (or survive) from both parents, and environmentally do better or poorer depending on their dam's genetic maternal ability. Maternal ability is a genetic trait expressed by the dam in the offsprings' performance, and is transmitted, like all genetic traits, from both parents. Maternal ability is only expressed by females when they have offspring (i.e., much like milk yield in dairy cows) [15, 16].

Data

The example data of Table 4 are weights on animals at an early age.

A model to account for maternal ability is

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_1\mathbf{a} + \mathbf{Z}_2\mathbf{m} + \mathbf{Z}_3\mathbf{p} + \mathbf{e},$$

where $\mathbf{y}$ is the growth trait of a young animal, $\mathbf{b}$ is a vector of fixed factors influencing growth, in this case contemporary group effects, $\mathbf{a}$ is a vector of random animal additive genetic effects (i.e., direct genetic effects), $\mathbf{m}$ is a vector of random maternal genetic (dam) effects, and $\mathbf{p}$, in this model, is a vector of maternal permanent environmental effects (because dams may have more than one offspring in the data – repeated records).

The expectations of the random vectors, $\mathbf{a}$, $\mathbf{m}$, $\mathbf{p}$, and $\mathbf{e}$ are all null vectors in a model without selection, and the variance-covariance structure is

$$\mathrm{Var}\begin{pmatrix}\mathbf{a}\\ \mathbf{m}\\ \mathbf{p}\\ \mathbf{e}\end{pmatrix} = \begin{pmatrix}\mathbf{A}\sigma_a^2 & \mathbf{A}\sigma_{am} & 0 & 0\\ \mathbf{A}\sigma_{am} & \mathbf{A}\sigma_m^2 & 0 & 0\\ 0 & 0 & \mathbf{I}\sigma_p^2 & 0\\ 0 & 0 & 0 & \mathbf{I}\sigma_e^2\end{pmatrix},$$

where σ_a^2 is the additive genetic variance, σ_m^2 is the maternal genetic variance, σ_{am} is the covariance between additive and maternal genetic effects, and σ_p^2 is the maternal permanent environmental variance. Also,

$$\begin{pmatrix}\mathbf{a}\\ \mathbf{m}\end{pmatrix}\Big|\ \mathbf{A},\ \mathbf{G}\Big) \sim N\left(\begin{pmatrix}0\\ 0\end{pmatrix},\quad \mathbf{G}\otimes\mathbf{A}\right),$$

where

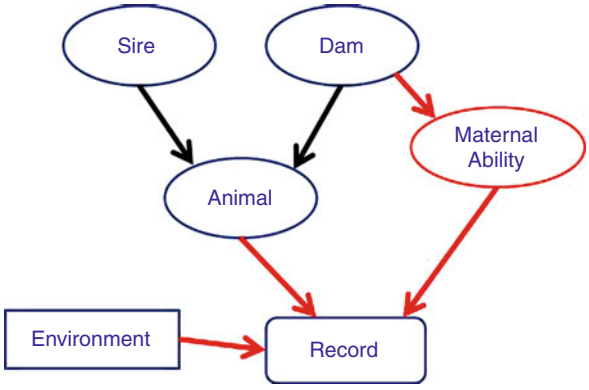
$$\mathbf{G} = \begin{pmatrix}\sigma_a^2 & \sigma_{am}\\ \sigma_{am} & \sigma_m^2\end{pmatrix},$$

and

$$\mathbf{p}|\mathbf{I}, \sigma_p^2 \sim N(0, \mathbf{I}\sigma_p^2),$$

and

$$\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2).$$



Animal Breeding, Modeling in. Figure 3 Diagram illustrating maternal genetic effects

Animal Breeding, Modeling in. Table 4 Example data for maternal genetic effects model

Animal	Sire	Dam	CG	Weight
5	1	3	1	156
6	2	3	1	124
7	1	4	1	135
8	2	4	2	163
9	1	3	2	149
10	2	4	2	138

In this model, a female animal, i, could have its own growth record for estimating $\hat{a}_i$. The same female could later have offspring for estimating $\hat{m}_i$ and $\hat{p}_i$, and the offspring would also contribute toward $\hat{a}_i$. The maternal effects model can be more complicated if, for example, embryo transfer is practiced. Recipient dams would have maternal effects, but would not have direct genetic effects on that calf [17].

Mixed Model Equations

The MME are represented as

$$\begin{pmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z}_1 & \mathbf{X}'\mathbf{Z}_2 & \mathbf{X}'\mathbf{Z}_3 \\ \mathbf{Z}'_1\mathbf{X} & \mathbf{Z}'_1\mathbf{Z}_1 + \mathbf{A}^{-1}k_{11} & \mathbf{Z}'_1\mathbf{Z}_2 + \mathbf{A}^{-1}k_{12} & \mathbf{Z}'_1\mathbf{Z}_3 \\ \mathbf{Z}'_2\mathbf{X} & \mathbf{Z}'_2\mathbf{Z}_1 + \mathbf{A}^{-1}k_{12} & \mathbf{Z}'_2\mathbf{Z}_2 + \mathbf{A}^{-1}k_{22} & \mathbf{Z}'_2\mathbf{Z}_3 \\ \mathbf{Z}'_3\mathbf{X} & \mathbf{Z}'_3\mathbf{Z}_1 & \mathbf{Z}'_3\mathbf{Z}_2 & \mathbf{Z}'_3\mathbf{Z}_3 + \mathbf{I}k_{33} \end{pmatrix} \begin{pmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{m}} \\ \hat{\mathbf{p}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'_1\mathbf{y} \\ \mathbf{Z}'_2\mathbf{y} \\ \mathbf{Z}'_3\mathbf{y} \end{pmatrix},$$

where

$$\begin{aligned} \begin{pmatrix} k_{11} & k_{12} \\ k_{12} & k_{22} \end{pmatrix} &= \begin{pmatrix} \sigma_a^2 & \sigma_{am} \\ \sigma_{am} & \sigma_m^2 \end{pmatrix}^{-1} \sigma_e^2, \\ &= \begin{pmatrix} 49 & -7 \\ -7 & 26 \end{pmatrix}^{-1} (81), \\ &= \begin{pmatrix} 1.7192 & 0.4628 \\ 0.4628 & 3.2400 \end{pmatrix}. \end{aligned}$$

The solutions to the MME are

$$\hat{\mathbf{b}} = \begin{pmatrix} 137.8469 \\ 150.4864 \end{pmatrix}, \quad \hat{\mathbf{p}} = \begin{pmatrix} 0.0658 \\ -0.0658 \end{pmatrix},$$

$$\hat{\mathbf{a}} = \begin{pmatrix} 2.3295 \\ -2.3295 \\ 0.1280 \\ -0.1280 \\ 5.1055 \\ -4.1143 \\ 0.2375 \\ 2.0161 \\ 0.5447 \\ -3.7896 \end{pmatrix}, \quad \text{and} \quad \hat{\mathbf{m}} = \begin{pmatrix} -0.3328 \\ 0.3328 \\ 0.1646 \\ -0.1646 \\ -0.6379 \\ 0.6792 \\ -0.1254 \\ -0.3795 \\ 0.0136 \\ 0.4499 \end{pmatrix}.$$

Comments

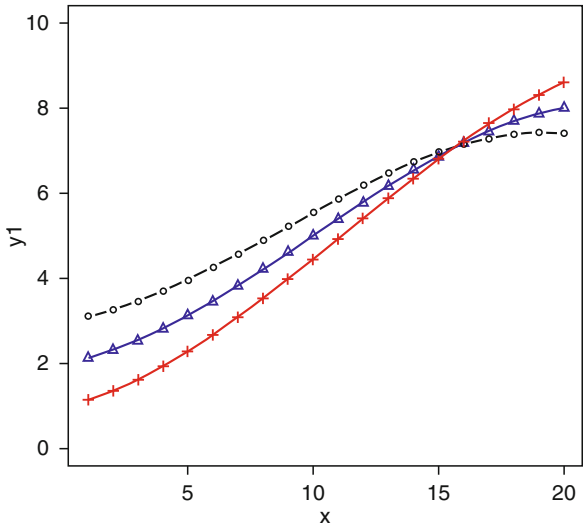
Maternal genetic models require a good data structure to be successful [18]. That means that there should be many females with weight records in the data who also have several progeny with weight records in the data. In this way direct genetic and maternal genetic effects can be efficiently separated during estimation. In the example data, the structure is not good because the females that were dams did not have any weight records on themselves. Hence the strong negative relationship between direct and maternal genetic estimates, which means the maternal genetic estimates are based mostly on the direct genetic estimates and the prior genetic correlation that was assumed, which was negative.

Sire structure is also important in that sires should have many daughters that have also had their own progeny. The maternal genetic ability of a sire's daughters cannot be accurately estimated without those daughters displaying their maternal ability on their own progeny. In many studies or application of maternal genetic effects models, the data structure is too poor from which to estimate variances and covariances of direct and maternal genetic effects.

Random Regression Animal Model

All biological creatures grow and perform over their lifetime. Traits that are measured at various times during that life are known as *longitudinal* data. Examples are body weights [19], body lengths, milk production [20], feed intake, fat deposition, and egg production [21]. On a biological basis, there could be different genes that turn on or turn off as an animal ages causing changes in physiology and performance. The time variable (or age) can be recorded in years, months, weeks, days, hours, minutes, or seconds, so that, in effect, there could be a continuum or continuous range of points in time when an animal could be observed for a trait. These traits have also been called *infinitely dimensional* traits.

If observations were plotted on a graph where the x-axis is time and the y-axis is the magnitude of the observations, then a *trajectory* is obtained for a group of animals. However, not every individual will follow



Animal Breeding, Modeling in. Figure 4
Trajectories of different animals for a trait measured over time

the average trajectory, see Fig. 4. There are variations in the shape of their trajectory, and the breeder may wish to change the shape for animals in his(her) production system in order to be more profitable.

The average trajectory, in black, is given by the equation

$$f(t_i) = A + Bt_i + Ct_i^2 + Dt_i^3,$$

where $A = 2$, $B = 0.1$, $C = 0.03$, and $D = -0.001$. The red and blue trajectories are extremes for animals in the population. The assumption is that $f(t_i)$ is the average trajectory and every animal will have its own trajectory, that means every animal will have different A, B, C, and D values. Because these parameters are regression coefficients, the model becomes the *random regression* model, and every animal will have four regression coefficients to be estimated, as deviations from the average trajectory regression coefficients.

Regression Functions

A problem in using time covariates to various powers is that the numbers can become very large, very quickly. For example, if the time variable, t, goes from 1 to 20, then t^3 would range from 1 to 8,000. In least squares like equations, the diagonal element for that variable would be $(8,000)^2$. Then there could be many thousands of observations. The large numbers can lead to serious rounding errors and may cause problems in solving the equations.

Another problem is that there will be high correlations among the time variables in the function, because they are all based on the same t value. This may also lead to near singularity and to problems in solving the equations. A solution for the above problems is to use Legendre polynomials which convert the time variable, t, into covariates that are firstly scaled to be between -1 and $+1$, and then converted to be independent of each other.

Scaling Time Variables Time variables have to be standardized to the interval between -1 and $+1$. The formula to standardize t_ℓ is

$$x_\ell = -1 + 2\left(\frac{t_\ell - t_{\min}}{t_{\max} - t_{\min}}\right).$$

Legendre Polynomials The first two Legendre polynomials are defined as

$$P_0(x) = 1, \quad \text{and}$$
$$P_1(x) = x,$$

then, in general, the $n+1$ polynomial is described by the following recursive equation:

$$P_{n+1}(x) = \frac{1}{n+1}((2n+1)xP_n(x) - nP_{n-1}(x)).$$

These quantities are "normalized" using

$$\phi_n(x) = \left(\frac{2n+1}{2}\right)^{0.5} P_n(x).$$

This gives the following series:

$$\phi_0(x) = \left(\frac{1}{2}\right)^{0.5} P_0(x) = 0.7071$$
$$\phi_1(x) = \left(\frac{3}{2}\right)^{0.5} P_1(x)$$
$$= 1.2247x$$
$$P_2(x) = \frac{1}{2}(3xP_1(x) - 1P_0(x))$$
$$\phi_2(x) = \left(\frac{5}{2}\right)^{0.5} (\frac{3}{2}x^2 - \frac{1}{2})$$
$$= -0.7906 + 2.3717x^2,$$

and so on. The first six can be put into a matrix, Λ, as

$$\Lambda' = \begin{pmatrix} 0.7071 & 0 & 0 \\ 0 & 1.2247 & 0 \\ -0.7906 & 0 & 2.3717 \\ 0 & -2.8062 & 0 \\ 0.7955 & 0 & -7.9550 \\ 0 & 4.3973 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 4.6771 & 0 & 0 \\ 0 & 9.2808 & 0 \\ -20.5206 & 0 & 18.4685 \end{pmatrix}.$$

Now define a vector, **m**, containing the polynomials of standardized time values,

$$\mathbf{m}' = \begin{pmatrix} 1 & x & x^2 & x^3 & x^4 & x^5 \end{pmatrix}.$$

The covariates to use in the model are equal to

$$\Lambda'\mathbf{m}.$$

To illustrate, suppose time goes from 10 to 60 days over which animals are observed for their growth, $t_{\min} = 10$ and $t_{\max} = 60$. An animal is observed on day 43. The standardized time variable is

$$x = -1 + 2\frac{(43 - 10)}{(60 - 10)} = -0.32,$$

and

$$\mathbf{m}' = \begin{pmatrix} 1 & -0.32 & 0.1024 & -0.0328 & 0.01048 \\ & -0.00336 \end{pmatrix}.$$

Finally,

$$\Lambda'\mathbf{m} = \begin{pmatrix} 0.7071 \\ -0.3919 \\ -0.5477 \\ 0.7446 \\ 0.0782 \\ -0.7961 \end{pmatrix}.$$

The order of Legendre polynomials is equal to the highest power of x. Research is needed to determine the best order of fit for any given situation.

Random Regression Model

Like other animal models, the random regression model (RRM) accounts for years, contemporary groups, and animal additive genetic effects, but in addition, it needs to account for the following:

- Curves for different groups of animals, such as age groups, month of calving groups, and breeds which could have different shapes of curves. These factors would be fixed effects in the model. The curves may be fit using Legendre polynomials, or other functions of time, or as classification variables with many levels.
- Curves for each individual animal, using Legendre polynomials, which are random factors in the model. Each animal has a number of regression coefficients to be estimated. For each animal, there are additive genetic parameters as well as permanent environmental parameters.
- The possibility of residual variances changing over the observable time period. For example, as animals grow, their mean weight increases and so does the variance of weights at a given age.

A simplified RRM for a single trait can be written as

$$y_{ijkn:t} = F_i + g(t)_j + r(a, x, m1)_k + r(pe, x, m2)_k + e_{ijkn:t},$$

where

$y_{ijkn:t}$ is the nth observation on the kth animal at time t belonging to the ith fixed factor and the jth group.

F_i is a fixed effect that is independent of the time scale for the observations, such as a cage effect, a location effect, or a herd-test date effect.

$g(t)_j$ is a function or functions that account for the phenotypic trajectory of the average observations across all animals belonging to the jth group.

$r(a, x, m1)_k = \sum_{\ell=0}^{m_1} a_{k\ell} x_{ijk:\ell}$ is the notation adopted for a random regression function. In this case, a denotes the additive genetic effects of the kth animal, x is the vector of time covariates, and $m1$ is the order of the regression function. So that $x_{ijk:\ell}$ are the covariables related to time t, and $a_{k\ell}$ are the animal additive genetic regression coefficients to be estimated.

$r(pe, x, m2)_k = \sum_{\ell=0}^{m_2} p_{k\ell} x_{ijk:\ell}$ is a similar random regression function for the permanent environmental (pe) effects of the kth animal.

$e_{ijkn:t}$ is a random residual effect with mean null and with possibly different variances for each t or functions of t.

The function, $g(t)_j$, can be either linear or nonlinear in t. Such a function is necessary in a RRM to account for the phenotypic relationship between y and the time covariables (or other types of covariables that could be used in a RRM). In a test day model, $g(t)_j$ accounts for different lactation curve shapes for groups of animals defined by years of birth, parity number, and age and season of calving within parities, for example. With growth data, $g(t)_j$ accounts for the growth curve of males or females of breed X or breed Y from young or old dams.

If the shape of the phenotypic relationship is not known or is nonlinear, then $g(t)_j$ could be a set of classification variables. Classification variables take up more degrees of freedom and require a large number of observations per level, but they do not force the user to explicitly define the shape of the trajectory. A mathematical function, on the other hand, does not use many degrees of freedom and gives a smooth trajectory over time regardless of the number of observations. The choice of classification variables or mathematical function is up to the researcher. If data are very numerous, and the mathematical function fits the data well, then either approach will generally lead to the same results. The phenotypic relationships, $g(t)_j$, are important to a RRM analysis and deserve care and effort in their correct specification.

Mixed Model Equations In matrix notation, the RRM is

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_1\mathbf{a} + \mathbf{Z}_2\mathbf{p} + \mathbf{e},$$

where $\mathbf{b}$ contains F_i and $g(t)_j$ effects, $\mathbf{a}$ contains $m_1 + 1$ additive genetic regression coefficients for each animal, $\mathbf{p}$ contains $m_2 + 1$ permanent environmental regression coefficients for each animal with data, and $\mathbf{e}$ contains the temporary environmental effects. Also,

$$\mathrm{Var}\begin{pmatrix}\mathbf{a}\\ \mathbf{p}\\ \mathbf{e}\end{pmatrix} = \begin{pmatrix}\mathbf{A}\otimes\mathbf{G} & 0 & 0\\ 0 & \mathbf{I}\otimes\mathbf{P} & 0\\ 0 & 0 & \mathbf{R}\end{pmatrix},$$

where $\mathbf{G}$ is the variance-covariance matrix of the additive genetic random regression coefficients of order $m_1 + 1$; $\otimes$ if the direct product operator which multiplies every element of $\mathbf{A}$ by the matrix $\mathbf{G}$; $\mathbf{P}$ is the variance-covariance matrix of the permanent environmental random regression coefficients of order $m_2 + 1$; and $\mathbf{R}$ is a diagonal matrix of temporary environmental variances which could vary depending on t, or $\mathbf{R}$ could be block diagonal with an autocorrelation structure for

Animal Breeding, Modeling in. Table 5 Example data for random regression model

Cow	Sire	Dam	Visit 1		Visit 2		Visit 3		Visit 4	
			Age(m)	Obs.	Age(m)	Obs.	Age(m)	Obs.	Age(m)	Obs.
1	7	5	22	224	34	236	47	239

each animal's records. The mixed model equations (MME) are represented as

$$\begin{pmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_1 & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_2 \\ \mathbf{Z}_1'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_1'\mathbf{R}^{-1}\mathbf{Z}_1 + \mathbf{A}^{-1}\otimes\mathbf{G}^{-1} & \mathbf{Z}_1'\mathbf{R}^{-1}\mathbf{Z}_2 \\ \mathbf{Z}_2'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_2'\mathbf{R}^{-1}\mathbf{Z}_1 & \mathbf{Z}_2'\mathbf{R}^{-1}\mathbf{Z}_2 + \mathbf{I}\otimes\mathbf{P}^{-1} \end{pmatrix} \begin{pmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}} \\ \hat{\mathbf{p}} \end{pmatrix} = \begin{pmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_1'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_2'\mathbf{R}^{-1}\mathbf{y} \end{pmatrix}.$$

Example Data Analysis by RRM

A very simplified example is given below to illustrate the degree of complexity of RRM. Four animals were observed multiple times at different ages for a trait, as shown in Table 5.

The model equation might be

$$\begin{aligned} y_{jik:t} = {} & V_j + b_0 + b_1(A) + b_2(A)^2 \\ & + (a_{i0}z_0 + a_{i1}z_1 + a_{i2}z_2) \\ & + (p_{i0}z_0 + p_{i1}z_1 + p_{i2}z_2) + e_{jik:t} \end{aligned}$$

where

V_j is a random contemporary group (visit) effect which is assumed to follow a normal distribution with mean 0 and variance, $\sigma_c^2 = 4$.

b_0, b_1, and b_2 are fixed regression coefficients on $(A) =$ age and age squared which describes the general relationship between age and the observations.

a_{i0}, a_{i1}, and a_{i2} are random regression coefficients for animal i additive genetic effects, assumed to follow a multivariate normal distribution with mean vector null and variance-covariance matrix, **G**.

p_{i0}, p_{i1}, and p_{i2} are random regression coefficients for animal i permanent environmental effects, assumed to follow a multivariate normal distribution with mean vector null and variance-covariance matrix, **P**.

z_0, z_1, and z_2 are the Legendre polynomials based on standardized ages and derived as indicated earlier. The minimum age was set at 18 and the maximum age was set at 68 for calculating the Legendre polynomials.

and e_{jik} is a temporary residual error term assumed to follow a normal distribution with mean 0 and variance, $\sigma_e^2 = 9$. In this example, the residual variance is assumed to be constant across ages.

The model in matrix notation is

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Wv} + \mathbf{Za} + \mathbf{Zp} + \mathbf{e},$$

where

$$\mathbf{X} = \begin{pmatrix} 1 & 22 & 484 \\ 1 & 30 & 900 \\ 1 & 28 & 784 \\ 1 & 34 & 1156 \\ 1 & 42 & 1764 \\ 1 & 40 & 1600 \\ 1 & 20 & 400 \\ 1 & 47 & 2209 \\ 1 & 55 & 3025 \\ 1 & 33 & 1089 \\ 1 & 66 & 4356 \\ 1 & 44 & 1936 \end{pmatrix}, \quad \mathbf{y} = \begin{pmatrix} 224 \\ 244 \\ 224 \\ 236 \\ 247 \\ 242 \\ 220 \\ 239 \\ 241 \\ 234 \\ 244 \\ 228 \end{pmatrix},$$

$$\mathbf{W} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

and for animal 1,

$$\mathbf{Z} = \begin{pmatrix} 0.7071 & -1.0288 & 0.8829 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0.7071 & -0.4409 & -0.4832 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0.7071 & 0.1960 & -0.7299 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

In order to reduce rounding errors, the covariates of age for the fixed regressions can be forced to have

a mean of approximately zero by subtracting 38 from all ages and 1642 from all ages squared.

The entire MME cannot be presented, but parts of the MME are given below.

$$\mathbf{W}'\mathbf{W} = \begin{pmatrix} 3 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 2 \end{pmatrix},$$

$$\mathbf{W}'\mathbf{X} = \begin{pmatrix} 3 & -34 & -2,758 \\ 4 & -16 & -1,648 \\ 3 & 21 & 1,397 \\ 2 & 34 & 3,008 \end{pmatrix},$$

$$\mathbf{X}'\mathbf{X} = \begin{pmatrix} 12 & 5 & -1 \\ 5 & 1,995 & 166,883 \\ -1 & 166,883 & 14,415,319 \end{pmatrix},$$

$\mathbf{Z}'\mathbf{Z}$ is composed of the following four blocks of order 3, for the four animals with records;

$$\text{Animal1} \quad \begin{pmatrix} 1.5 & -0.9006 & -0.2335 \\ -0.9006 & 1.2912 & -0.8383 \\ -0.2335 & -0.8383 & 1.5457 \end{pmatrix},$$

$$\text{Animal2} \quad \begin{pmatrix} 2 & 0.7275 & 0.0259 \\ 0.7275 & 2.0233 & 1.3612 \\ 0.0259 & 1.3612 & 2.1815 \end{pmatrix},$$

$$\text{Animal3} \quad \begin{pmatrix} 1 & -0.6235 & -0.4902 \\ -0.6235 & 0.5615 & 0.0648 \\ -0.4902 & 0.0648 & 0.5761 \end{pmatrix},$$

$$\text{Animal4} \quad \begin{pmatrix} 1.5 & -1.1085 & 0.0134 \\ -1.1085 & 1.5121 & -1.2082 \\ 0.0134 & -1.2082 & 2.2687 \end{pmatrix}.$$

and $\mathbf{Z}'\mathbf{X}$ for all animal is

$$\mathbf{Z}'\mathbf{X} = \begin{pmatrix} 2.12 & -7.78 & -761.55 \\ -1.27 & 19.99 & 1516.76 \\ -.33 & -18.76 & -1201.42 \\ 2.83 & 28.99 & 2458.59 \\ 1.03 & 46.44 & 4337.80 \\ 0.04 & 27.97 & 2979.60 \\ 1.41 & -5.66 & -636.39 \\ -.88 & 7.05 & 636.63 \\ -.69 & -2.14 & -22.46 \\ 2.12 & -12.02 & -1061.36 \\ -1.57 & 23.03 & 1684.81 \\ .02 & -24.57 & -1515.25 \end{pmatrix}.$$

The right hand sides of the MME are

$$\mathbf{X}'\mathbf{y} = \begin{pmatrix} 2,823 \\ 2,070 \\ 68,064 \end{pmatrix},$$

$$\mathbf{W}'\mathbf{y} = \begin{pmatrix} 692 \\ 945 \\ 714 \\ 472 \end{pmatrix},$$

and

$$\mathbf{Z}'\mathbf{y} = \begin{pmatrix} 494.2629 \\ -287.6596 \\ -90.7117 \\ 690.1296 \\ 249.1165 \\ 7.3023 \\ 329.5086 \\ -200.1692 \\ -168.8920 \\ 482.2422 \\ -351.3606 \\ -7.8918 \end{pmatrix}.$$

The variance-covariance matrices of the additive and permanent environmental effects need to be known for BLUP. Normally, these are not well known and must be estimated simultaneously with the other effects of the model. Let

$$\mathbf{G} = \begin{pmatrix} 94.0000 & -3.8500 & 0.03098 \\ -3.8500 & 1.5000 & -0.0144 \\ 0.03098 & -0.0144 & 0.0014 \end{pmatrix},$$

and

$$\mathbf{P} = \begin{pmatrix} 63.0000 & -2.1263 & 0.0447 \\ -2.1263 & 0.5058 & -0.00486 \\ 0.0447 & -0.00486 & 0.0005 \end{pmatrix}.$$

The solutions to MME are

$$\hat{\mathbf{b}}' = \begin{pmatrix} 234.9797 & 1.4670 & -0.01399 \end{pmatrix},$$

$$\hat{\mathbf{c}}' = \begin{pmatrix} -0.8630 \\ 1.2885 \\ 0.1443 \\ -0.5698 \end{pmatrix}.$$

Let the solutions for the animal additive genetic random regression coefficients be presented in tabular form as follows.

Animal	a_0	a_1	a_2
1	−2.021529	0.175532	−0.002696
2	5.751601	−2.139115	0.025848
3	−2.474456	2.554412	−0.029269
4	−5.376687	−0.370873	0.002174
5	−1.886714	1.464975	−0.016963
6	3.333268	−1.065525	0.013047
7	1.503398	−1.081654	0.012555
8	−2.948511	0.681643	−0.008633

Similarly, the solutions for the animal permanent environmental random regression coefficients can be given in tabular form.

Animal	p_0	p_1	p_2
1	−0.296786	0.246946	−0.002521
2	3.968256	−730659	0.009430
3	−0.834765	0.925329	−0.008164
4	−4.505439	−441805	0.001257

Ranking Animals The problem is to rank the animals for selection purposes. If animals are ranked on the basis of a_0, then animal 2 would be the highest (if that was desirable). If ranked on the basis of a_1, then animal 3 would be the highest, and if ranked on the basis of a_2, then animal 2 would be the highest. To properly rank the animals, an EBV at different ages could be calculated, and then these could be combined with appropriate economic weights. EBVs were calculated for 24, 36, and 48 mo of age, and economic weights of 2, 1, and 0.5, respectively, for the three EBVs were used to compute a Total Economic Value (TEV), as

$$2 * \mathrm{EBV}(24) + 1 * \mathrm{EBV}(36) + .5 * \mathrm{EBV}(48).$$

The Legendre polynomials for ages 24, 36, and 48 mo are given in the rows of the following matrix **L**,

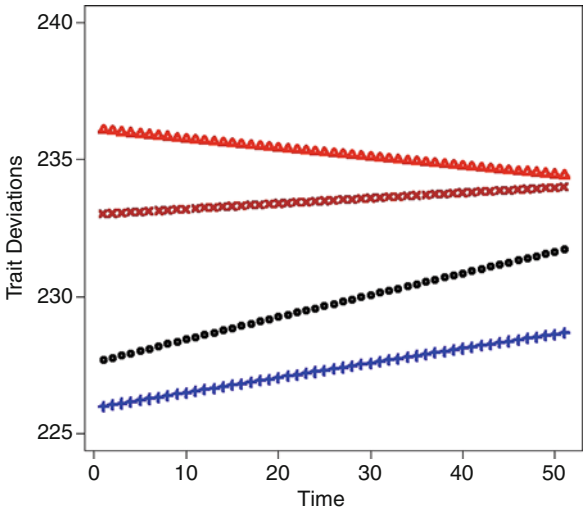
$$\mathbf{L} = \begin{pmatrix} 0.7071 & -0.8328 & 0.3061 \\ 0.7071 & -0.3429 & -0.6046 \\ 0.7071 & 0.2449 & -0.6957 \end{pmatrix}.$$

The results are shown in the following table.

Animal	EBV(24)	EBV(36)	EBV(48)	TEV
1	−1.58	−1.49	−1.38	−5.33
2	5.86	4.78	3.53	18.26
3	−3.89	−2.61	−1.10	−10.93
4	−3.49	−3.68	−3.89	−12.61
5	−2.56	−1.83	−96	−7.43
6	3.25	2.71	2.09	10.25
7	1.97	1.43	.79	5.76
8	−2.66	−2.31	−1.91	−8.58

The animal with the highest TEV was animal 2. All animals ranked rather similarly at each age on their EBVs. Rankings of animals could change with age. Thus, the pattern of growth could be changed.

Plotting Curves The shapes of curves of individual animals could also be plotted from the solutions, and shown as deviations from the average curves. Figure 5 contains animals 1 (black), 2 (red), 4 (blue), and 6 (brown).



Animal Breeding, Modeling in. Figure 5
Curves for animals 1 (*black*), 2 (*red*), 4 (*blue*), and 6 (*brown*), in the example data

Animal 2 had the highest TEV, but that ranking was achieved by Animal 2 having the highest initial deviation. However, the curve declines very rapidly after time 18. The curves of the other animals do not decline as rapidly, and the curve for Animal 1 actually increases slightly. Depending on the biology of the trait and the welfare of the animal, one may decide to select for animals with increasing curves rather than declining curves. The weights in the TEV could be adjusted accordingly.

Comments

The orders of the Legendre polynomials do not need to be equal for both the animal additive genetic and animal permanent environmental effects. The order of the fixed regressions could also be different, and as seen in this example can be based on a different function of time covariates.

There are other kinds of orthogonal functions that could be used in place of Legendre polynomials, and some of these have been tried without much benefit to the analyses (Yazdi?). Another alternative has been spline (split polynomial) functions, [19, 22] in which a curve is broken down into sections. Within each section, a simple linear or quadratic function is sufficient to fit the data within that section. The sections are joined together by "knots," the locations of which need to be estimated. Spline functions have gained some popularity lately.

Because random regression models were new to animal breeding in 1994, [20] they were applied to many different types of research problems. RRM have been most successful in the analysis of dairy cattle test day production within lactations, and in growth of pigs, sheep, rainbow trout, and beef cattle. One limitation with growth data is that animals are not usually weighed more than three or four times in their life due to the amount of labor involved in collecting weights and the stress induced on the animals during the weighing process. The orders of the regression coefficients for growth traits are usually limited to 2 or 3.

Multiple Trait Models

Animals are observed for many traits relating to production, reproduction, conformation, longevity or fitness, and health such that knowing the total economic merit of an animal helps to keep costs of production to a minimum. Most traits are genetically correlated to each other, meaning that some genes affect more than one trait. Because contemporary animals make their records in the same environment, environmental correlations due to management, feed, and temperature also exist to affect observations on all traits. Thus, a sensible approach is to analyze groups of traits using *multiple trait models* [23–26]. In this way, information from correlated traits can be used to improve the accuracy of all trait evaluations. A multiple trait (MT) model is one in which two or more traits are analyzed simultaneously in order to take advantage of genetic and environmental correlations between traits.

Low Heritability Traits: MT models are useful for traits where the differences between genetic and residual correlations are large (e.g., greater than 0.5 difference) or where one trait has a much higher heritability than the other traits. EBVs for traits with low heritability tend to gain more in accuracy than EBVs for traits with high heritability, although all traits benefit to some degree from the simultaneous analysis(24).

Culling: Another use of MT models is for traits that occur at different times in the life of the animal such that culling of animals results in fewer observations on animals for traits that occur later in life compared to those at the start. Consequently, animals which have observations later in life tend to have been selected based on their performance for earlier traits. Thus, analysis of later life traits by themselves could suffer from the effects of culling bias, and the resulting EBV could lead to errors in selecting future parents. MT analyses have been shown to partially account, to some degree, for the selection that has taken place [25, 26]. If the percentage of missing trait observations is high and the missing observations are not due to random chance, then biases could be very large in EBVs for that trait and maybe others.

The success of an MT analysis relies on the accuracy of the genetic and residual correlations that are assumed. Computations for MT models are more complicated than for single trait analyses. If m is the number of traits and N is the number of animals in the pedigree file, then there are at least mN equations to be

solved rather than just N, and the same relative difference in memory space to hold solutions. However, computer hardware advances (with gigabytes of memory) have been very rapid in the last decade. Consequently, many genetic evaluation systems are now multiple trait systems.

Models and Traits

Usually, traits are grouped together for MT analyses because they are observed at approximately the same point in time. For example, milk, fat, and protein yields of dairy animals are observed on the same day, per animal. Thus, for a group of similar traits, the linear models associated with those traits include the same major factors like years, ages, contemporary groups, and animal additive genetic effects. Another grouping of traits would be those for reproductive traits, observed primarily on females, such as conception rate, litter size, birthing ease, and offspring losses at birth. The linear models used for production traits are quite different from those used for reproductive traits, or health traits.

Even within a group, the linear models for the traits within a group could be different from each other. Consider two traits with a single observation per trait on animals. Let the model equation for trait 1 be

$$y_{1ij} = B_{1i} + a_{1j} + e_{1ij},$$

where B_{1i} is a fixed effect with p_B levels, a_{1j} is a random, animal additive genetic effect for trait 1, and e_{1ij} is a random residual environmental effect for trait 1.

The model equation for trait 2 might be

$$y_{2ij} = C_{2i} + a_{2j} + e_{2ij},$$

where C_{2i} is a fixed effect (different from B_{1i} for trait 1) with p_C levels, a_{2j} is a random, animal additive genetic effect for trait 2, and e_{2ij} is a random residual environmental effect for trait 2.

For example, y_{1ij} could be birth weight, so that B_{1i} could identify animals born in the same season. Trait 2 could be yearling weights and C_{2i} could identify contemporary groups of animals of the same sex, same herd, and same rearing unit within herd.

Because the two traits will be analyzed simultaneously, variances and covariances need to be specified for the traits together. For example, the additive genetic variance-covariance (VCV) matrix (between traits) could be written as

$$\mathbf{G} = \begin{pmatrix} g_{11} & g_{12} \\ g_{12} & g_{22} \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 2 & 15 \end{pmatrix},$$

and the residual environmental VCV matrix as

$$\mathbf{E} = \begin{pmatrix} e_{11} & e_{12} \\ e_{12} & e_{22} \end{pmatrix} = \begin{pmatrix} 10 & 5 \\ 5 & 100 \end{pmatrix}.$$

The genetic and residual correlations are, respectively,

$$\rho_g = 2/(15)^{0.5} = 0.516,$$
$$\rho_e = 5/(1000)^{0.5} = 0.158$$

with heritabilities specified as

$$h_1^2 = \frac{1}{11} = 0.0909,$$

and

$$h_2^2 = \frac{15}{115} = 0.1304.$$

For all data, using $\mathbf{A}$ as the additive numerator relationship matrix, then

$$\mathrm{Var}\begin{pmatrix} \mathbf{a}_1 \\ \mathbf{a}_2 \end{pmatrix} = \begin{pmatrix} \mathbf{A}g_{11} & \mathbf{A}g_{12} \\ \mathbf{A}g_{12} & \mathbf{A}g_{22} \end{pmatrix}.$$

Data Example

A two trait example with three factors is given in Table 6. Note that animals whose trait 1 observation was below 3.0 were not allowed to make a trait 2 observation. If the true variances and covariances are known, then this selection bias will be lessened through the multiple trait analysis, as long as the analysis includes the trait 1 records of animals with missing trait 2 observations.

There were two levels of factor B associated with trait 1, and 3 levels of factor C associated with trait 2. The models assumed are those given in the previous section including the covariance matrices that were given.

Animal Breeding, Modeling in. Table 6 Example data for multiple trait models

Animal	Sire	Dam	B-level	C-level	Trait 1	Trait 2
1	0	0	1	1	2.3	
2	0	0	1	2	2.6	
3	0	0	1	3	9.8	53
4	0	0	1	1	4.7	4
5	0	0	1	2	5.5	63
6	1	3	2	3	2.5	
7	1	4	2	2	8.4	35
8	1	5	2	3	8.2	41

10	2	4	2	1	7.8	32
11	2	5	2	2	2.8	
12	6	10	2	3	7.4	67

Mixed Model Equations

The models are written in matrix notation below.

$$\begin{pmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{pmatrix} = \begin{pmatrix} \mathbf{X}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_2 \end{pmatrix} \begin{pmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \end{pmatrix} + \begin{pmatrix} \mathbf{Z}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_2 \end{pmatrix} \begin{pmatrix} \mathbf{a}_1 \\ \mathbf{a}_2 \end{pmatrix} + \begin{pmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \end{pmatrix}$$

Let $\mathbf{R}$ be the covariance matrix of residual effects. If observations are ordered by traits within animals, then $\mathbf{R}$ is the direct sum of submatrices, one for each animal. The submatrices depend on which traits are observed for a given animal. If an animal has been observed for both (all) traits, then the diagonal block is $\mathbf{E}$ as given earlier. If an animal has been observed only for trait 1, then the block is

$$\mathbf{E}_1 = \begin{pmatrix} e_{11} & 0 \\ 0 & 0 \end{pmatrix},$$

and if the animal has been observed only for trait 2, then

$$\mathbf{E}_2 = \begin{pmatrix} 0 & 0 \\ 0 & e_{22} \end{pmatrix}.$$

With more than two traits, the number of combinations of missing traits increases. The covariance matrix of residual effects for the example data is a block diagonal matrix,

$$\mathbf{R} = diag(\mathbf{E}_1\ \mathbf{E}_1\ \mathbf{E}\ \mathbf{E}\ \mathbf{E}\ \mathbf{E}_1\ \mathbf{E}\ \mathbf{E}\ \mathbf{E}\ \mathbf{E}\ \mathbf{E}_1\ \mathbf{E}).$$

The inverse of $\mathbf{R}$ is needed for the mixed model equations, and this can be obtained by inverting the block diagonal matrices (ignoring the zero rows and columns when there are missing observations).

The resulting mixed model equations were of order 29 by 29. The solutions, for this example, were

$$B_{11} = 5.0209$$
$$B_{12} = 6.5592$$
$$C_{21} = 20.0882$$
$$C_{22} = 49.0575$$
$$C_{23} = 51.9553$$

Animal	Sire	Dam	Trait 1	Trait 2
1	0	0	−0.3573	−1.6772
2	0	0	−0.0730	1.0418
3	0	0	0.4105	1.1707
4	0	0	−0.0449	−1.4922
5	0	0	0.0646	0.9570
6	1	3	−0.1033	−1,410
7	1	4	−0.1975	−2.2983
8	1	5	−0.1410	−9,633
9	2	3	0.3079	1.6227
10	2	4	0.1426	1.1273
11	2	5	−0.1830	0.6418
12	6	10	0.1554	1.5089

Notice that every animal has an EBV for both traits, even though trait 2 was missing for some animals. The EBV for an animal with a missing trait observation is constructed based on the genetic and environmental correlations between traits, and based on their genetic relationships to other animals that were observed for both traits.

Economic Indexes

Many producers are so overwhelmed by the numerous EBV available for so many traits that they are unable to

visualize the relative contributions of different traits to their overall productivity. Thus, economic indexes were developed where trait EBVs are scaled to unit variances, and then relative economic values are applied to the scaled EBVs. Sometimes different types of indexes are derived depending on the market objectives of the producers. A beef producer, for example, may be producing animals of high carcass merit, and would use an index that puts more weight on carcass traits of marbling score, tenderness, and dressing percentage. Another producer may be producing calves and may want more weight on the reproductive ability of cows and calf survival from birth to weaning. A particular breed may wish to be known as the "Have Everything" breed and would utilize a different set of economic weights where many traits are emphasized.

Economic weights are dynamic in that they change over time, and can often change very dramatically and quickly, usually more quickly than a breeding program can be changed due to the long generation intervals of the species involved. Producers must therefore continually reassess their goals and objectives.

Economic indexes based on multiple trait EBVs tend to be more stable over time compared to the same EBVs computed on each trait separately.

Models for Categorical Data

Categorical data arise in animal breeding in situations where a trait is subjectively scored by the producer or a trained individual. For example, calves can be born with absolutely no assistance of the producer or to the other extreme where the producer must ask for veterinarian assistance to perform a caesarian section to deliver the calf and save the cow. Between those two extremes are different levels of difficulty of calving. Recording programs provide four or five categories of difficulty, and the producer must decide to which category a calving belongs. The assumption is that one producer assigns all calvings based on the same criteria, but a different producer may have slightly different criteria.

The number of calvings falling into each category depends on the subjectivity of the producers. In most breeds, the category for unassisted or easy births is usually very high (from 50% to 90% of all calvings), while the other categories are often much smaller and the category for caesarian births being the smallest. The categories are ordered from one extreme to the other.

In dairy cattle, cows are scored for 30 or more conformation traits (i.e., style points) by trained judges, and each trait has 9 or more categories. Judges are trained and updated annually, but judges can differ in their abilities to score traits, particularly when they are trained to score a cow in a few minutes.

Theory

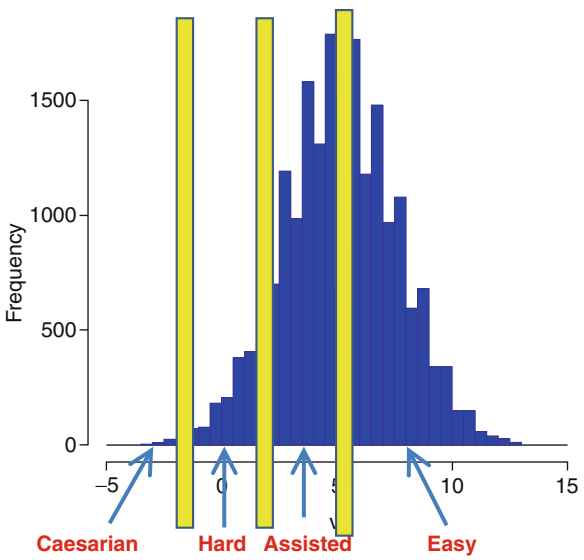
Although a trait may be scored into one of a limited number of categories, an underlying non-observable, normally distributed trait could be hypothesized [27–29]. Then thresholds along the scale are where the categories of the observed scores are defined, as shown in Fig. 6.

Thus, when an animal's underlying scale trait exceeds a threshold value, then it belongs to the next higher category. The threshold model is ideal for analyzing categorical data. The analysis follows Bayesian concepts and is nonlinear in the solutions to this model.

Write a model for the underlying scale variable.

$$\ell_{ijkm} = t_i + b_j + a_k + e_{ijkm},$$

where ℓ_{ijkm} is an unobserved value on the underlying scale for the trait of interest; t_i is one of the threshold



Animal Breeding, Modeling in. Figure 6
Normal distribution with thresholds for calving ease

points; b_j is a fixed factor such as age of the dam, breed, year, or season; a_k is an animal additive genetic effect; and e_{ijkm} is a residual error effect. The model could be much more complex than that described here, depending on the trait and situation.

Note that, instead of observations on the underlying scale, only the category to which an animal belongs is known. There are various quantities which need to be computed repeatedly in the analysis, and these are based on normal distribution functions.

1. $\Phi(x)$ is known as the cumulative distribution function of the normal distribution. This function gives the area under the normal curve up to the value of x, for x going from minus infinity to plus infinity (the range for the normal distribution). For example, if $x = 0.4568$, then $\Phi(x) = 0.6761$, or if $x = -0.4568$, then $\Phi(x) = 0.3239$. Note that if there are m categories and $k = m$, then $\Phi_k = 1$.
2. $\phi(x)$ is a function that gives the height of the normal curve at the value x, for a normal distribution with mean zero and variance 1. That is,

$$\phi(x) = (2\pi)^{-0.5} \exp -0.5x^2.$$

For example, if $x = 1.0929$, then $\phi(x) = 0.21955$.

3. $P(k)$ is the probability that x from a $N(0, 1)$ distribution is between two threshold points, or is in category k. That is,

$$P(k) = \Phi_k - \Phi_{k-1}.$$

If $k = 1$, then $\Phi_{k-1} = 0$.

Begin with phenotypic values for t_i based on a normal distribution. From the t_i, observations on the underlying scale can be "created." Each one would have a different weight in the analysis due to the frequency of a category being observed. Then new values of b_j and a_k are calculated. Finally, new values of t_i are determined, and the process is repeated. Eventually, the process converges until "solutions" for all variables do not change. This is an overly simplified explanation. For more details, see [30].

Solutions

Using the estimates from the nonlinear system of equations, the probability of a animal's offspring falling into each category can be calculated. Let $\hat{a}_k = 0.123$, and let there be a 3 category trait. The solutions for the two thresholds were $\hat{t}_1 = 0.376$ and $\hat{t}_2 = 1.012$. Then the value on the underlying scale for the first category would be

$$\begin{aligned} x &= \hat{t}_1 + \hat{a}_k, \\ &= 0.376 + 0.123, \\ &= 0.499. \end{aligned}$$

Then

$$\Phi(x) = \Phi(0.499) = 0.691.$$

Similarly, the probability of the animal's offspring to be in categories 1 or 2 would be based on the second threshold,

$$x = 1.012 + 0.123 = 1.135,$$

or $\Phi(x) = 0.872$. Thus, the proportion of offspring that would fall in category 2 would be $0.872 - 0.691 = 0.181$. The proportion that would be in category 3 would be $1.0 - 0.872 = 0.128$.

Animals could be ranked on their $\hat{a}$, or the result could be expressed as a probability of being in a particular category. For a trait like calving ease, for example, one might want to maximize the probability of having an easy birth.

Comments

While a threshold model is a theoretically best approach to the analysis of categorical data, research has found small differences in accuracy of ranking animals from procedures that treat the category numbers as any continuously distributed trait [31]. As the number of categories increases, the differences between a threshold model analysis and simple linear model analysis become smaller.

Computational problems may arise with threshold models due to small numbers of observations in one or more categories. This often causes two categories to be merged into one to bypass the problem.

Categorical traits are often standardized to a normal scale, and then analyzed with a usual linear model [32]. If the threshold values on a normal scale were 0.376 and 1.012 for a three category trait, then all observations in category 1 would receive a score of $(0.376 - 0)/2 + 0 = 0.188$. Category 2 observations would be scored $(1.012 - 0.376)/2 + 0.376 = 0.694$,

and category 3 would be scored $(3 - 1.012)/2 + 1.012 = 2.006$. Standardization is often conducted within years, or time periods in which the subjective scoring was applied consistently.

Because categorical traits are subjectively recorded, the subjectiveness can fluctuate over time. An animal that was assessed to be category 1 20 years ago, may now (if the animal were alive today at the same age) belong to category 2. The standards of the observer(s) have changed over those 20 years. The change is similar to the change in the value of the US dollar between now and 20 years ago. Today $1 does not buy as much as $1 back in 1990. The consequence of shifting standards (in animal breeding) is that genetic trends cannot be properly estimated. Comparing animals many years apart is not statistically accurate for categorical data. This is not a major problem because producers mainly want to compare animals that are alive today, and for this purpose, the assumption is that subjective standards change rather slowly and not by very much in a short time span of about 5 years.

Methods have also been developed for multiple trait models involving traits that are categorical and other traits that are continuous [33, 34]. These have primarily been cases of binomial traits, such as disease traits (yes or no situations). Binomial traits have only one threshold to be estimated, and binomial traits seem to benefit from a threshold model.

Models for Survival Data

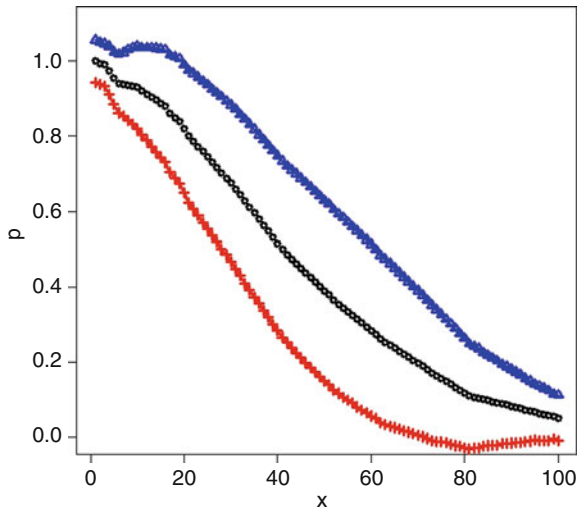
In animal production systems, animals remain in the herd or flock as long as they are productive and generate more income than expenses. Eventually, animals leave the production unit due to natural death or injury, or due to lowered production levels or reproductive problems such that the animal is deemed unprofitable. The latter factors are determined by the owner, and owners differ widely in their management skills, accounting, and decision-making abilities. There seems to be a small amount of genetic variability among animals in survival rates that do not depend on productive abilities, and genetic evaluation systems for survivability or longevity have been developed. The heritability of survival is usually less than 0.02. Dairy sires, for example, need thousands of progeny in order to have an accurate Estimated Breeding Value for survival ability of their progeny.

Survival has been defined in many different ways. In a binary sense, alive is equal to 1, every day until the animal dies and thereafter becomes 0 for the remainder of the observable time period. For example, in dairy cattle, the observable period is from first calving until 100 months later (approximately 10 years of age) when the majority of cows have died. The time intervals in that range can be hours, days, weeks, months, or years. Define a survival vector for the ith cow as $\mathbf{s}_i$, in terms of months (from 1 to 100), such that the values of $\mathbf{s}_i$ are equal to 1 for every month the cow was alive, and equal to 0 for the month in which it dies and every month thereafter to the limit of 100 months after first calving.

A cow at 44 months after first calving today is still alive, and its future death time is unknown, then the values for months 45–100 need to be considered missing or not observed. For a cow that is still alive 100 months after first calving, then $\mathbf{s}_i$ contains all ones. If a cow has gone missing from the data, in the sense that it was sold to another owner and that owner is not on a milk recording program, then the cow has not died, but the exact time of its death is not known. In this case, $\mathbf{s}_i$ will contain 1s up until the time it was sold, and all remaining values in $\mathbf{s}$ are unknown (neither 1 nor 0).

Having defined $\mathbf{s}_i$ for cow i, then let $\mathbf{S}$ be the average of all $\mathbf{s}_i$ for cows that do not have any missing values. The elements of $\mathbf{S}$ are equal to the probabilities of being alive at each month after first calving, and can be plotted as shown in Fig. 7. The value at a given time (month) is a probability, p_t. The black points refer to the average $\mathbf{S}$ for all cows, while the blue and red lines indicate 2 standard deviations above and below the average, respectively. Note that the variation is less around p_1 and p_{100} than in the middle of the range.

Because a curve is involved, a random regression model could be applied [35, 36] such that a separate set of curve parameters could be estimated for each animal. The model would include the year-season of first calving (with separate curves for each year-season), random herd within year-season of first calving, a variable that indicates whether the herd was increasing, decreasing, or being stable in size at a particular instance of time, a regression on the genetic EBV of an animal for production, random animal additive genetic regression coefficients, and random animal permanent environmental regression coefficients. The model would also need to account for different residual



Animal Breeding, Modeling in. Figure 7
Survival curve for Jersey cattle after first calving, in months

variances for each month after first calving. Meuwissen et al. [36] have shown links between various models for survival analyses. Jamrozik et al. [37] did a comparison of the effectiveness of different models for survival.

Another model is the proportional hazard model (PHM) [38],

$$\lambda(t) = \lambda_{0,s}(t)\exp[\mathbf{x}'_m\beta + \mathbf{z}'_m u],$$

where $\lambda(t)$ is the probability of a cow being culled at time t given she was alive before time t; $\lambda_{0,s}(t)$ is the Weibull baseline hazard function; β contains time-dependent covariates affecting the hazard function with $\mathbf{x}'_m$ being the corresponding design vectors; $\mathbf{u}$ is a vector of random factors including herd, year-seasons, and animal additive genetic effects; and $\mathbf{z}'_m$ is the associated incidence vector. Thus, a nonlinear system of equations needs to be solved.

Lastly, survival could be defined as a discrete trait, such as the survival of an animal to the end of first, second, or third lactation. The three "traits" can be analyzed as a multiple trait system, in which cows need not be observed for all traits. This is similar to the random regression approach except the number of months after first calving is reduced to just 3 or 4 broader periods of time instead of monthly.

Because the heritability of survival is so low, and analyses are affected by the animals that are still alive at the time of analysis, perhaps a better indicator of survivability would be a measure of profitability of the animal. The traits that are part of profitability would tend to have higher heritabilities, and would contribute toward an animal remaining in the herd. Further research on this area is needed.

Added Complexities

Heterogeneous Variances

In dairy cattle, the within contemporary group variation of records was deemed to differ between contemporary groups. That implied that the contemporary group effects were being sampled from different populations. Consequently, both the genetic and residual variation could be allowed to differ between contemporary groups. Bayesian methods were developed to simultaneously compute solutions to mixed model equations and to estimate the necessary contemporary group variances. Often, only the phenotypic variances within contemporary groups were assumed to differ such that the heritability was constant across contemporary groups.

Robust Estimation

Related to heterogeneous variances was the problem of outliers, records that were extreme values in the distribution of phenotypes. Sometimes the extremes were deliberately created by producers who thought they knew how to manipulate the data so that their good animals would receive high EBVs. Other times, the extremes were due to errors in recording, and occasionally were naturally extreme. Regardless of the reason for their existence, the result was a bias to EBVs of one animal or an entire group of animals. Robust estimation methods were introduced to pull the extreme records back toward the mean. Either the record itself or the estimated residual effect of the record could be modified toward the mean if it was beyond two and half standard deviations from the mean. Robust methods usually reduce the biases caused by extreme outliers, but the method requires nonlinear estimation.

Count Data

In swine and sheep breeding, interest is in litter size, which is not normally distributed and also not categorical, but is known as *count* data. Another trait is number of services to attain conception, or number of ovulations.

Behavioral traits can also be count data, such as the number of times an animal takes water during the day. The appropriate distribution for count data is a Poisson distribution, and Bayesian methods for handling and modeling this distribution have been developed.

Hierarchical Models

Another Bayesian development was that of hierarchical models where a trait is modeled in the usual way, but then a component of that model has its own separate model. Thus, two models are solved in steps, until the solutions satisfy both models.

Model Comparisons

Methods have also been developed to compare different models, but even further to select from among a group of models for the better fitting model. Model comparisons are usually conducted using an "estimation" data set (with which to estimate variances and solutions to mixed model equations), and a second, sometimes smaller, "validation" data set to judge how well observations and rankings of animals can be predicted.

International Comparisons

Some species of livestock are traded among countries, depending on health restrictions, and this necessitates comparing the genetic abilities of animals between countries. Usually the genetic evaluation of animals within a country has enough complexities to it such that the models used in country A are very different and incompatible with the models in country B. Thus, EBVs from the different countries are collated and a multiple trait model (where each country is a different trait) is applied to the EBVs of male animals. Genetic correlations among countries are less than unity and rankings of animals may differ between countries. The Interbull organization in Uppsala, Sweden routinely computes evaluations for dairy bulls from 23 or more countries every year.

Future Directions

Molecular genetics will dominate animal breeding research in the next 20 years. The discovery of millions of single nucleotide polymorphisms as genetic markers has forced animal breeders to restudy their basic quantitative genetics notes. The DNA genomes of animal species are being completely mapped, and someday soon all of the genes and their locations in the genome will be known. This is an exciting time for animal breeders and the opportunities for research will be huge.

Already DNA markers are being used to determine the relatedness of individuals to each other, to measure the amount of genetic diversity in a species, to identify genes with major effects on production traits, and to select future breeding animals more accurately than previously possible and as soon as an animal is born. Models for genetic evaluation of animals have been modified to include genetic marker information and are thus becoming more complicated, involving many thousands of markers such that computing issues are more demanding than for multiple trait models. The result is that animals are being selected more intensely at an early age, and the samples of progeny are no longer a random group of all possible progeny of a particular mating, but are highly selected. This lack of randomness of sampling progeny may cause biases in current genetic evaluation models. The possibility also exists that rates of inbreeding could be increased. Modeling of production systems and strategies for making continued genetic change will be utilized.

Bayesian methods will likely be utilized more heavily than the methods of Henderson [2] in order to deal with DNA modifications to statistical models. Structural equation models [39] will try to determine the cause and effects of multiple traits. Statistical models, linear and nonlinear, continue to be required background training for animal breeders. The complexity and usefulness of models will grow even with the emergence of genomics.

Animal Genetic in Environment Interaction

Erling Strandberg
Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Uppsala, Sweden

Article Outline

Glossary

Genotype by environment interaction It exists when the difference between the phenotypic values of two genotypes is not the same in two environments.

Plasticity The ability of an individual to respond to changes in the environment.

Reaction norms The phenotypic expression of a genotype as a function of the environment.

Definition of the Subject

The existence of genotype by environment interaction ($G\times E$) makes animal breeding more complicated. It means that the same genotype is not the best in all environments, and it implies that separate breeding programs might be needed to cater for these different environments. However, separate (and therefore, smaller) breeding programs might be less efficient than one large program. Small breeding programs might also encounter problems with inbreeding depression, but on the other hand, several populations with different breeding programs and breeding goals might increase the overall genetic diversity. Therefore, $G\times E$ is an important factor to consider when creating breeding programs for animals, especially in a global setting.

Introduction

The ability to respond to changes in the environment is a vital characteristic of all organisms. This ability is called *phenotypic plasticity* or sometimes, *environmental sensitivity*. Genetic variation in plasticity will lead to *genotype by environment interaction*. This paper starts by describing the phenomenon of plasticity, a term which is not well known in animal breeding. To describe it, several situations will be illustrated, with and without plasticity, by use of reaction norms. This will be followed by a description of various statistical models that can be used to study $G\times E$, including a brief description of genetic heterogeneity of residual variance. Finally, some consequences of $G\times E$ for breeding programs will be discussed.

Plasticity, Environmental Sensitivity, Reaction Norms, and Genotype by Environment Interaction

A *reaction norm* describes the phenotypic expression of a genotype as a function of the environment. One can say that the reaction norm translates the environmental values into phenotypic values. In Fig. 1, the reaction norm for a genotype is shown. The horizontal x-axis describes the environment, for simplicity let's assume a continuous scale, e.g., ambient temperature for a certain organism. The vertical y-axis gives the phenotypic value for this genotype for each environmental value. In this example, the reaction norm is linear, but it could have any form.

In Fig. 2a, genotypes that show no plasticity are depicted. Note that there is still variation in the level among genotypes, so there is genetic variation in the trait. In Fig. 2b, genotypes showing plasticity are presented. However, all genotypes react in the same way to an environmental change, i.e., there is no variation in plasticity.

In Fig. 2c, the genotypes are plastic, but some are more plastic than others. In other words, there is also variation in plasticity. Now, the genotype with the highest phenotypic value in the low environment also has the highest value in the highest environment. If high phenotypic value is desirable, which genotype to choose would be indisputable.

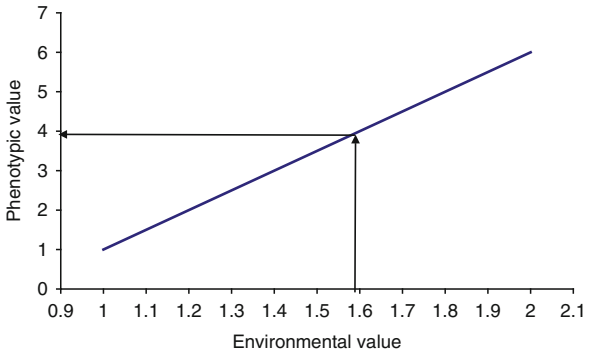
In Fig. 2d, there is also variation in plasticity; however, here the reaction norms also cross. Which genotype is the best, now depends on in which environment this genotype should be used.

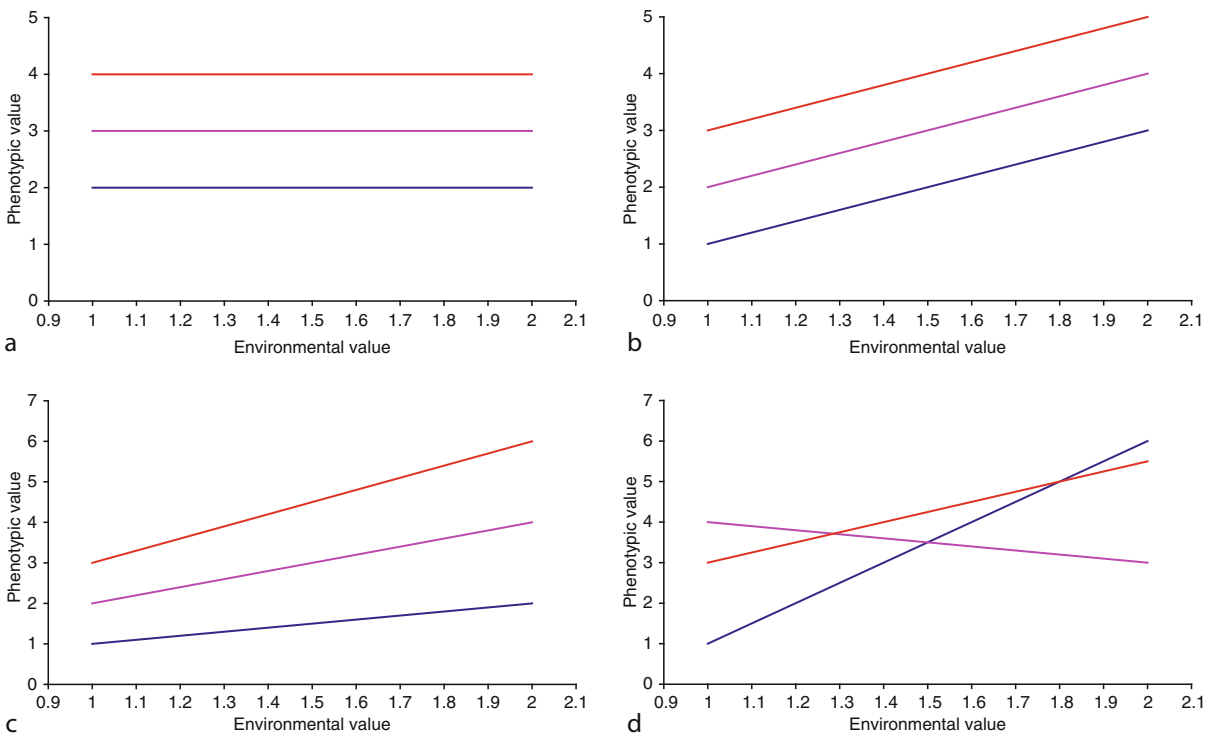


Animal Genetic in Environment Interaction. Figure 1
Schematic description of a reaction norm for a genotype

Thus, differences in phenotypic plasticity between genotypes result in *genotype by environment interaction*. Strictly speaking, $G \times E$ means that the difference between the phenotypic values of two genotypes is not the same in two environments. If the difference changes sign between environments, there is re-ranking of genotypes (Fig. 2d). If the difference changes in size only, there is a scaling effect (Fig. 2c). Note, however, that if the environmental scale had been drawn further to the left in Fig. 2c, there would have been re-ranking also here.

Comparison with the Usual Genetic Model

The most common quantitative genetic model is $P = G + E$ [1]. In this description, G is defined as the *genotypic value* and E as the *environmental deviation*. "We may think of the genotype conferring a certain value on the individual and the environment causing



Animal Genetic in Environment Interaction. Figure 2
Description of the reaction norms for three genotypes. (**a**) No plasticity but genetic variation in level. (**b**) Plasticity but no variation in plasticity. (**c**) Variation in plasticity but no re-ranking of genotypes. (**d**) Variation in plasticity and re-ranking of genotypes

a deviation from this, in one direction or the other" [1]. This might already from the beginning give the impression that G is the central factor, whereas E is just a nuisance, the contribution of which should be decreased as much as possible.

This standpoint actually makes sense from a traditional animal production point of view. The intention is to give all animals as good and standardized treatment as possible in order for them to produce in the best possible way. Therefore, as little as possible should be out of human control (E). Then it can be considered that all animals have the same macroenvironment (same production system, same kind of feed, etc.) and are only affected by microenvironmental effects. To the microenvironmental effects, one might count the effect of the individual farmer (within the rather standardized system), season of production or parturition, etc. These factors can be adjusted for, if known. Thus the environmental or residual variation (σ^2_E) can be decreased. However, there are always some unknown microenvironmental effects (e.g., that the cow is standing close to a door with a cold draft during winter). This will end up in the residual. Therefore, given a certain phenotypic variance, the more that can be adjusted away, the higher the heritability of the trait, and the higher the expected selection response.

Expressed in a graphic way, this traditional model ($P = G + E$) is described in Fig. 2a, the genotypic value only gives a shift in the level of the curve. There may be environmental effects affecting the phenotypic value (as in Fig. 2b), but they affect all individuals in the same way. After adjusting for them (e.g., by a regression), Fig. 2a still applies.

If there are sufficiently different environments (e.g., Northern hemisphere vs. tropical environments), one would still be able to use the traditional model, or rather, two of the traditional models. One would assume that the trait expressed in the tropics is actually a different trait genetically from that in, say, Europe. However, within each environment i, the model $P_i = G_i + E_i$ would still apply.

The difference between this viewpoint and that embodied in the reaction norm and phenotypic plasticity approach is quite substantial, certainly in a conceptual way. In the reaction norm approach, *the environment and the genotype are on equal standing* – there is no way a phenotype can appear without an environment. Philosophically, this makes a lot of sense; a genotype without its environment is nothing, or at least not a phenotype. Certainly, the environment is not something to be "adjusted away" [2, 3].

Staying on the rather philosophical level, it might even be somewhat hard to define what "the environment" is. Obviously, the external environment will qualify (temperature, climate, amount and quality of food etc.). However, the internal environment within an organism is also an environment for the genome. If Richard Dawkins were asked, the whole organism (except the genome) could be considered as the environment (for the genes) [4]. In animal breeding, these fine distinctions are usually disregarded; it is difficult enough to define the external environment!

As stated earlier, the $P = G + E$ model can be said to make sense from an animal (and plant) breeding perspective, at least given certain conditions. It is clear why this model was developed within this setting. The same applies to the reaction norm model and the developments related to phenotypic plasticity. These models were developed mainly within evolutionary biology and genetics, where the focus is on organisms living under natural conditions. Here, there is no way to standardize the environment – the environment is what it is and it is up to the organism to adapt (or die). Populations may adapt (to a changed or variable environment) by changing genetically, i.e., individuals with higher fitness give rise to more offspring that in turn survive better and so on. After some generations, the population has a different genetic constitution (gene frequencies have changed), which is better suited to this environment, and fitness is higher than before [2].

However, changing genetically is not an option for a given individual. So, what an organism really needs is plasticity! If it can change its phenotype – at least somewhat – it will have a better chance of surviving. Now, it is not necessarily so, that even though plasticity would be good for the individual, that it would occur: there has been a lot of discussing in evolutionary genetics literature about when plasticity is expected to develop in natural populations, but that will not be covered here [2, 5]. Students of natural populations and evolutionary genetics from very early on discovered that *there is phenotypic plasticity* in all organisms studied, at least for some traits. Therefore, it is a reality, and it should be modeled somehow.

Canalization, Homeostasis, and Plasticity

There are some terms that have been used in the evolutionary literature that need some explanation because they are sometimes referred to as the opposite of plasticity [2, 5].

Canalization means that a genotype can *buffer against small changes in the environment and in its own genotype* (mutations). The buffering means that even if small changes occur, the resulting phenotype is more or less the same. These terms are most commonly used for developmental traits, e.g., even if the environment is somewhat variable developmental plan is still followed and the resulting body, say, is still the same. It is, for instance, canalization that makes sure that cows have four legs whether they are born in Sweden or in Africa. In developmental genetics, if the environment has an effect on the phenotype, it is usually an either-or effect, i.e., one type or another, and not a gradual effect.

Homeostasis is the outcome of canalization. Homeostasis measures the degree of (in)variance in the phenotype when the individual is perturbed by changes either in the environment or in the genome (by mutation). A more canalized genotype has higher homeostasis (is changed less) and shows lower variance. In his definition of canalization, Waddington [6] defined it for *minor* variations in conditions, what might be called microenvironmental variation. As an example of canalization, he used the environmentally triggered metamorphosis of axolotls (salamanders)! They produce one of two distinct phenotypes; which one is defined by a large change in environment. Once the developmental pathway is chosen, however, small variations in environment do not affect the outcome, and within each phenotypic outcome, there is canalization.

Models to Describe Genotype by Environment Interaction

There are basically three different models to describe the extent of $G\times E$. For all methods, observations on the same or related individuals in two or more different environments are needed to study $G\times E$. In some organism (e.g., some plants), it is possible to use clones (i.e., numerous copies of the same genotype) and put them in different environments. With animals, that is generally not possible. However, the common use of artificial insemination in, e.g., dairy cattle makes it possible to compare the performance of daughters of the same sires in different environments [7].

In the following, the three methods will be described, not with the intent of understanding how to estimate $G\times E$ using these models (which is relatively straightforward), but more to understand the interpretation of these models, and the type of $G\times E$ that is detected.

Interaction Term Model

The traditional genetic model (e.g., as in [1]) is usually written as: $P = G + E$, where the phenotype P is made up of a genotypic value and an environmental deviation (a residual term) (The mean is either assumed to be included in G or that P is expressed as a deviation from the overall mean). This model corresponds to Fig. 2a, where the effect of the genotype is just to shift the level by a certain amount, regardless of the environment. In this terminology, the genotype by interaction is often simply written as $P = G + E + G\times E$. This terminology is incorrect and confusing: it doesn't make sense to have an interaction with the residual.

The model can be rewritten slightly such that the phenotypic value of an individual is described as the sum of the genotypic value, an environmental value, and a residual:

$$P = G + E + e \tag{1}$$

The environmental value E could, e.g., be classification into herds, herd production classes, production systems or countries. When interaction between genotype and environment exists an interaction component, $G\times E$, is added to the equation:

$$P = G + E + G \times E + e \tag{2}$$

The phenotypic variance (σ^2_P) of the observed phenotypes (P) can be derived from Eq. 2 as:

$$\sigma^2_P = \sigma^2_G + \sigma^2_E + \sigma^2_{GE} + \sigma^2_e \tag{3}$$

assuming all covariances being zero, and that all main effects are random (E might normally be considered as fixed, having only few levels).

If this model is compared to the graphs in Fig. 2, it is seen that in neither Fig. 2a nor 2b would this model detect any $G\times E$ (correctly so). The phenotype in Fig. 2b can be exactly described by the sum of the

genotypic values and an environmental value, which is the same for all genotypes. However, in both Fig. 2c and 2d, a nonzero $G\times E$ term would show up, simply as a deviation from main effects model. Whether the $G\times E$ would give rise to re-ranking or not is not directly seen from the size of the $G\times E$ term (σ^2_{GE}), however. One would have to add $G + E + G\times E$ for each genotype and check whether there is much re-ranking for the environments chosen.

From this model, one could define the amount of $G\times E$ as a "heritability" of plasticity as σ^2_{GE}/σ^2_P. This measure is similar to a heritability in that it is a variance ratio; however, it is not useful to predict response to selection for plasticity in the same way as the "additive," narrow sense heritability [2, 8–10].

There is no specific limitation to the number of environments that can be defined in the term E in Eq. 2, e.g., this type of model has been used to estimate sire by herd interactions.

Multiple-Trait Model

The second method used to describe $G\times E$ is based on phenotypic values in different environments and genetic correlations (r_g) between these. The phenotypic expression in the two environments is seen as two separate traits and r_g can be studied to see whether $G\times E$ exists. When r_g between the phenotypic values of the same genotype expressed in different environments is high, the phenotypic expression is considered as the same trait in the different environments. In other words, if r_g between the phenotypic expressions of the trait in two different environments is close to 1, there is no $G\times E$. When r_g is low, the phenotypic expressions in the different environments are not the same trait and this is an indication of $G\times E$ [1, 11].

The genetic correlation (r_g) can be estimated using a multiple-trait analysis based on grouping herds with similar production environments to clusters and treating the observations from the different clusters as separate traits.

By just considering the genetic correlation between two environments, the $G\times E$ of interest is that type which gives rise to re-ranking (Fig. 2d). However, one could also use the estimates of genetic variances from the multiple-trait analysis to describe the kind of $G\times E$ that only gives rise to a scaling effect (Fig. 2c). The genetic correlation is not affected by scaling if the scaling is purely multiplicative.

This method can be used even if the environments cannot be ordered according to some meaningful scale. However, if there exists a continuous underlying scale and the environments chosen are just some representations of that scale (e.g., herd production levels: low, medium, and high), this approach can be modified to describe, by a covariance function, an infinite number of separate traits over a continuous gradient. The covariance function model was developed to model, e.g., growth trajectories, morphology, and reaction norms [12, 13]. Briefly, this method is based on applying a function to the estimated (co)variance components from a limited number of traits. Using this function, one can predict the variance for any environment (normally within the range studied in the data) and also covariances between two environments. Further developments make it possible to estimate the covariance function directly without first using a MT approach (review in Gilmour and Thompson [14]).

Reaction Norm Model

When the production environment can be described as a continuous variable, a third method, called the reaction norm model, is possible to use [15]. The definition of the reaction norm (RN) has already been given: the phenotypic expression of a genotype as a function of the environment [16].

In population and evolutionary genetics, this model has often been statistically analyzed using a fixed regression approach as genotypes have been placed in the different environments. However, in animal breeding, predicting breeding values as random effects is a common practice, and therefore it is natural to estimate the parameters of the RNs for each genotype from a random regression approach [17]. A simple model based on ordinary polynomials with a fixed set of regression coefficients (an average RN) and a random set for each individual is:

$$y = \mu + \sum_{f=1}^{nf-1} \beta_f x^f + \sum_{i=0}^{ni-1} b_{im} x^i + e \qquad (4)$$

where x is the environmental value for the phenotypic value y, μ is the overall mean (fixed intercept), β_f are fixed regression coefficients, and b_{im} are random

regression coefficients for animal (or sire), m: b_{0m} is the BV for level, b_{1m} is the BV for slope, etc. $G\times E$ is defined by variation in linear and higher terms.

If the (co)variance matrix for the random coefficients is defined as $\mathbf{G}$ (order $n_i \times n_i$), then the genetic covariance between environments x_j and x_k can be written as $\mathbf{x}'_j\mathbf{G}\mathbf{x}_k$, where $\mathbf{x}_j$ is a column vector with elements $\{x_j^i\}$ for $i = 0\ldots n_i\text{-}1$. For the linear RN, the vector $\mathbf{x}_j = [1\ x_j]'$. The genetic correlation between environments j and k is $\mathbf{x}'_j\mathbf{G}\mathbf{x}_k/\sqrt{\mathbf{x}'_j\mathbf{G}\mathbf{x}_j\ \mathbf{x}'_k\mathbf{G}\mathbf{x}_k}$ and the genetic variance in each environment is $\mathbf{x}'_j\mathbf{G}\mathbf{x}_j$. These can then be used to describe the re-ranking and scaling $G\times E$. The heritability in each environment can be estimated as $h^2 = \mathbf{x}'_j\mathbf{G}\mathbf{x}_j/(\mathbf{x}'_j\mathbf{G}\mathbf{x}_j + \sigma_e^2)$, where σ_e^2 is the residual variance from Eq. 4.

Using phenotypic average as environmental scale. In the ideal situation, the environmental scale is determined by the researcher, e.g., by subjecting the animal to various temperature, light, or nutrient conditions, and the trait measured is some phenotypic character. Although this situation may occur also in animal breeding situations, more often the environmental scale is directly related to the phenotypic values studied. The simplest example is probably the use of herd (or herd-year) average milk yield as the environmental scale when analyzing the phenotype milk yield [18, 19].

The herd average is most likely a combination of many factors, but it may give a good overall description of the type of environment the cow is exposed to, and the herd average is a practically useful description of the environment. However, the same trait occurs as both dependent and independent variable. To avoid a direct relation, the individual's own phenotypic value could be excluded from the herd average used for that individual. But a further problem is that the phenotypic herd average contains also the genetic component of those animals' phenotypes and is not only a measure of the environment. If the genetic material is not used randomly over herds, one would expect some bias to be introduced. One suggestion is to use an iterative procedure, either in a repeated REML [20] or a Gibbs sampling approach [21], in a model where the fixed regression in Eq. 4 is replaced with a herd effect. Simply expressed, this effect is estimated, used as the x-value, estimated again, and so on. It has been shown that this method gives more unbiased estimates of $\mathbf{G}$ than using the phenotypic herd averages. The latter approach results in more uncertainty in the x-values, which gives an underestimation of variance of the slopes of the reaction norms [21].

Group size. The group size used as basis for the calculation of the environmental values is also of importance. Naturally, a large group size is desirable to get as precise estimate of the environment as possible. Imprecise values for the x-values in a regression analysis is expected to lead to lower regression coefficients, which in this situation means lower variance of slopes and $G\times E$ may be underestimated [20]. However, increasing the group size (e.g., using herd average over several years rather than herd-year average) may also mean that the same environment is not measured anymore, leading to the same problem as above. These two factors must be balanced in a pragmatic way.

Improved environmental scales. There has been some work on defining environmental scales that are not directly dependent on the trait analyzed. Climate and weather conditions (temperature, humidity, rainfall), herd-year SD of production, replacement rate, persistency of lactation curves, calving patterns, and other measures of management practices have been studied [22–26]. This work should continue, and factor or principal component analysis might be of help in defining few but distinct environmental scales [e.g., 27]. Improved farm and animal data (e.g., management practices, feeding system, and intensity) would be of great value in this respect.

Heterogeneous residual variance. In model (4), it was assumed that the residual variance was constant over all environments. For many traits and environmental scales, this is not reasonable. For a sire model, it makes even less sense. By including the random regression, it is assumed that ¼ of the genetic variance is dependent on the environment, but the remaining ¾ (included in the residual) are not. A rough description of the residual variance structure can be found by saving the residuals from fitting model (4), dividing them into groups along the environmental scale, and calculate the residual variance within each group. If this indicates heterogeneous variance, it should be accounted for [e.g., 28].

Multiple environmental scales. A given phenotypic trait may be influenced by several environmental scales. One can accommodate this by extending model (4) to:

$$y = \mu + \sum_{i=1}^{ni-1} \beta_i x^i + \sum_{i=0}^{ni-1} b_{im} x^i + \sum_{j=1}^{nj-1} c_{jm} z^i + e \qquad (5)$$

In a linear reaction norm, there is one intercept, and one slope for each environmental scale, x and z. The genetic covariance and correlation between environments can now be depicted as a function of both environmental scales, i.e., as three-dimensional graph [18, 22].

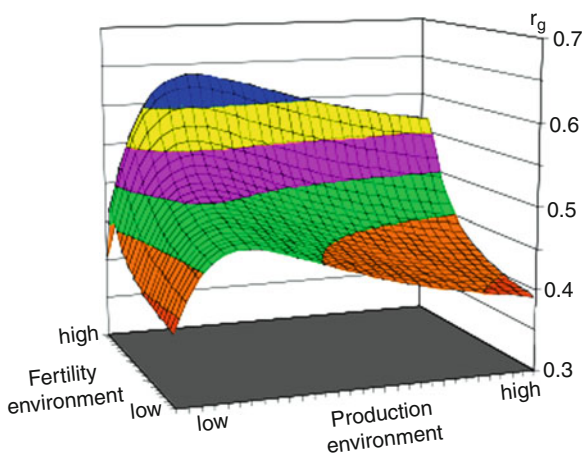
Multiple-trait reaction norms. Reaction norm models, as other models, can be analyzed for more than one trait at a time. The **G**-matrix would then contain off-diagonal sub-matrices pertaining to the covariance between the traits, and the diagonal sub-matrices would have the meaning as before. As an example, in Fig. 3, the genetic correlation between the traits protein yield and fertility (days open) is shown [18]. It can be seen that the genetic correlation changes with the environment. Note that traits could share the same environmental scale but also have specific scales. That a certain trait shows $G\times E$ with respect to a certain environmental scale does not mean that all traits will do so.

Type of reaction norm function. In the example given, ordinary polynomials were used with the origin set to the average environment. It is also recommendable to standardize the environmental scale(s); this makes (co)variance parameters easier to interpret. Another common approach is to use Legendre polynomials. These often make convergence easier than ordinary polynomials. The resulting regression coefficients are only defined within a predetermined interval (usually from minimum to maximum environmental value, redefined from −1 to +1). This means that the level is defined in the middle of this interval, which is not necessarily the average environment. For other purposes, splines have been successfully used. Regardless of the approach used, it is vital to describe exactly what was done, otherwise parameter estimates may be difficult to interpret.

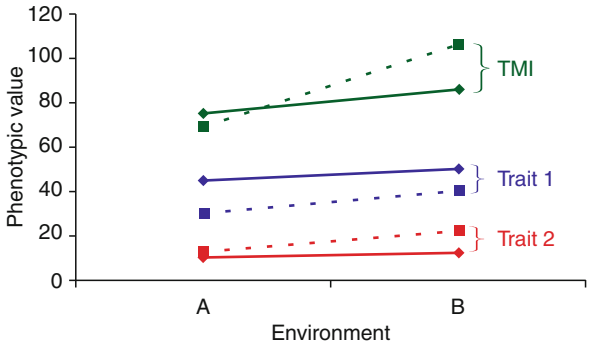
The shape of the reaction norm and the shape of the variance function are strongly connected. For a linear reaction norm, the variance function becomes $\sigma_a^2 + 2\sigma_{a,b1}x + \sigma_{b1}^2 x^2$. Because the term in front of the quadratic term is always positive, the variance curve will always be concave with an intermediate low point. In a certain data range, it may be increasing or decreasing as the minimum may be outside the range. However, it will never have a maximum intermediate point. This is a rather limiting feature of the linear reaction norm approach. With higher polynomial terms, the variance function becomes less constrained. The covariance function or character process approaches in a way work in the other direction and estimate the shape of the covariance function first. The shape of that function could be an indicator of what shape the reaction norms should be allowed to have. In most applications, only linear RNs have been found; however, there are exceptions where also higher-order RNs have been found [29–31].

Scaling can give re-ranking. It can be shown that even if there is only the scaling type of $G\times E$ for the traits, there can be re-ranking in the total merit index. A simple example is given in Fig. 4. Therefore, scaling $G\times E$ should not be considered irrelevant until the total evaluation has been done [32]; however, generally re-ranking $G\times E$ for traits is expected to be much more important.

The indication of $G\times E$ is that there is variation in the coefficients of the reaction norms. For linear reaction norms, this means that there is variation in the slopes. This definition would pick up plasticity of the kind shown in Fig. 2c–d. As for the interaction term



Animal Genetic in Environment Interaction. Figure 3
Genetic correlation between protein production and fertility (days open) in dairy cattle, in relation to environmental conditions (Data from Kolmodin et al. [22])



Animal Genetic in Environment Interaction. Figure 4
Breeding values for two individuals for two traits and total merit index (TMI) in two environments. There is scaling $G\times E$ for both traits, but re-ranking $G\times E$ for the total merit index (TMI = 1 × trait 1 + 3 × trait 2)

model, this variation does not directly tell us how much re-ranking there is: in order to find out, one could calculate the predicted performance in various environments and get the correlation (or rank correlation) between these values.

Genetic Heterogeneity of Residual Variation

The discussion so far has been related to macro-environmental sensitivity, i.e. the reaction of genotypes to large and known changes in the environment. However, as already mentioned, there is always unknown microenvironmental variation, variation that cannot be adjusted away or analyzed with any of the above methods, because it is not associated with any known factor. If there is genetic variation in how animals react to this variation, then there is genetic heterogeneity of residual variation (GHRV).

There are several different models possible to analyze GHRV, well summarized in Mulder [33]. The simplest additive model draws the residual not from a distribution with a constant variance but where it also depends on an additive breeding value, A_v. Thus, each individual has two breeding values, one (usual) breeding value for the mean (A_m) and one for the residual variance (A_v) [34]. One perhaps slight drawback with this model is that A_v is drawn from a normal distribution, and the sum of the average residual variance and A_v could become negative. The exponential model overcomes this problem: here the residual distribution is an exponential function of both the average residual variance and A_v, thus ensuring positive values [35]. Yet another option is to envision the microenvironmental sensitivity to be a special case of the reaction norm model, assuming an unknown environmental *x*-variable.

Selection for decreased heterogeneity is of interest for traits where large variation is undesirable. This might be true for, e.g., carcass traits where uniformity is favorable for the slaughtering process, but in general for traits with an intermediate optimum. When the mean performance is close to the optimum, more of the selection pressure will move toward reducing the residual variance [36]. Selecting for reduced residual variation might also be a way to select for more robust animals, animals that can cope with unknown changes in the environment [33]. It would also be interesting to study the relationship between macro- and microenvironmental sensitivity.

Consequences for Breeding Programs

The first obvious consequence of re-ranking $G\times E$ (Fig. 2d) is of course that if you select individuals to become parents based on information from one environment and plan to use them in another environment, you have partially selected the wrong animals. One example of this could be a nucleus herd with very good environment but where the production animals are used under less optimal commercial conditions. The equally obvious solution is to include information from the production environment into the genetic evaluation. Mulder and Bijma [37] showed that the loss in genetic gain (compared with if there was no $G\times E$) was lowest when progenies of males were tested in the production environment, and that this system was better than testing of sibs in that environment, and both systems were superior to testing only in the selection environment.

Another question is whether two breeding programs should cooperate even if their breeding goals differ to a certain extent. This could apply to two countries or to different production systems, e.g., organic and conventional production. It has been shown that long-term cooperation was beneficial if the correlation between breeding goals were higher than 0.8–0.9. However, initial cooperation was beneficial even when the correlation was as low as 0.4–0.6, but after some generations,

the two populations had diverged so much that selection was practiced only within population. Furthermore, small breeding programs benefited from long-term cooperation at values of genetic correlation also below 0.8 [38]. It was also shown that for dairy cattle breeding programs, the genetic correlation had to be lower than 0.6 before it was beneficial to run two separate breeding programs rather than progeny testing bulls in both environments. If the selection intensity was high, the genetic correlation increased to 0.7–0.8, below which separate programs were optimal. Again, for a small population (e.g., organic or niche production), the genetic correlation had to be even lower before two programs were optimal [39].

So, in summary, it seems that even if there is $G\times E$, it is beneficial to cooperate and use information from other environments, unless the $G\times E$ is extremely large. This is not the same as ignoring the existence of $G\times E$, rather it is to acknowledge its existence as something natural, and then adapting to that reality.

Future Directions

The trend toward globalization of breeding will emphasize the importance of $G\times E$. A breeding company that wants to be successful in a global setting must also take into account what environment the animal is going to encounter. This might be even more problematic with the advent of genomic selection because it requires reference populations with phenotypic observations from the appropriate environments, if $G\times E$ exists. And, in a global setting, there is no doubt that $G\times E$ exists to a large extent, e.g., between the industrialized production systems in Europe or USA and systems in tropical environments in Africa. Because an increase in production efficiency in developing countries is both a key factor in poverty alleviation and to decrease the ecological footprint, it is important that genetic improvement is aimed at the appropriate traits expressed in the appropriate environments.

Article Outline

Glossary

Additive genetic variance is usually the largest part of genetic variation in the quantitative trait and is due to average effects of genes. The change in mean caused by selection is proportional to the additive genetic variance.

BLUP is a short name for Best Linear Unbiased Prediction. It is now a norm in estimating breeding values within populations. It uses information on all kind of relatives and corrects the data for differences in production environment.

Breeding value of an individual is the expected value of its progeny relative to the population mean.

Candidate gene is a possible mutation underlying the mapped QTL. A positional candidate is a gene located in the same region as a mapped QTL. A biological candidate for a QTL is a gene which has a function related to the quantitative trait.

Effective population size (N_e) is the number of individuals that with random mating result in the same rate of inbreeding as the population itself.

Genetic marker is a specific detectable sequence of DNA with a know location in the genome.

Heterosis Is the extent to which the performance of crossbred animals is better than the mean of two parental populations.

Infinitesimal model assumes the genetic variation of a quantitative trait is due to infinitely many unlinked genes each with an infinitesimally small additive effect, so that selection produces negligible changes in gene frequency and variance at each locus.

Linkage disequilibrium is a non-random association of alleles across loci. Recombination between loci will gradually reduce the associations, more slowly the closer the loci are to each other. Adjacent markers with correlated allele frequencies could be used for mapping and selection.

Marker-assisted selection is selection on a quantitative trait where also the information on associated markers is used as a selection criterion. Gene-assisted selection is a special case where the marker is at the major gene causing the variation.

Mixed model equations are providing a method to simultaneously solve the predicted breeding values (random effects) for animals and estimate the fixed effects due to differences in production environment.

Morgan is the unit for a map distance in the genome.

Quantitative trait locus (QTL) A short genomic region with a large effect on a quantitative trait.

Single nucleotide polymorphism (SNP) is variation caused by a mutation at a single nucleotide.

Definition of the Subject

Animal breeding is a major contributor to the vast improvements in animal production over decades. The main tool in breeding operations is selection; now, more and more attention is also paid to the amount and nature of genetic variation. It is on these topics that the chapter is built on. It starts from the fundamental methods in determining the genetic value of animals. The normal distribution and linear methods stemming from the concept of large number of loci with tiny effects causing variation are the base line. For quite some time, there have been observations on major loci causing deviation in linear prediction of genetic values. There is a part introducing methods to get around such cases and turning them advantageous

by directly utilizing the variation mediated by major loci. The longest section is on introducing molecular genetic tools to find areas in the genome harboring such major loci and to further characterize the actual underlying genes. The most recent development in DNA technology is the availability of high throughput analysis of individual genomes with tens of thousands of signposts or markers. Without knowing the causal factors, the extensive marker panels can dissect the variation for named markers and recompose the piecewise information for prediction and selection for individuals with respective marker information. Thus, with a sufficiently large number of genotyped and phenotyped animals, selection decisions can be made immediately after birth and very speedy genetic progress is achieved. The same marker panels could be used to have a detailed picture on the state of genetic variation in a population and genome areas causing heterosis in crosses between populations. The theory of animal breeding is thoroughly introduced and discussed in many books, for example those by Falconer and Mackay [1] and Lynch and Walsh [22]. The recent developments in the utilization of DNA markers in characterizing the variation is well covered in the textbook by Weller [2].

Introduction: From Infinitesimal Model to Major Genes

Animal breeding has been very successful in improving production efficiency through utilizing genetic variation between animals. Most of the economic traits are measurable and require own type of approach in analyzing the genetic variation, that is, quantitative genetics. Quantitative genetics theory provides a statistical description of the genetic and environmental variation affecting a particular measurement in a random breeding population as it is at the moment and allows some short-term predictions of the response to selection. In essence, the *additive genetic variance* and its related concept, heritability (h^2), give a coherent framework into which observations on individuals and population, such as the effect of selection or the similarity between relatives, can be fitted.

When there is additive gene action across loci and random mating, the contributions from different loci will be independent, so that their sum will become asymptotically normal as the number of loci increases (while each locus has an infinitesimally small effect). This is referred to as an *infinitesimal model*. Also, the joint distribution of parent and offspring – or of any related individuals – will be approximately normal when the number of loci is large. Therefore, linear methods could be used for prediction. Animal breeding data is typically influenced by many nongenetic factors. The Best Linear Unbiased Prediction (BLUP), due to Henderson [3], has been developed to simultaneously handle both fixed (environmental) and random (mainly genetic) effects in a mixed model. In symbols, denoting individual performance record by y, production environment effects by β and individual animal's genetic value by u, there is an equation for the genetic value of the ijth animal (with known sire and dam and n progeny of varying genetic value u_p with known mates)

$$\beta_i + (1 + 2k + {}^1\!/_2 kn)u_{ij} - k(u_{\text{sire}} + u_{\text{dam}}) + \sum_{\text{progeny}} \left({}^1\!/_2 u_{\text{mate}} - u_p\right)k = y_{ij} \qquad (1)$$

where $k = (1 - h^2)/h^2$. The conventional *breeding value* estimation model for a large number of animals would contain the observation vector $\boldsymbol{y}$ explained by $\boldsymbol{u}$ of random additive genetic effects and $\boldsymbol{e}$ of random residual effects simultaneously correcting for the fixed environmental effects $\boldsymbol{\beta}$. The fixed effects and random genetic effects are connected to observations with the incidence matrices $\boldsymbol{X}$ and $\boldsymbol{Z}$, respectively, and $\boldsymbol{y} = \boldsymbol{X\beta} + \boldsymbol{Zu} + \boldsymbol{e}$. The genetic values are made of additive effects within and between loci, dominance deviations due to interaction within loci, and epistatic deviations due to interaction between loci. The covariance matrix of additive genetic effects can be expressed with the additive relationship matrix ($\boldsymbol{A}$) as $\boldsymbol{A}\sigma_a^2$. For solving the *mixed model equations*, one needs $\boldsymbol{A}^{-1}$ which is actually easier to form than the matrix itself [4]. From the inverse elements, one can extract equations like (1). Indeed, an approximate BLUP based on the consideration of a chosen set of close relatives gives satisfactory accuracy in comparing different selection schemes [5].

Matings between relatives cause inbreeding (increased probability for homozygosity) and inbreeding depression in loci with segregating recessive alleles with undesirable effects. In order to improve the genetic evaluation, the *mixed model equations* should

also include dominance effects, although the inverse of the joint covariance matrix of additive and dominance effects is very challenging under inbreeding [6]. It is indeed the inbred populations where the influence of dominance is more pronounced, or the crosses of inbred animals recovering from inbreeding depression or showing *heterosis*.

Selection at the Locus Level

All the concepts of quantitative variation can be expressed at the gene level [1], and therefore it is possible to describe how selection is altering allele frequencies of any locus causing variation in the quantitative trait. The genetic variance is made of contribution from individual loci. The change in mean or response to selection is proportional to the *additive genetic variance*. Hence, the contribution of any locus (or several loci) to the genetic progress under selection will be in proportion to its (their) contribution to the overall *additive genetic variance*. If a locus contributes 10% of the genetic variance, it will explain the same 10% of the total response to selection. Modifying the illustration in Alan Robertson's unpublished lecture notes at the University of Edinburgh, assume that in a dairy cattle population, there is an additively acting biallelic locus where the difference in average milk yield between two homozygotes is $2a$ = 400 kg. Further suppose that the two alleles have the same allele frequency of 0.5. If the selection lifts the mean milk yield by 500 kg, how much has the frequency (x) of the allele with increasing effect changed at the locus. Before selection, the locus contributes to the *additive genetic variance* by ½ x (1 − x) $(2a)^2$ = 20,000. The total genetic variance is – say – 250,000, so that the current locus controls 8% of the total variance and will therefore be responsible for a selection change of 40 kg. This kind of change could be caused by a change 0.1 in allele frequency so that after selection the allele frequency in the progeny generation is 0.6.

The relationship between individual loci and selection response could be described yet another way. The population must respond to selection with an increase in the frequency of those alleles which increase the trait value. The population genetic theory says that the change in gene frequency caused by selection is ½ s x (1 − x) where s is the selective advantage of one homozygote over the other. The aim is to find in the quantitative genetic context the selective advantage of the desirable homozygote compared to the other homozygote after imposing a certain selection intensity (i) for a measured trait. Or to know what is the relationship between a genetic effect on the quantitative trait and the consequent selective advantage caused by the selection on the trait. Falconer and Mackay [1] are showing that there is a linear relationship between the two so that $s = i\,2a/\sigma_p$ where σ_p is the phenotypic standard deviation, so the change in the population mean is equal to $2a$ times the change in allele frequency = $2\,i\,a^2x\,(1-x)/\sigma_p$. Since $2\,a^2x\,(1-x)$ is the *additive genetic variance* due to the locus, the response produced by a change in allele frequency at the locus is proportional to the *additive genetic variance* caused by the locus. Summing over all loci to compute the total response yields again the classical formula for the selection response $\Delta G = i\,\sigma_a^2/\sigma_p$.

Regarding the example and writing $\sigma_p = 1000$ (assuming h^2 = 0.25), if the selection response of 500 kg had taken place in just one generation, it would have to be caused by an intensity i = 2. The expected change of frequency at the studied locus then equals $^1/_2\ i\ 2ax\,(1-x)/\sigma_p$= 0.1. The example has been on a simple additive locus. The same exercise could be done for dominance – or even for epistasis – considering the average effect of allele substitution on the mean of individuals within the population and the effect of small changes of allele frequency on the population mean.

Major Genes

Genes with smaller effects may have their gene frequencies altered less by selection. Highly selected populations might therefore be expected to be segregating for loci with smaller effects on a selected trait compared to those with no previous history of selection. For loci with a tiny effect on the characteristic, directional changes of gene frequency due to selection will be low and changes will occur mostly by chance, depending on the number of parents used each generation.

Loci with very large effects on the trait will have their frequencies changed much more by selection. Since their contribution to the genetic variance depends on the allele frequency, the genetic variance

will also change. The immediate effect will depend on the starting frequencies in the population. When the allele effects are large, it is necessary to include also second-order terms of a/σ_p for the allele frequency change (e.g., [7]) and the respective response would have a quadratic terms of phenotypic values (or selection intensity). These effects would be more pronounced when there are dominance effects between the alleles. In case of carrying selection in one sex only, for example, if the variance is due to a locus with complete dominance and $x = 0.9$ and $a/\sigma_p = .5$, the response upward is going to be overestimated with linear prediction by up to 31% and 21%, when the proportion selected is 10% and 20%, respectively [8]. Also the *mixed model equations* would work less efficiently when the variation is caused by a small number of loci [9].

Over the decades, there have been findings on major genes segregating in farm animal populations: the halothane gene mutation causing stress syndrome and leanness in pigs [10], dwarf affecting body size in chicken [11], double muscling in beef cattle [12], booroola lifting prolificacy in sheep [13]. There is clear evidence that the contributions from the loci affecting the quantitative variation are vastly unequal, there being a small number of major loci and a larger number of minor loci. Such an understanding has generated research on developing tools to utilize major genes and to detect them with new available mapping tools made available by molecular genetics.

Improvement Schemes Utilizing Major Genes

The previous discussion shows that segregating major genes may bias the linear prediction of response in selection. On the other hand, a direct selection on a gene with large effect should give higher overall gains in a selection scheme. If one is able to type the different genotypes at the major locus, it is possible to carry out gene-assisted selection. Until recently, this has not been possible and selection has been based on marker loci close to the actual gene, therefore the term "*marker-assisted selection*" (MAS). Earlier the markers were typed by utilizing protein variants, now the markers are solely based on DNA polymorphism.

While conventional selection is favoring desirable alleles in an indirect way, it should be beneficial to have a tool which can influence the allele frequencies in a much more direct way. The ordinary selection with intensity i would change the mean by $i\,h\,\sigma_a$. Denoting the variance due to the major locus with σ^2_M and its size relative to the total *additive genetic variance* as R, it is possible to assess the advantages of exploiting the marker information in selection.

Lande and Thompson [14] used the selection index methodology in investigating the influence of gene or marker-assisted selection. The selection can be based both on phenotype (P) and marker genotype (M). First step is to compute the selection weights b_1 and b_2 in the index

$$b_1 \text{ phenotype} + b_2 \text{ marker genotype} = b_1 P + b_2 M$$

This could be used to generate equations for the covariance of the index with P and M (the genotypic value of the trait is denoted with G).

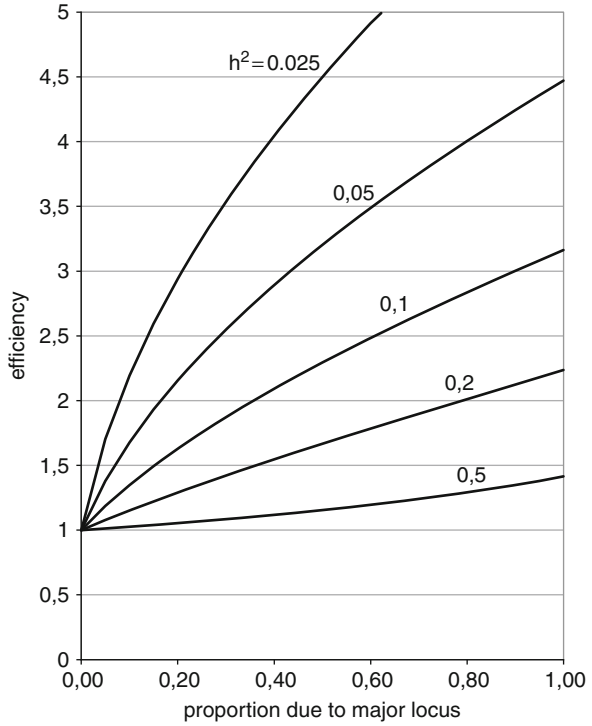
$$b_1 \operatorname{cov}(P,P) + b_2 \operatorname{cov}(M,P) = \operatorname{cov}(G,P)$$

$$b_1 \operatorname{cov}(P,M) + b_2 \operatorname{cov}(M,M) = \operatorname{cov}(G,M)$$

where $\operatorname{cov}(P,P) = \sigma^2_p, \operatorname{cov}(G,P) = \sigma^2_a$, $\operatorname{cov}(P,M) = \operatorname{cov}(G,M) = \operatorname{cov}(M,M) = \sigma^2_M$. The weights in the selection index are $b_1 = h^2(1-R)/(1-Rh^2)$ and $b_2 = (1-h^2)/(1-Rh^2)$. The correlation between the index and genotypic value is approximately $h\sqrt{1+R/h^2}$. In conclusion, the marker information would be useful, when R is high or when a major part of the variation is due the QTL and when the heritability of the trait is low (Fig. 1). Therefore, the selection of low heritability traits such as longevity traits (fertility or disease resistance) would benefit if useful genes or linked markers could be detected.

There are traits which are expressed only in one sex. The use of markers would be useful for such traits. Dairy cattle breeding is a good example: markers would allow pre-selection of bulls on milk traits which would mean savings in progeny testing. Selection could be carried out as early as the embryo stage, resulting even higher reductions in generation interval.

Genes or markers are also beneficial for traits that are difficult to improve under traditional selection. Good examples on such are carcass traits that require slaughtering before they can be measured. Meat pH, tenderness, and color are typical carcass traits. Traits that are available late in life, like longevity and lifetime



Animal Molecular Genetics from Major Genes to Genomics. Figure 1
Efficiency of marker-assisted selection relative to conventional phenotypic selection with the same selection intensity in large population with respect to the proportion of variance explained by a major gene, for different heritability values of the trait

fecundity, would benefit from MAS. The measurement and data collection of some traits, for example, disease resistance, is very expensive and therefore there is much interest in finding major genes for them.

In general, MAS has advantage over conventional selection for alleles that are initially rare and for alleles that are recessive. It is customary to think that the variation in a quantitative trait is caused by a large number of nongenetic factors. However, the marker genotype would be accurately known without environmental noise.

The consideration of gene or *marker-assisted selection* could therefore include the following points: difficulties of collecting performance records, heritability of the trait, proportion of variance explained by the major gene, and the availability of performance in the life cycle. Methods and applications of MAS are comprehensively reviewed by Dekkers [15].

The *marker-assisted selection* has also drawbacks. The direct selection on a gene would be efficient only for a short time. The desirable allele would quickly become common and new beneficial alleles should be found or new potential markers should be searched for useful segregation. If the selection is not directly on the gene, it is possible that the recombination between the used marker and QTL would gradually weaken the association. The use of markers would even be harmful if the association is not properly validated and efficiency of selection reduced compared to conventional selection.

There are also consequences for the overall genetic variation. The larger the effect of the QTL is, the faster it is fixed by selection and the more it will also reduce the variation in the surrounding genome area (e.g., [16]). An accelerated increase in the marker allele frequency may be accompanied by very unbalanced use of family lines. This is increasing the risks for the reduction of variance and enrichment of harmful recessives.

Introgression from Other Populations

Many local breeds carry interesting genetic variants that are considered beneficial to be introduced to a commercial main stream breed. The former is termed as a donor breed and the latter one as a recipient breed. The operation is usually done by an introgression program. It consists of forming an initial cross between the breeds followed by repeated backcrosses to the recipient one to recover the economically important genome. The target gene is maintained in the backcross generation through selection of donor gene carriers. After some generation of backcrossing the program will finish by a generation of intercrossing to make the population homozygous for the desired allele.

Genetic markers could be useful in introgression programs in two ways [17]. First, markers can be used to select individuals at each backcross generation which are heterozygous for the desired allele or homozygous in the last generation of intercross (foreground selection). Secondly, markers can be used to enhance the recovery of the recipient genome (background selection).

The introgression strategy is a popular genetic improvement method in plants, while there are still very few applications in domestic animals. An example is the naked neck gene in chicken which reduces plumage in chicken and makes animals more tolerant to heat. It was introgressed from low body weight landrace chickens into a commercial meat-type Cornish chicken [18].

Most of the economic traits in farm animals are complex ones with polygenic variation. One of the most promising cases of introgressing exotic germplasm to commercial production populations has been the impact made on western pig production by the Taihu breeds of the Shanghai area (China). The background for the interest and the results have been reviewed by Knap and Neeteson [19]. Some of these pig breeds (Meishan and Jiaxing) were imported into France, the UK, and the USA in the 1980s. The interest is in reproductive traits: low age at puberty, high ovulation rate and embryo survival resulting in high litter size, and high teat numbers. The disadvantage is in high body fat levels and slow growth rates.

Several commercial breeding organizations in France, UK and Canada have invested in the introgression of Jiaxing and particularly Meishan pigs into their dam lines. This was accompanied by studies into the trade-off between improved fertility and reduced leanness (e.g., [20]). These suggested that the feasible way to commercially exploit these genotypes would be to have commercial sows with 12.5% Taihu genes [21].

While the fertility is improved, as a compromise, leanness is reduced in Taihu-based genotypes, which is a serious obstacle toward large-scale commercial exploitation, although persistent genetic improvement in the latter trait obviously would solve the problem. A complicating factor here is that a few years after the Taihu imports, large data bodies and improved statistical methods allowed for a faster genetic change of reproductive traits in pigs, while genetic improvement of leanness continued at the same rate as before.

Western commercialization of the Taihu breeds has been successful so that almost 100,000 Taihu-based parent gilts are currently sold per year in Europe and North America. It represents less than 1.5% of the total market volume. A good working example on successful introgression of exotic genotypes into advanced animal breeding program is still missing for a polygenic trait.

QTL Mapping

Markers and Linkage Maps

Better understanding and utilization of major genes would benefit from the location of genes or genome areas responsible for the variation in quantitative traits. The prerequisite for this is to have a reasonable skeleton of the genome sites to survey and locate the findings. The genome is made of chromosomes. There are two homologues of each chromosome in a typically diploid animal genome. One homologue is originating from sire (paternal chromosome) and the other one from dam (maternal chromosome). The alleles at the loci on the paternal (maternal) chromosome tend to be inherited together or they are said to be linked. The genome is full of variable sites which could be used as markers to construct a detailed map of locations for further work. The closer the markers are to each other, the more likely they are inherited together or the tighter is the linkage between them or the rarer are the recombinants between them. The distant markers are on the other hand showing independent segregation. Physically, recombination is seen as a crossing over of chromosome strands. The chromosomes could be termed as linkage groups.

The linkage is measured as recombination frequency (c) or the proportion of recombinant ones among all the gametes. If markers are very far from each other, they may be several crossing-overs between them. When the loci are freely combining, the number of recombinant and nonrecombinant gametes is equal and $c = 0.5$. The map distance is expressed in *Morgan*s (M) with its hundredth being cM (centimorgan). A low recombination frequency 1% corresponds to 1 cM. For longer distances, the possibility of several crossing-overs should be considered, as, for example, two crossing-overs between distant markers would often result in nonrecombinants of the marker pair itself.

The detection of linkage or computing map distances would require variable sites and use of heterozygotes. Ideal markers for mapping are the (codominant) loci with alleles not showing dominance (or recessivity). Linkage could be demonstrated with different mating options. For example, there can be

double heterozygote $M_1\,N_1/M_2\,N_2$ mated with a double homozygote $M_1\,N_1/M_1N_1$, in which case the offspring numbers in different genotype classes would give a straightforward measure for linkage. Inbred lines are homozygous for all loci and the first generation cross F_1 heterozygous, respectively. When F_1 animals are crossed with one of the parental lines, the resulting backcross animals would give direct estimates on recombination frequencies. Using inbred line terminology, the mating is called double backcross.

Although there are often heterozygotes available, only a limited number of cases are informative on possible recombinants and determining the amount of linkage. There are five different cases with respective information content.

$\frac{M_1\ N_1}{M_1\ N_1}$	$\otimes$	$\frac{M_1\ N_1}{M_1\ N_1}$	Not informative
$\frac{M_1\ N_1}{M_2\ N_1}$	$\otimes$	$\frac{M_1\ N_1}{M_1\ N_1}$	Not informative
$\frac{M_1\ N_1}{M_2\ N_2}$	$\otimes$	$\frac{M_1\ N_1}{M_1\ N_1}$	Informative (double backcross)
$\frac{M_1\ N_1}{M_2\ N_2}$	$\otimes$	$\frac{M_1\ N_1}{M_2\ N_1}$	Informative (single intercross)
$\frac{M_1\ N_1}{M_2\ N_2}$	$\otimes$	$\frac{M_1\ N_1}{M_2\ N_2}$	Informative (double intercross)

From the last mating type, there are nine different progeny classes with respective expected numbers according to the recombination frequency.

Before a marker is used, its suitability is assessed studying the allele frequencies (x_i). So far it is obvious that homozygous parents are of no use and among the progeny of heterozygous parents only the homozygotes (or for multiple alleles, the heterozygotes M_1/no M_2 or M_2/no M_1) would signal which allele of the parent has been transmitted to the progeny. So the quality of the marker is based on polymorphism information content (PIC), which is the probability of identifying which homologue of a given parent was transmitted to a given offspring, the other parent being genotyped as well, or in other words, probability that the parent is heterozygous $\times$ probability that the offspring is informative. Summing over alleles, the PIC for a multiallelic marker would be $1 - \sum x_i^2 - 2\sum\sum_{i<j} x_i^2 x_j^2$.

Mapping Function

In order to fill the linkage map with markers and genes, there is a need to have a good measure for the map distance. As there can be several crossing-overs between distant markers, recombination frequency as such is not an appropriate measure. If there are markers *M*, *N*, and *O* (with respective recombination frequencies c_{MN}, c_{MO} and c_{NO}) and crossing-overs in the adjacent genome regions would be independent, then the recombination frequency $c_{MO} = c_{MN} + c_{NO} - 2\,c_{MN}c_{NO}$. In other words, the recombination frequencies are additive only if they are small enough so that the product term could be ignored. A map distance is required that would give the total number of crossovers between even very distant markers. The measure should be additive so that the number of crossovers between *M* and *O* is the number of crossovers in the interval *M*–*N* plus those in the interval *N*–*O*.

The probability of no crossovers is $e^{-\lambda}$ (from the Poisson distribution) and the probability of at least one recombinant gamete is $c = ½(1 - e^{-\lambda})$. The latter is true, because for each crossover event only one-half of the gametes will be recombinant types there being only two of four strands involved in a crossover. The map distance is then $-½\ \ln(1 - 2c)$ in *Morgan*s for an observed recombination rate *c*. For short chromosome segments ($c < 10\%$), the map distance equals the recombination rate, while 50 cM corresponds to recombination rate 32%. The approach is called Haldane mapping function and is valid when the crossing-overs across the genome occur independently. If some degree of interference needs consideration, Kosambi mapping function should be applied. For more details, see Lynch and Walsh [22].

The number of chromosomes varies quite much over the animal species:

Cattle	Chicken	Pig	Sheep	Carp	Human	Mouse
30	39	17	27	52	23	32

When there are so many chromosomes in livestock species, the average recombination across the genome is very high. In comparison, the well-known lab organism Drosophila has only four chromosomes and no recombination in males.

The genome in mammals is about 3×10^9 b (base) and 3 M. The chicken genome is only about 1×10^9 b, while the linkage map is still around 3 M. The well-known lab organism Drosophila has only 275 cM and 0.13×10^9 b.

DNA Markers

Ideal markers for mapping purpose should be widely distributed over the genome. At the same time, it is important that there are several markers available within short genomic regions allowing high-resolution mapping. Good markers should have many alleles, and with frequencies as equal as possible. The alleles should be codominant to allow easy detection of heterozygotes. The allele typing should be straightforward with satisfactory repeatability across analyses. Alleles should also be stable from generation to generation with a low mutation rate. The cost of genotyping could be reduced if the genotyping could be done simultaneously for many loci and the analysis could be easily automatized to provide high throughput.

The most common markers are either microsatellites (based on loci which have a variable number of repeats of a same short sequence) or single nucleotide polymorphism (SNP, which is a nucleotide site in the genome sequence, predominantly biallelic, but possibly having four alleles with each of the four nucleotide bases appearing in the same location). Both these marker types are widely distributed and codominant. Microsatellites are now less popular because their repeatability is lower and there is a limited number of them for a high-resolution mapping in a chosen short region. SNPs have gained popularity and it is nowadays possible to have very large SNP panels typed moderately cheaply in a single analysis with a small microarray chip.

Microsatellites are still used when sufficient information is delivered by only few markers (e.g., as required for parentage testing), and in some applications, this will offset the relative disadvantage of throughput in comparison to SNP markers.

From Segregation Analysis to Use of Markers

Since the genes affecting quantitative genetic variation are behaving like genes with classical discrete genotypes, there have been attempts to characterize them. If in the population there is segregation at a major locus mediating quantitative trait variation, alleles with very large effect and extreme frequency could be causing a skewed phenotypic distribution. Even if allele classes are equally common, the distribution may have several peaks. The consequences due to major gene can be studied with segregation analysis (e.g., [23]). Segregation analysis is full of factors which are hard to be itemized and tested as the effect of several major genes, extreme allele frequencies and dominance gene action produce similar distribution patterns and are therefore hard to separate. Segregation analysis is historically important and would still be used for providing preliminary understanding about the inheritance pattern, especially for human familial diseases.

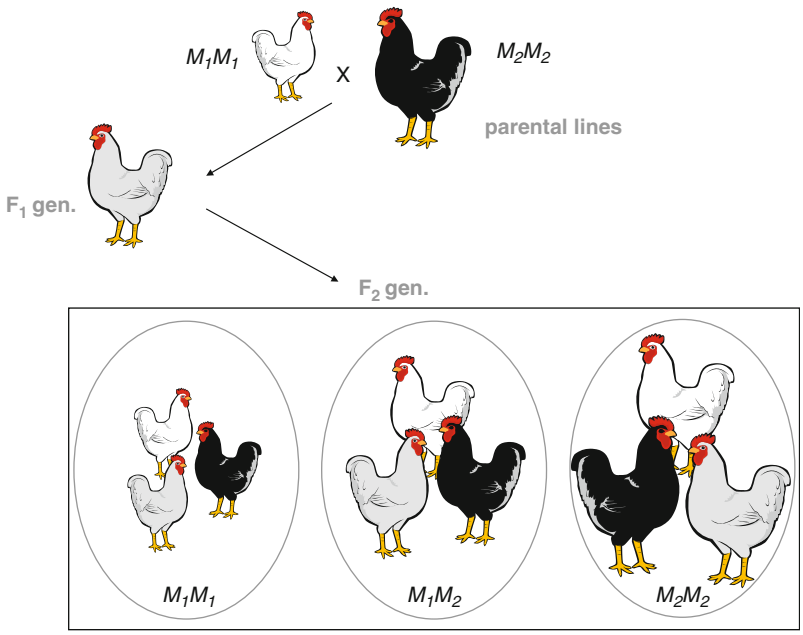
If one wants to demonstrate the existence of a major gene, it is better to anchor the analysis of distribution features to a known locus with visible genotype classes, and hope that the locus is a useful marker to demonstrate the existence of a linked major gene. Thereby, the analysis could be narrowed down to investigating one gene (or marker) at the time (Fig. 2). The statistical model could include the location of the gene, the effect size, dominance, and frequency of the alleles. Only the availability of marker loci supporting the localization was for a long time restricting the possibility for such a work.

It was half a decade ago when the blood group alleles became immunologically identifiable and possible signposts for analyzing quantitative genetic variation in farm animals. These markers were followed by electrophoretically (molecule size and electric charge) detected protein. The number of markers was still very low and even their rough location was not known. Enthusiastic researchers were facing frustrating results in hunting major genes, although the possibilities and optimum designs for analyzing quantitative traits were clearly envisaged by some groups (e.g., [24]).

The research chances improved a lot when molecular genetic techniques opened completely new kind of possibilities for mapping. With a lot of markers available all around the genome, it was soon rather rewarding to detect regions responsible for the variation. Also a new term, QTL or *quantitative trait locus*, for such genomic regions was coined.

QTL Mapping from Crosses of Inbred Lines

Inbred lines would be ideal resource populations for QTL mapping. They are homozygous for most of the genome, including, hopefully, the used marker locus and putative QTL, in which case the crossbred F_1 population would be heterozygous at both the loci. In other



Animal Molecular Genetics from Major Genes to Genomics. Figure 2

Two chicken lines differing in body weight and plumage color are fixed for a marker allele (M_1 or M_2). The lines are crossed to follow the possible co-segregation of the traits and also of the marker locus in the F_2 animals where all possible combinations of phenotypic classes and marker alleles are appearing. The animals are grouped by the genotypes M_1M_1, M_1M_2, and M_2M_2. The M_1M_1 animals are the heaviest, while the M_2M_2 ones are the lightest with the M_1M_2 ones being intermediate. This would suggest that the marker is close to a QTL related to body weight. However, the plumage color which is also showing a simple pattern of inheritance, is segregating independently as the color types occur with equal frequencies in the different weight classes

words in the F_1 generation, there is a very high correlation of allele frequencies across the loci, or using population genetic terms, the *linkage disequilibrium* between the marker and possible QTL is maximized. *Linkage disequilibrium* is reduced over generations as recombination is gradually breaking the associations. However, very little of *linkage disequilibrium* will be lost within short map distances in producing backcross and F_2 generation. Starting from inbred lines, it is easy to follow the variation in the marker loci and the allele phases across marker and QTL would remain the same over further generations. While the use of line crosses is enhancing marker variation, it is also beneficial to choose lines that are phenotypically very divergent. Such a starting point would increase the chances of finding QTL.

Assume there are parent lines (P_1 and P_2) homozygous for marker locus (two alleles M_1 and M_2) and QTL (B and b). The crossed generations are mixtures of distributions with respect to the marker genotypes. The line differences could be associated with the marker classes using alternative crossing designs. Then the expected distribution and contrasts for the marker genotypes between the lines are

	Expected distribution among marker genotype classes			
	M_1M_1	M_1M_2	M_2M_2	Contrasted classes
Backcross with P_1	½	½		M_1M_1–M_1M_2
Backcross with P_2		½	½	M_1M_2–M_2M_2
F_2	¼	½	¼	M_1M_1–M_2M_2 M_1M_1–M_1M_2 M_1M_2–M_2M_2

The efficiency of associating the computed phenotypic differences with the marker variation depends on how closely the analyzed single marker is to a gene affecting the variation. The F_2 generation (produced by intercrossing F_1 animals) is better than the backcrosses (crossing F_1 with one of the parent lines) as it is possible to estimate also the dominance effect via comparing the heterozygote class with the homozygote ones.

Random Breeding Populations

Typically, farm animals are forming a random breeding population. Such a population has many limitations for successful QTL mapping. The available phenotypes are within a relatively narrow range of variation and would generate much smaller class differences than in crosses from diverse inbred lines. The markers would also show less systematic polymorphism than crossbred populations, since in a large random breeding population the *linkage disequilibrium* is expected to be very low over moderate map distances. In that situation, the only chance to find QTL is to have a detectable marker at the gene itself or its immediate neighborhood. Still, some families or parent individuals may be useful for mapping studies as by chance they have marker and QTL variation phased in a useful manner. Although there is no *linkage disequilibrium* at the population level, there may be partial disequilibrium within families depending on the recombination rate. Such a *linkage disequilibrium* could be exploited in QTL screening. Assume sires that are heterozygous for the marker (M_1M_2) and have large progeny group of half-sibs with phenotype and marker genotype data. The data could be modeled for an analysis of variance around the average level μ as performance record = μ + marker genotype + residual.

Using the notation above, at the QTL locus the separation of two homozygotes is $2a$, the frequency of B allele in the population is x and the recombination rate between the marker and QTL is c. The analysis could be extended to include dominance by allowing the heterozygotes to deviate from the mean of the two homozygotes by da ($d = 1$ dominant, $d = 0$ additive, $d = -1$ recessive gene action with the intermediate values indicating partial dominance or recessivity).

Therefore the frequency of different progeny types would be across heterozygous sires with different QTL allele configuration as follows:

	QTL genotype in progeny		
	BB	*Bb*	*bb*
	0	$(1 + d)a$	$2a$
Sire genotype	M_1 allele from sire		
M_1B/M_2B	x	$1 - x$	0
M_1b/M_2b	0	x	$1 - x$
M_1B/M_2b	$(1 - c)x$	$(1 - c)(1 - x) + cx$	$c(1 - x)$
M_1b/M_2B	cx	$c(1 - x) + (1 - c)x$	$(1 - c)(1 - x)$
	M_2 allele from sire		
M_1B/M_2B	x	$1 - x$	0
M_1b/M_2b	0	x	$1 - x$
M_1B/M_2b	cx	$c(1 - x) + (1 - c)x$	$(1 - c)(1 - x)$
M_1b/M_2B	$(1 - c)x$	$(1 - c)(1 - x) + cx$	$c(1 - x)$

From these frequencies, one can compute for different progeny groups across the population:

Sire genotype	The expected phenotypic difference between M_1 and M_2 progeny
M_1B/M_2B	0
M_1b/M_2b	0
M_1B/M_2b	$(1 - 2c)[1 + (1 - 2x)d]a$
M_1b/M_2B	$-(1 - 2c)[1 + (1 - 2x)d]a$

Hence, the difference between subgroups disappears when recombination between the marker and QTL is 0.5 (or when the marker is very far from QTL). In general, it is not possible to separate the effect and location, for example, QTL which is 25 cM away from the marker would have an estimate like with the marker with half of the effect locating exactly at the QTL position. On the other hand, the frequency and dominance action will also affect the estimation and obviously the detection of rare recessives is very hard.

When at the population level there is no linkage disequilibrium, the occurrence of informative haplotypes in progeny depends on the allele frequencies at the marker and QTL. The heterozygous sires M_1M_2 are

investigated for the difference in performance between M_1/no-M_2 and M_2/no-M_1 progeny classes. In principle, the analysis should pool the results across sires to improve the power of the analysis. However, there are sires (like M_1 B/M_2 B, M_1 b/M_2 b) where the marker genotype contrast is zero. In some cases, the difference is positive (M_1 B/M_2 b) and in other cases negative (M_1 b/M_2 B). Therefore, the analysis is carried out within sires. Thereby, it is possible to include all the possible existing gametes (and alleles) with different combinations of marker and QTL alleles, and at the same time eliminate the spurious association caused by between sire variation [24, 25].

Interval Mapping

When the QTL screening is done marker by marker over the genome, the available information is utilized in a suboptimal way, and, for example, the effect and location of QTL cannot be separated. On the other hand, when there are many markers, some of them may by chance give a statistically significant result at the chosen risk level. If the significance threshold is 5%, then five out of hundred analyzed map positions may give a "significant" result. This could be taken into account by having a more stringent rejection criterion and have for testing each individual marker a statistical significance level of 1/(no. markers) times what it would be if only one hypothesis were tested (so called Bonferroni correction). When there are several (linked) markers available on the same chromosome, one should consider utilizing all the markers jointly and screen the whole chromosome interval by interval for existing of QTL.

Assume that the QTL is at the marker locus or in its immediate neighborhood. Therefore, it is possible to ignore how the recombination may reduce the estimate on the effect. When several linked markers are used, the localization part could be sharpened by the adjacent markers and subsequently, the estimation of QTL effect would receive better attention. Such an approach is called interval mapping. It was first developed for analyzing inbred lines [26].

Suppose there are now two markers M and N to test a case where B locus affecting the quantitative trait variation is assumed to be in the interval between them. Further, the alleles at B recombine with the alleles of M at the rate c_1 and with N with c_2. If the parental lines P_1 and P_2 are homozygous M_1 B N_1/M_1 B N_1 and M_2 b N_2/M_2 b N_2, respectively, then in the backcross to P_2 the expected progeny mean computed with respect to inheritance probabilities at the B locus is

$$\begin{aligned}&\text{prob}(B) \times \text{effect of } B \text{ allele} + \text{prob}(b)\\ &\times \text{effect of } b \text{ allele} = \text{effect of } b \text{ allele} + \text{prob}(B)\\ &\times (\text{effect of } B \text{ allele} - \text{effect of } b \text{ allele})\end{aligned}$$

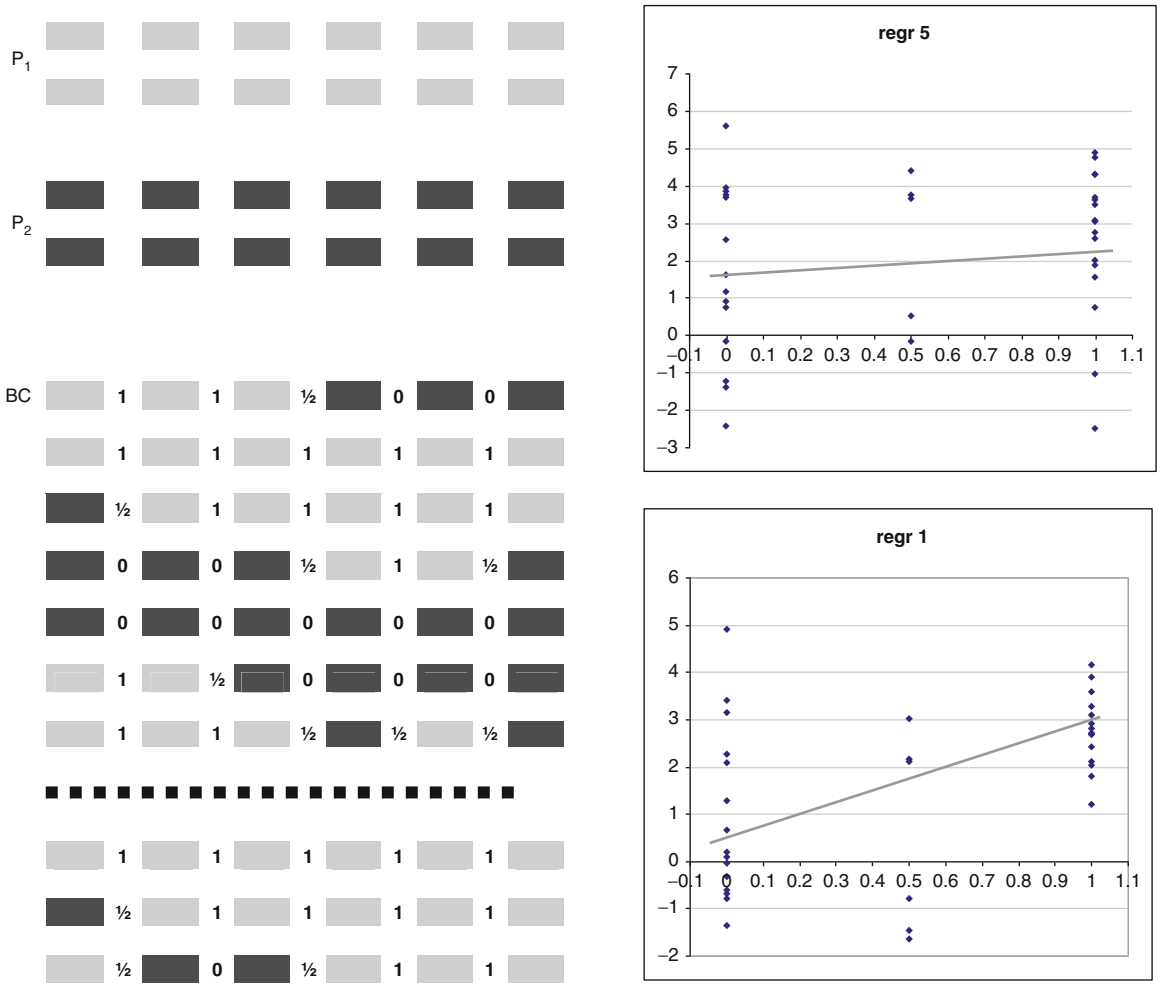
In terms of different combinations of M and N alleles in the backcross progeny, the probability for them having B allele from F_1 parent is (recalling that the recombination rate c between M and N can be expressed as $c_1 + c_2 - 2\,c_1\,c_2$)

$$\begin{aligned}&M_1N_1 \quad 1 - c_1c_2/(1-c)\\ &M_1N_2 \quad (1-c_1)c_2/c\\ &M_2N_1 \quad 1 - (1-c_1)c_2/c\\ &M_2N_2 \quad c_1c_2/(1-c)\end{aligned} \tag{2}$$

The prob (B) varies across the different positions between M and N. Different map positions could be converted to recombination rates in finding the map positions and allele effects that best explain the observations. The estimation could be done with computing the regression [27] at several positions between M and N with the model: performance record = intercept + regr coeff × prob (B) + residual. The regression coefficient is an estimate of the average effect of allele substitution at (biallelic) QTL. This is illustrated in Fig. 3. Like for any regression analysis, fitting the regression could be assessed with F test at different positions of the interval. If there are more markers along the studied chromosome, the analysis could be repeated over all the possible intervals.

When there is a reasonable coverage of the genome with interval mapping, the analysis is screening the whole genome for QTL. The same type of QTL analysis could be carried out for F_2 cross animals. In that case also the dominance deviations could be estimated for QTL.

In farm animals, the closest to an inbred line is a breed. The first major genome scan utilizing breed differences was reported in the mid-1990s in pigs from a cross between the Large White breed and the wild boar [29]. Large QTL effects were found influencing



Animal Molecular Genetics from Major Genes to Genomics. Figure 3
QTL interval mapping via regression for backcross setting. The backcross (BC) population is produced by crossing phenotypically diverse "light" and "dark" parental lines (P_1 and P_2). The light line animals of P_1 have a higher phenotype. The BC population is genotyped with a marker panel covering the shown genomic region at regular intervals of 20 cM. Markers are represented by shaded bars. The BC population is formed by crossing F_1 animals with the P_2 animals. When all the transmitted P_2 markers are black, the BC animals are illustrated with the chromosomes from F_1 parents, with possible recombinants. Marker intervals are considered one by one for the presence of QTL. The probability that individual has received the "light" QTL allele from F_1 parent is computed (values in the brackets between the markers) and used as an explanatory variable to compute the regression of phenotypic value on it. The regression coefficient provides an estimate of the allele substitution effect. The QTL is in the first bracket and leads to higher regression coefficient than in the last (5th) bracket, far away from the QTL, both examples shown on the right. The illustration is modified from Georges [28]

both growth and fatness. After that study, several genome scans have been developed involving the commercial and exotic breeds.

In random bred populations, there is less regularity in many respects and the interval analysis should be preceded by the examination of allele phases across adjacent markers in heterozygous (say $M_1/M_2N_1/N_2$) sires. The phase determination would require a large genotyped half-sib family from the sire. The non-informative heterozygous progeny M_1/M_2 cannot be

automatically used for the analysis but the considered interval should be extended until an informative locus in the progeny is found. If the sire chromosome phases over the markers are M_1N_1/M_2N_2 and there is a progeny that has inherited the combination M_1N_1 (and assuming that the QTL allele B is on the same chromosome with M_1 and N_1), the progeny has B allele with probability $1 - c_1\, c_2/(1 - c)$. The other probabilities could be derived and would resemble the ones listed for the backcross case above at (2).

The interval analysis is again performed within a family. The power of the analysis could be improved (or residual variation reduced) by analyzing several families and pooling the results at the end. The statistical model for progeny mean is therefore average level + sire_i + $\text{regr coeff}_i \times \text{prob}\ (B)$ + residual. The sum of squares due to the regression is then obtained by pooling the sum of squares due to regression across sires as $\sum \text{SS-regr}_i$/number of sires. The degrees of freedom in the F test for the residual variation are the total number of observations minus twice the number of sires. The analysis is repeated at several positions, say at cM intervals, between M and N and further across other intervals. The highest value for the test parameter is indicating the likely position for QTL with the regression coefficient itself giving the substitution effect. The first genome-wide screening for QTL was done in the outbred half-sib design for dairy cattle by Georges et al. [30].

Design of QTL Mapping Studies

It is important to understand what would be an optimal design and number of observations (n) for QTL mapping studies. First consider the regression with a single marker for a crossbred population (or single family). The explanatory variable (*prob*) is made of probabilities for the inherited QTL allele. For simplicity, there are so many observations (>50) that one can formulate the test for the regression coefficient as regr. coeff./its standard error = regr coeff/$\left(\sigma_e^2/SS_{\text{prob}}\right)^{1/2}$ = $\sqrt{n}\ \sigma_{\text{prob}}$ regr. coeff./σ_e In other words, the test parameter depends on the number of observations, variation range of explanatory variable, size of QTL effect and residual variation(σ_e).

Considering the type I error rate α and test power $1 - \beta$, then in terms of the respective standardized variates (z) of normal distribution, the number of observations required to detect a QTL with an effect a/σ can be deduced from $(z_{1-\alpha} + z_{1-\beta})^2/(\sigma_{\text{prob}}\ a/\sigma)^2$. For the 5% risk and power 90% with the effect sizes

0.1	0.4	0.7	1.0

the required number of animals (with observation and marker genotype) in a backcross is

4,202	262	85	42

Compared to backcross, the explanatory variable would double its variation in F_2 and therefore the F_2 cross would have twice the efficiency given the same number of genotyped individuals. So far it is assumed that in the single marker analysis, the marker is at QTL itself. When this is not so and the recombination between marker and QTL is c, then with the same criteria the number of genotyped individuals should be $1/(1 - 2\ c)^2$ times higher (for more details see [31]).

In conclusion, a cross between divergent lines is very powerful to detect QTL because the statistical power is high and a reasonable number (200–300) of animals is sufficient to detect a major gene. Experimental cross is also a useful approach for QTL screening as the production could be controlled in a small scale study and uncommon traits (disease resistance and quality traits) can be monitored. However, in farm animals, uniform lines are not common and rarely inbred enough to fully exploit the crossbreeding advantages. It is also very costly to maintain such lines or find facilities for generating and maintaining experimental crosses.

The random bred populations should be analyzed pooling within family results across families. When there are several groups in the analysis, the testing should follow the framework for the analysis of variance (F ratio). The test is improved with a large number of progeny. When there are s sires, the family size requirement could be computed from $F^2\sigma_e^2\ s/\Sigma\ SS_{prob}$. On the other hand, the more sires there are, the higher are the chances of finding a family with a segregating QTL.

With the half-sib design, the number of genotyped animals could be reduced by moving from daughter design to granddaughter design [32]. Instead of genotyping daughters for markers, the progeny tested

sons of the sires are now typed and their evaluation results are used in the analysis. Thereby the number of genotypings can be kept reasonable and the accurate genetic value of sons reduces the residual variation and thereby increases the power of analysis. The sons are genotyped for markers that are heterozygous in their sire. The analysis for a single marker is carried out within sires with the model: progeny test result value of son j from sire $i = \mu + \text{sire}_i + \text{son's genotype}_{ij} +$ residual.

With a given number of genotypings the test would be more powerful than the daughter design. When there are 200 daughters per sire versus 200 sons per sire and 100 daughters per son, one can compare the test power (risk 5%) with different effect sizes for daughter/granddaughter design.

Number of sires/paternal grandsires	No. genotypings	a/σ =.1	a/σ =.3
5	1,000	3/48	50/97
10	2,000	5/73	76/99
20	4,000	7/95	95/99

In order to reach the power of granddaughter design, the daughter design would need large progeny groups which – in terms of collecting DNA samples and carrying out genotypings – are workwise almost impossible.

For the interval mapping, both the variance of the explanatory variable and residual would be reduced while in general the aim should be to push down the residual variation as low as possible while keeping a wide range of alternatives for the explanatory variable. If only animals with extreme phenotypes are genotyped, the latter could be increased and the efficiency enhanced. Ultimately, genotyping only the very highest and lowest phenotypes, the variance of the explanatory variable is increased, and in the best situation the analysis would have only the extreme homozygotes for QTL. It is important to notice that the selective genotyping should be done within families to make sure that the selection is targeted on the QTL instead of the general genetic background. Selective genotyping has its drawbacks, as it would focus on a single trait at a time.

Genes Underlying QTL

In farm animals, the QTL mapping has been very popular since the microsatellites and later SNPs became available as mapping markers. Depending on the species, two designs have been used: crosses mainly in pigs and chicken and half-sib families in dairy cattle. The QTL investigations have been carried out with marker sets of 100–300 microsatellites covering the whole genome. This would correspond to a marker density of some 10–30 cM. QTL mapping in farm animals has been very prolific as it has been possible to have sufficiently large experiments or population samples to yield an adequate statistical power for QTL detection. Until today, thousands of QTL for numerous traits have been reported (see http://www.animalgenome.org/QTLdb/).

Year	Number of QTL (number of traits in brackets)		
	Cattle	Pigs	Chicken
2006	630 (89)	1,287 (246)	657 (112)
2011	4,682 (376)	6,344 (593)	2,451 (248)

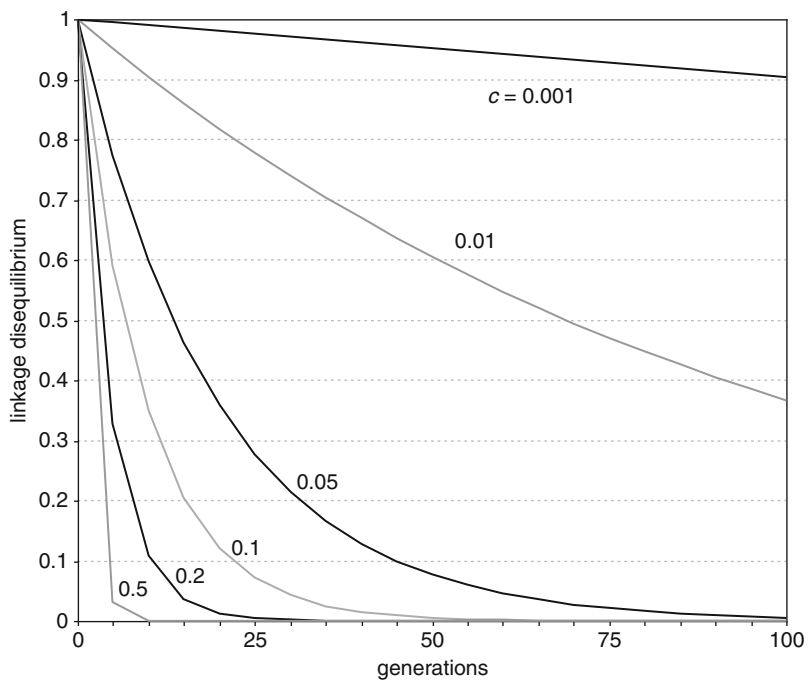
Fine Mapping

A successful *marker-assisted selection* requires that the applied marker is at the QTL itself or very close to it. Otherwise there is a need to resort to linked markers which may differ across families, depending on how they are showing *linkage disequilibrium* with the targeted QTL. There are other reasons for the interest to find the underlying genes, as the general aim is to understand more about their function and utilize them in further studies and applications. It is hard to resist the temptation of trying to find the genes, the allelic variants within them, the allelic effects and frequencies, co-effects with the alleles of other loci, and effects on other traits. Moreover, the never-ending curiosity drives research to distinguish coding areas and regulatory elements (e.g., [33]). In a typical QTL study, it is possible to locate a QTL only within a fairly wide region of a chromosome. A region of 10–30 cM may still contain 100–300 genes which is making difficult to identify and characterize the responsible mutations [28].

There are several factors that affect fine mapping. An obvious criterion is high marker density. The design consideration showed how the sample size of animals contributes substantially to the mapping resolution. As high as 5,000 individuals are required to increase the resolution down to 5 cM in crossbreeding designs. Therefore, it is necessary to think about ways to produce new recombinants. It is easier with experimental laboratory strains serving as model organisms where with a short generation turnover it is possible to have intercross populations F_3, F_4, F_5, . . . In that context, by generation t the confidence interval for the QTL location is reduced to $1/t$ of the F_2 one given the same number of animals per generation [31]. In farm animals, such operations would be money and time consuming and practically unfeasible.

It is easy to produce a large number of markers for an interesting QTL area and find the markers with the best association with QTL alleles. Usually, combining individual marker variation over the area and assessing the association between haplotypes and QTL alleles may be more fruitful than analyzing single markers one by one [34]. In farm animals, the density of observable recombinants could be increased by exploiting historical recombination events in comparing the same genomic region within population or even across breeds (Fig. 4). Many breeds are originating from a small number of founders or have experienced bottlenecks alternating with periods of population growth. These events affect sampling of haplotypes and thereby cause *linkage disequilibrium* which can be used in fine mapping QTL regions. *Linkage disequilibrium* extends over longer genome stretches in young populations which hampers localizing causal mutations. In modern dairy breeds, *linkage disequilibrium* is seen as long haplotype blocks [35]. The older haplotypes shared by breeds can be exploited in high-resolution mapping.

In a QTL analysis one is following the transmittance of the variants over a chromosome section and computing probabilities for assumed QTL in the marker bracket. The more detailed variation within the chromosome interval is ignored and further it is assumed that the variants of the interval are unrelated. The intervals could be filled with more markers, especially



Animal Molecular Genetics from Major Genes to Genomics. Figure 4
The decay of linkage disequilibrium over generations for different values of recombination rate (*c*) between loci. It is noticeable that with a recombination rate 1% it takes some 80 generations to halve very high linkage disequilibrium

around the found QTL, to classify the relationships between the interval variants given the linkage disequilibrium. When there is evidence for a QTL from linkage analysis and from *linkage disequilibrium* around the putative QTL position, the linkage and *linkage disequilibrium* analysis could be combined [36]. The analysis would eliminate QTL effects from distant regions of the chromosome and other chromosomes because they do not appear as linked QTL. Therefore, the combined analysis would produce a clearer signal for the QTL position compared to the two separate analyses [37]. Such a combined linkage and *linkage disequilibrium* approach has been successfully exploited in cattle to map QTL within less than 1 cM [38].

The discussion above shows how important it is to eliminate the spurious associations due to linked genes or other genetic background. One approach is to use transmission disequilibrium test or TDT [39]. This compares the effect of the two alternative types of gametes from a common parent. For example, a sire heterozygous for a studied marker (or a putative gene) may have a large progeny group allowing a test to find how regular the difference is between progeny inheriting the alternative alleles. Such an analysis is extended over sires by treating them fixed.

Few Examples on Causal Mutations

The characterization of mutations underlying QTL is very hard in any species, and it is not too surprising that there are only few validated examples on such mutations in domestic animals. The work has usually started from a genome-wide screening for QTL and then proceeded to find genetic and functional support for possible causative mutations.

Many independent QTL mapping studies in dairy cattle have shown that there is QTL for milk traits on chromosome 14. After lots of effort and international collaboration it has been shown that the associations could be explained by the *DGAT1* gene that is coding acyl-coenzyme A: diacylglycerol acyltransferase. The enzyme is known to catalyze the last step in the triglyceride synthesis and a missense mutation (K232A) influences milk fat content in cattle (e.g., [40]). The fine mapping and gene identification took some 7 years.

The second example is from pigs. A single-nucleotide substitution of IGF2 (insulin-like growth factor 2) is a causal gene behind a major QTL for growth [41]. This is a regulatory mutation. It has been present in four different breeds selected for lean growth and a major reason for the successful detection is the finding of an ancestral haplotype that differs only by one nucleotide substitution from the mutant haplotype [42].

Another example is a single nucleotide substitution in the myostatin gene (*MSTN*) causing increased muscle mass in Texel sheep [43]. This mutation creates a new target site for two microRNAs expressed in muscle which leads to down regulation of MSTN transcripts.

The findings have a clear message: farm animal populations have a high haplotype diversity allowing successful genetics research to locate genes underlying QTL irrespective of the mode of action. The examples show that the molecular nature of a QTL can be as simple as a missense mutation in a coding sequence or a single nucleotide substitution in noncoding DNA. It is also impressive how in farm animals the genes behind the found QTL are regulatory mutations. The regulatory factors are much more challenging in showing the effect on gene function than mutation changing the protein sequence and structure.

There are others reported but in many cases more work is needed to demonstrate their effect in independent samples. The number of actual genes in the QTL seems very low so far but is comparable with the modest findings in man and mice where the work volume is more substantial. One obvious reason for a small number is the poor resolution in QTL mapping experiments. The confidence interval for a QTL is at best very wide and may contain hundreds of genes. Another reason is that many QTL will not have such a simple explanation as the examples described above. Some QTL will be due to several mutations present in one or many genes. Such QTL may break up into several linked loci for the fine mapping. Mutations in noncoding DNA make their detection and functional characterization also very difficult (see [28, 42] for more discussion).

Candidate Gene Approach

In the characterization of genetic factors, there are basically two types of approaches. The linkage studies

are aiming to locate genomic regions or QTL that are important sources of variation, or biological knowledge is used to deduce the genes most likely responsible for the variation. The examples above are indicating that studies to identify positional *candidate gene*s have a rather limited success. It is not therefore surprising that many researchers have restricted their studies to investigate the role of biologically deduced *candidate gene*s in explaining the variation in the available data. This approach is much more economical, on the other hand there is very little new knowledge to be discovered as the analysis only spotlights the chosen gene or genes. Sometimes, the studies have switched to candidate approach after the linkage approach has failed or included *candidate gene*s as a marginal part of wider analysis not originally designed to explore individual genes. The research angle is naturally highly subjective in choosing candidates from numerous promising ones.

The report on functional candidates should provide full details why the particular genes were chosen, where the genotyped group of animals is originating, what kind of marker set was used to eliminate the other associated effects in the genome, etc. For any gene, the combined data on its vicinity should be used to convince others about hitting the true gene in the face of too much interfering information from dozen other genes. A good design in such studies should be aiming at balanced genotype frequencies. If a gene is picked up because of ease of genotyping, the only hope is to have much luck to hold marker variants that are in *linkage disequilibrium* with the alleles causing a trait deviation. There is also the trick of having a "significant" result surface from the data by permuting several genes and traits (see [44, 45]).

It is a common problem that *candidate gene*s are not providing consistent evidence when exposed to validation in subsequent generations of the same population or more importantly, in other populations. The most beautiful investigations are finalized by functional mutation studies (knock-out or in) or complementation tests in a modeled mouse experiment, practically impossible in livestock species. One way to improve the analysis is to define a trait more explicitly. For example, calving interval could be itemized to several sub-traits, which in turn may prove to be more rewarding objects for QTL analysis. Likewise with the markers, instead of associating gene variants, it is now possibly to go a level deeper and excavate the respective gene expression patterns. The difficulties are not over when it comes to deciding which tissues and which developmental stage would provide appropriate samples for expression studies and how to plan a comparable and uniform production environment for such studies. The expression profiles are obviously an outcome influenced by several factors and their interactions are ever so hard to interpret (for more discussion, see [28]).

The complex traits in medical studies have experienced similar disappointing conclusion, and there are hardly any major genes manifesting the familial multifactor diseases. Researchers have voiced this by talking about missing explanations for the observed genetic variation or heritability [46]. In quantitative genetics, it is more and more obvious that the variation is simply caused by lots of genes with tiny effects and variants that are not appearing among the prior candidates [47]. With the rapid growth of high throughput marker typing and re-sequencing, there is now a possibility with very large population samples and concerted actions to detect reliable associations even for the small effects [48]. Different techniques, such as detailed mapping and functional studies, could be combined [49]. What remains is the requirement for large bodies of data, as has always been in analyzing genetic variation for animal breeding purposes.

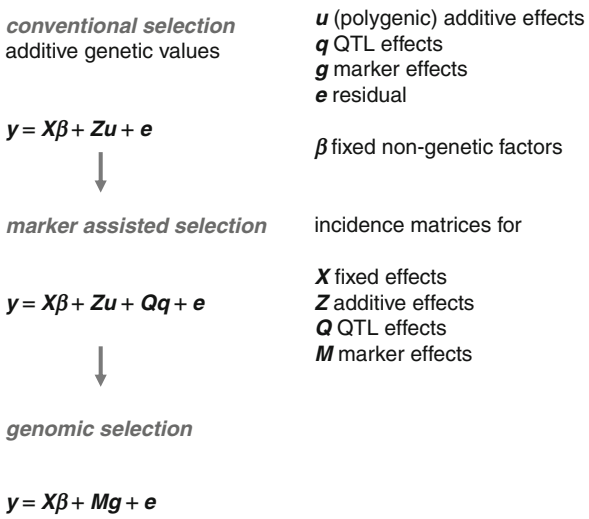
Genomic Revolution

The very fast development of molecular genetic techniques has resulted in exploitation of the existing nucleotide diversity. The genome sequence is available for chicken [50] and cattle [51]. The sequences of the whole genome in pig and sheep are still on the way. The sequence information is indicating that a typical animal genome has almost endless amount of potential variable sites. Several descriptive measures are used to summarize polymorphisms of DNA sequences. Under a neutral model, the expected level of diversity can be deduced from the generation of new alleles by mutations and from the elimination of alleles by drift (which is inversely proportional to effective population size), that is, $4\ N_e \times$ mutation rate. For comparison, in a human population two randomly chosen individuals differ at ~1 in 1,000 nucleotides (1 SNP per kilo base).

The genetic diversity of mankind is low compared to other (older) species. In cattle and sheep the mean nucleotide diversity is 2–2.5 SNPs per kilo base [52], whilst for chicken the estimate is 4–5.5 [53]. With modern DNA chip technology up to hundreds of thousands of loci across the genome could be used to genotype animals with a reasonable cost. These possibilities have opened up completely new kind of possibilities to understand and utilize the genetic variation.

MAS with More Markers

When there are several markers available, the *mixed model equations* for *breeding value* estimation could be extended to accommodate several markers with a vector of QTL effects. Using the previously introduced notation (Fig. 5), the use of several markers is with matrix presentation $\boldsymbol{y} = \boldsymbol{X\beta} + \boldsymbol{Za} + \boldsymbol{Qq} + \boldsymbol{e}$, where $\boldsymbol{Q}$ is the incidence matrix for $\boldsymbol{q}$ [54]. Var $(\boldsymbol{q}) = \boldsymbol{G}\,\sigma_q^2$ where σ_q^2 is the variance due to QTL and $\boldsymbol{G}$ is the matrix of probabilities for QTL alleles being identical by descent. These probabilities can be computed from the pedigree, marker, and linkage map information. So far QTL mapping has produced fewer useful genes or markers for MAS than was anticipated when the QTL screening work started. The found QTL are contributing much less to the variation than would be satisfactory for a successful use of MAS, as its efficiency is affected by the proportion of variation due to a major locus [55]. Much caution should be also taken in MAS, as most of the found QTL have an overestimated effect (so-called Beavis effect). The availability of vast amounts of SNP markers should improve both these aspects: a dense marker panel covering the whole genome would be able to wrap all the genetic variation and avoid the problems of few overemphasized markers.



Animal Molecular Genetics from Major Genes to Genomics. Figure 5
The mixed model methodology is a flexible tool to accommodate the models ranging from simple breeding value prediction with polygenic model to QTL effects associated with known markers. The effects of genome-wide marker sets are computed through a straightforward summation over the genome. ***X***, ***Z***, ***Q***, and ***M*** are the incidence matrices linking the observations to respective effects

From MAS to Genomic Genetic Values

For the future practical application in estimating the genetic values, the most promising approach seems to be simultaneous utilization of a vast number of markers over the entire genome [56]. The map density is so high that the recombination between markers and QTL can be ignored. With a genome-wide set of markers, the estimate of individual's genetic value or genomic estimated *breeding value* is obtained by estimating effects associated with the markers from animals with both the phenotype and marker genotype information and summing the marker effects for recently genotyped animals available for selection. With genome-wide marker panel one can hopefully catch most of the genetic variation and produce a more attractive way to exploit markers.

The process of predicting the *breeding value*s utilizing genomic information could be described in three steps:

1. Use a genome-wide marker panel to genotype animals. It is now a norm to use densely mapped SNPs as markers. The SNP variation is seen as two alleles (potentially with four). When the marker panel is very dense and genome-wide and each marker is wrapping the genetic variation for a measured trait in its neighborhood, the whole panel is covering all the genetic variation. With additive gene action the biallelic marker is assumed to have a substitution

effect. As the whole genome is covered with the dense map, the effects of the n SNP loci would sum the genetic value of the animal.

2. Estimate the effects of each marker locus. The model for the phenotype of animal i is $y_i = \sum_{j=1}^{n} m_{ij} g_j + e_i$ where m_{ij} (2, 1 and 0) is representing the marker genotypes in the ith animal, g_j is half of the substitution effect at the marker locus for the quantitative trait and e is the residual. The phenotype and genotype data could therefore be used to estimate the marker effects (ignoring all the nongenetic factors) with the model in matrix notation $\boldsymbol{y} = \boldsymbol{M}\,\boldsymbol{g} + \boldsymbol{e}$. The new method could be seen as part of the development in mixed model methodology (Fig. 5). The first two steps are carried out in a sufficiently large reference population with information on both marker genotypes and trait phenotypes.
3. The genomic *breeding value* could be computed for genotyped selection candidates by summing the estimated effects over the markers.

There are several options how the equations could be solved. Treating the marker effects as random, it is customary to assume that their variance is constant over the genome or that there are few loci with large effects with the majority having small effects. In addition, there are options for the distribution of the effects. The case of normally distributed effects with constant variance is interesting because the *breeding value* predictions would be equivalent with *BLUP* where the pedigree-based relationship matrix A is replaced by a relationship matrix estimated from the marker information [57]. The latter is also called genomic relationship matrix and is technically *MM'*. The genomic information has also been successfully used to incorporate the realized relationships into the A matrix used in *BLUP* [58].

It is the Bayesian methods that are able to cope with situations where an allowance for graduated effects of markers is made. This is beneficial as the QTL screening works is clearly showing that there are genomic regions having relatively large effects. Many distributions have been tried: a case where most markers have a small effect and very few a large effect, alternatively assuming 0 for several markers and nonzero for few markers. These were studied in the original paper [56] and the former approach is known as BayesA and the latter one as BayesB. Meuwissen and Goddard [36] also presented an alternative where the variances of marker effects are sampled from a mixture of two distributions allowing the variation in the effect size across markers. Simple methods are possibly favored so far, as pure Bayesian approaches would require more computing time. Related to this, the rapidly increasing number of markers – hundreds of thousands – and availability of sequence data and larger number of genotyped animals would also challenge the computing capacities.

The accuracy of genomic *breeding value*s depends of course on the number of records and proportion of genetic variation or heritability h^2. Small *effective population size* is generating linkage disequilibrium. Related to linkage disequilibrium, the genome contains regions of reduced haplotype diversity, termed haplotype blocks [59], separated by blocks of higher diversity. Within such blocks the frequencies of marker alleles may be highly correlated across loci. The genome blocking sets limits to the estimation even if the marker density is very high. The number of independent segments for a chromosome of length L (in *Morgan*s) is $2\,N_e\,L/\ln(4N_e\,L)$ [57]. So, a chromosome of 1M has some 33 independent segments and the whole genome of 30 such chromosomes would have 1,000 independent segments. If the *effective population size* is small, increasing more markers would not improve the accuracy or resolution in explaining the genetic variation and the best one can do in that situation, is increasing the number of animals in the analysis [57, 60]. In conclusion, the accuracy of genomic *breeding value*s would depend on the number of animals in the reference population, the heritability of the trait, the marker density, the number of independent genome segments (or effective population size) and the total length of the genome.

With best linear unbiased prediction and Bayesian method, the accuracy of predicting genetic values for offspring of the recorded animals has been shown to be of the order 0.7–0.8 [56], comparable to that of the progeny test. The genomic selection method was presented in 2001 and did not receive much attention, as at that time the required coverage of the whole genome with markers was not feasible, at least in terms of costs. When the high throughput genotyping

of SNPs with microarrays became available and Schaeffer [61] pointed out the remarkable returns and savings that the genomic selection could produce in dairy cattle breeding, the breeding companies rushed out to exploit the tool with unparalleled enthusiasm. He compared genomic selection with conventional progeny testing and assumed that there were marker effects available with accuracy 0.75 to select bulls and bull dams. As much less bulls would be kept after genomic "pre-selection," the cost of the marker-based improvement would be only 10% of the traditional one. Another radical feature of genomic selection, is the sufficiently reliable evaluation of young animals which would reduce the generation interval drastically, for example, in the bull–bull path from 6 years down to less than 2 years. When it takes 5–7 years to have the progeny test result for a dairy bull, the genomic genetic value is available at birth. Putting the slightly lower accuracy and shortened generation interval together, the annual genetic change is predicted to be doubled.

Much of the work on assessing the advantages of genomic selection has been done by simulation. The reliabilities of genomic *breeding value*s could be assessed by dividing the real data into two parts, usually over birth date and compare how the predictions based on older animals compare with the estimates obtained for the more recent ones with all the data. VanRaden et al. [62] concluded that the reliability is proportional to the size of the reference population while the increments in marker density had a smaller impact. They were implying that a reference population of few thousand progeny tested bulls is required to arrive at a satisfactory accuracy of genomic *breeding value*s. Only the Holstein breed has such numbers and even there the breeding companies would need collaborative efforts across countries for reaching a sufficient number of accurately known sires.

Breeds with smaller populations (and progeny tested bulls) could in principle resort to the marker effects estimated in a large population. If the marker density is very high, genomic *breeding value*s estimated in one breed may support the estimation in the other breed [63]. They may be some common *linkage disequilibrium* within a short distance across the breeds otherwise recombination has broken associations since the divergence. Selection and drift have also changed the genotype frequencies over time.

Management of Variation

Very intensively selected populations may suffer from losing variation or, in a more extreme case, from inbreeding depression and appearance of recessives defects. This is due to the reduced number of selected parents to generate the breeding bulls. The risk for inbreeding and drift is expressed with *effective population size* or rate of inbreeding ($\Delta F = 1/(2N_e)$). The safe areas for these would be over 50 and less than 1%, respectively (e.g., [64]). In dairy cattle, the awareness on rate of inbreeding was triggered by the breeding schemes utilizing multiple ovulation and embryo transfer (MOET). It was shown that the schemes could be optimized with respect to genetic progress and costs, by concentrating the MOET operation on cows in a nucleus of few hundred cows only. The apparent small number of parents and larger full-sib families accompanied by early selection would easily mean risks for higher rates of inbreeding. This kind of worries generated lots of research and now the better understanding about the related risks in selection programs has resulted in new tools. The most important aspect is to maximize the variation in selected groups of males and females while the formation of mating pairs is less relevant. Meuwissen [65] has developed so-called optimum contribution method which yields the guidance in choosing parents and their progeny numbers to maximize the genetic gain while minimizing the coancestry. The constraining on the coancestry is based on the relationship matrix and therefore the optimum contribution method could be easily integrated with the information needed for *BLUP* evaluation.

Genomic *breeding value*s are based on information on the individuals themselves and are therefore better than *BLUP breeding value*s which may more often lead to co-selection of sibs due to family information [66]. So the genomic selection has short-term advantages for the management of genetic variation. In the long-term an efficient genomic selection is automatically reducing variation. The genomic information is on the other hand giving an accurate estimate on the relationship between individuals. While the pedigree based matrix gives the expected relationships, the marker-based matrix yields the realized relationships. The earlier work (e.g., [67]) showed that tens or even hundreds

of markers (e.g., microsatellites), is of limited value in estimating the relationships and in controlling the rate of inbreeding. The use of genome-wide SNP panels has changed the situation and molecular similarities could be calculated very accurately and used like the genealogical information. Just like the relationship matrix in the *BLUP* context is improved by the genomic information, in the same way the genomic relationship matrix could enhance the management of variation. There are only preliminary results [68] which are indicating that high benefits could be anticipated from the use of genomic relationship matrix in promoting the sustainable use of genetic variation.

Genetic Correlation

It is a common observation that there is a negative genetic correlation between production traits and longevity, made of such traits as disease resistance and fertility. It is widely accepted that such a correlation is caused by pleiotropy so that the same genes would have opposite effects on the two sets of traits. This could be understood as a consequence of allocating limited metabolic resources to competing physiological compartments within an animal. If a genetic correlation between two traits is positive, it can be thought that the effects on the two traits are on average influencing to the same direction. On the other hand, if the majority of effects are of opposite "sign," a negative correlation would be seen. However, there should be some variation over the pleiotropic genes in the genome, there being also some with positive effect on both the traits. Therefore, selection could be differentiated over the genome to avoid undesirable effects in longevity traits while improving the production efficiency. This is something one is going to learn when multiple trait analysis are thoroughly investigated with the dense genome-wide marker information.

Extensions to a Pair of Populations

The introgression of multifactor traits from one population to another should enjoy the powerful genomic tools in making the procedure more precise and diminishing the compromises of receiving undesirable sections of the donor genome. Ødegård et al. [69] showed that genomic selection results in an efficient introgression of desirable QTL alleles from a donor line, as the genome of the donor apart from the QTL could be selected against. Lots of data is obviously needed for separating the beneficial and unattractive genome parts in a candidate exotic breed.

Heterosis or hybrid vigor in crosses has been long observed. Predicting which lines will give good crosses is a hit and miss affair. Simple dominance is sufficient to give crossbreds better performance than either parent provided that both parents are fixed for the dominant allele at some locus at which the other parent is fixed for the recessive one – that is with one parent being Bc/Bc and the other bC/bC, where B and C are the dominant alleles.

Several breeding procedures have been suggested and used in order to make best use of the *heterosis*, among them the reciprocal recurrent selection, proposed by Comstock et al. [70] makes the most use of quantitative genetic principles. The benefits from crossbreeding are highest with widely deviating allele frequencies between the breeds. There is a need for efficient methods with immediate returns to evaluate the most promising breed crosses jointly with the most potential mating pairs.

Starting from the results by Smith and Mäki-Tanila [6], theory and methods to compute genotypic means and covariances in a two-breed population under dominance inheritance have been presented by Lo et al. [71]. They showed that the genotypic mean is a linear function of 5 location parameters and that the genotypic covariance between relatives is a linear function of 25 dispersion parameters. These would include the additive (and the corresponding heritability) and dominance variance in both the purebred populations and the variation of contributions from the breeds to the F_1 individuals. Clearly simpler and more parsimonious methods are needed.

Genomic research has proven to be a powerful approach in quantifying the genetic distances between populations, in revealing history of animal populations, number and sites for domestication, population expansions and contractions, selection, origin, and mixing of maternal and paternal lineages (see [72]). Because *heterosis* is proportional to the differences in gene frequencies in the parental lines, it is possible to make marker-based prediction of hybrid performance based on genetic distances, despite having

only indirect estimates of allele frequencies for the interesting traits *via* the anonymous markers.

Xu [73] stimulated by the elegance of genomic selection has extended a Bayesian analysis to the F_2 population of inbred lines and has successfully also estimated the dominance deviations. However, the cases starting from random breeding populations – in subdivided population or in crossbred animals, typical in animal breeding – need research. Toro and Varona [74] have investigated the use of genomic information in predicting also dominance effects and the advantages of designing matings to have a full advantage of the extra component in the evaluation. First of all, the genomic approach was possible compared to the overcomplicated polygenic parameterization. Secondly, the prediction of additive effects had a higher accuracy. Finally, the immediate response was higher when dominance effects were estimated, although the subsequent progress stayed very much the same. If the cost of genotyping is reasonable, the estimation of dominance effects could be seen as a new tool in utilizing *heterosis* in chicken and pig production where crosses of different lines are a norm.

Research on Beneficial and Harmful Genes

Along the use of genome-wide marker sets in large reference populations, it is possible to map medium to large size QTL. This would yield genomic predictions that are stable across families and generations. If the genes underlying QTL are found, they may be further studied for the pleiotropic effects on other traits, dominance effects, interactions with other QTL (epistasis), or response to environmental changes. Information derived from such studies will lead to better models and better predictions and even management of phenotypes, which can be used for selection and production planning.

There are several Mendelian defects identified in farm animals. Recessive disorders are a problem in efficient improvement schemes, because healthy carriers can spread the disease allele quickly to a large number of progeny. A good example is BLAD (bovine leukocyte adhesion deficiency) causing a severe immunodeficiency. The mutation got widely distributed in the Holstein cattle due to a famous bull few decades ago. The missense mutation is now identified [75] and the eradication program has been successful. Charlier et al. [76] reported fine-scale mapping of five recessive disorders in cattle using large SNP panel. Between 25,000 and 50,000 SNPs were used in the discovery populations. Homozygosity mapping is used to detect mutations that cause disease when both copies are present (recessivity). Three disorders were mapped with a sufficient resolution so that the molecular basis could be characterized and effective eradication tools were established and used in mating planning. A prerequisite for finding recessive disorders is a well-organized recording of defects and diseases in the population. In general, molecular genetic techniques could be used to develop diagnostic tests. On the other hand the disorders are providing animal models to study human diseases.

Future Directions

The conventional prediction methods based on *infinitesimal model* have produced very impressive results in quantitative traits of animal production. There is, however, plenty of evidence on the existence of major genes mediation the variation in such measured traits. For some time now, it has been possible to map such genes in the genome using molecular genetic markers. The accurate localization is needed for estimating the gene effects and integrating their direct selection into methods predicting the polygenic effects. There has been extensive genome screenings for QTL carried out all the farm animal species, either with crossbreeding or half-sib design. The outcome is thousands of QTL while the high-resolution localization has yielded only very few causal mutations underlying the found QTL. Also the variation contributed by these QTL is far too low for efficient marker- or gene-assisted selection. The molecular genetic technology has in the mean time taken further leaps and now there are available microarray chips containing thousands or even hundreds of thousands of SNPs to allow genomic selection. Genomic selection is in principle genome-wide *marker-assisted selection*. As it covers all the genetic variation in the genome, the estimated of marker effects would give sufficiently reliable predictions of genetic values for young animals. Hence, the genetic improvements programs could be accelerated and high savings could be done in testing schemes. Genomic information could be further used for management of genetic

variation, mating planning utilizing non-additive variation, understanding genetic correlation architecture, etc. The animal breeding industry has quickly adopted the new technology and is now widely exploiting the latest SNP panels in the selection schemes. As a side product, the systematic genome-wide screening is picking up harmful and beneficial mutations for further research and applications. It is very tempting and certainly very challenging to try to model the variation via complicated pathways and interactions due to individual genes and regulatory factors. No doubt many would try. Luckily animal breeding research has a long and flourishing history of sophisticated mathematics and statistics. Hence, much research will be devoted to the area. The main test for a new method in animal breeding would consist of questions like: how it is going to help us in understanding variation, how would it help to improve prediction of breeding value, what gains are made in efficiency of selection programs, what kind of savings could be made in testing, etc. Finally, to have firm ground in analyses and decision making, there is a continuous need to have lots of information, both on the genomes and the measurable traits.

Glossary

Aquaculture Following the definition of the FAO [1, 2], *aquaculture* is the farming of aquatic organisms, including fish, molluscs, crustaceans, and aquatic plants with some sort of intervention in the rearing process to enhance production, such as regular stocking, feeding, and protection from predators. Specifically, *marine aquaculture*, also called *mariculture*, concentrates on aquatic organisms cultivated in brackish or marine environments.

Integrated Coastal Zone Management (ICZM) A process for the management of the coast using an integrated approach, regarding all aspects of the coastal zone, including geographical and political boundaries, in an attempt to achieve sustainability. The EU Commission [3] defines ICZM as a dynamic, multidisciplinary, and iterative process to promote sustainable management of coastal zones. It covers the full cycle of information collection, planning (in its broadest sense), decision making, management, and monitoring of implementation. ICZM uses the informed participation and cooperation of all stakeholders to assess the societal goals in a given coastal area, and to take actions towards meeting these objectives. ICZM seeks, over the long term, to balance environmental, economic, social, cultural, and recreational objectives, all within the limits set by the natural dynamics.

Mariculture See "aquaculture".

Offshore aquaculture A culture operation in a frequently hostile open ocean environment exposed to all kinds of sea states as well as being placed far off the coast.

Offshore co-management A dynamic partnership using the capacities and interests of different stakeholder groups for managing cross-sectoral activities in cooperation with governmental authorities in the open sea.

Offshore wind farms A group of wind turbines in the same confined area used for production of electric power in the open ocean. Moving off the coast to the offshore, wind turbines are less obtrusive than turbines on land, as their apparent size and noise is mitigated by distance. Since water has less surface roughness than land (especially in deeper waters), the average wind speed is usually considerably higher over the open water. Therefore, the capacity factors are considerably higher than for onshore and nearshore locations [4].

Open ocean aquaculture See "Offshore aquaculture".

Definition of the Subject

"Fisheries have rarely been sustainable." This statement by Pauly et al. [5] was based on the recognition that this lack of sustainability was induced by a serial depletion of wild stocks worldwide. Causative for this trend is due to the improved fishing technology, geographical expansion, and exploitation of previously spurned species lower in the food web. In exchange, aquaculture was often either regarded to bridge the gap between supply and demand or, in contrast, even to exacerbate this scenario.

Since the 1970s, aquaculture production has grown quite rapidly and is by now one of the fastest growing

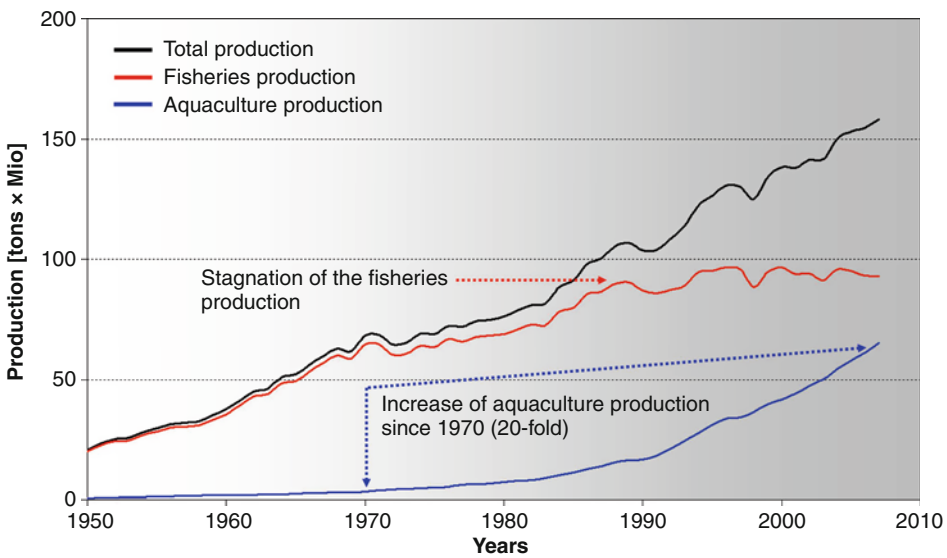
aquatic food production sectors in the world [6]. Besides the rapid development of this sector, the wide-ranging decline in fisheries yields has been enhanced by an increase in public demand for aquatic products. With an annual share of more than 15% of total animal protein supplies, the production of captured fisheries and aquaculture plays a significant role in the global food security [6]. In 2007, approximately 160 million tons of aquatic organisms were produced worldwide (Fig. 1). From that, the share of global aquaculture production amounts to almost 47%, totaling about 60 million tons annually of aquatic organisms [7, 10]. A wide range of aquatic species is raised in various systems, onshore as well as in the ocean. According to the FAO [6], approximately 300 different species, ranging from fish to shellfish, crustaceans and algae are produced in aquaculture systems. Most of these aquaculture enterprises are concentrated in well-protected and therefore favorable inshore water areas [11].

Even probably though over-reporting its aquaculture production [12], the People's Republic of China has contributed approximately 70% to the world's aquaculture production in 2004. It is nevertheless debatable, whether this production can compensate for the global deficiency in aquatic food. In addition, the intensive traditional aquaculture of carnivorous species does not automatically relieve pressure on ocean fisheries [13]. Salmon farming, e.g., requires large inputs of wild fish as fish oil and fish meal for the production of fish feed for aquaculture. Hence, the farming of non-carnivorous species that is not dependent on fishmeal-based feeds is considered a sustainable way of producing food. However, the global increase in production originates from herbivorous species. Further, the balance between carnivorous and non-carnivorous species in aquaculture production is heavily skewed towards herbivorous species [14].

On top of this issue, an increasing limitation of favorable coastal sites for the development of modern aquaculture is evident in various countries, such as Germany, the Netherlands, Belgium, as well as others [15]. This spatial limitation is mainly caused by the lack of protected nearshore areas and by the fact that regulatory frameworks that assign specific areas for aquaculture operations are diverse and still emerging.

Further, the utilizations of coastal marine waters are manifold and quite competitive, such as shipping (trade or private), recreational activities, extraction or



Aquaculture and Renewable Energy Systems, Integration of. Figure 1
Global production of aquatic organisms originating from fisheries and aquaculture within the last 55 years (Data source [7], modified after [8, 9])

disposal of gravel, marine missions, fisheries, mariculture, offshore wind farms, cable and pipelines, establishment of nature reserves, and other marine and coastal protected areas. In addition, overlapping use of coastal habitats adds to the increasing pollution of coastal waters in various situations and gives rise to spatial conflicts, thus leaving little room for the expansion of modern coastal aquaculture systems.

This situation in most industrialized countries is often in contrast to the production progress in developing countries. Here, the installation of aquaculture systems benefits from the often weak enforcement of integrated coastal management schemes, which regulate equal access to the coastal resources [16, 17]. Thus, the rise of aquaculture production has specifically taken place in developing countries, especially in Asia, which holds approximately 91.4% of the global production share [10, 18, 19]. In contrast, the number of competing users within offshore regions is relatively low, thus favoring the offshore environment for further commercial development, such as offshore wind farming and open ocean aquaculture. So far, spatial regulations offshore are scarce and clean water can be expected [20]. Thus, there is an enormous economic potential for *extensive marine aquaculture* in offshore areas.

Introduction

Aquaculture has been increasing dramatically in most parts of the world and now accounts for more than 47% of the total global seafood supply [7]. Many people generally assess aquaculture positively as a potential alternative to global fishery resources, which are globally under stress as a result of overfishing. However, it also raises concerns over pollution, disease transmission, and other socio-economic impacts. Almost all efforts to develop marine aquaculture have focused on state jurisdictional waters of the coastal sea, which are generally situated within 3 nautical miles off the shore [21, 22]. With the convergence of environmental and aesthetic concerns, aquaculture, which is already competing for space with other more established and accepted uses, is having an increasingly difficult time expanding in nearshore waters [23]. Therefore, alternative approaches are needed in order to allow the expansion of the marine aquaculture sector to make a meaningful and sustainable contribution to the world's seafood supply.

The political recognition – on a national as well as on EU level – that the implementation of integrated coastal zone management (ICZM) is still fragmentary, acted as incentive to investigate in more detail how this could be overcome [e.g., 24]. This lack was recognized and led to the operation of a EU-Demonstration Programme on Integrated Coastal Zone Management from 1996 to 1999. This Programme was designed around a series of 35 demonstration projects and six thematic studies. In 2002, based on the experiences and outputs of the Demonstration Programme, the EU-Commission adopted a recommendation concerning the implementation of Integrated Coastal Zone Management in Europe (Recommendation of the European Parliament and of the Council, 2002/413/EC). In Germany, this generated a call of the Federal Ministry of Education and Research to the various federal states to develop projects that address ICZM on a regional level. In 2004, the program *Coastal Futures* [25], which tied up various administrative and scientific bodies and the public along the west coast of the State of Schleswig-Holstein, was granted funding. This program focused primarily on two issues: [1] to develop the future of the coast as a living, working, and recreational space for the local population, and [2] to consider the potential contribution of coastal resources to the sustainable development on the national and EU/global level, i.e., by providing regenerative energy by wind power. In order to sustain sufficient open space for future development, the idea of combining offshore wind power generation with other uses, such as aquaculture operations, emerged [26]. Marine aquaculture is a growing enterprise in Germany as well as in the whole of Europe, strongly motivated by the decline of fisheries production and the search for alternative income options for rural peripheral coastal regions.

In order to stimulate multifunctional use of marine space, it was decided to develop a project on a showcase basis, which deals not only with different scientific fields but also with private–public partnerships and the relevant institutional bodies. In the following, an overview on the current state of research undertaken within this focus is provided. Offshore

wind farms will hereby act as a case example for renewable energy systems in the open ocean.

Offshore Aquaculture – A New Addition to Marine Resource Use

Farming in the open ocean has been identified as one potential option for increasing seafood production and has been a focus of international attention for more than a decade. *Offshore aquaculture* or *open ocean aquaculture* are operations in a marine environment fully exposed to all kinds of oceanographic conditions [27] as well as located at least 8 nautical miles off the coast [15] to avoid the many stakeholder conflicts in nearer coastal areas [28]. The procedures and applied techniques for the cultivation of organisms mainly depend on the species; their life cycle determines the phases of cultivation and the location for the grow-out, where market size will be reached. First trials of cultivation were based on *extensive marine aquaculture*, which – in contrast to intensive aquaculture – is a line of production with little impact on the marine environment. These aquaculture operations are characterized by (1) a low degree of control (i.e., environmental control, nutrition, predators, competitors, and disease agents), (2) low initial costs, (3) low level technology, (4) low-production efficiency, and (5) high dependence on local climate and water quality (natural water bodies, such as bays, ponds, embayments) [29]. Mostly, they are regarded as a sustainable line of production.

Moving to the open ocean has been considered as a means for moving away from negative environmental impacts and negative public perception issues in the coastal zone. Favorable features for the transfer to open ocean waters include ample space for expansion and thus reduced conflicts with other user groups, lower exposure to human sources of pollution, the potential to reduce some of the negative environmental impacts of coastal fish farming, and optimal environmental conditions for various marine species through the larger carrying and assimilative capacities. However, this move should not be seen as an "out of sight, out of mind" attitude, as open ocean development will also come under scrutiny by the institutional bodies as well as by a more and more educated public. It is expected that, because of economies of scale, the open ocean farms of tomorrow will be larger than the present nearshore farms. Therefore, higher levels of waste can be generated. Even if greater residual effects occur, deeper waters and lower nutrient baselines are expected to reduce impacts from open ocean operations through wider dispersion plumes of nutrients, as compared to similarly sized nearshore operations. However, there will be a point when open ocean ecosystems will eventually reach their assimilative carrying capacities [30].

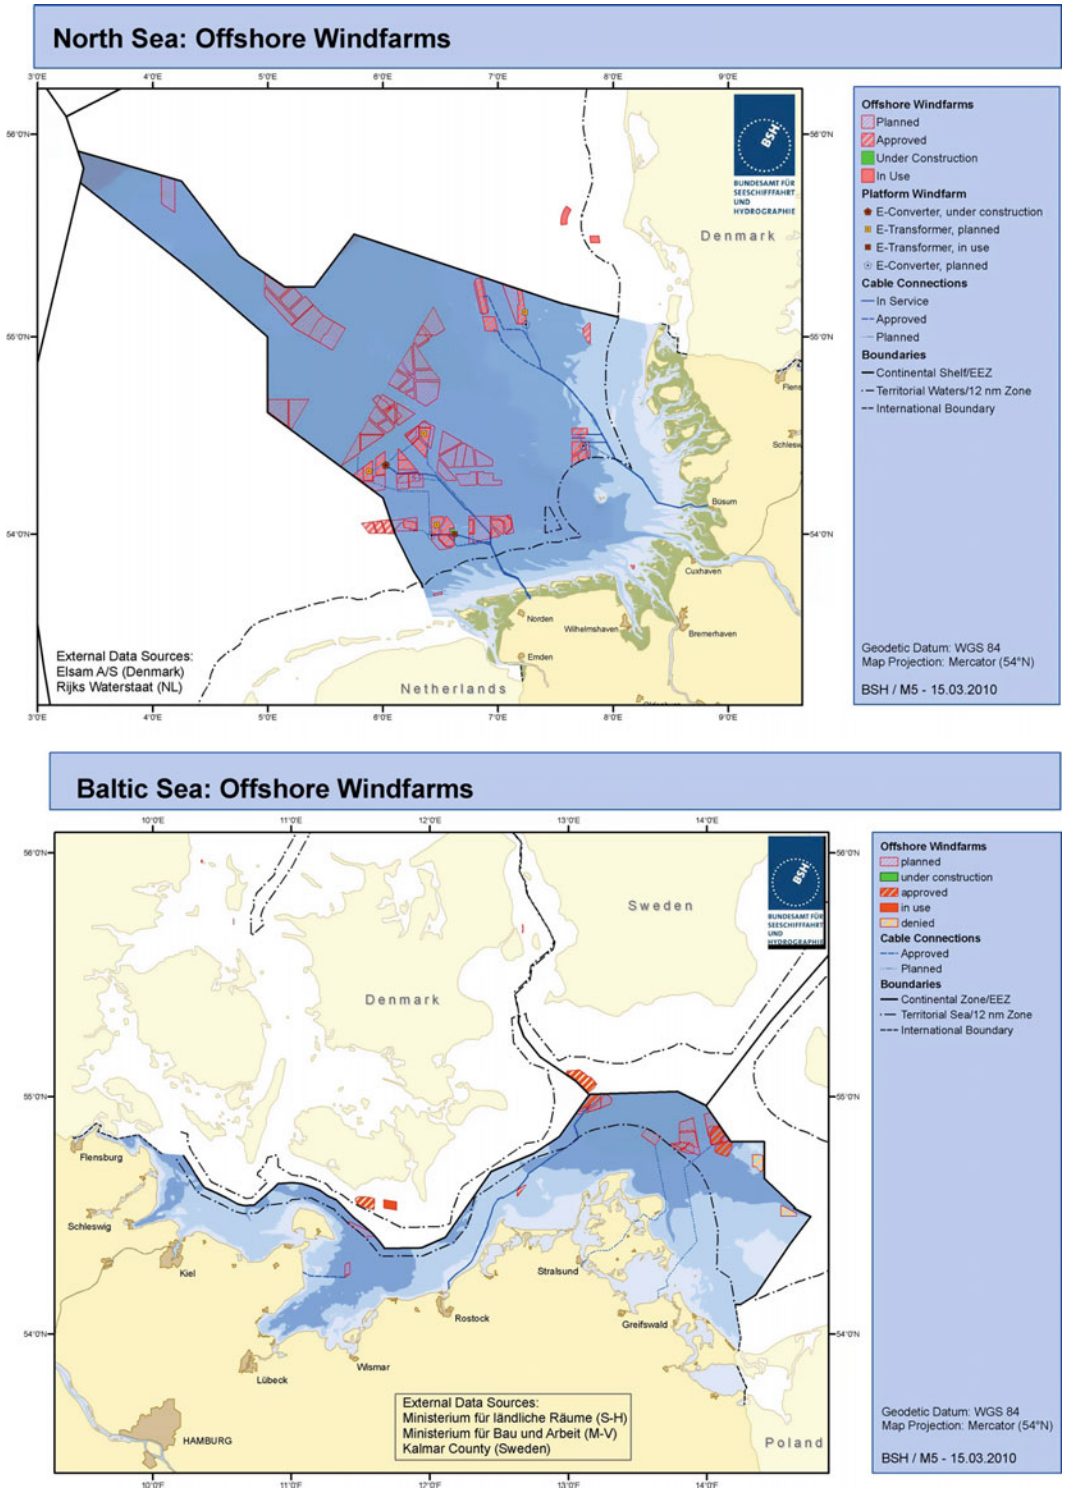
Offshore Wind Farms as a Case Example for Renewable Energy Systems

Wind energy continues to be the world's most dynamically growing energy source [31]. Drawing on the example of Germany, the first initiative toward an economy based on renewable energy resources was set by the governmental decision in the year 2000 to gradually reduce the use of nuclear energy and to respond to the gradually diminishing fossil- and nuclear-energy reserves. Simultaneously, the output of CO_2 to the atmosphere would be reduced in accordance with the Kyoto protocol as well as the dependence on conventional fossil-energy resources is lowered.

As high and reasonably steady wind speeds are characteristic in Northern offshore areas, these areas are prime candidates for renewable energy production by wind-energy farms. For instance in the North Sea, a major political incentive exists currently to install large offshore wind farms [32, 33]. Thus, the emerging branch of offshore wind farms appears as a new stakeholder on the list of users [34, 35].

So far, this development has been successful to such an extent that around 7.2% of the total energy consumption in Germany is covered by this technology. At the end of 2007, Germany had an installed capacity of 22,247 MW, generated by 19,460 mainly land-based operating wind turbines [36]. Within Europe, as the leading market for wind energy with over 57 GW, Germany thus accounted for 39% in terms of the total installed capacity and still remains the world's leader. However, with the North American market currently experiencing a strong growth, it is expected that the US market will soon overtake Germany [37].

At present, 60 project applications for wind farms in the Exclusive Economic Zone (EEZ) of the German



Aquaculture and Renewable Energy Systems, Integration of. Figure 2
Maps indicating all application sites for wind farm projects in Germany. At the top, the North Sea, below the Baltic Sea areas (Modified after [38])

North Sea and in the Baltic Sea are in the planning process stage with the total number of wind turbines per farm ranging between 80 and 500 [26] (Fig. 2). In November 2001, the Federal Maritime and Hydrographic Agency (BSH) granted the first approval for the installation of a pilot offshore wind farm. Since then, a total of 23 wind farm development projects have been approved in German waters, most of them planned seaward of the 12 nautical miles zone [38]. Currently, a larger test farm of about 12 wind turbines (5 MW class) at the "Borkum West" site are in operation (Fig. 3) [39]. Experience gained in this project should give developers practical knowledge in the construction and operation of offshore wind farms at depths (down to 50 m) and at distances from the shore (up to 50 nautical miles and more) that are beyond comparison to those anywhere in the world [31, 33].

In contrast to neighboring European states, the prospect of moving wind energy developments offshore stagnated in Germany for years mainly due to a very complex licensing procedure and the high environmental constraints [33, 40]. A further obstacle roots in the spatial competition of offshore wind farms with other utilization of the marine waters in the German Bight [41, 42]. However, despite the number of competing users within offshore regions being lower compared to coastal areas [43], the quest for spatial efficiency remains to be a key incentive also for offshore developments in the future.

Moving Offshore: The Multiple-Use Concept

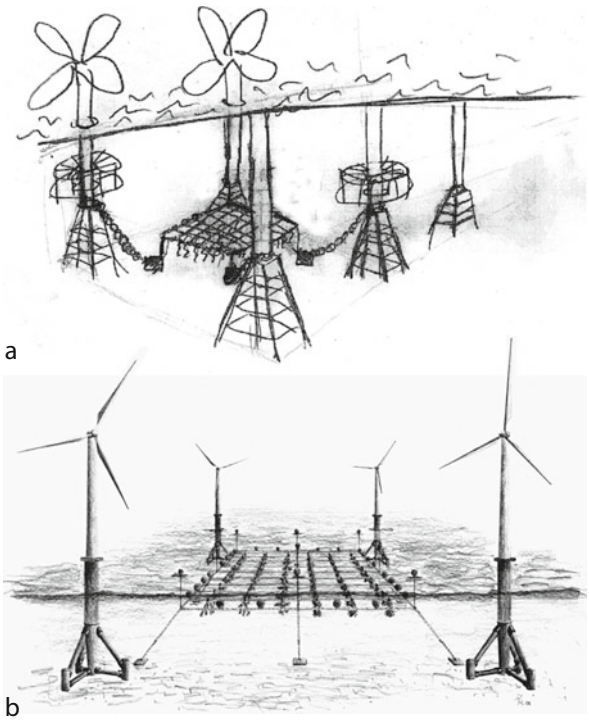
The plans for the massive expansion of wind farms in offshore areas of the North Sea triggered the idea of a combination of wind turbines with installations for extensive shellfish and macroalgae aquaculture [15, 26]. Offshore wind farms provide an appropriately sized area free of shipping traffic as most offshore

Aquaculture and Renewable Energy Systems, Integration of. Figure 3
Offshore wind farm Alpha Ventus. (**a**) Shows the transfer of the windmill tripods to the harbor of Wilhelmshaven and (**b**) displays the setup of an offshore windmill (REpower MI 068 [39])

wind farms are designed as restricted-access areas due to hazard mitigation concerns. Concurrently, the infrastructure for regular service support is readily available, and hence such sites provide an ideal opportunity for devising and implementing a multiple-use concept [42, 44]. However, in contrast to coastal inshore areas where beaches and their adjacent nearshore zones act as buffers to absorb wave energy, offshore regions are high-energy environments, fully exposed to waves, weather, and currents. Numerous studies have demonstrated that waves can reach remarkable heights (up to 10 m) in the offshore areas of the North Sea [e.g., 45, 46]. In this context, the solid foundation structure of wind turbines provides support for anchoring cultivation devices that can withstand the harsh oceanic conditions [47]. Furthermore, offshore structures are well known for their artificial reef function, thus supporting biodiversity in the ecosystem. The offshore water quality, which is a major issue in all kinds of aquaculture operations, is regarded to be excellent in comparison to inshore areas [48, 49]. Finally, the multifunctional use of offshore areas reduces conflicts between stakeholders if activities are concentrated and conjointly managed within so-called multiple-use marine areas. This, in turn, increases the amount of open ocean territory free of utilization by man. All of the above issues are considered as key incentives to move offshore with aquaculture operations.

In view of the many interests for the offshore move, different suggestions for technical structures for open ocean aquaculture were proposed (see proceedings of various OOA-Conferences [e.g. 50, 51]), which could cope with the harsh environmental conditions that place an enormous stress on the employed materials. It would be advantageous for the global offshore aquaculture development to plan for a combination of uses. While windmills use the wind above the surface to produce energy, their fixed pylons, commonly concrete fundaments (gravity foundation), metal jackets, tripods, or triples offer a possibility to connect systems used in aquaculture (Fig. 4). The combination of the respective two industries has to cope with the forces generated by the high-energy environment.

Since 2000, when the co-use of wind farms for off-bottom offshore cultivation [26] in the German Bight was proposed, several studies have been conducted to elucidate the potential as well as constraints of this offshore alternative for extensive aquaculture. Two



Aquaculture and Renewable Energy Systems, Integration of. Figure 4
Potential multifunctional use of fixed underwater structures of wind turbines for the operation of aquaculture facilities: 12 years ago and today (2010). (**a**) First drawing ever for the multi-use concept, including alternative solutions of oyster cages and mussel collectors attached to longlines in the inner section of the wind farm or offshore-rings (collar systems) attached directly to the pylon. The latter system can be submersed in case of wind-turbine maintenance. (**b**) Presents a design of a single mussel plot within a group of four wind turbines (not to scale) (Modified after [52], Buck personal drawing)

pioneer studies, the project *Roter Sand* and *Offshore Aquaculture* were conducted between 2002 and 2004 by the Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany. These two projects followed a complex approach to obtain data about suitable indigenous candidates for the offshore cultivation [15], the technical requirements of longline systems for the cultivation of mussels or oysters [8, 9] and algal cultivation systems [53]. Insights into the feasibility of offshore seed and mussel production concerning larval, nutrient, and phytoplankton concentrations [8, 9, 54] were provided, and the existing legislation and regulations concerning marine aquaculture in Germany were listed [21]. In addition, all stakeholders potentially involved in a multifunctional use of offshore wind farms for aquaculture were identified [42]. This successful multifaceted approach helped to disperse many concerns and doubts on the offshore idea and initiated a sequence of and relations between various following projects, which are displayed in Fig. 5.

Candidates and Techniques for the Multi-Use Concept

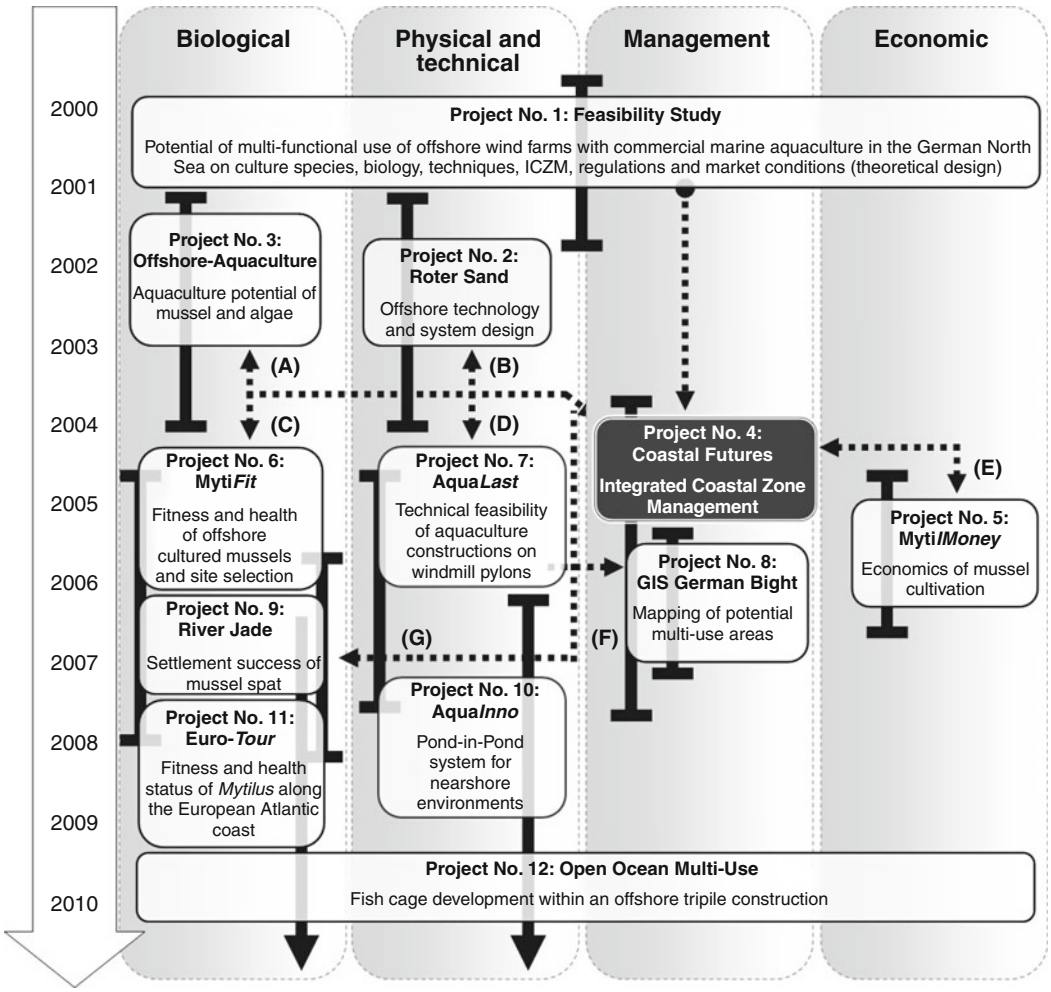
In general, the cultivation process should consider only indigenous species for marine aquaculture operations to avoid the disruption with the local marine flora and fauna. This limits the economic opportunities of marine aquaculture enterprises since in certain sites only a few indigenous candidates are regarded as high-value species. Following a feasibility study by Buck [26], in Germany only culture species with modest service needs can be considered as favorable candidates for offshore aquaculture. In the offshore test trials in Germany, most suitable candidates suggested and tested were the sugar kelp (*Laminaria saccharina*), oarweed (*L. digitata*), dulse (*Palmaria palmata*), the blue mussel (*Mytilus edulis*), and two oyster species, the Pacific oyster (*Crassostrea gigas*) and the European flat oyster (*Ostrea edulis*). Mussels and seaweeds, for example, are cultured mainly in extensive systems throughout the world [8, 56, 57]; the latter occurs for historical and traditional reasons mostly in Asian countries.

According to Tseng [58], the cultivation procedure of brown seaweeds can be divided into two separate steps: In step (1), the seedling phase, spores are artificially released from mature sporophytes and seeded on a given substrate (ropes wrapped around plastic frames), where germination of gametophytes, the sexual maturation of male and female gametophytes, and finally, the development of zygotes into juvenile sporophytes takes place. In step (2), the grow-out phase, culture ropes with juvenile sporophytes are transferred to the open sea. In the grow-out phase, the macroalgal sporophytes grow on ropes for one season to a frond length of approximately 2 m.

When natural reproduction of mussels occurs, gametes are released into the water column where fertilization takes place [59]. The larvae undergo all trochophore and veliger stages when settling on a given substrate to start metamorphosis. According to Pulfrich [60] and Walter and Liebezeit [61], this process normally takes place at spring time (larval peak in May) in the German Bight. The cultivation of blue mussels can be divided into two steps: in step (1) the naturally occurring spat collection is achieved by deploying artificial substrates [62]. Usually, spat collectors are made out of unraveled polypropylene lines or sisal ropes, to offer the mussel's post larvae substrate for settlement [56]. After several months (step 2), collectors are retrieved and mussels thinned out and reseeded on ropes to provide space to improve growth and allow fattening [63, 64].

To operate culture phase (2) of both species, macroalgae and bivalves, an appropriate system design, such as suspended longlines or floating ring-structures, have to be deployed and securely moored in order to resist the stress forces of incoming waves and tidal currents, as well as swell. In addition, it was necessary to assess what kind of technical structure supports best the growth of the organisms (e.g., prevention from loss or mortality) while also assessing whether such systems provide reasonable production returns. Finally, potential combinations with offshore wind turbines had to be assessed.

However, currently even candidates requiring a semi-intensive as well as intensive cultivation process



Aquaculture and Renewable Energy Systems, Integration of. Figure 5
Chronological order of conducted and ongoing research projects dealing with the combination of offshore wind farming and open ocean aquaculture. Project No. 1, the feasibility study, constituted the basis for all subsequent research. The *Coastal Futures Project* acts as a key node project to which the other projects either have contributed or by which they have been stimulated because of its transdisciplinary approach. It is visible that: (**a**) calls the wind farm developers' attention to offshore aquaculture; (**b**) and (**c**) include authorities and fishermen into the planning process for site-selection criteria of appropriate aquaculture sites; (**d**) involves offshore engineers and wind farm developers/operators into the technical part of an offshore aquaculture enterprise; (**e**) introduces (mussel) fishermen to the co-management idea and appraises the economics of mussel cultivation; (**f**) supplies authorities with maps and tools to limit regional stakeholder conflicts, (**g**) establishing an inshore reference station to support the data collected offshore, and (**h**) testing the first fish cage mounted within a tripile construction (Modified after [55])

are in the testing phase. Salmon (*Salmo salar*), seabass (*Dicentrarchus labrax*), seabream (*Sparus aurata*), or some flatfish species are discussed for aquaculture in fish cages below windmill platforms at different offshore sites worldwide. Fish will firstly be reared in land-based facilities and will then be transferred as fingerlings to the offshore site and released into the submergible fish cages. After reaching market size, the fish will be harvested and removed to the land and will undergo normal processing procedures.

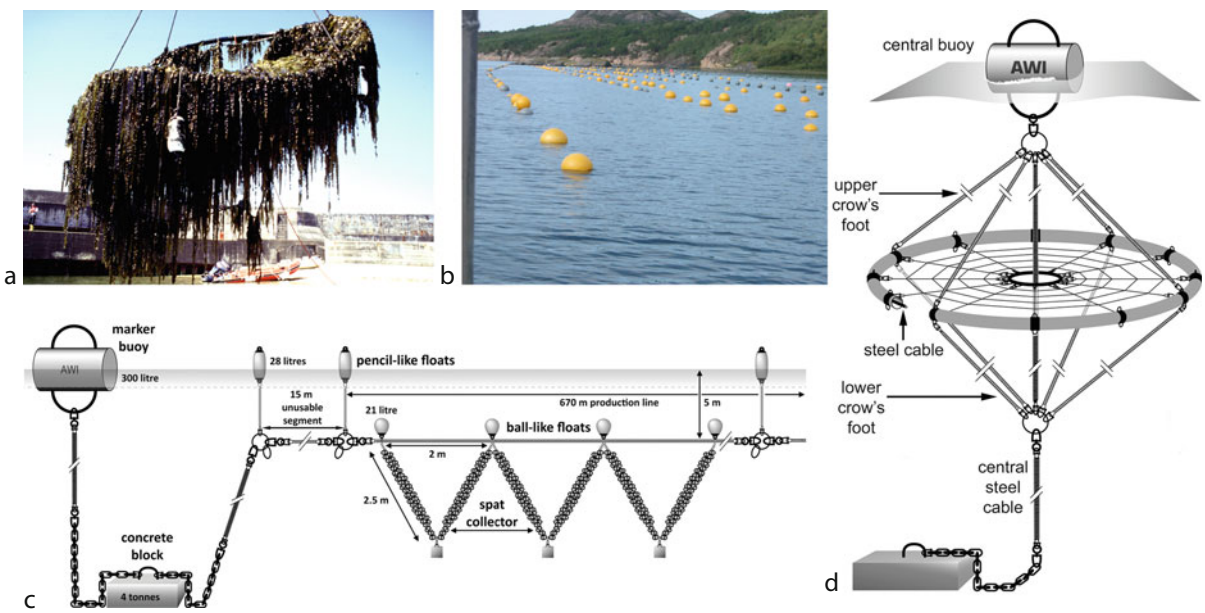
Relocating cultivation systems offshore into high-energy environments requires the development of suitable culture techniques able to withstand the harsh conditions and minimize risk of economic loss [65].

Several techniques exist to cultivate mussels and seaweed either in co-culture or in single culture. Basically, both organisms are cultured in a suspended manner in the water column, floating or submerged. The use of rafts, longlines, and ring methods dominate. The latter two were the main cultivation techniques used in test trials offshore wind farm areas [8, 53, 56] (Fig. 6).

Major difficulties in the development of suitable techniques for open ocean aquaculture are – as mentioned above – the harsh environmental conditions which place an enormous stress on materials. Depending on the acting hydrodynamic forces, different technical setups can be distinguished. One of the interesting possible linkages of aquaculture is the combination with offshore wind farms as these would provide stable fixing structures for the cultivation systems. This is especially relevant from an economic point of view as so far the costly infrastructure for offshore aquaculture systems is one of the major drawbacks in the development.

Status Quo of Offshore Aquaculture Research Activities in Wind Farms

Only a few scientific studies dealing with the prospects of offshore aquaculture were available before 2000, and little was known about the biotechnological requirements, economic potential, or the socio-economic influence on the general feasibility of offshore aquaculture. Very few long-term experiments under harsh hydrodynamic conditions exist, e.g., Langan and Horton for offshore mussel cultivation [66]; Neushul and Harger [67]; Neushul et al. [68] for offshore seaweed cultivation. However, data on system and species performance are urgently needed to derive methodologies for the assessment of its environmental and economic viability. Therefore, the assessment of the potentials and constraints for sustainable aquaculture development in all marine habitats requires input from various scientific disciplines in order to direct this development towards



Aquaculture and Renewable Energy Systems, Integration of. Figure 6
Aquaculture constructions suitable for the cultivation in high-energy environments. (**a**) Offshore ring design for the cultivation of macroalgae (here: harvesting after grow-out in the harbor of Helgoland), (**b**) example of a nearshore, submerged longline design for mussels and oysters, (**c**) schematic drawing of a submerged longline suitable for exposed sites, and (**d**) a technical illustration of the ring design and its mooring system (Modified after [8, 9, 53])

a successful aquaculture undertaking. In particular, this holds true for offshore aquaculture, where little practical experience is available to date, although research in this area is evolving rapidly (e.g., Buck [15], Turner [69]; Pérez et al. [70]; Bridger and Costa-Pearce [51]; Dalton [71]; Naylor and Burke [72]).

The offshore wind farm and aquaculture investigations initiated an integrated assessment of theoretical and practical challenges of aquaculture operations in the North Sea. Several studies were carried out, all of which contributed to specific aspects of such a combined utilization of offshore space. These were:

(a) *Biological studies*, in which the focus was placed on cultivation and subsequent performance characteristics of indigenous bivalve, seaweed, and fish species exposed to extensive offshore aquaculture farming conditions. Further, the health status and infestation rates with parasites, bacteria, and viruses of candidates were determined to gain reliable predictions on where the highest growth rates and best product quality for consumers can be achieved. In nearshore intertidal areas, mussels and oysters are particularly exposed to high concentrations of pollutants, pesticides, near surface agents, estuarine run-offs, etc. that can pose a threat to consumer health. Buck [8, 9, 15] reported high growth rates for mussels cultivated in the German Bight. The scope of growth, i.e., the energy available for growth, is usually directly and positively correlated to a good overall health condition of the respective organism [73]. But organisms with high growth rates and a healthy appearance are no guarantee of a healthy food for human consumers. For instance, in coastal waters, eutrophicated by urban sewage, mussels show good growth performance. The microbial status of these mussels, however, mostly excludes them from consumption since they might carry various human pathogens. Even in developed countries with strict legislation for the treatment of wastewater, mussels can function as carriers of vector diseases. Whether this is also true for offshore cultivated mussels, where the environment is cleaner due to dilution of contaminants, remains open. Data for offshore-produced mussels, generated according to the analysis protocols of controlling authorities, are not readily available for all cultivation sites. However, new regulations are in the implementation process in all of the EU states and will fulfill the prerequisites for an official sampling design and assessment (i.e., sanitary survey).

To evaluate the significance and comparability of the employed parameters in a broader geographical context, the area of investigation was extended along the Atlantic coast from southern Portugal to northern Denmark. Further on, the closely related Mediterranean mussel *Mytilus galloprovincialis* was included in the analysis to test the effectiveness of all the parameters in different species.

Investigations on fish species for submerged cage-systems included aspects on growth, welfare, stress in exposed environments, and health.

(b) *Physical and technical studies* investigated the effects of the prevailing hydrodynamics on candidates and culture constructions at specific offshore sites. At the same time, the necessary technical requirements for farming structures in high-energy environments and their possible combination with offshore wind farms were assessed. New system designs for offshore farming were developed and prototypes (e.g., offshore ring, offshore collector) were tested. Technical details about the microstructure of artificial substrates were addressed to increase production per meter longline under offshore conditions. In addition to offshore seaweed and mussel cultivation, new technologies for submerged fish cages were investigated.

(c) *Management and institutional studies* focussed on the analysis of potential management approaches to implement a multi-use concept of offshore areas. Hereby, the various stakeholders and their respective views and knowledge systems were integrated. Against the background of the social and institutional dimensions, particular emphasis was given to the interrelationship between scientific findings on the one hand and effective implementation on the other. Key aspects included the social acceptance of combined use, as well as the possible management strategies that would govern it. This endorsed the examination of the prevailing case laws and regulative and management framework conditions, as well as a suggestion of decisive offshore co-management strategies to support such activities. In this process, the continuous inclusion of the stakeholders in a participatory manner was

a prerequisite. To address the respective technical, economic, social, and political challenges of mariculture and offshore wind farms, specific co-management strategies were elaborated that are either more results-oriented (e.g., for integrating technical knowledge of the two sectors) or more process-oriented (e.g., for establishing new linkages between different groups). Thus, in cooperation with governmental authorities, co-management in the offshore makes use of the capacities and interests of the respective stakeholder groups and employs these in managing cross-sectoral activities.

(d) *Economic studies* conducted an economic evaluation of such multi-use concepts in offshore locations that take into consideration market conditions as well as investment and operating costs.

All the above listed conceptual approaches relied on results of a theoretical feasibility study (Fig. 5) [26], which was carried out prior to practical research in the field. All of the results contribute to the *Coastal Futures* Program and support the quest to find innovative new approaches for sustainable use and alternative livelihoods of coastal populations.

Overview of Biological and Technical Investigations

Over the last decades, substantial insights have been gained on the terms and conditions active in the offshore environment. However, these data are only partly useful for the selection of offshore aquaculture sites because they have been gathered primarily for other user needs and thus lack the essential specificity to address the biological and cultivable potential of these sites. Prior to a multifunctional development comprising mariculture activities, it is therefore necessary to determine the appropriate biological, technological, and management requirements, as well as the performance characteristics that would allow the employment of favorable and cost-effective methodologies. To meet this end, special focus was placed on the combination of extensive offshore shellfish, seaweed, and fish farming at exposed sites within the proposed offshore wind farm boundaries.

Due to the wide spectrum of open questions, the outcomes are quite manifold. In the following, first results according to their contributions towards the main research topics involved are presented.

Biological Studies The theoretical *Feasibility Study* [13, 24] was aimed to ascertain the biological, technical, and economic feasibility of an offshore marine aquaculture structure with respect to the cultivation of marine organisms within wind farm sites in the German North Sea. One result was that to date, in terms of commercial marine aquaculture, Germany had little knowledge and background in offshore aquaculture compared to many other coastal countries throughout the world. Nevertheless, a synthesis of a selection of parameters (e.g., geophysical and biological parameters) allowed the identification of suitable candidates for commercial offshore aquaculture. These candidates include blue mussels (*Mytilus edulis*) and oysters (*Ostrea edulis*, *Crassostrea gigas*), which could be maintained extensively in the offshore region. Moreover, labor requirement for these candidates as well as for seaweeds, such as the sugar kelp (*Laminaria saccharina*) and dulse (*Palmaria palmata*), is supposed to be low.

Further, the biological feasibility of cultivating mussels, oysters, and kelp within offshore wind farm sites was assessed. The growth of these species is excellent in the rather eutrophicated offshore environments of the North Sea, but can differ depending on exposure sites, system designs, installation modes, and season.

For instance, settlement of young mussels on artificial collector substrates decreases with increasing distance from the shore [74]. However, this does not limit the economic potential if the thinning procedure will be omitted, following a "One-Step-Cultivation" concept [15]. In general it was found that mussels are free of parasites at offshore locations due to dilution effects and the interrupted reproduction cycles of some macroparasites [75]. Special focus was placed on the overall health status of mussels cultured under different conditions, and the impact on economic aspects was investigated [76]. Specific aims of the projects were the development of suitable offshore spat collecting techniques, detailed knowledge about parasites (macro and micro), bacteria and virus infestations at different sites, implementation of biodiagnostic techniques for the health analysis of cultured mussels, and collection of all relevant data (e.g., shell stability and attachment strength of mussels), for the further processing of mussels as a product for human consumption.

Hydrodynamic forces support length increase of seaweed blades when transferring young sporophytes to sea. These algae will adapt to the occurring loads and develop strong holdfasts, preventing detachment of the entire plant [77].

Modified and improved techniques for offshore farming withstand high-energy environments, but will certainly cause higher investment costs. Therefore, site-selecting criteria for a culture area should be clearly identified to assess economic risks. Important for the cultivation success is the water quality. The analysis of the cultured organisms with biodiagnostic tools provides detailed insights into the water conditions the animals live in. By this approach, reliable predictions are possible as to which locations grant highest growth rates and best product quality for consumers. Preliminary results attest offshore areas satisfying settlement success and excellent growth rates [78], and low infestations with macroparasites [79], microparasites, bacteria, and toxins [76]. The results on consumption suitability show that water quality regarding the concentrations of pollutants in offshore areas of the German Bight is quite good. Lysosomal membrane stability is mostly relatively low at all tested nearshore and offshore sites. Interestingly, growth rates of the hanging cultivated mussels are not affected by this low fitness parameter [58].

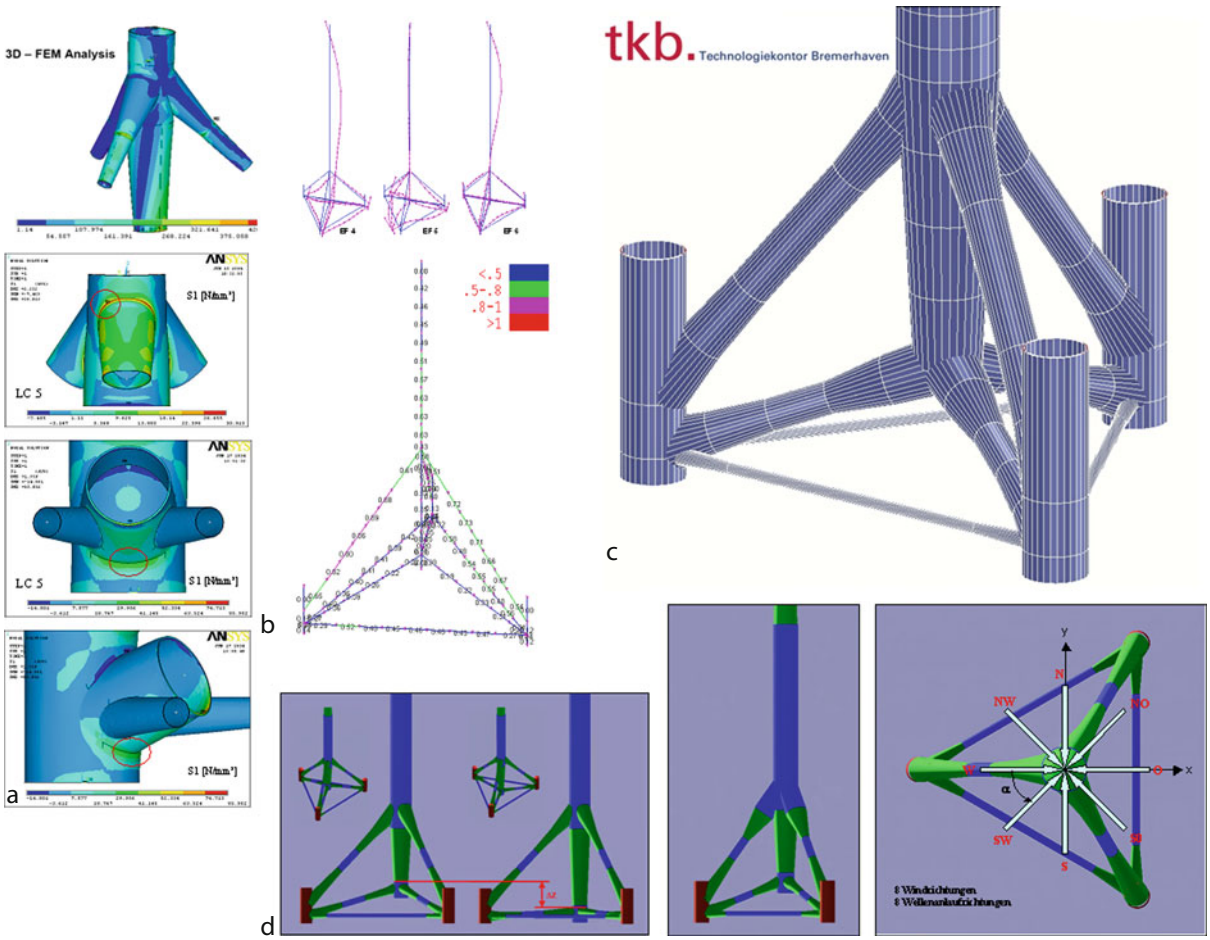
First results on investigations along the Atlantic Coast show that mussels originating from offshore habitats have a better health status regarding the infestation with macroparasites and microparasites (Buck and Brenner, unpublished data). While macroparasites are still infesting mussels in nearshore areas in the Wadden Sea (the Netherlands, Germany, Denmark), microparasites are absent.

Physical and Technical Studies The results above allowed the identification of two offshore aquaculture systems that were best suited for offshore operations from a biological point of view. Depending on the acting hydrodynamic properties, different technical setups are regarded as favorable. The first one is a floating and submergible ring system for the cultivation of seaweed. It withstands rough weather conditions and allows easy handling [53]. The second system is a submerged longline design for blue-mussel culture [8]. The longline should ideally be installed 5 m below the water surface and should be connected to foundations of offshore windmills (Fig. 7) [47]. For the longline, polypropylene proved to be an appropriate material. The system design is made of various connected segments allowing an easy harvest and replacement of all parts of the construction. However, more technical engineering research is required to find the most cost-effective mode of construction and the best choice of materials (e.g., little corrosion, longevity in spite of mechanical stress) so that easy handling can be guaranteed under relatively harsh weather conditions (cf. construction, deployment, retrieval, service, repairs).

The experimental design also allowed work on such issues as the efficiency of the collecting devices themselves. Healthy mussels will reach market size in offshore conditions only if they are firmly attached to their artificial substrate. As mussels growing on suspended substrates need about 15 months [8, 9] on average to reach market size, they must survive one winter and withstand storm events producing wave heights up to several meters. Continuing investigations on the health and quality of market-sized mussels would be moot if mussels failed to stay attached to substrate gear.

To date, most available substrates are designed and deployed for nearshore use under calm water condition. However, it was found that improvement for construction of new collectors that are feasible for offshore cultivation is in mandate. Research showed that new substrates should have felt-like structures around the core of a collector for larval attraction and long appendices in high density to interweave the mussel conglomerates with the substrate [80]. Future investigations should focus further on the fabrication and testing of a prototype of this collector, concerning the results of this study. Besides providing optimal larval attraction and attachment for juvenile mussels even under winter conditions, any new substrate should proof its durability under conditions of a daily farming routine. This would include mechanical thinning, harvesting processes, and tests on the reusability of the material.

The technical realization and the implications of aquaculture technical requirements on design and construction of the grounding construction of offshore wind turbines were considered. So far, modeling and experimental validation of a submerged 50 m longline aquaculture construction mounted between two steel piles, 17 nautical miles off the coast, show significant



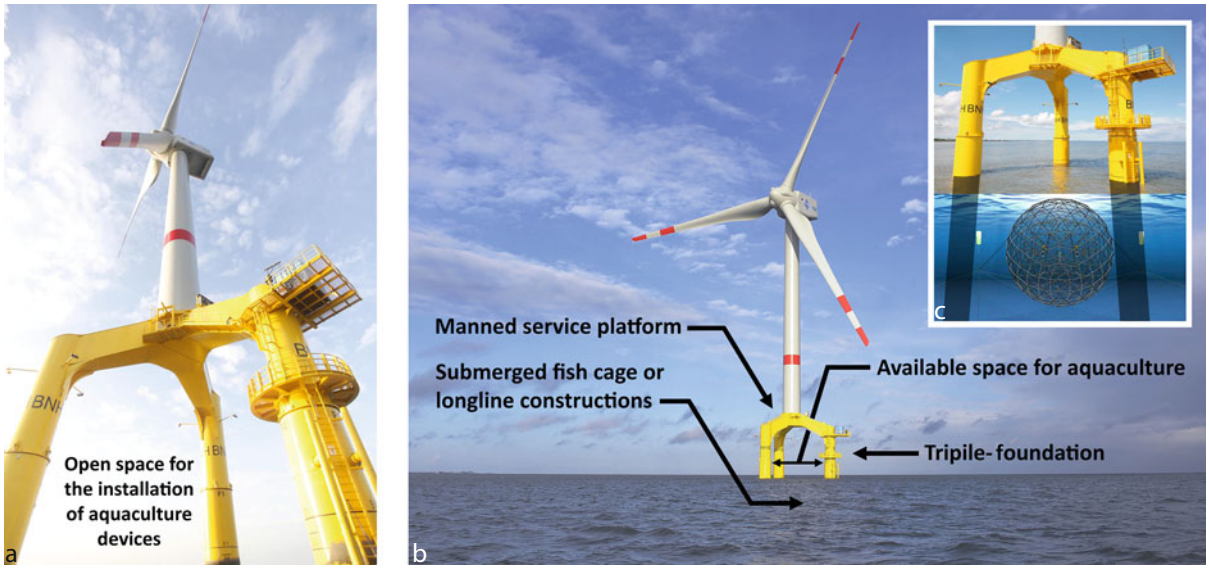
Aquaculture and Renewable Energy Systems, Integration of. Figure 7
Modeling of potential attachment points for the combination of longline connections to a tripod foundation. (**a**) Displays alternative connection points, (**b**) shows the generation of representative loads on the wind-energy installation, including vibrations, (**c**) shows the respective tripod foundation for offshore use in depths of about 20–50 m, and (**d**) shows the development of a static model (3–5 MW class) [47]

forces of up to 90 kN (equivalent to 9 t) induced by waves of up to 1.8 m significant wave height and tidal currents of up to 1.0 m/s [81]. Given the high-energy environment in the North Sea and the non-linear relationship between water movement and its resulting forces, even higher mechanical loads are to be expected within the life cycle of such an arrangement. These must be taken into account when developing techniques for larger-scale offshore cultivation within wind farms.

Finally, a new cage design project has been initiated, where it will be investigated whether aquaculture of fish in between a tripile construction below a windmill has the potential to enlarge the diversity of candidates to be grown offshore (next to bivalve and seaweed) as well as widening the potential of offshore farming within wind farms. First insights are shown in Fig. 8 [82, 83].

Management and Institutional Considerations

From a spatial planning perspective, the ocean space in the Exclusive Economic Zones (EEZ) cannot be considered any more as "commons" in the sense of Ostrom et al. [84] wherein individuals or groups have the right to freely consume and return any kind of resources.



Aquaculture and Renewable Energy Systems, Integration of. Figure 8
Tripile construction for the secondary use for fish cages. (**a**) Shows the open space within a tripile foundation to be used for aquaculture purposes, (**b**) displays a lateral view of the Bard Windmill and the access to the fish cage, and (**c**) is a photo animation and gives an idea how a fish farm, such as an aquapod, could be moored below [82, 83]

As a matter of fact, the "tragedy of the commons" situation Hardin described in 1968 [85], has already been reached for most of the oceans today. Offshore waters are in a process of transition, revealing diverse and heterogenic interests in marine resources. For instance, the development of offshore renewable-energy systems is an international priority driven by the need to reduce the dependence on fossil fuels and decrease human impacts on the global climate regime. Simultaneously, the demand for high-quality seafood is accelerating globally. This leads to an increased complexity and thus to limitations in developing and managing the different and often spatially overlapping maritime activities independently of one another. The upcoming new utilization patterns of the German North Sea, such as wind farms, but also Marine Protected Areas (MPAs) reported to the EU commission in Brussels for the "European Natura 2000 network," reveal a trend toward the development of permanent constructs. Both are examples for new forms of use with a high spatial demand [86]. Not all uses are compatible with each other and user conflicts with existing activities, such as fisheries, maritime traffic, or military missions are preordained. The planned large-scale offshore wind farms as well as designated MPAs are prime examples for the development of lasting marine structures that take up a surface area of several square kilometers each [55].

At the same time, the increasing demand for high-quality foods worldwide accelerates the development of marine aquaculture. This potential newcomer can be expected to become an additional competitor in offshore waters [87], contributing to the increase in spatial competition and complexity in the ocean [20]. Conflicts among the respective user groups are inevitable. The growing competition for space represents a major challenge for further developing or even maintaining all forms of marine aquaculture, as well as freshwater fish farming. However, area choice is crucial and spatial planning has a key role to play in providing guidance and reliable data for the location of an economic activity, giving certainty to investors, avoiding conflicts, and finding synergies between activities and environments with the ultimate aim of sustainable development [88]. The inclusion of all stakeholders in this process to find synergies in the open ocean is crucial.

Ongoing multidisciplinary social-science research in Europe shows that it is feasible to establish spatially

efficient and effective wind farm–mariculture co-management regimes. A window-of-opportunity has opened as both groups have realized that they may benefit through the integration of operation and maintenance (O&M) activities vis á vis gaining support in collaborative action by the current impetus of the new EU Maritime Policy. The operation and maintenance of any offshore installation is a major challenge due to restricted logistics and accessibility, forming a large part of the overall costs. A five-to-ten time more expensive scale of operation and more difficult logistics for maintenance and/or harvesting compared to nearshore or onshore sites have to be taken into account [89–91]. Experiences with existing wind farms and mariculture sites off the coast show that work at the sea is not only significantly more cost-intensive, but also more time consuming than on land [92].

There are certain rights and duties involved if prospective spatial and organizational interaction of O&M activities of offshore wind turbines and mariculture installations are to be combined [20]. Different values, perspectives, and demands of the stakeholder groups need to be harmonized [93]. So far, disagreements on the distribution of entitlements to benefits and profits between the different stakeholder groups can be observed (Table 1). The two potential adopters of such a multi-use scheme illuminate different sets of skills and capacities in terms of offers, needs, and constraints characteristics. These are vital resources, which provide the basis for forming any sustainable offshore

Aquaculture and Renewable Energy Systems, Integration of. Table 1 Offers, needs, and constraints characteristics of mariculture operators and offshore wind farmers concerning O&M activities. Interrelated aspects between the two actor groups are indicated in bold (modified after [86])

Characteristics	Actor groups	
	Wind farmers	Mariculture operators
		Offers	• Fixed offshore infrastructure • Logistic platform • Financial support (EEG amendment)	• Upgradeable sea-going vessels • Offshore mentality • Offshore skills and experience
Needs	• Specialization of equipment (construction vs hire; "marinization" of onshore equipment) • Specialization of personnel • Sea-going vessels • Service demands (man-hours) • Suitable O&M pattern (corrective vs preventive maintenance) • Suitable O&M pattern (opportunity vs periodic maintenance)	• Specialization of equipment (construction vs alteration of existing oil industry/fishery vessels) • Specialization of personnel • Fixed offshore infrastructure • Technical and logistic support • Service demands (man-hours) • Offshore skills and experience • Offshore mentality
Constraints	• Operation costs • Technical challenges • Distance to farm site • Available working days (estimated 100/year) • Difficult logistics for O&M • Reliability of offshore wind turbines	• Access to farm site (uncertain regulatory and permit requirements) • Distance to farm site • Available working days (estimated 30–100/year) • Difficult logistics for maintenance and harvesting • Reliability of culturing devices

co-management arrangements [85]. Hereby, a fair negotiation and bargaining process is the most essential component to effectively orchestrate co-management of offshore wind farmers and future mariculture operators, such as mussel harvesters. The latter already dispose vital skills and experiences for working in the open sea. Still, working methods have to be adjusted to the offshore culture production mode.

If such an offshore co-management is considered as a network activity between private actors, such as wind farmers or mariculture operators/fishermen and public authorities, one of its basic characteristics is the fact that a third party can coordinate the activities of formally separated parties [94]. Ways and means have to be developed that balance the respective interests of dominant and politically supported wind farming participants with small-scale entrepreneurial mariculturists. The key question is how institutional arrangements could act as "boundary organizations" [95] in an offshore co-management process. Such a process is more likely to develop and succeed if an interface management that acts as moderator, disclosing the interests of the actor groups and offering possibilities for concerted action, guides it. With respect to the decision-making arrangements at the three levels (operational level, organizational level, and legislative level), the interface management would thus help to determine the rules for interaction among the actor groups and state authorities at the organizational level. Besides, it would facilitate organizing and decision making of the day-to-day activities at the operational level. However, to authorize and legitimize new co-management arrangements for interacting offshore O&M activities, new policies must be developed or existing laws amended. Following a dynamic process of forming new institutional structures, the establishment of a communication arena may (a) support a common understanding of the entire co-management process, (b) provide the overall framing for an improved communication among the participating actor groups, (c) increase the level of trust among the actor groups, and (d) promote sustainability and efficiency in times of scarcity of spatial resources [85]. However, top–down induced management schemes by, e.g., the national government, hold a high potential for failure. Involving the relevant actors improves the social acceptability of innovative concepts and their applicability [96]. Consequently, it appears that for developing and implementing a wind farm–mariculture multiple-use concept, co-management, such as that described by Carlsson and Berkes [94], should ideally be carried out with the participation of different actors that typically try to find ways to learn from their actions and adapt the behavior to the consequences of their own and other's actions. This must be supported by the relevant authorities at all levels and must find its way into the legislative framework at the EU and national level.

On EU level, the issue of access to space for maritime activities, including aquaculture, has been recognized in several communications over the past years, e.g., in 2007 pertaining to the Integrated Maritime [97] Policy or in 2009 concerning a new impetus for sustainable aquaculture in Europe. In the latter, all Member States are asked to develop marine spatial planning systems, in which they fully recognize the strategic importance of aquaculture. This Strategy also aims at providing EU leadership and guidance to both stakeholders and administrations to ensure consistency and clarity in designing the necessary policies for the future sustainable development of European aquaculture. In this context, a partnership between public authorities and interested parties at EU, national, and local level play a crucial role.

Hence, European aquaculture should benefit from an improved framework for governance; however, it is stressed that the national authorities have a primary role in shaping aquaculture development in their territory. While in some countries aquaculture is defined and regulated under the agricultural laws, in other countries regulations are dispersed, and consequently the responsibilities are in the hand of several agencies with no clearly defined lead agency. So far, a number of important challenges that limit the development of European aquaculture directly depend on policies and actions taken at national or regional level. A bottom–up approach is therefore needed so that the public authorities can establish an appropriate framework for the vision of multiple-use of offshore areas to become operational. A participatory approach contributes to lifting bottlenecks in national legislation. This framework needs to be transparent, consistent and cost-effective in order to allow the industry to realize its potential. Unless these and other regulative issues pertaining to multi-use offshore conditions remain unresolved, an

establishment of offshore co-management arrangements may be very difficult. Still, the current lack of legislation in the EEZ holds the potential to implement concerted innovative concepts of offshore constructions and thereon-interacting activities.

However, several restrictions are still needed to be resolved. Questions pertaining to access rights within the wind farm area have to be deciphered. So far, approved offshore wind farm territories in, e.g., the German EEZ, are designated as restricted area, prohibiting any kind of public access [98, 99]. However, conveying access rights to a second party is inevitable if wind farm O&M is performed by a commissioned subcontractor and not by the licensee itself. In a wind farm–mariculture multiple-use arena, the same access and user rights have to be guaranteed to a mariculture operator who enters the territory for purposes not related to wind farming but for maintaining culturing devices and harvesting procedures. In this case, precise positioning of aquaculture installations within the wind farm territory as well as access lanes for both parties have to be specified.

In addition, the question of harmonizing the tenure or duration of a lease for offshore resources has to be tackled. If there is, i.e., significant discrepancy in the length of lease tenures between the two uses to be combined, the resource users may not be inclined to create long-term co-management arrangements. Furthermore, cooperative management structures also benefit if the leasing process was combined and/or effectively coordinated, since it facilitates, i.e., integrating O&M within a co-management scheme once the projects are operational.

Yet, in order to define the functional structure of such a co-management regime in detail, reliable outcomes on economic and technical integration prospects of a joint wind farm–mariculture venture have to be produced. The latter is a major research demand, which was voiced by most of the interview partners along the North Sea coast so far [93]. Cumulative impacts of different economic sectors, such as offshore wind farms and mariculture need to be addressed, which provides an opportunity to create synergies between different industrial sectors prior to their installation.

Outcome of Economic Studies

The *Feasibility Study* [13, 24] provided a general overview on market prices, market demands, classification of candidate species as high-value products, and the cost of some infrastructure. The study showed possible market value of offshore aquaculture products in comparison to the performance of existing conventionally operated farms in coastal waters.

Basic data for offshore mussel cultivation in close vicinity to a designated offshore wind farm in the open sea of the German Bight were compiled. It contained different case-scenario calculations to illustrate the impact of changing parameter values on overall profitability or non-profitability of this activity. Primary focus was placed on the production of consumer mussels, but seed mussel cultivation is also taken into consideration. This study concluded with providing some recommendations on how favorable terms or actions could further improve profitability of offshore mussel cultivation. Results intended to shed some light on business management topics that future offshore mariculture operators should follow in order to be efficient [100].

Nontheless, the economics of a joint offshore wind farm–mariculture utilization scheme still remain to be evaluated in more detail.

Future Directions

By setting higher value on an inclusion of stakeholder knowledge and opinions, the initiation of the *Coastal Futures Project* resulted in a stronger focus on the practicability of multifunctional use of offshore areas. It can be shown that such innovative new concepts are highly complex and interdependent. First, results indicate that secure technical and economic feasibility appears to be a basic prerequisite to assure that both offshore wind farm operators and aquaculturists will support the multi-use concept, especially as far as the management of joint activities is concerned.

This suggests that as soon as technical and economic aspects are evaluated in more detail, it is important to initialize a comprehensive communication program to provide information to the key public and private actor groups (stakeholders). Furthermore, effective and continuous participation of all stakeholders on all levels from the very beginning of the multi-use approach must be ensured. This supports the orchestration of scientific and local user knowledge in an overall approach to combine different offshore uses. In addition, it contributes to adding a joint wind farm–mariculture venture to their future portfolio.

More detailed data are needed to calculate the economic potentials and risks of a co-used wind farm area for the production of seafood. Apart from the principal feasibility of an area as an aquaculture site, growth rates and product quality must be predictable. First, results on blue mussels from test areas show that highest product qualities can be expected from testing areas offshore. A proven product quality ensures higher market prizes, should compensate for higher investment costs for the culture systems, and help to install a functioning offshore aquaculture system in the German Bight.

Generall, science for open ocean aquaculture needs a transformative moment. It seems necessary to learn the skills to interact constructively with different scientific disciplines and different stakeholders. This will require a new science for managed marine seascapes [101]. Creating a system biology paradigm in ecosystem science and aquaculture will require a multidisciplinary input, with scientific interactions not just at the margins of each discipline, but focused collaboratively on the realization of a vision of multifunctional, spatially effective, and sustainable use of ocean space. This will require new kinds of scientists (with new kinds of career structures) who are trained to work in multidisciplinary teams. The need for such training is now widely recognized and is reflected in the emerging curricula's of many new MSc courses.

It is mandatory to discover what to do, at what scale, in what modality – engineering, farming, legislation, social organization, economic initiatives, etc. – and how to do it. Since the activities in the ocean realm are concerted in integration, future activities must also be integrated over all these modalities.

Aquaculture, Ecological

Barry A. Costa-Pierce
University of New England, Marine Science Center, Biddeford, ME, USA

Article Outline

Glossary

Biofloc A mixture of detritus, bacteria, and other microscopic organisms that aggregates in flocs, which are used for controlling water quality and enhancing the delivery of natural foods to omnivorous species in aquaculture.

Ecosystem An area of the natural environment in which the structure and functions of the physical (rocks, soil, etc.) and natural (all living organisms) environments are considered together in interacting food webs.

Escapees The unintended releases of cultured organisms from captivity into the wild.

Polyculture The practice of making compatible the culture of multiple species in the same physical space by stocking or planting organisms having different food, spatial, or temporal niches.

Resilience The ability of a natural or aquaculture system to absorb abrupt changes or disturbances without collapsing. A resilient aquaculture ecosystem can withstand physical and economic shocks and rebuild itself.

Stewardship An ethic that engages all affected stakeholders in the cooperative planning and management of the environmental quality to prevent degradation and facilitate recovery in the interest of long-term sustainability.

Watershed An area of land where all of the water that is under it or drains off of it goes into the same place.

Definition of Ecological Aquaculture

Ecological aquaculture is an alternative model of aquaculture development that uses ecological principles as the paradigm for the development of aquaculture [1, 2]. Ecological aquaculture plans, designs, develops, monitors, and evaluates aquatic farming ecosystems that preserve and enhance the form and functions of the natural and social environments in which they are situated. Ecological aquaculture farms are integrated "aquaculture ecosystems" designed to deliver both economic and social profit (Fig. 1).

Ecological aquaculture incorporates at the outset – and not as an afterthought – planning for not only the sustainable production of aquatic foods, but also for innovation [3], community development, and the wider social, economic, and environmental contexts of aquaculture at diverse scales, both large and small, and at the commercial, school, and homeowner scales [4, 5]. Ecological aquaculture also uses the "aquaculture toolbox" [6] to play vital roles in non-food, natural ecosystem rehabilitation, reclamation, and enhancement.

Introduction

The roots of ecological aquaculture are in Asia [7, 8]. In this century, however, Asia, especially China, during the period from 1980s to present has chosen the industrial model of aquaculture development, and has dismantled much of its rich ecological aquaculture heritage, and choosing instead to intensify and import vast quantities of feedstuffs. As a result of intensification and the use of imported feeds, freshwater aquaculture yields from China have increased 10X in just 20 years, and comprise the world's largest aquaculture industries [9].

The FAO ecosystems approach to aquaculture [10] creates a new code for global aquaculture development, combining into one common framework the two most

Aquaculture, Ecological. Figure 1
Aquaculture ecosystems mimic the form and functions of natural ecosystems, but are a sophisticated, knowledge-based designed farming ecosystem that are planned as combinations of land and water-based aquatic plant, agronomic, algal, and animal subunits, which are embedded into the larger context of human social systems

important social-ecological trajectories for global aquaculture – aquaculture for the world's rich, and aquaculture for the world's poor. Knowledge of the rich archeology and anthropology of aquaculture connects this FAO code to antiquity, creating a single development pathway for aquaculture throughout human history.

Key Principles

There are seven principles of ecological aquaculture:

1. **Ecological aquaculture systems are "aquaculture ecosystems" that mimic the form and functions of natural ecosystems.**

   Ecological aquaculture farms are designed, farming ecosystems. Sophisticated site planning occurs so that farms "fit with nature" and do not displace or disrupt invaluable natural aquatic ecosystems or conservation areas. If localized displacement or degradation does occur, active support of innovative, collaborative research and development programs for ecosystems redesign, relocation, rehabilitation, and enhancement efforts are initiated and supported by the ecological aquaculture farms throughout the life of their farming operations.
2. **Ecological aquaculture is integrated with communities to maximize not only local but also regional economic and social multiplier effects in order to provide maximal job creation and training, and create "aquaculture communities" that are an essential part of vibrant, working waterfronts.**

   Ecological aquaculture operations export to earn profits but also promote and market products locally to contribute to the development of society. Ecological aquaculture operations are committed to building the "culture" of aquaculture in order that "aquaculture communities" can develop and evolve as a source of innovation, education, and local pride. Aquaculture development as a means of community development can result in numerous, innovative economic and social multiplier effects such as aquaculture restaurants, marketing of "sustainable seafoods" that are branded as local and bioregional, and aquaculture tourism.
3. **Ecological aquaculture results in economic profit by practicing trophic efficiency to ensure that aquaculture is humanity's most efficient protein producer.**

   Non-fed, shellfish and algae culture are preferred choices for ecological aquaculture developments. In fed aquaculture, fish meals/oils are not used as either the major protein or energy sources, but are included in animal diets to solve issues of diet palatability only; and, if used, fish meals and oils originate from certified, sustainable fishmeal/oil fisheries only. Fed aquaculture ecosystems rely on protein and oil sources from agricultural sources and seafood processing wastes, and include science innovations such as the development of detrital food webs ("bioflocs") to feed cultured, aquatic organisms.
4. **Ecological aquaculture results in social profit by integrating aquaculture developments into global fisheries, food, and poverty alleviation programs.**

   Ecological aquaculture is part of the global movement to eliminate extreme hunger and

starvation (Millennium Development Goal #1) by being a part of comprehensive plans for sustainable fisheries for poverty alleviation. Ecological aquaculture uses alternative feeds to support programs to deliver more of the world's feed fisheries (sardines, anchovies, mackerels, etc.) away from aquaculture to the world's poor.

5. **Ecological aquaculture practices nutrient management by using ecosystems design, reuse, and recycling, and does not discharge any nutrient or chemical pollution causing irreversible damage to natural aquatic or terrestrial ecosystems.**

   No harmful metals, chemicals, or pharmaceuticals potentially harmful to long-term human or ecosystem health are used in the ecological aquaculture production processes. Ecological aquaculture farms have "sustainability strategic and implementation plans" in place to develop comprehensive, full cycle reuse, and recycling systems for all farming operations.

6. **Ecological aquaculture uses native species/strains, and does not contribute to "biological" pollution.**

   Escapees from aquaculture, especially aquarium operations, have severely impacted aquatic ecosystems worldwide. Exotics species/strains can be good choices only if long-term monitoring data and scientific research indicate that exotic species are unlikely to establish; if exotic species are widely established and provide economic and social profit without irreversible environmental harm; or, the use of native species puts at risk indigenous genetic diversity. Ecological aquaculture operations ensure that innovative engineering and complete escapement technologies are used; that control and recovery procedures are in place; that active research and development programs provide alternatives and new options; and that complete, transparent, public documentation and information are available.

7. **Ecological aquaculture is a global partner, producing information for the world, avoiding the proprietary.**

   Ecological aquaculture farms are aquaculture ecosystems that go beyond "meeting the regulations." They are sites of collaboration, leadership development, and innovation. They are outstanding community citizens and models of stewardship [4]. Successful leadership development triggers developments of innovation and more efficient aquaculture-related technology, and more ecologically appropriate legislation and regulations.

The FAO Ecological Approach to Aquaculture (EAA)

In 2006, the Fisheries and Aquaculture Department of Food and Agriculture Organization (FAO) recognized the need to develop an ecosystem-based management approach to aquaculture similar to the Code of Conduct for Responsible Fisheries. FAO [10] suggested that an ecological approach to aquaculture (EAA) would have three main objectives: human well-being, ecological well-being, and the ability to achieve both via effective governance, within a hierarchical framework that was scalable at the farm, regional, and global levels.

In 2008, FAO defined an EAA as: A strategy for the integration of the activity within the wider ecosystem such that it promotes sustainable development, equity, and resilience of interlinked social-ecological systems. An ecosystem approach to aquaculture, similar to other systems approaches to management, accounts for a complete range of stakeholders, spheres of influences, and other interlinked processes. Applying an ecosystem-based approach must plan for physical, ecological, social, and economic systems as a part of community development, taking into account stakeholders in the wider social, economic, and environmental contexts of aquaculture [10]. FAO developed three principles and key issues at different scales of society:

Principle 1: Aquaculture development and management should take account of the full range of ecosystem functions and services, and should not threaten the sustained delivery of these to society.

The key issue is to estimate ***resilience capacity***, or the limits to "acceptable environmental change." A range of terms has been used to estimate the limits to environmental change, including "environmental carrying capacity," "environmental capacity," "limits to ecosystem function," "ecosystem health," "ecosystem integrity," "fully functioning ecosystems," all of which are subject to a specific social/cultural/political context [11]. Conventional

environmental impact assessments touch on just some of these issues. Application of the precautionary approach is important but inadequate in aquaculture; use of aquaculture risk assessment is becoming widespread [12].

Principle 2: Aquaculture should improve human well-being and equity for all relevant stakeholders.

Aquaculture should provide equal opportunities for development, which requires its benefits to be more widely shared especially locally so that it does not bring detriment to any sector of society, especially the poor. Aquaculture should promote both food security and safety as key components of human well-being.

Principle 3: Aquaculture should be developed in the context of other sectors, policies, and goals.

Interactions between aquaculture and its influences on the surrounding natural and social environment must be recognized. Aquaculture often has a smaller impact than other human activities, e.g., agriculture and industry, but it does not take place in isolation. There are many opportunities to couple aquaculture activities with other primary producing sectors in order to promote materials and energy recycling, and the better use of resources in general.

Applying an Ecological Aquaculture Approach at Different Scales of Society

There are three physical scales important in the planning for and assessment progress toward an ecosystem approach to aquaculture: farm scale, watershed/aquaculture zone, and global. Each of these has important planning and assessment needs.

Farm Scale

Planning for aquaculture farms is easily defined physically and could be few meters beyond the boundaries of farming structures; however, the increasing size and intensity of some farms (e.g., large-scale shrimp farming or salmon farming) could affect an entire water body or watershed. Assessment of an EAA at the farm scale entails an evaluation of planning and implementation of "triple bottom line" programs – ecological, economic, and social programs – that in a comprehensive manner account for impacts to the wider ecosystem and social impacts of farm-level aquaculture developments, including use of better ("best") management practices, and use of restoration, remediation, and mitigation methods. Proper site selection, levels of production intensity, use of species (exotic vs. native), use of appropriate farming systems technologies, and knowledge of economic and social impacts at the farm level should be considered.

For fed aquaculture, there are many concerns as the current trajectory and growth of the large-scale aquaculture industries. Current aquaculture development models are being modified rapidly by advances that will affect the widespread adoption of ecological aquaculture, which, if projected to 2050, confirm that large-scale aquaculture may move fully toward ecological aquaculture approaches (Table 1). There are a growing number of well-documented success stories in ecological aquaculture (Table 2).

Watershed/Aquaculture Zone Scale

Planning for an EAA at watersheds/aquaculture scale is relevant to common ecosystem and social issues such as diseases, trade in seed and feeds, climatic and landscape conditions, urban/rural development, etc. Assessment of an EAA at this scale is a two-phase process and will include, at phase I, assessments of

1. Inclusion of aquaculture as a part of regional governance frameworks, e.g., the overall framework of integrated coastal zone management or integrated watershed, land-water resource management planning, and implementation. Assessments take into account existing scenarios, user competition, and conflicts for land and water uses, and comparisons of alternatives for human development.
2. Impacts of aquaculture on regional issues such as escapees, disease transmission, and sources of contamination to/from aquaculture.
3. Social considerations such as comprehensive planning for all of the possible beneficial multiplier effects of aquaculture on jobs and the regional economy, and considerations of aquaculture's impacts on indigenous communities.

At phase II, progress toward a full implementation of an EAA at watersheds/aquaculture zone scale can be assessed by measuring the

Aquaculture, Ecological. Table 1 Major issues with fed aquaculture today (2010) and projections of these to 2050

Issues	Concerns	Modern developments (2010)	Trajectory of issues to 2050
Feeds/no net gain	Schroeder [28] documents pond can be a net consumer rather than a producer of animal protein. Fishing down and farming up marine food webs (Naylor et al. [29]; Pauly [30])	Food conversion rates improve to ~1:1; fish in/out (FIFO) ratios drop to ~1.7; domestication of farmed species turns carnivores into domesticated omnivores	FIFO ratios drop to 1 or less; aquaculture uses ~50% of world's fish meal and oil with balance met by agricultural meals/oils
Feeds/ocean sustainability	Integrity of marine ecosystems damaged by high removal rates of feed species	Aquaculture use dropping due to rapid cost increases in meals/oils; poverty/social concerns recognized	Ecosystem modeling parcels out science-based removal rates/allocations for aquaculture and ecosystems
Feeds/poverty	Massive poverty and hunger in fish meal/oil producing countries	New recognition in Peru; new international attention to role of meal/oil fisheries & fed aquaculture in poverty alleviation	Governments move to develop food products/prioritize human needs
Habitat destruction	Mangrove destruction and water diversions disrupt nearshore and riverine ecosystems (Macintosh and Phillips [31]; Pullin et al. [32]	Some nations (ex. Thailand) develop policies to prevent damage by proper siting and to rehabilitate damage of shrimp farms	Governments worldwide ban developments in sensitive conservation areas; widespread use of carrying capacity models (McKindsey et al. [33]) and ecological valuation for decision-making
Eutrophication	Intensive aquaculture operations are feedlots producing nutrient pollution loads comparable to human sewage (Folke et al. [21]; Costa-Pierce [34])	Complete feeds, automated feed delivery systems, and nutrition research deliver less pollution; wastes are primarily in the form of soluble nutrients and feces, not waste feeds	Development of land-based recirculating systems; widespread use of land-based integrated aquaculture and water-based IMTA systems
Energy	Intensive aquaculture operations are energy intensive comparable to industrial agriculture and fisheries (Weatherly and Cogger [35])	Scattered R&D in energy use, mostly Life Cycle Analyzes in aquaculture; little/no movement toward use of renewables	Renewable energy systems used

1. Abilities of governments to implement new methods of coastal and water governance to include ecological aquaculture
2. Development of ecological aquaculture approaches that allow agencies responsible for permitting aquaculture to consider and manage activities impacting aquaculture and aquatic ecosystems (e.g., capture fisheries, coastal zone development, watershed management organizations, agriculture, forestry, and industrial developments) more holistically, such as new mechanisms to communicate, cooperate, and collaborate across sectors
3. Design of ecological aquaculture management zones and parks that encourage aquaculture education, research, and development innovations and partnerships, and also emphasize streamlined permitting of integrated aquaculture, polyculture, or innovative, integrated aquaculture–fisheries businesses and initiatives

Global Scale

Planning for an EAA at a global scale considers aspects of transnational and multinational issues for global commodities (e.g., salmon and shrimp). Assessment

Aquaculture, Ecological. Table 2 Global success stories in ecological aquaculture

Region/countries	Aquaculture ecosystems	References
Asia (China, Vietnam, Indonesia)	Rice-fish culture benefits millions of rural people; rice-fish aquaculture ecosystems have been designated as a "Globally important Agricultural Heritage System" (GIAHS)	FAO [9]; Dela Cruz et al. [36]
Asia (China, Thailand, Cambodia, Vietnam, Indonesia)	Integrated aquaculture benefits millions of rural people	Edwards [8]
Asia (China)	Integrated Multi-trophic Aquaculture (IMTA) of fish, shellfish, and seaweeds bioremediates and increases total yields up to 50%	Zhou et al. [37]
Egypt	Integrated aquaculture produced over 650,000 tons of tilapia in 2008, ~60% of total fish production; provision of cheap source of fish at approx. same cost as poultry	McGrath [38]
Canada	IMTA has been adopted by Cooke Aquaculture, the largest salmon aquaculture company in eastern Canada	Chopin et al. [39]; Chopin [40]; Ridler et al. [41, 42]
Canada & USA	Shellfish aquaculture has become widely accepted as environmentally friendly and socially acceptable	National Academy [43, 44]
Tanzania	Seaweed and shellfish aquaculture	Seaweed grown by ~2,000 producers most women; new half-pearl industry growing

of progress toward an EAA at the global level entails evaluation of issues such as: availabilities of fisheries and agriculture feedstocks for formulating aquaculture feeds and impacts on distant marine and social ecosystems, the economic and social impacts of aquaculture on fisheries and agriculture resources, impacts of aquaculture on markets, and impacts of globalization on social sustainability (social capital, goods, and social opportunities). Applications of tools such as lifecycle assessments of aquaculture commodities and the use of innovative social enterprise management guidelines and tools are useful to determine impacts at the global scale.

Social Ecology of Aquaculture

Many analysts are calling for more integrated, multidisciplinary ways of developing ecologically and socially responsible food, energy, water, and waste systems to meet society's needs [13]. Among the first was Lubchenco [14] who called for a new social contract for science and society. Industrial aquaculture in its current development phase does not have a social contract or social license to expand in many areas of the world, especially at the watershed/aquaculture zone and global scales.

Just as important are social investments in aquaculture at the individual level. Aquaculture has an urgent need for developing and engaging leaders who are well trained and experienced decision-makers who are "honest brokers of policy alternatives" [15]. Keen et al. [16] believe transformation toward more sustainable practices will be much more likely if the individuals who make up society can accept change and modify their personal behaviors [17]. Changes in the behavior of individuals can "scope up" and result in larger changes at the community and societal scales by employing a combination of trust-building, favorable performance, accountability, flexibility and innovation, and the inclusion of stakeholders in strategic planning [18, 19].

Folke et al. [20] challenge our education system to continually adapt to the emergence of such new questions and changing social compacts as aquaculture. Any rapid progress toward an ecological approach to aquaculture will require development of education programs that promote broad awareness, recognition, and implications of new approaches to aquaculture, and the creation of new institutions. Bransford et al. [22] suggest that for such subfields of sustainability science as aquaculture more attention needs to be given to educating the next generation of leaders by teaching metacognitive skills such as practicing different ways of thinking in a variety of contexts, with less emphasis being placed on trying to fill students with a large volume of facts and knowledge.

An Ecological Aquaculture Strategy for the "Triple Bottom Line"

Aquaculture development plans will be incomplete unless both economic and social goals are articulated, and agreed upon, at the outset, in transparent, participatory processes. Only then can aquaculture can "evolve" as an integral part of – not separate from – farmers, fishermen, sustainable community development, and the future of "working waterfronts." Aquaculture's success cannot simply be defined as having successfully developed the hatchery, feed, and marketing components of a business plan – the old alignment of the "seed, feed, and the need." Rather, sustainable, ecological aquaculture nurtures "society's success" for the "triple bottom line" of economic, environmental, and social profit [23].

Adversarial social processes occur in jurisdictions where aquaculture is not being developed using a social-ecological "ecosystem approach." In these places, the blue revolution is being televised, tweeted, and blogged. Adversarial processes (conflicts) occur when stakeholders do not recognize each other's interests as legitimate. These processes increase conflict; thrive on uncertainty; have poor communication; are exclusive, divisive, opaque, and closed, and lack trust. Collaborative processes must be created that create trust through shared learning and ownership, creative problem solving, joint fact finding, and employ adaptive management. Robertson and Hull [24] call this a "public ecology" that has both process and content that emphasizes the participation of extended peer communities of research specialists, policy-makers, and concerned citizens. Dasgupta and Maler [25] have used tools developed by economists and ecologists to valuate choices in the midst of this complexity. In general, since aquaculture is such a dynamic, evolutionary field, managers, policy-makers, and community leaders need to participate to allow understanding of new and emerging problems and to stimulate multidisciplinary research; as analysts report that such work is the highest impact science being published today [26].

Clear, unambiguous linkages between aquaculture and the environment must be created and fostered, and the complementary roles of aquaculture in contributing to environmental sustainability, rehabilitation, and enhancement must be developed and clearly articulated to a highly concerned, increasingly educated, and involved public. New aquaculture operations must plan, at the outset, to:

1. Become an integral part of a community and a region.
2. Plan for community development by working with leaders to provide needed inputs and recycle wastes.
3. Create a diversity of unprocessed and value-added products, and provide local market access, since in rich societies, aquaculture products are high-value discretionary purchases that can easily be rejected by the public.
4. Plan for job creation and environmental enhancement on both local and regional scales.

It is well documented that most aquaculture jobs are not directly in production, rather in the affiliated service industries. In the USA, Dicks et al. [27] found that aquaculture production accounted for just 8% of the income and ~16,500 jobs. Aquaculture goods and services accounted for 92% of the income and ~165,500 jobs (most jobs were in equipment, supplies, feeds, fertilizers, transport, storage, processing). However, most aquaculture development plans focus almost exclusively on production concerns and have little/no comprehensive plans for localization of seed, feed, markets, or other aquaculture service industries that produce the most benefits to local economies – to say nothing about employing local professionals (most industrial aquaculture operations import high paying professionals from the outside). In the vast majority of

cases, feed and services are imported to sites, and local people cannot even buy the produce!

An ecological aquaculture development model will create new opportunities for a wider group of professionals to get involved in aquaculture since new advances will be needed not only in technology but also in information, community development, and facilitation. Ecological aquaculture as a "new" field, and one that is important for the future food security and environment of the planet, requires the much more comprehensive planning in order to evolve a new social contract with society.

Future Directions

By 2030, fed aquaculture will turn from the ocean to land-based agriculture to provide its feeds and oils. As such, more sophisticated, ecologically designed and integrated aquaculture systems will become more widespread because they better fit the social-ecological context of both rich and poor countries. Ecological aquaculture provides the basis for developing a new social contract for aquaculture that is inclusive of all stakeholders and decision-makers in fisheries, agriculture, ecosystems conservation, and restoration.

The wildly optimistic scenarios for aquaculture's expansion will not occur unless alternative ecological approaches and ecological intensification of aquaculture are widely adopted. Aquaculture needs to be better integrated into overall fishery societal plans for securing sustainable seafood supplies and restoring damaged, supporting fisheries ecosystems.

The overuse and degraded state of nearly all of the world's aquatic ecosystems, combined with public concerns about adding any "new" uses or sources of aquatic pollution to already overburdened natural and human systems, require aquaculture to develop ecosystems approaches; sustainable operating procedures; and to articulate a sustainable, ecological pedagogy. The fact that an ecological aquaculture approach can ensure aquaculture is a net gain to humanity; and it could be the key organizing paradigm to form a new social contract for aquaculture worldwide.

The massive globalization of seafood trade has meant less dependence on local natural and social ecosystems, and has resulted in some virulent opposition to aquaculture development, especially as industrial aquaculture has removed the local sources of production and markets, and jobs have been externalized. One major consequence of this globalization has been the increased dependence of industrial, "fed" aquaculture on the southeastern Pacific Ocean marine ecosystem for fish meals and oils. The global implications for the Humboldt ecosystem, for local poverty, and the scoping of this unsustainable situation to the entire global protein food infrastructure are profound, and are still largely unrealized.

Aquaculture sites are not only economic engines of primary production that meet the regulations of a society, but can be sites of innovation and pride if they can be well designed as community-based, aquaculture farming ecosystems. A review of the progress toward such an ecosystems approach to aquaculture is necessary to inspire planners and environmental decision-makers at many societal scales (national, regional, local) to make use of such innovative approaches. Sophisticated site planning of aquaculture can occur so that farms "fit with nature" and do not displace or disrupt invaluable natural, aquatic ecosystems, or conservation areas; but contribute to the local economy and society [5].

An ecological aquaculture approach to comprehensive planning for aquaculture at many different scales will integrate aquaculture into plans for not only environmental benefit and the restoration of coastal ecosystems, but also local market developments and the future of coastal communities. As such, ecological aquaculture can move aquaculture beyond endless user conflicts, and could stabilize the regulatory environment and ensure a more equitable process of eco-social design of aquaculture for the future.

Article Outline

Glossary

Biomitigative services provided by extractive aquaculture The environmental, economic, and societal services and benefits received by ecosystems – in their broad definition which includes humans who depend on them – from the conditions and processes of cultivated species, such as seaweeds extracting inorganic nutrients and suspension- and deposit-feeders extracting organic particles recaptured from the activities of fed aquaculture (e.g., fish or shrimp aquaculture), to maintain their health. Biomitigative services can also be provided by natural populations of similar organisms.

Integrated multi-trophic aquaculture (IMTA) The farming, in proximity, of aquaculture species from different trophic levels, and with complementary ecosystem functions, in a way that allows one species' uneaten feed and wastes, nutrients, and by-products to be recaptured and converted into fertilizer, feed, and energy for the other crops, and to take advantage of synergistic interactions between species. Farmers combine fed aquaculture (e.g., finfish or shrimps) with extractive aquaculture, which utilizes the inorganic (e.g., seaweeds or other aquatic vegetation) and organic (e.g., suspension- and deposit-feeders) excess nutrients from fed aquaculture for their growth. The aim is to ecologically engineer balanced systems for environmental sustainability (biomitigative services for improved ecosystem health), economic stability (improved output, lower costs, product diversification, risk reduction, and job creation in disadvantaged communities) and societal acceptability (better management practices, improved regulatory governance, and appreciation of differentiated and safe products).

Definition of the Subject

Fulfilling aquaculture's growth potential requires responsible technologies and practices. Sustainable aquaculture should be ecologically efficient, environmentally benign, product-diversified, profitable, and societally beneficial. Integrated multi-trophic aquaculture (IMTA) has the potential to achieve these objectives by cultivating fed species (e.g., finfish or shrimps fed sustainable commercial diets) with extractive species, which utilize the inorganic (e.g., seaweeds or other aquatic vegetation) and organic (e.g., suspension- and deposit-feeders) excess nutrients from fed aquaculture for their growth. Thus, extractive aquaculture produces valuable biomass, while simultaneously rendering biomitigative services for the surrounding ecosystem and humans. Through IMTA, some of the uneaten feed and wastes, nutrients, and by-products, considered "lost" from the fed component, are recaptured and converted into harvestable and healthy seafood of commercial value, while biomitigation takes place (partial removal of nutrients and CO_2, and supplying of oxygen). In this way, some of the externalities of fed monoculture are internalized, hence increasing the

overall sustainability, profitability, and resilience of aquaculture farms. A major rethinking is needed regarding the definition of an "aquaculture farm" (reinterpreting the notion of site-lease areas) and regarding how it works within an ecosystem, in the context of a broader framework of Integrated Coastal Zone Management (ICZM). The economic values of the environmental/societal services of extractive species should be recognized and accounted for in the evaluation of the true value of these IMTA components. This would create economic incentives to encourage aquaculturists to further develop and implement IMTA. Seaweeds and invertebrates produced in IMTA systems should be considered as candidates for nutrient/carbon trading credits (NTC and CTC) within the broader context of ecosystem goods and services. Long-term planning/zoning promoting biomitigative solutions, such as IMTA, should become an integral part of coastal regulatory and management frameworks.

Introduction: Aquaculture Is Needed But Some Practices Need to Evolve

The global seafood industry is at a crossroads: as capture fisheries stagnate in volume, they are falling increasingly short of a growing world demand for seafood. It is anticipated that by 2030, there will be a 50–80 million ton seafood deficit [1]. This gap will likely not be filled by capture fisheries but by aquaculture operations, which already supply almost 50% of the seafood consumed worldwide [1]. Consequently, it is imperative to design the ecosystem responsible aquaculture practices of tomorrow that maintain the integrity of ecosystems while ensuring the viability of this sector and its key role in food provision, safety, and security.

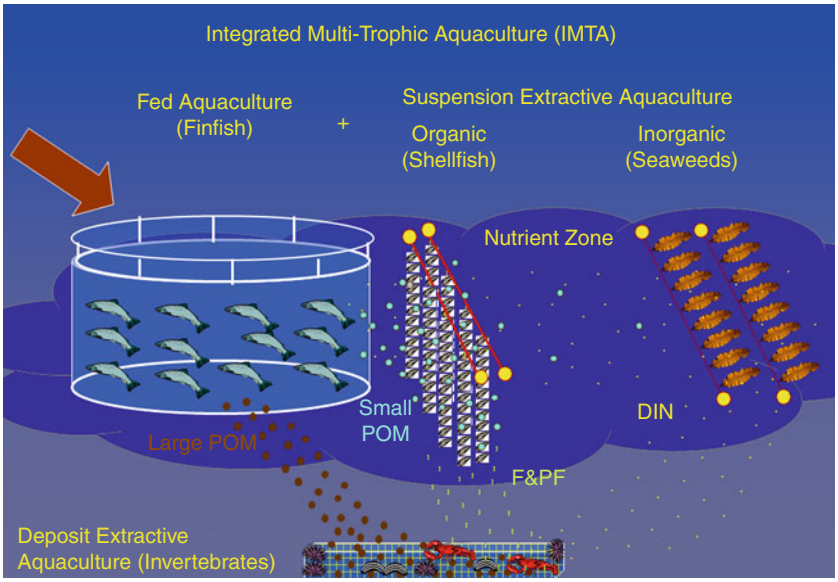
Without a clear recognition of the industry's large-scale dependency and impact on natural ecosystems and traditional societies, the aquaculture industry is unlikely to either develop to its full potential, continue to supplement ocean fisheries, or obtain societal acceptance. The majority of aquaculture production still originates from relatively sustainable extensive and semi-intensive systems [2]; however, the rapid development, throughout the world, of intensive marine fed aquaculture (e.g., carnivorous finfish and shrimp) is associated with concerns about the environmental, economic, and social impacts that these, often monospecific, practices can have, especially where activities are highly geographically concentrated or located in suboptimal sites whose assimilative capacity is poorly understood and, consequently, prone to being exceeded. There are also some concerns with shellfish aquaculture, especially at high density, as shellfish occupy an intermediate trophic level and often play a dual role of organic filtering organisms and waste/nutrient generating organisms [3].

For many marine aquaculture operations, monoculture is, spatially and managerially, often the norm. Species are cultivated independently in different bays or regions. Consequently, the two different types of aquaculture (fed versus extractive) are often geographically separate, rarely balancing each other out at the local or regional scale, and, thus, any potential synergy between the two is lost. To avoid pronounced shifts in coastal processes, the solution to nutrification by fed aquaculture is not dilution, but extraction and conversion of the excess nutrients and energy into other commercial crops produced by extractive aquaculture.

To continue to grow, while developing better management practices, the aquaculture sector needs to develop more innovative, responsible, sustainable, and profitable technologies and practices, which should be ecologically efficient, environmentally benign, product-diversified, and societally beneficial. Maintaining sustainability, not only from an environmental, but also from economic, social, and technical perspectives, has become a key issue, increased by the enhanced awareness of more and more demanding consumers regarding quality, traceability, and production conditions. Integrated multi-trophic aquaculture (IMTA) has the potential to play a role in reaching these objectives by cultivating fed species (e.g., finfish or shrimps fed sustainable commercial diets) with extractive species, which utilize the inorganic (e.g., seaweeds or other aquatic vegetation) and organic (e.g., suspension- and deposit-feeders) excess nutrients from aquaculture for their growth (Fig. 1).

IMTA: A Flexible and Functional Concept

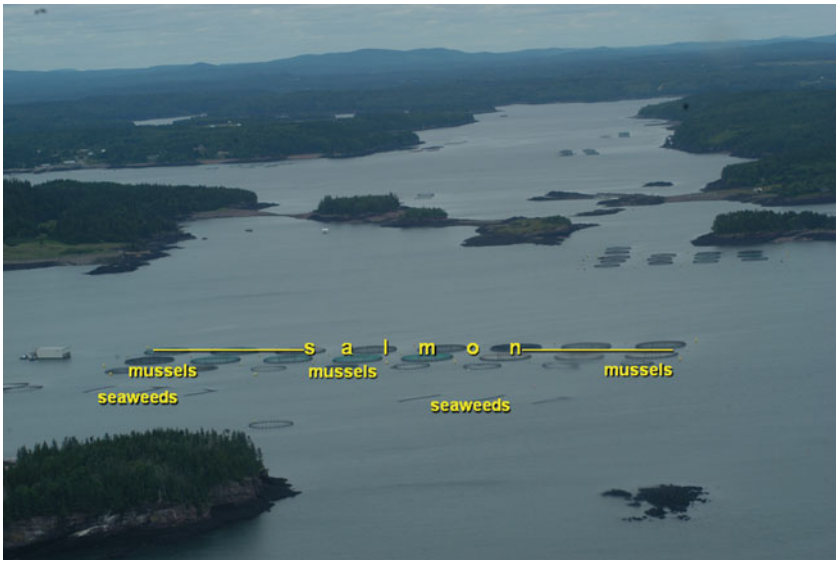
The IMTA concept is extremely flexible [4]. To use a musicology analogy, IMTA is the central/overarching theme on which many variations can be developed according to the environmental, biological, physical,



Aquaculture, Integrated Multi-trophic (IMTA). Figure 1
Conceptual diagram of an Integrated Multi-Trophic Aquaculture (IMTA) operation including the combination of fed aquaculture (e.g., finfish) with suspension organic extractive aquaculture (e.g., shellfish), taking advantage of the enrichment in small particulate organic matter (POM); inorganic extractive aquaculture (e.g., seaweeds), taking advantage of the enrichment in dissolved inorganic nutrients (DIN); and deposit organic extractive aquaculture (e.g., echinoids, holothuroids, and polychaetes), taking advantage of the enrichment in large particulate organic matter (POM) and feces and pseudo-feces (F&PF) from suspension-feeding organisms. The bioturbation on the bottom also regenerates some DIN, which becomes available to the seaweeds

chemical, societal, and economic conditions prevailing in parts of the world where the IMTA systems are operating. It can be applied to open-water or land-based systems, marine or freshwater systems (sometimes called "aquaponics"), and temperate or tropical systems. What is important is that the appropriate organisms are chosen at multiple trophic levels based on the complementary functions they have in the ecosystem, as well as for their economic value or potential. In fact, IMTA is doing nothing other than recreating a simplified, cultivated ecosystem in balance with its surrounding instead of introducing a biomass of a single type one thinks can be cultivated in isolation from everything else. Integration should be understood as cultivation in proximity, not considering absolute distances but connectivity in terms of ecosystemic functionalities.

It should be made clear that in the minds of those who created the acronym "IMTA," it was never conceived to be viewed with the minimalist perspective of only the cultivation of salmon (*Salmo salar*), kelps (*Saccharina latissima* and *Alaria esculenta*), and blue mussels (*Mytilus edulis*) within a few hundred meters: this is only one of the variations (Fig. 2) and the IMTA concept can be extended to very large ecosystems like the Yellow Sea (see below). This also means that IMTA variations include integrated agriculture aquaculture systems (IAAS), integrated sylviculture (mangrove) aquaculture systems (ISiAS), integrated green water aquaculture systems (IGWAS), integrated peri-urban aquaculture systems (IPUAS), integrated fisheries aquaculture systems (IFAS), sustainable ecological aquaculture systems (SEAS), integrated temporal aquaculture systems (ITAS), and integrated sequential aquaculture systems (ISAS, also called partitioned aquaculture systems, PAS, or fractionated aquaculture systems, FAS) [5–7]. There is no ultimate IMTA system to "feed the world." There is not one world but climatic, environmental, biological, physical, chemical, economic, societal, and political conditions,



Aquaculture, Integrated Multi-trophic (IMTA). Figure 2
One of the Integrated Multi-Trophic Aquaculture (IMTA) sites in the Bay of Fundy, New Brunswick, Canada, operated by Cooke Aquaculture Inc.: two rows of salmon cages in the background, then a row of mussel rafts and two seaweed rafts in the foreground

each of which can lead to different choices of systems for feeding these microworlds.

The paradox is that IMTA is not a new concept. Asian countries, which provide more than two thirds of the world's aquaculture production, have been practicing IMTA (often described as a type of "polyculture") for centuries, through trial and error and experimentation. Why, then, is this common sense solution not more widely implemented? The reasons for this generally center around social customs and practices, and market-driven economic models not considering externalities that one is already familiar with, even if common sense tells one that one should modify them. Human society does not change quickly unless there are compelling reasons to do so. What to do when early large profit margins create short-term economic booms, followed within a few decades by dwindling meager profit margins? Often, the temptation is to throw more large volume cultivation operations and destructive methods into the mix, without proper regulations and business plans. Pollution, disease and economic busts generally ensue, major restructuring of the industry becomes necessary, and a few clairvoyant visionaries remain afloat and adapt to jump to the next curve to survive. This evolution is not exclusive to the aquaculture industry. Why do humans have such short and selective memories resulting in them repeating mistakes, regularly?

The fact that humans are currently at a crossroad should motivate them to improve current aquaculture practices, without further delay. Fishery management plans in most countries have been single-species approaches, completely neglecting the interactions between species, not understanding the synergies, or antagonisms, between them and how an ecosystem works based on the complementarities of the different functions of the different organisms inhabiting it. It seems that, despite the knowledge of the limitations of mono-agriculture and mono-fisheries, people are ready to develop similar plans for the management of mono-aquaculture. It should be recognized that there is still a chance for incorporating all the learning about the problems of terrestrial monocultures into the relatively new frontier of aquaculture. To better manage marine, brackish, or freshwater environments to the benefits of mankind and the ecosystem, one needs to develop a new science, marine agronomy, learning from the mistakes made in land agriculture over the

centuries to do a better job with aquaculture. It is interesting to note that traditional agricultural practices, such as crop alternation and fallow, are now being transposed to aquaculture practices.

Why, then, is IMTA not more widely adopted, especially in the western world? Paul Greenberg, in his fascinating book "Four Fish" [8], mentioned a very interesting point. In Leviticus, the third book of the Hebrew bible in which, according to the Jewish tradition, God dictated commandments to Moses, one can read (19:19): "You must not sow your field with two different kinds of seed" (also translated as "two kinds of seed" or as "mixed seed"). One can wonder if this represents, in fact, one of the most ancient treatises recommending mono-agricultural practices and if it is not the reason why integrated culture techniques have been ignored for centuries in the Judeo-Christian civilization, while they have flourished in other civilizations, especially in Asia. Moreover, if Asian cultures are accustomed to the concept of considering wastes from farming practices as resources for other crops rather than pollutants, this attitude still has a long way to progress in the western world where aquaculture is a more recent development.

The Need for Diversifying Responsible Aquaculture Systems and for an Ecosystem Approach

The common old saying "Do not put all your eggs in one basket," which applies to agriculture and many other businesses, should also apply to aquaculture. Having excess production of a single species leaves a business vulnerable to sustainability issues because of fluctuating prices in what has become commodity markets and potential oversupply, and the possibility of catastrophic destruction of one's only crop (diseases, damaging weather conditions). Consequently, diversification of the aquaculture industry is advisable for reducing economic risk and maintaining sustainability and competitiveness.

From an ecological point of view, diversification also means cultivating more than one trophic level, i.e., not just raising several species of finfish (that would be "polyculture"), but adding into the mix organisms of different and lower trophic levels (e.g., seaweeds, shellfish, crustaceans, echinoderms, worms, bacteria, etc.) to mimic the functioning of natural ecosystems. Staying at the same ecological trophic level will not address some of the environmental issues because the system will remain unbalanced due to nondiversified input and output needs. Evolving aquaculture practices will require a conceptual shift toward understanding the working of food production systems rather than focusing on technological solutions.

One of the innovative solutions promoted for environmental sustainability (biomitigative services for improved ecosystem health), economic stability (improved output, lower costs, product diversification, risk reduction, and job creation in disadvantaged communities), and societal acceptability (better management practices, improved regulatory governance, and appreciation of differentiated and safe products) is IMTA. The aim is to increase long-term sustainability and profitability per cultivation unit (not per species in isolation as is done in monoculture), as some of the uneaten feed and wastes, nutrients, and by-products of one crop (fed animals) are not lost but recaptured and converted into fertilizer, feed, and energy for the other crops (extractive plants and animals). These, in turn, can be harvested and marketed as healthy seafood, while feed costs are reduced because of their reuse in multiple niches and biomitigation is taking place (partial removal of nutrients and CO_2, and supply of oxygen). In this way, all the cultivation components have a commercial value, as well as key roles in recycling processes and rendering biomitigative services. Some of the externalities of fed monoculture are internalized, hence increasing the overall sustainability, long-term profitability, and resilience of aquaculture farms. The harvesting of the different types of crops participates in the capture and export of nutrients outside of the coastal ecosystem.

The biomass and functions of the fed and extractive species naturally present in the ecosystem in which aquaculture farms are operating must also be accounted for or this will lead to the development of erroneous carrying/assimilative capacity models. For example, the 158,811 t (fresh weight) of the intertidal seaweed, *Ascophyllum nodosum* (rockweed), in proximity to salmon aquaculture operations in southwest New Brunswick, Canada, are not neutral in the ecosystem and represent a significant coastal nutrient scrubber which should be taken into consideration to

understand the functioning of that part of the Bay of Fundy.

IMTA, While Not the Panacea to and for Everything, Is, Nevertheless, One of the Improvement Options

IMTA has never been portrayed as the solution to and for everything! For example, IMTA does not address the issues of escapees from open-water fish farms. It is, of course, in the interest of everybody, especially the industry (to not lose money) to reduce the number of escapees. This is, however, a question of engineering of the rearing systems (cages, netting material, etc.) and the suitability of the environment to survival should escapes occur. To solve the escapee issue, it has been suggested that fish farms should be pulled from the open water and placed on land or in closed containment. Moving on land is, however, not a guarantee for zero escapees. There are well-known escapee cases from land-based operations, with serious consequences. For example, the bighead carp (*Hypophthalmichthys nobilis*) and the silver carp (*Hypophthalmichthys molitrix*) were brought from Asia to the southern USA in the 1970s to help control algal proliferation in channel catfish (*Ictalurus punctatus*) farms. There are reports of escapees into the lower Mississippi River system, especially associated with flood episodes in the early 1990s. Self-sustaining populations have been able to move northward to enter the Upper Mississippi River system and the Illinois River system. Presently, there are fears that these fish could enter the Great Lakes system through the Chicago Sanitary and Ship Canal and the Des Plaines River to finally reach Lake Michigan, after an escape of around 2,000 km in approximately 20–30 years. Electric fish barriers have been put in place, but their efficiency has been questioned. The use of rotenone, a biodegradable piscicide, was authorized but seemed to have killed more common carps (*Cyprinus carpio*; itself an introduced species from Europe in the 1830s) than bighead and silver carps. On April 26, 2010, the US Supreme Court decided not to get involved in a dispute over how to prevent these carps from making their way into the Great Lakes; it turned down a new request by the State of Michigan to consider ordering permanent closing of the Chicago-area shipping locks. What the impacts on the ecosystems could be, should these fish get into the Great Lakes systems, is unknown, but they are well-known for their ability to consume large amounts of algae and zooplankton, eating as much as 40% of their body weight per day, and they are fierce competitors when it comes to securing their food needs. The silver carp is also a danger to recreational fishers, water skiers, and boaters because of its habit to jump out of the water when startled by boat motors or other noises, creating life-threatening aerial hazards with high speed impacts.

The number of escapees from land-based facilities is not as well documented as with cage-based aquaculture. Perhaps because land-based fish escapes are more likely to occur as a continuous "trickle" instead of a single major event such as a net tear that would lead to "large-scale" escapes. However, reports do surface from time to time in the media, particularly if there is some novelty in the story. A recent example is the report of the cultured salmonid brown trout, *Salmo trutta*, escaping from a pond farm in the UK. A wildlife photographer caught them in action, making large leaps out of the water straight into a metal feed pipe a meter above and connected to a tributary of a river (http://www.telegraph.co.uk/earth/earthnews/3318094/Photographer-captures-trouts-great-escape.html). Ideally, land-based recirculation systems would reduce the potential for escapes. However, most recirculation systems have at least partial water exchange [9] and where there is water exchange and discharge, there is a potential for escapees. These systems are still not widely used and to the authors knowledge there has not been any initiative taken to document escapees, or lack thereof, within these systems. It may, therefore, be premature to classify such systems as "escape proof." It is unlikely that any land-based aquaculture operations could ever be 100% "escapee-proof" and, consequently, they will also need to develop anti-escapee strategies (avoiding flood plains, electric fences, grids of the appropriate mesh, catchment basins, etc.).

Moving to land-based or closed-containment operations is one approach that may help address some sustainability issues but is not without its problems. Large amounts of energy, often diesel or electric power, are required to pump and aerate water. Nutrients are either pumped back into the water or settled somewhere and "trucked" offsite. All of these processes leave a "carbon footprint," and only partly solve the issue of

excess nutrients. IMTA, or its variation called "aquaponics," will have to be added to closed-containment or land-based systems to treat the effluents. One "impact" may simply be traded for another. Ayer and Tyedmers [10], in their life cycle assessment of alternative aquaculture technologies, warned that one could be in a case of environmental problem shifting, not solving, where, while reducing local ecological impacts, the increase in material and energy demands may result in significant increased contributions to several environmental impacts of global concern, including global warming, nonrenewable resource depletion, and acidification.

Land-based or closed-containment operations have also been advocated as a way of controlling diseases and their transmission. However, the proponents very often equate diseases to the sole problem of sea lice, leaving the issues related to viral or bacterial pathogens unaddressed. Some concerns have been expressed that multiple species on the site might increase the risk for disease transmission. It must, however, be realized that sites in the ocean and on land will always have additional unintended species associated with the operation, ranging from microorganisms to marine mammals, depending on the situation. The question is not whether to have only one species on the site, but at what density do negative interactions occur with the unintended ones and whether there are any positive interactions associated with more diversified systems. In fact, two studies [11; Robinson, pers. comm.] have demonstrated in laboratory experiments that the blue mussel, *Mytilus edulis*, is capable of inactivating the infectious salmon anemia virus (ISAV), as well as the infectious pancreatic necrosis virus (IPNV). Mussels are, consequently, not a likely reservoir host or vector for ISAV and IPNV. Put in an IMTA perspective, this could mean that mussel rafts could be strategically placed to serve as a kind of sanitary/biosecurity cordon around salmon cages to combat certain diseases. Pang et al. [12, 13] also reported reduced total bacteria and *Vibrio* counts in a seaweed-abalone IMTA system.

In regard to parasites, two studies [14; Robinson, pers. comm.] indicate that blue mussels can consume copepodids, the planktonic and infectious stage of sea lice, and several studies, in both Europe and New Zealand, have highlighted the fact that mussels can consume small zooplankton. Having a biofilter such as mussels at IMTA sites may decrease the frequency of exposure to pathogens and planktonic parasites. The hope is that having multiple species on a farm will result in some positive interactions between species allowing some biological control of the outbreaks of pathogens and parasites, hence reducing the number of costly chemical treatments required. If this is validated, filter feeders may have additional contributions to sustainability beyond reduction of the particle load. One of the 14 projects of the recently created Canadian Integrated Multi-Trophic Aquaculture Network (CIMTAN) is investigating the role of bivalves in potentially reducing sea lice populations. Most of the work has been conducted in the lab so far, but results are very positive and it has been demonstrated that mussels eat the larval forms. Ongoing work is developing a trap system that exploits various behaviors of sea lice to attract and filter them out of the system. Another CIMTAN project is looking into the possibility that mussels could reduce the horizontal transmission of *Loma salmonae*, responsible for microsporidial gill disease of salmon (MGDS), a serious endemic gill disorder in marine netpen reared, and wild, Chinook (and other Pacific) salmon. Trials will examine the proof of principle that blue mussels remove microsporidial spores from water and to what extent these spores retain short-term infectious potential as determined by branchial xenoma expression in test fish.

IMTA is not entering directly the debate regarding the inclusion of fishmeal and fish oil in commercial feeds (nor are land-based or closed-containment operations). IMTA could, however, provide a partial solution. Modern commercial salmon diets in Canada contain much less fishmeal (about 15–25%) and fish oil (about 15–20%) than they did less than 10 years ago (40–60%). By-products (trimmings, offal) of wild catch fisheries are now used to supply a major portion of the fishmeal ingredients. Finding replacements for marine ingredients is a priority and there are several large research projects worldwide addressing this issue. The feed company Skretting has now produced a salmon feed which includes no marine ingredients. Turning toward land plant proteins is not without its impacts. Extra farmland area (more deforestation) would be needed, which, moreover, would need to be irrigated and fertilized on a planet already suffering from water availability problems and with fertilizer

prices soaring. The price of some staple food crops used in traditional agriculture (corn, soya bean, sugar cane, etc.) would rise considerably due to announced competition for their uses, as recently seen when they were potentially sought out as energy crops for the production of first-generation biofuels [15–17]. Reallocation of acreage for subsidized potential biofuel crops such as corn, sugar cane, oil palm, canola, switch grass, etc., has already had significant ecological and societal costs due to its impacts on ecosystem health, biodiversity, and food security [18–21]. Partial substitution with organisms already living in water and not needing extra fertilization in an IMTA setting, such as seaweeds, could, in fact, be a very interesting option, fitting well within the sustainability and management concept of IMTA, and representing a logical loop for companies developing an IMTA and diversification strategy. If cultivated in the water column in IMTA systems, there would, moreover, be no issue of raking natural beds of seaweeds attached to the bottom of the ocean (destruction of seafloor and impact on ecosystem functions such as nursery ground for animals).

Some environmental nongovernmental organizations arguing for fishmeal/fish oil replacement have also voiced concerns that, after all, marine fish should eat marine ingredients . . . obviously, one cannot have it both ways! There is also the paradoxical situation of farmed freshwater fish, which are being grown less and less on humans and animal wastes and naturally occurring algal blooms, but more and more on already competing staple foods such as corn and soy: they have lost their off-flavored or muddy taste to become tasteless or "unfishy"! So, what does one want to receive in one's kitchen? A flavor-neutral, versatile product easily adapted with numerous sauces, while one is lamenting that farmed salmon or bass are not what wild salmon or bass used to be? Quite an irony, even more so when people learn that these herbivorous whitefish are more and more being fed pellets containing fishmeal and fish oil because they grow faster! What is really important is a balanced diet using balanced sourcing of raw material.

Some will argue that "fish require nutrients, not ingredients." At the same time, there is also the well-known saying "You are what you eat," and in this case, people have to realize and accept that humans are mostly corn, soya, and fishmeal, if they look at what the four mammals (cow, pig, sheep, and goat) and four poultry (chicken, turkey, duck, and goose) that they have selected as their meat choices are eating. Historically, most of the reduction fishery (small fish such as anchovies, herring, sardines, and menhaden) went into the production of pet feeds and farm animal feeds. Subsequently, this fishery supplied a significant part of the marine ingredients for fish feeds. The landing of the reduction fishery has been fairly stable (fluctuating between 15 and 30 million metric tons since the 1970s) and, in the absence of aquaculture, the fishery would likely return to supplying pet and farm animal feeds, and a current resurgence of interest directly by humans. This is not to justify relaxed vigilance for finding replacements for marine ingredients in fish feed, but simply to suggest that an absence of fish farming will not stop the use of this resource. How can one get out of this vicious circle? Cultivating several organisms, at different trophic levels, in proximity so that the food and wastes are utilized efficiently more than once through a cascade of recapturing and remetabolizing is one approach: that is IMTA. The other is to consider that if terrestrial food production systems are close to their limits, one does not have other options but to turn again to the sea, this time not for fish but to have seaweeds and invertebrates entering one's food habits, either directly or delivered through feed given to intermediates to what reach one's plate. The discrepancy between the marine and agricultural production systems has to be reduced: presently, especially in the western world, humans feed approximately two steps higher in the marine food web than in the agricultural food web.

People should continue to eat seafood (fish but also invertebrates and seaweeds), not according to seafood pocket guides which simplistically paint species with one stroke of green (best choice), orange (good alternative), or red (avoid), but according to the fishing and aquaculture practices used to grow, harvest, and process them: an admittedly more complex mosaic, but also much more realistic and attractive to look at than a traffic light!

Interestingly, what is referred to as the fifth tasting sense by Japanese (after sweet, sour, salty, and bitter) and called umami (= savoriness or good flavor) comes from seaweeds. The product responsible for umami was first identified in 1908 by Professor Kikunae Ikeda,

of the Tokyo Imperial University, searching for the chemical reason of the strong flavor in seaweed broth (mostly of the kelp *Saccharina japonica*, formerly *Laminaria japonica*). It is due to the detection in our mouth of the carboxylate anion of the amino acid called glutamic acid and its salts, glutamates, in particular monosodium glutamate (MSG). Inosine monophosphate (IMP) and guanosine monophosphate (GMP), degradation products of the energy-storing molecule adenosine triphosphate (ATP) greatly enhance the perceived intensity of umami. This explains, chemistry displacing romantics, why a dead tuna (once full of energy) served with seaweeds is such a savory delicacy, the very essence of the success of the sushi bar fad gaining the western world.

We have never pretended that IMTA is the solution, the silver bullet, to and for everything. It is now up to us to develop the better aquaculture practices of tomorrow. IMTA is based on several common sense principles:

- The solution to nutrification is not dilution, but extraction and conversion through diversification.
- This is, in fact, a rewording of the first law of thermodynamics "Rien ne se perd, rien ne se crée, tout se transforme" ("Nothing is lost, nothing is created, everything is transformed") as summarized by Antoine Laurent de Lavoisier, the well-known French chemist and physicist (but also tax collector, which explains his premature death at age 51 in 1794 under the Terror period of the French Revolution).
- What is waste for some is gold for others.
- Do not put all your salmon eggs in the same basket.

A lot of common sense, but, unfortunately, common sense is not that common! IMTA is one of the promising options, but, certainly, it needs to be tailored to the location in the world where it is implemented. It should also be developed in association with other practices. Like for energy, not one solution will satisfy all the needs and it is a variety of solutions that will help one secure one's seafood procurement in a responsible manner. The solutions will be at the interfaces of these techniques and will be interdisciplinary. They will embrace both scientific and technological advancements and traditional knowledge. IMTA is exactly at this interface, modernizing traditional practices: combining ecosystem complementary crops, bay management area, and fallowing are nothing new, but revisited and updated, based on what humans have learned from past experience (which includes a lot of mistakes over the centuries, but not assimilated by the characteristically short-term memory of humans!).

Recognizing and Valuing the Biomitigative Services Rendered by the Extractive Components of IMTA: Should a System of Nutrient and Carbon Trading Credits Be Developed?

A few economic analyses have indicated that the outlook for increased profitability through IMTA is promising [22, 23]. However, these analyses were based solely on the commercial values from the sale of biomass – being of fish, shellfish, or seaweeds – and used conservative price estimates for the cocultivated organisms based on known applications. One aspect not factored into these analyses is the fact that the extractive component of an IMTA system not only produces a valuable multipurpose biomass, but also simultaneously renders waste reduction services to society. It is particularly important to recognize that once nutrients have entered coastal ecosystems, there are not many removal options available: the use of extractive species is one of the few realistic and cost-effective options. The economic values of the environmental/societal services of extractive species should, therefore, be recognized and accounted for in the evaluation of the true value of the IMTA components. Further development of economic models is needed to help shed light on the economic (society) and commercial (industry) attractiveness of IMTA.

Ecosystem services have been ignored until recently [24]. To improve the sustainability of anthropogenic nutrient loading practices such as aquaculture, incentives such as Nutrient Trading Credits (NTC) should be established as a means to promote nutrient load reduction or nutrient recovery. During the last few years, there has been much talk and excitement about carbon credits. However, within coastal settings, the concerns have largely been with nitrogen, due to the fact that its typical role as the limiting nutrient is not any longer the case in some regions. Potential effects of carbon loading in the marine environment should also be considered: localized benthic anoxia and, consequently, hydrogen

sulfide release may occur when solid waste deposition rate exceeds aerobic decomposition rate. Ocean acidification due to increased dissolved CO_2 levels has also prompted serious new concerns [25] and a Carbon Trading Credit (CTC) system should also be contemplated. With an appropriate composition of cocultured species, IMTA has the potential to reduce the amounts of dissolved (inorganic) and solid (organic) forms of nitrogen, carbon, phosphorus (more an issue in freshwater environments), etc., making extractive aquaculture a good candidate for a NTC and CTC, or other suitable approaches, to deal with the pressing issues of coastal nutrient loading.

Currently, there are few countries with laws or regulations that require aquaculture operations to responsibly internalize their environmental costs, such as nutrient discharges. There are some precedents, such as where land-based trout farmers in Denmark are allowed to increase their feed quota with documented evidence of reduced effluent discharge [26], but such incentives are not widely spread. In most jurisdictions, adjacent ecosystems are left to accommodate the nutrient load, and performance-based standards are used to determine if farms have exceeded their assimilative capacity.

The implementation of regulations resulting in internalization of environment costs by fish farms, without a direct economic compensatory response such as the Danish feed quota increase, could result in a significant reduction in profitability. In land-based systems, it is relatively easy to quantify nutrient load and concentration via comparison between farm inflows and outflows, thereby creating a benchmark for "economic compensation." Such values are practically impossible to empirically measure in an open-water system, "leaky" by definition, and, consequently, so is the practical implementation of such incentives. However, Troell et al. [27] and Chopin et al. [28] demonstrated that by integrating the seaweed, *Gracilaria*, in the dual role of nutrient scrubber and commercial crop (for agar production), with salmon farms in Chile, the environmental costs of waste discharges would be significantly reduced and profitability significantly increased.

Interestingly, the removal of nitrogen could be much more lucrative, by approximately a factor of 100, than that of carbon. The cost of removing nitrogen is not clearly defined, but there are several interesting studies that may help define a range of possible prices for economic evaluation of the NTC concept. The cost of removing 1 kg of nitrogen varies between US$3 and US$38 at sewage treatment facilities, depending on the technology used and the labor costs in different countries [28]. The municipality of Lysekil, in Sweden, is paying approximately US$10/kg removed by the filter-feeding mussel, *Mytilus edulis*, to the farm Nordic Shell Produktion AB [29, 30]. Ferreira et al. [31, 32], with the development of the Farm Aquaculture Resource Management (FARM) model, determined a net value of €18–26 billion/year of nutrient eutrophication reduction services provided by shellfish aquaculture in the coastal waters of the European Union. Gren et al. [33] calculated that the cleaning costs of nutrients by mussel farming can be considerably lower than other abatement measures and estimated that mussel farming should be credited between €0.1 and €1.1 billion/year in the Baltic Sea.

Using this information, and without presuming what the final design of IMTA sites will be in the future, preliminary calculations for the relatively small-scale IMTA project on the East coast of Canada indicate that the annual harvesting of kelps (Fig. 3) would equate to the removal of 35.75 t of nitrogen from the ecosystem, representing an NTC of between US$357,504 and US$1,072, 512. The same could be applied to another key nutrient, phosphorus. With an annual removal of 4.09 t and a value of US$4/kg removed [28], this would represent another contribution to the NTC of US$16,343, a much smaller amount but it could also be an important way of extracting phosphorus, at a time when some are predicting it to be the next element human society will be short of (in its natural or mined forms).

Carbon Trading Credits (CTC) could also be calculated. There may be some arguments about what is meant by trapping and sequestering carbon. Some may argue that it should be reserved to long/geological term storage (sink) and not to transient storage [34]. This is, in fact, a question of how long one allows the recycling clock to run. There is no permanent storage of carbon; it happened that a particular fossil biofuel, petroleum, has been sequestered over geological time to suddenly be reused at an accelerated rate over the last few centuries. But the first law of thermodynamics,

Aquaculture, Integrated Multi-trophic (IMTA). Figure 3
Harvesting of the kelp, *Saccharina latissima*, at an Integrated Multi-Trophic Aquaculture (IMTA) site in the Bay of Fundy, New Brunswick, Canada. Kelps remove dissolved nutrients from the ecosystem while providing commercial products

as enunciated by Antoine Laurent de Lavoisier more than two centuries ago, still applies: "Rien ne se perd, rien ne se crée, tout se transforme," i.e., "Nothing is lost, nothing is created, everything is transformed." If even temporary removal of carbon from the ocean by biomass harvesting until further transformation (and rerelease of carbon) can be credited for potentially increasing seawater pH and absorbing CO_2 from the atmosphere and/or the cultivated animals, then CTC should be calculated. Marine vegetation is getting more and more recognition as a sink for anthropogenic carbon emissions (the so-called blue carbon [35]). Marine primary producers contribute at least 50% of the world's carbon fixation and may account for as much as 71% of all carbon storage in oceanic sediments. Then, micro-algae, macro-algae, and marine plants, such as mangroves and seagrasses, have a role to play in CO_2 sequestration and removal, and carbon storage [36]. Marine photosynthesis accounts for 50% of the total primary productivity of the planet (54–59 PgC/year from a total of 111–117 PgC/year [37]). Of this, marine macrophytes (seaweeds and seagrasses) account for approximately 1 PgC/year concentrated in coastal regions where they can play a significant role in the sequestration of anthropogenic carbon emissions and the global carbon cycle. Brown marine macro-algae (such as *Macrocystis*, *Saccharina*, *Laminaria*, *Ecklonia*, *Sargassum*, *Ascophyllum*, and *Fucus*), red algae (such as *Porphyra*, *Palmaria*, *Eucheuma* and *Gracilaria*) and green algae (such as *Ulva*), are capable of very high rates of photosynthesis and productivity. These rates of productivity compare very favorably to those of terrestrial crops that have been recommended as possible sources of first-generation biofuels (corn, *Zea mays*) or second-generation biofuels (switch grass, *Panicum virgatus*; E-grass, *Miscanthus giganteus*) and position marine macro-algae very well for being part of the third-generation biofuels [36].

Coming back to the IMTA project on the East coast of Canada, using a value for carbon removal of around US$30/t [34], the annual harvesting of kelps would represent an annual removal of 306.43 t and a CTC of US$9,193: a larger amount of carbon, but for a much smaller value of trading credits, underlining the difficulty in removing dissolved nutrients from aquatic systems and the acute issue of their presence in coastal systems. Similar calculations could be applied to the organic extractive component of IMTA. In the case of shellfish, accumulation of nitrogen, phosphorus, and carbon should be considered both in meat and shells, which are especially rich in calcium carbonates.

At a much larger scale, the occurrence of large and recurrent "green tides" should also be brought into focus. Large proliferations of opportunistic green algae, especially of the genus *Ulva*, in response to large anthropogenic nutrient loading, have been in the news over the last few years in places around the world such as Northern Brittany in France, the southern regions of the UK, and Venice in Italy. The green tide in Qingdao, China, just before the sailing competitions of the 2008 Olympic Games, got a lot of attention (Fig. 4). The following question needs to be asked: Are these green tides a negative media photo opportunity, or are they reminders of the significant role seaweeds play in coastal processes and the services they render? Within 3 weeks, 1 million tons of *Ulva prolifera* were removed from the vicinity of Qingdao to allow the sailors and windsurfers to compete (but it is estimated that approximately 2 million tons of *U. prolifera* sank to the bottom of the Bay; another environmental problem shifting, but not a solution). The harvesting of 1 million tons equated to between 3,000 and 5,000 t of nitrogen removal for a NTC value between US$30 and US$150 millions! Additional NTC of US$1.6 million for the removal of 400 t of phosphorus, and CTC of US$900,000 for the removal of 30,000 t of carbon, should also be factored in.

A smaller green tide occurred in 2007. Large ones were also reported in 2009 and 2010 but they stayed offshore in the Yellow Sea [38, 39]. Out of sight should, however, not mean out of mind. If urgent measures are not taken, this will be a recurrent event for years to come. Is there a solution? Green tides are not the cause, but the unintentional consequence of coastal eutrophication. With the presence of sufficient nutrients and solar energy, these opportunistic species, with a well-adapted anatomy, morphology, and physiology, will proliferate. Obviously, it would be beneficial to reduce nutrient loading at the source, but this may not be possible in the present context of economic development along China's coastal zone. The problem is that *U. prolifera* is presently an unwanted and uncontrolled growing nuisance species of limited commercial value. To control its proliferation, the solution may be to create a competition for nutrients by intentionally cultivating algal species, which not only carry on the biomitigation, but also have a commercial value,

Aquaculture, Integrated Multi-trophic (IMTA). Figure 4
A green tide of *Ulva prolifera* in Qingdao, China, just before the 2008 Olympic Games, triggered a massive cleanup

where *U. prolifera* starts to enter the coastal environment (discharges from juvenile river crab land-based aquaculture ponds along Jiangsu province, south of Shandong province where Qingdao is located). This time, the IMTA concept has to be interpreted as an integrated land pond/coastal aquaculture system in a supra Integrated Coastal Zone Management (ICZM) effort, beyond provincial borders, to address issues at the Yellow Sea scale. It is understood that this "out of the box" approach to ICZM will, initially, raise eyebrows as the idea of growing more seaweeds (but of commercial value) to contain the proliferation of other seaweeds, presently considered nuisances, is not the most intuitive approach for a lot of people or decision makers! The question is simple: what are the best nutrient scrubbers once nutrients are in a dissolved state and have reached coastal waters? The answer is seaweeds, but can people, preferably, grow the ones they have applications for?

At the present time, there seems to be a stage of recognition, awareness, and communication of the concepts of ecosystem services and biomitigative services rendered by extractive aquaculture (the differences between the two not always being clearly identified and explained in some publications). Next will come the time to transform the concepts into biomitigative solutions and then their inclusion in regulatory and management frameworks. Establishing and implementing a structure for the payment schemes (credits or incentives) of these services will be a delicate matter. Will it be one agency, but with funds coming from where? Should it be a regional, national, or international agency(ies), trading at which scale(s)? Will an extractive aquaculture operation in existence for many years receive credits, or will only the new ones? Would a fed aquaculture operation also practicing extractive aquaculture be eligible for credits, or will it be the case for the extractive only aquaculture operations? What about the situation in which people run both types of farms. Moreover, due to complex hydrographic and current patterns, it is obvious that extractive species at a site are not limited to absorbing/sequestering the nutrients generated exclusively at that site. Consequently, is it possible to establish a clear spatial nutrient removal budget which would be associated with the corresponding credits/incentives? Will the sequestration have to be "permanent," or will a temporary removal/storage be acceptable and more realistic? A lot of regulatory details will have to be worked out before this complex scheme becomes a reality.

What Will It Take to Increase the Acceptance and Adoption of IMTA as a Responsible Aquaculture Practice of the Future?

Presently, the most advanced IMTA systems in open marine waters and land-based operations have three components (fish, suspension feeders or grazers such as shellfish, and seaweeds, in cages, rafts, or floating lines), but they are admittedly simplified systems [40]. More advanced systems will have several other components (e.g., crustaceans in mid-water reefs; deposit feeders such as sea cucumbers, sea urchins and polychaetes in bottom cages or suspended trays; and bottom-dwelling fish in bottom cages) to perform either different or similar functions, but for various size ranges of particles, or selected for their presence at different times of the year (e.g., different species of seaweeds). The most advanced IMTA systems, near or at commercial scale, can be found in Canada, Chile, South Africa, Israel, and China [41, 42]. Ongoing research projects related to the development of IMTA are taking place in the UK (mostly Scotland), Ireland, Spain, Portugal, France, Turkey, Norway, Japan, Korea, Thailand, the USA, and Mexico. It will also be interesting to observe how new seaweed cultivation initiatives in different parts of the world for biofuel production could be an additional driver to adopt IMTA practices.

For IMTA to develop to a commercial scale, appropriate regulatory and policy frameworks need to be put in place. Present aquaculture regulations and policies are often inherited from previous fishery frameworks and reasoning, which have shown their limitations. It is, therefore possible that some of the existing regulations and policies could impose unintentional constraints on the future growth of IMTA. To develop the aquaculture of tomorrow, current governance structures pertaining to aquaculture need to be revisited and reviewed with the aim of identifying changes in the regulatory/policy environment that are needed to facilitate the operation of IMTA farms. Adaptive regulations need to be developed by regulators with flexible and innovative minds, who are not afraid to put in place mechanisms that allow the testing of innovative

practices at the R&D level, and, if deemed promising, mechanisms that will take these practices all the way to C (commercialization). As the IMTA concept continues to evolve, it is important that all sectors of the industry are aware of the implications of the changes involved, so that they can adapt in a timely and organized manner.

To move research from the "pilot" scale to the "scale up" stage, some current regulations and policies may need to be changed or they will be seen as impediments by industrial partners who will see no incentive in developing IMTA. For example, an earlier version of the Canadian Shellfish Sanitation Program (CSSP) prevented the development of IMTA because of a clause that specified that shellfish could not be grown closer than 125 m of finfish netpens. This paragraph was clearly not written with IMTA in mind, but it seriously impinged its development. After 4 years (2004–2008), it was amended so that IMTA practices could develop to commercial scale legally, based on recent, reliable, and relevant data and information provided by three government departments and the IMTA project on the east coast of Canada. While 4 years may seem long, it is a relatively short delay considering that regulations and legislations require thorough review with due governmental process involving several federal and provincial departments. This suggests that new aquaculture practices should be accompanied by timely regulatory review to avoid market delays for new products. As governments move to revise current regulatory regimes, it will be necessary to press the importance of accommodating and indeed encouraging new sustainable solutions such as IMTA. IMTA also requires approaching aquaculture development and management with a holistic approach and not one species, or group of species, at a time. It is known that this approach has led to many failures in the management of the fisheries; vigilance is required so that the same flaw is not repeated in the management of aquaculture.

Most current aquaculture business models do not consider or recognize the economic value of the biomitigative services provided by biofilters, as there is often no cost associated with aquaculture discharges/effluents in land-based or open-water systems. In order to ensure further development of IMTA systems worldwide, from the experimental concept to the full commercial scale, defining and implementing the appropriate regulatory and policy frameworks, and financial incentive tools such as NTC and CTC, may therefore be required to clearly recognize the benefits of the extractive components of IMTA systems. Better estimates of the overall costs and benefits to nature and society of aquaculture waste and its mitigation would create powerful financial and regulatory incentives to governments and the industry to jointly invest in the IMTA approach, as the economic demonstration of its validity would be even more obvious. Moreover, by implementing better management practices, the aquaculture industry should increase its societal acceptability, a variable to which it is very difficult to give a monetary value, but an imperative condition for the development of its full potential. Reducing environmental and economic risk in the long term should also make financing easier to obtain from banking institutions [43].

The determination to develop IMTA systems will, however, only come about if there are some visionary changes in political, social, and economic reasoning. This will be accomplished by seeking sustainability, long-term profitability, and responsible management of coastal waters. There is still a large amount of education required to bring society into the mindset of incorporating IMTA into their suite of social values. Some of the attitudinal surveys conducted in Canada [23, 44] and the USA [45] indicate that the general public is in favor of practices based on the "recycling concept." Consumers' perceptions and attitudes may also have to change. Why is recycling and the concept of "what is waste for some is gold for others" well accepted in agricultural practices, but is not yet acquired when transposed to aquaculture practices? Will consumers come to accept eating products cultured in the marine environment in the same way they accept eating products from recycling and organic agricultural practices, for which they are willing to pay a higher price for the perceived higher quality or ethical premiums? After all, regulations require mushrooms to be specifically grown on farmyard manure and animal excrements to receive organic certification (European Community Regulations No 2008R0889 – Article 6). Will a greater appreciation of the sustainable ecological value of the IMTA concept, a willingness to support it tangibly with shopping money, and an increased pressure on elected representatives emerge? This will be the ultimate test.

The degree to which researchers and extension people become creatively involved with this educational component will be vital to the success of IMTA practices. The differentiation of IMTA products through traceability and eco-labeling will also be key for their recognition and command of premium market prices.

Some have argued that the adoption of IMTA in the western world is slow. For example, on the east coast of Canada, there were obviously no IMTA sites in the Bay of Fundy in 2001 when IMTA research started. Nine years later, 8 of the 96 finfish sites in southwest New Brunswick have the combination salmon (or cod)/mussels/kelps and 8 other sites have been amended to develop IMTA. This is a respectable conversion of almost 16% in 9 years. Moreover, it would not be reasonable to anticipate an instant conversion, as the industry needs to develop markets to absorb the cocultured biomass: this also takes time and can only be progressive.

Future Directions: The Path Forward

Several IMTA projects, worldwide, have now accumulated enough data to support the proof of concept at the biological level. The next step is the scaling up of more experimental systems to commercial scale to further document the economic and social advantages of the concept, which will be key to offering IMTA to practitioners of monospecific aquaculture as a viable option to their current practices. Emerging responsible aquaculture approaches must generate net economic benefits for society if they are to be advocated. Working on appropriate food safety regulatory and policy frameworks in the respective countries will be essential for enabling the development of commercial scale IMTA operations in a more universal fashion.

It has taken decades to reach current finfish aquaculture production levels and learn new species husbandry. A major rethinking is, however, needed regarding the definition of an "aquaculture farm" by reinterpreting the notion of site-lease areas and regarding how it works within an ecosystem, in the context of a broader framework. Within Integrated Coastal Zone Management (ICZM), integration can range from the small scale (a leased site with its spatial limits) to a Bay Management Area (BMA) and to the larger scale of a region connected by the functionalities of the ecosystem. Amending regulations to allow a new type of aquaculture systems will not occur overnight. This should, however, not discourage the finfish aquaculture industry from practicing IMTA, as even small amounts of cocultured species production are useful at the initial stage of development.

Selecting the right combination of species will be critical. They will have to be appropriate for the habitat, the available culture technologies and labor forces, and the environmental, climatic, and oceanographic conditions. They will have to be complementary in their ecosystem functions, growing to a significant biomass for efficient biomitigation, commanding an interesting price as raw material or presenting an interesting added value for their derived products. Their ecological interactions and synergies within an IMTA system will have to be identified and understood to take full advantage of them. Their commercialization should not generate insurmountable regulatory hurdles.

Optimal design will not only facilitate nutrient recovery, but should also promote augmented growth beyond what would be expected were these species cultured in isolation. In addition to the obvious economic return from increased growth rates from additional species, some less tangible benefits should also be factored in, such as the biomitigative services rendered by the extractive species. Economic analyses will have to recognize and account for the values of the environmental/societal services of extractive crops to estimate the true value of these IMTA components. Economic analyses will need to be part of the overall modelling of IMTA systems, as they get closer to commercial scale and their economic benefits and costs, as well as their impacts on coastal communities, are better understood. It will then be possible to add profitability, resilience, social/economic desirability, and economic impacts to the comparison between IMTA and monoculture settings. They will have to include the pricing and marketing potential and impact of organic and other eco-labellings, the value of biomitigative services for enhanced ecosystem resilience, the savings due to multi-trophic conversion of feed and energy which would otherwise be lost, and the reduction of risks through crop diversification and increased societal acceptability of aquaculture (including food safety, food security, and consumer attitudes toward buying sustainable seafood products). This would create

economic incentives to encourage aquaculturists to further develop and implement sustainable marine agronomy practices such as IMTA, and would increase the societal acceptability of aquaculture by the general public. Seaweeds and invertebrates produced in IMTA systems should be considered as candidates for a variety of regulatory measures that internalize these benefits. For example, nutrient and carbon trading credits (NTC and CTC) could be used to promote nutrient removal, CO_2 sequestration, oxygen provision, and coastal eutrophication reduction within the broader context of ecosystem goods and services. Long-term planning/zoning promoting biomitigative solutions, such as IMTA, should become an integral part of coastal regulatory and management frameworks.

Nutrient extractive aquaculture appears to be a viable ecological engineering option for managing/internalizing some of the externalities generated by aquaculture operations. Effective government legislation/regulations and incentives to facilitate the development of IMTA practices and the commercialization of IMTA products will be necessary. The development and adoption of technology often depends in part on the level of legislative pressure from a nation's government, itself reacting to pressures from consumers, environmental nongovernmental organizations, and the public at large. If environmental legislation remains a low priority with government, then little progress toward the use of biofilters (as a means of effluent mitigation) will occur. The only motivator will be profits obtained from additional product growth and regulatory incentives. Therefore, if governments put legislative pressure on the proper management of wastewater effluent, openly support the use of biomitigation for effluent management, and put in place the appropriate corresponding financial tools (funding for IMTA Research & Development, outreach and technology transfer, and NTC and CTC incentives), then the development of IMTA will be encouraged.

Caution: Let's Not Promise the Moon and Let's Be Conscious of Societal Constraints, Particularly in the Western World

During the last few years, there has been a renewed interest in the mariculture of seaweeds and their uses, something that should make phycologists and ecologists rejoice, as this group of organisms, never clearly systematically circumscribed, has been misunderstood, unappreciated and under/misused over the centuries. There is now an opportunity to explain what seaweeds are, and the many applications, benefits, and services they can provide. However, how can people do that appropriately and responsibly, without "promising the moon" that they will not necessarily attain, and risking another "purgatory period" in between each energy crisis?! Seaweeds (and algae in general) made the news in the 1970s–1980s; they are back in the news now (2000s–2010s). If people are not careful to distance themselves from charlatanistic claims, which abound in the media and even in certain scientific circles, they could be in a situation of not developing a sustained public interest and use of these organisms, but be in another phase of denial until the next fad cycle (2030s–2040s?), which is not productive for the acquisition of still much needed scientific knowledge, nor the teaching of our discipline or the placement of our in-between fashion students. While everyone wants the seaweed sector to develop, some biotechnological issues and societal constraints, particularly in the Western World, should be recognized and a responsible and gradual implementation strategy for the long term should be adopted.

The western marine biology community has been dominated by people who have received a mostly zoological training from kindergarten to high school, very often reinforced by a monospecific (or monogrouping) specialization at university, instead of receiving and developing an ecosystem approach to knowledge and issue solving, which are then sadly missing when concepts of ecosystem-based management, species cocultivation, and interdisciplinarity are mentioned. Not surprisingly, the knowledge of seaweeds and their functions and services in/to the ecosystem is reduced and remains at universities and research institutions that have been wise in keeping their diverse expertise, instead of succumbing to fad cycles, which, then, force them to periodically reinvent the wheel. The consequence is that every time one wants to raise the possibility of using seaweeds in research and development and commercialization (R&D&C), one has to go through a lonely period of "preaching in the desert" before facts and common sense start to prevail.

One key, common, and deeply rooted misunderstanding to shake from the minds of people is that there is more than fish in the ocean! Over the centuries humans have been quite minimalist in their meat choices: four mammals (cow, pig, sheep, and goat) and four poultry (chicken, turkey, duck, and goose), hence, Paul Greenberg's idea of four fish (salmon, sea bass, cod, and tuna) for the title of his book [8]. However, the ocean cannot function with only fish, and the seafood solutions cannot come from within only this group of organisms. Maybe the problem resides deeply among the English-speaking people with this overuse of "fish": fish is a noun, which can even encompass shellfish and seaweeds in its general use, and fish is a verb... if you go harvest seaweeds along the shore you could be paradoxically fishing seaweeds, which for a Cartesian French-speaking person does not make much sense! In French, there is "poisson" as a noun and "pêcher" as a verb, even if both come from "pisces" in Latin. So, when a French person "va à la pêche," it is not necessarily to get a fish, but also to go "à la pêche aux moules" (mussels), "aux oursins" (sea urchins), or "aux algues marines" (seaweeds, for which many languages also have a higher opinion, as marine algae, instead of weeds of the sea!). To function, IMTA requires, in fact, not four components but five: the fed organisms (e.g., fish or shrimps), the extractive inorganic component (e.g., seaweeds or other aquatic vegetation), the extractive small organic component (e.g., suspension feeders such as shellfish), the extractive large organic component (e.g., deposit feeders such as sea-urchins, sea cucumbers, or sea worms), and certainly a fifth component, the microbial component, of which presently not much is known. So, if people want aquaculture to work, they have to stop being obsessed with fish aquaculture! Paradoxically, it is interesting to know that fish aquaculture, of which so much is heard, represents, in fact, only 9% of the total mariculture (aquaculture in the marine environment). Shellfish aquaculture represents 43%. Seaweed aquaculture represents even more (46%), but 99.8% of it is carried out in Asia, hence the ignorance in the western world [46, 47].

It is also important to understand that sustained successful ventures rarely happen overnight and that more than a 3 year grant is generally necessary to successfully take a concept along the R&D&C continuum. For example, the IMTA program on the east coast of Canada is starting to collect the fruits of its tireless efforts as it enters its 15th year of activities, which so far could be divided into four periods: (1) the "preaching in the desert" period from 1995 to 2000 [48], (2) the R&D proof of concept period from 2001 to 2006, (3) the R&D&C pilot scale period from 2006 to 2012, overlapping with (4) the R&D&C industrial-scale and networking period with the establishment of CIMTAN since 2009. People, consequently, have to stay away from claims of solving hunger in the world, converting everybody into frequent direct "seaweedivores," 100% biomitigation (which, in fact, is not necessarily the goal), renewing energy at unbelievable rates that defy the rules and equations governing photosynthesis, and all that within the next 5 years with the almighty, miraculous seaweeds and micro-algae!

If there is no shortage of interesting ideas that work at the small demonstration scale, the problems generally appear when scaling up is contemplated and people start to realize what the consequences will be and, especially, the realistic, or unrealistic, deployment footprints required to implement these experimental ideas to commercial-market scales, which should make sense from environmental, economic, and production perspectives and also have an acceptable societal impact.

People should also stay away from the cliché that around 71% of this planet is covered by oceans and that, consequently, there is a lot of space for aquaculture development. If aquaculture will most probably expand into more exposed and open ocean locations in the future, due to the reduced availability of new and appropriate sheltered nearshore sites, it is doubtful that one will see farms in the middle of the Atlantic, Pacific, and Indian Oceans, due to simple logistics and weather issues. Moreover, the present international law of the sea is not that comforting for privately owned equipment (farms in this case) found at sea. The vagueness of territorial jurisdictional competence in the Exclusive Economic Zone (EEZ) in different countries, and certainly in international waters, has been a major impediment to progress of the so-called offshore aquaculture. Moving to the open ocean has been considered a means for moving away from environmental and public perception issues in the coastal zone. However, this move should not encourage an "out of sight, out of mind" attitude, as open ocean development will also come

under scrutiny by a more and more educated public. Even if greater residual currents, deeper waters, and lower nutrient baselines are expected to reduce impacts from open ocean operations through wider dispersion plumes of nutrients, as compared to similarly sized nearshore operations, there will be a point when reasonably accessible and manageable open ocean ecosystems will eventually reach their assimilative carrying capacities. Why should one think that open ocean aquaculture, the "last frontier," will be without its own border/limits? Despite the sea being so immense, one is now learning the hard way the concept of overfishing . . . Instead of taking the position that in open ocean environments the hydrodynamic conditions will be appropriate for dispersion (a way of exporting problems, not solving them) and reduced environmental impacts (but at a significant cost in lost food), the open ocean aquaculture sector will also have to capitalize on recapturing the by-products of fed aquaculture and, hopefully, engineer, right from the beginning, efficient open ocean IMTA systems with their built-in biomitigative functions. The solution to nutrification in the open ocean environment, like in the nearshore environment, should not be dilution, but extraction and conversion through diversification. Why repeat what was done with the development of nearshore aquaculture (fish aquaculture development in the 1970s and IMTA development in the 2000s) with open ocean aquaculture (moving the fish to the open ocean in the 2010s . . . oh, the extractive species should have also been moved in the 2050s!)? These open ocean systems will also require trophic diversification from an environmental and economic perspective, with "service species" from lower trophic levels (mainly seaweeds and invertebrates) performing ecosystem balancing functions while representing value-added crops [49, 50]. Open ocean IMTA should not be an afterthought for 2050.

For some, the ecological, engineering, economic, and social challenges remaining to be solved may be daunting. However, our goal is to develop modern IMTA systems, which are bound to play a major role worldwide in sustainable expansions of the aquaculture operations of tomorrow, within their balanced ecosystem, to respond to a worldwide increasing seafood demand with a new paradigm in the design of the most efficient food production systems. There are no simple solutions, but one thing is certain – the human population is increasing on this planet and as people get richer, and their standards of living increase, they want more meat and dairy products in their diet, the temptation of the "western diet," while, ironically, Westerners aspire to change their diets! Will terrestrial agriculture be able to continue to supply most of this food? A balanced and responsible diet is required, and some of this food will have to come, increasingly, from aquatic food production systems, be them in seawater, brackish water, or freshwater. As was the case on land, where the acquisition of food by hunter/gatherer societies had to evolve toward agricultural practices, humans will have to accept an evolution in seafood procurement. It has to be understood, particularly in the western world, that "the modern global supermarket has a basic internal ecology" [8]. The average consumer is not a "foodie" and is not that interested in or cannot afford local, seasonal, less-than-100-miles food if not rich enough or not living within a region graced by a clement climate year long. The modern supermarket wants guaranteed supply on a 12 month basis, with limited variability in seasonality and quality. Most of the time, agricultural products can provide that comfort, barring the occurrence of an unexpected disease, contamination, drought, flood, economic protectionism, or political barrier. The seafood counter is a much more variable department to manage, at the present time, with a convoluted succession of many intermediates before seafood arrives on ice at a supermarket. It is interesting to note that the aquaculture industry's ability to provide 12 month availability of its products, moreover of consistent quality, is improving.

People are presently witnessing the emergence of a plethora of organizations developing their own standards and eco-label/certification schemes as they jockey for position in the global marketplace. The problem is that there are presently too many possible horses to ride and nobody really knows which one(s) will cross the finish line and, consequently, which one (s) to bet on as worth being associated with. One can only wonder what will happen when so many fisheries and aquaculture operations will be eco-certified. If everything is certified, nothing will be certified . . . and certification will lose its aura the same way some argue organic labelling is losing its significance, after having been used and overused. All that, of course,

to the great confusion of the consumers, who cannot follow this contradictory debate/competition among standard setters, and may decide to simply stay away from seafood all together when, in fact, seafood products are healthy [51]. One of the problems is that some of these standards are passing or failing grades, with no incentives for continuous improvement from a minimal baseline to be decided, followed by a tiered approach. Some argue that it would give accreditation to companies at a very low level. However, putting the bar so high is not a recipe for gradual improvement of everybody involved, to progress and gradually reach the ultimate goal, although admittedly not overnight. If 20% of the global farmed seafood producers are certified at the highest threshold, what happens to the remaining 80% and the chance of incentivizing them to improve their practices? What happens when, in a bay management area, several aquaculture companies have taken the appropriate measures to be certified, but a "black sheep" (should it be a black cod?!) makes the whole certification scheme crumble once the hydrodynamics of the bay are considered? By analogy, in which the vector this time is not water but wind, one sees the same dilemma in parallel agriculture situations where conventional and organic agriculture practices are separated by illusionary buffer zones. On one hand, one can understand the desire by suppliers and retailers to see a hard to meet certification scheme so as to differentiate themselves from the others (most probably amounting to the privilege of displaying a sticker or logo on the packaging); on the other hand, too high a certification carrot, or moving goalposts, may not be the best strategy if progress toward overall better and more responsible aquaculture practices is the goal. The market will ultimately decide who remains in the competition and which logo(s) will be trusted by the general public, but there still are several years of confusion ahead.

Agricultural development has been associated with significant changes in landscape and land use; one can expect that the evolution of sourcing one's seafood more and more through aquaculture will also trigger significant "seascape" and "sea use" modifications, all the way to one's deepest human social structures and governance. The transformation from hunters/gatherers to farmers happened many centuries ago on land. Humans are in the middle of this transformation at sea and that is maybe why they are so uncomfortable with this evolution they are part of, and not able to sit back and analyze without being emotional. It is up to them to be a link in the chain, which will hopefully lead to fishing and aquaculture practices done right, enabling them to become herders and farmers of the sea. It should not be forgotten that they are still in the infancy of modern, intensive aquaculture and that some agricultural practices have taken centuries to develop into better, not necessarily yet best, management practices.

Beyond the market and marketing issues and the biological, environmental, economic, technological, engineering, and regulatory issues of aquaculture developments, the basic question will be that of societal acceptance. Are humans ready to evolve in their use of the "last frontier" of this planet and consider not only the challenges of the physical forces at sea (wave exposure, winds, currents, depth, etc.) but also those of shipping routes, fishing zones, offshore gas and mineral extraction areas, migration routes for marine mammals and birds, recreational uses, and then finally deal with the concept of zoning some portions of the oceans for large aquaculture parks, as sustainable food production systems for an ever-seafood-hungry human population? Despite all the campaigns, boycotts, documentaries, books, seafood pocket guides, scare tactics, sustainable/local/seasonal movements among affluent restaurant goers in weather clement regions and western world well offs, one can only admit that the global human population continues to grow and eat more seafood than ever per capita per year. So, where does that leave people? Paul Greenberg wrote that very often people consider fish as "a crop, harvested from the sea that magically grew itself back every year. A crop that never required planting" [8]. But are they investing in the principal, being in fisheries or in aquaculture, to only harvest the interests every year so as to not reduce/eat the capital for long-term sustainability? Are people ready to put some savings aside in the form of Marine Protected Areas (MPAs), not only for their natural beauty, but also for their functions in the ecosystem such as breeding grounds, nursery habitats, and food production areas? It seems that the concept of zoning the sea, or what is now called, in a softer terminology, "marine spatial planning" (MPS), is finally starting to be legislated in some countries, notably in the UK and the USA.

The same question of readiness for marine spatial planning could also be applied to emerging projects of wind farms and biofuel farms at sea. In fact, combining IMTA open-ocean farms with wind, underwater turbine, and/or biofuel farms into large multipurpose integrated food and renewable energy parks (IFREP) could be a means for reducing their cumulative footprint, while integrating green energy with food and fuel production and processing [52]. Our business models will have to change from "one species – one process – one product" to a streamed bioeconomic chain, or web, approach among different industry sectors for the production, on one hand, of a wide range of bio-based, high-valued food and feed products/ingredients/supplements, specialty fine and bulked chemicals, agrichemicals, biostimulants, pharmaceuticals, nutraceuticals, functional foods, cosmeceuticals, botanicals, pigments and, on the other hand, lower-valued commodity energy carrying molecules/biofuels, all of them produced within reduced footprint requirements. The synergies and the services rendered by cultivating organisms of different trophic levels in an integrated manner will have to be understood and valued. The physiological, biochemical, and production performances of the different organisms will have to be improved to make the systems even more efficient, profitable, and competitive. The aquaculturists and different multi-sector end users will need to become interdisciplinary in their approach and learn to collaborate and share/integrate the biomass cultivation and processing steps (production, harvesting, pretreatment and transportation, separation and fractionation, and sequential biomass processing), while aiming at the lowest resource and energy inputs. Culture diversification into species that might otherwise be inappropriate for food markets fits well within the sustainability and management concept of IMTA. Functionalities will have to be maintained, as much as possible, along the process for optimal use/valorization of the multipurpose biomass, and not necessarily the maximization of just one end product, as some coproducts will, in fact, reveal themselves as the real drivers of the emerging integrated sequential bio-refinery (ISBR) concept [53], extended to macro-algae instead of only considering micro-algae. Market volumes/values, biomitigative services, and public acceptance will have to be included and fit into the models.

If the "Not In My BackYard" (NIMBY) and the "Build Absolutely Nothing Anywhere Near Anything" (BANANA) attitudes continue to prevail, especially in the western world, then humans will not be able to secure their food, chemicals, and energy in an intricately interconnected ecosystem responsible manner, despite all the rhetoric heard today regarding alternative technologies and solutions (the so-called "greenwash"). Self-sufficiency of humans will not be ensured but will become dependent on other food, chemicals, and energy "masters," who may no longer be in the Middle East but instead in the Far East (99.8% of the 15.8 million tons of cultivated seaweeds come from China, Indonesia, the Philippines, Korea, and Japan [46, 47]). It is time to walk the talk and recognize the implications – notably regarding marine spatial planning and our societal production and food habits – of the policies elaborated for the future.

The 1960s were the time of the "Green Revolution" on land, but some would question if it was really "green" (increased dependence on synthetic fertilizers and irrigation to increase crop yields per hectare at the expense of long-term soil health and yields per unit of input; increased dependence of indebted farmers on multinational producers of seeds, increasingly genetically modified, and which have not always delivered the touted benefits). It was thought that the sea was so immense that one needed not to worry about fishery limits, but now it is known that it is not always the case with many examples of overfishing of some populations. The 1980s were the time of the "Blue Revolution" of aquaculture development at sea, but it is also known that it is not always "green." It is, consequently, time to make the "Blue Revolution" greener; it is time for the "Turquoise Revolution" to move aquaculture to a new ERA of Ecosystem Responsible Aquaculture at sea and on land, in seawater and freshwater, and in temperate and tropical regions.

Acknowledgments

I greatly appreciate the support this work received from the Natural Sciences and Engineering Research Council of Canada (NSERC) strategic Canadian Integrated Multi-Trophic Aquaculture Network (CIMTAN) in collaboration with its partners, Fisheries and Oceans

Canada, the University of New Brunswick, Cooke Aquaculture Inc., Kyuquot SEAfoods Ltd. and Marine Harvest Canada Ltd.

Article Outline

Glossary

Stewardship Ecosystem stewardship is an ethic practiced by aquaculture practitioners, organizations, communities, and societies who strive to sustain the qualities of healthy and resilient ecosystems and their associated human communities. Stewardship takes the long-term view and promotes activities that provide for the well-being of both the present and future generations.

Nested systems of governance Environmental and societal issues relating to sustainable aquaculture impact, and are influenced by, conditions and actions (at both higher and lower levels) in an ecosystem governance hierarchy. Some issues can be addressed more effectively at one level, and less effectively at another. The choice of the issue or set of issues to be addressed within a given site must therefore be made in full knowledge of how responsibility and decision-making authority are distributed within a layered governance system. Planning and decision-making for aquaculture at one scale, for example, within a municipality or province, should not contradict or conflict with planning and management at another scale, for example, planning for large-scale aquaculture at the nation-state scale. The reality is that such contradictions and conflicts are common. A major challenge for the aquaculture practitioner is to recognize these differences and work to either change them or select goals and strategies that recognize that such contradictions must be accommodated or resolved. In practical terms, this means that a central feature of ecosystem-based aquaculture is that all planning and decision-making must recognize and analyze conditions, issues, and goals in respect to the next higher level in a governance system. Thus, ecosystem-based aquaculture at the municipal scale must – at a minimum – be placed within the context of governance at the scale of the province.

Participation One of the defining characteristics of the practice of the ecosystem approach to aquaculture is its emphasis on participation and its relevance to the people affected. The emphasis upon participation recognizes that if an aquaculture program is to be successful, those whose collaboration and support is needed must be involved in the processes of defining the issues that the program will address, and in selecting the means by which goals and objectives will be achieved. Both individuals and members of communities and institutions are more likely to comply with a management program when they feel that it is consistent with their values, responds to their needs, and to their beliefs of how human society should function. Voluntary compliance by a supportive population lies at the heart of the successful implementation of a program. A participatory approach helps stakeholders and the public to see the efforts of an aquaculture program as a whole.

Area of focus The area of focus (AoF) is the geographically defined area that an ecosystem-based aquaculture project or program has decided to address and that therefore is the focal point for a baseline.

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

The term "area of focus" is a geographic limit set to model the choices available to the aquaculture practitioner and allows for a dialogue between stakeholders as to the influence of the production. The AoF is a simplification of the far more complex concept of an "action arena" put forward by Ostrom [1] to model the choices of individuals when studying the behavior of institutions.

Adaptive management A central feature of the practice of any form of ecosystem-based aquaculture is that it must respond positively to changing conditions within its AoF (and to its own experience). In other words, the practice of aquaculture must be grounded in a process of learning and adaptation (the "evolution of the blue revolution" [2]). Adaptive management is not reactive management, but proactive thinking and acting. This does mean that the aquaculture practitioner simply responds to the unexpected. Adaptive management in aquaculture is a conscious process of examining the course of events as these events are revealed by preselected indicators of changes in an aquaculture ecosystem (both its social and environmental components), and by events occurring at differing spatial scales.

Capacity building There is growing international recognition that the lack of human capacity to practice an ecosystem approach to aquaculture is a key factor in limiting forward progress in the conservation and sustainable use of aquatic systems [3, 4]. To date, however, no accepted performance standards have been developed for assessing the effectiveness and impacts of aquaculture projects and programs that have adopted the ecosystem approach. Conceptual frameworks and methods for assessing the maturity of aquaculture development and management initiatives, and gauging their impacts upon the condition of coastal ecosystems are offered herein. These are the core ingredients for an ecosystem's approach to aquaculture that builds the capacity of local populations and leaders to identify forces that shape the coastal ecosystems of which they are a part, and to select the actions that can maintain and enhance qualities that are critical to a desirable future.

Carrying capacity The carrying capacity is the number of organisms or farming operations that the environment can sustain indefinitely without environmental harm, given the food, habitat, space, water, and other requirements from the environment.

Precautionary principle A principle that states that if an action or policy has a suspected risk of causing harm to the public or to the environment that in the absence of scientific consensus the burden of proof rests on those who advocate taking the action.

Sustainable development The management and conservation of the natural resource base and the orientation of technological and institutional change in such a manner as to ensure the attainment and continued satisfaction of human needs for present and future generations. Sustainable development conserves resources, is environmentally non-degrading, and is technically appropriate, economically viable, and socially acceptable [5].

Transdisciplinary A modern research strategy that crosses many disciplinary boundaries to create a holistic approach. Transdisciplinary research efforts are focused on problems that cross the boundaries of two or more disciplines, and develop new or reframe old concepts, methods, and findings that were originally developed by one discipline, but are now used by several others.

Definition

There is no one definition of "sustainability" as the concept applies to aquaculture. Most aquaculture scientists define sustainability as synonymous with "environmental sustainability." Sustainable aquaculture is however a concept broader than determinations of site-specific environmental impacts since it embodies a scientific knowledge of systematic impacts of aquaculture off-site, and impacts to combined human-environmental systems. Sustainable aquaculture incorporates the concepts of "stewardship," "design with nature," the "precautionary principle," "risk analysis," and "carrying capacity." Sustainability science in aquaculture is used to undertake more comprehensive planning for multiple impacts on multiple time and spatial scales to better understand and plan for the consequences of aquaculture development options.

Introduction

- "The changes taking place [on planet Earth] are, in fact, changes in the human-nature relationship. They are recent, they are profound, and many are accelerating. They are cascading through the Earth's environment in ways that are difficult to understand and often impossible to predict. Surprises abound" [6].

There are many definitions of "sustainability" as the concept applies to aquaculture. The most popular definition of sustainable development is to "meet present needs without compromising the ability of future generations to meet their needs" adopted at a United Nations conference in 1987. Most definitions of sustainability are synonymous with "environmental sustainability" of air, water, and land systems. Sustainability is however a concept broader than examining the site-specific environmental impacts of externalities in planning for site-specific developments; it also accounts for systematic impacts off site, and impacts to combined human-environmental systems for food, water, waste, energy, and shelter. The many definitions of sustainability all embody in common, the concepts of "stewardship," "design with nature," plus incorporate recent concepts of the "precautionary principle," and "carrying capacity." Sustainability science uses the wisdom from multiple disciplines in decision-making (e.g., it is "transdisciplinary"). In aquaculture, it is used to undertake more comprehensive planning for multiple impacts on multiple time and spatial scales to better understand and plan for the consequences of development options.

The emerging fields of ecological aquaculture [2,3] and agroecology [7, 8] recognize that the implementation of more sustainable food production systems require knowledge about how ecosystems are utilized and how conflicts among social groups are addressed. A baseline of response to social–ecological changes is the foundation for the implementation of more sustainable food systems, and the practice of adaptive management must be included as responses to changes in the condition of ecosystems in which new food production is conducted requires incorporation of an iterative learning process.

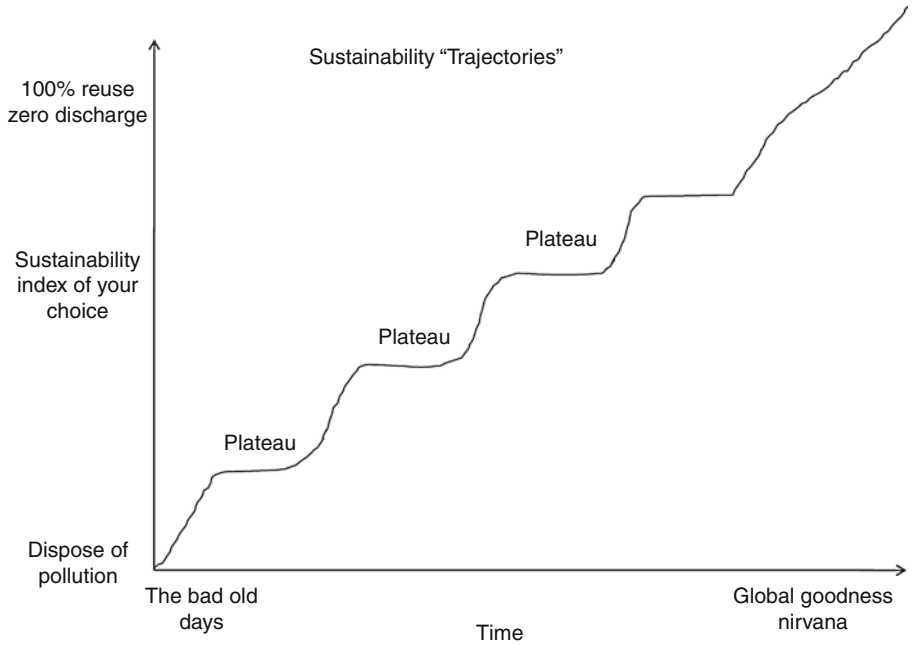
The use of sustainability science in aquaculture marks the path toward encouraging a long-term perspective and an appreciation of the roles played not only by ecologists, but also by civil societies, markets, and governments in adapting to food systems and ecosystems changes. The use of sustainability science in aquaculture is an approach that is fundamentally a knowledge-based enterprise that incorporates baseline information on natural and human ecosystems, then develops, evaluates, encourages, and communicates imagination, ingenuity, and innovation at both the individual and institutional levels [9].

This information is designed for use by teams of aquaculture professionals working to apply the principles of ecosystem-based management. Information obtained is typically cross sectoral as interdisciplinary groups are needed that are educated in such diverse fields as the natural and social sciences, law, and business. Applying the notions of sustainability science in aquaculture is intended to inspire engagement of governmental agencies, businesses, nongovernmental groups, and academics to achieve the highest form of sustainable development in any known protein production food system by using the concepts of ecological design and through the many forms of stewardship. At present, there is a paucity of information targeted specifically for those engaged in aquaculture programs and projects in places where the ability of government to regulate and direct the processes of ecosystem change is weak or severely constrained.

Sustainability Strategic and Implementation Planning for Aquaculture

The concept of sustainability and the methods to measure the evolutionary progress toward more sustainable systems are limited, but have become a necessity. Wurts [10] stated that "Whether the word sustainability has become overused or not, it has catalyzed a forum for oversight of the growth and development of aquaculture on a global scale."

Sustainability is not a "black/white" phenomena; rather, it is many "shades of gray," an evolutionary process that is called the "sustainability trajectory" (Fig. 1). To measure and evaluate progress along a trajectory requires establishment of baselines for the main issues of public concerns, then developing a diverse but targeted set of resource and social indicators. These indicators are then used to report progress on and analyze interactions between social, environmental,



Aquaculture, Sustainability Science in. Figure 1
Sustainability is neither a "black or white," nor an "either or" concept. It is the evolution of practices and principles over time toward ameliorating environmental and social impacts, with plateaus along the way in changed states. In many cases, these "pauses" are done to ensure economic viability. In this diagram, one example indicator (water use, other important indicators have been proposed [17]) is plotted along such a "sustainability trajectory"

and economic impacts (both positive and negative ones). It is important to note that sustainability science as applied to aquaculture is driven as much by social as by environmental/ecological concerns; thus, sole involvement of technical experts in sustainability plans and assessments is insufficient.

Developing an operational framework for how the sustainability of aquaculture operations operates is the first step. Having such a blueprint is rare for aquaculture businesses and management entities, and is very much needed. There are numerous certification bodies that are vying for the opportunity to use their labels/logos to claim ownership of the sustainability rubric in aquaculture. An overall sustainability science approach is proposed, which can step above the cacophony of approaches and assist in developing a common language and can be used by international and national, non-advocacy organizations such as the FAO, ICES, or governments and industry.

The approach used here is based upon the development of a baseline that has two parts and then follows a sequence of five steps:

The *first part of a baseline* is an ecosystem audit of the AoF that defines the natural and social systems within which aquaculture is planned.

This involves the documentation and analysis of both natural and social systems, draws upon case studies of other aquaculture systems in the region and how the governance system in a specific place has responded – or failed to respond – to the trajectories of ecosystem change. It examines the long-term trends in both human well-being and the environmental conditions in the AoF and examines responses to the issues raised by past and current expressions of food production systems.

The *second part of the baseline* is an outline of the strategic approach to designing a new aquaculture program, or adapting an ongoing program, to address the ecosystem management issues of the place in terms of economic, environmental, and societal benefits. Together, these parts form the reference points against which future changes in the aquaculture ecosystem will be gauged. These methods encourage a long-term perspective, an appreciation of the roles played by civil

society, markets, and government, and offer a holistic, ecosystem-based, approach to stewardship.

Baselines are not formulaic but are designed planning exercises with buy-in from key stakeholders such as the client, community, regulatory community, or identified group of people involved in the project. While not formulaic, baselines do comprise a set of common metrics to include

- Ecological aquaculture design (or redesign) of production practices (see Ecological Aquaculture chapter in this Encyclopedia)
- Health and quality control standards
- Social goals at both the individual and community levels for local food, job, and regional development (e.g., "green jobs," "local foods")
- Governance goals

The following five steps encompass some essential parts of any baselining process:

1. *Define the sustainability issues*. Aquaculture systems can use environmentally derived feeds, water, and energy, occupy land and water space, and generate wastes. There are at least eight issues of wide public and regulatory concerns regarding aquaculture development:
   - Destruction of habitats
   - No net gain to global seafood supplies
   - Environmental impacts of discharged wastes
   - Impacts of escapees
   - Diseases in farmed fish
   - Chemical use and discharge
   - Impacts on coastal marine mammals
   - Improper siting causes visual pollution

   Once issues are defined, a baseline can be further developed which can measure progress over time by
2. *Completing a sustainability assessment* of these issues by evaluating the status of current aquaculture practices that affect natural and social resource systems (Table 1), which also includes an assessment of governance systems (Tables 2 and 3) [11–13]
3. *Completing a detailed risk analysis* for all components of this comprehensive assessment [14]
4. *Completing a plan for ameliorating identified impacts* by incorporation of better (or best) practices [15–17], and/or enhancing reuse or recycling pathways, and
5. *Completing a plan for communicating* the evolution of operations toward greater stewardship and sustainability [14]

To be effective, sustainable aquaculture initiatives must: (a) be "profitable" over long periods of time – ideally many decades; (b) be capable of being adapted to changing conditions; and (c) provide the mechanisms to encourage both wise resource use and collaborative behaviors. Much of the challenge lies in achieving changes in the behavior of those who may be unaware of the benefits of sustainable aquaculture.

Sustainable aquaculture integrates the best available science with a transparent, equitable, and democratic approach to planning and decision-making. This ecosystem approach to management needs to be carried out in a strategic manner that tailors principles of good practice to the culture and the needs of a specific place. Successful, sustainable aquaculture operations advance through linked cycles of planning, implementation, and reassessment. These features of ecosystem management signal the transition from traditional sector-by-sector planning and decision-making to a more holistic approach based on the interactions between sectors and within and among ecosystems.

Aquaculture that is constructed upon principles that encourages high-energy consumption and the profligate use of natural resources must give way to new locally derived values and new forms of practice. As suggested by Daly [18], qualitative development rather than quantitative growth is the path of future progress. If such ideas are to be made operational at the scale of an aquaculture operation, a trajectory can be established based on goals for profit as well as social and environmental benefit. Once the goals of an aquaculture program or project have been defined as expressions of the ecosystem approach, much of the day-to-day work is concerned with the well-known best practices of aquaculture management.

For example, there has been much debate about the impacts of shrimp pond mariculture on mangrove forests through the Topics. Mangrove ecosystems provide essential goods and services to humanity, harboring an extraordinarily large biodiversity for the small

Aquaculture, Sustainability Science in. Table 1 Important sustainability science tools used to assess and communicate the sustainability of aquaculture[1]

Social Sustainability	Environmental Sustainability	Economic Sustainability
Stakeholder analysis: analysis of attitudes of stakeholders at the initiation of and throughout a project. Allows tracking of how stakeholders change attitudes over time with educational processes [46–50]	**Life cycle analysis**: complete assessment of products from raw material production, manufacture, distribution, use and disposal, including all transportation; used to optimize environmental performance of a single product or a company. A similar analysis called a MET (Materials, Energy, and Toxicity) Matrix is also used [53–55]	**Cost-benefit analysis**: analysis of cost effectiveness of different uses to determine if benefits can outweigh costs [59]
ISO 26000 guidelines for corporate social responsibility [51]	**ISO 14000 certification:** norms to promote more effective and efficient environmental management and provide tools for gathering, interpreting, and communicating environmental information [56]	
ICLEI (International Council for Local Environmental Initiatives) provides software and tools to help local governments achieve sustainability goals [52]	**Environmental impact assessment**: the process of identifying, predicting, evaluating, mitigating biophysical, social, and other effects of development proposals prior to policy decisions [57, 58]	**Triple bottom line or "full cost" accounting:** costs considered for all environmental, economic, and social impacts; costs measured in terms of opportunity costs (the value of their best alternative use); guiding principle is to list all parties affected and place a monetary value on effects on welfare as valued by them [60, 61]
	Environmental indicators: the use of quantitative indicators of resource use, efficiency, and waste production in aquaculture [17]	

[1]This table does not contain a comprehensive list of all available tools; rather, tools selected here were chosen since they appear regularly in the modern sustainable aquaculture research, industry, and management literature. Gibson et al. [62] give a most complete analysis of all of the available tools for sustainability assessments.

areas of the planet that these systems occupy, and provide a sustainable source of timber and charcoal to coastal communities while protecting fragile coastlines from erosion and storms. Establishment of proper scientific baselines to measure the true impacts of mariculture on coastal ecosystems is essential. Pullin [19] cautions that, "Analysis on depletion of mangrove cover in Asia point towards the fact that shrimp ponds have recently been and/or now being constructed either on former mangrove areas that were cleared long ago and considered degraded), or on more recently cleared areas for which the primary purpose of clearance was timber abstraction (logging, wood chip industries or charcoal production) or by adopting traditional trapping ponds. . . . Aquaculturists in Asia are therefore more often than not the end users of already degraded or destroyed mangroves rather an the primary culprits of mangrove destruction."

Good examples globally of an ecosystem approach to aquaculture at the watershed/aquaculture zone scale are found in both Israel and Australia. Both nations face severe land, water, and energy constraints. In Israel, highly efficient, landscape-sized integrations of reservoirs with aquaculture and agriculture have been developed [20, 21], as well as highly productive, land-based aquaculture ecosystems for marine species [22]. These aquaculture ecosystems are productive, semi-intensive enterprises that are water and land efficient, and are net

energy and material gains to society. Aquaculture ecosystems are organized following well-established ecological principles similar to the fields of agroecology and agroecosystems [23].

In Australia, an Ecologically Sustainable Development (ESD) framework approach to aquaculture development was used [24]. This ESD framework identified important issues, developed comprehensive reports for each issue, and then prioritized each using risk assessments. The ESD process employed extensive community consultation that considered social and environmental values of all other marine users, and users' management plans for operations and administration as well as environmental administrative attributes, then proposed development and monitoring plans.

As a result of this ESD approach, nine marine aquaculture zones of 2,400 ha in Port Phillip Bay and Westernport, Victoria, Australia were permitted. The Australian ESD approach combined analytical and participatory methods and developed sustainability plans that considered both ecosystem and human well-being, then developed implementation strategies by designing and enhancing effective governance systems for the expansion of aquaculture.

The development of a sustainability baseline should be the responsibility of a lead aquaculture agency. Its full implementation may require alternative methods of governance and employ innovative management approaches. There may be a need to facilitate an operational definition of aquaculture ecosystem boundaries for assessment, or area of focus, to set geographical limits to assess parameters such as carrying capacity or water management needs, and to understand the governance regime within which the area of focus is nested in order to understand and clarify such things as administrative and legal jurisdictions.

Using such guidance and sustainability science frameworks, the possibilities for designing productive aquaculture ecosystems that better fit into the local social and ecological context are many, since aquaculture can encompass the wide availability of species, environments, and cultures.

Improved Governance of Aquaculture Ecosystems

To be effective, ecosystem-based aquaculture initiatives must (1) be sustainable over long periods of time – ideally over many decades, (2) be capable of being adaptable to changing conditions, and (3) provide the mechanisms to encourage or require specified forms of resource use and collaborative behaviors among institutions and user groups that are stakeholders of the aquaculture system. Much of the challenge lies in both understanding and achieving changes in the behavior of the stakeholder groups and institutions associated with the aquaculture production systems. Ecosystem-based aquaculture integrates the best available science with a transparent, equitable, and democratic approach to planning and decision-making. Management needs to be carried out in a strategic manner that tailors principles of good aquaculture practice to the culture and the needs of a specific place. Successful aquaculture programs advance and change through linked cycles of planning, implementation, and reassessment. These features of ecosystem management signal the transition

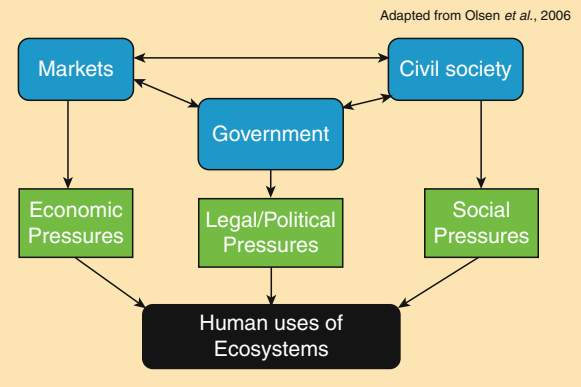
Aquaculture, Sustainability Science in. Table 3 Orders of governance outcomes [12, 13] applied to an ecosystem approach to aquaculture [2, 3]

Orders	Explanations	Indicators
First Order	Government at the national level commits to a plan of action designed to adopt an ecosystem approach to aquaculture (EAA) by issuing a formalized commitment to an EAA, thereby putting in place the "enabling conditions"	New laws, programs, and procedures are initiated that provide the legal, administrative, and management mechanisms to achieve the desired changes in behavior by:
		(i) Building constituencies that actively support EAA with the user groups that will be most affected; with government institutions involved; and with the general public
		(ii) Developing a formal government mandate for an EAA with the authority necessary to implement actions in the form of laws, decrees, or other high-level administrative decisions that create an EAA as a permanent feature of the governance structure of aquaculture; creation of commissions, working groups, user organizations, and nongovernmental organizations (NGOs) dedicated to the advancement of an EAA agenda; designating EAA zones
		(iii) Devoting resources, especially sustained annual funding, adequate to implement an EAA
		(iv) Developing an implementation plan of action for an EAA that is constructed around unambiguous goals
		(v) Creating the institutional capacity necessary to implement the new EAA plan of action
Second Order	Evidence of successful implementation of an EAA	1. Changes in the behavior of institutions and interest groups have occurred such as collaborative planning and decision-making through creation of task forces, commissions, civic associations, etc.
		2. Successful application of conflict mediation activities
		3. Evidence of functional changes such as establishment of new public–private partnerships, new collaborative actions undertaken by user groups, implementation of new school curricula that incorporates an EAA
		4. Changes in behaviors directly affecting ecosystem goods and services, such as the elimination of socially and environmentally destructive aquaculture practices
		5. Investments in infrastructure supportive of EAA policies and plans
Third Order	Evidence of sustained achievements in institutional and behavioral change due to an EAA as seen in the environment and indicators for the quality of life, incomes, or engagement in alternative livelihoods that have improved target communities	1. Improvements in ecosystem qualities, such as sustained conservation of desired ecosystems and habitats, halting or slowing undesired trends such as nutrient releases, feed wastage, diseases, damaged benthic ecosystems, etc.
		2. Improvements in society as evidenced by monitoring of social indicators such as increases in indices of quality of life, reduced poverty, greater life expectancy, better employment opportunities, greater equity in access to coastal resources, and the distribution of benefits from their use, greater order, transparency, and accountability in how planning and aquaculture development decision-making processes occur, greater food security, or greater confidence in the future

from traditional food production sector planning and decision-making to a holistic approach based on the interactions between sectors and within and among ecosystems.

FAO Fisheries and Aquaculture Department [25] found that one of the key trends toward more sustainable forms of aquaculture development and management is enhanced regulation and better governance. Governance is defined as the formal and informal arrangements, institutions, and mores that structure and influence how resources or an environment are utilized, how problems and opportunities are evaluated and analyzed, what behavior is deemed acceptable or forbidden, and what rules and sanctions are applied to affect how natural resources are distributed and used.

As shown in Table 2, there are three mechanisms by which the processes of governance are expressed: the marketplace, the government, and the institutions and arrangements of civil society [11]. These mechanisms interact with one another through complex and dynamic interrelationships that are examined and contrasted and documented in a baseline. Each of the three governance mechanisms influence and can alter patterns of behavior through measures such as those identified in Fig. 2. For sustainable, ecosystems-based aquaculture, it is important to distinguish between management and governance. Management is the process by which human and material resources are harnessed to achieve a known goal within a known institutional structure. Aquaculture business management, park management, personnel management, or disaster management is therefore spoken about. In these instances, the goals and the mechanisms of administration are well known and widely accepted. Governance, in contrast, addresses the values, policies, laws, and institutions by which a set of issues are addressed. It probes the fundamental goals and the institutional processes and structures that are the basis for planning and decision-making. Governance sets the stage within which management occurs [12].

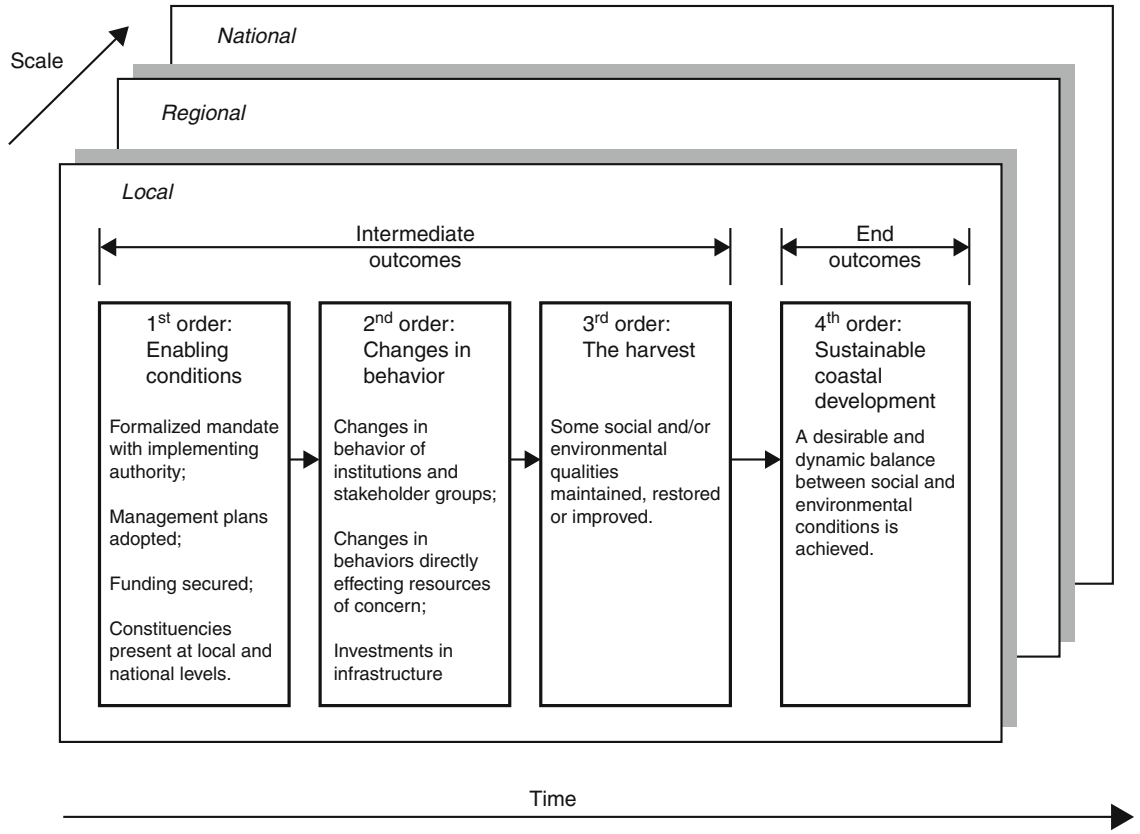


Aquaculture, Sustainability Science in. Figure 2
The three mechanisms by which the processes of governance are expressed interact with one another through complex and dynamic interrelationships that are vital parts of sustainability science assessments of aquaculture as each alter behaviors and decision-making that determine human uses of ecosystems [11–13]

The future of sustainable aquaculture is highly dependent on understanding the response by all three expressions of governance: markets, civil society, and government. For example, Kenya has fostered a participatory policy formulation for aquaculture, providing a legal and investment framework through government, establishing public–private partnerships to engage markets, providing basic infrastructure support, promoting self-regulation, providing a research platform for civil society to be engaged, undertaking zoning for aquaculture, and providing monitoring and evaluation support [25].

Adaptation of sustainability frameworks used to evaluate the needs and progress of governance on coastal management plans are essential to evaluate progress toward an ecosystem approach to aquaculture and build in adaptive learning and action into the strategic planning process. Governance frameworks recognize not only the importance of changes in practices such as changes over time in aquaculture farming ecosystems, but also recognize that for each change, there are correlated changes in the behavior of key partners and stakeholders within the sphere of influence of the management activity, and that these changes can be measured at local, regional, and national levels (Fig. 3, Table 3).

Sectoral agencies responsible for managing activities impacting aquatic ecosystems (e.g., capture fisheries, coastal zone development, watershed management organizations, agriculture, forestry, and industrial developments) will have to develop new ways of interacting to regularly communicate, cooperate, and



Aquaculture, Sustainability Science in. Figure 3
The four orders of coastal governance outcomes. This framework is used to develop governance baselines in environmental programs [12, 13]. An example of how progress toward better governance for sustainable aquaculture is shown in Table 3

collaborate. The need for innovative governance to implement an ecosystem-based approach to aquaculture can be seen as an obstacle but can also be seen as an opportunity to increase the social benefits that are likely to develop through synergies among food production sectors.

Social Ecology of Aquaculture

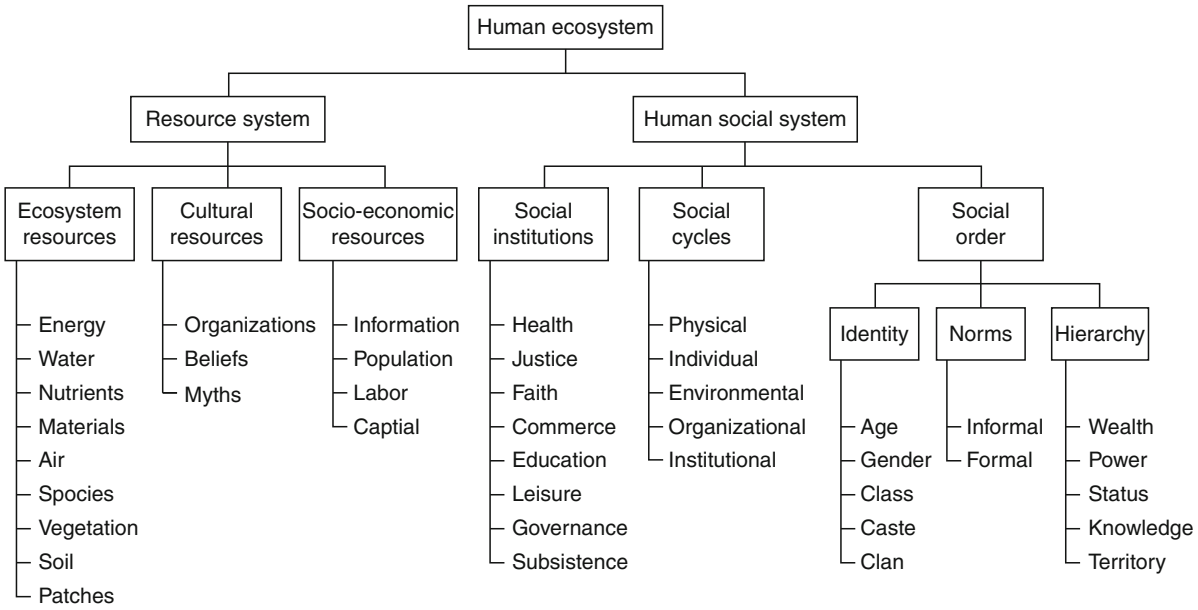
While there is much information on the natural ecology of food-producing ecosystems, there are few comprehensive frameworks for capturing the necessary social ecology of aquaculture.

Cadenasso et al. [26] have developed a "Human Ecosystem Framework" that could contribute to a baseline approach and assist in organizing multidisciplinary, social–ecological approaches to aquaculture development (Fig. 4). The most sustainable growth trajectories for aquaculture are to move toward more sustainable, social–ecological approaches to development; to shift patterns of production and consumption patterns from global to bioregional and local foods production and job creation; and to develop the indigenous human and institutional capacities that clearly demonstrate to society that "aquaculture is culture."

Future Directions: Sustainability Science Opportunities for Aquaculture

There are at least four major opportunities for sustainability science in the field of aquaculture in the

1. Determination of "sustainable aquaculture" for retail seafood companies
2. Growing fields of marine ecosystem and habitat restoration, conservation biology, and ecology



Aquaculture, Sustainability Science in. Figure 4
The Human Ecosystem Framework [26]. Assessment of new interventions such as aquaculture into societies requires knowledge of not only biophysical and natural resource systems but also social resources and human social systems

3. Accelerated use of agricultural meals and oils, and
4. Development of sustainable aquaculture for the poor

Determination of Sustainable Aquaculture for Retailers

Sustainability science approaches to aquaculture can be used to better plan and develop aquaculture production networks for multiple species. Such planning approaches can be used to plan for the creation of highly diversified, segmented aquaculture networks, for maximal job creation at every unit step from "farm to plate" (e.g., seafood value chain planning), by creating numerous interconnections supplying inputs and outputs using local resources and recycled wastes and materials and expertise, and to close "leaky" loops of energy and materials that can potentially degrade natural ecosystems.

Behavioral changes will be required by industry. Social investments, strategic incentives/subsidies, and innovative market mechanisms can help facilitate change in behaviors. Self-regulation by the aquaculture industry has led to codes of practice and better management practices.

Sustainability assessments are predicated upon the fact that the modern aquaculture industry desires to be seen as a responsible steward. This means going beyond "meeting the regulations." There are a cacophony of certification bodies and seafood watch cards – there are an estimated 200 sustainable seafood guides available internationally – which has created a far too complex and sometimes conflicting recommendations to both consumers and retailers on what is "sustainable seafood" [27, 28]. Roheim [27] states that "Shrimp, in some form, appears as a green, yellow, red, and non-consensus list item" in the seafood "watch cards."

The logic behind consumer approaches is that informed consumers who care about sustainable seafood will demand aquaculture products that carry a label or fit into the "green" (buy) area of a watch card, as opposed to those products that do not have the label, sending a market signal back to aquaculture industries that only products from sustainable aquaculture farms are preferred. Many of the independent certification programs that have developed ecolabels and "seafood watch cards" to provide consumers with additional information come from nongovernmental organizations (NGOs) with specific advocacy agendas

and not from neutral, scientific sources, or from regulatory bodies charged with protecting the environment and society. For example, many fisheries and aquaculture scientists are deeply concerned that consumer recommendations of NGOs are moving demand (and use) from farmed stocks to already overburdened wild fisheries. The Monterey Bay Aquarium's (MBA) Seafood Watch Program has produced millions of folding wallet cards featuring a "stop light" system of green (sustainable), yellow (chose with caution), and red (do not choose) recommendations. Farmed shrimp and salmon, two of the world's largest aquaculture industries are on the MBA red list. Roheim [27] mentions that the Compass Group a major food service company has used the MBA cards to decrease purchases of farmed shrimp and salmon, which, in effect, has created additional fishing pressure on wild shrimp and salmon stocks.

Most organizations believe that consumers' increasing awareness of environmental and food safety issues will lead them to accept a wide variety of standards and labels, most of which are specifically intended to allay consumers' concerns about negative environmental consequences.

However, Roheim [27–29] points out concerns over ecolabeling, especially the lack of transparency and opportunity for participation in the development of standards, and concerns of developing countries that ecolabeling schemes are an attempt at disguised protection of domestic industries to restrict market access and erode competitiveness. In addition, Wessels et al. [30] found that successful ecolabeling programs must accelerate consumer education programs so that consumers become more aware of differences in species, geographic regions, and certifying agencies.

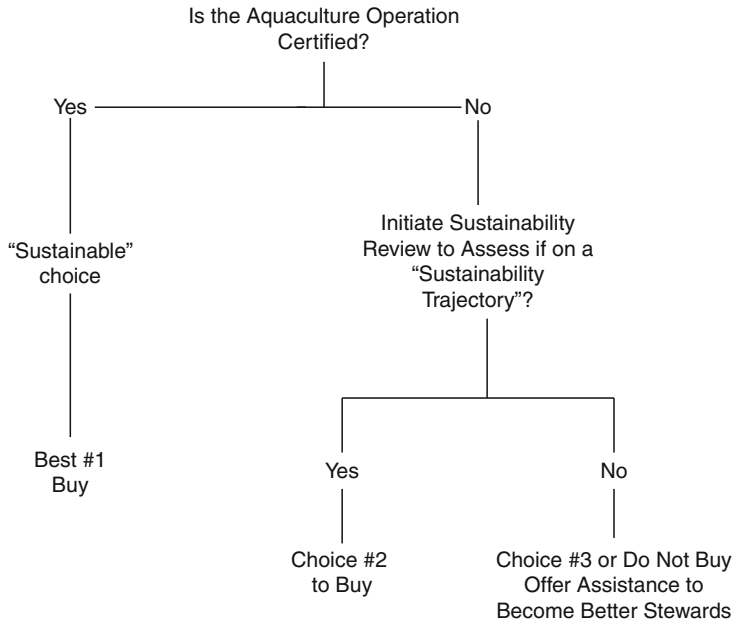
Roheim [29] states that ecolabels require traceability. Traceability is the ability to follow the movement of a food through specified stages of production, processing, and distribution. Essentially, it is a record-keeping system that identifies and tracks products, transportation of products, and ingredients of products from origin to consumption, while providing the ability to quickly trace back products at any point along the supply chain. It is necessary for food safety purposes, in order to track backward in the food chain the source of food that made consumers ill, so that products could be removed from store shelves.

For consumers, Roheim [27] argues the need for ecolabels determined at the larger international levels, such as the Marine Stewardship Council (MSC), so that consumers "do not need to inquire about catch area or gear types, but only need to look for the label." The plethora of efforts has also confused and perplexed retailers who are the main "drivers" of certification at present, not consumers [27–29]. However, even though many buyers wish to purchase sustainable seafood, most seafood products are not certified, and they are very confused by the many NGO efforts. A purchasing policy determined by assessing which seafoods are "sustainable" by making an assessment of the plethora of NGOs, "opinions" seems confusing, risky, and costly. Rather, a simple, buying protocol (Fig. 5) that incorporates a sustainability assessment (where needed) as discussed here is recommended.

Aquaculture and the Restoration of Ecosystems

Aquaculture science can be viewed as a "toolbox" with great potential for restoring aquatic ecosystems. There is an unbalanced focus on marine animal husbandry (e.g., "fed" aquaculture) causing a lack of appreciation for the positive environmental attributes of nonfood aquaculture such as marine agronomy, endangered species aquaculture, and aquaculture for environmental enhancement and rehabilitation, all of which use modern marine hatchery and nursery aquaculture practices [31].

Aquaculture technologies (hatchery, nursery, grow-out) for marine plants are used for the restoration of mangroves, sea grasses, and coastal wetland plants such as *Spartina sp.* In addition, live rock and coral aquaculture facilities are active for not only the aquarium trade, but also for the environmental restoration of coral reefs (liveaquaria.com). In this regard, there is little difference between sustainable aquaculture and the emerging fields of ecological engineering and industrial ecology. Indeed, tidal wetland, mangrove forest, coral, and sea grass restoration aquaculture – in addition to establishment and maintenance of oyster reefs – are important examples of aquaculture creating, enhancing, and maintaining productive marine ecosystems and habitats, and improving water quality.



Aquaculture, Sustainability Science in. Figure 5
A simple decision tree for determinations of the sustainability of aquaculture products by retailers

Aquaculture and Agriculture Science

Here, science questions as to whether aquaculture contributes to the depletion of world fisheries. Fed aquaculture depends on both wild and farmed fish stocks and on intact aquatic habitats and excellent water quality, plus a growing quantity of agricultural resources. There is much ongoing policy, research, and management concerns on the interactions of marine food fish fisheries ("biomass fisheries") with aquaculture and human welfare. There is much less planning and research regarding the future impacts of fed aquaculture on agriculture.

Agricultural meals and oils as alternatives to marine sources are developing rapidly. Current projections forecast that fed aquaculture may use 50% or less of the world's fish meal [32], which would mean a large expansion of use of agricultural and other terrestrial sources of feed proteins and oils. Terrestrial proteins and oils from soybeans, sunflowers, and lupins are available at volumes larger than the available global quantities of fish meal. Soybeans have high protein content of ~28%, peas have ~22%, and these have good amino acid profiles. Other abundant agricultural cereals have lower protein contents of ~12–15%. Processing can create protein concentrates with protein levels of >50% [33]. Vegetable oils have very low EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) levels. However, substitution of plant oils upward of 50% of added dietary oil has not resulted in growth reductions or increased mortalities in fish such as salmon and trout.

If agricultural sources of meals and oils are the future of fed aquaculture, there will be a need for a new sustainability planning and science on the impacts of fed aquaculture as a driver of agriculture production, especially so for soybeans. Increased aquaculture consumption of the world's grains and oils raises the concern over the spread of unsustainable agriculture practices. Brazil has been targeted as one of the world's major soybean suppliers. Costa et al. [34] have demonstrated that soybean farms are causing reduced rainfall in the Amazonian rainforest. About one seventh of the Brazilian rainforest has been cut for agriculture, about 15% of which is soybeans. Soybeans, which are light in color, reflect more solar radiation, heating the surface of the land less and reducing the amount of warm air convected from the ground. Fewer clouds form as a result, and less precipitation falls. In soybean

areas, there was a 16% less rainfall compared to a 4% decrease in rainfall in land areas cleared for pasture.

Aquaculture for the Poor

Approximately 1.3 billion people live on less than a dollar a day, and half of the world's population lives on less than 2 dollars a day. FAO has stated that the world will need to produce 70% more food for an additional 2.3 billion people by 2050 [4]. Scarce natural resources will need to be used more efficiently, and there will be a need for proper socioeconomic frameworks to address imbalances and inequities to ensure that everyone in the world has access to the food they need. Food production will have to be carried out in a way that reduces poverty and takes account of natural resource limitations [4].

The world's population will rise from 6.8 to 9.1 billion in 2050, with nearly all population growth occurring in the economically developing countries. Without additional global food strategies, an estimated 370 million people will be hungry in 2050. The magnitude of the problem is most acute in Africa. In 10 African countries of an estimated 316 million persons where aquatic proteins are an important dietary component, 216 million live on US$2/day, 88 million are undernourished, and 16 million children under 5 are malnourished [35].

Small-scale coastal and inland freshwater fisheries provide more than 90% of the fish consumed in Africa. Over 2.5 million people are involved in fishing and 7.5 million in trading, marketing, and processing. The most important fisheries/aquaculture ecosystems are located on the coasts of west and southern Africa and the river basins of Senegal, Niger, Volta, Congo, Lake Chad, Nile, and Zambezi Rivers. But today, aquaculture provides less than 5% of Africa's fish, with most concentrated in Egypt and Nigeria [35].

Aquaculture is a global enterprise with local roots. There are strong concerns that aquaculture is evolving away from its global responsibility to provide net benefits (additional foods) for a protein-hungry planet [36–38]. Greater than 75% of global fisheries are traded. In 2000, more than 60% of fish meal was traded. Only 7% of meat is traded, 17% of wheat, and 5% of rice. To tackle this huge challenge, the FAO ecosystems approach to aquaculture [39] has created a new code for responsible global aquaculture development, and has combined this into one common development framework for a global implementation strategy for aquaculture that can be used to measure the trajectory of social responsibility for global aquaculture.

If aquaculture is designed, implemented, and evaluated as aquaculture ecosystems, a new social contract would have a close relationship between aquaculture professionals who not only develop an alternative model of aquaculture development but also interact closely with capture fisheries and agriculture but help deliver to the world's poor its needs for nutrient dense, protein-rich seafoods. Components of a global strategy could be to:

1. **Allocate more food fish and oils for poverty alleviation and human needs worldwide, and allocate less marine resources for feed fish for fed aquaculture so as to: (a) increase the ecosystem resilience of the Humboldt ecosystem, and (b) relieve the increasing overdependence of aquaculture countries such as Thailand (shrimp) and Norway (salmon) on this southeastern Pacific Ocean marine ecosystem.**

   Alder et al. [37] estimated that about 36% of the world's fisheries catch (30 million tons) are processed into fish meal and oil, mostly to feed farmed fish, chickens, and pigs. Daniel Pauly of the University of British Columbia has stated that "Globally, pigs and chickens alone consume six times the amount of seafood as US consumers and twice that of Japan." Jacquet et al. [28] reported that Peru exports about half of the world's fish meal from its catch of 5–10 MMT/year of anchovies while half of its population of 15 million live in poverty and 25% of its infants are malnourished. A campaign launched in 2006 combining scientists, chefs, and politicians to demonstrate that anchovies are more valuable to the Peruvian people and its economy as direct foods has resulted in a 46% increase in demand fresh and 85% increase in canned anchovies. One ton of fillets has sold for five times the price of 1 t of meal and requires half the fish (3 t for 1 t fillets vs. 6 t for 1 t meal). Peru has decided to dedicate 30% of its annual food security budget (approx. US$ 80 million) for programs to supply anchovies to its people. Higher prices for

fish used as direct human foods for food security will limit processing of fish to meals for terrestrial animal and aquaculture feeds, thereby decreasing the supply of fish meals and oils for global aquaculture trade and development, but meeting the Millennium Development Goals of eliminating everywhere extreme hunger and starvation.

2. **Accelerate research into the elucidating functional feed ingredients in fish diets that are showing the potential to eliminate the needs for fish meal and oils in aquaculture.**

   Skretting Aquaculture Research Centre [40] reported a research on "functional ingredients" that are contained in fish meals and oils, which contribute to efficient feed conversions and high growth rates, fish health, and welfare. Initial research focused on beta-glucans that not only stimulate the immune system of fish and protect against the effects of bacterial furunculosis but also allow reductions in fish meal contents in diets to 25%. Additional research with phospholipids in meals, triglycerides in fish oil, and antioxidants in 2008 have resulted in excellent fish performances from feeds with almost no marine fish meal and oil. Current research is exploring the extraction of functional ingredients from other non-marine by-products.

3. **Develop alternative ecological aquaculture models that accelerate the movement toward use of agricultural, algal, bacterial, yeasts meals, and oils.**

   Aquaculture uses most of the world's fish meal (68%) and fish oil (88%); however, Tacon and Metian [32] predict that fish meal and oil use in aquaculture will decrease to become high priced, specialty feed ingredients. Currently, about 40% of aquaculture depends on formulated feeds: 100% of salmon, 83% of shrimp, and 38% of carp. As stated previously, research on the use of agricultural meals and oils to replace use of ocean resources especially on the functional components of fish meals/oils needed for fish nutrition is a major subject of aquaculture research and development [41, 42]. Turchini et al. [43] reported that for all of the major aquaculture fish species that 60–75% of dietary fish oil can be substituted with alternative lipid sources without significantly affecting growth performance, feed efficiency, and feed intake. Naing et al. [44] found that palm oil could replace fish oil in rainbow trout diets, and reduce the dioxin contents in fish.

4. **Develop new governance systems that integrate aquaculture, agriculture, and fisheries using ecosystem-based management approaches, which combine production, distribution, and consumption networks that do not institutionalize poverty and hunger, but provide new alternative tools and education in multisectoral ecosystem approaches.**

   The massive environmental change being brought about by the accelerated growth of the world's population has caused profound change to the world's ecosystems. Crutzen and Stoermer [45] have called this new era the "Anthropocene." In this era, massive quantities of additional foodstuffs will be needed to sustain humanity; nutrient-dense, high-quality aquatic proteins will be especially important. The tools and training for creating the next generation of transdisciplinary, sustainability scientists will need to be further developed and well utilized; otherwise, it will result in serious consequences for the Earth's living systems.

Aquapod Systems for Sustainable Ocean Aquaculture

Stephen H. Page
Ocean Farm Technologies, Inc., Morrill, ME, USA

Article Outline

Glossary

Artisanal fisheries Traditional fisheries involving fishing households (as opposed to commercial companies), using relatively small amount of capital and energy, relatively small fishing vessels or canoes, often beach-based, making short fishing trips, close to shore, mainly for local consumption.

Biofouling The accumulation of living organisms on some surface by bacteria, fungi, protozoa, algae, and invertebrates.

Geodesic The shortest line between two points on a specific surface.

Open ocean aquaculture The culture of marine organisms in exposed ocean locations, not sheltered by islands or embayments.

Definition of the Subject

Open ocean aquaculture is not well defined by the industry, but in general refers to culture of marine fish, invertebrates, or algae in exposed ocean locations. Open ocean aquaculture is contrasted to near-shore marine aquaculture in that it occurs in areas removed spatially from land, typically by 1 km or more; deep water, generally deeper than 20 m; and exposure to wind, waves, and ocean currents without shelter from the mainland or islands. The subject of this entry is principally the design and engineering of containment systems suited for open ocean aquaculture.

Introduction

Near-shore finfish aquaculture worldwide is challenged and constrained by resource user competition, environmental carrying capacity of near-shore environments, and, in most cold-water regions of the world essentially a monoculture of Atlantic salmon. Expansion of marine aquaculture in the next 20 years will happen substantially in offshore, exposed open ocean areas, with a diversification of species.

The patented Aquapod™ is a unique containment system for marine aquaculture, suited for rough open ocean conditions and a diversity of species. The Aquapod is constructed of individual triangular net panels fastened together in a spheroid shape (Fig. 1). The majority of the panels are simply structural members and netting. Some individual panels or groups of panels have other functions, such as access, feeding, fish transfer and grading, harvest, mooring, and mortality recovery. Other individual panels may have pneumatically controlled flotation devices which allow an almost infinite orientation of the Aquapod in the water. The Aquapod functions as a total containment system for finfish while submerged or partially surfaced.

Elements of the design have benefits for reduction in labor for routine husbandry tasks, reduction in maintenance costs, and reduction of stress on aquatic animals during handling operations such as transfer, treatment, and harvest. The "exoskeleton" design of the Aquapod containment system also allows for internal structures to provide for the cultivation of flatfish species such as halibut and flounder.

Features of the Aquapod Containment System

Submersibility: Submersion is the preferred, if not the only way to operate fish containment systems in the open ocean. Submergence is necessary to operate a fish pen below the destructive energy of surface waves. Submergence also allows fish to be kept at favorable temperatures below warm water thermoclines. The Aquapod can be operated partially surfaced (Fig. 2) or fully submerged (Fig. 3). Although there are other pen designs which are designed to operate submerged, the spherical Aquapod design is well suited for species such as Atlantic salmon, which require periodic access to substantial surface area in order to gulp air.

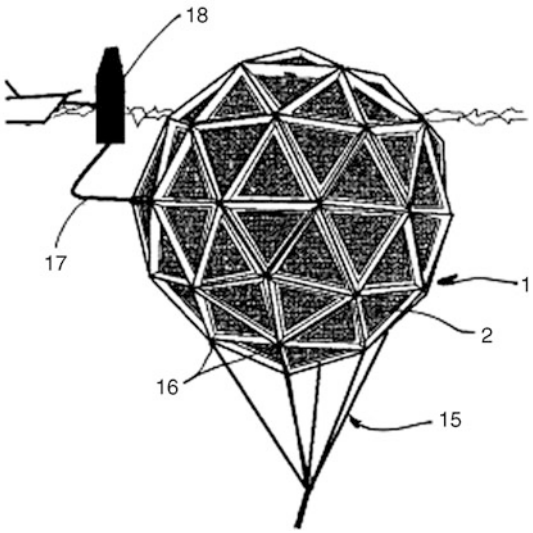
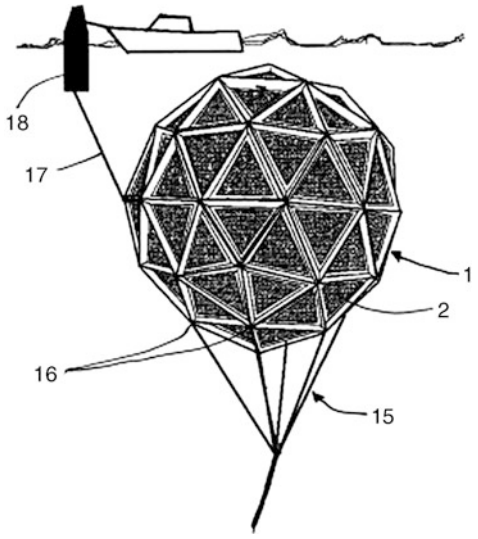
Aquapod Systems for Sustainable Ocean Aquaculture. Figure 1
The scale of contemporary net pens to date has become problematic especially in terms of net-handling activities, which are labor intensive, require significantly sized hydraulic equipment, and cannot be performed in rough ocean conditions. The modular nature of the Aquapod solves this problem by utilizing individual net panels which are interchangeable and scaled to be handled without difficulty in adverse conditions. These net panels are fastened together to form a secure enclosure, tailored to each customer's specific requirements



Aquapod Systems for Sustainable Ocean Aquaculture. Figure 2
The structure of the Aquapod net pen allows for many configurations of mooring attachment. Figure 2 shows an Aquapod net pen partially surfaced



Aquapod Systems for Sustainable Ocean Aquaculture. Figure 3
An Aquapod net pen submerged

Fixed volume: The Aquapod maintains its shape and volume in strong currents or undertow, reducing stress and physical damage to the fish contained within. Aquapod net pens can be constructed to any size to fit individual customer's needs, with a practical range of 8 m diameter (212 m^3) to 24 m diameter (7,000 m^3).

Containment: The structural exoskeleton of the Aquapod provides a high ratio of structural support to net area. Each triangular panel is comprised of an essentially rigid frame supporting tensioned netting. Frames can be constructed of marine grade aluminum, fiber-reinforced polymer, or even a combination of materials. The modular nature of the Aquapod containment system provides for easy inspection and inventory control as required by today's mandated containment management systems. Individual net panels are coded so they can be brought into a regular schedule of inspection, maintenance, repair, and replacement. While surfaced in suitable conditions, a single net panel or a group of net panels can be removed and replaced without compromising the integrity of the containment. No other system can offer this convenience.

Predator control and escapement: Tensioned netting has proven to be relatively predator proof in other engineered systems. The Aquapod goes one step further. Due to the modular structure and the relatively small triangular units, different types of wire mesh can be used in place of synthetic netting. This enhances predator control in areas where triggerfish, sharks, sea lions, and crocodiles have made fish farming impractical. Wire mesh also prevents escapement by chewing fish such as cod and sea bream, which readily chew through synthetic fiber netting.

Husbandry and fish health: Fish can be moved from one Aquapod containment to another without seining or pumping. Patent pending displacement technology is capable of transferring fish from one Aquapod containment pen to another without brailing or pumping, or from an Aquapod containment to a harvesting pump without seining or other stressful means of crowding the fish. While being transferred, fish can be graded and counted with automated technology. In competitive designs, these fish-handling operations are either impossible or very labor intensive and stressful on the fish.

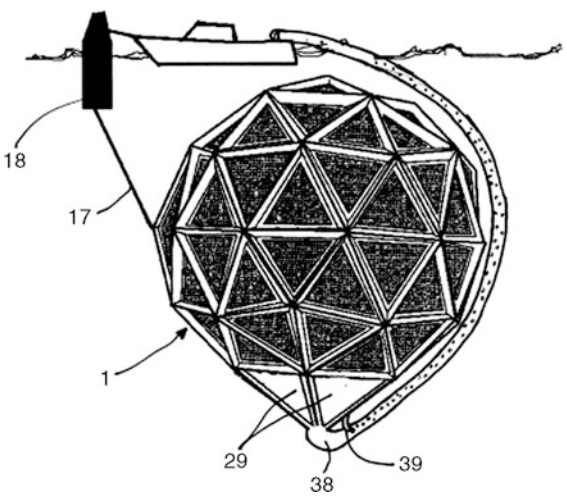
Feeding: One or more panels in each Aquapod containment is modified to receive and distribute hydraulically supplied feed from a centralized feed barge or service boat. The semirigid and modular exoskeleton of the Aquapod allows easy attachment of any number of feeding ports. Multiple feed outlets provide better distribution of feed to the fish.

Safety: Worker safety is a paramount concern when operating fish farms in open ocean conditions. Since conception, the Aquapod containment system has been designed to maximize automation of routine husbandry tasks and reduce the amount of time divers are needed in the water. Although any containment system will need some diving, the ability of the Aquapod to rotate within its mooring grid, bringing any segment of the pen to the surface or near to the surface, reduces the amount of diving, and when diving is needed, the depth of the dives will be greatly reduced. One of the most dangerous jobs on a fish farm is net changing, and the Aquapod eliminates this chore by providing a means to clean nets at the surface.

Waste management: The spherical design of the structure causes mortalities to collect at the bottom of the pen where they can be brought to the surface with a conventional airlift pump, eliminating the routine and hazardous task of mortality collection by divers (Fig. 4).

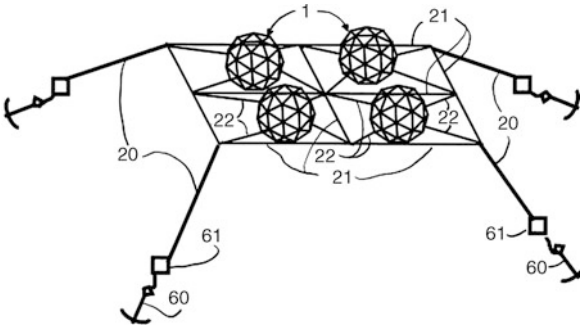
Mooring. There are many options for mooring an Aquapod net pen. Each hub of the frame is a potential mooring point, which allows enormous flexibility in mooring placement and the ability to distribute loads over a large area for safety. Any specific net panel can be strengthened to facilitate predicted maximum mooring stresses, whether the Aquapod is attached to a single-point mooring or whether it is installed in a conventional submerged grid system (Fig. 5). Another mooring option available in suitable site is a two-point mooring (Fig. 6) that facilitates Aquapod rotation.

Cost: On a capital cost per cubic meter of containment basis, the Aquapod containment system is significantly more than conventional surface pens but significantly less than the cost of currently available submersible net pens. Furthermore, when submerged, the volume used to calculate containment is accurately figured, unlike surface pens which calculate the volume in the top part of the water column, although that space is not used by the fish. Operational costs are less than



Aquapod Systems for Sustainable Ocean Aquaculture. Figure 4
A simple air lift suction pump can remove mortalities and waste from the bottom of the Aquapod net pen for removal and processing

existing systems due to the efficiency of the proprietary fish transfer technology for routine husbandry tasks. Maintenance costs are reduced by the modular nature of the net panels and the ability to orient the Aquapod so that any part of the net pen is at or near the water surface, making it easy to inspect, remove, and replace individual net panels. When optional vinyl-coated wire mesh is used for netting, net replacement is reduced and net washing is greatly facilitated.



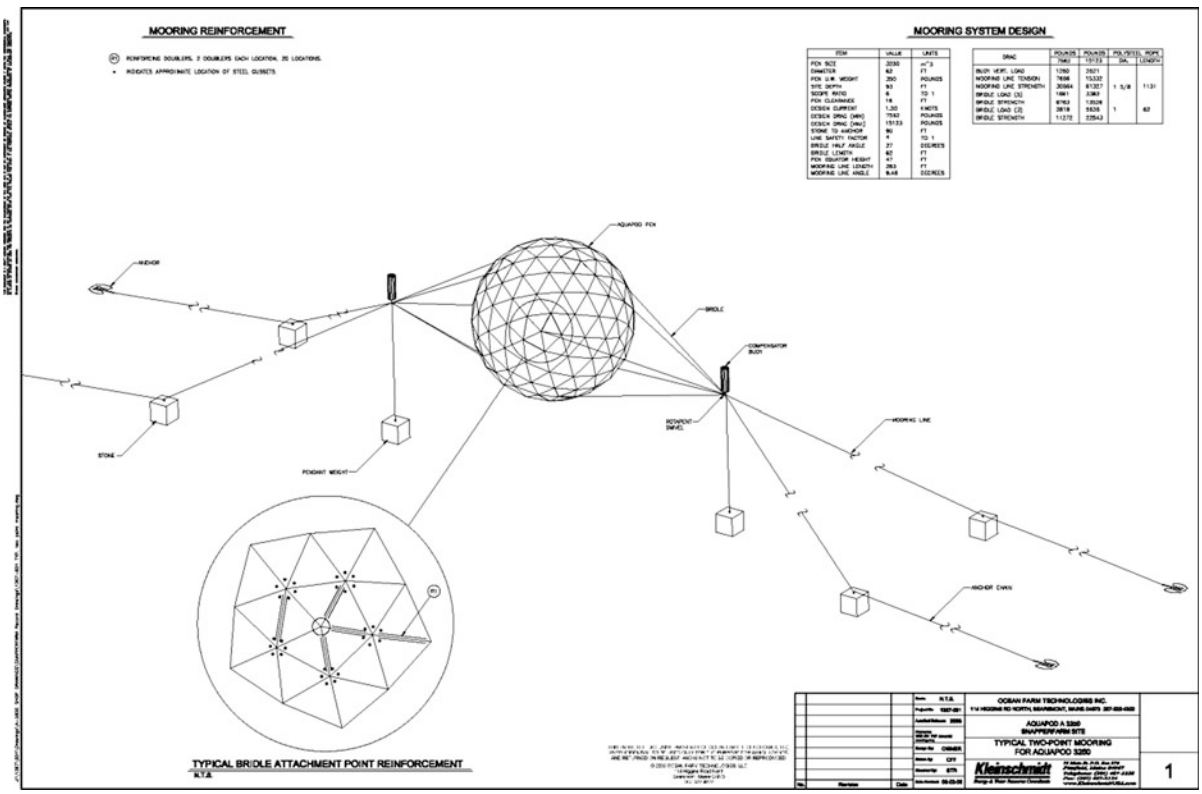
Aquapod Systems for Sustainable Ocean Aquaculture. Figure 5
Aquapod net pens can be moored in many different configurations of grids

The true cost of any system is not only the initial capital cost, but the life cycle cost and the cost of operations, including risk. The Aquapod has been designed with these factors as principal drivers.

Aquapod Technology and Engineering Description

Current State of Design and Materials

The engineering work to date on the Aquapod design has centered primarily on early 10 m (31 ft) diameter units, the larger 19 m (64 ft) diameter A3600 size, and more recent 8 m (27 ft) A212 Micropods. All these models have used recycled HDPE materials as the



Aquapod Systems for Sustainable Ocean Aquaculture. Figure 6
Single Aquapod net pens can be moored individually in a two-point mooring. With swivels at the bridle attachment points, this allows for rotation of the net pen

primary element for the struts, and plastic-coated welded wire mesh for the net fabric. Selective reinforcement around the mooring attachment points has addressed strength issues. So far these materials seem to work well and have been a basis for all Aquapod installations to date. The innovations by Ocean Farm Technologies (OFT) with testing and analysis have been steadily advancing the design, learning the relative cost and difficulty of various ideas, with the goal of refining the concept and improving the economy of the design, manufacture assembly, and installation procedures.

Mooring system components have been selected to create a two-point design allowing movement in the vertical direction and rotation, and single-point moorings. Buoyancy calculations have been done to confirm the near-neutral buoyancy of the system.

The main engineering goal is to design an economical pen that is strong enough, but not excessively heavy or expensive, by defining the real safety factor of the current design, and seeing where further structural design improvements might be made. With a large structure with so many repetitive elements, the changes in any one element are repeated hundreds of times, and thus has a real effect on cost and fabrication. Further work is also being done by OFT with more long-range improvements and concepts for different types of designs using different materials or assembly ideas.

Further data from the real size pens has been used to confirm drag forces. Loading of the pen has to date been based on a tow test performed by a University of New Hampshire boat on the 31-ft geodesic pen and has been scaled up for the 62-ft pen [1]. OFT plans to measure drag loads on existing pens as a function of current velocity and thus more accurately establish this relationship. The current drag forces used to date are on the conservative side, allowing for the effect of biofouling that increases drag.

The structural effect of wire mesh on the Aquapod is obvious but difficult to measure or model. The mesh contribution has not been credited in the analysis to date, except to provide buckling restraint for the compression member weak axes. As far as basic strength, the mesh can help reduce tension stresses, but will do nothing to reduce compressive stresses in the struts, and since these are usually of about the same magnitude over the sphere, the overall effect may not be of much importance.

Results of University of Maine Engineering Study

The use of recycled HDPE [2] plastic extrusions in this type of structural engineering application is rare and, for the designer, the available data on materials and fasteners in the material is limited. For design of the Aquapod struts, it is necessary to check the capacity of the tension and compression members. Needed for compression members are values to use for modulus of elasticity, maximum allowable stresses for compression, based on buckling, yielding, and crushing, and creep rupture of the real life struts. For design of the tension members, the modulus of elasticity, maximum and allowable tensile stresses, and fastener strengths are needed. In addition, bolts and other fasteners are used in the Aquapod and data is needed regarding end and edge distances, strengths, and yield points. Testing of the full size members and hub assemblies has been desirable to confirm the actual strength of real life members, and thus provide an indication of the real safety factor provided in the pen.

The Hybrid Structures Testing Laboratory in the Mechanical Engineering Department, at the University of Maine, was engaged by OFT and performed initial testing (1) to determine engineering data for the plastic material that is used in the Aquapod net pen system and (2) to test sub-component details of the Aquapod system. The goal has been to have design guidance to use as the limits for the members, as calculated for the pen under the various load scenarios. Testing was performed under the direction of Vincent Caccese, Ph.D., P.E., Professor of Mechanical Engineering (Caccese).

The testing consisted of a total of 62 structural tests of components as follows:

1. Material Bolt Bearing, Tensile, and Shear-out Capacity (40 tests performed)
2. Column Compression Tests (20 tests performed)
3. Mesh Assembly Buckling (2 tests performed)

The bolt tests were done first and arrived early enough to size the bolts in the Aquapod 3250. These tests were primarily to determine the bolt capacities for the tension members in the Aquapod, and to determine how many, and what size bolts would provide the required tension transfer from component to component, principally in the steel-reinforced connections

around the mooring attachment points. These tests also showed that the tensile capacity of the struts is a controlled by the holes, and tension members will fail first at the bolt holes.

The compression tests were primarily aimed at determining maximum compression loads that could be assigned to struts, which should be a safe percentage of the ultimate compression demonstrated by the full size tests, and should also be a safe amount below the maximum stress that induces the beginning of buckling.

While the sample sizes for the compression tests were small, the results indicate that the actual modulus of elasticity for design use is significantly higher than the published data provided by the plastic vendor for design of compression posts, but well under the value listed as an engineering property in their material property tables. The actual reinforcement of members with doublers could have been reduced somewhat and the current design is conservatively reinforced.

Assessment of Structural Stability of Aquapod Net Pens

The geodesic sphere that has been used for this pen is based on an icosahedron. The icosahedron is a geometric shape consisting of ten triangular faces that are further subdivided into triangular panels, in the process of creating the geodesic sphere. Each of the ten faces is subdivided into 16 triangular panels of 10 ft on a side. Each strut is a pair of extruded fiberglass-reinforced HDPE members. All panels are faced with $1'' \times 1'' \times 16''$ gage vinyl-coated galvanized steel wire mesh.

The geodesic sphere has been structurally analyzed using finite element computer modeling, for load cases due to various loading conditions that might be encountered in the life of a pen. Under each load case, an appropriate safety factor related to the likelihood of the case was used. The load cases are:

- Drag force from current at the site or when being towed. Using a total drag force that was extrapolated from the tow testing results, the total force is distributed around the pen based on locating maximum forces on the leading and trailing faces, as oriented to the current.
- Dead load of a pen hanging from a crane on its five part bridle.
- Drag forces with the pen in a current but with one and two broken bridle lines.

There have been numerous numerical simulations made of mooring line arrangements to refine the mooring system arrangement, and this has been an iterative process of examining the forces in the pen from a given loading and mooring arrangement. Through examination and rejection of a number of possible mooring schemes, OFT was able to come up with the final bridle arrangement that minimizes and localizes the maximum loading in the struts. This arrangement features five tangent bridle lines attached at the intersections of the base icosahedron faces, which, in the pen, are seen as a five panel intersection. The five panels form a pentagon. The analysis has found that locating the mooring at this position and angle will reduce the maximum strut forces and provide a superior distribution of loads within the structure.

The hub reinforcement consists of bent steel gusset replacements for the plastic gussets in each corner of the panels framing into the pentagons, in effect creating a steel ring at each of these hubs. The central hub of each pentagon receives a steel fabrication that reinforces the hub and provides an attachment point for the mooring bridle. The design for the central hub was developed for the conservative a 2-knot current loading, and a lighter design was developed for the Beta pen where the current is less.

When the member strut forces from each load case were sorted by magnitude, they were compared to critical allowable loading, assigned to the compression or tension members. When mapped to the actual positions, in all cases, the maximum strut loads, both tension and compression, are relatively concentrated in the pentagons around the mooring forces, and a few panels around them. The geodesic sphere distributes loading very quickly away from these areas and the struts forces become very low. Thus, OFT developed the recommended reinforcement of the pentagons related to the mooring attachments. This consisted of selective triangle receiving steel gussets and some additional bolting.

In addition, OFT looked at the sphere under the same drag forces but with various broken tension or

compression struts, and did not find much difference as compared to a broken bridle line. Critical strut failure, next to a mooring attachment, at most will relieve the mooring force of that line and redistribute load to the others. Failure of struts elsewhere in the sphere just redistributes around the broken strut area to adjacent struts, which have plenty of reserve. Thus, the structure appears to be very robust and redundant.

OFT has engineered on the conservative side with reinforcement requirements. The total test compressive load of 4,800 lbs on the unmeshed strut is more than the load previously calculated using the material properties provided by the vendor, and the load with the mesh included is even greater. The design has been using 3,800 lbs for the buckling strength of the short sides of the mooring panels, which is quite a bit less than either of the test results. The test data shows that the compressive buckling modulus of elasticity from the published value of the vendor is too low, since the test buckling strength is several times higher than the predicted strength. In the A3250, all members with compression loads greater than their buckling load calculated with E = 75,000 were reinforced. Since the tests show greater E, around 150,000, this reinforcement is quite conservative.

Feasibility of Scale-Up

OFT performed a preliminary analysis of a 28-m diameter pen using a scaled-up version of the A3250. This is an icosahedron but uses many additional panels of the same basic size of about 10 ft to a side, and encloses 11,000 m^3. The dead load case is the most severe. This is the load seen if the sphere were hung from a crane. The drag load with one broken mooring line appears to cause a similar magnitude axial loading in the worst struts. Since the dead load is 90,500 lbs., it will exceed the drag load determined using the drag calculation. The drag at 1 m/s current (2 knots) would be around 60,000 lbs.

The most-loaded members are all associated with the mooring line attachment points as before. The pentagon at each mooring line is highly loaded, more so than the previous A3250 aquapod, and will be specifically reinforced as before. These loadings are relatively discrete areas and an inexpensive reinforcement will be devised for these pentagons, or they will be specially fabricated from a different material or configuration.

There are also high loads in the next members radiating from the pentagon on the downstream side. After the pentagon, most of the highest stressed members are in the hexagon of six panels just downstream of the pentagon. This hexagon will be treated like the pentagon and reinforced to handle the loads. The rest of the pen seems to have relatively lower loads. The extruded HDPE material with wire mesh is very capable of these loadings.

Aquapod Installations and Experience to Date

Ocean Farm Technologies has installed 26 Aquapod net pens prior to 2011. Initial prototypes were deployed in Maine and New Hampshire (Figs. 7–9). The first commercial-sized installation of a Beta model was in Culebra Puerto Rico at Snapperfarm Inc (Fig. 10). A commercial crop of cobia (*Rachycentron canadum*) was grown in this Aquapod. OFT proceeded to develop small net pens with installations in Panama (Figs. 11, 12 and 13) and Mexico 9 (Fig. 14). The first commercial sale, in 2008, was to a company in South Korea which was in transition from wild-catch fishery to farming (Figs. 15 and 16). Most recent sales have been to Mexico, where several sizes of Aquapods are deployed to grow shrimp (*p. vannemei*) (Figs. 17, 18, and 19).

Future Directions

Low-Volume High-Density Net Pen Culture for Open Ocean Aquaculture

The emergence of an open ocean aquaculture industry provides an opportunity to reexamine traditional practices, such as the preference for ever-larger net pens for fish containment. The industry's focus on maximizing net pen size is driven by the convention that large net pens provide more growing volume for a given investment. Because net pen costs can vary with the square of linear dimension while the volume varies by the cube, this assumption has merit. However, the assumption that larger net pens are more cost effective requires that stocking density remain unchanged throughout the size comparison. Stocking density in terms of kilograms per cubic meter is a useful fish-husbandry parameter in pond- and tank-based aquaculture where extensive research has been done and where water exchanges are predetermined. There is

Aquapod Systems for Sustainable Ocean Aquaculture. Figure 12
Woods Hole, Massachusetts, USA 2008 Aquadome

Aquapod Systems for Sustainable Ocean Aquaculture. Figure 13
South Korea, 2009 A3600

Aquapod Systems for Sustainable Ocean Aquaculture. Figure 15
Panama, 2010 A132 copper mesh

also a growing body of data regarding stocking density in salmon net pens; however, these studies have been done in near-shore, low-energy environments. Little or no research has been done in open ocean net pen culture comparing density optimization over a range of net pen volumes, especially small net pens.

The principle advantage of small pens is that ongrowing fish are closer to their source of clean water. By similar logic, the small net pen, as a whole, because of its shorter stream-wide dimension experiences more water exchanges in a given current. From the perspective of an individual fish in an ocean net pen, water quality depends on how many other fish are metabolizing between it and its source of clean and oxygenated water from outside the containment. At constant kg/m^3, interior fish in a large net pen experience significantly degraded water quality compared to interior fish in a small net pen.

The potential advantage of low-volume, high-density (LVHD) net pen culture is not a new concept. Schmittou pioneered the concept of LVHD in 1968, and the approach has since been applied in a project

sponsored by the American Soybean Association in China [4]. Growing densities of up to 200 kg/m^3 are recorded. McMaster et al. [5] suggests stocking density ranges for Florida pompano between 35 and 100 kg/m^3. Even at close to typical salmon stocking densities, the economics of small net pens become apparent. Table 1 shows a constant crop yield per capital investment in containment as density in the smaller net pens is increased.

In addition to this economic advantage, strong, secure small net pens will alleviate some of the economic barrier to entry for offshore fish farming. Small net pens require smaller vessels and support equipment; they are easily shipped, assembled, and deployed. In the near term, OFT sees a potential market for net pen hardware export to developing world economies that are transitioning from capture fisheries to fish farming, and who want to skip the near-shore environmental problems and user conflicts by moving directly offshore. This includes third world artisanal fishermen who in global aggregate contribute to marine fish resource depletion. Also, the mooring gear required for smaller net pens is lighter and more secure; scuba diving is reduced – especially deep diving; harvesting is easier; small pens are easier to tow; and risk is diversified.

Use of Small Aquapods for Artisanal Fish Farming

According to the FAO, "Artisanal Fisheries" are traditional fisheries involving fishing households (as opposed to commercial companies), using relatively small amount of capital and energy, relatively small fishing vessels or canoes, often beach-based, making short fishing trips, close to shore, mainly for local consumption. Artisanal fisheries can be subsistence or commercial fisheries, providing for local consumption or even export. They are sometimes referred to as small-scale fisheries or day fisheries.

Numbers of artisanal fishermen are hard to obtain because the sector is informal, often outside the regulated fishery (some illegal) and part-time. In Ghana, for

Aquapod Systems for Sustainable Ocean Aquaculture. Figure 19
Mexico 2010 A212 under tow

Aquapod Systems for Sustainable Ocean Aquaculture. Table 1 The 212 m^3 net pen stocked at 51 kg/m^3 gives interior fish better access to clean water (less biomass between center of net pen and net) and an equal yield per capital cost of containment

Yield from various-sized Aquapod net pens							
Size of pen m^3	Radius (m)	Diameter (ft)	Approximate cost of aquapod (USD)	Final stocking density (kg/m^3)	Biomass of fish between center of pen and net	Yield per pen (kg)	Yield (kg) per capital cost of containment (kg/$)
7,000	11.87	77.8	$218,000	17	202	119,000	0.55
3,600	9.51	62.4	$140,000	21	200	75,600	0.54
212	4.04	26.7	$20,000	51	189	10,812	0.54

example, canoe fishermen go to sea for about 150 days a year. Half the catch is obtained in 2 months, so it is obviously a part-time endeavor. The FAO estimates that as much as 95% of the annual catch in Africa is from artisanal fisheries. In Mexico, the FAO estimates that 96.6% of the fishing fleet (108,205 boats) are *panga* (skiffs). Worldwide, the UN estimates there are 35-million people whose primary livelihood comes directly from fishing, and that artisanal fishermen outnumber large- and medium-scale fishermen by 4 or 5 to 1. This would put the number of artisanal fishermen in the range of 28 million to 30 million individuals worldwide (Table 2).

From NIOSH Second Conference on International Fishing Industry Safety and Health Overexploitation of coastal resources and decreasing catches has forced subsistence artisanal fishermen to go further offshore in search of fish in vessels designed for near-shore use. In a study done in 2000, the FAO reports an alarming increase in fishing-related fatalities as a result.

Small-scale marine aquaculture is one way to bring sustainability and consistency to this often-overlooked fishery sector. Turning artisanal fishermen into artisanal fish farmers will not be an easy task. However, small Aquapods have several advantages, beside affordability, that makes them advantageous for artisanal aquaculture:

- Size of boats and equipment can be smaller
  - The 7–10-m diameter Aquapods can be serviced with existing artisan vessels, whether motorized or not. Equipment needs are minimized and may include a small air compressor or pump.

Aquapod Systems for Sustainable Ocean Aquaculture. Table 2 Estimates of the number of fishing vessels in Pacifica [3]

- Ease of assembly and deployment – lighter mooring gear
  - Small Aquapods are easy to assemble, and can be put together by several men using hand tools on a beach and rolled into the water (or rolled out of the water for harvest). The small sectional area means a relatively low drag resistance, so mooring gear can be much lighter than traditional net pens.
- Single-point moorings are simple and inexpensive
  - An attractive option from a cost and environmental standpoint for these small pens is a single-point mooring, allowing the net pen to swing in a watch circle just as a boat moored in a harbor. Low drag forces on the anchor make this feasible.
- Less deep diving, most diving can be done by hookah
  - A net pen less than 10 m in diameter, when brought to the surface for maintenance, will allow almost all underwater activity to be performed without scuba gear. The spherical shape of the pen and the ability to rotate it allows for all portions of the net to be surfaced.
- More available deployment areas due to shallower water depth
  - Conventionally sized submersible pens require water depths of more than 30 m. The small Aquapods can be deployed in water depths of 12–25 m. This means boat trips far offshore are not necessary.
- Easier harvest – selective harvest by netting or whole pen harvest is possible.
- Diversification of risk as opposed to "all eggs in one basket."
- Ease of towing – their small size and rigidity facilitate easy repositioning, or towing of a pen to market port.
- Predator proof
  - Sharks, seals, and sea lions are a huge risk to artisanal fisheries – in some places, sharks are one of the main targets of artisanal fishermen. According to the Chamber of Commerce in

Somalia, sharks constitute 90% of the artisanal catch. Artisanal fish farmers cannot tolerate this risk to the crop and to human safety, and the shark proof Aquapod is the solution.

- Storm resistant
  - The Aquapod net pens are submersible, so they can be submerged below storm waves when a hurricane or typhoon approaches, eliminating a potentially devastating risk.

Economics of Artisanal Fish Farming with Aquapods

Catch estimates from artisanal fishermen are difficult to obtain – most are subsistence harvests, some excess is sold locally, and a little is exported. The sparse data that exists can only estimate the amount of fish that are consumed by the fisherman's family and community based on how much is sold. However, FAO estimates of annual catches range from 2.5 t per year per boat (Yemen) to 3.6 t per year per (Mexico). Considering that the smallest Aquapod ($212m^3$) could easily contain 5–10 t of fish at harvest, several of these small pens could probably produce more harvest than most artisanal fishermen ever see in a year.

Following is a spreadsheet analysis of what the economics of a small artisanal fish farm would look like. The assumptions include realistic and current pricing for commercial fish farm expenses, as low-volume pricing and sourcing of feed and fingerlings is unknown, and most likely would require some public sector support. As with all producing units, the sensitivity of market price trumps all other variables. Labor costs are assumed to be nil, as this is a family-scale operation.

The establishment of artisanal fish farms will likely be a private/public cooperative effort with governments and/or NGO's subsidizing some capital costs, providing low interest loans, organizing distribution of feed and fingerlings, and providing training to artisanal fishermen as incentives to evolve from dependence on shrinking capture fisheries to a sustainable farming economy.

Artisanal Aquapod Farm					
A212 Aquapod Net Pens (No. of Aquapod Net Pens: 4)					
Sales	$212,000		*Assumptions*		
Cost of goods sold			Biological FCR	1.7	
Feed	$124,879		Feed cost per kg	$1.65	
Fingerling	$34,980		Harvest size in kg	2.0	
Outside services	$1,000		Price of fingerlings	$1.50	ea.
Dive/Scuba expenses	$2,000		m^3 of growing vol.	848	
Workboat expenses	$3,000		Stocking final density	50	kg/m3
Fuel and oil expense	$1,500		Number of fish harvested	21,200	
Small tools	$250		Kg Harvested	42,400	
Concession	$500		Sale price	$5.00	Kg
Consumables	$750		Amortization period	7	years
Maintenance	$1,500		Aquapod A212 net pen cost	$19,000	ea.
Miscellaneous	$800		Mooring cost	$3,000	ea.
Fish health	$1,000		Total capital cost	$88,000	
Amortization of Aquapods	$12,571		Annual amortization expense	$12,571	
Cost of goods sold	$184,730				
Gross margin	$27,270				
Other overhead	$1,200				
Net Income	$26,070

Article Outline

Glossary

Founder bird (F_0) A bird into which a genetic vector was introduced. This vector may become incorporated into the chromosomes of some of the somatic and germ cells of the bird.

F_1 bird The offspring of the F_0 bird. Transgenic F_1 birds will contain the transgene incorporated into a chromosome in every cell of the animal.

Germ line chimera A genetically modified founder bird (F_0) in which the introduced biological material (i.e., DNA, virus, cells) has contributed to cells of the germ cell lineage of the host animal.

Primordial germ cells Cells in the developing embryo belonging to the germ cell lineage at a developmental stage before any sexual differentiation has occurred. These primitive germ cells may be located in the embryo in tissues other than the forming gonad.

Retrovirus A virus that carries its genome as an RNA molecule. After infecting a cell, the RNA is reverse transcribed into a DNA molecule that is inserted into the genome of the infected cell at which point it is referred to as a provirus. The provirus is passed to all daughter cells as part of the host cell's genome.

Recombinant proteins A protein produced using recombinant DNA technology. The DNA sequence encoding the protein of interest is artificially constructed using genetic engineering and the protein is produced by inserting the DNA along with DNA regulatory regions into a bacterium, a eukaryotic cell, or an animal.

Transgenic bird Any avian species in which part of its genetic component contains DNA deriving from an exogenous source, or that the genome of the bird has been altered by human intervention.

Transgenic bird lines A flock of birds deriving from a F_1 bird containing a transgenic modification at a defined genetic locus.

Definition of the Subject

Transgenesis is the process by which an *exogenous* DNA molecule is incorporated into the genome of an animal. This technology promises the possibility to investigate and manipulate the production traits of poultry, produce recombinant proteins in the eggs of genetically engineered layer lines, and directly intervene in the health and welfare of avian species. The complexity of the avian egg and the precocious development of the avian embryo in the female before oviposition (laying) have hindered endeavors in avian transgenesis. Three decades of effort have been carried out to achieve the genetic modification of the avian genome. The generation of novel methods for the modification of the avian genome has led to the current advances in the field of avian transgenesis. This entry will delineate the methods used for avian transgenesis, the current state of the art, and the potential future directions research in this field will take.

Introduction

Due to its use in meat and egg production and also as a model organism for developmental biology studies in laboratories, the chicken is the most widely used bird species for the development of transgenic technologies. There are three commonly cited incentives for the development of transgenesis in the chicken. These are the production of biopharmaceutical proteins in eggs, the generation of disease-resistant flocks along with an increase in understanding disease resistance in poultry, and the generation of useful transgenic lines for studies of developmental biology. With the recent

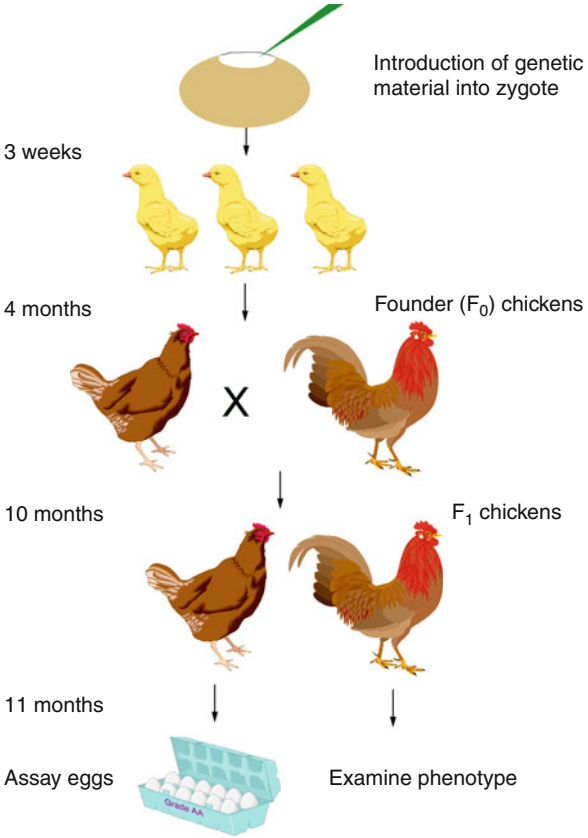
development of novel avian transgenesis techniques, these goals are beginning to be achieved.

The principal rationale behind this emerging field is industry driven and is to produce a platform for the biosynthesis of biopharmaceutical proteins in chicken eggs. Animal-based bioreactors, a process sometimes referred to as animal "biopharming," were proposed as a non-cell-based method for the production of recombinant human proteins in the 1980s (reviewed in [1]). Animal-based bioreactors were inferred to be a lower cost, safe, and more efficient system in which to produce large quantities of bioactive recombinant proteins than cell-based production platforms. Efforts to produce recombinant proteins in larger animals have focused on the secretion of the target protein into the milk of the transgenic animal using the regulatory regions from a milk protein gene. Potential mammalian species commonly proposed and studied for recombinant protein production include cows, pigs, sheep, goats, lamas, and rabbits. After over two decades of investigations, the first biopharmaceutical protein produced in an animal's milk has been approved for use in humans in Europe and the United States. This product is recombinant human antithrombin (ATryn-GTC Biotherapeutics) produced and isolated from goat's milk. Profitability in the marketplace along with consumer acceptance will be the key factor in determining the success of this and similar ventures using large animal delivery systems. In addition, the regulatory approval of this recombinant protein validates the use of animal bioreactors for protein production.

The chicken has also been proposed as a potential animal-based platform for the production of recombinant human proteins. In this case, the recombinant protein is produced in the oviduct of the hen and secreted in the forming egg as it passes down the oviduct. The target protein would be targeted to the egg white of the egg using the regulatory regions from one of several proteins expressed in the albumen of chicken eggs (reviewed in [2]). The chicken has several advantages over larger animal-based bioreactors. The chicken has a shorter generation time than a larger mammal (4 months for egg production vs. 14 months for first milk production in goats), which means a more rapid time from production of the transgenic animal until production of the recombinant protein (Fig. 1). This, in turn is reflected in the second advantage, which is the lower cost of protein production in chickens. One estimate predicts that the cost of recombinant proteins in chickens will be 1/5 of that of larger mammals [3]. This is due to the reduced costs of housing, feed, and quantity of recombinant protein produced per animal. In addition, the glycosylation pattern of secreted proteins in chickens is closer to the pattern seen on human proteins than those seen on proteins secreted in several large mammals [4].



Avian Specific Transgenesis. Figure 1
Time line for production of transgenic chicken lines. The time line from the introduction of a transgenic construct into a fertilized chicken egg until the generation of F_1 offspring. The F_1 animals can be analyzed for gene expression or bred to transmit the transgene to the next generation

Several studies have reported the production of bioactive recombinant protein in chicken eggs [5–7]. The methods used to produce these transgenic animals will be discussed in the following sections. These initial

reports demonstrated that bioactive recombinant human proteins can be produced in the eggs of transgenic chickens. To date, excluding the production in influenza vaccines, no proteins produced in chicken eggs have been approved for use in humans.

A second reason for the production of transgenic chickens is the development of transgenic models for the study of the biology of the chicken and developmental biology in general. The chicken has long been a model system for the study of developmental biology due to the accessibility of the chicken embryo in the developing egg [8]. The preeminence of the chicken as the model system for embryological studies is now taken by the mouse and the zebra fish due to the lower costs associated with maintaining colonies of these animals, quicker breeding times between generations, and most importantly, the ability to investigate gene function using transgenesis. New developments in avian transgenesis have led to the development of new avian models for developmental biology [9, 10]. The generation of transgenic lines containing the green fluorescent protein (GFP) in every cell of the developing animal permits the fate mapping of living cells, the study of cells and their descendants during embryogenesis. This has facilitated the investigation of axial stem cell populations in the chicken embryo and the formation of a novel hypothesis for cellular sex identity in avian species [10, 11]. The development of more advanced methods of transgenesis will permit the generation of chickens containing genetically modified alleles, which will serve as models for investigations of early development, avian physiology, and production traits.

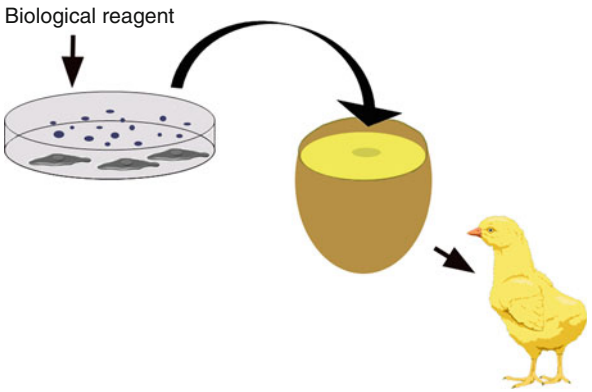
A third major reason for the generation of transgenic chickens is to use genetic modification for the increase of production traits that would lead to a decrease in environmental impact for poultry production. This could also be viewed as means of addressing the sustainability of the poultry industry with increasing demand on production and decreases in available resources. One manner in which this could be accomplished is by reducing waste production during rearing and increasing meat production for unit energy (reviewed in [12]). Several transgenic models have been developed in mammalian farm animals which exemplify the potential benefits of trait modification. A transgenic pig producing less organic phosphate waste products has been produced [13] and a similar strategy has been proposed for the chicken [14].

A comparable impact could be achieved on poultry production by reducing the losses attributable to disease. Avian transgenesis offers the potential to generate disease-resistant poultry and to investigate the genetic traits of disease resistance in poultry. It is estimated that during the avian influenza outbreak of 2004–2005, 100 million chickens were culled in Southeast Asia [15]. Using transgenic technology, the capability exists to generate a transgenic animal which will be resistant to several of the endemic diseases affecting poultry production (Avian influenza virus, Marek's disease, Newcastle disease, fowl cholera). While the production of these birds for use in meat and egg production is not currently accepted, transgenic chickens will be of use for investigating the pathogenesis of infection and the determination of viral targets of infection and pathogenesis. This in turn could generate targets for directed vaccine development. In addition, the validation of genetic traits for disease resistance also necessitates an analysis of the disease loci using transgenic technology in avian cells or the whole animal. Currently, no disease-resistant transgenic chicken models have been developed, but the production of transgenic cattle with resistance to mastitis suggests that this will be a profitable area of investigation [16]. With increasing demands on poultry production, an increase in methods of disease resistance will be needed.

Methods of Avian Transgenesis

The first efficient method developed for the introduction of exogenous DNA into mammals to create germ line chimeras was using pronuclear injection [17]. This technique entails the microinjection of DNA encoding the gene of interest (transgene) into the male pronucleus of the recently fertilized oocyte at a developmental stage previous to the first cell cleavage. Although pronuclear microinjection was primarily developed for transgenesis in the mouse, it has been exploited to generate transgenic animals in rats, sheep, cows, pigs, and rabbits [18–20]. Rates of transgenesis using pronuclear injection (transfer of the injected transgene to the genome of the offspring) in species other than mice are low. In general, only 1–5% of the offspring will have incorporated the transgene into their genome.

The use of pronuclear injection is even more problematic in the chicken. The laid chicken egg consists of a single epithelial layer of unpatterned cells termed the blastoderm consisting of 45,000–60,000 cells [21]. Injection of any biological material at this stage signifies that only a small proportion of the embryonic cells will be potentially exposed to and incorporate the transgene into their genome. The development of the chicken zygote in the hen before the egg is laid necessitates that pronuclear microinjection can only be carried out with surgical removal of the fertilized oocyte from the hen. This entails that the egg is subsequently surgical transferred to a surrogate host hen or cultured in vitro for 21 days until hatching [22]. The ovum of the avian egg is the large opaque yolk of the egg. The ovum contains a small pool of cytoplasm lying on the yolk material in which the pronuclei are located. Microinjection into the pronuclei is not possible because of the opacity of the yolk material underlying the nuclei; thus any injected biological material must be injected into the cytoplasm surrounding the pronuclei. For this reason, the rate of transgenesis for using pronuclear injection chickens is much lower than in other vertebrates and the delivery of biological material is usually performed in the laid egg (Fig. 2).



Avian Specific Transgenesis. Figure 2
Introduction of genetic material into the fertilized zygote. The genetic material to be introduced into the egg (DNA, viruses, transposons, purified proteins) is either first transfected into cells for packaging or directly introduced into the egg at an early stage of development (laid egg or fertilized oocyte). The embryo is subsequently incubated until hatching in its own shell or a host chicken shell. The hatchling will then be analyzed for the genetic modification

Injection of DNA into Early Avian Oocytes

Microinjection of DNA transgenic constructs into the early chicken oocyte has proven to be a feasible procedure for the production of transgenic chickens. As described above, the DNA construct is injected into the cytoplasm of the fertilized oocyte at an early developmental stage (Fig. 2). The egg is subsequently cultured *ex ovo* in a host shell until normal hatching occurs. Love [23] introduced a β-galactosidase reporter construct into the fertilized chicken oocyte and cultured the embryos *ex ovo* until hatching. In this report, 50% of the injected embryos contained the transgene and 14% of the hatched founder birds transmitted the transgene to the next generation. This is a similar transmission rate to that observed in mammalian species using microinjection. A comparable result was observed in which founder transgenic chickens were obtained using microinjection and a modified *ex ovo* culture system [24]. In this example, no germ line transmission to the F_1 generation was observed.

Although it is possible to produce a transgenic bird using microinjection, this avenue of research has not proven fruitful due to the cost and difficulty in obtaining and manipulating the early chicken oocyte. Instead, research has focused the use of retroviral vectors for the introduction of transgenes into the genome of the chicken at laid egg stages of development.

Replication-Competent Viral Vectors

A more efficient method to create genetically modified chickens is using retroviral vectors to introduce transgenes into the chicken genome. Retroviruses are RNA viruses that reverse transcribe the RNA genome into a DNA intermediary that is integrated into the genome of the infected cell. The integrated virus, or provirus, transcribes new copies of the viral genome that are packaged into new viral particles that bud from the infected cell and in turn infect neighboring cells. In this manner, most cells of the developing embryo will be infected along with the germ cells. Germ cells containing the integrated provirus in their genome will transmit this modification to all of the cells of the

offspring deriving from that germ cell. Using recombinant DNA technology, it is possible to remove part of the viral genome and replace it with an inserted transgene. In this manner, a line of genetically modified chickens can be produced containing a transgene of interest.

The first use of retroviruses in chicken for transgenesis used viruses that were replication-competent (i.e., infective). In this case, the virus was injected at the laid egg stage and incubated until hatching. Though initially only a small portion of the blastoderm may be infected, because the viral infection spreads during development, many more cells will contain proviral inserts. The first demonstration of the genetic modification of the chicken germ line was accomplished using a replication-competent avian retrovirus. Salter [25] injected either reticuloendothelial virus or avian leukosis virus under the blastoderm of laid eggs. They demonstrated that the integrated provirus could be found in the offspring of the injected hosts [25]. As a further demonstration of this technology, using the ALV retrovirus, 24% of founder animals contained the integrated provirus and this was transmitted to F_1 offspring with a transmission rate between 1% and 11% [26]. A replication-competent retrovirus was also used to introduce a transgene containing the bovine growth hormone under control of the mouse metallothionein promoter into founder (F_0) chicken [27]. Thus, replication-competent viruses offered an initial alternative to pronuclear injection for chicken transgenesis.

It must be noted that replication-competent viruses are limited in their usefulness in transgenesis for several reasons. First, since replicative virus can reintegrate into the genome, it is difficult to correlate a single integration site with the synthesis of recombinant protein from the integrated transgene. This is important as any regulatory approval procedure will require genetically defined transgenic animals containing a single defined transgenic insert which produces consistent levels of recombinant protein [28]. Second, insertion mutagenesis caused by the insertion of a retrovirus can disrupt an endogenous genetic locus and also lead to malignant cell growth in the host animal (reviewed in [29]). Third, and most important, a process called viral or transgene silencing is often observed in animals containing replication-competent proviral inserts. In transgene silencing, the transgene becomes silenced after it is introduced into early embryos, which is correlated with a high level of cytosine methylation throughout the proviral genome [30]. In the transgenic offspring of these founder animals, the transgene is not expressed or expression levels are severely reduced and the proviral genome is usually methylated in the long terminal repeat (LTR) region. It is believed that retroviral silencing occurs in the stem cell populations of the early embryo and leads to permanent silencing of transcription from the integrated provirus (reviewed in [31]). For these aforementioned reasons, replication-defective retroviruses have become the tool of choice for avian transgenesis.

Replication-Defective Viruses

Replication-defective retroviruses are modified retroviral vectors that are capable of infecting a host cell but lack key viral genes necessary to complete the viral life cycle and produce infective viral particles. In replication-defective retroviral vectors, a large portion of the viral genome has been removed from the virus and these genes are supplied in *trans* to allow for packaging of the defective viral particles. The envelope proteins of the viral vector can also be modified (viral pseudotyping) to permit infection of cell types and species normally outside of the retrovirus host range. The integrated provirus will contain a viral promoter in the LTR and few viral genes. It is also possible to incorporate a large transgene (8–9 kb) into the provirus in place of the truncated viral genome.

The first demonstration of germ line transgenesis in chicken used a replication-defective reticuloendothelial retroviral vector containing a neomycin reporter gene injected into the blastoderm of laid eggs [32]. Twenty-two percent of the F_0 hatchlings contained proviral integrations and the transmission rate to the F_1 generation was between 2–8%. Expression of the neomycin transgene in these birds was not demonstrated.

Since this first report, replication-defective retroviruses have been used extensively for chicken transgenesis. The most common retroviral vectors used are spleen necrosis virus, avian leukosis virus, reticuloendothelial virus mentioned previously, and Moloney murine leukemia virus (MMLV). All of these vectors have been used to generate several lines

of transgenic chickens [33–36]. Transmission rates of the integrated provirus after blastodermal injection from F_0 cockerels to F_1 offspring have been reported to be as high as 8%.

A novel development of this technology is to induce expression of the recombinant protein at defined timepoints to avoid possible transgene toxicity during development. This was achieved by using a replication-defective MMLV containing a tetracyline-regulated promoter to drive expression of human-recombinant erythropoietin protein in chicken eggs only in the presence of the inducer, doxycycline [7]. More than 90% of the F_0 chickens contained proviral integrations, and these birds transmitted the transgene to between 0.7% and 1.8% of the F_1 generation. Recombinant erythropoietin was produced in eggs after doxycycline induction.

In some replication-defective retroviral vectors, there is ongoing transcription from viral regulatory LTRs in the proviral insert. This transcription is thought to lead to a partial silencing of the adjacent transgene. An example of transgene silencing in birds was observed in transgenic quail containing a replication-defective MMLV using a LTR to drive expression of a GFP reporter construct [37]. Transgene expression was silenced in F_1 and F_2 birds. Other lines of transgenic chicken have displayed some suggestions of silencing between generations using the MMLV virus [38]. Researchers have attempted to circumvent this problem by using modified MMLV vectors containing internal promoters to drive transgene expression. This strategy appears to have worked in some transgenic birds that had no transgene silencing between generations [39]. Still, because of the perceived problems of silencing of these retroviral vectors, researchers have turned to a different class of retroviruses, the lentiviruses, for avian transgenesis.

Lentiviral Vectors

Lentiviral vectors have primarily been developed as potential viral agents for gene therapy in humans. Some of the advantages of lentiviral vectors are that the integrated provirus is preferentially incorporated into the open chromatin structure surrounding expressed genes, lentivectors will infect and integrate into the genome of post-mitotic cells, and the viral vector accepts a transgenic insert up to 9 kb in size. Moreover, there appears to be no transgene silencing upon transmission of the integrated transgene between generations [40, 41].

As an alternative to other retroviral vectors and to pronuclear microinjection, replication-defective retroviruses of the lentivirus class have proven to be very efficient for use in mammalian transgenesis [42, 43]. These vectors have been used successfully to generate transgenic cattle, pigs, rats, sheep, rabbits, and primates [44–48]. In these cases, the viral particles are injected into the perivitelline space surrounding the fertilized zygote. The zygote is reintroduced into surrogate hosts and the animals are bred and tested for germ line transmission.

The first demonstration of the use of lentiviral vectors for avian transgenesis used viral vectors containing transgenes encoding either GFP or β-galactosidase reporter genes [49]. Viral particles were injected into the blastoderm of laid eggs as described above. Efficiency of transmission of the integrated transgene from founders to the F_1 generation was between 4% and 45% and no transgene silencing was observed between generations. Since this report, lentiviral vectors have been used successfully to generate transgenic chickens containing a range of transgenes [6, 9, 10, 50, 51] and transgenic quail [52–54] and also transgenic zebra finch [55]. These vectors have also proven useful to generate biopharmaceutical proteins in eggs. Recombinant human β-interferon has been produced in the egg white of transgenic chicken [6], and recombinant human interleukin-1 receptor antagonist has also been produced in the eggs of quail [56].

While lentiviral vectors may now be the preferred method for generating transgenic birds, there will be public concerns with the use of transgenic birds containing retroviral transgenes, in particular, HIV-based lentiviral transgenes, for the production of biopharmaceutical recombinant proteins and the development of advanced production traits in avian species. It remains to be determined if consumer acceptance of these products will be forthcoming.

Transposons

Transposable elements were first identified by the seminal work by Barbara McClintock in maize [57].

Transposable elements are mobile genetic elements found in the genome of all organisms and are able to move (i.e., translocate) from one region of the genome to another. These are modules of selfish DNA that exist only to replicate their own DNA and are postulated as parasitic invaders of most genomes [58]. Transposable elements differ from viruses in that they do not spread by infection of neighboring cells; they are usually passed passively through cell division to daughter cells. Class II DNA transposons are a distinct type of transposable element that moves through the genome using a "cut and paste" method. The DNA transposon encodes an enzyme called a transposase which mediates the removal of the transposon from one chromosomal location and the insertion into a second chromosomal location. DNA transposons have been modified for the use in transgenesis in many vertebrates. This entails that the coding sequence for the transposase is deleted from the transposon and subsequently introduced into the cell with the transposon in *trans* [59]. The transposon will be incorporated into the genome of the cell but cannot "jump" to a new genomic location because it lacks the transposase gene. This is similar in approach to the packaging of replication-defective retroviruses for transgene delivery. The truncated transposon can be engineered to contain additional DNA sequences which will be inserted into the genome of the cell upon transposon integration. The size of the transgene carried by the transposon can be up to 10 kb in size [60, 61].

Transposable elements have been shown to be efficient in the generation of transgenic chickens. The mariner transposon from Drosophila *maritiana* containing an internal transposase was used to generate transgenic chickens [62]. Mariner was microinjected into the fertilized zygote and chickens were hatched and bred to generate F_1 birds. One founder bird transmitted the mariner transposon to 29% of its offspring. This result demonstrates that transposable elements can be used to modify the genome of birds although no transgene cargo was introduced in this example. So far, no reports have been made to generating a transgenic chicken line using transposons containing a transgene. However, the Tol2 and piggyBac transposons have been shown to be functional in transient transgenesis in the chicken [63, 64] and other transposable elements have been used successfully for mammalian transgenesis [59].

Use of Chicken Embryonic Stem Cells

Whist the early embryonic development of the chicken is significantly different from that of a mammal, cells of the early chicken blastoderm do contribute to somatic and germ cell lineages when transferred to host chicken embryos [65]. This indicates that the early chicken blastoderm may have the developmental equivalence of the inner cell mass of the early mouse embryo, further suggesting that embryonic cell lines derived from the chicken blastoderm may be developmentally equivalent to mouse embryonic stem cells. In support of this hypothesis, several groups were able to derive cell lines from early chicken embryos that were putatively identified as chicken embryonic stem cells because of their ability to contribute to many tissues in chimeric birds [66, 67]. The isolation of embryonic cell lines that contribute to the forming avian embryo offers the opportunity to carry out gene targeting, whereby the introduced transgene can be targeted to a precise genetic locus. Gene targeting uses the process of homologous recombination. In this process, one genomic copy of a gene can be replaced by a second copy of this gene using normal DNA repair mechanisms. The replacement gene will display homology over most of its length but can be engineered to contain a foreign piece of DNA which could encode a recombinant protein or a selection marker. Using homologous recombination, researchers can disrupt a genetic locus, introduce a gene encoding a recombinant protein, or replace one genetic allele with a second allele. Homologous recombination has been carried out in chicken cells [68]. Genetic modification of chicken embryonic stem cells also has been achieved and chimeric animals have been produced which contain extensive contribution of these cells to all germ layers of the forming embryo [69].

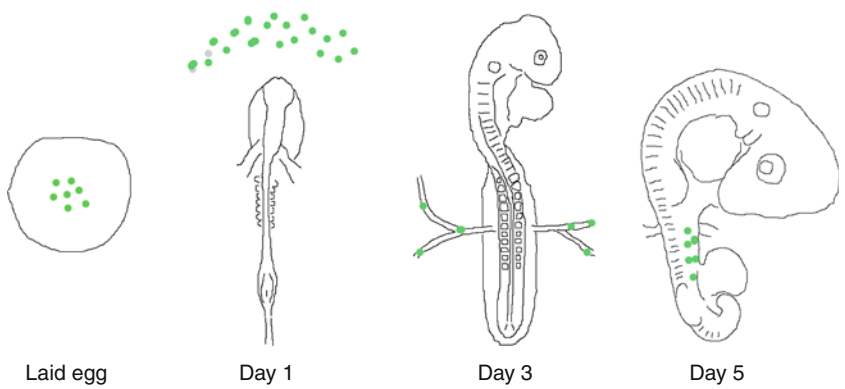
An important caveat to this work is to note here that the germ cell lineage is segregated from the somatic cell lineage very early in development (see section "Methods of Avian Transgenesis"). It is believed that for this reason cESCs do not contribute to the germ lineage in chimeras after more than 7 days of in vitro culture [67, 69]. So, although cESCs may be useful for creating somatic chimeras, these cells will not be useful for generating lines of transgenic chickens.

Recent experimental evidence suggests that it may be possible to differentiate cESCs into germ cells in vitro. These cells could then be introduced into host birds and the cells could differentiate into gametes and be transmitted to the next generation [70]. If this is achievable, it will create the possibility to carry out gene targeting in the chicken and create transgenic chicken lines using homologous recombination in chicken embryonic stem cells.

Improved Transgenesis by the Directed Targeting of the Germ Cell Lineage

Most attempts to generate transgenic chickens have resulted in inefficient transmission of the integrated transgene from F_0 to F_1 animals. This inefficiency leads to an increase in cost for production of transgenic animals due to increase in both time and breeding numbers of F_0 founder birds (reviewed in [2]). Several methods have been developed to increase the rate of transgenesis. These methods attempt to amplify the interaction of the exogenously introduced DNA or virus with the germ cell lineage of the avian embryo. The avian germ cell lineage comprises the only cells of the animal that will contribute genetic material to the next generation. Two methods developed to increase the interaction of DNA/virus with the avian germ cells are described in the next section. These methods are the purification of primordial germ cells from the developing embryo and the propagation of primordial germ cells for use as a cell-based method of transgenesis.

The germ cell lineage in birds is considered to be determined. The maternal determinants (protein, RNA) that specify the germ cell fate are thought to be deposited in the developing oocyte as it matures in the hen. During the initial segmentation of the zygote, these factors (maternal determinants) are segregated into a small number of cells of the forming embryo [71]. Descendants of these early germ cells will give rise to all cells of the germ cell lineage and are referred to as primitive or "primordial" germ cells. Moreover, since the germ cell lineage is segregated from the somatic cell lineage so precociously, chicken embryonic stem cells derived from the blastoderm will not contribute to the germ lineage when reintroduced into early embryos. The primordial germ cells are initially found in the center of the blastoderm of the laid egg [72] (Fig. 3). These cells actively migrate anteriorly in the embryo to an extraembryonic location near the future head, termed the germinal crescent. When the primitive circulatory system forms, the primordial germ cells enter the circulation and are carried to the lateral plate mesoderm adjoining the prospective gonad. During the next 2 days of development, the primordial germ cells migrate through the lateral plate mesoderm and enter the developing gonad. The germ cells subsequently differentiate into the gametes, sperm and eggs, in the



Avian Specific Transgenesis. Figure 3

Germ cell migration in the developing embryo. The primordial germ cells are initially found in the center of the developing blastoderm. From here the cells migrate anterior to the head region. The cells enter the circulation and congregate in the lateral plate adjoining the future gonad. The primordial germ cells subsequently migrate into the forming gonad

maturing gonad. In the hens, the germ cells enter meiosis by day 16 of development. In the adult cockerel, a stem cell population of germ cells remain, the spermatiogonial stem cells, which generate spermatogonia during the life of the bird.

All methods of germ line transgenesis in all species are dependent on the integration of the introduced transgene into the genome of a germ cell, which will subsequently contribute its DNA to the next generation. Any interactions between the exogenously introduced DNA/virus and non-germ-line cells of the animal will lead to a reduction of transmission of the transgene to the F_1 birds. Thus, investigations in the chicken have concentrated on increasing the interaction of the transgenic vector with the germ cells of the founder animal to increase the rate of transgenesis. The next sections detail methods to isolate avian germ cells and increase this interaction.

Germ Cell Purification

The germ cell lineage of birds can be isolated and returned to a host embryo in which these donor germ cells will migrate to the gonad and produce functional gametes [73, 74]. The intrinsic ability of donor germ cells to colonize the host germ cell lineage extends to germ cells from the germinal crescent, the circulatory blood, or post-migratory germ cells in the nascent gonad (Fig. 3). This provides the opportunity to genetically modify the donor germ cells before their introduction into host embryos. The first demonstration of this technique was carried out by Vick [75]. Primordial germ cells from the blood or the germinal crescent were incubated with replication-defective avian leukosis virus and subsequently returned to a host embryo. They observed that 3–23% of founder chickens were transgenic, and these birds transmitted the transgene to 2–4% of F_1 birds.

Several methods have been developed to purify PGCs from the developing embryo before which they are subsequently incubated with virus or transfected to introduce a transgenic vector before being reintroduced into host embryos. Primordial germ cells express the pluripotent stem cell marker, SSEA-1. Using an antibody to SSEA-1, these cells can be purified by either magnetic-activated cell sorting (MACS) or fluorescence-activated cell sorting (FACS). Both isolation techniques have been optimized for the isolation of thousands of germ cells from the blood or embryonic gonads of chicken embryos. After short periods of incubation, the isolated primordial germ cells still retain the ability to migrate to the gonad and contribute to the germ cell lineage [76]. Similarly, due to the large size of the PGC in comparison to other cells in the blood, it is possible to isolate these cells from the blood using density gradients. Density gradients have been used successfully for the purification of PGCs [77–80].

Kim [49] isolated PGCs from day 5 gonads using MACS. These cells were incubated with a lentivirus for 6 h and reinjected in host embryos. One (of 21) injected cockerels transmitted the transgene to F_1 offspring. A similar approach was used to generate transgenic quail. The rate of transmission from founder to F_1 birds was 1.9%, which was almost equivalent to what was found when the virus was injected under the blastoderm (1.6%) [54]. These results suggest that PGC isolation did not increase rates of transgenesis in comparison to blastoderm injection but further improvements on the interaction of the virus with the germ cells may augment rates of transmission.

Propagation of the Avian Germ Cell Lineage

The in vitro propagation of germ cells offers the prospect to carry out gene targeting in avian species. Both spermatogonial stem cells [81] and gonadal embryonic germ cells [82] have been cultured in vitro for shorter periods (5 and 30 days, respectively) and after culturing have contributed to the germ lineage. Moreover, the cultured gonadal embryonic germ cells generated F_1 offspring. These culture techniques, if extended, could offer the opportunity to carry out gene targeting in chickens. Recently, a breakthrough was described for the culture of primordial germ cells from the circulatory phase of development (Fig. 3). The culture of embryonic blood from day 3 chicken embryos using modified avian embryonic stem cells protocols led to the long-term expansion of primordial germ cells in vitro [83]. These cells contained telomerase activity suggesting that they may be immortal and the transmission of genetic material from both the male and female germ cells to subsequent generations was demonstrated after 110 days in culture

(0.1–86% transmission). The authors genetically modified the cultured primordial germ cells using a transgene flanked by insulator sequences to prevent silencing. Founder birds containing the modified germ cells transmitted the transgene to 1–92% of F_1 birds which accurately expressed the GFP transgene. Important caveats for this procedure were that the derivation efficiency of primordial germ cell lines was low (12%), and this culture technique has not been repeated by other research groups. It was later shown that gene targeting using homologous recombination is also possible in cultured primordial germ cells [84]. This research presents the prospect of carrying out gene targeting in avian species for the production of pharmaceutical recombinant proteins and to investigate the function of genetic pathways that may be involved in production traits by directly modifying these pathways.

Future Directions

The field of avian transgenesis has progressed rapidly in the last 5 years. Useful transgenic chicken models for use in biological studies have been developed [9, 10, 51, 85]. In the near future, it can be expected that a plethora of new transgenic models for both production traits and disease resistance to be generated. These transgenic models will generate impetus for trait selection breeding programs and rational vaccine development, first and foremost in the investigation of avian influenza.

Future uncertainties exist regarding the potential for commercialization of biopharmaceuticals proteins produced in chicken eggs and the acceptance of genetically modified chickens in general. To date, several recombinant human proteins have been produced in chicken eggs at levels up to 1 mg of protein per egg [5–7, 38, 56]. In addition, it remains to be seen if there will be consumer acceptance of genetically modified poultry products and if a functional transgenic chicken product will be brought to "market." The benefits of increased disease resistance and increased feed conversion will need to be weighed against consumer demand and acceptance. These opposing forces will have direct impact on the sustainability of the poultry industry as food demands continue to grow. The issuing of guidelines by the FDA for the regulation of genetically modified animals containing recombinant DNA should facilitate this process [28].

The development of new vectors, both viral and nonviral, for transgenesis should decrease the cost and accelerate the development of new avian transgenic models and the use of nonviral vectors may assuage public fears of transgenic modification of farm livestock. DNA transposons hold great promise as useful vectors for avian transgenesis. The next few years should bring new advances as some of the DNA transposable elements that are showing promise in mammalian transgenesis (Tol2, PiggyBac, Sleeping Beauty) are used for chicken transgenesis.

The greatest advance in avian transgenesis lies in the development of efficient gene targeting of specific genomic loci using homologous recombination. This objective may be accomplished using SSCs, gonadal embryonic germ cells, or primordial germ cells [80–83]. Gene targeting of primordial germ cells appears to be a viable technique [84] although it remains to be proven if this will be a viable method for avian transgenesis. The use of zinc finger nucleases which target specific loci in the vertebrate genome has proven to be useful for gene targeting in both zebra fish and rats [85, 86]. These proteins hold great promise for the potential manipulation of the avian genome. The generation of induced pluripotent cells (IPS cells) from somatic cells also needs to be investigated in avian species [70]. If this technique were further coupled with the conversion to germ cells, it would lay open new possibilities in avian cloning for species rescue.

Primordial germ cell culture also promises to be a viable technology for the preservation of avian germplasm (reviewed in [87]). Semen cryopreservation in avian species has proven problematic and for this reason an alternative method of germplasm cryopreservation is needed. An efficient method to preserve avian genetic resources is of importance for commercial breeders and also rare breed conservationists. The development of a robust method for avian cryopreservation would significantly enhance the biosecurity of the avian breeding industry and greatly reduce animal numbers bred for line maintenance. The use of PGCs could provide an alternative source of cellular material for cryopreservation efforts. At this stage, PGC cryopreservation offers only a slight advantage

over semen cryopreservation for the preservation of single traits. Therefore, what is needed to extend this technology is to develop improved culture conditions for the efficient expansion and cryopreservation of both male and female PGCs from different breeds of chickens. This technology will need to be coupled with an efficient methodology to reconstitute the *complete genome* of avian lines from the cryopreserved cells.

Several recent reports have described transgenic offspring from quail [52, 54] and zebra finches [55] using the genetic techniques described above. To date, no transgenic modifications have been published for turkeys and duck. Since these are also important food production animals, it can be expected that advances in transgenesis will be made in these species in the near future. These potential models will be significant to the study of avian production traits but may also be pertinent to the investigation of avian influenza in which natural disease reservoirs reside in wild duck populations. It will be difficult to foresee if the transgenic technology being developed for the chicken will be easily transferred to other poultry species beyond the use of retroviral vectors. An illustration of foreseeable problems comes from investigations of embryonic stem cells. Derivation of ES cells from mammals excluding the mouse has proven to be exceedingly difficult to achieve [88]. This may also hold true for avian transgenesis.

Article Outline

Glossary

Agriculturally marginal land Land that is not arable without compromising soil stability and increasing salinity. It requires large number of inputs.

Bio-based products Products derived from biological sources as opposed to oil.

Bioenergy Energy derived from biological, renewable sources – not from petroleum.

Biofuel Fuels derived from biological sources.

Biomass Materials derived from plant or animal origin, i.e., dedicated agriculture, agricultural residues, municipal waste, and forestry.

Corn stover The remaining stalks and leaves of the corn plant after the grain has been removed.

Dedicated energy crops Crops grown only for use in the biofuels industry, e.g., switchgrass and *Miscanthus*, poplar and *Eucaly*ptus.

Herbaceous Plant materials that have green, nonwoody above-ground parts rather than lignified stems and those parts generally die at the end of the growing season.

Lignocellulose Cell wall materials from plants that contain cellulose, hemicellulose, and lignin.

Megagram (Mg) A unit of mass equal to 1,000,000 g. Also referred to as a metric ton (US)

Perennial Plants that persist for multiple years and often have woody stems.

Renewable resources Materials and products derived from plants that are generated through growth using energy from sunlight and nutrients from soil.

Sustainable Materials that can be maintained through inputs that are equal or less than harvested output.

Water use efficiency The amount of biomass produced from photosynthesis compared to the amount of water taken up by the plant. C4 plants are more efficient in photosynthetic sugar production per CO_2 taken in, thus lowering the amount of water required to obtain the CO_2 and thus the sugars.

Definition of the Subject and Its Importance

Humans currently consume at least 25% more raw materials every year than are replaced through biological growth [150]. In order to sustain quality of life and have adequate environmental resources, those resources must be balanced and renewable. Pressure on those resources has never been greater with the world population nearing seven billion people, and estimated to plateau at 10.5 billion by 2050. That number represents 35–40% more people than currently inhabit the earth.

Sustainable, renewable resources are those derived from biological sources, primarily plant biomass. The underlying principal is that the materials can be reproduced with minimal inputs using energy from the sun. Biomass is thus derived directly or indirectly from original sources that grow and reproduce biologically.

Biomass for biofuels and bio-based products can include many sources of material. In general, biomass includes any biological materials whether of plant or animal origin: agricultural harvests such as grains, agricultural residues such as stalks and leaves, perennial crops such as hay and trees, animal manures, building waste wood, municipal solid waste such as paper, and various food industry wastes.

Introduction

The heavy reliance of the western economies on fossil fuels has given rise to energy security concerns. These concerns taken together with the sustainability issue, negative environmental impacts, and the rising cost of petroleum fuel have prompted the development of viable alternatives that are sustainable, cleaner, and environmentally neutral. Biofuels, which have emerged as one of the alternatives to address these concerns, are obtained from renewable biomass which represents a key long-term component of a sustainable biofuels industry. Ethanol from corn is the first-generation biofuel produced in USA and Europe. However, corn ethanol alone will not be sufficient to address the nation's energy needs. Cellulosic ethanol from renewable resources such as forest and agricultural biomass must also be considered. The "Billion Ton Study" supported by the US Department of Energy (DOE) and US Department of Agriculture (USDA) estimated that renewable resources are available from forest and agricultural lands to produce enough cellulosic ethanol to displace 30% or more of transportation fuel needs annually [1]. This will significantly reduce the country's dependence on imported oil.

This review deals only with plant-based crops that are used as biomass sources. Crop categories discussed include agricultural residues, dedicated woody crops – poplar and *Eucalyptus*, perennial herbaceous grasses – *Miscanthus* and switchgrass, and grass species that produce soluble sugar streams – sweet sorghum and sugarcane. Although many other crop sources are generally considered as potential sources of biomass, these are the front line crops that are considered to be "near term" candidates.

Agricultural Residues for Bioenergy

Availability of Feedstock

The Billion Ton Study on biomass estimated that 388 megagrams (Mg) of agricultural postharvest residues per year could be available from agriculture for conversion to energy resources in the USA within the next 20 years [1]. The estimated crop residues were primarily from corn stover, wheat straw, rice straw, and hulls as well as other crops with lesser individual contributions. The estimated amount of ethanol that can be derived from crop residues totals 138 billion liters assuming 356 L Mg^{-1} (85 gal t^{-1}). Additionally, the study made the assumptions to support three different scenarios for productivity. The first scenario was to maintain the status quo for all resources available today, and those would be available at the same level in the future. The second scenario focused on technology changes being applied to current crops to generate higher yields. The third and most lucrative scenario assumed that the technology changes would be applied to current crops as well as new perennial crops, combined with significant land use changes. The 388 Mg estimate is based on the third scenario.

One of the major contributors to crop residue potential in the USA is corn stover, whether under current production or assuming increased crop yields [1]. Stover can be used for many bio-based products, and the use of corn stover for those products would remove it from its contribution to liquid transportation fuels. Some of these current and potential uses include pulp and paper, animal feed, composite products such as boards, and chemicals, such as furfural [2].

Impact on soil fertility: Crop residues contribute an interesting array of benefits to the soil from which grain is harvested. These benefits include lowering soil erosion, increasing moisture content, and increasing soil organic matter and total carbon. When removing crop residues from agricultural land, the loss of these benefits must be managed [3].

However, in some situations removal of residues is recommended because they cover too much of the surface and prevent warming of the soil in the spring, delaying seed germination and thus lowering yields (Table 1; [4, 5]). Moreover, too much organic matter on the surface of the soil also can increase moisture and the threat of increased fungal growth, contributing to diseases. Clearly, the issues vary with location and crop. Each situation will have a unique solution.

The most important practice that will need to be adopted for residues to be sustainably removed from crop land is no-till agriculture. Currently, only 20% of corn acreage and 15% of wheat acreage are cultivated with no-till practices [5]. Tillage increases the rate at which organic matter is decomposed and increases

Biomass Crops for Biofuels and Bio-based Products.

Table 1 Potential effects of corn stover harvest [4]

Factor	Benefits of removal	Cost of removal
Economic	Stover sale revenues ($35/t);	Yield decreases in dry years due to lower soil moisture
	Greater seed germination in colder climates	Yield decreases with increased soil loss; Poorer germination but no yield effect
Fossil fuel use	Increased EtOH production	More field passes required; Fossil fuel needed for conversion to biofuel
Micro-climate	Warmer spring temperatures	Increased evaporation, lower soil moisture
Pests and disease	Increased control for some	Decreased control of others
Carbon and nutrients	Decreased but moderated by tillage and N rate	Nutrient loss predicted greatest in Midwest
Erosion	Moderated by amount of harvest and tillage type	Increased soil loss and water run-off

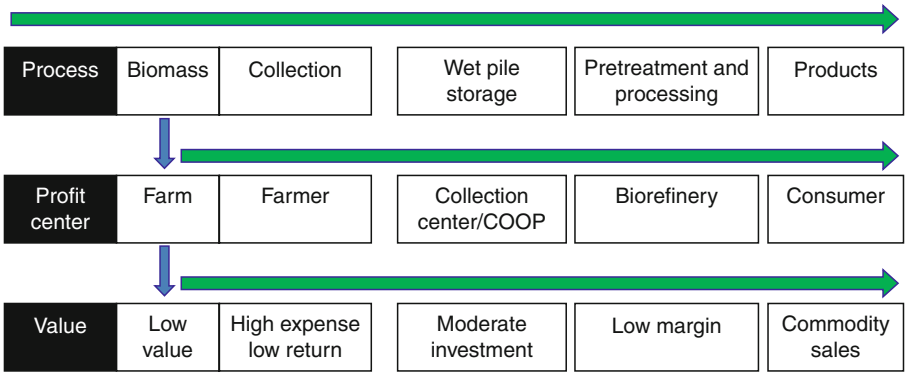
nitrogen losses due to microbial activity. No-till cultivation allows more of the remaining residue to be removed for alternative uses.

Farmer involvement: One of the major concerns with agricultural residues being used for a reliable supply of biomass is compliance of the farmer for collection and delivery of the residues. Because the residues vary by year and region, management of the residues requires consideration of many factors including maintenance of soil fertility, weather, crop yields, and economics.

The average age of US farmers is 62. This is both an advantage and a disadvantage. The collective experience of farmers is tremendous – management practices are based on their extensive knowledge. In contrast, their retirement is eminent and their replacement uncertain. Their motivation to try new crops is often high though their approach is conservative. Although most farmers may be willing to try new crops, they will approach the change cautiously, planting only a few hectares in the beginning until yield and economics are understood [5]. If the results are economically favorable, in that inputs are lower than harvested material profits, the farmers are often willing to change their practices and participate in the new system. In directed dialogs conducted in 2000–2002, farmers generally agreed that US$20 ha^{-1} pre-tax margin would generate their interest in harvesting residues, as long as grain harvesting is not hindered [5]. The value of the residues is not near to the value of the grain, thus logistics and income must make it worth the farmer's time and investment to participate in the residue harvest. The industry estimate for biomass that is delivered to biorefineries is US$30–$50 Mg^{-1} in order to produce commodity ethanol at target prices. However, in order for the farmer to reap a benefit considering the equipment, time, and field issues, the price would have to approach US$70–$100 Mg^{-1}. Clearly, policy and logistics research must address this discrepancy.

Logistics and economic issues: Small grains, mostly wheat, produce straw that can be baled and stored. However, the amount available from nonirrigated wheat is minimal after leaving USDA recommended amounts of residue on the ground to improve fertility. If the average dry land wheat straw yield is 2.7 Mg ha^{-1}, and 1.34 Mg ha^{-1} must be left on the surface to avoid erosion, then less than 2.5 Mg ha^{-1} of straw would be available for harvest [5]. Because corn stover yields about 11 Mg ha^{-1}, leaving 2.24 Mg ha^{-1} on the soil surface for organic matter and erosion control, leaves 8.8 Mg ha^{-1} for harvest. However, in each case if a cover crop is employed, the residues are not required for erosion control and can be harvested in larger amounts.

Because wheat is harvested early in the summer, the straw has low moisture content and can be immediately baled. In contrast, collecting residues as feedstocks from corn fields in particular requires altering harvesting practices. Corn is harvested in the fall and the stover moisture content is usually 30–50%, and must be left in the field to dry, although often fall rains prevent this from happening in a timely manner. In addition, if stover is harvested separately after grain harvest, field machinery must be deployed a second time and this compacts the soil more. The stover that is raked and baled also



Biomass Crops for Biofuels and Bio-based Products. Figure 1
Agricultural residue value chain. Residue collection and processing must yield value to each link in the chain for the process to be instituted. One solution to this is to have the farmer involved in the collection and storage of the residues to be sold to the biorefinery during the production year

contains rocks and soil particles which have a negative impact on biorefinery machinery. These issues suggest that one-pass harvesting is an alternative that must be considered.

A detailed description of grain and stover harvesting logistics was recently published [5]. The additional requirements for trucks, combines, and potentially one-pass harvesters, baling equipment, and additional personnel are enormous. The personnel needs are transient in that the harvest window is usually 30–50 days. However, the investment in additional equipment, whether purchased or leased is significant. Harvesting stover while harvesting corn grain requires three times the number of trucks and personnel if using a one-pass harvester. Although this equipment is not yet commercially available, several agricultural machinery manufacturers are designing these harvesters. Because most of the stover currently is either left in the field, tilled under, or used for bedding, or local markets (e.g., corn cobs), baling equipment is not adequate in most farm operations to handle a large increase in biomass harvest. One possible solution could be transporting the field materials to a collection station, possibly associated with a grain elevator operation, and the stover separated from the grain at these off-field locations. The stover then could be stored either as stacked bales or as a wet pile. Bales require protection from the elements, they are dry when baled and must remain dry, at less than 20% moisture, to keep them from deteriorating. In addition, the height of the stacks is limited by the weight and heat that is generated, thus requiring large amounts of field space. However, if the biomass is in compacted, anaerobic, wet piles at greater than 60% moisture, fungal growth is inhibited and the biomass is very stable [5]. The pile size is only limited by the height of a pump head that continuously recycles the water from a base collection reservoir. This configuration has the added advantage of washing contaminants out of the biomass that were collected from the field. These "haystacks" are large and much higher than bale stacks and thus have far less of a footprint on the ground, minimizing field requirements. Wet storage is a proven industry logistic in that the nonwood fiber pulpers moved to this method of feedstock storage several decades ago.

Recommendations: The production of ethanol from corn stover as opposed to grain has significantly more greenhouse gas reduction potential, 79% versus 25%, when burning E85 (85% ethanol with 15% gasoline) on a per km basis [4, 6]. This fact alone motivates development of logistics and infrastructure solutions to develop the industry for all concerned. Nevertheless, county by county plans will be required to sustainably harvest agricultural residues from any crop, based on climate, tillage, and residue type. Farmer networks should be included as part of the value chain to encourage participation (Fig. 1). Small biomass facilities,

including portable facilities, could be a positive development for on-farm production of ethanol from excess residues without investment in large biorefinery infrastructure.

Perennial and Annual Herbaceous Biomass Crops

Sugar Crops

Introduction Sugar cane and sweet sorghum which produce sugary syrup in their stems are members of the Panicoid subfamily of the *Poaceae* family [7]. They share the physiologically distinctive and highly productive C4 photosynthetic pathway. The C4 pathway is fundamentally more efficient than the C3 classic Calvin cycle alone and C4 plants are able to convert up to 2% of incident solar energy into biomass [8]. Compared to C3 plants, C4 plants lose less water as they can photosynthesize with stomata nearly closed, thus reducing water loss to the environment and increasing water use efficiency. In addition, plants using the C4 photosynthetic pathway are better equipped to handle high temperatures, drought, and nitrogen limitations than closely related C3 plants [9, 10].

Sugar from sugar-producing plants can be used for direct fermentation into ethanol. Among three major sugar-producing plants, sugar cane and sweet sorghum are adapted to warm temperate to tropical areas, whereas sugar beet is grown only in temperate areas. Sugar cane is the major crop in the Brazilian national ethanol program which produces 15.9 billion liters of ethanol a year [11]. Sweet sorghum is considered to be one of the promising feed stocks for the production of first-generation ethanol. Studies are being conducted to produce ethanol from sweet sorghum sugary syrup in the USA, India, and China [12–14]. Most ethanol production using sugar beet takes place in Europe; however, using sugar beet to produce ethanol could potentially increase soil erosion and lower net energy balance [15]. All the three sugar-producing plants are a good source for first-generation ethanol production. Compared to sugar beet, both sugar cane and sweet sorghum produce higher biomass and additionally are a good source of lignocellulosic biomass which can also be used for second-generation ethanol production.

Sugar Cane Crystallized sugar from sugar cane was reported in India 5,000 years ago [16]. Sugar cane is a tall perennial grass of the genus *Saccharum*, native to warm temperate to tropical regions of Asia. The plant grows in clumps, and has solid, jointed, fibrous stalks that are rich in sugar. Sword-shaped leaves, similar to those of the corn plant, fold in a sheath around the stem. Mature canes may be 3–6 m tall and 2.5–7.5 cm in diameter (Fig. 2a). All sugar cane species interbreed, and the major commercial cultivars are complex hybrids. Different species likely originated in different locations with *S. barberi* originating in India and *S. edule* and *S. officinarum* coming from New Guinea. Sugar cane is grown in over 110 countries with an estimated total production of 1,627 million Mg in 2009, (FAOSTAT, http://faostat.fao.org/site/339/default.aspx) more than six times the output of sugar beet. Brazil is the world's largest producer of sugar cane, producing about one-third of the world's crop, followed by India (FAOSTAT).

Cultivation: Sugar cane cultivation requires a tropical or temperate climate, with a minimum of 60 cm of annual moisture. In prime growing regions of India, Peru, Brazil, Bolivia, Colombia, Australia, Ecuador, Cuba, Philippines, El Salvador, and Hawaii, sugar cane can produce 20 kg m^{-2} biomass exposed to the sun. Although sugar cane species produce seeds, sugar cane propagation is through stem cuttings of immature canes 8–12 months old, called "setts." The setts are best if taken from the upper third of the cane because the buds are younger and less likely to dry out. Each sett must contain at least one bud. The setts can be planted at a 45° angle or laid horizontally in a furrow. It takes 12,500–20,000 setts to plant 1 ha. The setts are lightly covered with soil until they sprout (10–14 days) and then the sides of the furrow are turned inward [17, 18]. In the USA and Australia, billet planting is common. Billets harvested from a mechanical harvester are planted by a machine which opens and recloses the ground.

Sugar cane is a perennial crop which usually produces harvests for about 3–6 years before being replanted. The first crop is called the "plant crop" and takes 9–24 months to mature, depending on location [18, 19]. The cane is cut close to the ground because the lower stem has the highest sugar content and low cuts aid in ratooning, the emergence of new crops from the stems and trash (leaves and tops) left behind. Ratoon crops take about 1 year to mature.

Biomass Crops for Biofuels and Bio-based Products. Figure 2
(**a**) Sugar cane. (**b**) Sweet Sorghum

As many as four or more ratoon crops may be produced before replanting is necessary, mostly due to the slow decline in yields.

The complete sugar cane crop cycle is variable, depending on local climate, varieties, and cultural practices. In Brazil, usually it is a 6-year cycle, in which five cuts, four ratoon cultivation treatments, and one field reforming are performed. Generally, the first harvest is made 12 or 18 months after planting. The following ratoon cane harvests are made once a year, during 4 consecutive years [20].

Sugar cane is harvested by hand and mechanically. Hand harvesting accounts for more than half of the production, and is dominant in the developing world. Mechanical harvesting uses a sugar cane combine, a harvesting machine that can harvest 100 Mg each hour, but machine-harvested cane must rapidly arrive at the processing facility. Once cut, sugar cane begins to lose its sugar content, and damage to the cane during mechanical harvesting accelerates this decline. Some sugar cane varieties are known to be capable of fixing atmospheric nitrogen in association with a bacterium, *Acetobacter diazotrophicus*. Unlike legumes and other nitrogen fixing plants which form root nodules in the soil in association with bacteria, *A. diazotrophicus* lives within the intercellular spaces of the sugar cane's stem [21].

Breeding: The goal of cane breeding is to produce an economic yield of sugar that can be sustained over several ratoons. Breeding and selection of cane are not simple processes since viable seeds are seldom produced. Sugar canes are highly polyploid, wind-pollinated outbreeders. They are clonally propagated, highly heterozygous, and intolerant to inbreeding. New varieties are sought from the first-generation progeny of crosses between clones. Five species are of interest to cane breeders. *S. officinarum* ($2n = 80$) has good sugar quality and low fiber, although it is susceptible to most

of the main diseases, except gumming disease and smut. *S. spontaneum* ($2n$ = 40–128) is a source of resistance to many diseases, including "Sereh," mosaic, gumming, red rot, and downy mildew. *S. barberi* ($2n$ = 82–124) are considered the most important breeding canes and are immune to gumming and mosaic and resistant to downy mildew, but susceptible to smut and red rot. *S. sinense* ($2n$ = 82–124) is difficult to breed, but has given rise to some useful breeding lines. *S. robustum* ($2n$ = 60–194) has been used to some extent in breeding lines [22].

Yields: The annual global production of dry cut sugar cane (sugar content: 55% dry basis) is about 328 million Mg. Asia is the primary production region, which produces 44% of the total. South America stands second with a total production of 110 Tg of sugar cane (34%). The annual yield of dry sugar cane ranges from 14 to 22 Mg ha^{-1} with an average of 17 Mg ha^{-1}. Brazil is the largest single producer of sugar cane with about 27% of global production and a yield of 18 Mg ha^{-1}. The highest yield occurs in Peru, which produces more than 32 Mg ha^{-1} of dry sugar cane [23].

Diseases and pests: Many diseases and pests affect sugar cane. Bacterial diseases include gumming disease caused by *Xanthomonas vasculorum* (Cobb) Dows. Yellowish stripes occur at the leaf tips, leaf blisters occur, and the vascular bundles exude a yellowish gum when cut. *X. albilineans* (Ashby) Dows causes yellow stripes to occur on the leaf blade, many side-shoots are produced, and the vascular bundles of the stalk are red [24]. Fungal diseases such as red rot (*Colletotrichum falcatum* Went), root rot (*Pythium graminicolum* Subr.), pineapple disease (*Thielaviopsis parodoxa* (de Seynes) C. Moreau), downy mildew (*Sclerospora sacchari* Miy), and smut (*Ustilago scitaminea* Syd.) can also cause damage. Red rot causes the setts to be seriously damaged at low temperatures. Root rot was responsible for the failure of "Otaheite" (a noble cane) in Mauritius in 1846. Downy mildew is currently only found in the western Pacific and was responsible for severe losses in Queensland until rigorous controls were initiated. Smut causes black whiplike organs to emerge from the center of the leaf-roll and affects crops in southeastern Asia and South Africa [18]. Mosaic is a viral disease, whose vectors include *Aphis maidis* Fitch. It was first documented in Java in 1892 and causes severe stunting in some cases. Other viral diseases include ratoon stunting, chlorotic streak, Fiji disease, and Sereh disease. The most destructive insects of sugar cane are stem-borers, the larval stage of several genera of moths. The larvae burrow into the stem and on emergence cause weakened stems and loss of sucrose. Biological control and use of transgenic *Bt* sugarcane are the most efficient control for these insects [18].

Commercial and industrial use: Sugar cane has many industrial uses and is one of the most widely used and cheapest sources of domestic products, including table sugar, molasses, and ethanol. Cane juice contains 10–20% sucrose and about 1 Mg ha^{-1} of raw sugar can be extracted from 8 to 9 Mg ha^{-1} of cane. Molasses is a by-product of the manufacturing of cane sugar. It is residual syrup from which no more crystalline sucrose can be obtained by simple techniques. Approximately 2.7% of cane can be extracted as molasses, which can be used as an animal feed as it has high carbohydrate contents. Molasses along with cane juice and other by-products can be fermented to produce an alcoholic distillate, rum, or similar liquors. Ethanol is also produced from molasses, which can be used in vinegar, cosmetics and pharmaceuticals, cleaning preparations and solvents, and coatings [16]. One of the important uses of ethanol is as a transportation fuel (see below). Still other products from molasses are butanol (a solvent), lactic acid (a solvent), citric acid (mostly for foods and beverages), glycerol, and yeast media [25].

Sugarcane as a bioenergy crop: Sugar cane being a C4 plant is one of the most efficient photosynthesizers in the plant kingdom [26]. Sugar cane's high concentration of sugar, which is readily available to microorganisms, makes it uniquely suitable for ethanol production. As a producer of sugar for fermentation bio-products, sugar cane is found to have advantages in relation to fossil-energy input, emissions of greenhouse gases, and possibly acidification, when compared with corn and sugar beet [15]. Another useful by-product of sugar production is bagasse, the fibrous residue left after the juices are extracted from the cane. It is the main source of fuel in sugar factories. It can also be used in paper, cardboard, fiber board, and wall board [27]. It is quite possible that further uses of sugar cane will be developed in the future, but even now it can be seen that sugar cane is a very important and useful plant crop worldwide. Uses of sugar cane in different

Biomass Crops for Biofuels and Bio-based Products. Table 2 Uses of sugar cane [23]

World	1.91	2.35	0.97	91.88	2.40	0.48

parts of the world are shown in Table 2. The resulting energy and greenhouse gas benefits of sugar-cane-derived products have been shown previously [28]. For sugar cane, the main co-product is surplus energy from bagasse. The most successful story of using sugar cane as a bioenergy feed stock is in Brazil. Brazil is considered to have the world's first sustainable biofuels economy and is the biofuels industry leader. Its sugar cane ethanol program is considered a model for other countries and is the most successful alternative fuel program to date. Brazil's 40-year-old ethanol fuel program is based on the most efficient agricultural technology for sugar cane cultivation in the world. It uses modern equipment and cheap sugar cane as feedstock. The residual cane-waste (bagasse) is used to produce heat and power, which results in a very competitive price and a high-energy balance (output energy/input energy). This energy balance varies from 8.3 for average conditions to 10.2 for best practice production. Brazil is recognized as the world's second-largest producer of ethanol (DOE-EIA, 2007, http://www.eia.doe.gov/emeu/cabs/Brazil/full.html). Brazil and the USA lead the world in global ethanol production, accounting for nearly 70% of the world's production. Brazil produces approximately 37% of the world's total ethanol and 48% of the world's ethanol uses as fuel. They began promoting the production of crops for ethanol in the mid-1970s after the first global energy crisis. In 2008, 454,000 barrels per day (bbl/day) of ethanol were produced, up from 365,000 in 2007. Because ethanol production continues to grow faster than domestic demand, Brazil has sought to increase ethanol exports, becoming the largest ethanol exporter in the world, holding over 90% of the global export market. According to industry sources, Brazil's ethanol exports reached 86,000 bbl/day in 2008, with 13,000 bbl/day going to the USA (DOE-EIA, 2007).

Sugar cane bagasse is the residue obtained after crushing of sugar cane during sugar production and consists of cellulose 43.6%, hemicellulose 33.8%, lignin 18.1%, ash 2.3%, and wax 0.8% on a dry weight basis [29]. About 180–280 kg ha^{-1} of sugar cane bagasse could be produced after squeezing [30]. The second-generation process revolves around accessing the large amounts of cellulosic material blocked within the lignin-based shell and creating ethanol from it [31]. Currently the leftover bagasse is burned to co-generate power. In the future, the process should be similar, but instead of burning all of the bagasse, the material will be sorted so that the cellulose and hemicellulose are processed further into cellulosic ethanol with only the remaining high-lignin content materials being used as an alternative energy source. The move toward utilizing sugar cane bagasse for the production of ethanol instead of power generation is a question of economics. The current process of burning the bagasse for energy is not as energy efficient as using it to produce ethanol. Theoretically, 1 Mg of sugar cane bagasse can produce up to 300 L of ethanol. In reality the yield depends on a number of parameters including efficiency of the process. Currently, 6,000–7,000 L of ethanol is produced from 1 ha of sugar cane-not including the bagasse. When bagasse can be utilized for ethanol production, the output could double to 12,000–15,000 L ha^{-1} [31].

Sweet Sorghum Sweet sorghum is a C4 crop in the grass family belonging to the genus *Sorghum,* which also includes grain and fiber sorghum and is characterized by high photosynthetic efficiency. Sweet sorghum is of interest as a dedicated agricultural energy crop because of its drought tolerance, relatively low input requirements and ability to produce high yields under a wide range of environmental conditions [12, 32]. These traits make sweet sorghum a potentially important feedstock for bioenergy production, mainly in regions where conditions are not favorable for growing starch-rich crops such as maize. The great advantage of sweet sorghum is that it can become dormant under adverse conditions and can resume growth after relatively severe drought which has implications for crop management. Sweet sorghum is typically an annual, but some cultivars are perennial. Like other sorghum types, sweet sorghum probably originated from East Africa and spread to other African regions, Southern Asia, Europe, Australia, and the USA. Plants grow in clumps and height of stalks ranges from 0.8 to 4 m (Fig. 2b). The thickness of stalks also varies, ranging between 1.25 cm and 3.75 cm. Prop roots regularly grow from the lower nodes. Seeds are produced by self-pollination from a panicle that emerges at the top of the plant and contains both the male and female inflorescences. Seeds are small, round, and may be white, yellow, brown, or red in color. Each panicle can produce up to 4,000 starch-containing grains. Although native to the tropics, sweet sorghum is well adapted to temperate climates. Like its close relative sugar cane (*Saccharum* spp.), sweet sorghum has been selected to accumulate high levels of edible sugars in the stem. Sweet sorghums are tall and produce high biomass in addition to sugar. In all varieties, the primary carbohydrate is sucrose, with variable amounts of reducing sugars and starch [33].

Cultivation: Sweet sorghum is very drought resistant and shows good adaptability to poor soil types including saline soils. It has a very short vegetation period and thus is ideal for double cropping, either three crops of sweet sorghum or with an alternative crop [13]. Propagation is accomplished through seeds. It is easily grown in areas that are too dry for maize. Seeds are typically sown in widely spaced rows (75–100 cm) manually or using a corn planter in spring after the rainy season and as soon as the soil temperature remains above 15–18°C. The ideal seeding rate for most sweet sorghum varieties is 3–4 seeds per foot of row with a final stand of 2–3 plants per foot of row. If plant populations are too high, the canes will be spindly and contain less juice than an equal tonnage of larger diameter canes. Seed germination takes place within 24 h in warm and moist soils, and the time to maturity lies between 90 and 120 days. The plant grows to a height of from about 1.2 to above 4 m, depending on the varieties and growing conditions. Even though sweet sorghum is predominately self-pollinating, hybrids and crosses can be produced using male-sterile maternal parents. Sugar content in the juice increases with maturity, and is low prior to seed development. Controlling nitrogen fertilizer and its application time promotes sucrose content and growth rate in sweet sorghum. Application of adequate amounts of K fertilizer increases yield responses more than high levels of nitrogen fertilizer alone [34]. Currently, the only commercially viable harvest method for sweet sorghum is removing the entire crop with a forage harvester and transporting it to a mill/pretreatment/ethanol facility. Bennett and Anex [12] indicate that fermentable carbohydrates can be produced at less expense from sweet sorghum than from corn grain. Further results on costs associated with off-farm transportation, storage, or capital costs associated with milling and energy recovery equipment reevaluates sweet sorghum as a biocommodity feedstock [12].

Breeding: Roughly 4,000 cultivars of sweet sorghum are distributed throughout the world [35] providing a diverse genetic base from which to develop regionally specific, highly productive cultivars. In addition to producing large amounts of sugar-rich biomass, hybrids can be developed from crosses between grain-type seed parents and sweet-type pollen parents [36]. The product of these crosses typically increases biomass yields and sugar content when compared to the original grain-type seed parents. Such hybrids can co-produce grain at levels approaching the yields of the grain-type seed parent [37]. The co-produced, protein-rich grain can be consumed as food, animal feed, or converted to bioproducts like ethanol [13, 36]. Proper variety selection will play a large role in the success of sweet sorghum production for ethanol. The ideal variety for a particular location should produce high yields with minimal inputs, have a high percentage of high quality

Biomass Crops for Biofuels and Bio-based Products. Table 3 Uses of sweet sorghum [23]

and easily extractable juice, be disease and insect tolerant, and tolerate both drought and wet conditions.

Yields: Sweet sorghum yields vary considerably depending on the varieties/hybrids that are used, the location (soil, water, climate, pests and diseases), inputs, and production practices. The annual global production of dry sorghum is about 53 Tg with the an average yield of 1.2 Mg ha^{-1}. The USA is the largest producer of sweet sorghum (23%) at a yield of 3.7 Mg ha^{-1}. The highest yield occurs in Israel and Jordan, which produce more than 10 Mg of dry sorghum per hectare [23]. When considering sweet sorghum for ethanol production, the most important yield components are biomass yield, juice yield, and sugar production per hectare. The concentration of soluble sugars in sorghum ranges widely depending upon variety. Biomass yields of sweet sorghums are also variable ranging from 20 to 120 Mg ha^{-1} and juice content from 65% to 80% of biomass. The combined sugar content of the juice varies between 9% and 15%. Sugar yields vary from 4 to 17 Mg ha^{-1}. The bagasse (crushed stalks) and leaves make up the remainder of the wet biomass. The bagasse represents approximately two-thirds of the dry matter and leaves represent the remaining portion. Fermentation of the sugar in the juice yields 600–900 L ha^{-1} of ethanol [38].

Diseases and pests: Disease and insect problems may also limit yield potential, suggesting that further research in this area is essential. Leaf diseases are the most troublesome for forage producers. These are anthracnose caused by *Colletotrichum graminicola* (which can be overcome by using resistant varieties) and leaf blight caused by *Helminthosporium turcicum*. Charcoal rot (*Macrophomina phaseoli*) causes plants to lodge badly. Grain may be affected by covered smut (*Sphacelotheca sorghi*) in which the seed is replaced by a sac of spores; fungicidal seed treatment before planting prevents this latter malady (FAO, 2009, http://www.fao.org/ag/agp/agpc/doc/gbase/data/pf000319.htm). From a forage point of view, grasshoppers appear to be the worst pest, and feral pigs can damage the crop in some locations. Grain pests include the sorghum midge, *Contarinia sorghicola*, whose larvae feed on the developing seeds. Bird damage is also important with the weaver bird, *Quelea quelea*, causing major losses in Africa. Damage can be prevented by using awned varieties of sorghum, giving some hope of reducing losses. The high tannin content of sweet sorghum seed is another deterrent, and early harvesting for silage avoids the major problems.

Commercial and industrial use: Worldwide, the major uses of sweet sorghum are animal feed (49%) and human food (40%; Table 3). In Africa and Asia, over 60% of sweet sorghum is used for human food. In the other regions, most sorghum is used for animal feed. There is no use of sorghum for human food in Europe and South America. Although the juice, grain, and bagasse from sorghum provide many opportunities, most applications around the world are for syrup and forage. An average yield of 1,900 L ha^{-1} of syrup can be achieved, although yields of 800–1,200 L ha^{-1} can result if weather conditions are poor. In forage applications, chickens can be fed with seed heads and ruminant livestock can use the grains, leaves, and

stalks. The organic by-product from sweet sorghum syrup processing is often fed to livestock, left on the field, or composted. Sweet sorghum bagasse is used currently to manufacture chemical pulp. The quality of the pulp obtained is excellent for the paper industry. Sweet sorghum can be considered as a major raw material for the paper industry [39].

Sweet sorghum as a bioenergy crop: Sweet sorghum is attractive for bioethanol production because of its high fermentable sugar content and very high yield of green biomass (20–30 dry Mg ha^{-1}), its low requirement for fertilizer, high water use efficiency, and short growth period; and, it is well adapted to varied climate and soil conditions. These advantageous agricultural characteristics make sweet sorghum a promising substitute feedstock for fuel ethanol production in the southern USA [32]. Based on a recent economic analysis, sweet sorghum is considered to be one of the most drought-resistant crops and has higher biomass yield and lower production costs than many other plants [40]. Sweet sorghum can produce fermentable sugars (sucrose, glucose, and fructose) in its juice, starch in its grain, and lignocellulose, which can be used in both current starch-based ethanol plants and future cellulosic ethanol plants. Of the 20–30 dry Mg ha^{-1} of biomass, approximately 40–45% is fermentable sugars and starch, equivalent to more than 500 bushels ha^{-1} of corn yield. If all fermentable sugars in sweet sorghum are converted to ethanol, potential ethanol yield could be 5,500–6,100 L ha^{-1}. However, normal pressing can recover only ≈50% of the total sugars in the sorghum stalk [41]. Increasing the juice yield or making proper use of remaining sugars in the bagasse is crucial for realizing the high ethanol yield of sweet sorghum and is of important economical value.

Similar to sugar cane bagasse, sweet sorghum bagasse is the residue obtained after crushing of sweet sorghum cane for sugar production and consists on average of cellulose 34%, hemicelluloses 25%, lignin 18%, and ash 4% on a dry weight basis [42]. Sweet sorghum bagasse was found to be a remarkable raw material for the paper industry, yielding high-quality pulp [39]. The most promising future utilization of bagasse is cellulose-based ethanol production, while the residual solids (mainly lignin) can be burned to provide heat and power. Hydrolysis of the cellulose and hemicellulose fractions can be catalyzed by acids or cellulolytic enzymes. Enzymatic processing needs a pretreatment step to increase the susceptibility of the cellulose, which can be degraded by cellulolytic enzymes to glucose.

Miscanthus and Switchgrass – Dedicated Perennial Energy Crops

Introduction *Miscanthus* and switchgrass are two perennial herbaceous crops with attributes generally considered as ideal for biomass crops, making them well suited as dedicated energy crops for biofuel production (Table 4). They are members of the grass family, *Graminae* (*Poaceae*). The perennial herbaceous crops have long-lived roots that may establish beneficial interactions with root symbionts, facilitating acquisition of mineral nutrients from the soil which may result in lesser amounts of fertilizer needed [44]. This can translate into cost saving on fertilizer and

Biomass Crops for Biofuels and Bio-based Products.

No known pests or disease			*M. giganteus*
Uses existing farm equipment	⋆		⋆

[a]Coppice is a grove of densely growing small trees pruned to encourage growth

minimizing water pollution from leachates and run-off. A very important physiological characteristic of the perennial herbaceous crops is the recycling of nutrients within the plants. Nutrients are moved from roots to growing shoots at the beginning of each growing season and from the senescing shoots to the roots at the end of the growing season [45]. This recycling characteristic gives the perennial herbaceous crops many advantages over other plants and at the same time reduces the amount of fertilizer needed. In spring, when mineral nutrients are translocated from the roots to the shoots, the perennial grasses get a rapid start in forming a photosynthetically active canopy leading to biomass accumulation when many annuals are still seedlings. Conversely, in fall, mineral nutrients from the senescing shoots are transferred to the roots where they are stored over the winter. This has the positive effect of lowering the ash content of the shoots, improving their overall energy content and quality for biofuel production and at the same time improving the viability of the roots during the cold winter. Another advantage of the perennial grasses is the low input cost in establishing the crops. Once the perennial grasses are established, they can be harvested annually without replanting and no tillage is needed for the next 15–20 years. This leads to a substantial saving in labor cost and at the same time reduces soil erosion and nutrient loss. *Miscanthus* and switchgrass are C4 plants [46]. A higher solar energy conversion rate should lead to a higher total biomass yield per unit of land area. Perennial grasses are also known to exhibit increased soil-carbon levels by sequestering portions of atmospheric carbon in the soil in root biomass and in root turnover creating soil organic matter. The perennial herbaceous crops therefore, represent significant soil carbon sinks [47]. The perennial grasses are also known to be better adapted than conventional crops to different types of soils which means they can also be grown on marginal land not used for food crops.

Miscanthus *Origin and distribution*: *Miscanthus* is native in many parts of Asia such as China, Japan, and the Pacific Islands, and can grow up to 4 m tall. *Miscanthus* was first introduced into Denmark from Japan in 1935 as an ornamental plant and is now cultivated throughout Europe and North America primarily for energy production with other end uses being explored. It is estimated that there are about 14 species of *Miscanthus* [48] and the most common species investigated as a biofuel in Europe and North America is *Miscanthus* × *giganteus*, a naturally occurring sterile triploid hybrid that has its origin in Japan [49]. The genetic origin of *M.* × *giganteus* is uncertain but some evidence suggests that this hybrid is a result of a cross between *M. sinensis* (diploid) and *M. sacchariflorus* (tetraploid) [50]. In general, *M. sinensis* types are well adapted for cooler climates, whereas *M. sacchariflorus* can provide genetic resources for warmer regions [51].

Growing conditions: Extensive studies and evaluation of *Miscanthus* as a biomass resource for biofuel and bio-based products have been going on in Europe for the last 2 decades under the umbrella of the *Miscanthus* Productivity Network [52]. These studies have provided much of the currently available information on *Miscanthus* as a renewable feedstock for bioenergy. In recent years, similar studies have also been conducted in the Midwest of North America but on a smaller scale. The studies in Europe were conducted in 15 cities from southern Italy (37° N latitude) to Denmark (56° N latitude) [53]. Although *Miscanthus* prefers the mild temperatures and high water availability of its natural habitats in the tropics and subtropics, the successful establishment of *M.* × *giganteus* in Europe and North America suggests that it is relatively tolerant of temperate temperatures and low water availability. In North America, *M.* × *giganteus* has been established successfully in the Midwest from latitude 38° N to 48° N covering Ohio, Michigan, Indiana, and Illinois, and expanding into other areas in the south like Georgia and Florida and as far north as Quebec, Canada. *M.* × *giganteus* has been demonstrated to be more tolerant of low temperatures than most C4 perennials [54, 55]. Nevertheless, low temperature still limits the growth of *Miscanthus*. It is estimated that *Miscanthus* requires a minimum of 500 mm of annual rainfall and where the annual rainfall is typically below that amount, irrigation is necessary for substantial growth and biomass yields [53]. *M.* × *giganteus* can adapt to a wide range of soil, from sands to high organic matter soils. It is also tolerant to a wide range of pH, the optimum being between pH 5.5 and 7.5 [56]. Generally, areas with higher rainfall and

soils with high water-holding capacity will favor production of *Miscanthus*. Limited soil water availability during the growing season will decrease production.

M. × *giganteus* being a sterile hybrid is established from rhizomes. The rhizome pieces, approximately 200 mm in length, are planted directly into the soil at a depth of 200 mm [56]. Fresh rhizomes are generally used because rhizomes stored for a period of time are likely to dry out and exhibit less vigor. Planting takes place after the risk of the latest spring frost is over, typically between March and May. The annual fertilizer requirement is very low. Results from field trials in Europe and from reviews of literature showed that nitrogen has only a modest influence on the yields of *M.* × *giganteus* [43]. It is estimated that the annual requirement of nitrogen is 50–70 kg ha^{-1}, phosphorus is 5–10 kg ha^{-1} and potassium is 70–100 kg ha^{-1} [56, 57].

Harvesting is carried out after the crop has senesced with moisture content preferably at its lowest and with nutrients translocated into the rhizomes. Harvesting is timed to achieve a balance between attaining lowest moisture content and minimizing biomass losses caused by adverse winter conditions. Crops grown in cooler climates are typically harvested in early spring when moisture content is lowest. Crops grown in warmer climates reach their maturity earlier and can be harvested in late autumn or delayed until early spring. However, delaying harvest until early spring will result in yield reduction by as much as 30–50% due to winter losses of dead and decaying leaves and upper stem parts. But such loses are tolerated because the lower moisture content (20%) improves the fuel quality, permits ease of handling, and requires little drying.

Yield: Miscanthus takes about 2–3 years to establish and so the first-year crop does not yield sufficient biomass to merit harvesting. The crop is normally harvested from the second year onwards but yields will continue to improve after year two until they level off. Ceiling yields can be reached in 2 years under good growing conditions but may take up to 5 years at some locations. The ceiling yields are attained more quickly in warmer climates and those total yields are higher than in cooler climates. The winter yields reported for Europe following the third growing season varied with location and ranged between 6.4 and 23.6 Mg ha^{-1} from northern to southern Europe [53]. Data on *Miscanthus* productivity in North America are still lacking but mathematical productivity modeling [58] based on the European studies projected yields of *Miscanthus* in the Midwest to far exceed those of switchgrass [43]. A recent report comparing productivity of *Miscanthus* and a locally adapted switchgrass cultivar (Cave-in-Rock) grown side by side in field trials in Illinois seems to support the projection [59]. The reported average winter yields of dry matter for the 3 years following the third growing season were 19, 30.3, and 31.4 Mg ha^{-1} in the northern, central, and southern plains, respectively [59]. The average yield per year across the three sites is approximately 27.2 Mg ha^{-1}. This yield is significantly higher than the yields reported in Europe and almost three times higher than for switchgrass cv. Cave-in-Rock, grown side-by-side with *Miscanthus* in the same field trials (Table 5). A yield of 27.2 Mg ha^{-1} would achieve the projected target of 342 million Mg on 12.6 million hectares, half the area estimated in the billion-ton-study projections [1]. No disease has been reported to date for *Miscanthus* but the crop has been known to be susceptible to *Fusarium* blight and Barley Yellow Dwarf Luteovirus [52]. Weed control is essential during the long establishment phase. Fields are typically sprayed with herbicide before planting followed by at least two sprayings a year for the first 2–3 years.

Uses: Miscanthus is grown primarily to be used in the bioenergy industry. It is being tested in Europe as solid fuel for combustion in farm-heating plants as well as for co-combustion with coal, straw, and wood to generate power [53]. Its potential lies in the abundance of raw cellulose biomass that can be converted to cellulosic ethanol. Nonenergy applications for *Miscanthus* include material for thatching [60], paper pulp production [61], and as a bio-composite in construction/building materials such as panel board and building block [62] and as a substitute for the plastics or light metals in the core of light natural sandwich material (LNS). LNS materials are light building materials used for plane and molded structural parts with high form stability at low weight, used for a broad range of applications. Such substitutions are used in carrying cases for musical instruments and lab tops, rotor blades of wind power stations, small boats, and parts of yachts [63].

Biomass Crops for Biofuels and Bio-based Products. Table 5 Comparison of mean harvestable dry matter, Mg ha^{-1} ($\pm$ 1 SE), at the time of peak biomass production (Hmax), and after complete plant senescence (H1) from *Miscanthus* (M) and switchgrass (S) grown at three locations in the Midwest USA during 2004–2006 (n = 4) [59]

		North		Central		South		State average

*Data is not available for these points. Bold values highlight geographic and temporal averages of both parameters in both species

Future directions: One of the drawbacks of using *Miscanthus* as a biomass crop is its narrow genetic base. However, efforts have been undertaken to broaden the genetic base of *Miscanthus* and maximize the productivity and adaptive range of the crop through traditional breeding as well as modern genetic engineering by the European *Miscanthus* Improvement (EMI) project (www.biomatnet.org/secure/Fair/F659.htm) and research institutes across North America. Even with an unimproved *Miscanthus* crop, the yields achieved so far look very promising. Therefore, yield would be expected to increase dramatically and the cost of production to fall with breeding improvement efforts. A potential hybrid of *M. sinensis* that combines winter hardiness with high biomass potential has been identified through the effort of the EMI project. This hybrid will result in improved crop quality through delayed harvest without significant loss in yield [53]. The high cost of establishment is another major concern associated with cultivating *Miscanthus* as a biomass crop. This concern can be addressed with improvement in farming equipment and farming practices that will help to reduce loss of harvested material, time, and labor cost. The development of new machinery to process rhizomes (that includes lifting, cleaning, splitting, sorting and boxing) and carry out precision rhizome planting has made commercial rhizome multiplication farming and commercial production of *Miscanthus* feasible. Improvement in the crop together with improvement in farming technology and processing of this biomass crop into fuel will undoubtedly make *Miscanthus* a very attractive crop to the biofuel industries.

Switchgrass *Origin and distribution:* Switchgrass (*Panicum virgatum*) is a warm-season grass indigenous to the Central and North American prairie with its northern limit of adaptation at about 51° N [64]. In the USA its adaptive range stretches from the eastern seaboard to as far west as the east side of the Rocky Mountains and from the Texas Coastal Plain to as far north as Hudson Bay [65]. This wide geographic distribution can be seen as the manifestation of the great genotypic and consequently phenotypic variation seen within the species. In addition to its broad adaptation, switchgrass exhibits great adaptability to diverse edaphic conditions. Switchgrass can reach the height of 0.5–3 m or more in wetter areas of the country. Switchgrass has been extensively studied and planted in North America. Historically, switchgrass grown in the USA has been used as forage but over the last 2 decades it has been investigated intensively for its potential as an energy crop. In 1991 switchgrass was identified by

Biomass Crops for Biofuels and Bio-based Products.

Table 6 Characteristics of Upland and Lowland switchgrass ecotypes [67]

Upland ecotypes	Lowland ecotypes
Developed on higher "mesic" (moderately moist) sites	Developed in lower lying, "hydric" (considerably moist) sites, more sensitive to moisture stress
Adapted to mid- to northern latitudes	Adapted to lower latitudes
Predominantly octaploid ($2n = 7x = 72$)	Tetraploid ($2n = 4x = 36$)
Longer root length and internodes	Bunch form, larger root diameter
Shoots: originate from more active rhizomes and basal nodes of previous year culms	Shoots: originate from buds on rhizomes
Shorter and fine stems	Taller, coarser, thick stems, long, wide bluish-green leaves with long ligules, large panicles

the US Department of Energy for development as a model herbaceous energy crop because of its ability to tolerate a wide range of environmental conditions and at the same time offer high biomass yield [66].

Ecotypes: A fair amount of genetic variability exists in the switchgrass populations found across North America. The environment exerts a selective pressure on the population's diverse genotypes. The interaction between environment and genotype has over time created different ecotypes as well as variations within an ecotype (reproductive phenology, cold, heat, and drought tolerance) resulting in varieties with specific genetic and morphological characteristics that provide a good "fit" to a particular region. Through natural selection, two genetically and phenotypically distinct types of switchgrass have emerged, the lowland and the upland varieties (Table 6) [68]. The lowland varieties are vigorous, tall, thick-stemmed and generally found in wetter and more southern habitats. The upland forms are typically shorter and fine-stemmed and mainly found in drier mid- and northern latitudes. The ecotypical differences are generally related to local soil and climatic characteristics, with eastern and southern varieties adapted to higher moisture conditions, and western and northern varieties adapted to drier conditions. The phenotypic and ecotypic variation between the lowland and the upland ecotypes can be explained by their cytotypic diversity. Lowland switchgrass ecotypes are tetraploid, with a base chromosome number of 9 (diploid number 18), leading to 36 chromosomes ($2n = 4x = 36$). Upland ecotypes with the exception of the cultivar Summer, which is tetraploid, are octoploid ($2n = 8x = 72$) and less frequently, hexaploid ($2n = 6x = 54$) [69]. Breeding programs aimed at improving the forage yield have developed cultivars that adapt to specific locales ensuring the success of switchgrass in a large variety of conditions, from arid sites in the shortgrass prairie to brackish marshes and open woods [70].

Growing conditions: Switchgrass will grow in a wide range of soil types from fine to coarse textured soils but prefers soils of finer texture. Loamy and sandy soils will allow the roots and crown to spread more easily than do denser clay soils. Sandy soils dry out quickly potentially limiting the establishment success and biomass yield. Switchgrass can grow in acidic soil with pH as low as 4.3 [71] but optimum growth occurs at a pH between 5.0 and 8.0 [72]. Lowland switchgrass fares better in heavier and wetter soils while the upland types favor drier soils. Within the species, upland types are generally considered more drought tolerant [73]. Switchgrass grows best in association with site-adapted mycorrhizal fungi. The presence of mycorrhizae is thought to enhance phosphorus uptake by the plants [74, 75]. Therefore, mycorrhizae play a key role in moderating switchgrass growth in phosphorus-limited environments as well as reducing fertilizer inputs for biofuels production. Warm soil temperature and moisture are important in the successful establishment of switchgrass. Once established, switchgrass can survive extreme periods of drought. Under nonirrigation conditions switchgrass grows best in areas with greater than 500 mm of average annual rainfall.

Switchgrass seed germination is temperature and pH sensitive [72]. The optimum temperature for germination and growth are cultivar-dependent. Some cultivars such as the southern uplands germinate at about 11°C [76] while other cultivars may require as

high as 35°C to germinate [77]. Planting is typically done in spring from mid-March to late May. Dormant seeds require a breaking step for them to germinate. Dormancy-breaking can be achieved by stratification. Planting dormant seeds into a cool soil (10–20°C) and allowing them to stratify in situ has been shown to increase germination [77] but this may lead to weed control problems. The cool season weeds can germinate first and choke out the switchgrass seedlings when the soil warms [78]. Weed control is very important in the early stages of establishment. Unfortunately, there are very few herbicide options available to control the weeds after switchgrass emergence. The herbicides almost universally used for some time as pre- or post-emergent herbicides for switchgrass and other warm-season grasses are triazines [79–82]. However, the types of herbicides and the rates used will best be determined by considering the weed species to be controlled and switchgrass' tolerance to the chemical.

Most research on switchgrass fertility has focused on its use as forage and higher nitrogen applications can ensure high yields and better quality feed. Nonetheless, some researchers have considered nitrogen fertilizer recommendations for switchgrass to be higher than necessary for biomass production. Switchgrass has a remarkable ability to extract nitrogen from unfertilized soils and is inherently thrifty in its use of phosphorus and potassium and often shows little or no response to additions [83, 84]. Mineral cycling within the plant and the presence of mycorrhizae in the soil play an important role in nitrogen and phosphorus nutrition of switchgrass. Switchgrass as a biomass crop in general can be grown without fertilizer or limited addition of fertilizer and still maintain productivity [67]. The nitrogen, phosphorus, and potassium recommendations should ideally be specific to a site or soil.

Harvesting switchgrass for biomass as opposed to forage should preferably be delayed until shoots have essentially all senesced and died which may not be until November or December. This will allow nutrients to be recycled from shoots to below-ground parts at the end of the growing season [85]. Harvesting once per year in late fall or early winter is recommended to maintain the highest sustainable biomass yields in the long term [67]. Harvesting late in the fall or early winter allows moisture content of the crops to drop to 15% or less which will facilitate quick baling and ease of transport as well as improving the quality of the biomass feedstock. For co-firing in coal plants the moisture content should preferably be around 12% to 13% [86]. Harvesting can be carried out with conventional haying equipment.

Yield: Switchgrass becomes fully productive only upon the third year after planting. Unlike other crops where yield data have been available for many years, data for switchgrass as a biomass crop are rather limited and are based mainly on small-plot research. A search across the literature provides switchgrass yield estimates that vary considerably, from less than 0.9 Mg ha^{-1} to almost 36.3 Mg ha^{-1}. Nonetheless, the most frequently observed yield class across all ecotypes, cultivars, soils, and management practices is between 9 and 10.9 Mg ha^{-1}. This great variability in yields is explained by the wide range of ecotypes as well as the strong interactions between genotypes and the environment. Gunderson et al. [70] observed higher yields on average within the lowland cultivars, 11.9 Mg ha^{-1} versus 8.4 Mg ha^{-1} in upland cultivars. Among the lowland varieties Alamo and Kanlow give the highest yield while Cave-in-Rock gives the highest yield for the upland varieties [87].

With newer varieties of switchgrass, yields in excess of 18.2 Mg ha^{-1} have been reported for test plots. Sanderson et al. [88] have reported yields of 13.6–18.2 Mg ha^{-1} in field trials in Texas and Thomason et al. [89] have reported yields in excess of 27.2 Mg ha^{-1} from field work in central Oklahoma. These yields are relatively high and site-specific. In a larger scale study, Parrish and Fike [67] reported average biomass yield in a 10-year study of 12.9 Mg ha^{-1}. Schmer et al. [90] reported on-farm yields ranging from 4.7 to 10.1 Mg ha^{-1} for field trials in the USA. According to the US Agricultural Research Service, growers can expect yields from 15.4 to 36.2 Mg ha^{-1} in the southeast, 10.9–13.6 Mg ha^{-1} in the western Corn Belt, and 2.3–9.1 Mg ha^{-1} in the northern plains [91].

Uses: Switchgrass was originally used as forage, either grazed [92, 93] or for making hay [94, 95]. The use of switchgrass has since been expanded to include nonforage purposes such as for bioenergy, soil stabilization and erosion control in critical areas like strip-mine soils, sand dunes, and dike, and soil improvement

in areas degraded by overcropping. "Alamo" switchgrass has also been tested for its ability to remediate soils contaminated with cesium-137 and strontium-90, two radionuclides released during nuclear testing, nuclear reactor accidents, and weapons production. The level of cesium and strontium removed over a 5 months period was reported at 36% and 44%, respectively [96].

Benefits: Benefits associated with switchgrass are numerous. Planting switchgrass, even as a monoculture, is expected to enhance prairie biodiversity by providing forage, habitat, cover, and nesting areas for a diverse prairie wildlife that includes mammals, birds, amphibians, reptiles, invertebrates, and insects. Hohenstein and Wright [97] estimated a 95% reduction in soil erosion rates and a 90% reduction in pesticide use for herbaceous energy crops such as switchgrass relative to annual row crops like corn and soybean. It is also suitable for short windbreak plantings in truck farm fields [98] and it has been shown to improve water and soil quality by reducing carbon emissions through carbon sequestration [99]. Switchgrass can be easily integrated into existing farming operations because conventional equipment for seeding, crop management, and harvesting can be used [100].

Future directions: A significant amount of knowledge of the biology and agronomy of switchgrass has accumulated over the years through research on switchgrass as forage and recently as a biomass feedstock. There is now an understanding of the adaptation of existing cultivars and the development of new cultivars with improved yield and adaptation ability for different agro-ecoregions. However, there are still constraints that limit the use of switchgrass as a bioenergy crop. Problems with seed dormancy, improper or nonuniform planting depth, lack of weed control options at establishment, and variable weather and soil conditions precluded the development of reliable and economic establishment methods [101]. A better understanding of how nitrogen is used and recycled in switchgrass under different growing conditions will help to develop fertilizer guidance and nutrient management specific to sites and soils [102]. Current research on the genetics, breeding, and molecular biology of switchgrass will result in new switchgrass cultivars with improved yield, greater establishment ability, and altered cell-wall properties for more efficient conversion.

Woody Biomass Crops

Introduction

Biomass, especially woody biomass and energy crops, already contribute substantially to cover energy demands around the world. Dedicated woody crops for biofuels have the potential to be an important energy source and will contribute to the substitution for fossil fuel energy [103]. In fact, the US Department of Energy has a vision to replace 30% of the liquid petroleum fuel for transportation with biofuels and similarly, the European Union Directive 2003/30/EC has targeted 5.75% of all petrol and diesel transport fuels to be derived from biomass by December 2010 [104]. Clearly, a multifaceted approach that includes both agricultural crops and dedicated woody crops will be necessary to attain these goals.

The principal challenge for biomass production is to develop and grow crops with improved physical and chemical traits while increasing biomass yields. Woody perennial plants like trees and shrubs grown for biofuels have the potential to play a central role in providing a renewable source of biomass for conversion to fuels while also providing a wide array of conservation benefits and ecological services, such as favorable habitat for wildlife, clean surface and ground water, conservation of soil and species diversity, that will exceed those associated with conventional annual crops [105].

Poplar

Origin and distribution: Hybrid poplars (*Populus* spp.) are among the fastest-growing trees in North America and among the oldest types of dicotyledonous plants. The genus *Populus* consists of close to 35 species of deciduous flowering plants in the family *Salicaceae*, native to most of the Northern Hemisphere. It includes the cottonwoods, poplars, and aspens, all of which are sometimes termed poplars. The hybrids themselves represent crosses among various cottonwood species [106].

Cottonwood (*Populus deltoides*) was first introduced by early French explorers in North America,

which crossed naturally with Black Poplar (*Populus nigra*), creating what is referred to as *Populus* × *euramericana* hybrids (http://www.ag.ndsu.edu). They were first cultivated around fields as windbreaks and were selected for fast-growing characteristics. In 1912, hand-pollinated poplar hybrids were produced in Britain. The shortage of timber after World War II spurred an increase in hybrid poplar plantations in Europe. Even though some of these European varieties were reintroduced to North America in the early 1920s, it was not until the 1970s that commercial planting of hybrid poplar started in the USA. Since then, a national consortium involving government researchers from several agencies, universities, and the private sector has been working on improving hybrid poplar. Research in this area is targeting reduction of production costs by targeting pest and disease resistance, increasing yields and improving management systems. Also, studies are being performed to establish the environmental impact of producing hybrid poplar [107] (http://bioenergy.ornl.gov/main.aspx).

Physiology: Poplars are deciduous trees with alternate leaves, furnished with the appendages known as "stipules." Their flowers are dioecious; the calyx and corolla are replaced by simple scales. The female flower consists of a solitary one-chambered ovary, containing many ovules. Flowers are borne in long, sessile (attached directly to the stem) or pedunculated (growing from a stalk) aments, which are produced from buds formed in the axils of the leaves of the previous year. Leaves are green to dark green and measure 5–12 cm. The fruit is a two- to four-valved capsule, ripening before the full development of the leaf. The seed is light brown and surrounded by a tuft of long, soft, white hairs. Poplars can grow from anywhere between 15 to 50 m, with trunks of up to 2.5 m in diameter They grow upright, with spreading branches and their root system is shallow and wide-spreading, equal or greater than the height of the tree (Fig. 3). *Populus* species are somewhat susceptible to insects and diseases. Common diseases may include *Melampsora* leaf rust, *Septoria* leaf spot and canker, *Cytospora* canker, wetwood, and stem decay. Common insect pests include poplar borer, aphids, poplar bud gall mite, poplar vagabond aphid, and poplar leaf beetles (http://www.2020site.org/trees/poplar.html).

Biomass Crops for Biofuels and Bio-based Products. Figure 3
Hybrid poplar grove

Culture: Hybrid poplar is a short-rotation woody crop (SRWC). SRWC's are species that usually are planted and harvested in less than 15 years [108]. Hybrid poplar stands are typically planted at 750–1,700 trees ha^{-1} and allowed to grow for 6–12 years before harvest. Hybrid poplars are capable of resprouting from their rootstocks after harvest but it is recommended to reestablish the cultures to reduce the potential of diseases and also to exploit the new improved hybrid varieties. For the production of hybrid poplars, clay loams or sandy-loam, slightly alkaline (pH 5 to 7.5) and medium-textured soils are recommended. They require a moist site and will not tolerate drought on upland sites. The use of herbicides or manual weed removal must be used in the first 3 years, but this is no longer necessary when the canopy closes, creating its own weed control. Furthermore, fertilizer applications are only necessary if the nitrogen level in leaves falls below 3% on a dry weight basis (http://www.ag.ndsu.edu, [107]).

Biomass Crops for Biofuels and Bio-based Products.

Table 7 Hybrid poplar yields in regions of the USA [109]

Region	Hybrid poplar yields	
	Average Mg ha^{-1} per year	Range Mg ha^{-1} per year
Lake States	9.9	7.9–11.8
Corn Belt	10.4	8.4–11.7
Southeast	10.1	8.6–11.7
Appalachia	8.0	9.0–11.7
North Plains	8.6	7.3–9.7
South Plains	8.4	7.3–9.0
Northeast	9.0	7.7–10.0
Pacific Northwest	12.9	12.4–13.5

Yield: Hybrid poplars, when grown under short-rotation silviculture, can produce between 8 and 22 Mg ha^{-1} per year and achieve a height of 20 m in as little as 6 years. Average yields in the USA and range of yields by geographic region on hectares currently planted are shown in Table 7 [109].

Hybrid poplar growth and biomass yield could vary greatly depending on the site, the soil properties and weather conditions, as well as the species genotype. The above-ground biomass yield of 4-year-old hybrid poplar stands in Europe (in short-rotation coppice culture) and north central USA averaged between 2 and 11 Mg ha^{-1} per year. In comparison, a recent study at the University of Saskatchewan reported growth and yield data in western Canada of 4-year-old Walker hybrid poplar stands from five locations to average from 0.17 to 0.19 Mg ha^{-1} per year [110]. It has been suggested that once the crop is established, the combination of precipitation and temperature and its influence on soil moisture becomes the most limiting factor for maximizing biomass production [111].

Advantages: Many advantages can be linked to growing hybrid poplars, from its positive effect on the environment to the fact that they are expected to be grown on agricultural cropland using standard production methods, thus reducing the need for new technology. Environmental benefits are linked to hybrid poplar's perennial nature. Chemical and fertilizer applications are considerably lower and these trees can intercept run-off nutrients to rivers and wetlands close by. Also, wind and water erosion over the life of the rotation is inferior to the erosion caused by annual crops and there is a clear ecological benefit of year-round trees for birds and habitat for small mammals. Their buds provide a source of food for birds, and their twigs and young branches make good forage for wildlife (http://www.ag.ndsu.edu, [107]).

The use of SRWCs for bioenergy production could substantially decrease the overall use of fossil fuels for energy. It would reduce CO_2 emissions into the atmosphere, increase soil organic carbon sequestration, and improve soil erosion control. Additionally, growing woody species like poplar on waste disposal sites and agriculturally marginal lands would definitely benefit rural communities [110].

Uses: Hybrid poplars are grown on plantations mainly for pulpwood used in the manufacture of paper. This wood is also sold as inexpensive hardwood timber, used for pallets and cheap plywood [106]. Wood and wood-derived fuels are a primary energy source in developing countries' domestic households as well as industrial facilities. From a medical point of view, *Populus* species can be a source of salicin, used for fevers and headaches. (http://www.ag.ndsu.edu, [107, 112]). More importantly, they are well suited for the production of bioenergy (e.g., heat, power, transportation fuels) and other bio-based products (e.g., organic chemicals, adhesives).

Poplar as a source of biofuels: Bioethanol is traditionally produced by converting either starch from grains such as corn, or sugar from sugarcane into ethanol. A second technology is based on the hydrolysis of cellulose or lignocelluloses into sugars, followed by fermentation to produce fuel ethanol [113]. The cellulose comes from woody parts of plants or trees, such as hybrid poplar and other short rotation woody crops. The main objective in the production of ethanol from cellulose is to obtain a maximum biomass output with a minimum input. Developing new poplar varieties could expand the biofuel production without incurring the type of environmental problems that intensive agriculture can generate [114]. Major improvements have been achieved through breeding and genetic selection.

Poplars are the first tree for which the entire genome has been sequenced. Its 45,000 genes are

being investigated to find ways to improve this tree, from genes that regulate its root system, improving water and nitrogen absorption, to cell wall modification for more extractable cellulose [115, 116]. New varieties focusing on more efficient roots not only would result in higher tolerance to drought but also in bigger trees and thus more biomass for the biofuels industry [115]. Alternatively, modification of cell wall polymers, such as lignin, which interfere with the enzymes needed to degrade cellulose, can benefit the extraction of cellulose from poplar trees for the production of ethanol [116].

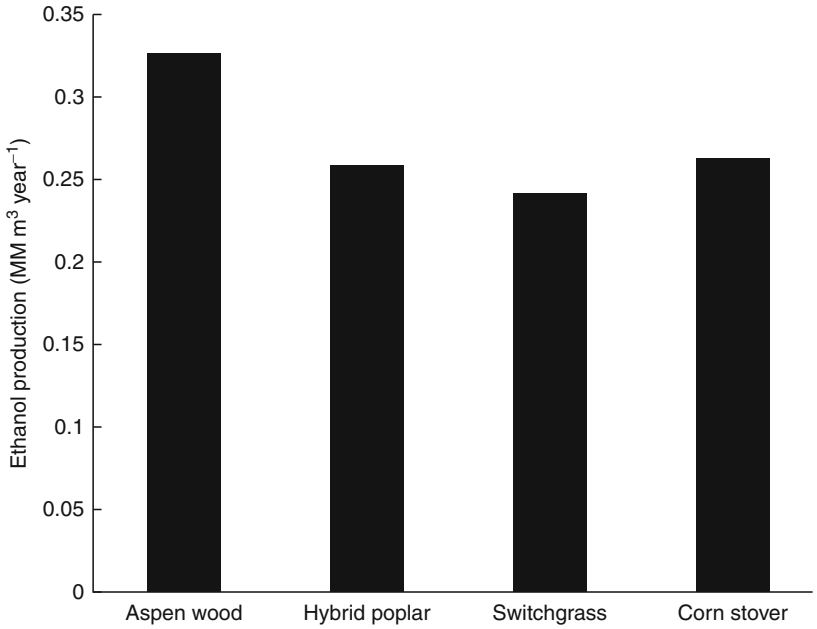
To increase vigor and yield of poplar species, new crosses are being performed and examples of studies on new varieties are easy to find. Among these, a cross is found between *Populus trichocarpa* and *Populus deltoides* which has achieved a hybrid with leaves about four times as large as the leaves of either parent at a similar age, expanding their photosynthetic surface area. Other projects are looking at the biochemical indicators for drought tolerance in these hybrids, by growing them with or without irrigation and characterizing biochemical changes. All efforts are focused on fast-growing highly adapted poplar clones [106].

Up to now, traditional row crops like corn have been utilized for ethanol production. Several corn-to-ethanol plants are commercially in use around the world and it is known that they offer an alternative green energy source while minimizing greenhouse gas (GHG) emissions [117]. Nonetheless, poplar trees might have several additional benefits. In fact, corn ethanol reduces GHG emissions by about 13%, while cellulosic ethanol could greatly reduce GHG by 88% [118]. Even though wood from hybrid poplar can produce roughly the same ethanol production per unit biomass (Fig. 4), hybrid poplar generates 40% more excess electrical energy than corn. In addition, fast-growing cellulosic energy crops such as hybrid poplar can be grown on a variety of land types, without having to compete with cropland for food and feed needs, as it is necessary for crops such as corn [117]. Poplar plantations do not require intensive inputs and are not harvested every year. There is a wide range of varieties and they could be grown in an equally wide range of climates, from subtropics in Florida to subalpine areas in Alaska. It should not be forgotten that the machinery necessary for poplar growth already exists and the infrastructure to handle the trees is already available [116].

The use of dedicated energy crops, such as hybrid poplars will not only address energy security issues, but will also inevitably be beneficial for the environment while addressing global climate change and economic development.

Eucalyptus

Origin and distribution: Eucalyptus is indigenous to Australia, Indonesia, and Papua New Guinea. There are more than 700 species of *Eucalyptus*, almost all (except for two) are native to Australia [119]. Species of *Eucalyptus*, prized globally for excellence in paper and energy production, are cultivated throughout the tropics and subtropics in more than 90 countries worldwide representing 8% of all planted forests (FAO, ftp://ftp.fao.org/docrep/fao/008/A0400E/A0400400.pdf). A few cold-tolerant species and their hybrids grow in the temperate regions of Europe, New Zealand, and South and North America. The global land area under *Eucalyptus* cultivation is estimated at over 20 million hectares and Brazil has emerged as the major global producer and exporter of *Eucalyptus* wood with approximately 4.2 million hectares on plantations followed by India and China with ~3.5 million hectares and 2.9 million hectares, respectively [120]. *Eucalyptus* was first introduced to California as an ornamental plant in 1853. Soon after, it was widely planted throughout the state because it was fast growing and a renewable source of timber and fuel [121]. Its popularity was later replaced with the criticism that *Eucalyptus* forests compete with native plants and do not support native animals. Eucalypt forests in some parts of California were eventually removed [122]. The fuel crisis in the 1970s brought back *Eucalyptus* species as prime candidates for woody biomass cultivated on experimental farms mainly in central California. Two other places in the USA where *Eucalyptus* short-rotation research projects are conducted are located in Hawaii and Florida [123, 124]. Other regions in the USA considered highly suitable for growing *Eucalyptus* are in Texas, Louisiana, and Georgia. Only four *Eucalyptus* species, *E. grandis (EG), E. urophylla (EU), E. camaldulensis, and E. globulus*, and their hybrids



Biomass Crops for Biofuels and Bio-based Products. Figure 4
Comparison of ethanol production utilizing aspen, hybrid poplar, switchgrass, or corn stover

account for nearly 80% of the eucalypt plantations worldwide with *E. grandis* being the most widely used species in tropical and subtropical areas while *E. globulus* is the premier species for temperate zone plantations [125]. *E. grandis* is also used as a parental species in hybrid breeding and is rated worldwide as one of the fastest growing species and has the widest adaptability of all *Eucalyptus* species [125]. The greatest area of plantations of *EG* and its hybrids with other species are in Brazil and several other Central and South American countries.

Importance: *Eucalyptus* species are fast-growing woody perennials with many uses making them economically important trees. Eucalypts are commonly cultivated for the paper and pulp industries because of their high fiber yields and use as fuelwoods. In many poor countries in Africa [126], South America [127], and Asia [128] eucalypts are grown as a cash crop. *Eucalyptus* woods are used as mine props, poles, firewood, and charcoal [119]. The nonwood products derived from eucalypts include essential oils, honey made by bees from its flowers, and tannin [129]. The potential of *Eucalyptus* as a biomass feedstock for cellulosic ethanol has drawn attention to this species of woody perennial. The US Department of Energy (DOE) identified *Eucalyptus* as one of the crops with the potential to contribute to the biomass needed for biofuel to reduce the nation's dependence on imported fossil fuels [1]. *Eucalyptus* has many attributes and advantages that make it suitable as a dedicated energy crop. As a perennial, *Eucalyptus* can be cultivated under the coppice system. The cut stumps resprout to provide another crop. The retained roots with stored carbohydrates and access to soil water and nutrients help sustain rapid regrowth rates [130]. The tree withdraws the mineral nutrients into its roots at the end of a growing season, thus reducing the amount of fertilizer needed and thereby reducing the fertilizer costs and minimizing water pollution caused by run-off. The fact that harvesting only once every few years over a period of 15–20 years reduces the environmental impact created by disturbances at harvesting and planting (soil erosion and nutrient loss) and saves on the cost of establishment (site preparation, seedling, and planting costs). *Eucalyptus* is one of the fastest growing hardwoods which grows well even on environmentally harsh lands (infertile soils, arid lands) [131]. It is a low input crop requiring minimum fertilizer and

precipitation. *Eucalyptus* is also the world's most widely planted hardwood species that has multiple end uses, including feedstock for traditional forest products and energy products such as cellulosic ethanol and power generation through direct firing, co-firing or wood pellets in short rotation. In regions of the USA where *Eucalyptus* will most likely be cultivated, infrastructure already exists for planting, harvesting, handling, and processing wood for pulp that could also support the production, processing, and distribution of *Eucalyptus* crops. Last but not least, *Eucalyptus* species have been grown in the USA for many decades and have not demonstrated any invasive characteristics.

Growing conditions: Eucalypts are hardy trees and the majority of *Eucalyptus* species will grow in a range of soils from pH 4.5 to 8.5. They do not require fertile soils and many species naturally occur in shallow, low fertility soils. When grown on deeper more fertile soils they generally grow faster, bigger, and more luxuriant. Some species do require good drainage while others will grow on heavy clay and even on boggy, partially waterlogged sites. Several species grow well on high pH soils, and most species adapt to higher pH soils, although usually with reduced growth rates. *Eucalyptus* will tolerate an annual rainfall of 500–5,000 mm and an annual temperature of 12.3–27.9°C (Table 8). *Eucalyptus* is considered one of the most adaptable plant genuses, and the trees are remarkably hardy in all kinds of weather conditions. Once established the mature trees adapt to the local growing conditions and become very tolerant to drought and prolonged dry periods. However, the young trees of most *Eucalyptus* species do not tolerate frost very well and will succumb to extreme fluctuation of temperatures [132]. Fertilization and nutritional studies of *Eucalyptus spp.* in Australia, Brazil, and Hawaii pointed to a general need for supplementary nitrogen, and sometimes phosphorus, especially at planting and soon thereafter [133, 134]. Fertilizer (N-P-K) is generally applied at planting and again about 6 months later. Subsequently, only nitrogen is needed on most sites. The total amount required depends on the nitrogen status of the topsoil and may range from 224–673 kg ha^{-1} in four to eight applications (depending on the site quality and rotation length) [123]. The application of nitrogen may be eliminated or reduced with the practice of intercropping with nitrogen-fixing species such as *Leucena* or *Albizia*. Such practices were studied in Hawaii [135], Brazil [136], and India [137] and have shown that it is possible to maintain both the yields and nitrogen status of the soils without using nitrogen fertilizers, or with much reduced fertilizer inputs. *Eucalyptus* can be planted at any time of the year in tropical and subtropical areas but spring time is recommended for colder regions. Young *Eucalyptus* trees do not compete well with weeds; therefore, weed control in the early stages of establishment is very important in the management of *Eucalyptus* cultivation. Weed control is carried out before planting the trees and during the first 2 years of establishment. Pre-emergence and post-emergence herbicides found safe and efficacious for *Eucalyptus* are listed in a report by Elmore [138]. The projected rotation age for bioenergy production is 5 years under optimum growing conditions and a year or two longer under less favorable conditions [125]. However, new and high-yielding varieties have the potential to reduce rotation length to 4 years or less [139].

Yield: The yield of *Eucalyptus* biomass varies widely from species to species and also with provenances (place of seed origin), sites, and management systems around the world. Small plot studies conducted at the University of Massey, New Zealand, comparing the yields of 19 *Eucalyptus* species grown under similar conditions and managed under a coppice regime highlighted the differences in survival rates, the number of shoots per tree, the shoot/tree sizes and ultimately the yields between different species. The yields obtained vary from 4 to 20 Mg ha^{-1} per year and only six species: *E.brookerana*, *E. botryoides*, *E. botryoides* × *saligna*, *E. ovata*, *E. elata,* and *E. oblique* had yields averaging 16 Mg ha^{-1} per year [140]. The yield evaluation of *Eucalyptus* species in small plot trials in Hawaii emphasized the suitability of sites and species (Table 9). *E. grandis* and *E. urophylla* are relatively highly productive at a higher elevation with moderate to high precipitation but not at a lower elevation. *E. camaldulnesis* performed poorly at low elevation even with irrigation. *E. urophylla* has the highest annual yield with ∼35 Mg ha^{-1} per year at the moderately upland site [141]. The importance of provenance selection for different sites was brought out in the data for *E. camaldulensis* planted in Afaka, Nigeria. Five-year-old trees had a mean annual increment (MAI) that ranged from

17.3 to 5.1 Mg ha^{-1} per year depending on where in Australia the seed had come from. This demonstrates a possible threefold increase in yield achieved simply by selecting a seed source location [131].

A well-managed *Eucalyptus* plantation will improve the performance of the crop and will maintain a relatively high level of yield throughout the coppice regime. *Eucalyptus* cultivated with irrigation and fertilizer gives a higher yield over *Eucalyptus* grown without these additions. This was demonstrated in a pilot experiment in Brazil under the Brazil *Eucalyptus* Potential Productivity Project (BEPP). The yields of *Eucalyptus* cultivated with no fertilization were 28% lower than yields achieved with fertilization, and the response to irrigation was found to be far larger than that of fertilization. The growth increase from irrigation ranged from a low of 7% at the cooler, higher elevation site to 67% at the driest site [142]. The stand uniformity also has an influence on the yield. Stands with uniform structure (trees in plots planted in a single day) showed 13% greater growth than stands with higher heterogeneity of tree sizes (owing to staggered planting). The yields reported 2 decades ago in field trials in California, Florida, and Hawaii were typically 20–24 Mg ha^{-1} per year [124, 141]. Over the last 10–20 years of intensive research, improved silviculture (site preparation, fertilization and weed control) and superior clones have improved yields, exceeding 37 Mg ha^{-1} per year with the potential to reach ~66 Mg ha^{-1} per year [124]. In Brazil, commonly planted *Eucalyptus* hybrids such as *E. grandis* × *E. urophylla* routinely yield ~24–30 Mg ha^{-1} per year [142]. Large gains in yield can be achieved by the careful selection of species, sites, provenances, and management system to suit the local conditions.

Economics: Growing biomass and producing bioenergy require a substantial financial investment. Hard numbers on the economics of growing *Eucalyptus* for bioenergy on a commercial scale are unavailable. However, the cost projection from small plot trials in Hawaii for producing and delivering biomass feedstock

Biomass Crops for Biofuels and Bio-based Products. Table 9 *Eucalyptus* biomass yields at five Hawaiian sites after 5 years [141]

Site/Island	Tree species	Elevation (m)	Annual rainfall (mm)	Average temperature (°C)	Agronomic conditions	Planted density (trees/ha)	Annual yield (Mg ha^{-1} per year)
Mountain View, Hawaii	*E. grandis*	296.3	4,623	21.1	Wet, upland	405	20.16

to the central facility, excluding storage, processing, and biomass conversion ranges from US$30 to US $100 per dry Mg [143]. The estimated cost of producing and delivering *Eucalyptus* in the southern USA ranges from US$50 to US$60 per dry Mg, based on a yield of 28–16.8 Mg ha^{-1} and on a delivery range within 48 Km of the processing site [144]. Factors that contribute to the cost of production are establishment, maintenance, harvesting, transportation, rotation length, and productivity. The cost can be greatly reduced by growing highly productive species, having higher tree stand density and a shorter rotation length. The economic feasibility of growing *Eucalyptus* for biomass can be improved by increasing productivity through improved germplasm, an efficient management system, and improvements in biotechnology. Introducing traits such as improved growth, stress tolerance, reduced lignin composition for easier processing of the biomass, and improved wood quality through increasing cellulose composition will increase productivity and add value to the crop.

Conclusions and Future Directions

Agricultural residues: Residues can contribute as much as 428 million dry Mg per year to biomass harvests for conversion to transportation fuels. Nevertheless, it is clear that although there is a positive energy balance from residue utilization, many factors other than ethanol output have an impact on the use of these residues. Maintenance of soil fertility is paramount to the sustainability of this biomass source. Compensation for the farmer is highly important as well, with potential of their participation in farmer cooperatives (co-op's) to capture part of the value chain and ensure their continued involvement. Additionally, harvest and storage logistics must be explored and resolved. Handling large quantities of loosely packed biomass, transporting it over long distances and storing it in bales or wet stacks are only a few of the logistics issues. Harvesting activities must be coordinated so that the process of grain collection and storage is not slowed with resultant loss in their valuable revenues. However, the potential of

this biomass source is important enough for the investments necessary to make these residues a feasible feedstock.

Sweet sorghum and sugar cane: Sugar cane and sweet sorghum are members of same family and share physiological characteristics. Their use as bioenergy crops is almost identical. For the last 40 years, sugar cane has been used as a bioenergy crop in Brazil, which is a successful example of a country that has reduced its gasoline usage by producing bioenergy. Sweet sorghum is considered to be one of the most drought-resistant agricultural crops as it has the ability of remaining dormant during the drought period. de Vries et al. [145] analyzed different biofuel production systems in geographical regions where they are currently important for ethanol. Among the six "first generation" biomass crops, e.g., maize (USA), wheat (Northwest Europe), sugar beet (Northwest Europe), cassava (Thailand), sweet sorghum (China), and sugar cane (Brazil), biofuel production from sugar cane and sweet sorghum delivers substantially more energy per unit energy spent than from the other crops. These two C4 sugar-producing plants appeared to be most sustainable and most efficient in the use of land, water, nitrogen, and energy resources, while pesticide applications were relatively low in relation to the net energy produced. An agronomic and yield comparison of sugar cane and sweet sorghum is presented in Table 10.

Both sugar cane and sweet sorghum are excellent feed stock for first-generation bioethanol production. However, in order to reduce the usage of fossil fuel and attain the goal of sustainability, utilization of lignocellulosic biomass for the production of cellulosic ethanol plays a vital role. Lignocellulosic-rich bagasse from sugar cane and sweet sorghum has the most positive net energy balance among the common feedstocks potentially used for bioethanol production. Sugar cane and sweet sorghum have comparable energy balance, with 8.3 and 8 units of energy produced for every unit of energy invested in their cultivation and production, respectively, especially when compared with 1.8 units for corn grain. On the other hand, only 0.8 unit of energy is produced in fossil fuel production for every unit invested [147]. Currently eight times more energy is produced from sugar cane than what is used in its creation. When bagasse is included in the equation, it is estimated that the number may increase to as much as 16 times. Bagasse is the feedstock with the most positive energy balance available in the near term. Sugar cane bagasse shows significant potential for making the biomass-based ethanol an economically viable solution.

Biomass Crops for Biofuels and Bio-based Products.

Table 10 Comparison of sugar cane and sweet sorghum [146]

	Sugar cane	Sweet sorghum
Crop duration	About 7 months	About 4 months
Growing season	Only one season	One season in temperate and two or three seasons in tropical area
Soil requirement	Grows well in drain soil	All types of drained soil
Water management	36,000 m^3 h^{-1}	12,000 m^3 h^{-1}
Crop management	Requires good management	Little fertilizer required; less pest and disease complex; easy management
Yield (ha^{-1})	70–80 Mg	54–69 Mg
Sugar content on weight basis	10–12%	7–12%.
Sugar yield	7–8 Mg ha^{-1}	6–8 Mg ha^{-1}
Ethanol production directly from juice	3,000–5,000 L ha^{-1}	3,000 L ha^{-1}
Harvesting	Mechanical harvested	Very simple; both manual and through mechanical harvested

Switchgrass and Miscanthus: Perennial grasses are nonfood crops which can yield high-quality materials for both energy and fiber production. Switchgrass and *Miscanthus* are immense biomass producers and show great potential as bioenergy crops. They can be grown over a wide range of conditions and with minimal agricultural inputs. Switchgrass has deep roots that makes it less susceptible to drought stress and enables

it to adapt better in areas where the water precipitation is lower than that required by *M.* × *giganteus*. An analysis of published yields indicates *M.* × *giganteus* produces more biomass per unit area and per unit input than switchgrass but the yields of *M.* × *giganteus* are more strongly influenced by water, while those of switchgrass are more strongly controlled by nitrogen [43]. Therefore, in locations with ample rainfall but with concern over nitrogen contamination of water supplies, it may be better to grow *M.* × *giganteus* while conversely, in arid areas without contamination concerns, greater yields may be obtained growing switchgrass as long as adequate nitrogen fertilization is provided.

Woody crops: Woody crops such as Poplar and *Eucalyptus* represent a critical component of the bioenergy future. They have the potential to be a significant part of the bioenergy solution in the USA and in many other parts of the world. In the USA, perennial woody crops are expected to account for part of the 377 million dry Mg of the 1.37 billion dry Mg total biomass resource potential. The projected yield for the long-term feasibility of renewable energy production defined by DOE is 20 Mg ha^{-1} per year [1]. The projected yield is not only achievable but can be exceeded with improved silviculture, the use of superior clones, and genetic improvement. Investments in research and technology are needed to improve productivity and bring down the cost of production. Recent advances in genetically modified *Eucalyptus* include a freeze-tolerant variety and a low-lignin and high-cellulose variety. The freeze-tolerant variety was developed using a highly productive tropical hybrid, *E. grandis* × *E. urophylla* [139]. A field test of the freeze-tolerant variety demonstrated its ability to maintain its productivity even at temperature as low as −9°C. This has made possible commercial plantings of tropical *Eucalyptus* species in the Southeastern USA where cold winter temperatures would normally restrict such cultivation. The low-lignin and high-cellulose variety with 18% less lignin and 4.5% more cellulose developed by a team of Taiwanese and US scientists (China Post, 2007, http://www.chinapost.com.tw/taiwan/2007/09/14/122524/Gene-modified-eucalyptus.htm) would add value to the crop by improving efficiency in the pretreatment step utilized in fermentation systems for biofuels production from lignocellulosic raw materials. The authors estimated that an output of 0.9 million Mg of this new variety could generate extra revenues of about US$36 million every year. Advances in research and technology in growing *Eucalyptus* in Brazil over the last 40 years have paid off significantly. Productivity of *Eucalyptus* biomass has increased twofold to fivefold depending on the site quality [148, 149]. Improved new varieties of poplar trees are currently being obtained through genetic engineering and breeding. Varieties with larger leaves, improved root system, and modified lignin are associated not only with higher biomass yields and better net energy balance but they would definitely have a lower environmental impact [115, 116].

Growing *Eucalyptus* and hybrid poplar for biomass is sustainable and will be economically feasible with improved varieties and technology. The use of woody crops for bioenergy offers many benefits with no anticipated long-term environmental impact and may be part of a long-term solution to the nation's energy security.

In order to ensure feedstock availability whether from dedicated crops or from residues, changes in farm and energy policies will need to be made, making sure they are connected to incentivize this new industry.

Article Outline

Glossary

Antinutrients Substances that interfere with the absorption of nutrients.

Bioavailability The amount of a nutrient in food that can be absorbed and utilized.

Biofortification Any fortification strategy that improves nutritional content at source (before harvest).

Conventional breeding Any process used to create new plant varieties without recombinant DNA technology (e.g., introgression, mutagenesis, and hybridization).

Gene silencing Prevention of gene expression, usually through epigenetic means such as antisense RNA, RNA interference, or de novo DNA methylation.

Genotype The total genetic constitution of an organism.

Inbred Progeny produced as a result of breeding between genetically similar parents.

Introgression The introduction of a new allele from one species into the gene pool of another by repeated backcrossing of an interspecific hybrid with one of its parents.

Locus The position of a gene or other genetic marker on a chromosome.

Macronutrient A nutrient required at levels exceeding 100 mg/day (includes carbohydrates, fats, proteins, water, and fiber as well as certain minerals).

Malnutrition The situation resulting from a nutrient imbalance in the diet, usually referring to a lack of one or more nutrients but equally applicable to nutrient excess.

Micronutrient A nutrient required in minute amounts (typically less than 10 mg/day); includes vitamins and many minerals.

Mineral An inorganic nutrient, usually represented by a soluble ion.

Phenotype The sum of observable characteristics of an organism.

Phytate (phytic acid) A phosphorus-containing compound in the outer husks of cereal grains that, in addition to limiting the bioavailability of phosphorous itself, binds to other minerals and inhibits their absorption.

Promoter The DNA sequence upstream of a gene that regulates transcription.

Quality protein maize (QPM) A variety of maize (corn) developed by CIMMYT that contains 70–100% higher levels of lysine and tryptophan in the grain compared to normal varieties.

Transgene A gene from one species that has been incorporated into the genome of another organism using recombinant DNA technology.

Transgenic plant A plant that carries integrated exogenous DNA in the nuclear genome.

Vitamin An organic micronutrient.

Definition of the Subject and Its Importance

Food insecurity is one of the most important social issues faced today, with nearly one billion people

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

enduring chronic hunger and an additional two billion people suffering from nutrient deficiencies, mostly in the developing world. Strategies to address food insecurity must ultimately address underlying problems such as poverty and poor governance/infrastructure, but the improvement of agricultural productivity in the developing world is an important goal, and biotechnology is one of a raft of measures being considered to achieve it. Genetically engineered plants provide one route to sustainable higher yields, which will increase the quantity of food available. However, genetic engineering can also increase the nutritional quality of crops, and this is the definition elaborated in this article. In particular, the focus is on biotechnology-based methods to increase the availability of essential nutrients, which are often limiting in human diets and lead to specific deficiency diseases.

Introduction

Food security is taken for granted in the industrialized world, where stable political and social structures ensure that everyone has access to enough safe and nutritious food. In contrast, almost one billion people are chronically undernourished in the developing world, regularly consuming less than 2,000 calories per day [1]. There are also a further two billion people who, despite having access to an adequate source of calories, nevertheless lack essential nutrients; perhaps surprisingly, a significant number of these people are citizens of industrialized countries. This means that up to half the world's population at any one time may suffer from malnutrition [1].

The underlying causes of food insecurity in the developing world are complex but poverty is one of the main factors, reflecting the fact that more than one billion people live on less than US $1 per day and another two billion are only marginally better off. The world's poorest people tend to be rural farmers in developing countries, depending entirely on subsistence agriculture, whereas less than 1% of the population in the industrialized world are farmers and they tend to farm for profit. Because of limited purchasing power, the poorest farmers cannot irrigate their crops or buy fertilizers, herbicides, and pesticides. This leads to soil exhaustion, falling yields and quality, and the crops become susceptible to pests, diseases, and natural disasters such as drought. In the industrialized world, malnutrition can reflect poverty on the fringes of society, but is also an educational/lifestyle issue that needs to be approached differently [1].

Any long-term strategy to address food insecurity in the developing world must tackle the underlying problem of poverty by providing rural employment–based income through increased agricultural productivity. Given projected increases in the world's population, the higher cost of oil, falling reserves of fresh water, and greater urbanization, it will certainly be necessary to increase the quality, quantity, and diversity of major food crops. A variety of strategies have been proposed, including the efficient use of organic and inorganic fertilizers, irrigation strategies, soil and water conservation, pest and disease management, and the production of improved plant varieties with higher yields or novel products. Biotechnology provides a range of tools that can be used to improve agriculture in the developing world by lifting yields or increasing food quality, and the latter aspect of biotechnology is considered in this article – the use of biotechnology for nutritional improvement [2, 3].

Overview of Essential Nutrition in Humans

Nutrients and Their Roles in Human Health

Nutrients are chemical substances in food that are necessary for humans to have healthy and active lives. Humans require at least 49 defined nutrients to meet their metabolic needs (Table 1), some highly specific and some represented by families of related molecules. Inadequate consumption of even one of these nutrients will result in adverse metabolic effects leading to poor health, impaired development in children, and (if this is a population-wide problem) an economic impact on society. Table 2 lists the daily guideline amounts in adults for some of these nutrients, as reported by the Food and Agricultural Organization (FAO) of the United Nations and the World Health Organization (WHO) [4]. Table 3 shows some common dietary sources of different nutrients. Generally, nutrients are divided into two broad categories: macronutrients (needed in gram or hundred milligram quantities per day, mainly for energy, structural components of body tissues, and bulk composition of body fluids) and

Biotechnology and Nutritional Improvement of Crops. Table 1 The 49 nutrients essential for sustaining human life [37]

Water and energy	Protein (amino acids)	Lipids-fat (fatty acids)	Macro-elements	Micro-elements	Vitamins
Water	Isoleucine	Linoleic acid	Na	Fe	A
Carbohydrates	Leucine	α-Linolenic acid	K	Zn	D

micronutrients (needed in microgram or milligram quantities per day, for many diverse functions). Macronutrients include carbohydrates, fats, proteins, certain mineral ions, water, and fiber, whereas micronutrients include a range of inorganic ions (minerals) and organic molecules (vitamins) [4].

Macronutrients

Carbohydrates and fats consist only of carbon, hydrogen, and oxygen. They are primarily used to derive energy, although they also contribute to some structures in the body, such as the carbohydrates heparan sulfate, chrondoitin sulfate, and hyaluronic acid in the extracellular matrix, and various lipid components of cell membranes. Carbohydrates range from simple monosaccharides (e.g., glucose, fructose, and galactose) to complex polysaccharides (e.g., starch, glycogen, the matrix carbohydrates listed above, and cellulose, the predominant component of plant cell walls). All polysaccharides are polymers of monosaccharide units. Therefore, carbohydrates that can be digested by humans are broken down into monosaccharides and metabolized for energy, used as substrates to synthesize other molecules, or reassembled into energy-storing or structural polymers. Many carbohydrates cannot be broken down in the human digestive system because the corresponding enzymes are not present (e.g., cellulose, inulin) and these are collectively known as dietary fiber. Insoluble fibers such as cellulose help the digestive system function properly (preventing constipation and diarrhea), but there are also many soluble forms of fiber such as inulin which have positive roles in digestion, slowing the movement of food through the gut and facilitating nutrient absorption. Both insoluble and soluble fibers are thought to help prevent colon cancer and cardiovascular disease. Although carbohydrates as a general class of

Biotechnology and Nutritional Improvement of Crops. Table 2 Recommended nutrient intakes for males and females between the ages of 25 and 50 years [37]

Nutrient	Assessment	Male	Female
Energy (kcal)	AEA[a]	2,900	2,200
Protein (g)	AEA	63	50
Vitamin A (mg retinol equivalent)	RDA[b]	1,000	800

Biotechnology and Nutritional Improvement of Crops. Table 3 Sources of some essential nutrients [4, 5]

Component	Examples of sources
Carbohydrates	Cereal grains and potato
Insoluble fiber	Whole grain barley and vegetable peels
Soluble fiber	Fruits, vegetables, and legumes
Essential fatty acids	Fish, flax seed oils, soybeans, pumpkin seeds, sunflower seeds, walnuts, most vegetables, nuts, seeds, and marine oils
Dietary protein	Tofu and other soy-products, eggs, grains, legumes, and dairy products such as milk and cheese, meat, fish
Vitamin A	Carrots, yams, pumpkins, yellow or orange fruits, fish, eggs, and tuna
Vitamin B1	Whole grains, rice bran, lean meats, legumes, wheat germ, oranges, poultry, fish, and enriched pastas
Vitamin B2	Fortified grains and cereals, leafy green vegetables, poultry, fish, yogurt, milk, and cheese
Vitamin B3	Fortified breads and cereals, brewer's yeast, broccoli, carrots, cheese, dandelion greens, eggs, fish, milk, peanuts, potatoes, tomatoes, tuna, beef liver, and chicken breast
Vitamin B6	Whole grain breads and cereals, fish, chicken, and bananas
Vitamin B9	Pinto beans, navy beans, green leafy vegetables, beef, brown rice, bran, cheese, lamb, liver, milk, mushrooms, oranges, pork, and tuna
Vitamin B12	Ham, clams, cooked oysters, king crab, herring, salmon, tuna, lean beef, liver, and low fat dairy products
Vitamin C	Citrus fruits, strawberries, broccoli, melons, peppers, collards, dandelion greens, onions, radishes, and watercress
Vitamin D	Sun exposure, sardines, salmon, fortified milk, fortified cereals, herring, liver, tuna, margarine, and cod liver oil
Vitamin E	Whole grains, wheat germ, nuts, spinach, and sunflower seeds
Vitamin K	Dark-green leafy vegetables and the skins of fruit and vegetables
Calcium	Dairy products and green leafy vegetables
Magnesium	Fish, dairy products, nuts, soybeans, and cocoa
Phosphorus	Milk, cheese, meats, fish, and eggs
Sulfur	Meats, fish, dairy products, eggs, and garlic
Potassium	Legumes, whole grains, and bananas
Sodium	Table salt (sodium chloride, the main source), milk, and spinach
Chlorine	Table salt and unprocessed foods
Iron	Red meat, and leafy vegetables (especially spinach)
Zinc	Wheat germ, pine nuts, sesame seeds, sunflower seeds, and beefsteak
Manganese	Avocados, berries, nuts, egg yolks, whole grains, green leafy vegetables, and legumes
Iodine	Seafood, dairy products, and iodized salt (table salt)
Fluorine	Drinking water, seafood, teas, and toothpaste
Selenium	Nuts, lamb's kidney, mushrooms, and sunflower seeds
Molybdenum	Legumes, dark green leafy vegetables, and grains
Nickel	Chocolate, nuts, fruits, and vegetables
Chromium	Whole grain breads, brown rice, cheese, and lean meats

Biotechnology and Nutritional Improvement of Crops. Table 3 (Continued)

Component	Examples of sources
Vanadium	Seafood, mushrooms, olives, whole grain breads, carrots, and vegetable oils
Cobalt	Vitamin B12, red meat, fish, eggs, cheese, and milk
Silicon	Whole grain breads and cereals, beets, bell peppers, and legumes
Copper	Beans, almonds, broccoli, garlic, soybeans, peas, and seafood

Source: Revised and updated from [4, 5]

compounds are essential nutrients, no specific carbohydrate is essential because the human body can synthesize all the carbohydrates it needs from simple sugars.

In contrast, fats in the diet include both essential and nonessential molecules. The majority of dietary fat is in the form of triacylglycerides (fatty acid esters of glycerol) and the fatty acids can be interconverted or converted into more specialized phospholipids and sphingolipids that have numerous roles in the body, such as cell membrane components and signaling molecules. Other lipids are derived from cholesterol, which is synthesized in the liver. There are several essential fatty acids as well as fat-soluble vitamins that the body cannot synthesize de novo, and these are discussed in detail below.

Proteins are the third major class of macronutrients and these contain nitrogen in addition to carbon, oxygen, and hydrogen. Many proteins also contain sulfur (see below). Fibrous proteins form the structural and mechanical components of tissues (e.g., muscles owe their contractile ability to the proteins actin and myosin, hair and nails are comprised predominantly of keratin, and skin contains large amounts of collagen and elastin). In contrast, most globular proteins are enzymes, the biological catalysts that ensure chemical reactions can take place at the body's ambient temperature. Other proteins fulfill a range of biological functions – signaling molecules and receptors, transmembrane conduits such as ion channels, components of the immune system, effectors of blood clotting, transport and storage of other molecules (e.g., hemoglobin, oxygen, ferritin, and iron), and the control of gene expression. Proteins are linear polypeptides derived from a panel of 20 "standard" amino acids specified by the genetic code (as well as two specialized variants encoded through unique mechanisms), plus a range of posttranslational forms that are generated by chemical modification after protein synthesis. Many of the standard amino acids can be synthesized de novo by humans but some cannot, and these are known as essential amino acids (see below). Proteins are described as "complete" in the sense of nutritional completeness if they provide a source of all the essential amino acids but this designation refers to the sum of all proteins in a meal, not an individual protein molecule.

Essential Amino Acids

Of the 20 standard amino acids, eight (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) (Table 1) are described as essential because the human body cannot synthesize sufficient amounts de novo so they must be obtained from food [5]. A diet that contains adequate amounts of essential amino acids is particularly important during pregnancy, lactation, early development, and following injury. Most plants are deficient in at least one essential amino acid but a balanced diet provides adequate quantities of all. For example, cereal storage proteins are generally deficient in lysine and threonine whereas legumes lack the sulfur-containing amino acids methionine and cysteine. A diet solely comprising one of these protein sources will therefore be deficient for one or more essential amino acids, but it is possible to combine two incomplete protein sources (e.g., rice and beans) to make a complete protein meal, and such characteristic combinations are the basis of distinct cultural cooking traditions. Food from animals, such as meat, eggs, fish, milk, and cheese, provide all the essential amino acids.

Essential Fatty Acids

Fats are more correctly described as triglycerides (three fatty acids attached to one glycerol backbone), and most fatty acids are nonessential in that the body can synthesize them by interconverting other fatty acids. The exceptions are the omega-3 and omega-6 polyunsaturated fatty acids (PUFAs), so named because the first double-bond is found at the third (or sixth) carbon from the terminal CH_3 group. These cannot be synthesized de novo from saturated fats, nor interconverted, and must be obtained from the diet [6]. There are several essential fatty acids in each category, but the body can synthesize any omega-3 fatty acid given a source of one of them (ditto for the omega-6 fatty acids) and therefore only the group is defined as essential. The simplest source of omega-3 is α-linolenic acid and the simplest source of omega-6 is linoleic acid. Good sources of both these molecules include fish, shellfish, seeds, nuts, and leafy vegetables.

Macrominerals

Minerals are inorganic molecules, and those required at levels exceeding 100–200 mg/day (calcium, chlorine, magnesium, phosphorus, potassium, sodium, and sulfur; see Table 2) are known as macrominerals [4]. Their function is generally structural and/or electrolytic/osmotic, although they may also perform additional specialized roles. For example, calcium is an important electrolyte in muscles and in the digestive system, but is also a structural component of bones and teeth, and furthermore acts as a signaling molecule and as a trigger for the transmission of nerve impulses. Sodium, potassium, and chlorine are key electrolytes that maintain osmotic balance in cells. Magnesium is an important buffer and stabilizer for organic phosphates including nucleic acids, and is absolutely required for the activity of adenosine triphosphate (ATP). It is also part of the active site of many enzymes. Phosphorus is the key energy currency in cells (as part of ATP). It is also an important structural component of nucleic acids and some proteins, the basis of a key regulatory mechanism in signal transduction pathways, a component of membrane lipids, and (along with calcium) forms the mineral structure of bones and teeth. Finally, sulfur is found in two essential amino acids (methionine and cysteine) as well as two posttranslational variants with central roles in core metabolism (homocysteine and taurine). The ability of cysteine residues to form disulfide bridges is critical to the structural integrity of many proteins. Sulfur is also found in coenzyme A, which is needed for carbohydrate and fatty acid metabolism, as well as providing the thiol group in many other reactions.

Micronutrients

Micronutrients are required in small quantities (generally less than 100 mg/day) and are divided into organic molecules (vitamins) and inorganic molecules (microminerals). Vitamins are organic substances that (a) are not carbohydrates, amino acids, or fats, and (b) cannot be manufactured by the body in sufficient amounts in all circumstances and must therefore be obtained from the diet. There are 13 human vitamins, although some are represented by a small family of interconvertible molecules rather than a single substance. Most are required because humans lack the metabolic capability to produce them, although vitamin D is an exception because it is produced in the skin during exposure to UVB irradiation albeit not always in sufficient quantities to make dietary sources unnecessary. Vitamins are classified as either water soluble or fat soluble. In humans, there are four fat-soluble vitamins (A, D, E, and K), which are transported throughout the body in fat globules and stored in the liver and other fatty tissues, and nine water-soluble vitamins (eight B vitamins and vitamin C) that are not stored in the body and must be replaced every day.

Minerals that are required at levels below 100–200 mg/day are known as microminerals or trace minerals (Table 2) and these are required in minute amounts usually because they are required for the catalytic activity of a small number of specific enzymes. However, certain microminerals have more significant roles [4]. For example, iron can act as both an electron donor and acceptor, and in this context forms the functional core of the heme complex, which is found in the oxygen-binding molecules hemoglobin and myoglobin, and in the catalytic center of cytochromes (enzymes that carry out redox reactions). Iron is therefore required for oxygen transport in the body and for energy metabolism, also contributing to the catalytic activity of a range of nonheme enzymes such as

ribonuclease reductase. Zinc also has multiple functions – it is an essential component of hundreds of enzymes (e.g., carboxypeptidase, liver alcohol dehydrogenase, and carbonic anhydrase) as well as transcription factors (zinc fingers and related molecules) and signaling proteins. The roles of other microminerals are more specialized and are discussed below.

Facultative Nutrients

The eight essential amino acids are needed by everyone. In addition, cysteine, tyrosine, histidine, and arginine are essential for infants and children because they are required in large amounts for growth and development, and that demand cannot be satisfied without a dietary source [5]. For the same reason, children have greater requirements for the essential fatty acids than adults, although these are not facultative because they are also essential nutrients in adults despite being required in lower quantities. The amino acids arginine, cysteine, glycine, glutamine, histidine, proline, serine, and tyrosine are also considered conditionally essential, meaning they are not normally required in the diet, but must be supplied to specific populations that do not synthesize them in adequate amounts [7].

It is sometimes more convenient to define the essentialness of amino acids on a group basis in the same way as the essential fatty acids, since interconversion is possible within a group but no member of that group can be synthesized de novo. This applies to the sulfur-containing amino acids methionine, homocysteine, and cysteine, and to the aromatic amino acids phenylalanine and tyrosine. Likewise, arginine, ornithine, and citrulline, which are interconvertible within the urea cycle, can be considered as a group for nutritional purposes.

Nutrient Deficiencies

The lack of essential nutrients causes widespread malnutrition, a hidden problem in many communities because its effects are often subclinical or affect physical and cognitive development in a cumulative manner. Micronutrient deficiencies in particular have been referred to as "hidden hunger"; such deficiencies occur on a population-wide basis when the diet lacks diversity or is overly dependent on a single staple food [4], but in individual cases may reflect a genetic abnormality that prevents nutrient absorption or metabolism. Some important nutrient deficiencies and disorders are discussed below.

Macronutrient Deficiencies and Disorders

A lack of carbohydrates in the diet leads to a calorie deficit and results in hunger, then eventually catabolysis and atrophy as the body uses its own tissues as a source of energy to maintain essential functions. These are the early signs of starvation, and can result in permanent organ damage and ultimately death. Besides this general process, there are several specific disorders of carbohydrate metabolism such as galactosemia and glycogen storage diseases, which reflect an inability to break down or synthesize particular carbohydrates. As in the case for carbohydrates, a general deficiency in fats results in a calorie deficit, which if prolonged results in the symptoms of starvation. Deficiencies for essential fatty acids occur rarely, and mostly in infants. The symptoms include scaly dermatitis, alopecia, hair loss, thrombocytopenia, and stunted growth. The symptoms can be reversed by supplying adequate quantities of omega-3 and omega-6 fatty acids in the diet.

The essential amino acids are components of many proteins, so the symptoms associated with deficiency are often quite general. In adulthood, amino acid deficiencies may result in tiredness, inability to concentrate, irritability, bloodshot eyes, and in the longer term stunted growth, hair loss, anemia, connective tissue defects, inefficient wound healing, and reproductive problems. Acute amino acid deficiencies in childhood are more severe and result in a disease called kwashiorkor which involves swelling of the feet and abdomen, anorexia, ulcerating dermatoses, loss of hair, nails, and teeth, an enlarged fatty liver, and irritable behavior. It is possible that the symptoms of kwashiorkor may also be caused in part by concomitant micronutrient deficiencies and in some cases by poisoning. The disease also affects the immune system, often rendering children incapable of producing antibodies against vaccines.

As well as deficiency diseases, there are also several disorders of amino acid metabolism that need special dietary provisions. These include phenylketonuria (PKU), in which the enzyme phenylalanine hydroxylase is missing so phenylalanine cannot be converted into

tyrosine, and maple syrup urine disease (MSUD), in which the body is unable to use the amino acids isoleucine, leucine, and valine.

Vitamin A Deficiency

Vitamin A in its reduced form (retinal) is required for the production of rhodopsin in the eyes, and helps to maintain epithelial and immune cells (making it necessary for a healthy immune system). In its acidic form (retinoic acid), it is a morphogen in development. Although many foods are said to be good sources of vitamin A, it should be noted that these generally do not contain retinal itself but derivatives that can be converted into retinol and then into either retinal or retinoic acid. Meat and dairy sources of vitamin A primarily contain an esterified form called retinyl palmitate, whereas plants produce pro-vitamin A carotenoids such as β-carotene that are cleaved to produce retinol. These are abundant in a wide variety of dark green, yellow, and orange fruits; and vegetables such as oranges, broccoli, spinach, carrots, squash, sweet potatoes, and pumpkins [8].

Vitamin A deficiency (VAD) causes night blindness, i.e., the deterioration of light sensitive cells (rods) essential for vision in low light intensity and it can also damage the cornea resulting in a total form of blindness called xerophthalmia. The lack of vitamin A has a particularly severe effect on the immune system leaving individuals susceptible to infections [4]. More than four million children worldwide exhibit signs of severe VAD, including 250,000–500,000 per year that become partially or totally blind [9]. During pregnancy, women have a higher demand for vitamin A, and VAD in pregnancy causes nearly 600,000 deaths every year [9].

Vitamin B Group Deficiencies

The vitamin B complex comprises eight distinct molecules with different properties and functions. Vitamin B_1 (thiamine) is a coenzyme in carbohydrate metabolism, with the triphosphate derivative particularly active in neurons. Deficiency causes beriberi, a nervous system disorder resulting in weight loss, various degrees of amnesia and psychosis (in its severest form known as Korsakoff's syndrome), impaired perception, limb weakness, arrhythmia, and swelling, possibly leading to heart failure and death.

Vitamin B_2 (riboflavin) is the central component of the important enzyme cofactors flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), whereas vitamin B_3 (niacin) is converted into the cofactors nicotinamide adenine dinucleotide (NAD) and its phosphate derivative NADP. Therefore, both vitamins are required in many enzymes that take part in carbohydrate, fat, and protein metabolism as well as other functions. Riboflavin deficiency causes ariboflavinosis, which is characterized by sensitivity to light, cracked lips, dermatitis, and swelling of the tongue, pharyngeal and oral mucosa, and genitals. Niacin deficiency causes pellagra, which has varied symptoms including diarrhea, dermatitis, insomnia, fatigue, and mental confusion leading in severe cases to dementia. Vitamin B_5 (pantothenic acid) is needed for the synthesis of coenzyme A (CoA), and is therefore critical in the metabolism and synthesis of carbohydrates, proteins, and fats. Deficiency is rare and complete deficiency in humans has not been observed. Vitamin B_6 (pyridoxal, pyridoxine, or pyridoxamine) helps to balance sodium and potassium levels; it is also the precursor of pyridoxal phosphate, a cofactor required for the synthesis of heme and several important neurotransmitters. Deficiency may therefore lead to anemia due to the lack of heme, depression due to its impact on neurotransmitter production, high blood pressure and water retention due to the impact on electrolyte balance, and also elevated levels of homocysteine. Vitamin B_7 (biotin) is a coenzyme in the metabolism of fatty acids and leucine, and it plays a role in gluconeogenesis. Deficiency may lead to stunted growth and neurological disorders in infants. Vitamin B_9 (folic acid) is the source of tetrahydrofolate which is essential in DNA synthesis and many other core metabolic reactions. Deficiency in adults causes macrocytic anemia and elevated levels of homocysteine, but the impact in pregnant women is much more severe, leading to neural tube defects in the fetus. Spina bifida, in which bones of the spine do not completely enclose the spinal cord, is the most common congenital abnormality associated with folate deficiency [10]. Vitamin B_{12} (cobalamin) is involved in the regeneration of folate, which means that deficiency in many cases mimics folic acid deficiency and can be alleviated by folate in the diet. However, it is also the cofactor for two specific (non-folate-dependent) enzymes, methylmalonyl coenzyme A mutase

(MUT), and 5-methyltetrahydrofolate-homocysteine methyltransferase (MTR). Therefore, even in the presence of adequate folate, cobalamin deficiency can result in the failure of these reactions, leading to the accumulation of metabolites that weaken and destabilize myelin, resulting in neurological symptoms associated with demyelination. Finally, choline is a B vitamin that has three primary roles: structural integrity and signaling in cell membranes, cholinergic neurotransmission (acetylcholine synthesis), and the provision of methyl groups via its metabolite, trimethylglycine (betaine), for the synthesis of S-adenosylmethionine. Choline deficiency is rare because, like vitamin D, humans can synthesize some choline although not always adequate amounts.

Vitamin C Deficiency

Vitamin C (ascorbic acid) is a powerful electron donor (antioxidant) and a cofactor in several metabolic pathways, including those forming the mature form of collagen. It plays an important role in the synthesis and stabilization of neurotransmitters, and also reduces iron compounds, enhancing the gastrointestinal absorption of dietary nonheme iron [11]. Insufficient vitamin C in the diet causes scurvy, which involves the breakdown of connective tissue fibers and muscular weakness [11]. High levels of vitamin C are found in citrus fruits and green vegetables [4].

Vitamin D Deficiency

Vitamin D is required for normal calcium and phosphorus homeostasis. It is a ligand that, when bound to its receptor, acts as a transcription factor controlling genes that affect calcium and phosphorus absorption; it is therefore particularly important for bone growth and maintenance. Deficiency results in impaired bone mineralization, which leads to bone-softening diseases such as rickets, a childhood disease characterized by stunted growth and deformity of the long bones, and osteomalacia, an adult bone-thinning disorder characterized by proximal muscle weakness and bone fragility, with chronic musculoskeletal pain.

Vitamin E Deficiency

Vitamin E is a group of compounds with powerful antioxidant activity. It protects fatty acids, low-density lipoproteins (LDLs), and other components of cell membranes from oxidation by free radicals [4]. Although it protects all cells, vitamin E is particularly important in red blood cells and neurons, so severe vitamin E deficiency results in anemia and neurological problems associated with nerve degeneration in the hands and feet. Vegetable oils, nuts, and green leafy vegetables are the major sources of vitamin E, and the consumption of foods rich in vitamin E is thought to reduce the risk of cancer, cardiovascular disease, and cataracts [4].

Vitamin K Deficiency

Vitamin K is a group of fat-soluble vitamins derived from 2-methyl-1,4-naphthoquinone that are needed for γ-carboxylation, a form of protein posttranslational modification. This is particularly important for the formation of the calcium-binding Gla domain, which is present in several blood-clotting proteins and osteocalcin. Vitamin K deficiency therefore affects blood coagulation as well as bone mineralization. Vitamin K1 (phylloquinone) needs to be sourced from the diet whereas vitamin K2 (menaquinone) is produced by bacteria in the large intestine and deficiency is rare except in maladsorption disorders or in patients with reduced gut flora (e.g., after treatment with broad-spectrum antibiotics). There are also several synthetic forms of the vitamin.

Iron Deficiency and Toxicity

Iron is the component of heme that binds oxygen, allowing oxygen to be transported from the lungs to peripheral tissues as part of oxyhemoglobin and carbon dioxide to be transported in the opposite direction. Iron also acts as an intracellular electron transporter to transfer energy (especially to the mitochondria) and it is a part of enzyme systems involved in the synthesis of hormones and neurotransmitters [4]. Iron deficiency is the most widespread nutritional disorder in the world, affecting an estimated 1.2 billion people [12]. In children, low iron intake is associated with cognitive dysfunction whereas in adults it causes iron deficiency anemia (IDA), oxidative DNA damage, reduced immunity, and (in pregnant women) premature births/low birth weight [12]. The true prevalence of iron deficiency in a population is greater than the level of clinically detectable IDA because most

individuals are likely to be iron deficient long before a detectable drop in hemoglobin levels [12]. Iron deficiency is often caused by inadequate intake, but it can also result from the consumption of antinutritional molecules such as phytic acid/phytate which inhibit the uptake of bioavailable iron even if sufficient amounts are present in the diet. Foods rich in phytate include many cereal grains, so people with cereal-rich diets are particularly susceptible to iron-deficiency diseases.

The upper limit for iron consumption is 25–50 mg/day. Symptoms of iron toxicity include fatigue, anorexia, dizziness, nausea, vomiting, headache, weight loss, shortness of breath, and possibly a grayish color to the skin [13]. Chronic excess iron intake results in symptoms such as liver cirrhosis, diabetes, and heart failure, and can promote some cancers. Acute overdose (e.g., iron supplements) is toxic and may induce gastrointestinal side effects as well as causing secondary hemochromatosis [13].

Zinc Deficiency and Toxicity

Zinc is a key functional component of over 300 enzymes and also coordinates the functional domains of numerous transcription factors. Zinc deficiency therefore affects many aspects of metabolism and gene expression, and has notable detrimental effects on the immune system, basal metabolism, and development, particularly spermatogenesis and testosterone steroidogenesis [14]. Severe and prolonged zinc deficiency in humans reduces appetite and bone growth, delays sexual maturation, causes skin lesions, diarrhea, and alopecia (hair loss), and reduces the ability of the cellular immune system to fight infections [14]. Zinc, like iron, is affected by the amount of phytate in the diet, so deficiency is particularly prevalent in populations that subsist on cereal-rich diets.

The upper level of Zn intake in adults is 45 mg/day, although tolerance is lower in women, children, and the elderly. Excessive long-term zinc intake interferes with iron and copper metabolism, so the symptoms of zinc toxicity overlap with those of iron and copper deficiency, e.g., anemia, neurological symptoms, and lower immunity [14]. Excessive levels of zinc also affect the relative levels of LDL and HDL cholesterol and increase the risk of cardiovascular disease [14].

Iodine Deficiency and Toxicity

Iodine is an essential component of the thyroid hormones thyroxine (T4) and triiodothyronine (T3), whose function is to increase the basal metabolic rate (therefore affecting carbohydrate, fat, and protein metabolism), stimulate protein synthesis, regulate long bone growth in concert with growth hormone, stimulate neuronal maturation, and regulate how cells respond to catecholamines [15, 16]. For some of these functions, iodine acts in concert with iron, zinc, and selenium [16]. Iodine deficiency disorder (IDD) generally reflects a lack of iodine in the soil, which places more than 1.5 billion people in the world at risk, particularly children and pregnant or lactating women [4, 15]. The initial effects of IDD are to suppress the synthesis of thyroid hormones, which leads the pituitary gland to produce more thyroid-stimulating hormone and causes the thyroid to enlarge in an attempt to capture more iodine from the blood. This condition, known as goiter, can be reversed by iodine supplementation (see below). The effects of long-term iodine deficiency in pregnancy and childhood cannot be reversed – these include stunted physical and mental development, resulting in a condition known as cretinism [16].

Iodine toxicity is unusual because a daily intake of 1 mg or more appears to be safe. However, where there is prolonged excessive consumption or an underlying disease that prevents iodine metabolism, the excess iodine can inhibit thyroid hormone synthesis, a phenomenon known as the Wolff–Chaikoff effect [4].

Selenium Deficiency and Toxicity

Selenium is a component of the nonstandard amino acids selenocysteine and selenomethionine, which are required for the activity of a number of enzymes (selenoenzymes) such as glutathione peroxidase, tetraiodothyronine 5′ deiodinase, thioredoxin reductase, formate dehydrogenase, and glycine reductase. Its presence in thyroid hormone deiodinase means that selenium is necessary for the normal function of the thyroid gland. Many of the other selenoenzymes act as antioxidants with a range of protective roles in the body, helping to prevent cancer and cardiovascular disease, often in concert with vitamin E [4, 16, 17]. Selenium may also play a role in the regulation of other micronutrients, such as iron and zinc [16].

Selenium deficiency can lead to Keshan disease, a potentially fatal cardiomyopathy associated with increased susceptibility to infectious diseases, and also Kashin–Beck disease (usually if selenium and iodine deficiency occur concurrently) which is characterized by cartilage atrophy and necrosis leading to damaged joints [4, 18]. Selenium deficiency is unusual, but occurs where the mineral is particularly scarce in the soil, as in some parts of China. Interestingly, in other parts of China, the soil is so rich in selenium (>9% selenium content) that eating corn grown on this soil can result in acute selenium toxicity (selenosis). The maximum safe dietary intake of selenium is thought to be 400–800 μg/day, and most people consume only 10% of this amount, but in villages surrounding this selenium-rich area, a typical diet yields 3,200–6,690 μg of selenium per day, which is 100-fold the normal level. In these villages, morbidity can approach 50% with typical symptoms including a garlic-like odor to the breath, gastrointestinal disorders, loss of hair and nails, fatigue, irritability, and progressive neurological damage, leading eventually to liver cirrhosis and death [4, 18].

Other Microminerals

Whereas iron, zinc, iodine, and selenium are the "big four" micronutrients with diverse functions in the body, a variety of additional mineral ions are required for specific purposes. Copper is an essential component of several enzymes including cytochrome c oxidase, cobalt is a component of vitamin B_{12}, manganese is an essential cofactor for enzymes such as the antioxidant superoxide dismutase, molybdenum is a component of several redox enzymes, and nickel is present in urease. Fluorine is a special case in that it is not essential for life, but the addition of fluoride to drinking water helps to prevent dental caries, so it certainly contributes to human health and well-being. Other minerals, such as boron, vanadium, silicon, and arsenic, are thought to have biological roles although this has yet to be demonstrated in humans. Many of these microminerals are known to cause rare deficiency disorders as well as toxicity effects. Chronic copper deficiency, e.g., has multiple effects on metabolism because the corresponding enzymes cannot function, and also leads to anemia because copper is required for efficient iron absorption. Excess copper competes with zinc so the symptoms overlap with zinc deficiency, but acute copper toxicity is rare other than in individuals with metabolic disorders due to the efficiency of copper secretion.

Responses to Malnutrition

The most effective intervention to alleviate micronutrient malnutrition is the implementation of a varied diet including fresh fruit, vegetables, fish, and meat. This is impractical in many countries because food is not widely available, but even where fresh food is abundant, there can be compliance issues that result in persistent low-level malnutrition. Where infrastructure allows, micronutrient nutrition can be improved using supplements (usually in tablet/sachet form) or conventional fortification (where micronutrients are added to processed foods, such as packaged cereals). Unfortunately, such strategies have been largely unsuccessful in developing countries because of insufficient funding, poor governance, and a poor distribution network. There has been some success in a limited number of cases discussed later, including mineral fortification (iodized salt) and vitamin supplementation (vitamin A), although coverage has been incomplete. Developing country governments must address the risk of micronutrient malnutrition and should actively participate in the establishment of intervention programs, seeking international expertise and assistance where necessary. A more recent development is biofortification, where intervention takes place before plants are harvested. Different strategies to alleviate micronutrient malnutrition have been ranked according to their cost-effectiveness by the Copenhagen Consensus, a panel of expert economists that decide the most cost-effective strategies for addressing global challenges (Table 4). In this section, the different interventions for improving micronutrient nutrition are summarized, mainly in the context of developing countries where malnutrition has the greatest impact.

Emergency Measures (Short-Term Relief): Supplementation Programs

Supplementation is the distribution of pills or mineral solutions for immediate consumption and is the most effective short-term intervention to improve nutritional health. Supplementation helps to alleviate acute

Biotechnology and Nutritional Improvement of Crops.

Table 4 Copenhagen Consensus Center strategies [23]. The Copenhagen Consensus Center is a think-tank based in Denmark that advises governments and philanthropists about the best ways aid and development money can be used to address the world's greatest challenges. Currently, strategies to address malnutrition represent five of the top ten strategies providing the best value

Rank	Solution	World's greatest challenges
1	Micronutrient supplements for children (vitamin A and zinc)	Malnutrition
2	The Doha development agenda	Trade
3	Micronutrient fortification (iron and salt iodization)	Malnutrition
4	Expanded immunization coverage for children	Diseases
5	Biofortification	Malnutrition
6	Deworming and other nutrition programs at school	Malnutrition and Education
7	Lowering the price of schooling	Education
8	Increase and improve girls' schooling	Gender equality
9	Community-based nutrition promotion	Malnutrition
10	Provide support for women's reproductive role	Gender equality

mineral shortages but is unsustainable for large populations and should be replaced with fortification at the earliest opportunity [19]. In developed countries, where mineral malnutrition is rare, supplementation is focused on a small subset of the population with specific deficiencies resulting from medical conditions. In developing countries, where acute and chronic deficiencies are commonplace, supplementation is highly recommended as a complement to the diet (fortified or otherwise) for the entire population. Supplementation has also been recommended by WHO, the World Food Program (WFP), and UNICEF [20] for extreme situations such as refugee camps, where it can also help to address diseases such as acute diarrhea.

The distribution of vitamin A supplements has been one of the most cost-effective and successful acute intervention programs in the developing world [19], but this is a rarity. Like fortification, successful supplementation strategies require a robust infrastructure and a government determined to improve the nutritional health of its population [19]. Supplementation requires compliance monitoring because people often neglect to take regular supplements at prescribed intervals. For example, in some communities with both chronic iodine deficiencies and no access to iodized salt, the distribution of iodine capsules to women is a short-term but more expensive measure to avoid IDD [21]. Many studies have shown that zinc supplements are beneficial, particularly in areas with zinc-depleted soil [4, 22]. Zinc supplementation has been adopted by WHO and UNICEF in their guidelines for the treatment of acute diarrhea [20]. Zinc supplements are normally formulated as tablets or as oral rehydrated solutions, requiring the active compliance of families and communities. The supplements must be administered frequently, and may be more efficient when other micronutrients such as vitamin A are administered simultaneously [14, 19].

Long-Term Measures (Sustainable Relief): Fortification Programs

Food fortification is one of the most cost-effective long-term strategies for micronutrient nutrition [23] and ranks third in terms of cost-benefit balance according to the Copenhagen Consensus (Table 4). Fortification takes place during food processing and increases the product price. These factors make fortified products unaffordable to the most impoverished people living in remote rural areas. Even in more accessible areas, fortification requires government awareness and policies for implementation and compliance monitoring. The Flour Fortification Initiative (FFI) claims that food fortification must be implemented at a national level to be successful, and must involve the public, private business and government sectors. The FFI supports mandatory fortification based on scale, equity, business, cost, and sustainability. The creation of partnerships among countries with established fortification policies would help other countries to establish their own infrastructure.

Although the implementation of mandatory fortification would take time, there are enormous benefits for the country and its population [24].

Before considering case studies, it is important to note that food fortification targets must be selected carefully. Research must be carried out to identify the best vehicles to deliver micronutrients, i.e., those with the widest and most frequent consumption reflecting the staple diet of individual countries and/or regions. Also, a suitable fortification agent must be identified – one that is stable but easily mobilized in the gut, one that does not alter the quality of the food to which it is added, and one that can be stored and distributed easily. Since many parts of the world suffer from multiple deficiencies, strategies must also be developed to fortify foods simultaneously with several micronutrients, without adverse interactions among them. The addition of a single micronutrient would have approximately the same cost implications as the addition of several, but more research is needed to determine the most cost-effective way to make nutritionally complete foods [23, 24].

Iodization of Salt Iodine fortification of salt is one of the nutrition success stories of the twentieth century, helping to eliminate IDD in many parts of the world. Even though alternative food vehicles have been proposed, salt is thus far the most economical and sustainable fortification target. In 1990, 20% of households in the developing world consumed iodized salt. In 1994, WHO and UNICEF recommended mandatory salt iodization in all countries to ensure consumption and prevent access to unfortified salt. By the year 2000, iodized salt had reached 70% of households in the developing world. Although some countries still lack access to iodized salt, the reach is improving all the time, with many countries becoming self-sufficient and no longer needing donations to support their fortification programs [25]. Countries with no nutrition policies or monitoring are the main challenges for intervention strategists, because fortification requires external funding and IDD reappears if salt iodization is discontinued.

Organizations such as WHO, UNICEF, and The International Council for the Control of Iodine Deficiency Disorders (ICCIDD) have created and distributed guidelines for the implementation of iodine fortification. They work together to eliminate iodine deficiency through the Universal Salt Iodization (USI) in partnership with the Micronutrient Initiative (MI), the World Bank, Kiwanis International, and with public and private sector involvement including consumer organizations, schools, and medical authorities around the world.

Iron and Folate Fortification of Wheat Flour Another successful fortification approach is the inclusion of minerals in wheat flour, so that widely consumed products such as bread become nutritionally beneficial as well as providing calories. Indeed, bread is often double fortified with iron and folate, most recently in Iran [26]. The mandatory fortification of wheat flour has been established in several developing countries in Latin America, leading to a reduction in IDA [19]. The FFI has created a network that involves the participation of public, private, and government sectors, resulting in an increase in the global prevalence of iron-fortified wheat flour from 18% in 2004 to 27% in 2007, helping 540 million people to avoid IDA [26]. The MI also supports this strategy and works with FFI in developing countries.

Iron fortification can be technically challenging because iron compounds that are easily absorbed by the gut tend to leach easily and also change the taste of food, whereas those with less impact on taste are the most difficult to absorb [27, 28]. Encapsulation has been investigated as a potential solution and this is an active area of current research [29].

Other Examples Zinc fortification has been implemented in the industrialized world but rarely in developing countries. One exception is zinc-fortified wheat and corn flour in Mexico, which is used to make bread and tortillas, the two principal staples [30]. Organizations such as the Zinc Task Force (ZTF) and the International Zinc Nutrition Consultative Group (IZINCG) are fighting zinc deficiency by promoting diverse strategies to eliminate it. As zinc and iron deficiency tend to go hand in hand, it has been suggested that double fortification would be effective with little additional cost, particularly if iron fortification were already in place.

Selenium-fortified products such as salt, margarine, cereals, and soft drinks have been produced although not widely distributed [18]. Salt fortified with selenium has been used in parts of China where the soil is naturally depleted but it has not been supported to the same degree as iodized salt [17]. The multi-micronutrient fortification of biscuits with iron, zinc, iodine, and vitamin A has been implemented with Vietnamese schoolchildren, reducing the risk of IDA, IDD, and VDA, and increasing the effectiveness of deworming [31].

Long-Term Measures (Sustainable Relief): Biofortification

Conventional interventions have a limited impact, so biofortification has been proposed as an alternative long-term approach for improving nutrition [23, 32]. Biofortification focuses on enhancing the micronutrient qualities of crops *at source*, encompassing processes that increase both micronutrient levels and their bioavailability in the edible parts of staple crops. The former can be achieved by agronomic intervention (in the case of minerals), plant breeding or genetic engineering, whereas only plant breeding and genetic engineering can influence nutrient bioavailability.

Plant breeding and genetic engineering are often regarded as similar means to achieve a common goal because, in contrast to agronomic interventions, both involve changing the genotype of a target crop. The two processes are similar in aim, albeit different in scope. Both attempt to create plant lines carrying genes that encourage the efficient accumulation of bioavailable micronutrients – plant breeding achieves this by crossing the best-performing plants and selecting those with favorable traits over many generations, whereas genetic engineering accesses genes from any source and introduces them directly into the crop. Plant breeding is restricted to genes that can be sourced from sexually compatible plants and the limited amount of genetic variability therein, whereas genetic engineering has no taxonomic constraints and even synthetic genes can be used.

The main advantage of genetic engineering and plant breeding approaches for mineral enhancement is that investment is only required at the research and development stage, and thereafter the nutritionally enhanced crops are entirely sustainable. Furthermore, as stated above, mineral-rich plants tend to be more vigorous and more tolerant of biotic stress, so the overall yields are likely to improve in line with mineral content [27]. Unlike conventional intervention strategies, genetic engineering and plant breeding are both economically and environmentally sustainable. A combination of both strategies has also been proposed [33] and can produce significant synergic improvements compared to each strategy applied individually [34]. Although there are no commercial nutritionally enhanced plants derived from either method at the current time, this approach has the greatest cost-effectiveness in the long term and is likely to have the most important impact over the next few decades.

Biofortification is also likely to be more accessible than conventional interventions in the long term because it removes hurdles such as the reliance on infrastructure and compliance. Moreover, plants assimilate minerals into organic forms that are naturally bioavailable and contribute to the natural taste and texture of the food. Economic studies have shown the many potential health benefits of biofortification, especially in combination with conventional strategies [35].

Nutritional Improvement Through Agronomic Approaches Farmers have applied mineral fertilizers to soil for hundreds of years in order to improve the health of their plants, but within certain limits the same strategy can also be used to increase mineral accumulation within cereal grains for nutritional purposes. This strategy only works if the mineral deficiency in the grain reflects the absence of that mineral in the soil, and if the mineral fertilizer contains minerals that can be mobilized rapidly and easily. Also, even if plants can absorb minerals efficiently from the soil, they may store the mineral in inedible organs (e.g., leaves but not fruits or seeds), or they may accumulate the mineral in a form that is not bioavailable, thus having no impact on nutrition [27].

In industrialized countries such as Finland and New Zealand, this strategy has been applied successfully to increase the amount of selenium in the diet [18]. It is difficult to apply to iron, because most of the inorganic iron in the soil is inaccessible to plants. Like supplements and fortification, agronomic intervention is probably best applied in niche situations or in combination with other strategies [36].

One drawback of agronomic intervention in developing countries is the cost and impact of fertilizers. Fertilizer use increases the cost of food, thus reducing its availability to the most impoverished people. To be effective, fertilizers must be applied regularly, but impoverished farmers would be under financial pressure to "cut corners" to save costs, even though seeds produced from mineral-rich soil tend to germinate more vigorously than those in poor soils, thus increasing yields [36].

Iodine fertilizers have received comparatively little attention due to the success of fortification programs, but they have been used in regions of China where the soil has low iodine levels. The addition of iodine to irrigation water (fertigation) in China has successfully increased the level of iodine in rice, but despite the technical success such projects have not addressed IDD due to poor infrastructure [16]. Iron has a very low mobility in soil because it binds rapidly to soil particles when applied as fertilizer in the form of $FeSO_4$. It is converted rapidly from Fe^{2+} to Fe^{3+} under these circumstances, rendering it unavailable for absorption [27]. In poor soils lacking the macronutrients nitrogen, phosphorus, and potassium, the application of NPK fertilizers can promote the capture of iron, although this also depends on the soil pH. Alkaline conditions in the rhizosphere prevent the uptake of iron and zinc, whereas slightly acidic soil promotes the absorption of these minerals [27]. Foliar sprays of $FeSO_4$ or chelates allow the direct uptake of iron.

Unlike iron, zinc is very mobile in soil and is easily absorbed, especially under slightly acidic conditions. Zinc fertilizers such as $ZnSO_4$ can increase the yield of cereals and legumes in zinc-deficient soils, and can also increase zinc levels in the grain (although this is dependent on genotype). Zinc fertilization has been used in Turkey, where NPK fertilizers are enriched with zinc and applied normally for crop production. Soils in Turkey are extremely deficient in zinc and this program has successfully increased plant growth and yield. Although it is likely that the population has benefited from the nutritional properties of crops grown with zinc fertilizers, no population studies have yet been carried out to determine the impact on human health [36].

Finally, selenium provides probably the most successful example of agronomic intervention by mineral fertilization because it fulfills the three major requirements for such a strategy to work: (1) sodium selenate is highly mobile in many soil types; (2) it is absorbed easily by plants and, in the case of cereals, accumulates in the grain; and (3) it accumulates in a readily bioavailable form, selenomethionine [17]. As is the case for zinc, selenium added to NPK fertilizers has been used successfully in Finland and New Zealand to increase the selenium content of grains, with a positive impact on the general health and well-being in the population [18].

Nutritional Improvement Through Conventional Breeding Plant breeding programs focus on improving the level and bioavailability of nutrients in staple crops using their natural genetic variation [37]. The HarvestPlus program was established by the Consultative Group on International Agricultural Research (CGIAR) to improve human nutrition by breeding new varieties of the staple food crops consumed by the poor. It is a global alliance of institutions such as the International Rice Research Institute (IRRI), the Centro Internacional de Mejoramiento de Maíz y Trigo (CIMMYT), the Centro Internacional de Agricultura Tropical (CIAT) and the International Institute of Tropical Agriculture (IITA) and other academic institutions world-wide. Its aims include the discovery of genetic variation affecting heritable mineral traits, verification of its stability under different conditions and the feasibility of breeding to increase mineral content in edible tissues without affecting yields or other quality traits. Feasibility data, mainly for iron and zinc, has been collected and a summary has been published [38].

Although breeding for increased mineral levels is more sustainable than conventional interventions, no high-mineral varieties have been introduced to the market thus far. This reflects the long development times, particularly if the mineral trait needs to be introgressed from a wild relative. Breeders utilize molecular biology techniques such as quantitative trait locus (QTL) maps and marker-assisted selection (MAS) to accelerate the identification of high-mineral varieties, but they have to take into account differences in soil properties (e.g., pH, organic composition) that may interfere with mineral uptake and accumulation. For example, the mineral pool available to plant roots

may be extremely low in dry, alkaline soils with a low content of organic matter [36].

Conventional breeding could also be useful for the enhancement of organic nutrients, although there has been no coordinated international effort to achieve progress in this area. Even so, crosses between inbred lines have been used to identify QTLs affecting carotenoid and tocopherol levels in corn [39], as well as carotenoid levels in carrot and tomato [40], and these could be used in the future for nutritional improvement programs. Recently, natural genetic variation at several loci in corn has been exploited to generate lines with increased levels of specific carotenoids [41, 42].

Although some variation in iodine content has been found in staple crops [43], the focus remains on manual intervention strategies because salt iodization has been so successful. However, the HarvestPlus initiative has proposed the inclusion of iodine in its program because of widespread iodine deficiency in some countries and the interaction between iodine and other micronutrients (mainly iron, zinc, and vitamin A [16]). Iron and zinc levels vary significantly in many crops, and CGIAR is looking into the possibility of breeding high-mineral varieties of cereals using this genetic diversity. The amount of iron in rice grains varies between 6 and 22 mg kg^{-1}, whereas in corn it varies between 10 and 160 mg kg^{-1}, and in wheat the range is 15–360 mg kg^{-1} [44]. Zinc levels are similarly broad – between 14 and 61 mg kg^{-1} in rice, 14 and 190 mg kg^{-1} in wheat, and between 12 and 96 mg kg^{-1} in corn [43, 44]. Despite this natural variation, commercial varieties of wheat still have low mineral levels compared to wild wheat, where the grain may contain up to tenfold the normal amount of zinc. Furthermore, wild emmer wheat accessions have been identified in which the seeds contain up to 139 mg kg^{-1} zinc, up to 88 mg kg^{-1} iron, and up to 380 g kg^{-1} protein, as well as showing strong tolerance of drought stress and low zinc levels in the soil [44]. There also appears to be moderate genetic variation in the selenium content of modern cereals although wild wheat varieties, with higher selenium levels, are potential sources of additional diversity [43, 44].

Nutritional Improvement Using Biotechnology

The major advantages of genetic engineering over conventional breeding are the diversity of the potential sources of genetic information, the speed with which improved elite varieties can be generated and, perhaps most important, the fact that nutritional traits for different vitamins and minerals can be stacked in the same plant without highly complex breeding programs [32]. Genetic engineering currently offers the only opportunity to produce nutritionally complete staple foods.

Despite these advantages, there are no high-micronutrient, genetically engineered crops on the market thus far. Whereas with conventional breeding this reflects the long development phase, in the case of genetic engineering this reflects the current uncertain regulatory environment, particularly trade barriers and differences in national regulatory systems that inhibit the production, transport, and use of transgenic products. Trade barriers for transgenic crops have been established de facto in the EU because of the precautionary approach to regulatory oversight, so developing countries (such as China and India) are pressured not to grow such products for export even though they may still benefit the domestic population by improving health and wealth [2, 3].

Biotechnology Strategies to Increase Nutritional Content

Many biotechnology strategies can be used to enhance the nutritional value of crops and these offer a rapid way to introduce such traits into elite varieties. The best approach for a given nutrient depends predominantly on whether the plant synthesizes the nutritional compound de novo or obtains it from the environment. Organic molecules such as amino acids, fatty acids, and vitamins are synthesized by the plant, and increasing the nutritional content therefore requires some form of metabolic engineering with the aim of increasing the amount of the desirable compound, decreasing the amount of a competitive compound (e.g., one that uses the same precursors but diverts them into a different pathway) or even extending an existing metabolic pathway to generate a product that is not usually made in that species [32]. In contrast, mineral nutrients are obtained from the environment and mineral enhancement therefore involves strategies to increase uptake, transport and/or to increase accumulation in harvestable tissues [23].

Increasing the Availability of Essential Amino Acids

Among the eight essential amino acids discussed above, methionine, lysine, and tryptophan are the most limiting in legumes and cereals, and since these are the major types of staple crops they are also the primary targets for nutritional enhancement. Generally, four strategies have been applied to increase the content of essential amino acids in plants: (1) mimicking natural mutants, (2) the expression of recombinant storage proteins with desirable amino acid profiles, (3) genetic engineering to enhance the free amino acid pool, and (4) combination approaches.

Mimicking Natural Mutants The naturally occurring *opaque2* mutant in corn has higher lysine and tryptophan levels than wild-type corn but has a soft, chalky kernel which is unsatisfactory for cooking. The higher content of essential amino acids in the mutant results from lower levels of certain storage proteins (e.g. α- and β-zeins) allowing other proteins (e.g. 27-kDa γ-zein) to replace them and increase the prevalence of the two limiting amino acids. Breeding programs have resulted in the development of quality protein maize (QPM) which benefits from the higher lysine and tryptophan levels of the *opaque2* mutant but combines this with a hard kernel for superior cooking qualities [45]. Although QPM has lower levels of α- and β-zeins compared to wild-type corn, it has higher levels of γ-zein. Zarkadas et al. [46] showed that QPM may provide up to 73% of human protein requirements, compared to 28–50% for common corn. Success with *opaque2* corn has stimulated extensive research to identify similar mutants in other cereals such as barley (*Hordeum vulgare*) and sorghum (*Sorghum bicolor*).

The *opaque2* corn mutants have inferior agronomic traits that cannot be overcome easily, but the laborious breeding program that gave rise to QPM can be replicated much more rapidly by genetic engineering. The transformation of corn with an RNAi construct to suppress target storage protein genes resulted in a phenocopy of the *opaque2* phenotype; transgenic seeds contained less α-zein than normal but higher levels of lysine [47, 48].

Expression of Recombinant Storage Proteins The main source of essential amino acids in sink tissues such as developing seeds is the storage proteins; therefore, one reason for the lack of certain amino acids in some staple crops is the absence of major storage proteins containing them. Thus, one of the main strategies for improving the levels of limiting amino acids is to express heterologous storage proteins that are rich in these specific amino acids.

One of the earliest attempts using this approach was the expression of pea legumin, which is rich in lysine, in rice endosperm, where lysine is limiting; in the best lines, heterologous legumin represented up to 4.2% of the total protein content [49]. Similarly, Stöger et al. [50] generated transgenic wheat plants expressing pea legumin using the low molecular weight (LMW) glutenin promoter, with legumin representing 1.5% of total soluble protein in the best transgenic lines. More significant increases in lysine content have been achieved by modifying cereal storage protein genes before deployment to increase the number of lysine codons. For example, Jung and Carl [51] modified the barley hordothionine protein to include 12 lysine residues (hordothione-12, HT12) and the barley high lysine protein to include eight lysine residues (barley high lysine-8, BHL8) and expressed them in corn along with the bacterial enzyme dihydrodipicolinate synthase (DHPS, see below). This resulted in a total lysine content of nearly 0.8%, about four times the level in wild-type seeds. The expression of HT12 in sorghum increased the lysine content by 50% compared to wild-type grain, and the expression of *sb401*, encoding another high-lysine storage protein, increased lysine levels in corn by 54.8% and total protein content by up to 39% [52].

Lysine levels can also be increased by expressing the animal equivalent of storage proteins, such as the nutritional proteins found in milk. The principle was established when porcine α-lactalbumin was expressed in corn and either targeted for secretion to the apoplast or for retention in the endoplasmic reticulum (ER), but individual amino acid levels were not reported [53]. More recently, Bicar et al. [54] repeated the experiment and showed that α-lactalbumin expression in corn increased the lysine content up to 47%. The lysine content of transgenic corn has also been increased up to 26% by expressing a heterotypical Arabidopsis lysyl tRNA synthetase, which inserts lysine residues in place of other amino acids during the synthesis of seed-storage proteins [55].

The expression of heterologous storage proteins has also been used as a strategy to increase the levels of methionine in transgenic crops, focusing on the 2S storage proteins which are unusually methionine rich. For example, expression of Brazil nut 2S albumin in soybean and narbon bean doubled the methionine content of the seeds, and increased methionine content by 33% in canola [56]. Similarly, the expression of sunflower 2S albumin increased total methionine content by up to sevenfold in potato tubers [57]. This approach does not always work well, e.g., the expression of the sunflower albumin SFA8 in rice and chickpea [58] merely redistributed the sulfur-containing amino acids (more methionine, less cysteine) with no net improvement in nutritional properties. The 2S sulfur-rich albumins are allergenic in some human populations, reducing their usefulness for improving nutritional quality [59].

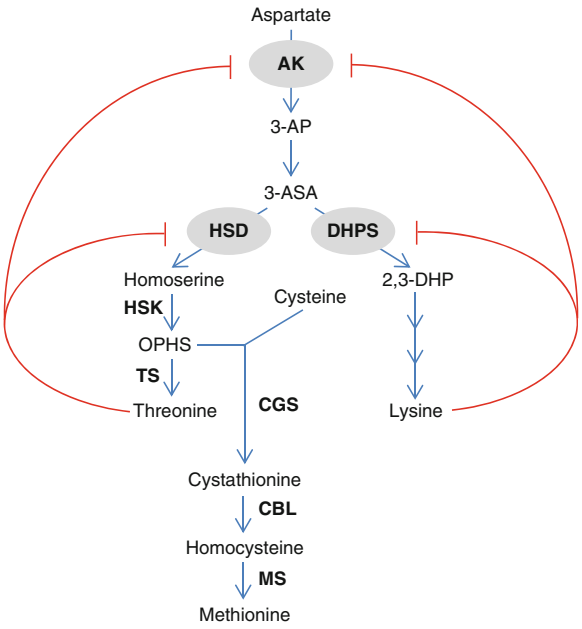
Ideally, a single protein would provide nutritional completeness in terms of essential amino acids. Grain from the pseudo-cereal amaranth (*Amaranthus hypochondriacus*) not only has a high protein content compared to traditional crops (17–19% of seed dry weight (DW) compared to ~10%), but that protein is rich in essential amino acids such as lysine (5%, more than twice the amount in wheat flour), threonine (2.9%), tyrosine (3.4%), and the sulfur-containing amino acids cysteine and methionine (4.4%). This provides a nutritional composition fairly close to the ideal as recommended by WHO, and the protein is not allergenic [5]. The cDNA for this protein has therefore been expressed in a number of crops with nutritionally incomplete proteins to increase overall protein levels and provide greater amounts of limiting amino acids. Rascón-Cruz et al. [60] expressed amaranthin in corn using the rice glutelin-1 promoter and increased the amount of protein by up to 32% while simultaneously boosting the levels of the three most limiting amino acids, lysine, tryptophan, and isoleucine. Chakraborty et al. [57] expressed the protein in potato tubers using the granule-bound starch synthase (GBSS) promoter, and increased total protein levels by up to 45%. Most recently, the protein was expressed in wheat using the LMW glutenin promoter with the amaranthin protein representing nearly 2.5% of total seed protein in some lines, increasing the levels of lysine to 6.4%, and tyrosine to 3.8% [61].

As well as natural heterologous storage proteins, completely synthetic proteins (i.e., proteins designed from first principles) can also be expressed to boost the levels of particular amino acids. For example, a synthetic protein matched to human amino acid requirements was expressed in cassava [62]. Even in these ideal cases, however, the levels of essential amino acids in the resulting transgenic crops tend to fall below expectations given the composition of the heterologous proteins. The inability of heterologous proteins to change the essential amino acid content of target crops abruptly and predictably often reflects the limited free amino acid pool, which provides the substrates for protein synthesis.

Engineering the Free Amino Acid Pool

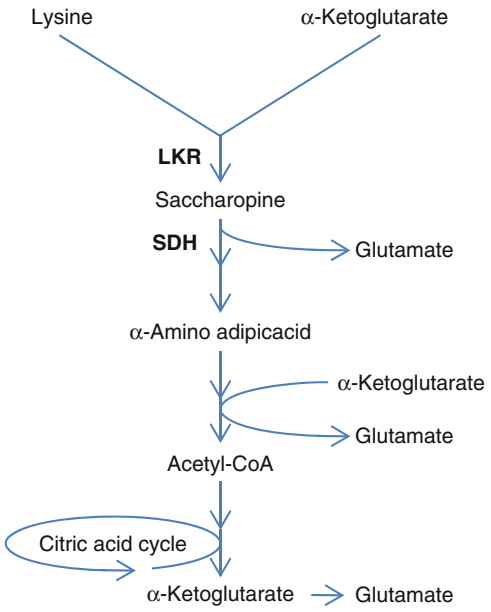
In higher plants, lysine, threonine, and methionine are synthesized from aspartic acid via a pathway that is highly branched and under complex feedback control (Fig. 1) [63]. Two key enzymes are aspartate kinase (AK), which functions early in the pathway and is inhibited by both lysine and threonine, and dihydrodipicolinate synthase (DHPS), which is the first enzyme specifically committed to lysine biosynthesis and is inhibited by lysine alone. Feedback-insensitive versions of the bacterial enzymes have been expressed in model plants with encouraging results, e.g., the free lysine content in tobacco and Arabidopsis seeds was increased by expressing feedback-insensitive DHPS [63]. Similarly, the expression of feedback-insensitive DHPS in corn embryos increased the levels of free lysine from <2% to almost 30% of the free amino acid pool, with concomitant increases in threonine [64]. Analogous approaches have increased the lysine levels in canola and soybean [65, 66]. However, high levels of lysine in all plant tissues can cause abnormal vegetative growth and flower development that reduce seed yield [63].

The increased accumulation of lysine in tobacco seeds correlated with the enhanced activity of a bifunctional enzyme, lysine-ketoglutarate reductase/saccharopine dehydrogenase (LKR/SDH), which controls the first two reactions of the α-amino adipic acid pathway of lysine catabolism (Fig. 2) [67, 68]. To determine the impact of lysine catabolism on the levels of free lysine in the amino acid pool, a feedback-insensitive DHPS was expressed in wild-type



Biotechnology and Nutritional Improvement of Crops. Figure 1

Synthesis of the essential amino acids lysine, threonine, and methionine [63]. The three key enzymes (*gray circles*) are aspartokinase (AK), dihydrodipicolinate synthase (DHPS), and homoserine dehydrogenase (HSD), all of which are subject to end-product feedback inhibition (*red arrows*). Abbreviations for substrates: 3-AP, aspartyl-3-phosphate; 3-ASA, aspartate semialdehyde; OPHS, *O*-phosphohomoserine; 2,3-DHP, 2,3- dihydrodipicolinate. Abbreviations for other enzymes: HSK, homoserine kinase; TS, threonine synthase; CGS, cystathionine-γ-synthase; CBL, cystathionine β-lyase; MS, methionine synthase. Multiple arrows indicate several unspecified reactions



Biotechnology and Nutritional Improvement of Crops. Figure 2

Lysine catabolism in plants, showing the production of three glutamate molecules for every molecule of lysine [63]. Enzyme abbreviations: LKR, lysine-ketoglutarate reductase; SDH, saccharopine dehydrogenase. Multiple arrows indicate several unspecified reactions

Arabidopsis seeds and those of a LKR/SDH knockout mutant [69]. Whereas transgenic seeds without the mutation contained 12 times the normal levels of lysine, transgenic mutant seeds contained 80 times normal lysine levels, showing the importance of lysine catabolism in strategies to increase the accumulation of this amino acid. Similarly, it has been possible to cross transgenic corn lines where one parent expresses a feedback-insensitive enzyme for lysine synthesis that doubles the amount of free lysine [70] and the other expresses an RNAi construct against LKR/SDH thus inhibiting lysine catabolism [71]. In the double transgenic progeny, the amount of lysine was 40 times the level present in wild-type corn [64].

The major enzyme-controlling methionine synthesis is cystathionine γ-synthase (CGS), and its activity in Arabidopsis is under feedback control reflecting the abundance of the important metabolic intermediate S-adenosylmethionine (SAM) [72]. Mutations in the N-terminal portion of CGS that affect this feedback regulation result in methionine overproduction [72, 73], and this can be combined with the expression of a feedback-insensitive AK to increase methionine levels even further [74].

The expression of feedback-insensitive AK also increases the abundance of threonine. In some cases, the increases in threonine levels were matched by smaller, although still significant, increases in the levels of isoleucine, methionine, and lysine, indicating that AK activity is more important for threonine synthesis than it is for lysine synthesis [63].

Tryptophan synthesis in plants is strongly regulated by high levels of tryptophan inhibiting the enzyme anthranilate synthase, which catalyzes the conversion of chorismate to anthranilate. As is the case for other amino acids, a preferred strategy to overcome this limitation is the expression of a feedback-insensitive version of this key enzyme, as has been achieved in tobacco leaves and the roots of the forage legume *Astragalus sinicus* [75]. A mutant anthranilate synthase from rice has been shown to increase the amount of free tryptophan in transgenic rice seeds by over 400-fold [76], in potato tubers by approximately 30-fold [77], and in soybean seeds by approximately 20-fold [78]. A similar mutant gene from tobacco increased free tryptophan levels by sixfold in transgenic soybean leaves and twofold in seeds [79].

Tabe et al. [80] have recently shown that cysteine levels can be increased by up to 26-fold in developing lupin seeds by expressing a feedback-insensitive serine acetyltransferase (SAT). The levels of glutathione were also higher in developing seeds, but methionine levels were unaffected. Interestingly, the overall levels of cysteine and methionine in mature seeds did not change, suggesting feedback to counter the accumulation of cysteine later in development. The above strategy was also combined with the overexpression of a seed storage protein by crossing transgenic lines expressing the SAT enzyme with those expressing a sunflower albumin gene. Again, this resulted in higher levels of cysteine during development but no change in the amount of methionine; there was no significant change in either amino acid in mature seeds [80].

Increasing the Availability of Essential Fatty Acids

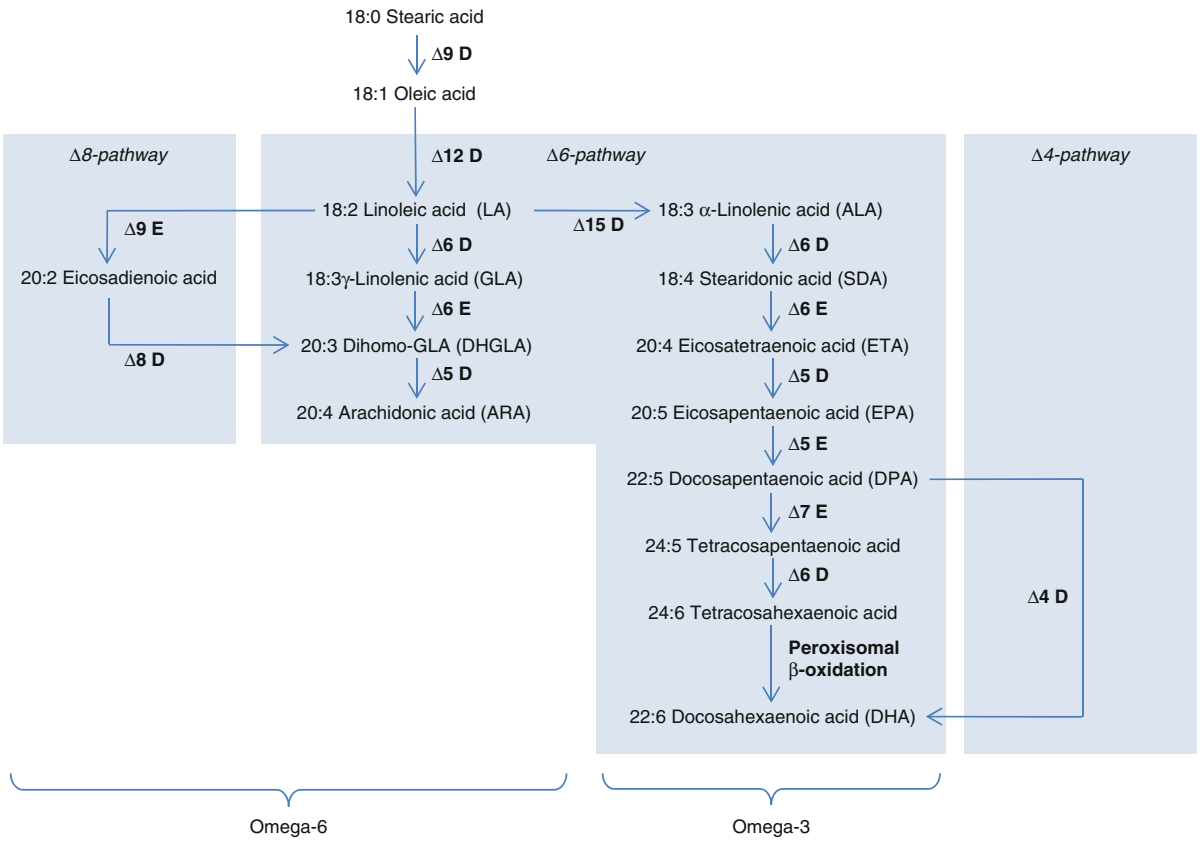
Polyunsaturated fatty acids (PUFAs) are synthesized from saturated fats through an alternating sequence of desaturation and elongation reactions, each requiring a different class of enzymes (Fig. 3). Humans are unable to synthesize PUFAs because they lack the necessary Δ12 and Δ16 desaturases to convert oleic acid into α-linolenic acid (omega-3) and linoleic acid (omega-6). However, they do possess Δ6 and Δ5 desaturases, so if adequate amounts of α-linolenic acid and linoleic acid can be sourced in the diet they can be converted into longer-chain molecules in the liver, yielding the very-long-chain (VLC) PUFAs eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and arachidonic acid (ARA) [81]. Even so, this is a slow process because the Δ6 and Δ5 desaturases are inefficient, and these molecules can become limiting. Strategies to increase the availability of essential fatty acids in plants therefore not only concentrate on the accumulation of α-linolenic acid and linoleic acid but also on the VLC-PUFAs EPA, DHA, and ARA.

As shown in Fig. 3, the synthesis of EPA and ARA requires three enzyme activities: Δ6-desaturase, Δ6-elongase, and Δ5-desaturase; DHA synthesis requires an additional β-oxidation step which occurs in peroxisomes [82]. The elongation steps require an acyl-CoA substrate, whereas the desaturations require the presence of phosphatidylcholine. The switching of fatty acids between the phosphatidylcholine and CoA pools is facilitated by acyltransferases and these are often the limiting step in VLC-PUFA synthesis [83] (Fig. 4). However, this bottleneck can be alleviated using the alternative Δ8-pathway, in which the elongation and saturation steps are realized by a Δ9-elongase, Δ8-desaturase, and Δ5-desaturase [84] (Fig. 3). This pathway is more efficient for ARA and EPA synthesis because there is less reliance on acyl exchange [82].

Four main strategies have been used to enhance VLC-PUFA biosynthesis in plants: expressing enzymes that increase the availability of precursors for α-linolenic acid and linoleic acid synthesis, enhancing the typical Δ6-pathway, introducing the alternative Δ8-pathway and importing the microbial Δ4-pathway (Fig. 3). Thus far, enhancing the Δ6-pathway has been most successful (Table 5), increasing the levels of ARA, EPA, and DHA by up to 25%, 15%, and 0.5%, respectively [85, 86]. However, Kinney et al. [87] showed that the levels of EPA and DHA could be increased by 19.5% and 3%, respectively, in soybean by enhancing the Δ4- and Δ6-pathways simultaneously, and Qi et al. [88] increased EPA levels to 3% and ARA levels by 6.6% in *Arabidopsis* by importing the Δ8-pathway and removing the acyl exchange bottleneck.

Increasing Vitamin Levels

Vitamin A In plants, carotenoids such as β-carotene (pro-vitamin A) are synthesized in the plastids via the

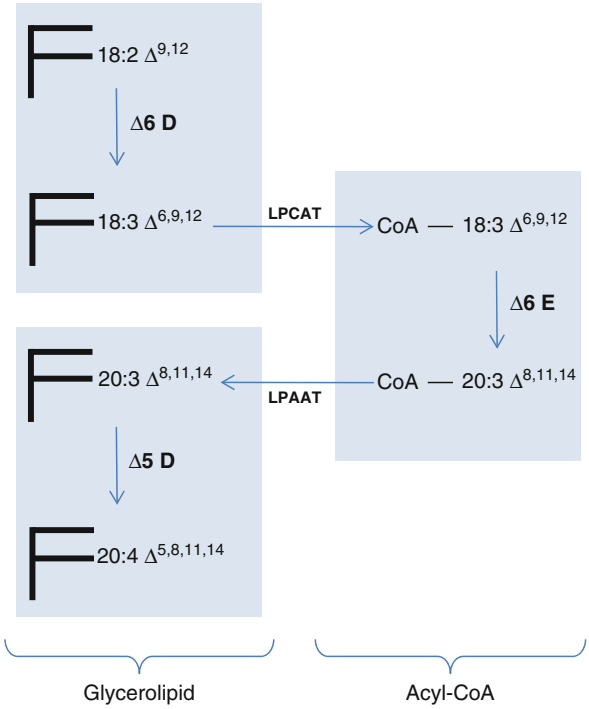


Biotechnology and Nutritional Improvement of Crops. Figure 3

Overview of very-long-chain polyunsaturated fatty acid synthesis focusing on the strategies that have been used in transgenic plants either by enhancing the standard Δ6-pathway or importing enzymes from the alternative Δ8-pathway and microbial Δ4-pathway [82]. Enzymes identified by "D" and "E" are desaturases and elongases, respectively. Humans lack the Δ12 desaturase that converts oleic acid into linoleic acid

methylerythritol-4-phosphate (MEP) pathway, also known as the non-MVA pathway. Initially, pyruvate and D-glyceraldehyde-3-phosphate are converted into 1-deoxy-D-xylulose-5-phosphate (DXP) by DXP synthase (DXS), and DXP is then converted into the isomeric C5 precursors isopentenyl diphosphate (IPP) and dimethylallyl pyrophosphate (DMAPP). Three molecules of IPP condense with one molecule of DMAPP to form the C20 precursor geranylgeranyl diphosphate (GGPP), which is used for the synthesis of carotenoids, tocopherols, chlorophylls, plastoquinones, and gibberellins [89]. The first committed reaction in carotenoid biosynthesis is the conversion of GGPP to phytoene by phytoene synthase (PSY). In plants, phytoene then undergoes four desaturation steps catalyzed by phytoene desaturase (PDS) and ζ–carotene desaturase (ZDS) to generate the first colored carotene, *cis*-lycopene, which is converted to all-*trans*-lycopene by carotene isomerase (CRTISO) [90]. Lycopene is the substrate for two different enzymes – lycopene β-cyclase (LYCB), which adds β-ionone rings to both ends generating β-carotene; and lycopene ε-cyclase (LYCE), which adds an ε-ionone ring to one end, the other being cyclized by LYCB to generate α-carotene [90]. Both molecules can be hydroxylated to produce xanthophylls such as lutein, zeaxanthin, and violaxanthin (Fig. 5) although these do not have pro-vitamin A activity [90].

The amount of β-carotene produced by plants can be enhanced by increasing the availability of carotenoid



Biotechnology and Nutritional Improvement of Crops. Figure 4

Fatty acid desaturation in plants requires glycerolipid substrates, whereas elongation requires acyl-CoA substrates. Successive desaturation and elongation steps therefore require substrates to be shuttled between phosphatidylcholine and coenzyme A (CoA) using enzymes known as acyltransferases. Enzymes identified by "D" and "E" are desaturases and elongases, respectively. Abbreviations: 18:2 $\Delta^{9,12}$, linoleic acid; 18:3 $\Delta^{6,9,12}$, γ-linolenic acid; 20:3 $\Delta^{8,11,14}$, dihomo-γ-linolenic acid; 20:4 $\Delta^{5,8,11,14}$, arachidonic acid; LPCAT, lysophosphatidylcholine acetyltransferase; LPAAT, lysophosphatidic acid acyltransferase

precursors, by expressing enzymes in the common part of the pathway (between GGPP and lycopene), by biasing the pathway toward the β-branch through the expression of LYCB at the expense of LYCE, or by increasing the storage capacity for carotenoids (Table 6) [90].

The first approach has been successful in producing plants that synthesize high levels of GGPP, but because this is used in several pathways not all of the flux is directed toward carotenoid synthesis. For example, the overexpression of DXP synthase in tomato and potato increased the total carotenoid content by up to 1.6-fold compared to wild type, but the levels of tocopherols and plastoquinones were also affected [91].

The expression of enzymes in the committed part of carotenoid pathway is a more targeted approach, and is particularly necessary in cereal grains where the pathway is blocked at the first committed step. In rice endosperm, the carotenoid pathway terminates at GGPP because there is very limited PSY activity. "Golden Rice" is a transgenic variety expressing daffodil PSY and LYCB as well as the multifunctional bacterial enzyme CrtI, which carries out all the desaturation steps between phytoene and lycopene. The β-carotene content of the original Golden Rice was 1.6 μg/g DW [92], but the replacement of daffodil PSY with the more active corn enzyme resulted in Golden Rice 2, in which the β-carotene levels reached 31 μg/g DW [93]. Similar results have been achieved in corn endosperm. For example, Aluru et al. [94] expressed the bacterial enzymes CrtB (PSY) and CrtI under the control of an enhanced seed-specific promoter, increasing the total carotenoid level to 33.6 μg/g DW and the β-carotene level to 9.8 μg/g DW. More recently, Zhu et al. [95] used a combinatorial transformation strategy to introduce up to five carotenogenic transgenes into corn, with the best-performing line (Ph-3, expressing PSY and CrtI), producing over 60 μg/g DW of β-carotene. Another recent breakthrough in this area was the creation of transgenic corn plants transformed with four genes enabling the simultaneous modulation of three metabolic pathways [96]. As above, the carotenoid pathway was engineered with the genes encoding PSY and CrtI, resulting in a 169-fold increase in β-carotene levels to 57 μg/g DW. These combinatorial and stacked transgene approaches are discussed later in detail.

Similar progress has been made in the brassicas. The expression of bacterial CrtB (PSY) in canola resulted in a 50-fold increase in total carotene levels compared to wild-type seeds (1,617 μg/g fresh weight (FW)), with a β-carotene content of 949 μg/g FW [97]. Ravanello et al. [98] achieved 1,341 μg/g FW total carotenoids with the same gene. The combined expression of CrtB (PSY) and CrtI boosted levels to 1,412 μg/g FW, but further addition of CrtY (LYCB) reduced total

Biotechnology and Nutritional Improvement of Crops. Figure 5

The extended carotenoid biosynthetic pathway in plants [171]. The precursor for the first committed step in the pathway is GGPP (geranylgeranyl pyrophosphate), which is converted into phytoene by phytoene synthase (PSY, CrtB). GGPP is formed by the condensation of IPP (isopentenyl pyrophosphate) and DMAPP (dimethylallyl pyrophosphate), which are derived predominantly from the plastidial MEP (methylerythritol 4-phosphate) pathway as shown in the upper part of the figure. The pathway is linear until lycopene, involving three steps catalyzed by separate enzymes in plants but by the single, multifunctional enzyme CrtI in bacteria. Lycopene is the branch point for the α- and β-carotene pathways, which usually end at lutein and zeaxanthin, respectively, through the expression of β-carotene hydroxylases (*arrows* with *circles*). An elaborated ketocarotenoid pathway can be introduced by expressing β-carotene ketolases (*arrows* with *diamonds*) since these compete for substrates with β-carotene hydroxylases and generate diverse products. Other abbreviations: GA3P, glyceraldehyde 3-phosphate; DXP, 1-deoxy-D-xylulose 5-phosphate; DXS, DXP synthase; DXR, DXP reductoisomerase; IPI, IPP isomerase; GGPPS, GGPP synthase; PDS, phytoene desaturase; ZDS, ζ-carotene desaturase; CRTISO, carotenoid isomerase; LYCB, lycopene β-cyclase; LYCE, lycopene ε-cyclase; HydE, carotene ε-hydroxylase

Source: Data updated from [171]

carotenoid levels to 1,229 μg/g FW although it increased the relative amount of β-carotene to 846 μg/g FW. Recently, Fujisawa et al. [99] introduced seven bacterial transgenes into canola encoding the enzymes isopentenyl pyrophosphate isomerase (which interconverts IPP and DMAPP), CrtE (GGPP synthase), CrtB (PSY), CrtI (carotene desaturase), CrtY (LYCB), and two additional enzymes (CrtZ and CrtW) that catalyze downstream steps converting β-carotene into ketocarotenoids. Although this resulted in the production of several ketocarotenoids, the predominant carotenoid was still β-carotene, which accumulated to 214.2 μg/g FW, 1,074-fold higher than in wild-type seeds.

Diretto et al. [100, 101] expressed CrtB, CrtI, and CrtY in potato tubers, increasing total carotenoid levels to 114 μg/g DW and β-carotene levels to 47 μg/g DW. They also silenced the endogenous *lyce* and *bch* genes, thereby eliminating competition at the branch point between the α- and β-carotene pathways and preventing the further metabolism of β-carotene.

Ripening tomatoes accumulate low levels of β-carotene and in order to address this deficiency, several investigators have attempted to overexpress either the endogenous *lycb* gene or equivalent heterologous genes [102–106]. D'Ambrosio et al. [103] have been the most successful with this approach, achieving a 32-fold increase in β-carotene levels and generating orange-colored tomato fruits. Another successful strategy was the suppression of the endogenous *DET1* gene, which regulates photomorphogenesis. The expression of a *det1* RNAi construct in tomato chromoplasts increased β-carotene levels eightfold to 130 μg/g DW [107].

An alternative strategy to achieve β-carotene accumulation in plants is to modify the storage capacity of chromoplasts, where β-carotene accumulates in specialized lipoprotein-sequestering structures. A spontaneous mutation in the cauliflower *Orange* (*Or*) gene resulted in deep orange cauliflower heads associated with the hyperaccumulation of carotenoids in

chromoplasts [108, 109] and the mutant allele has been cloned and expressed in potato tubers, where it increased the level of β-carotene tenfold and turned the tuber flesh orange [110].

Vitamin E Vitamin E is a collection of four tocopherols and four tocotrienols (each as α, β, γ, and δ derivatives), collectively known as tocochromanols [111]. All eight isomers can be absorbed equally efficiently during digestion but the hepatic α-tocopherol transfer protein (α-TTP) shows preferential retention of α-tocopherol, making it the most important form in terms of vitamin E activity in the human body [111].

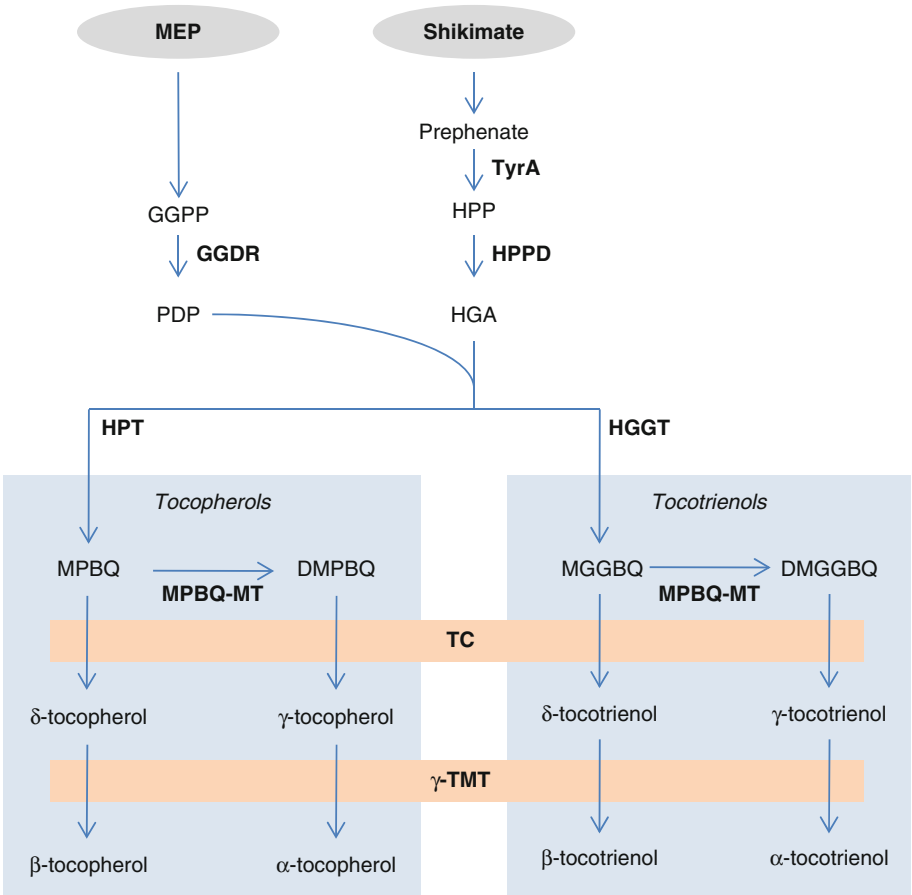
Tocochromanol biosynthesis in higher plants (Fig. 6) occurs in the plastids and requires precursors from the cytosolic shikimate pathway and the plastidial MEP pathway [111]. The tocochromanol head group is derived from the shikimate pathway, and this involves the conversion of p-hydroxyphenylpyruvic acid (HPP) to homogentisic acid (HGA), by HPP dioxygenase (HPPD); the MEP pathway contributes the side chain [111]. The first committed step in tocochromanol biosynthesis is the prenylation of HGA. There are two enzymes that carry out this reaction. If prenylation is carried out by homogentisate phytyltransferase (HPT), the product is 2-methyl-6-phytylplastoquinol (MPBQ), which leads to the synthesis of tocopherols. Alternatively, HGA can be prenylated by homogentisate geranylgeranyl transferase (HGGT), producing 2-methyl-6-geranylgeranylplastoquinol (MGGBQ), which leads to the synthesis of tocotrienols [111].

The eight isomers form through a complex series of reactions involving enzymes with multiple substrates at each stage. Both MPBQ and MGGBQ are substrates for tocopherol cyclase (TC), leading to the production of δ-tocopherol and δ-tocotreinol, respectively. They are also substrates for the enzyme MPBQ methyltransferase (MPBQ-MT), which adds a second methyl group to form 2,3-dimethyl-5-phytyl-1,4-benzoquinone (DMPBQ) and 2,3-dimethyl-5-geranylgeranyl-1,4-benzoquinone (DMGGBQ), respectively. These methylated derivatives are also substrates for TC, leading to the production of γ-tocopherol and γ-tocotreinol, respectively. Finally, all four of these products (the δ- and γ-tocopherols, and the δ- and γ-tocotrienols) can be methylated by γ-tocopherol methyltransferase (γ-TMT) to produce their β- and α- counterparts [111].

Plants can be engineered to accumulate higher levels of vitamin E by overexpressing the genes involved in tocochromanol synthesis, and this can be achieved either by increasing the total tocochromanol content or skewing tocochromanol synthesis toward the more potent vitamers, particularly α-tocopherol (Table 7). In the first approach, the overexpression of HPT increased tocopherol levels by up to 1.6-fold in the seeds and 4.4-fold in the leaves of transgenic Arabidopsis plants [112]. The overexpression of HPPD increased tocotrienol levels tenfold in Arabidopsis leaves [113], twofold in tobacco leaves, and 1.5-fold in tobacco seeds [114]. In the second approach, the expression of Arabidopsis γ-TMT in lettuce increased the α/γ tocopherol ratio but had no effect on the total tocopherol content [115]. However, by crossing the lines expressing HPT and γ-TMT, both the total tocopherol content and the α/γ tocopherol ratio were increased [115]. In canola, total tocochromanol levels have been doubled by expressing genes encoding HPT, HPPD, and TC [116].

The impact of HPPD expression can be enhanced by the simultaneous expression of TyrA, the enzyme responsible for the synthesis of HPP from prephenate (Fig. 6). TyrA expression has little effect on its own, but when combined with HPPD in tobacco, tocochromanol levels in the leaves increased eightfold [117]. Similar results have been achieved in Arabidopsis, canola, and soybean seeds using the same combination of genes, although the total tocochromanol content increased only 2–2.5-fold in these cases [118]. The expression of HPT, HPPD, and TyrA increased the tocochromanol content of seeds fivefold, and the further addition of geranylgeranyldiphosphate reductase (GGDR), which provides the precursor phytyldiphosphate, increased the tocochromanol content by up to 15-fold [118].

The seed-specific expression of Arabidopsis MPBQ-MT and γ-TMT in soybean resulted in a complete conversion of β-, γ-, and δ-tocopherols to α-tocopherol, with a fivefold enhancement in the vitamin E activity of soybean oil [119]. Similarly, Tavva et al. [120] achieved a 10.4-fold increase in α-tocopherol levels and a 14.9-fold increase in β-tocopherol levels in soybean seeds expressing *Perilla frutescens* γ-TMT.



Biotechnology and Nutritional Improvement of Crops. Figure 6
Vitamin E synthesis in plants [111]. The pathway involves the prenylation of homogentisic acid (HGA), derived from the shikimate pathway, with phytyldiphosphate (PDP), derived from the methylerythritol phosphate (MEP) pathway. Prenylation may be carried out by two different enzymes – HPT (homogentisate phytyltransferase) or HGGT (homogentisate geranylgeranyl transferase) – to generate alternative intermediates that give rise to the tocopherol and tocotrienol branches of the pathway, respectively. These intermediates are substrates for the same three enzymes, yielding eight different products. Additional substrate abbreviations: GGPP, geranylgeranyl pyrophosphate; HPP: ρ-hydroxyphenylpyruvic acid; MPBQ, 2-methyl-6-phytylbenzoquinol; DMPBQ, 2,3-dimethyl-5-phytylbenzoquinol; MGGBQ, 2-methyl-6-geranylgeranylplastoquinol; DMGGBQ, 2,3-dimethyl-5-geranylgeranylplastoquinol. Additional enzyme abbreviations: GGDR, geranylgeranyl diphosphate reductase; HPPD, HPP dioxygenase; MPBQ-MT: MPBQ methyltransferase; TC, tocopherol cyclase; γ–TMT: γ-tocopherol methyltransferase

Vitamin C Most vitamin C (ascorbic acid) in plants is synthesized through the L-galactose pathway [121], although other routes through galacturonic acid, L-glucose, and *myo*-inositol have been proposed [122]. Oxidation of ascorbic acid produces the short-lived radical monodehydroascorbate (MDHA), which is either converted to ascorbic acid by MDHA reductase (MDHAR) or undergoes spontaneous degradation into ascorbic acid and dehydroascorbate (DHA). DHA is then either recycled to ascorbic acid by dehydroascorbate reductase (DHAR), using glutathione as the reductant, or undergoes irreversible hydrolysis to generate 2,3-diketogulonic acid (Fig. 7).

Biotechnology and Nutritional Improvement of Crops. Table 7 Transgenic plants with enhanced tocochromanol levels [111]

Species	Genes (source)	Promoters	Tocochromanol levels in transgenic plants
Tobacco (*Nicotiana tabacum*)	*hppd* (barley; *Hordeum vulgare*)	CaMV 35S	50 μg/g DW in seeds (1.5–2-fold)
	tyrA (*Erwinia uredovora*)	Arabidopsis histone gene H4748	67 μg/g DW in leaf (1.3-fold)
	tyrA (*E. uredovora*), *hppd* (Arabidopsis)		14.3 μg/g DW of α-tocotrienols
			551 μg/g DW in leaf (10-fold)
Corn (*Zea mays*)	*hggt* (barley)	Embryo-specific	>800 nmol/g DW in seeds (6-fold)
	hppd and *vte3* (Aradidopsis)	CaMV 35S	9.5 μg/g DW (3-fold)
Lettuce (*Lactuca sativa*)	*vte4* (Arabidopsis)	CaMV 35S	Improved α-/γ –tocopherol ratio up to 0.4–544 as compared to α/γ ratio in wild type, which is 0.6–1.2
Mustard (*Brassica juncea*)	*vte4* (Arabidopsis)	CaMV 35S	62.29 μg/g of α-tocopherol levels in seeds (6-fold)
Canola (*Brassica napus*)	*hppd* (Arabidopsis)	DC3Ω	819 μg/g oil in seeds (1.2-fold)
	hppd, *hpt1*, *vte1* (Arabidopsis)	DC3Ω (*hppd*), napin (*hpt1, vte1)*	1,850 μg/g oil in seeds (2-fold)
	tyrA (*E. uredovora*)	Lac	540 μg/g of total tocochromanols in seeds (2.3-fold)
	tyrA (*E. uredovora*), *hppd*, *hpt1* (Arabidopsis)	Lac	3.7-fold increase in seeds
	vte1 (Arabidopsis)	Napin	1,018 μg/g oil of total tocochromanols in seeds (20–50% increase)
	vte1 (corn)	Napin	1,159 μg/g oil of total tocochromanols in seeds
Soybean (*Glycine max*)	*tyrA* (*E. uredovora*), *hppd*, *hpt1* and *ggh* (Arabidopsis)	Lac	4,806 μg/g of total tocochromanols in seeds (15-fold)
	vte3 (Arabidopsis)	7Sα	The majority of the tocopherol accumulated as γ-tocopherol (75–85%) with increased α-tocopherol as well. By contrast, these seeds had very low levels of β- and δ-tocopherol, only 0.5–1.5% of total tocopherols
	vte4 (Arabidopsis)	7Sα	100% of α-tocopherols in seeds
	vte3 and *vte4* (Arabidopsis)	7Sα	8-fold increase in α-tocopherol in seeds
	vte4 (*Perilla frutescens)*	Vicilin	390 nmol/g FW of α-tocopherol content in seeds (10.4-fold)
			52 nmol/g FW of β-tocopherol content in seed (14.9-fold)

Biotechnology and Nutritional Improvement of Crops. Table 7 (Continued)

Species	Genes (source)	Promoters	Tocochromanol levels in transgenic plants
Arabidopsis (*Arabidopsis thaliana*)	*vte4* (Arabidopsis)	DC3	328 μg/g α-tocopherol in seeds (86-fold)
	hppd (Arabidopsis)	CaMV 35S, DC3	37% and 28% increase of tocopherol levels in leaf and seed respectively
	hpt1 (Arabidopsis)	CaMV 35S	4.4-fold increase in total leaf tocopherol content (mainly α-tocopherols)
	hpt1 (Arabidopsis)	Napin	2-fold increase of tocopherols in seed

Synthesis of ascorbic acid in plants [96]. Abbreviations: Gal, galactose; GalL, galactonolactone; GDP guanidine diphophate; Gul, gulose; GulL, gulonolactone; Man, mannose; P, phosphate; UDP, uridine diphosphate

Since at least three separate metabolic pathways are involved in the biosynthesis of ascorbic acid in plants in addition to the recycling of oxidation products, three different strategies have been used to enhance ascorbate levels: overexpression of enzymes involved in ascorbate biosynthesis, overexpression of recycling enzymes (such as DHAR) to enhance regeneration, and antisense suppression of ascorbate oxidase (Table 8). Enhancing ascorbate regeneration has been the most successful approach [122]. The expression of wheat DHAR increased ascorbate levels by twofold in transgenic corn seed and fourfold in

Species	Genes (source)	Promoters	Ascorbate levels in transgenic plants
Corn (*Zea mays*)	*dhar* (wheat; *Triticum aestivum*)	Corn Ubi-1 (constitutive)	~150 nmol/g FW in kernel (1.9-fold)
	dhar (rice; *Oryza sativa*)	Barley (*Hordeum vulgare*) D-hordein	607.2 nmol/g FW (6.1-fold)
Tomato (*Solanum lycopersicum*)	*mMDH*	CaMV 35S (constitutive)	(5–6-fold)
Lettuce (*Lactuca sativa*)	*GLOase* (rat; *Rattus norvegicus*)	CaMV 35S	430–580 nmol/g FW (4–7-fold)
Tobacco (*Nicotiana tabacum*)	*GLOase* (rat)	CaMV 35S	480 nmol/g FW (7-fold)
	dhar (wheat)	CaMV 35S	2,800 nmol/g FW (2.4-fold)
	GalLDH (tobacco)	CaMV 35S	(1.5–2-fold)
	GMP (*Malpighia glabra*)	MgGMP	800–1,000 nmol/g FW (2-fold)
	GGT (GDP-L-galactose D- mannose-1-phosphate guanyltransferase) (*Actinidia chinensis)*	CaMV 35S	1,000 μg/g FW (3-fold)
	PMM (*M. glabra*)	MgGMP	700 μg/g FW (2-fold)
Arabidopsis (*Arabidopsis thaliana*)	*GalUR* (strawberry; *Fragaria* × *ananassa*)	CaMV 35S	~600 nmol/g (3-fold)
	miox4 (Arabidopsis)	CaMV 35S	~500 nmol/g FW (2–3-fold)
	GGT (GDP-L-galactose guanyltransferase) (*Actinidia eriantha*)	CaMV 35S	8.6–12-fold
	GME (GDP-L-mannose-3′,5′-epimerase) (*A. eriantha*)	CaMV 35S	

Source: Data updated from [122]

transgenic tobacco leaves, with concomitant reductions in the levels of DHA [123], whereas the expression of rice DHAR in corn increased the level of ascorbate in the seeds by more than sixfold [96].

Jain and Nessler [124] achieved a sevenfold increase in ascorbate levels by expressing L-gulono γ-lactone oxidase (GLOase) in tobacco and lettuce (the lack of this enzyme accounts for the inability of primates to synthesize their own ascorbic acid). Transgenic tobacco plants expressing phosphomannomutase (PMM) or GDP-D-mannose pyrophosphorylase (GMP) also accumulated double the normal levels of ascorbate [125].

Plants of the genus *Actinidia* are particularly rich in ascorbic acid, so genes from the ascorbate biosynthesis pathway in *Actinidia* species have been expressed in model plants to ascertain if this can be used to boost ascorbate levels. Transgenic tobacco plants expressing *Actinidia chinensis* GDP-L-galactose guanyltransferase contained threefold the normal levels of ascorbate in the leaves [126] whereas Arabidopsis plants expressing the equivalent enzyme from *Actinidia eriantha* contained 4.2-fold more ascorbate than normal. Expressing this enzyme in concert with GDP-L-mannose-3′,5′-epimerase achieved a 12-fold increase in ascorbate revealing an important bottleneck in the L-galactose pathway [127].

Folate Folic acid is a tripartite molecule combining pterin, p-aminobenzoate (PABA), and one or more glutamate moieties. The three parts of the molecule are produced separately in different subcellular compartments (plastids, cytosol, and mitochondria) and then joined together. Pterin is formed from guanosine triphosphate (GTP) in the cytosol and PABA is formed from chorismate in the plastids. These moieties are then transported to the mitochondria, where they condense to form dihydropteroate and are converted to polyglutamates (Fig. 8). Metabolic engineering can be used to increase folate levels in plants but the compartmentalization of the pathway adds a degree of complexity (Table 9).

Initial strategies involving modulation of individual branches of the pathway have been moderately successful. For example, expressing GTP cyclohydrolase 1 (GCH1) enhances the cytosolic (pterin) branch of the pathway and increases pterin levels, which ensures that the other two branches become rate limiting. In tomato, this approach doubled the normal levels of folate in the fruit [128]. Similar results were achieved by enhancing the PABA branch of the pathway by overexpressing aminodeoxychorismate synthase (ADCS) [129]. Each of these experiments revealed the limitations of the other pathway branches, but by crossing the two transgenic lines, the enhanced pathways were combined resulting in complementation between them and the creation of transgenic tomato fruits containing 25-fold the normal levels of folate [129]. The strategy has been replicated in other crops with similarly impressive results: the expression of Arabidopsis GCH1 and ADCS in rice endosperm, e.g., increased folate levels by up to 100-fold [130].

Pantothenate Although most work in the area of vitamin enhancement in plants has focused on vitamins A, B_9 (folate), C, and E, there have been a small number of studies addressing other vitamins. Fouad and Rathinasabapathi [131] expressed the *E. coli panD* gene encoding L-aspartate-α-decarboxylase (ADC) in tobacco and increased the level of pantothenate (vitamin B_5) in the leaves by up to 4.1-fold. Similarly, Chakauya et al. [132] expressed the *E. coli panB* gene encoding ketopantoate hydroxymethyltransferase (KPHMT) in canola, increasing levels of pantothenate in leaves, flowers, siliques, and seeds by 1.5–2.5-fold compared with the wild type.

Increasing Mineral Levels

In contrast to the situation with vitamins and essential amino acids and fatty acids, the mineral content of plants cannot be increased by metabolic engineering because minerals are not synthesized de novo by plants; instead they are taken up from the environment. Therefore, increasing the mineral density of plants using biotechnology involves a different set of strategies, focusing on the introduction of genes that improve the efficiency of mineral extraction from the soil (through improved mobilization and/or improved uptake), improve the efficiency of transport from the roots to storage organs such as seeds and fruits, and increase the capacity of storage organs to store minerals in a form that is available in the diet and not toxic to the plant [23, 32]. In addition, these strategies can be supplemented with those seeking to reduce the abundance of antinutritional compounds such as phytate, which inhibits mineral absorption in the gut, and/or to increase the abundance of nutritional enhancer compounds such as inulin, which facilitate mineral absorption by slowing down the progress of food through the gut (Table 10).

Biotechnology and Nutritional Improvement of Crops.

Table 10 Some examples of mineral nutritional enhancers and antinutrients in plant foods [37]

Nutritional enhancers	Major dietary source
β-Carotene (pro-vitamin A)	Green and orange vegetables
Certain amino acids (cysteine, lysine, etc.)	Animal meats
Certain organic acids (ascorbic acid, citrate, etc.)	Fresh fruit and vegetables
Hemoglobin	Animal meats
Inulin	Chicory, garlic, onion, wheat, artichoke
Long-chain fatty acids	Human breast milk
Antinutrients	**Major dietary source**
Phytic acid (phytate)	Whole legume seeds and cereal grains
Goitrogens	*Brassicas* and *Alliums*
Hemagglutinins	Most legumes and wheat
Oxalic acid (oxalate)	Different vegetables (spinaches, beet, linseed, oca)
Tannins and other polyphenolics	Tea, coffee, beans, sorghum

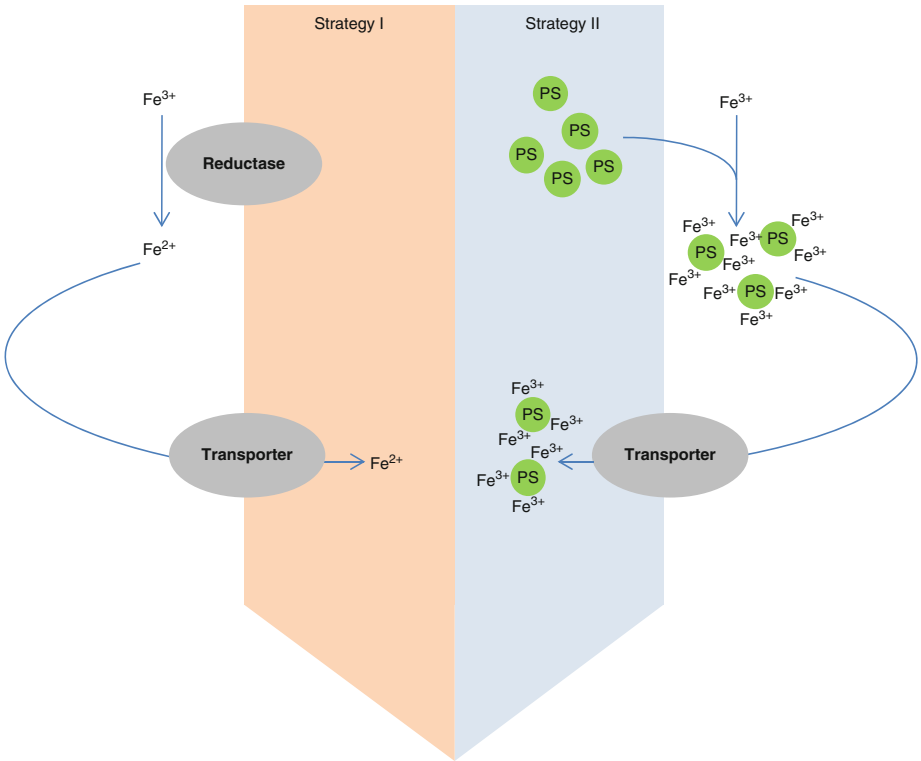
Mineral Uptake and Transport The efficiency with which minerals are taken up from the soil depends on their accessibility, which in turn reflects their solubility



Biotechnology and Nutritional Improvement of Crops. Figure 9
Strategies for iron acquisition by plants [134]. Strategy I, as used by non-graminaceous plants, involves the acquisition of Fe^{2+} after reduction of Fe^{3+} in the rhizosphere by secreted reductases. Strategy II, as used by graminaceous plants, involves the secretion of phytosiderophores (PS) which chelate Fe^{3+}, allowing absorption of the chelated complexes

and interactions with soil particles. Iron is present in the soil mainly as Fe^{3+}, an insoluble form with the tendency to bind strongly to inert particles. Therefore, plants have evolved two distinct strategies to facilitate iron absorption (Fig. 9). Strategy I is used by non-graminaceous plants and involves acidifying the rhizosphere through the secretion of protons, reducing Fe^{3+} to Fe^{2+} using reductases and then absorbing the soluble Fe^{2+} using specific transporters. Strategy II is used by graminaceous plants and involves the direct acquisition of Fe^{3+} by secreting chelating agents (phytosiderophores) into the rhizosphere, followed by adsorption of the chelated iron complexes. Specific root transporters are then required for the uptake of the soluble Fe^{3+}-phytosiderophore complexes [133]. Zinc is present in soil as Zn^{2+} and can be directly absorbed in this form. Many of the genes required for zinc uptake, sequestration, and redistribution in plants have been identified [44] and it is thought that zinc-hyperaccumulating plants sequester large amounts of zinc in the vacuole, a strategy that confers zinc tolerance. However, Zn^{2+} can also form chelates with phytosiderophores, and the Zn^{2+}-phytosiderophore complexes share the same channels as those used for iron chelates. Therefore, some strategies that have been developed to improve the uptake of iron also improve the uptake of zinc as a beneficial by-product, and vice versa, although this depends on the genes involved [134]. Other minerals are taken up through specific transporters, e.g., plants take up selenium from the soil in the form of selenate (via sulfate transporters), selenite (via phosphate transporters), or as organic compounds (selenoproteins), and they take up calcium via specific Ca^{2+}/ H^{+} antiporters (CAX). Once inside the plant, minerals may also share transport mechanisms – e.g. Fe^{2+}, Zn^{2+}, and Ca^{2+} may all form complexes with nicotianamine for transport through the phloem to sink tissues.

Biotechnology and Nutritional Improvement of Crops. Table 11 Transgenic plants with enhanced mineral levels [23]

Species	Genes (source)	Promoters	Mineral content in seeds (and increase relative to wild type)
Iron			
Corn (*Zea mays*)	*ferritin* (soybean; *Glycine max*) + *phytase (Aspergillus niger)*	Rice glutelin-1	38 μg/g DW (2-fold)
Rice (*Oryza sativa*)	*ferritin* (soybean),	Rice gluB-1	38.1 μg/g DW (3-fold)
		Corn Ubi-1	No increase in seeds
		Rice GluB-1	34.7 μg/g DW (4.4-fold)
		Rice Glb-1	27 μg/g DW (3-fold)
	ferritin (pea; *Pisum sativum*),	CaMV-35S	31.3 μg/g DW (4.82-fold)
	ferritin (common bean; *Phaseolus vulgaris*) + *phytase (Aspergillus fumigatus)*	Rice glutelin-1	22.07 μg/g DW (2-fold)
	nas1 (Arabidopsis; *Arabidopsis thaliana*) + *ferritin* (common bean)	CaMV35S + rice globulin	7 μg/g DW (6.3-fold) (in polished rice)
Tobacco (*Nicotiana tabacum*)	*nas1* (barley; *Hordeum vulgare*)	CaMV35S	(2.3-fold in leaves)
	nas1 (Arabidopsis)	CaMV35S	(1.5-fold in leaves)
Calcium			
Carrot (*Daucus carota*)	sCAX 1 (Arabidopsis)	CaMV35S	3.9 mg/g DW (1.6-fold) (in carrot)
Lettuce (*Lactuca sativa*)	sCAX 1 (Arabidopsis)	Cell division cycle (cdc2a)	18.9 mg/g DW
Potato (*Solanum tuberosum*)	sCAX 1 (Arabidopsis)	CaMV35S	1.7 mg/g DW (3-fold) (in tuber)
	CAX2B chimeric (Arabidopsis)	CaMV35S	2.5 mg/g DW (3-fold) (in tuber)
Rice	sCAX 1 (Arabidopsis)	CaMV35S	not determined
Tomato (*Solanum lycopersicum*)	CAX 4 (Arabidopsis)	CaMV35S	1.8 mg/g DW (in fruit)

Source: Data updated from [23]

In order to improve iron uptake from the soil, transgenic plants have been created expressing heterologous iron transporters, reductases, and enzymes involved in phytosiderophore biosynthesis (Table 11). For strategy I plants, such approaches have usually involved the expression of iron transport proteins, whereas for strategy II plants, iron accumulation can be enhanced by the production of higher levels of phytosiderophores, with the anticipated collateral effects on zinc absorption [23]. In rice, e.g., iron and zinc uptake was improved by the expression of the barley *naat-A* and *naat-B* genes encoding nicotianamine aminotransferases, which are involved in phytosiderophore biosynthesis [135]. Similarly, the overexpression of barley nicotianamine synthase in tobacco doubled the iron and zinc concentrations in leaves [136]. Transgenic barley expressing the Arabidopsis ZIP1 iron/zinc transporter, despite having smaller seeds, accumulated twice the amount of zinc and iron as wild-type plants [137]. In contrast, constitutive overexpression of barley ZIP7 increased the zinc content of the grain by 50%, but had negligible effect on the iron content regardless of the abundance of zinc in the soil, showing that iron and zinc are not always

co-absorbed [138]. Interestingly, expression of the Arabidopsis putative zinc transporter MTP1 in barley led to a dramatic short-term increase in the amount of zinc stored in the roots under high zinc loads, but no difference in the amount of zinc in the seeds over the long term [139].

Several different approaches can be envisaged to enhance the uptake and storage of selenium, based on the multiple inorganic and organic sources of selenium in the soil and the manner in which they are interconverted [140]. ATP-sulfurylase (APS) is rate limiting for selenate reduction and accumulation in most plants, so the overexpression of this enzyme can increase the uptake of selenate [141]. Selenocysteine methyltransferase (SMT) converts selenocysteine into selenium-methylselenocysteine (MetSeCys), a nontoxic form found at high levels in the selenium-hyperaccumulator, *Astragalus bisulcatus*, so the overexpression of this enzyme would be a suitable approach for increasing the accumulation of organic selenium.

Pilon-Smits et al. [141] expressed Arabidopsis APS in Indian mustard, resulting in a threefold increase in selenium levels in leaves and greater tolerance for high selenate levels in the soil. The levels of organic selenium also increased because of the increased capacity for selenate reduction [141, 142]. Indian mustard plants overexpressing both APS and SMT accumulated 10-fold more MetSeCys than normal, reflecting the increased uptake of selenate and its conversion to MetSeCys as well as the reduction of selenite [143]. More recently, McKenzie et al. [144] expressed *Brassica oleracea* APS and *Astragalus bisulcatus* SMT in tobacco plants supplied with selenate. The expression of SMT increased total selenium levels up to 4-fold, and whereas the expression of APS did not increased total selenium level, when combined with the SMT, a greater proportion of selenium was converted into MetSeCys.

The calcium content of crops has been enhanced by expressing specific Ca^{2+}/ H^{+} antiporters located in the vacuolar membrane (Table 11). For example, the Arabidopsis cation exchanger 1 antiporter (sCAX1) [145], enhances the level of bioavailable calcium when expressed in transgenic potato tubers and carrot taproots [33, 146–148]. The same protein has been expressed in transgenic lettuce, which accumulated higher levels of calcium than wild-type leaves without impacting on flavor or crispness [149]. Kim et al. [150] constructed a chimeric Arabidopsis gene (*CAX2B*) by combining a truncated N-terminal portion of *CAX2* with the "B" domain from *CAX1*. Transgenic potatoes expressing this recombinant construct accumulated calcium without affecting the levels of related cations such as Mn^{2+}. Transgenic tomatoes expressing the Arabidopsis *CAX4* gene also accumulated higher levels of calcium than wild-type fruits [150].

Mineral Storage in Sink Tissues In cereal grains, minerals are predominantly stored in the bran (embryo and aleurone layer) rather than the endosperm, which means that much of the nutritional value of cereals is lost during polishing [151]. Encouraging plants to absorb more minerals from the soil is therefore not sufficient to increase the nutritional value of *food*. In addition to improving mineral uptake, cereals must be engineered to accumulate minerals in the endosperm.

Minerals in plants are found both as free ions in solution and as complexes with dedicated proteins that have evolved for the specific function of mineral transport and storage (protecting the plants against both mineral deficiency and overload). Ferritin, e.g., is a 450-kDa protein consisting of 24 subunits that form a shell, enabling the storage of up to 4,500 Fe^{3+} ions as crystallites with hydroxide and phosphate. Recombinant soybean ferritin has been expressed in the endosperm of several cereals allowing the accumulation of iron in the endosperm [152–155] and pea ferritin has also been constitutively expressed in rice [156]. In the best cases, the level of bioavailable iron exceeded 35 mg kg^{-1}.

Combined Strategies to Increase Mineral Density in Cereal Grains Although increasing the uptake of iron and the ability of plants to accumulate iron both work as individual strategies to improve the mineral content of cereal crops, there are limitations when each strategy is applied alone. Increasing the uptake of iron without considering its distribution will result in the hyperaccumulation of iron in vegetative tissues as well as the seeds, eventually resulting in overload and toxicity. Conversely, the overexpression of ferritin without compensating for the increased iron storage capacity results in the sequestration of free iron needed by plant cells for normal physiological functions, inhibiting

photosynthesis and causing chlorosis even if plenty of iron is available in the soil [154]. These issues can be overcome by combining the strategies, i.e., increasing both uptake and storage capacity in the same plant. For example, the combined expression of Arabidopsis nicotianamine synthase and soybean ferritin in rice resulted in rice grains with 6.3-fold more iron in the polished endosperm than wild-type plants (and also elevated levels of zinc), but no adverse effects [157].

Strategies to Ensure Stored Minerals Are Bioavailable Increasing the levels of minerals in plants does not necessarily increase their bioavailability, i.e., the proportion of the mineral that can be absorbed in the human gut [23]. In some cases, bioavailability depends on the chemical form in which a mineral is presented. For example, selenomethionine is a more bioavailable form of selenium than any inorganic source [18], and heme iron is more bioavailable than nonheme iron [158]. For cereals in particular, bioavailability reflects the presence of antinutritional compounds that inhibit absorption, such as phytate and oxalic acid, which chelate divalent cations (Table 10). It has been shown that high levels of such compounds can reduce mineral bioavailability to the extent of causing marginal deficiency diseases even if absolute mineral levels are adequate [159]. This can easily be overcome with a varied diet, but is particularly challenging in developing country settings where a monotonous diet of staple cereals in commonplace.

Strategies to tackle the presence of antinutritional compounds include conventional breeding to reduce the level of phytate in cereals, and biotechnology-based approaches to either reduce phytate levels or increase the levels of nutritional enhancers that counteract the effect of phytate. For example, natural variation in levels of the nutritional enhancer inulin has been investigated to increase the bioavailability of zinc [160]. Mutagenesis and conventional breeding have been used to generate low-phytate corn, barley, rice, and soybean [161, 162], which have 66%, 95%, 64%, and 80% less phytate, respectively, than corresponding wild-type lines, as well as beans with a 90% reduction of the normal levels of phytate but with no adverse effects on plant growth and development [163]. A *Medicago truncatula* mutant has also been bred with low levels of oxalic acid and therefore 22.87% higher calcium bioavailability [164]. Phytate levels have also been reduced in transgenic cereals by expressing a recombinant fungal enzyme (phytase) that degrades the compound. This strategy has been used to increase iron bioavailability in wheat (86% reduction in phytate [165, 166]) and corn (23% reduction in phytate [167]). The combined expression of ferritin and phytase was used in rice [168] and corn [169] (95% reduction of phytate) to increase iron levels and bioavailability in simulated digestion/absorption trials.

Stacking Nutritional Enhancement Traits The vast majority of transgenic plants engineered for nutritional enhancement have been created with the specific intention of tackling one particular nutrient (or class thereof). In many cases, this has involved the transfer of a single gene. In others, discussed above, two transgenic lines have been crossed to combine enhancements in an additive or synergistic manner, e.g., enhancing iron uptake and accumulation, or enhancing two branches of a metabolic pathway to increase the levels of folate. An alternative approach is supertransformation (the transformation of transgenic plants with additional transgenes), which has been used to produce VLC-PUFAs in Arabidopsis [88]. Both methods have two major drawbacks – the long and labor-intensive development process involving several breeding generations, and the fact that the different transgenes are unlinked, leading to segregation in subsequent generations [170]. Cotransformation refers to the simultaneous introduction of two or more transgenes, and its major advantages are that plants carrying multiple transgenes are produced in one generation and all the transgenes are likely to integrate at the same locus, thus preventing segregation. Cotransformation has been used to introduce up to seven transgenes simultaneously for the purpose of nutritional enhancement, in this case, the enhancement of carotenoid synthesis in canola [99], but even in this case, the aim was to modulate the levels of a single nutrient, β-carotene.

It is clear that, regardless of the success of experiments involving individual nutrients, the deployment of a transgenic plant line enhanced for a single nutrient will only serve to shift the problem of nutrient deficiency onto a different compound. In order to

address the challenge of micronutrient deficiency in a global manner, the next objective must be to enhance staple crops for all essential nutrients simultaneously. Zhu et al. [95] reported a unique and surprisingly straightforward approach to this challenge based on combinatorial nuclear transformation in corn. They chose the carotenoid biosynthetic pathway and transformed corn with a collection of five transgenes encoding the enzymes phytoene synthase, phytoene desaturase, lycopene β-cyclase, β-carotene hydroxylase, and β-carotene ketolase. Unlike other transformation experiments where the aim is to achieve a defined outcome, here the aim was to generate maximum diversity, i.e., a library of transformants expressing different combinations of transgenes. Transgenic plants expressing different enzyme combinations and showing distinct metabolic phenotypes were generated, allowing the identification and complementation of rate-limiting steps in the pathway. Individual transgenic lines were identified with extraordinarily high levels of β-carotene (as discussed earlier) and other carotenoids, providing the mechanism to generate plants with high levels of different nutrients in the same experiment. The same group expanded this principle by breeding selected transgenic lines with selected non-transgenic cultivars to generate lines with unprecedented levels of zeaxanthin [34] and by repeating the process with additional transgenes to identify plants simultaneously enhanced for multiple vitamins. Using four transgenes encoding enzymes from three metabolic pathways (corn PSY and bacterial CrtI for carotenoid synthesis, rice DHAR for ascorbate synthesis, and *E. coli* GCH1 for folate synthesis), Naqvi et al. [96] generated transgenic corn lines with a 407-fold increase in β-carotene (57 μg/g DW), a 6.1-fold increase in ascorbate (106.94 μg/g DW), and a 2-fold increase in folate (200 μg/g DW) compared to the non-transformed control plants.

Future Directions

Biotechnology has the potential to address some of the major elements of food insecurity both by increasing the availability of food and making that food more nutritious. The nutritional properties of plants can be improved by increasing the levels of essential amino acids, PUFAs, and vitamins, and by favoring the accumulation of minerals in a bioavailable form. Golden Rice and Multivitamin Corn are key developments in the history of nutritional enhancement, providing models for the development of crops that will particularly benefit subsistence farmers in developing countries. It is imperative that the focus shifts away from single gene strategies and single nutrients and toward the introduction of multiple genes that simultaneously enhance multiple pathways, leading ultimately toward the creation of transgenic crops that are in every sense of the word nutritionally complete.

Breeding in Beef Cattle

Matthew L. Spangler
Department of Animal Science, University of Nebraska, Lincoln, NE, USA

Article Outline

Glossary

Beef Improvement Federation (BIF) accuracy A metric of accuracy that is more conservative than true accuracy. It is linearly related to prediction error variance.

Bio-economic index A collection of EPD that are relevant to a breeding objective whereby each EPD is multiplied by an economic weight.

Composite A crossbred animal. Generally thought of in terms of a pedigreed seedstock animal that is a cross of two or more breeds.

Expected progeny difference Equivalent to half of a breeding value.

Molecular breeding value The sum of marker effects multiplied by the number of copies of a given marker.

Definition of the Subject

The beef cattle industry represents a diverse and unique sector of animal agriculture with varying breeds, production climates, and marketing objectives. The industry is not vertically integrated and thus breeding and selection decisions are controlled by individual farmers and ranchers. In the United States, the average herd size is less than 30 cows. However, there exists sound tools from which to make genetic selection decisions to ultimately make genetic change and improve profitability. These tools, some of which have been utilized for decades, are available to all beef cattle producers. The utilization of current genetic selection tools can aid in the profitability and ultimately the sustainability of beef enterprises.

Introduction

The beef cattle industry is comprised of seedstock and commercial producers. In general, genetic improvement, or accumulation of breeding value, occurs in the seedstock sector and flows to the commercial industry via the purchase of bulls and/or semen. Less than 10% of producers in the United States utilize artificial insemination (AI). Selection decisions can be made based on a plethora of information, but the most informative are breeding values or expected progeny differences (EPDs) in the US and economic index values. There are several EPD and index values across multiple breeds.

There have also been an increasing number of commercially available genomic tests made available for multiple traits. Some of these have undergone independent validation, while others have not. This technology holds the promise to increase the rate of genetic progress and to allow for selection on those traits that are expensive or challenging to measure routinely. However, there still exist several caveats to solve before this is completely brought to fruition.

Sustainability from a beef perspective will depend on economics and consumer perception. Genetic selection will need to focus on tools that aim solely at the genetic component of phenotypes and tools that apply economic parameters need to be quantified such that a return on investment can be determined. Consumer demand will ultimately be dictated by price and product quality suggesting that efficient genetic selection is needed and that selection tools need to evolve to improve end-product quality.

Structure of the Beef Industry

In other species, such as swine and poultry, the breeding pyramid is much more clearly defined than in

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Breeding in Beef Cattle. Figure 1
The breeding pyramid representing the three broad segments of the beef industry

beef cattle given formalized breeding companies. However, it still exists in beef cattle (Fig. 1) as some purebred producers have a much larger influence over the gene pool of a breed compared to others. At the nucleus level, animals (particularly sires) are produced for use at the multiplier level although some nucleus animals are sold directly to commercial herds. The nucleus herds are the drivers of genetic change. The multiplier herds, as the name implies, multiply genes from the nucleus populations to produce animals for use in the commercial sector. It is possible, and does occur, for animals from multipliers to enter into nucleus herds.

There are four main pathways from which herds can influence the rate and direction of genetic change: producing sires of sires, sires of dams, dams of sires, and dams of dams. The most influential is sires of sires. As an example, Marquez et al. [1] characterized the population structure of the Red Angus breed and found that indeed it could be divided into nucleus and multiplier herds and that only 30% of the total herds produced sires of sires.

Basic Principles of Genetic Improvement

In order to make genetic improvement the target trait (s), observable or measureable characteristics of an animal, must display variation. The goal of genetic improvement is to improve the phenotype, observed category or measured level of performance for a trait, by improving the genotype or genetic makeup of an animal to best fit the system and to make the best product for consumers. The phenotype (P) of an animal is comprised of both genetic (G) and nongenetic factors such as the environment (E) such that

$$P = G + E$$

These two primary factors, G and E, can be further divided into additive (A), dominance (D), and epistatic (I) genetic effects and both permanent (E_P) and temporary (E_T) environmental effects such that

$$P = G_A + G_D + G_I + E_P + E_T$$

Temporary genetic effects can be thought of as differences in feeding regime or climate and are generally accounted for by contemporary groups whereas PE are long lasting changes that influence future performance (i.e., the loss of one-quarter of the udder). Contemporary groups are considered to be a group of animals that have been subjected to the same environmental effects or managed alike such as being born in the same year, season, and herd, being of the same sex, and fed the same diet.

Trait Types

There are two broad categories of traits, simply inherited and polygenic traits. Simple traits are expressed qualitatively, controlled by only one or two genes, and are typically influenced little by environment. In contrast, polygenic traits are controlled by many genes, are greatly influenced by the environment, and are quantitative in nature (i.e., they are expressed numerically or on a continuous scale).

Simple Traits

In beef cattle, the phenotype of horns is controlled by dominance wherein the horned allele is recessive. If a heterozygous male is mated to a heterozygous female the resulting calf has a 25% chance of being

horned and a 75% chance of being polled (absence of horns). This is illustrated in the Punnett Square below where P denotes the polled allele, and p represents the horned allele.

	P	p
P	PP	Pp
p	pP	pp

Black and red coat color is controlled in the same manner where black is dominant to red such that homozygous (BB) and heterozygous (Bb) animals are black and only homozygous animals for the recessive allele (bb) are red.

Similarly, many genetic defects in cattle are also recessive in nature. A list of known genetic defects in beef cattle can be found in Table 1. Use the example of Neuropathic Hydrocephalus (NH), a recessive lethal mutation found in Angus cattle. If a heterozygous bull (Nn) is mated to a homozygous normal female (NN) then the resulting offspring would be 100% normal (i.e., not afflicted) with 50% of them being homozygous and the other 50% heterozygous.

	N	N
N	NN	NN
n	nN	nN

Coat color in shorthorn cattle is controlled by co-dominance. There are three possible phenotypes that can result from the pairing of two alleles, red (R) and white (W). When two R or two W alleles pair together the resulting animals is either red (RR) or white (WW), respectively. However, the heterozygous animals (RW or WR) or an intermediate color, a mixture of both red and white called "roan." The example below illustrates the genotypes and phenotypes that would be expected from the mating of a roan bull to a roan cow. In this example there is a 25% chance the calves will be red, 50% chance they will be roan, and 25% chance the will be white.

	R	W
R	RR	RW
W	WR	WW

Sex-influenced traits have different expressions in different sexes given the same genotype. A classic example of a sex-influenced trait in beef cattle is the presence

Breeding in Beef Cattle. Table 1 Genetic defects currently monitored by US breed associations

Genetic abnormality	Primary breed(s) of incidence	Lethal or nonlethal	Mode of inheritance	DNA test available
Alpha (α)-mannosidosis	Red Angus	Lethal	Simple recessive	Yes
Arthrogryposis multiplex (AM)	Angus and derivatives	Lethal	Simple recessive	Yes
Beta (β)-mannosidosis	Salers	Lethal	Simple recessive	Yes
Fawn calf syndrome (FCS)	Angus	Nonlethal	Simple recessive	Yes
Neuropathic hydrocephalus (NH)	Angus	Lethal	Simple recessive	Yes
Hypotrichosis (hairless calf)	Hereford	Nonlethal	Simple recessive	No
Idiopathic epilepsy	Hereford	Nonlethal	Simple recessive	Yes
Osteopetrosis	Angus and Red Angus	Lethal	Simple recessive	Yes
Protoporphyria	Limousin	Nonlethal	Simple recessive	Yes
Pulmonary hypoplasia and anasarca (PHA)	Maine-Anjou and Shorthorn	Lethal	Simple recessive	Yes
Tibial hemimelia (TH)	Shorthorn and Maine-Anjou	Lethal	Simple recessive	Yes

or absence of scurs. Here the scured allele (Sc) would appear to be dominant in males but recessive in females.

Males	Females
SS = no scurs	SS = no scurs
SSc = scurs	SSc = no scurs
ScSc = scurs	ScSc = scurs

Polygenic Traits

The number of gametes that an individual can produce is equal to 2^n where n is the number of heterozygous loci. The number of possible genotypes that can be produced from any one mating is equal to $3^n \times 2^m$ where n is the number of loci where both parents are heterozygous and m is the number of loci where only one parent is heterozygous. From this, it is obvious that from a single mating there can arise numerous possible genotypes.

	Individual heterozygous at every loci	Both individual heterozygous
Number of genes	Number of gametes	Number of genotypes
1	2 (2^1)	3 (3^1)
2	4 (2^2)	9 (3^2)
10	1,024 (2^{10})	54,049 (3^{10})

Basics of an EPD

A breeding value (BV) is cumulative additive value of an animal. A transmitting ability (TA) is the average of gametes an individual passes to offspring.

$$TA = 1/2BV$$

In beef cattle, a TA is referred to as an expected progeny difference (EPD).

EPDs allow for the comparison of animals within a breed for their genetic potential as parents for a given trait. EPDs have existed in the beef industry for decades and their use has produced intended genetic change in many traits.

Many traits (e.g., weaning weight, yearling weight (YW), ultrasound measurements, etc.) must be recorded within certain age windows (ranges when it is acceptable to measure animals). Animals measured outside of defined age windows will not have their own record incorporated into an EPD calculation. This allows for a fair comparison of animals. Specific age windows can be found on the corresponding breed association Web site. Records are then adjusted to a constant endpoint, most generally age (Table 2).

Breeding in Beef Cattle. Table 2 Beef Improvement Federation (BIF) standard adjustment factors for birth and weaning weight

AOD	Birth weight	Male	Female
2	+8	+60	+54
3	+5	+40	+36
4	+2	+20	+18
5–10	0	0	0
11 and older	+3	+20	+18

Too often, seedstock producers and bull buyers focus on actual weights and ultrasound data when selecting sires. Expected progeny differences provide a measure by which animals within a breed can be compared to one another for their genetic potential as parents for specific traits. EPDs incorporate multiple sources of information, including full pedigree, an animal's own record, and progeny information. As additional sources of information become available, the accuracy of the EPD value increases. Prior to a National Cattle Evaluation (NCE), animals are given interim EPDs. During a genetic evaluation, all pedigree information would be included.

Pedigree estimate:

$$\text{Sire EPD} = 0.20 \quad \text{Dam EPD} = 0.10$$

$$\searrow \qquad \swarrow$$

$$\text{Progeny EPD} = \left(\frac{0.20 + 0.10}{2}\right) = 0.15$$

Pedigree estimate + animal record:

$$EPD_I = (0.5 * \text{EPD}_S) + (0.5 * \text{EPD}_D) + (0.5 * \phi)$$

Where EPD_I is the EPD for some individual I, EDP_S is the EPD for the sire of animal I, EPD_D is the EPD for the dam of animal I, and ϕ is the Mendelian Sampling

effect. The phenomena of Mendelian sampling arises due to the fact that each parent passes a sample half of its alleles to its offspring and every allele has an equal likelihood of being passed on. This effect can be quantified using contemporary group deviations and is a measure of how much better or worse an animal is compared to the average of his parents. One could envision a scenario where an animal could receive only the most desirable alleles from both parents resulting in a favorably large Mendelian sampling effect or the exact opposite which could result in an unfavorably large sampling effect. Perhaps the best example is a set of flush mates. Although all of them have the same pedigree estimate, they differ considerably in terms of performance and consequently their EPD, once they have a record, differ due to Mendelian sampling.

When using EPD it is important to understand that the role of EPD is to provide a measure of comparison within a breed. To compare animals across breeds, estimates from the US Meat Animal Research Center (MARC) can aid in determining differences between EPD of different breeds (Table 3). These across breed adjustment factors, adjusted to an Angus basis, are updated annually and can be found at http://www.beefimprovement.org/proceedings.html.

Example:

If a Hereford bull has a birth weight EPD of 1.5 and a Simmental bull has a birth weight EPD of 1.0 these adjustment factors can be used to approximate what these two bulls birth weight EPD would be on an Angus basis so that they can be compared. On an Angus basis, the Hereford bull would have a birth weight EPD of 4.2 (1.5 + 2.7) and the Simmental bull would have a birth weight EPD of 6.4 (1.0 + 5.4). Therefore, it can be expected in this scenario that the Hereford bull would sire calves that are 2.2 lbs. lighter at birth. This table can be an effective tool to determine differences in weight and milk potential between major US breeds. This information can be used to help determine which breed(s) are better suited to different environments. For instance, in a low input environment, breeds with a negative adjustment factor for milk might be more desirable.

Breeding in Beef Cattle. Table 3 2008 Adjustment factors for comparison of expected progeny difference (EPD) across various breeds

Breed	Birth weight	Weaning weight	Yearling weight	Milk
Angus	0.0	0.0	0.0	0.0
Charolais	9.6	39.0	47.3	2.9
Gelbvieh	4.4	5.0	−22.4	7.0
Hereford	2.7	−2.9	−12.8	−15.3
Limousin	4.0	−3.8	−27.8	−11.9
Red Angus	2.8	−5.2	0.9	−3.9
Simmental	5.4	23.3	16.9	13.9

Breed Average and Percentile Ranks

Table 4 illustrates a percentile rank table. These will be different for every breed and will change yearly with the addition of new animals with performance information recorded. The 50th percentile represents breed average. If an animal is in the top 1% for a given trait then it can be said that 99 animals in a hundred are "worse" for that trait. Conversely, if an animal is in the 95th percentile then it can be said that 94 in 100 animals will be better than him/her for that trait. Knowledge of percentile table gives you an idea of how an individual ranks within a breed for a specific trait or index. However, it may not be beneficial to choose extreme animals. For instance, even though a sire might be in the top 1% of

Breeding in Beef Cattle. Table 4 Percentile rank

Top %	CED	BW	WW	YW	Milk
1	14	−2.5	67	117	34
5	11	−.9	59	105	30
10	10	−.1	55	99	28

EPD Definitions

	BULL A	BULL B
Calving ease direct	10	6
Birth weight	+2.0	+3.5
Weaning weight direct	20	+22
Yearling weight	+40	+52
Yearling height	.3	.6
Milk	+3	−2
Maternal weaning weight	+13	+9
Gestation length	−.1	+1.1
Calving ease maternal	4	6
Mature daughter height	+.5	+1.0
Mature daughter weight	0	+30
Scrotal circumference	+.1	−.45
Heifer pregnancy	6	9
Carcass weight	+2.0	+20
Percent retail cuts	0	+.2
Marbling	0	−.3
Ribeye area	+.06	+1.6
Fat thickness	−.01	−.09
Tenderness	−.1	.1
Days to finish	15	10
Stayability	10	6
Maintenance energy	0	10
Docility	6	2

Calving ease direct – Bull A should have 4% more unassisted births from first-calf heifers than Bull B. While birth weight is an indicator of calving ease, it does not tell the whole story. Calving ease is an economically relevant trait. Producers should not use both birth weight and calving ease EPD together since the birth weight EPD is already used in the calculation of calving ease.

Birth weight – Bull B's calves would be on the average 1.5 lb heavier at birth. Normally, producers should select bulls for use on heifers that are at or less than the breed average for birth weight. Keep in mind that when crossing breeds, heterosis or hybrid vigor can increase birth weights 10–15% over a straight-bred average.

Weaning weight direct – Calves from Bull B should average 2 lb more on adjusted weaning weights because of additional growth. Because of the low accuracy associated with yearling bulls, the amount of emphasis placed on such a small difference should be limited. These EPDs are virtually the same even if the accuracies were high.

Yearling weight – Bull B's calves should average 12 lb heavier at 1 year of age.

Yearling height – Bull B's calves should be 0.3 in. taller on average at a year of age compared to the offspring of Bull A. Height measurements are taken at the hip. Height (the actual measurement and not the EPD), along with age, is used to calculate frame score.

Milk – Daughters from Bull A should produce calves that are 5 lb (the difference between +3 and −2) heavier at weaning. This is not a measure of pounds of milk but rather weaning weight due to milk production. This 5 lb, unlike the weaning weight figure attributed to growth from the bull, is the result of differences in the daughters' milk production and mothering ability. Excessively high milk levels in low input environments should be discriminated against due to increased nutrient requirements of cows.

Total maternal (maternal weaning weight) – Daughters from Bull A will produce calves that are 4 lb heavier at weaning because of their combined genetics for growth and milk. This is a calculated figure of one-half the bull's weaning weight direct EPD plus his milk EPD. For example, Bull A has a maternal weaning weight value of 13 which is equal to half of his weaning weight direct EPD (20/2 = 10) plus his milk EPD [3].

Gestation length – Calves from Bull A should have a 1-day shorter gestation.

Calving ease maternal – Bull B's daughters should calve as first-calf heifers with 2% more unassisted births (6–4) than the daughters of Bull A.

Mature height – Bull B's daughters should be.5 in. taller at maturity.

Mature weight – Bull B's daughters should be 30 lb heavier when mature.

Scrotal circumference – Bull calves from Bull A should have.55 cm larger adjusted scrotal circumferences. Scrotal circumference is an indicator of the age of maturity of a bull's daughters. Bulls with larger scrotal circumference should have daughters that reach puberty earlier.

Heifer pregnancy – Daughters of Bull B are 3% more likely to become pregnant as heifers.

Carcass weight – Bull B should produce calves that have 18 lb more adjusted carcass weight.

Percent retail product – The calves from Bull B should yield 0.2% more closely trimmed, boneless retail cuts from the round, loin, rib, and chuck. Some breeds may report a Yield Grade (YG) EPD. The same factors (back fat, ribeye area, and carcass weight) would be included but a lower YG is more desirable as opposed to percent retail product where a higher value is more desirable. In either percent, retail product or YG fat thickness contributes the most to these two calculations. Consequently, selecting for decreased YG or increased percent retail product will lead to leaner animals so caution should be used to avoid extremely lean replacement females.

Marbling – Calves from Bull A should have a marbling (MARB) score of >0.3. Marbling scores range from 1.0 which is devoid of marbling and a utility quality grade to 10.9 which is abundant marbling and a prime + quality grade. For example, if calves sired by Bull B had a marbling score of 5.0 then calves sired by Bull A are expected to have a marbling score of 5.3. Ultrasound EPDs were calculated for a number of breeds for traits of ribeye area (REA), fat, and intramuscular fat (IMF), which is correlated to marbling, but now the majority of breeds use these ultrasound measurements in the calculation of carcass EPDs. Therefore, instead of seeing both an IMF EPD and a marbling EPD you just see the marbling EPD but it has ultrasound measurements included in the calculation.

Ribeye area – At a given end point, calves from Bull B should have ribeye areas that are 1.54 square inches larger than Bull A's calves.

Fat Thickness – At a given end point, calves from Bull A should be.08 in. fatter when measured at the 12th rib. This would be less desirable on a carcass animal, but extremely lean females going back into a cowherd may also be undesirable.

Tenderness – Calves sired by Bull A should produce meat that is more tender than that of calves sired by Bull B by 0.2 lbs. of shear force. Tenderness is measured by Warner Bratzler Shear Force (WBSF) that is reported in the pounds of force required to cut through a one inch thick piece of meat. A lower value is more desirable.

Days to finish – Calves sired by Bull B should spend 5 fewer days on feed to reach a constant fat endpoint.

Stayability – A measure of reproductive longevity. Daughters of Bull A are 4% more likely to stay productive in the herd to age 6.

Maintenance energy – The Red Angus Association of America calculates a Maintenance Energy (ME) Expected Progeny Difference (EPD) that indicates differences in the Mcal/month needed for maintenance due to mature size (corrected for body condition score) and milking ability (The Rancher's Guide to EPD available at www.redangus.org). A much simpler way to think of it is that a bull with a ME EPD of +10 compared to one that is +0 will produce daughters that will require approximately 11 more pounds of average quality forage per month (assuming average quality forage =.86 Mcal/lb.).

Docility – Bull A should sire 4% more calves that have a temperament in the most docile score than Bull B. The actual measurement of docility is recorded either at weaning or at yearling (depending on the breed association) and is categorized as the animals' behavior as they enter, are restrained in, and exit the chute.

Beef Improvement Federation (BIF) temperament scoring system.

1. Docile – Mild disposition – gentle and easily handled. Stands and moves slowly during processing, undisturbed, settled, and somewhat dull and does not pull on the headgate when in the chute – exits the chute calmly.
2. Restless – Quieter than average but slightly restless, might be stubborn during processing, might try to back from the chute, pulls back on the headgate, some tail flicking, exits the chute promptly.
3. Nervous – Typical temperament – manageable but nervous and impatient with a moderate amount of struggling, movement, and tail flicking as well as repeated pushing and pulling on the headgate – exits the chute briskly.

4. Flighty – Wild, jumpy and out-of-control, quivers and struggles violently, might bellow and froth at the mouth, continuous tail flicking, defecates and urinates during processing, frantically runs the fence line and might jump when penned individually, exhibits long flight distance, and exits the chute nervously.
5. Aggressive – Similar to Score 4 but with added aggressive behavior, fearful, extreme agitation, continuous movement that might include jumping and bellowing while in the chute, exits the chute frantically, and might exhibit attack behavior when handled alone.
6. Very Aggressive – Extremely aggressive temperament. Thrashes about or attacks wildly when confined in small, tight places. Pronounced attack behavior.

Breeding in Beef Cattle. Table 5 Approximate number of progeny needed to reach accuracy levels (true (r) and the Beef Improvement Federation standard) for three heritabilities (h^2)

Accuracy		Heritability levels		
R	BIF	h^2 (0.1)	H^2 (0.3)	h^2 (0.5)
0.1	0.01	1	1	1
0.2	0.02	2	1	1
0.3	0.05	4	2	1
0.4	0.08	8	3	2
0.5	0.13	13	5	3
0.6	0.2	22	7	4
0.7	0.29	38	12	7
0.8	0.4	70	22	13
0.9	0.56	167	53	30
0.999	0.99	3,800	1,225	700

Accuracy

The uncertainty surrounding early predictions of genetic merit are a result of Mendelian sampling. Every animal is passed a random sample of alleles from each parent, half coming from the dam and half from the sire. An estimate of the average effect of what was passed from parent(s) to offspring in the form of pedigree estimates can be calculated, but the certainty of how correct this estimate is (i.e., the accuracy) is low. As more information is collected, such as an individual's own record and data from progeny, accuracy increases. For lowly heritable traits, like measures of reproduction, it can take a considerable number of offspring to reach high BIF accuracy levels, given that the BIF scale is more conservative than true accuracy (r) as illustrated in Table 5. To calculate r in the context of progeny test sires the following equation can be used where n is the number of progeny:

$$r = \sqrt{\frac{nh^2}{4 + (n-1)h^2}}$$

To convert BIF accuracy to true accuracy (r) the following equation can be used:

$$r = \sqrt{1 - (1 - \text{BIF})^2}$$

Theoretically, accuracy is the correlation between an animal's predicted EPD and its true EPD. However, it is much simpler to think of it as a measure of risk indicating how much an animal's EPD may change with the inclusion of additional information. Accuracy is not an indication of how variable a particular sire's calves will be but rather how the estimate of an animal's EPD is likely to change. As the accuracy value increases, the amount by which an EPD is likely to change decreases. Possible change values differ for every trait and for every breed (e.g., an Angus bull with an accuracy of 0.30 may have a different possible change value than a Limousin bull with the same accuracy value for the same trait). Possible change tables are available on breed association Web sites.

Example: Possible Change in the Marbling EPD of a Limousin Sire

Assume that a young Limousin sire has a marbling EPD of 0.10 with an accuracy of 0.20. Using the values in Table 6, it is expected that 2/3 of the time his true EPD would fall within +/− 0.20 (one standard deviation) of his printed EPD or between −0.10 and 0.30. If there is 2 in 3 chance that the true EPD is between −0.10 and 0.30 then there must be 1 in 6 chance that his true EPD is below −0.10 and a 1 in 6 chance that his true EPD is above 0.30.

Breeding in Beef Cattle. Table 6 Accuracy related to possible change in Limousin cattle

BIF accuracy	Ribeye area EPD possible change	Marbling score EPD possible change
0.0	0.46	0.24
0.1	0.41	0.22
0.2	0.37	0.20
0.3	0.32	0.17
0.4	0.28	0.14
0.5	0.23	0.12
0.6	0.18	0.10
0.7	0.14	0.07
0.8	0.09	0.05
0.9	0.05	0.02

Multiple-Trait Selection

Through genetic correlations, selection for one trait can influence other traits. This knowledge is useful when practicing multiple-trait selection. There are three primary methods of multiple-trait selection: tandem selection, independent culling levels (ICLs), and selection indexes.

Tandem selection. Tandem selection is the process of placing selection pressure on one trait and once the desired level of the trait under selection has been reached. Then selection for a new trait would begin. This is the simplest form of multiple-trait selection and the most inefficient. The two (or more) traits involved are selected for independently such that progress made in one trait could be eroded once selection for another trait becomes the focus of the breeding scheme. This is the poorest way to select for multiple traits.

Independent culling levels. Independent culling levels (ICLs) describe the process where threshold criteria for multiple traits are set and any animal not meeting all criteria (threshold levels for all traits) are excluded as candidates for selection. Although this ensures a certain level of superiority across multiple traits it may cull a particular animal that is just below the threshold level for one trait.

Economic Index

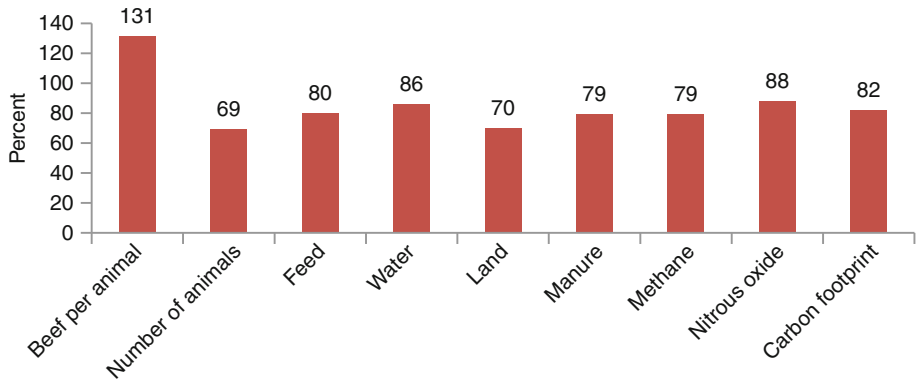
An economic index is a collection of EPDs that are weighted by their economic value such that traits with a greater impact on a production goal have a larger economic weight associated with them. Assume that there is an index centered on improving profit potential of terminal animals sold on a grid. In this particular index, the traits of economic importance might be yearling weight (YW), ribeye area (REA), marbling (MARB), and external fat (BF). Below is an example of how this index might look.

$$I = EPD_{YW} \times a_{YW} + EPD_{REA} \times a_{REA} + EPD_{MARB} \times a_{MARB} + EPD_{BF} \times a_{BF}$$

Where I is the index value, EPD_{YW} is the animal's EPD for yearling weight, and a_{YW} is the economic weight associated with trait yearling weight. The same approach is used for the other traits in this index, MARB and BF, where the animal's EPDs for these traits are multiplied by an economic weight. The economic weights are derived by computer simulation work to determine the economic value of changing particular traits.

Several breeds publish economic indexes including Angus, Hereford, Gelbvieh, Charolais, Simmental, and Limousin. Each index has an intended purpose and is catered toward particular breeding objectives.

An addition the breeding objective of beef cattle in the future will likely be some measure of environmental impact, such as green house gas (GHG) emissions. There are conflicting estimates of how much beef cattle production contributes to worldwide GHG production, but there are convincing estimates that suggest that per unit of product, beef cattle production is more environmentally friendly now that at any time point in the past despite decades of artificial selection to increase output. Figure 2 illustrates that in 30 years, from 1977 to 2007, beef production has increased while the number of cows has decreased. During the same three decades, the resources needed for beef production (land, water, feed) decreased along with gas emissions and the carbon footprint [3].



Breeding in Beef Cattle. Figure 2
Changes in metrics of beef production from 1997 to 2007 in the United States

Breed Selection

Correct breed selection is the critical first step to initializing a crossbreeding system. Choosing a breed(s) is dependent upon:

1. Production and marketing goals
2. Production environment
3. Available feed and labor resource

Choosing a breed that is best suited to your production environment is dependent on several factors including the availability of feed, and level of stress (temperature, amount of moisture, etc.). Table 7 outlines the biological type of cattle that are best suited for particular levels of feed resources and stress.

The decision of whether or not to utilize a particular strategic system of crossbreeding depends upon individual production goals. In order to take advantage of breed complementarity, breeds must be paired such that they excel in different areas that are critical to the overall production goal(s). For instance, if the goal were to sell calves at weaning then it would make sense to use a breed, most likely Continental, which will maximize direct weaning weights. However, this purebred system will maximize outputs, but may require large inputs as well. With that in mind, perhaps it would make more sense from an economic perspective to use a British breed as the genetic base for all dams and use a continental breed for sires thus minimizing the input costs from the female side yet still capturing added growth in the calves due to the direct growth provided by the sire breed. This would be a very simple example of a crossbreeding system.

Matching Biological Type to Environment

Benefits of heterosis make it important for producers to have a crossbreeding program. It is just as important that the producer match the type of crossbred cow to the environment and management system. This can be viewed as the foundation of a crossbreeding program. If the biological type does not match the resources, the system will fail, regardless how perfect the end product may be.

Cow weight is probably easier to understand than milk production, but research has shown that cows with the genetic propensity to milk heavily require more nutrients year round, not just when they are milking. The National Research Council (NRC) data shows that a cow producing 25 lbs. of milk at peak lactation requires 10% more feed energy than a cow producing 15 lbs. of milk at peak lactation. To see a 10% difference in feed energy with regards to mature weight it would require moving from a 1,000 lb. cow to a 1,200 lb. cow, or a change of 200 lbs. of body weight. There are breed differences in lactation yields so breed selection is critical when matching genetics to your environment. These breed differences can be found in literature from research at the Meat Animal Research Center (MARC). Moderating mature cow size and selecting for an optimal window of milk production is beneficial when it comes to cutting costs regardless of

Breeding in Beef Cattle. Table 7 Matching genetic potential for different traits to production environments

Production environment			Traits

[d]*L* low, *M* medium, *H* High

your production environment. However, in limited feed environments females with high maintenance energy requirements may also have difficulty maintaining an acceptable body condition score and rebreeding. Nugent et al. [5] determined that with limited nutrient availability, breeds with a high genetic potential for milk production had longer anestrous periods which lead to lower conception rates during a fixed breeding season. Other researchers have concluded that selection for increased milk production past an adequate threshold is not economically or biologically efficient [6]. It can be challenging to determine if cows within a herd have too much milking potential. Other than knowledge of the genetics of sires used in the past, it is important to note the body condition score of females. Extremely thin females fed the same as those with an acceptable body condition score may produce too much milk for their environment. If a producer is constantly supplementing females to maintain body condition to ensure they will successfully breed back, this might be an indication that bulls you buy in the future should have a more moderate value of milk genetics.

Another critical aspect of fitting genetics to the production environment is regional adaptation. If natural selection is allowed to play a large role in selecting the parents for the next generation, indigenous breeds should be well suited to their production environment. An example of an indigenous breed that has thrived in number is the Nelore breed in Brazil. The Nelore breed makes up roughly 65% of the world's bovine population and is well suited to tropical conditions. With adaptation in mind, indigenous breeds can be used as the base and exotic (foreign) breeds used in strategic crossbreeding systems to change target traits such as growth or carcass attributes. A case study [7] in Zimbabwe compared indigenous breeds of Afrikaner (a breed developed in South Africa), Tuli, Nkone, and Mashona, to breeds developed outside of the African Continent such as Brahman, Charolais, Hereford, Simmental, Aberdeen Angus, and Sussex. The results showed that indigenous breeds excelled in fitness traits (fertility and survivability) while the foreign breeds excelled in growth, feed conversion, and carcass attributes.

Crossbreeding

Heterosis

Too often heterosis (hybrid vigor) is thought to be the exclusive goal of crossbreeding. Heterosis is nothing more than an unexpected and often beneficial deviation from the average of the two parental lines. Hybrid vigor can also be thought of as the

"anti-inbreeding." Inbreeding increases uniformity by increasing homozygosity but also creates "inbreeding depression" or a general decrease in survival and reproductive traits that can be caused by a decrease in heterozygosity. Percent heterosis can be calculated as:

$$\%\,\text{Heterosis} = \left[\frac{(\text{crossbred average} - \text{straightbred average})}{\text{straight bredaverage}}\right] \text{x}100$$

A simple example would be the percent heterosis realized in the average weaning weight from breeding a herd of Breed A cows to a group of Breed B bulls. Let 525 lb be the average weaning weight of the F1 calves, 450 lb be the average weaning weight of the Breed A population, and 550 lb be the average weaning weight of the sire's population.

The pounds of heterosis would be:

$$\text{Pounds of heterosis} = 525 - \left[\frac{(450 + 550)}{2}\right] = 25\ \textit{pounds}$$

and the percent of heterosis would be:

$$\%\ \text{heterosis} = \frac{25}{[(450 + 550)/2]} = .05\ \text{or}\ 5\%$$

The amount of heterosis that is realized for a particular trait is inversely related to the heritability of the trait. This is logical since traits that are lowly heritable have a small additive component (proportionally speaking) and crossbreeding takes advantage of dominance and epistatic effects. With that in mind, traits of low heritability (e.g., reproductive traits) generally benefit from heterosis the most (Table 8). They generally have a heritability of less than 10% and can be improved through the adequate use of crossbreeding systems. End-product traits on the other hand that benefit from heritability in the moderate to high range benefit less from heterosis. Another benefit of crossbreeding may be a decrease in methane production per unit of beef produced. In a comparison of the methane production per ton of live weight weaned from a 16,000 ha farm in Australia, changing from Shorthorns (mean cow weight 422 kg) to composite breed cattle in (mean cow weight 507 kg), reduced methane production per ton of weight weaned by 31%. This was largely due to higher weaning rates of composite breed females (80 vs 55%) [8].

Breeding in Beef Cattle. Table 8 Individual heterosis: advantage of the crossbred calf

Trait	Observed improvement	% Heterosis
Calving rate	3.2	4.4
Survival to weaning	1.4	1.9
Birth weight	1.7	2.4
Weaning weight	16.3	3.9
ADG	0.08	2.6
Yearling weight	29.1	3.8

Source: Adapted from Cundiff and Gregory [9]

There are three main types of heterosis:

1. Individual
2. Maternal
3. Paternal

Retained Heterosis Unfortunately there exists a popular misconception that heterosis exists only in the first generation of crossbreds (F1). Heterosis is *retained* in the breeding of crossbred animals and is related to the probability of alleles from different parental lines joining together. For instance, if two F1 animals are mated, heterosis in the corresponding offspring is called *retained heterosis* and is equal to the following:

$$\text{Heterosis retained} = 1 - [(P_{S1}P_{D1}) + \ldots + (P_{Sn}P_{Dn})]$$

Where P_{S1} is the proportion of the sire from breed 1 and P_{D1} is the proportion of the time from breed 1 and n is equal to the total number of breed involved.

Maternal Heterosis The offspring of an F1 female will benefit from maternal heterosis (Table 9), thought of as realized heterosis of milk production.

Paternal Heterosis Fewer examples of paternal heterosis exist and consequently crossbred sires have often been ignored. The benefit of crossbred or composite

Breeding in Beef Cattle. Table 9 Maternal heterosis: Advantage of the crossbred cow

Trait	Observed improvement	% Heterosis
Calving rate	3.5	3.7
Survival to weaning	0.8	1.5
Birth weight	1.6	1.8
Weaning weight	18.0	3.9
Longevity	1.36	16.2
Cow lifetime production		
No. Calves	0.97	17.0
Cumulative weaning weight, lb.	600	25.3

Source: Adapted from Cundiff and Gregory [9]

sires lies in their ability to inject heterosis and breed complementarity into a herd with greater ease than the rotational crossbreeding systems described above.

Composites

Some of the first such animals are the American Breeds, or Brahman Derivatives. Perhaps there is no greater example of breed complementarity (breeding animals to adapt to a specific environment) and consequently of heterosis.

The American Gelbvieh Association, North American Limousin Foundation, and American Simmental Association are three breed associations that have implemented new programs to introduce composites such as the Balancer, Lim-Flex, and SimAngus, respectively. There is no doubt that some of these programs have met with opposition from within the respective associations due to an ignorant stance that purebred animals are superior. I greatly admire those who have pushed, pulled, and prodded these programs through.

Crossbred females have proven to be very profitable and well accepted from a commercial standpoint. The use of crossbred bulls has not been accepted so easily. Some common fears have been the perception of larger amounts of variation within composite populations and the lower accuracy of EPDs of composite animals. In a study of three composite lines at MARC and their parental purebreds, there were no statistical significant differences in the coefficient of variation for reproduction, production, or carcass traits measured (Table 10).

Breeding in Beef Cattle. Table 10 Coefficients of variation for purebred versus composite steers

Trait	Purebreds	Composites
Birth weight	0.12	0.13
Wean weight	0.10	0.11
Carcass weight	0.08	0.09
Retail product %	0.04	0.06
Marbling	0.27	0.29
Shear force	0.22	0.21

Source: Adapted from [10]

Breed Complementarity

In addition to heterosis, crossbreeding programs can increase production efficiency by using additive (highly heritable) traits through *complementarity*. Differing breeds can be matched to complement traits, more closely fitting the genetic goals for biological type.

Complementarity is fully exploited under a system when crossbred cows of lower frame size, and optimum milk are crossed with a large framed terminal breed, noted for rapid growth and carcass leanness in order to produce market animals [11].

Simulation work by Lamb et al. [12] shows that generally English breeds are more biologically efficient, while Continental breeds are more economically efficient. The English X Continental cross was the most biologically and economically efficient. In some environments, heat and disease tolerance of the Brahman (*Bos Indicus*) may be required to complement the carcass traits, disposition, and age at puberty of an English breed [13].

Crossbreeding Systems

There are many other crossbreeding systems that vary significantly in terms of difficulty. Items that

can influence the success of a crossbreeding system include:

1. Number of cows in the herd
2. Number of available breeding pastures
3. Labor and management
4. Production and marketing system
5. Availability of high-quality bulls of the various breeds

Terminal Cross All offspring from a terminal cross are sold. The sire used is usually from a breed noted for high growth, and desirable carcass end product. Under this system, genetic differences between maternal and terminal breeds can be exploited through complementarity. Individual heterosis is improved an additional 5% from this type of cross [11]. If female replacements are not generated, little emphasis needs to be placed upon milking genetics of the sires used. By purchasing crossbred F1 females, maximum maternal heterosis can also be achieved.

Two-Breed Terminal In this simple situation, cows of breed A are bred to bulls of breed B and all offspring are sold. In this system, the offspring are F1s and will benefit from 100% of the possible individual heterosis.

Three-Breed Terminal In this situation, cows that are F1 females comprised of ½ breed A and ½ breed B are mated to bulls of breed C for the production of terminal offspring. In this system, calves not only benefit from 100% of the possible individual heterosis, but maternal heterosis is realized as well. In general, the females should be a cross of two maternal breeds that emphasize efficiency and milking ability while the sire breed should inject growth.

Rotational Systems The three-breed rotation is similar to the two-breed rotation. A third breed is added to this system, thus a third breeding pasture is needed, unless AI is utilized. Management of this system is patterned after the two-breed rotation. If the maximum amount of heterosis is 23.3% (14.8% + 8.5%) then the expected level of heterosis is higher with a three-breed than two-breed rotation, 86% versus 67% [14].

Two-Breed Rotation A two-breed rotation is a simple crossbreeding system requiring two breeds and two breeding pastures. The two-breed rotational crossbreeding system is initiated by breeding cows of breed A to bulls of breed B. The resulting progeny (A*B) chosen as replacement females would then be mated to bulls of breed A for the duration of their lifetime. The service sire is the opposite breed of the female's own sire. These progeny are then one-quarter breed A and three-quarters breed B. Since these animals were sired by breed B bulls, they are mated to breed A bulls. Each succeeding generation of replacement females is mated to the opposite breed of their sire. Initially only one breed of sire is required. Following the second year of mating, two breeds of sire are required. After several generations, the amount of retained heterosis stabilizes at about 67% of the maximum heterosis, resulting in an expected 16% increase in the pounds of calf weaning weight per cow exposed above the average of the parent breeds [14]. In this system, a minimum of two breeding pastures and 50 cow units are required.

Three-Breed Rotation A three-breed rotational system achieves a higher level of retained heterosis than a two-breed rotational crossbreeding system does. After several generations, the amount of retained heterosis stabilizes at about 86% of the maximum heterosis, resulting in an expected 20% increase in the pounds of calf weaning weight per cow exposed above the average of the parent breeds [14]. Like the two-breed system, distinct groups of cows are formed and mated to bulls of the breed that represents the smallest fraction of the cows breed makeup. A cow will only be mated to a single breed of bull for her lifetime.

A minimum of three breeding pastures is required for a three-breed rotational system. Replacement females must be identified by breed of sire to ensure proper matings. The minimum herd size is approximately 75 cows with each one-third being serviced by one bull of each breed. Scaling of herd size should be done in approximately 75 cow units to make the best use of service sires, assuming one bull per 25 cows. Replacement females are mated to herd bulls in this system, so extra caution is merited in sire selection for calving ease to minimize calving difficulty. The progeny produced from these matings that do not conform to the breed type of the herd should all be marketed.

Breeding in Beef Cattle. Table 11 Summary of crossbreeding systems by advantage and other factors

Type of system		Advantage[a]	Retained heterosis[b]	Minimum no. of breeding pastures	Minimum herd size	No. of breeds
2-breed rotation	A*B rotation	16	67	2	50	2
3-breed rotation	A*B*C rotation	20	86	3	75	3
Terminal cross with straightbred females[c]	T*A	8.5	0	1	Any	2
Terminal cross with purchased F1 females	T*(A*B)	24	100	1	Any	3
Rotating unrelated F1 bulls	A*B x A*B	12	50	1	Any	2
	A*B x A*C	16	67	1	Any	3
	A*B x C*D	19	83	1	Any	4

[a]Measured in percentage increase in lb of calf weaned per cow exposed
[b]Relative to F1 with 100% heterosis
[c]Cundiff and Gregory [15]

Breeds used in rotational systems should be of similar biological type to avoid large swings in progeny phenotype due to changes in breed composition. The breeds included have similar genetic potential for calving ease, mature weight and frame size, and lactation potential to prevent excessive variation in nutrient and management requirements of the herd.

When choosing a crossbreeding system it is critical to consider more than the amount of heterosis retained. After all, each system requires different levels of input (pastures, etc.) and differing levels of difficulty. Table 11 describes the advantages and requirements for the above mentioned crossbreeding systems.

Molecular Information

Molecular Information: Paternity and Simply Inherited Traits

Molecular-based tools are another source of information that has received considerable attention by producers throughout the beef industry and by both the academic community and the private sector. These tools initially came in the form of candidate genes but have now grown to the inclusion of multiple markers called Single Nucleotide Polymorphisms (SNPs). The use of molecular information has grown from simple applications such as identifying animals that are carriers of the red allele to identifying animals that are carriers of lethal genetic defects, to paternity assignment, and a growing number of diagnostic tests for a suite of complex traits ranging from reproduction to carcass.

Genotyping to determine parentage allows for a sire to be correctly linked to a corresponding calf. The identification of an animal's sire via DNA marker technology can be advantageous in multi-sire breeding pastures, or for ascertaining if a calf is the product of an artificial insemination (AI) mating or a clean-up bull. This promotes knowledgeable culling and breeding decisions by determining which sire(s) are contributing the most (or least) to a particular breeding objective. In the case of commercial ranch settings, for example, it may be beneficial to determine the sire that is responsible for calving difficulties.

Because paternity identification is a process of excluding potential sires on the basis of their genotype, it is important that DNA from all possible sires be included in paternity tests. It will be more difficult to definitively make paternity assignments on closely related bulls in a multiple-sire breeding pasture, given they are likely to share a similar genotype. Although microsatellites have typically been the marker of choice for paternity analysis, the use of SNP markers is becoming more common for a number of reasons including

their abundance, high potential for automation, low genotyping error rates, and ease of standardization between laboratories.

Although identifying carriers of genetic defects is a rather simple application of DNA technology, it is an important tool when making mating decisions. It is known that afflicted animals can only arise if two carrier animals are mated. In this scenario, there exists a 25% chance that the corresponding calf will have the defect. Unfortunately, this added information has been used as the primary selection tool whereby carrier animals are automatically discarded. If a producer potentially has carrier females, then carrier bulls should be avoided. However, if this is not the case, then it could be beneficial to use the best available bull, regardless of his status as a carrier. As an industry, there is the ability to make informed decisions based on science concerning this issue and not throw away animals that are superior across the remainder of their genome because they have a flaw that can be effectively managed around.

Molecular Information: Complex Traits

Several advancements in molecular technology have occurred with regard to complex traits (i.e., production, carcass, and reproduction traits). Including the number of markers included in a given panel, reporting styles of the results, and the number of traits for which a diagnostic test exists. Recently, this information is included in the Angus National Cattle Evaluation (NCE) for the first time.

The promise of the inclusion of marker information into EPD calculations holds three primary benefits:

1. Increased accuracy for young animals (i.e., yearling bulls), which is particularly beneficial when selecting on traits that are measured late in life (e.g., stayability)
2. Shortened generation intervals
3. EPD values for novel traits (i.e., efficiency, end-product healthfulness, disease susceptibility) that may have, at best, sparse collection of phenotypes

However, the magnitude of these benefits will depend on the proportion of variation explained by a given marker panel. At present, the best objective source of information regarding this is the National Beef Cattle Evaluation Consortium (NBCEC) Web site (www.nbcec.org). Pertinent information from this Web site includes population, trait, regression coefficient (b), and the p-value (p). The population defines what breed(s) were used to validate the test. If the test was validated in *Bos taurus* animals then it is possible that the test will not explain the same proportion of variation in *Bos indicus* animals. The trait defines what the test was validated for. If it is a metric of efficiency like residual feed intake (RFI) then it will explain how the trait is defined. Generally, a p-value of less than 0.05 suggests that the test is a statistically significant predictor of differences in phenotypes. The regression coefficient is equal to the regression of phenotypes for the trait of interest on the molecular score. It explains the units of change in the phenotype that would be expected for a one-unit change in the molecular score (i.e., MBV). Ideally, these b values should be 1. For example, if two animals have molecular scores for RFI of −1.5 and 1.0, respectfully, the difference between those scores is 2.5. Normally it is expected that, on average, these two animals' phenotypes would differ by 2.5 lb of RFI. However, if the regression coefficient is 0.4 then their phenotypes are expected to differ by 1 lb (2.5*0.4).

Without the seamless integration of this technology into EPD calculations, the industry is faced with two disjoined pieces of information: traditional EPD and marker panel results. In this scenario, it is impossible to directly compare EPD to marker panel results even if the results come in the form of molecular breeding values (MBVs). This is because the molecular scores only explain a portion of the additive genetic variation. Further, some of the marker panel results have a metric of accuracy associated with them. At the current time, this metric is not comparable to the Beef Improvement Federation accuracy value associated with EPD simply due to differences in the way they are computed. While it is logical that the accuracy value of a MBV should be related to the proportion of additive genetic variation explained by the test there is not a standardized metric that is being used. Thallman et al. [16] analyzed different methods of calculating this proportion for MBV in light of the fact that there is not a standardized method and recommended the use

of the square of the additive genetic correlation between the MBV and the trait of interest.

In contrast to the thought process of DNA marker panel results being a separate and disjoined piece of information, these test results should be thought of as a potentially useful indicator that is correlated to the trait of interest. As such, the MBV can be included in NCE as a correlated trait following methods of Kachman [17]. Other methods have been proposed including using large (50,000 +) SNP panels to form a genomic relationship matrix that could allow for known relationships between animals based on genotypes across SNP loci. Combining these sources of information, molecular tools and traditional EPDs, has the potential to allow for the benefits of increased accuracy and increased rate of genetic change as discussed earlier.

MacNeil et al. [18] utilized Angus field data to look at the potential benefits of including both ultrasound records and MBVs for marbling as correlated traits in the evaluation of carcass marbling score. MacNeil and colleagues used a 114 SNP marker panel that was developed using 445 Angus animals and calculated to have a genetic correlation (r) of 0.37 with marbling (i.e., the test explained $(0.37)^2 = 0.137$, or 13.7%, of the additive genetic variation). For animals with no ultrasound record or progeny data, the marker information improved the BIF accuracy of the Angus marbling EPD from 0.07 to 0.13. Assuming a heritability of 0.3 for marbling, a BIF accuracy of 0.13 is equivalent to having approximately 5 progeny carcass records on a young animal or an ultrasound record on the individual itself. In this particular study, both ultrasound records and MBV were found to be beneficial indicators of carcass marbling. The genetic correlation between MBV and ultrasound was found to be 0.80. Some breeds have begun to integrate this technology and it is likely that more will do so in the future.

Considerations

Current marker panels are likely to work best in the populations where discovery occurred, but will potentially decrease in predictive power as the target population becomes more genetically distant from the discovery population [19]. Below is an example of scenarios where the discovery population is close to the target population and progresses to more distant populations.

Discovery	Target	
Angus	Angus	Closest relationship
Angus	Charolais	
Angus	*Bos indicus*	Most distant relationship

Marker panels are likely to become larger in the future with the possibility of whole genome selection (WGS). Currently, genome selection in beef cattle is in its infancy. Although preliminary data from the dairy industry look promising [20], the structure of the beef industry offers unique challenges. It is not known how well this approach will work in beef cattle with its diversity of breeds, diverse sector-specific selection goals, and less extensive phenotype and data collection resources.

Future Directions

Undoubtedly, molecular discoveries and their seamless integration into existing infrastructures and genetic selection tools will aid in the increased rate of genetic change and hopefully profitability of producers. These molecular tools will be in the form of larger (770 K) SNP panels and genome sequences. At the same time, a suite of reduced marker panels will be commercialized for use on progeny while the larger panels are used for herd bulls. These molecular tools will be integrated into breeding value estimations allowing for higher accuracy values on younger animals and allowing for genetic predictions of traits that have not yet been exploited such as the nutrient content of beef, feed efficiency, and susceptibility to disease. Effort will also be placed on precision mating, or specific combining ability, when developing composite animals, aided by molecular technology. One final area of effort includes the robustness of marker effects across breeds and environments, and how to accommodate these differences in national cattle evaluations. All of this has the potential to allow for selection on total profitability and not just production, ultimately aiding in the sustainability of the beef industry worldwide.

Article Outline

Glossary

Fitness A measure of the ability of an organism to survive and reproduce in a particular environment.

Genetic resource Genetic material of plants or animals of value as a resource for future generations of humanity.

Genomics The study of the genomes of organisms, including intensive efforts to determine the entire DNA sequence of organisms as well as fine-scale genetic mapping.

Phenotype The appearance of an organism based on an interactive combination of genetic traits and environmental factors.

Selection Choosing organisms with desirable genetic characteristics for propagation from candidates available.

Sustainability The capacity to endure, that is, the ability of biological systems to remain diverse and productive over time.

Definition of the Subject and Its Importance

Species breeding has led to marked genetic improvement of production by livestock in the developed world over the past decades. Selection has been so successful that the emphasis in the breeding objective has been changed to welfare, behavior, and other consumer-orientated objectives. The same level of progress has not been achieved in the developing world. Current and projected future population growth requires that food production from farm animals in these regions be improved markedly from the present inadequate levels. Limitations in the institutional infrastructure and the unique challenges of livestock production in the emerging world and the tropics were discussed in detail. This led to recommendations on how these challenges can be overcome and how "new" issues like global warming and animal welfare should be handled in a sustainable manner. Focus should be on the phenotyping of individuals for production and particularly for traits associated with fitness. Data should be linked to pedigree information where possible, to generate a broad-based institutional environment where the genetic improvement of animals in the developing countries can be strived for. Samples for the acquisition of DNA should be obtained from phenotyped individuals, for possible later genomic studies. Continued further learning and the accrual of information as well as collaboration to mutual benefit across institutional and national boundaries are needed to enable this. Sustainable livestock improvement in the developing world could accrue if these prerequisites are met.

Introduction

It is fair to say that the past decades have been marked by rapid change. Mankind had to adapt to immense technological progress, rapid urbanization, instability on monetary markets, as well as becoming part of the global village. The changes listed above are by no means exhaustive and many other challenges to the current generation can also be noted.

Yet it is important to note that there is still immense poverty in parts of the world, despite groundbreaking scientific breakthroughs as well as rapid progress in communication systems allowing easy access to the information that are generated elsewhere in the global

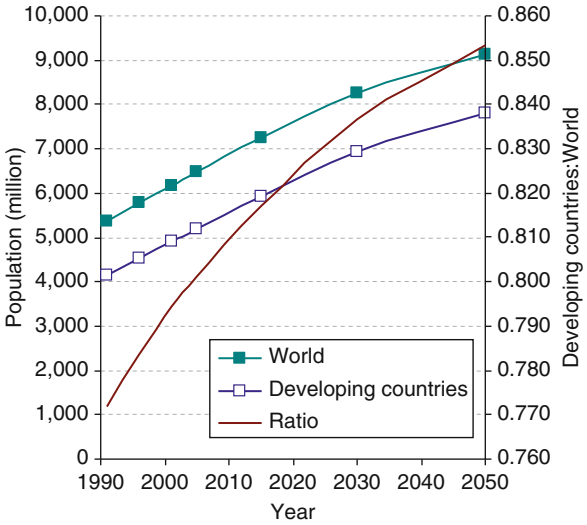
village. While the developed world appears to be going from strength to strength in the acquisition and application of knowledge, the developing countries are lagging behind. In the Millennium Development Goals Report [1], Kofi Annan (the then secretary general of the United Nations) stated: "We will not enjoy development without security, we will not enjoy security without development, and we will not allow either without respect for human rights. Unless all these causes are advanced, none will succeed."

As a point of departure it has to be observed that the fundamental human rights of millions of people in the developing world are closely interwoven with livestock and the meat, milk, or fiber they produce [2–5]. The livestock industry is inextricably linked with the eradication of extreme poverty and hunger (Goal 1) and the ensuring of environmental sustainability (Goal 7) [1]. Improved and sustainable levels of animal production could not only contribute to improved household food security, but also to an increased household income in the developing world. This could lead to spinoffs indirectly benefitting other millennium development goals, such as the achievement of universal primary education (Goal 2), the reduction of infant mortality (Goal 4), and an improved maternal health (Goal 5). The benefits of including meat in diets of vulnerable groups are becoming evident now [6, 7].

During an exercise where livestock and poverty in the developing world were mapped by Thornton et al. [4] it became evident that large areas of the developing countries are only fit for rangeland-based livestock production. Considerable other areas are also utilized by livestock in combination with cropping in rainfed or irrigated mixed production systems. Ruminant livestock strongly depends on crop residues and the intercrops planted in the ley-farming systems which are preferred at present [8].

Against this background, it is reasonable to assess the contribution of livestock breeding to the sustainability of livestock production systems. This topic is addressed by providing background information leading to thoughts on global food security, information pertaining to farm animal genetic resources and livestock products contributing to food security, and external and internal challenges, the advent of the technological age and challenges stemming from it. These topics culminate in proposed future directions to place sustainable farm animal breeding in the developing world and the tropics on a solid foundation, before some concluding remarks.



Breeding in Developing Countries and Tropics. Figure 1 The population growth of the developing countries relative to the entire human population of the world from 1990–1992 to 2004–2006, and extrapolated beyond that to 2050. The human population in the developing countries is also expressed as a ratio of the world population (Source: FAO [9])

Setting the Scene

World Population

The world population grew steadily from 1990–1992 to 2004–2006 (Fig. 1). Extrapolation beyond the data to 2050 suggests sustained population growth from 5,358 million people in 1990–1992 to 9,136 million people in 2050, an increase of 71%. In the case of the developing world, this increase amounts to 89%, from 4,135 million people in 1990–1992 to 7,797 million people in 2050. Expressed as a ratio, 0.77 of people were living in the developing world in 1990–1992, compared to an estimated 0.85 in 2050. The impact of this change of population structure on the available resources in terms of plant and animal production is evident.

Global Food Production

Given the increase in the global population and the even faster population growth in the developing

Breeding in Developing Countries and Tropics. Table 1
Per capita production of grain and animal products (meat, milk, and eggs) in developing and developed countries during 1995, 2000, and 2005

Product type and regions	Year		
	1995	2000	2005
Grains			
Developing regions	281.9	275.4	286.0
Developed regions	563.1	582.8	611.3
Livestock products			
Developing regions	90.4	95.0	107.4
Developed regions	293.4	306.5	308.2

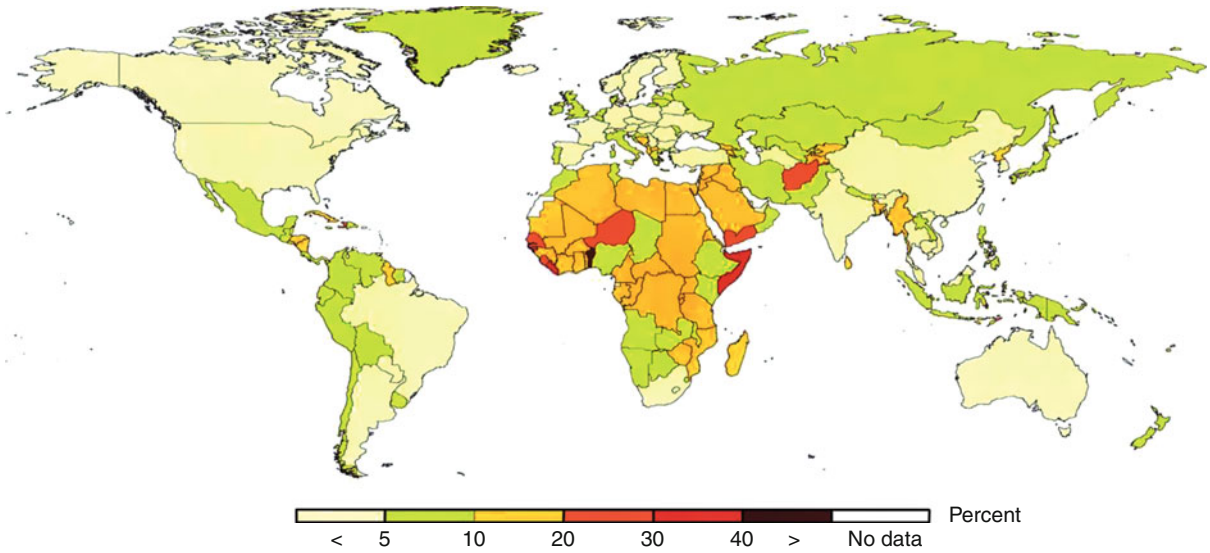
Source: FAO [10].

countries, it is imperative to have a look at global food production. The production of grain in the developing world has increased from ~1.3 million kilotons in 1995 to just below 1.6 million kilotons in 2007 (Fig. 2). Expressed relative to 1995 production, this increase amounted to 23%. Grain production in the developed world amounted to just below 0.69 million kilotons in 1995 and 0.78 million kilotons in 2007, an increase of about 12%. Animal products (meat, milk, and eggs) in the developing world increased from 0.41 million kilotons in 1995 to 0.59 million kilotons in 2007, an increase of 44%. Animal products in the developed world, in contrast, remained fairly stable at between 0.36 and 0.40 million kilotons over the entire period. There thus seems to be an effort on the part of the developing world to compensate for the faster population growth by a higher food production. However, this increase has to be seen in relation to the relative size of the respective populations in the developing and developed countries. Grain production per head of the developed world increased by 8.5% from 563 kg/head in 1995 to 611 kg/head in 2005 (Table 1). Grain production per head in the developing world, in contrast, remained relatively stable at a substantially lower level of between 275 (during 2000) and 286 (during 2005) kg/head (a difference of 4.0%). The output of animal products accordingly ranged from 293 to 308 kg/head in the developed world, compared to between 90 and 107 kg/head in the developing world.

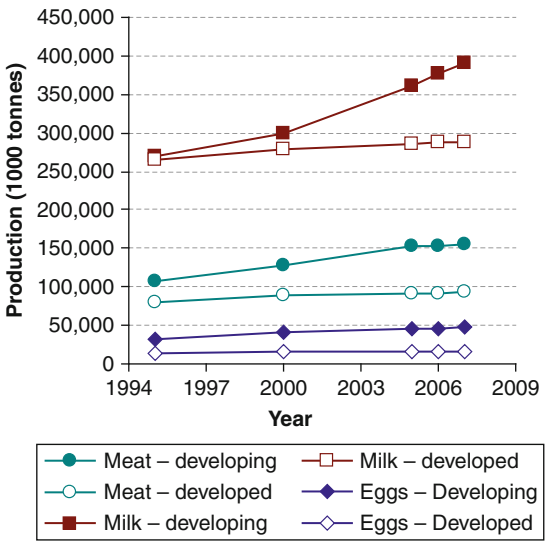
The lower per capita production of food in the developing world results in the need for imports to contribute to the food supply of the local population. The global importation of food in relation to total imports is provided in Fig. 3. It is evident that food imports exceed 5% of overall imports in many countries in the developing world. Africa and the Middle East are particularly dependent upon imports of food to contribute to local food security, with food imports exceeding 10% of total imports in most countries. On the upper end of the scale, food imports contribute more than 30% to total imports in some countries in these regions.

Products of an Animal Origin

Table 1 suggests substantial differences between the developing world and the developed world in terms of per capita animal production. As this entry deals with animal products, this topic needs to be elucidated further. In terms of quantity, milk was the most important animal product, followed by meat and eggs (Fig. 4).



Breeding in Developing Countries and Tropics. Figure 3
The share of food imports in relation to total imports on a global basis (Source: FAO [10])

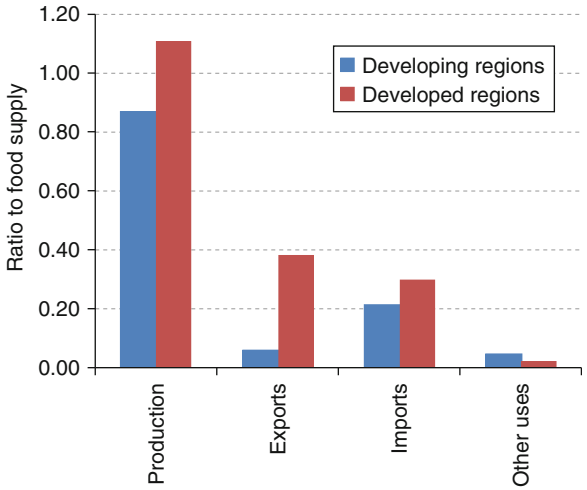


Breeding in Developing Countries and Tropics. Figure 4
Relative quantities of the most important livestock products in developing and developed countries (Source: FAO [10])

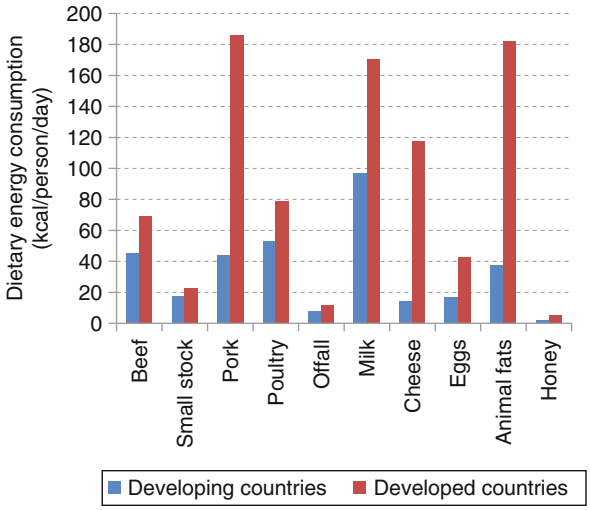
The same ranking applied both in developing and developed countries. It is evident that the production of all livestock products increased substantially over the past decade in the developing world (Fig. 4). Production in the developed world, on the other hand, remained stagnant or increased by smaller increments. These trends are set to continue in the future [11]. However, it needs to be considered that the population of the developing world exceeded 80% of the global population during 2005. It is thus evident that the somewhat higher animal production in these regions is canceled by the larger population density, hence the almost threefold lower per capita output of animal products in Table 1.

Against this background, local meat production is balanced against overall food supply for this commodity in developing countries and developed countries in Fig. 5. It is seen that there is a clear deficit in local production in the developing countries, as opposed to an oversupply in the developed countries. The deficit in own production in the developing countries is negated by imports, while only a small proportion of meat is exported. Developed countries are more likely to export meat, but also import relatively more meat than developing countries. The proportion of meat affected by stock changes and other purposes (mostly cultural) is relatively small, but appears to be somewhat higher in developing countries.

Table 1 suggests a substantially lower per capita production of animal products in developing countries



Breeding in Developing Countries and Tropics. Figure 5
A food balance for animal meats for the developing world and the developed world relative to the overall food supply in kiloton (Source: FAO [10])



Breeding in Developing Countries and Tropics. Figure 6
Per capita energy consumption of the top ten animal products in the developing world and in the developed world (Source: FAO [10])

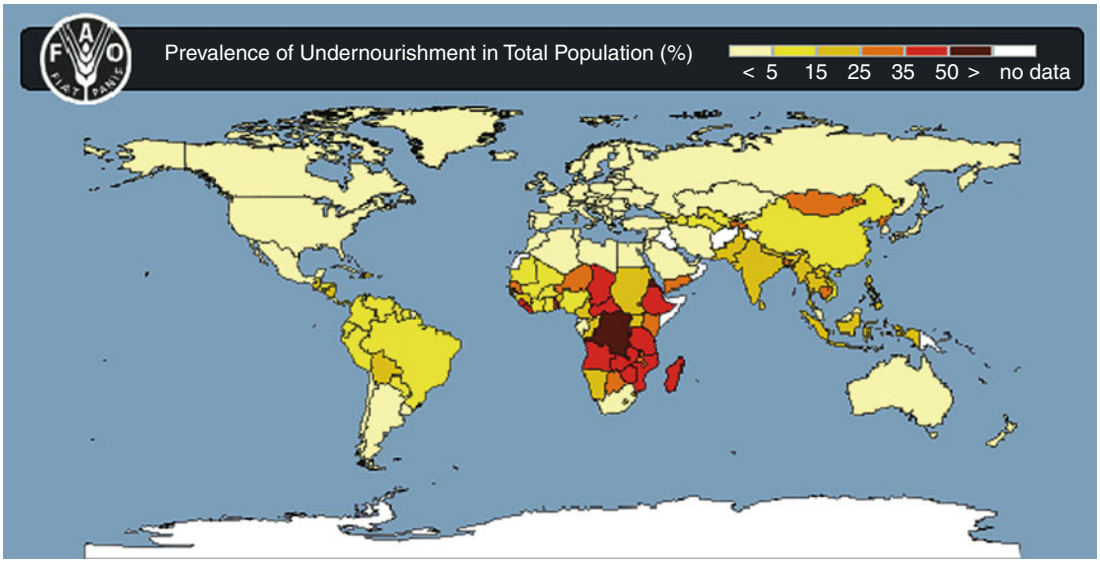
relative to developed countries. In Fig. 6, this tendency is quantified for the top ten animal products globally. Per capita energy consumption from small stock (sheep and goat) meat in the developing regions amounted to 79% of that in the developed world. Other products where per capita energy consumption of the developing world exceeded 50% of the corresponding figure in the developed world are poultry (67%), offal (67%), beef (65%), and milk (57%). Inhabitants of the developing world consumed energy from eggs (39%), honey (38%), pork (24%), animal fats (21%), and cheese (12%) at much lower quantities than their counterparts in the developed world.

Global Food Security

It is evident from Fig. 6 that inhabitants of the developing world consume substantially less energy from animal products than their counterparts in the developed world. It is thus important to consider relative food security of both groupings in view of these results. It is estimated that ~854 million people in the world lack adequate nourishment for a healthy and productive lifestyle, a figure that remained fairly stable over the last two decades [9]. The number of people dependent on one or other form of food aid for a livelihood is estimated at ~73 million worldwide. It is notable that the most insecure areas in terms of the provision of food are in developing countries in Asia and the Pacific, Latin America and the Caribbean, and Near East and Sub-Saharan Africa. Figure 7 depicts the frequency of undernourishment in different areas of the world as a percentage of the total population. It is evident that people in the central part of Africa are particularly at risk from undernourishment, but that variable levels of undernourishment also occurs in South and Central America, in South and central Asia, and in Oceania.

The percentage of undernourished people worldwide was estimated at 16% in 1990–1992, 14% in 1995–1997, 14% in 2002–2004, and at 13% in 2004–2006 [10]. It is notable that less than 5% of the total population suffered from undernourishment in the developed world. Less than 5% of the population of the developing states in Northern Africa correspondingly suffers from undernourishment. The occurrence of undernourishment is compared for other regions in the developing world over time from 1990–1992 to 2004–2006 in Fig. 8.

It is notable that most regions reported a slight decline in food insecurity, but that it still remains at



Breeding in Developing Countries and Tropics. Figure 7
The prevalence of undernourished people as a percentage of the total population in different countries throughout the world (Source: FAO [9])

The frequency of undernourishment in regions within the developing world over time from 1990–1992 to 2004–2006 (Source: FAO [9])

unacceptably high levels. Sub-Saharan Africa and Southern Asia were the regions where the population was most at risk during recent years (Fig. 8).

So far the discussion has centered around trends in the global human population, livestock products, as well as the issue of food security. The animal resources at the disposal of the global community for the alleviation of food insecurity need to be considered next.

Animal Resources

Domestication

Present-day production systems depend on Livestock species domesticated in the distant past. Fifteen out of 148 non-carnivorous species weighing more than 45 kg were domesticated, while only 10 out of an estimated 10,000 avian species were domesticated [12]. The time lapses since domestication of mammal livestock (in ascending order) is estimated at 10,000 years for goats, 8,500 years for sheep, 7,000–9,500 years for cattle, 6,500 years for horses and the South American camelids, 6,000 years for donkeys, 4,500–5,000 years for camels, 4,500 years for yaks and 4,000–4,500 years for water buffalo [12]. Chickens were domesticated between 5,000 and 7,500 years ago.

Distribution of Livestock Domestication, the resultant controlled breeding and selection, and the dispersal of domesticated livestock by human migration resulted in a wealth of diverse animal genetic resources. These livestock species are widely dispersed and adapted to a wide variety of environments and production systems. The percentages of countries in regions throughout the world that reported the presence of a specific domesticated mammalian species are listed in Table 2.

The wide representation across countries among the mammalian livestock species traditionally used

for food production (cattle, sheep, goats, and pigs) is evident from Table 2. The exceptions are sheep that are somewhat underrepresented in the Southwest Pacific at 31%, and pigs that are underrepresented in the Near and Middle East at 8%. Species like buffaloes, rabbits, and deer are important contributors to food security in some regions. Other species (yaks, camels, South American camelids, and guinea pigs) also contribute to regional food security, but are extremely localized in their distribution.

Domestic chickens are the most important avian livestock species by far (Table 3). Livestock species like turkeys, ducks, geese, Muscovy ducks, pigeons, quails, and guinea fowl also contribute in most regions of the world, but are nowhere close to the role played by domestic chickens. Other species (partridges, pheasants, peacocks, and the ratite species) also contribute to regional food security, but are fairly to extremely localized in their distribution.

At ~1.35 billion head, cattle have to be considered as the most important mammalian livestock species in the World (Table 4). Cattle are closely followed by sheep (1.08 billion head), pigs (0.96 billion head), and goats (0.81 billion head). The only other species exceeding half a billion head are rabbits at 0.54 billion head. Regions housing more than 10% of the world cattle population are Asia (32%), Latin America and the Caribbean (28%), Africa (14%), and Europe and the Caucasus (11%). Sheep are mostly found in Asia (36%), Europe and the Caucasus (18%), and Africa (16%). Asia (62%) and Europe and the Caucasus (20%) house the majority of the global pig population, while the most important goat-rearing regions are Asia (62%) and Africa (22%). Rabbits are mostly found in Asia (74%) and Europe and the Caucasus (24%). Most of the world's camels are found in Africa (40%), the Near and Middle East (38%), and Asia (20%). Table 4 confirms the status of buffaloes and South American camelids as truly regional livestock species.

Domestic chickens are by far the most important avian livestock species, with a more than tenfold

Breeding in Developing Countries and Tropics. Table 4 The world's population of the most important mammalian livestock species, with the relative contribution of the different world regions as percentages

advantage above ducks in the second place (Table 5). Most chickens are found in Asia (48%), while Latin America and the Caribbean (15%), Europe and the Caucasus (14%), and North America (13%) also house more than 10% of the world population.

Turkeys are found in Europe and the Caucasus (43%), North America (33%), and Latin America and the Caribbean (18%). Ducks and geese are almost exclusively found in Asia, where 90% of the world population can be found for both species.

It is also notable that most livestock can be found in the developing countries of Asia, the only exceptions being horses, camels, camelids, and turkeys (Tables 4 and 5). This is not surprising, given the high population density in this region, and the need for food produced by mammalian and avian farm animal genetic resources.

Biodiversity as Reflected by Breed Animal biodiversity is also illustrated by the number of distinct breeds that are identifiable in domestic livestock. The mammalian livestock species with the highest number of distinct breeds is sheep, followed by cattle, horses, pigs, goats, and rabbits (Table 6).

About half of the sheep breeds are found in Europe and the Caucasus, a quarter in Asia and about 12% in Africa. Regions with more than 10% of the cattle breeds are Europe and the Caucasus (31%), Asia (26%), Africa (19%), and Latin America and the Caribbean (14%). Most pig breeds are found in Asia (41%), followed by Europe and the Caucasus (32%), and Latin America and the Caribbean (12%). The regions with the most goat breeds are Asia (35%), Europe and the Caucasus (33%), and Africa (18%). Domestic chickens are the most diverse avian livestock species in terms of breed, with nearly five times as many distinct breeds than ducks in the second place (Table 7). Most chicken breeds are found in Europe and the Caucasus (58%)

Breeding in Developing Countries and Tropics. Table 6 The biodiversity, as reflected by distinct breeds, of the most important mammalian livestock species, with the relative contribution of the different world regions as percentages

Species	Region							Number of breeds

and Asia (22%). None of the other regions had more than 10% of the chicken breeds of the world. Regions with more than 10% of the world's duck breeds are Asia (38%), Europe and the Caucasus (36%), and Latin America and the Caribbean (11%). Goose breeds mostly originate from Europe and the Caucasus (65%) and Asia (24%). Most turkey breeds are found in Europe and the Caucasus (42%), with Africa, Asia, Latin America and the Caribbean, as well as North America all contributing 13% to the global animal diversity in terms of breeds The contribution of Europe and the Caucasus to biodiversity, as reflected by distinct breeds, is higher than suggested by the contribution of this region to the overall livestock populations (Tables 4 and 5). The only exception in this respect is the turkey, where the contribution of the region to the population size and the number of breeds are roughly equal. It has been suggested that many of the breeds in this region are recognized as separate entities, while being quite similar genetically [13]. In contrast, breed recording and characterization may be constrained by technical and human resources in parts of the developing world, such as Sub-Saharan Africa. This topic will be addressed later.

The Most Important Livestock Products for Ensuring Food Security

From the foregoing, it is possible to rank the domestic livestock species in terms of their importance to human food security, based on their population size and breed diversity. There is little doubt that chickens, cattle, pigs, sheep, and goats need to be regarded as the most important livestock species in this context. More attention will thus be given to these species in the subsequent text. The importance of other regional species also needs to be considered. However, this would involve substantial additional information, which cannot be accommodated within the constraints of the present study.

Meat products are seen as important dietary sources of protein, iron, zinc, and vitamin b12 among others [7]. Meat products were related to increased live weight gains and improved cognitive function in children [14]. Meat thus has to be considered as an extremely important product for both the developed world and the developing world. Milk also provides calcium, phosphorus, vitamin B12, desirable fatty acids, and good-quality protein, and was also reported to have similar benefits to live weight and height of children under conditions where food supply is marginal [14]. The outlook for animal products (meat and dairy products) is subsequently provided per species for the major species listed above.

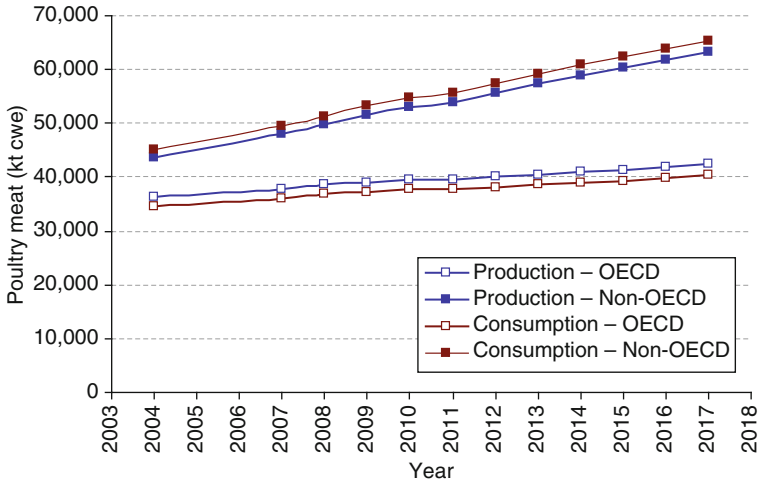
Meat from avian origin in this section is termed as poultry meat. However, with domestic chickens constituting more than 90% of avian livestock in the world (Table 5), it is safe to assume that the trends would also hold true for this species. Data were obtained from the outlook document of the OECD-FAO [11], and the results are provided for OECD-member states (representing the developed world) and non-OECD countries (representing the developing world). After considering production and consumption figures per species, attention is focused upon the per capita consumption of the various species meats.

Poultry

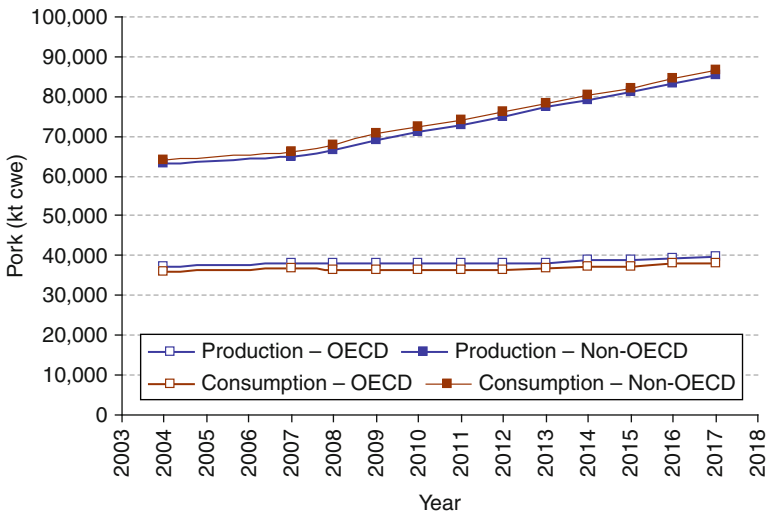
Poultry meat production in the non-OECD countries is forecast to increase steadily by 45% from ~43,600 kt carcass weight equivalent (cwe) in the early 2000s to ~63,300 kt cwe in 2017 (Fig. 9). The corresponding increase in the OECD countries is forecast to be more modest, namely, an increase of 17% from ~26,400 to ~42,400 kt cwe. Poultry consumption, on the other hand, is seen to increase by 17% from ~34,600 to ~40,400 kt cwe in OECD countries, while the concomitant increase in non-OECD countries is expected to amount to 45% (from 45,100 to 65,300 kt cwe). A deficit in non-OECD countries is evident from Fig. 9, which can be partly offset by a surplus in production in the OECD countries.

Pigs

The production of pork is expected to increase from ~63,200 kt cwe in 2004 to ~85,500 kt cwe in 2017 in the non-OECD countries, an increase of 35% (Fig. 10). OECD countries are likely to record a comparatively small increase, from ~37,100 to ~39,800 kt cwe. This increase only amounts to 7%. Consumption in the non-OECD countries is seen to increase by 36% from



Breeding in Developing Countries and Tropics. Figure 9
Poultry meat production and consumption in kiloton carcass weight equivalent (cwe) in OECD and non-OECD countries (Source: OECD-FAO [11])

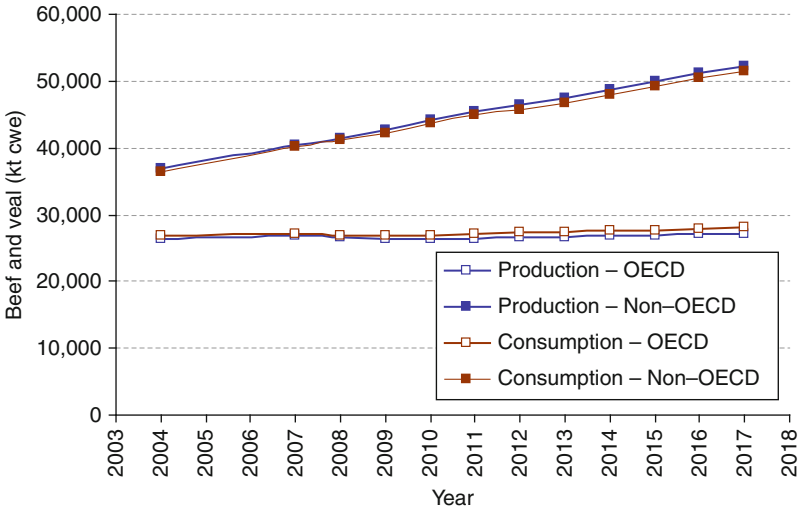


Breeding in Developing Countries and Tropics. Figure 10
Pig meat production and consumption in kiloton carcass weight equivalent (cwe) in OECD and non-OECD countries (Source: OECD-FAO [11])

63,900 to 86,900 kt cwe, while a modest increase of 7% was predicted for OECD countries (~35,800 to ~38,200 kt cwe). As for poultry meat, it was noted that a slight overproduction in OECD countries can once again be of value to counter a deficit in the non-OECD countries.

Cattle

Beef and veal production is expected to increase by 41% in the non-OECD countries, from ~37,000 kt cwe in 2004 to 52,200 kt cwe in 2017 (Fig. 11). In contrast, production in OECD countries is



Breeding in Developing Countries and Tropics. Figure 11
Beef and veal production and consumption in kiloton carcass weight equivalent (cwe) in OECD and non-OECD countries (Source: OECD-FAO [11])

forecast to be relatively stable at between 26,500 and 27,200 kt cwe. As with production, consumption of beef and veal in the non-OECD region is expected to increase by 41%, from 36,500 to 51,500 kt cwe over the period from 2004 to 2017. A slight increase of about 5% is expected in the consumption of beef and veal in the OECD countries (from 26,800 to 28,000 kt cwe). Production and consumption seem to be in closer correspondence in both regions for this commodity.

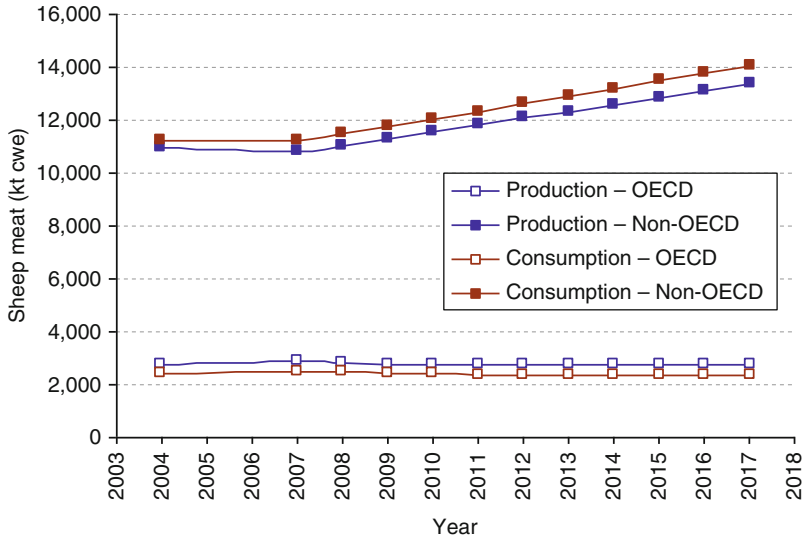
Small Stock

Global production of sheep meat (mutton and lamb) is modest compared to the other types of meat. Production in non-OECD countries is expected to increase by 22% from ~10,900 kt cwe in 2004 to ~13,500 kt cwe in 2017 (Fig. 12). No increase in sheep meat production is forecast for OECD countries, and figures are expected to remain stable at 2,300–2,400 kt cwe over the entire period. Consumption of sheep meat is expected to increase by 25% in non-OECD countries (from ~11,300 to ~14,100 kt cwe), while sheep meat consumption is expected to decline by 3% in OECD countries (from 2,417 to 2,340 kt cwe). As for other meats, surplus production of sheep meat in the OECD countries may play a role in alleviating the deficit expected in non-OECD countries.

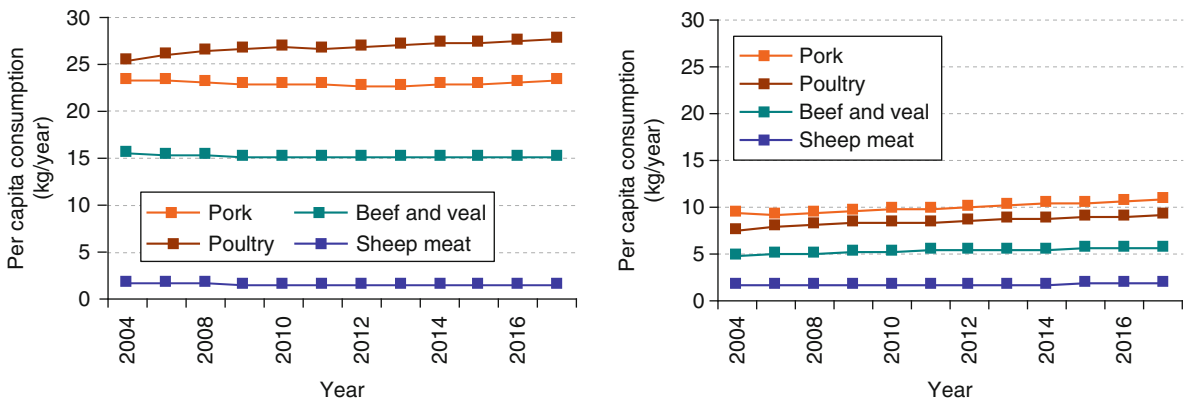
Global goat meat (chevron) production all but doubled from 2.05 million ton in 1985 to 4.05 million ton in 2005 [15]. This trend could mostly be ascribed to a 2.5-fold increase in goat meat production from 1.3 million ton in 1985 to 3.3 million ton in 2005 in Asia. Less spectacular increases from 1985 to 2005 were reported for other countries in the developing world, namely, from 0.53 to 0.86 kt in Africa and from 0.59 to 0.83 kt in South America. In the developed world, Europe led the way with a 33% increase in chevron production from 0.09 to 0.12 kt. In contrast, goat meat production in Oceania declined markedly from 0.12 kt in 1985 to 0.02 kt in 2005 [15].

Per Capita Meat Consumption

Per capita consumption of pork as well as of beef and veal is forecast to remain largely stable up to 2017 in the OECD countries, at respectively ~23 and ~15 kg/person/year (Fig. 13). The per capita consumption of poultry meat is expected to increase by 9% from 25.4 to 27.8 kg/person/year. In contrast, the consumption of sheep meat is predicted to decline by 11% from 1.8 to 1.6 kg/person/year. The ranking of the meat from the various species is consistent over years, the sequence being poultry, pork, beef and veal, and finally sheep meat. The per capita consumption of all meat types, with the exception of sheep meat, is



Breeding in Developing Countries and Tropics. Figure 12
Sheep meat production and consumption in kiloton carcass weight equivalent (cwe) in OECD and non-OECD countries (Source: OECD-FAO [11])



Breeding in Developing Countries and Tropics. Figure 13
Per capita consumption of meat from the various species in the OECD countries (*left*) and in the non-OECD countries (*right*) for the period from 2004 to 2017 (Source: OECD-FAO [11])

forecast to be lower in non-OECD countries (Fig. 13). Per capita consumption of meat from all the different species is predicted to increase over time in the latter grouping. In sequence of the importance of the different types of meat, per capita consumption is expected to rise by 15% for pork (from 9.5 to 10.9 kg/person/year), by 22% for poultry (from 7.6 to 9.3 kg/person/year), by 18% for beef and veal (from 4.9 to 5.8 kg/person/year), and by 5% for sheep meat (from 1.9 to 2.0 kg/person/year).

It is evident from Fig. 13 that the wealthier OECD countries are able to sustain high levels of protein intake from livestock. With the exception of sheep meat, developing countries are lagging behind,

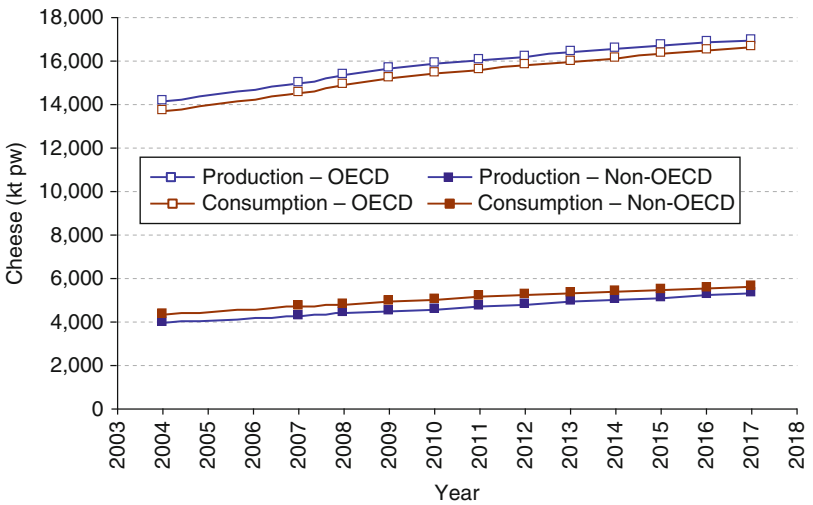
suggesting that there is almost unlimited scope for the improvement of livestock productivity for meat production in these regions. When the relatively small contribution of sheep meat in both regions is considered, it is tempting to discard this industry as an important contributor to food security. However, it is recognized that the sheep industry is able to thrive under marginal conditions where other livestock species find it difficult to adapt. Because of this, expansion in numbers (and thus product quantity) is not always easy to achieve. It is thus important to recognize the importance of this species to local food security, and also to the sustainable utilization of resources in marginal areas [8].

Dairy Products

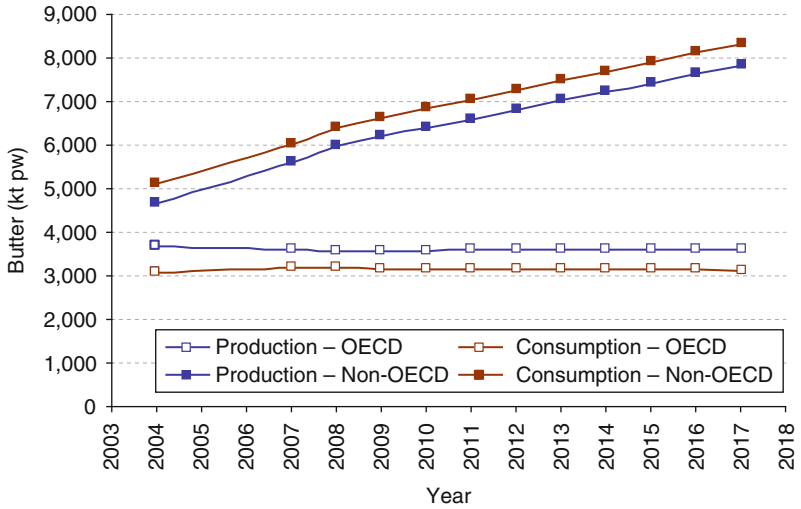
The outlook is for both the OECD countries and non-OECD countries to increase their production and consumption of cheese in the immediate future (Fig. 14). Production is expected to increase from respectively ~14,200 and ~4,000 kt product weight (pw) in 2004 to respectively ~17,000 and ~5,300 kt pw in 2017. When expressed relative to 2004 production, these changes amount to respectively 20% and 35%. Corresponding increases in consumption amount to respectively 21% and 31%, from ~13,700 kt pw in OECD countries and ~4,300 kt pw in non-OECD countries to respectively ~16,600 and ~5,700 kt pw. As for other commodities, the surplus in OECD countries is forecast to be able to assist in alleviating the deficit in non-OECD countries.

World production of goat cheese increased by 28% from 343 kt in 1985 to 438 kt in 2005 [15]. Regional production in the developing world more than tripled from 35 kt in 1985 to 122 kt in 2005, stayed constant at ~4 kt in South America, and declined by 13% from 114 kt in 1985 to 99 kt in 2005. In the developed world, European goat cheese production rose by 36% from 132 kt in 1985 to 180 kt in 2005, while production in northern and central America halved from 34 kt in 1985 to 18 kt in 2005. According to Dubeuf and Boyazoglu [15], selection of goats is limited to milk goats in developed countries. There thus seems ample scope to improve performance at all levels of the dairy goat industry in developing countries.

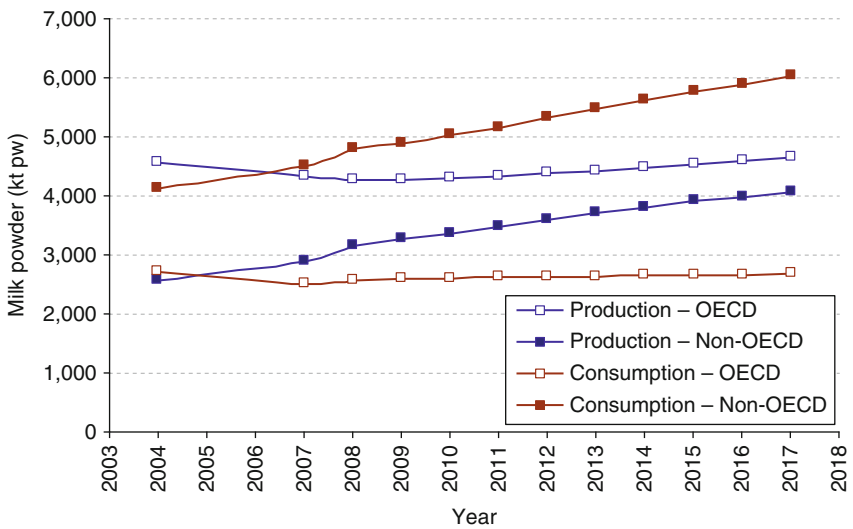
When butter is considered, it is evident that production and consumption are predicted to remain constant at respectively between 3,600 to 3,700 kt pw and 3,100 to 3,200 kt pw in OECD countries (Fig. 15). In the case of the non-OECD countries, production of butter is expected to increase by 68% from ~4,700 kt pw in 2004 to ~7,800 kt pw in 2017.



Breeding in Developing Countries and Tropics. Figure 14
Cheese production and consumption in kiloton product weight (pw) in OECD and non-OECD countries (Source: OECD-FAO [11])



Breeding in Developing Countries and Tropics. Figure 15
Butter production and consumption in kiloton product weight (pw) in OECD and non-OECD countries (Source: OECD-FAO [11])



Breeding in Developing Countries and Tropics. Figure 16
Milk powder production and consumption in kiloton product weight (pw) in OECD and non-OECD countries (Source: OECD-FAO [11])

Consumption is forecast to increase by 61% from ~5,100 to ~8,300 kt pw over the same period.

Milk powder production (the sum of skim milk powder production and whole milk powder production) is projected to increase by 58%, from ~2,560 kt pw in 2004 to 4,060 kt pw in 2017, in non-OECD countries (Fig. 16). Consumption of milk powder is forecast to increase by 46%, from 4,140 to 6,030 kt pw over the same period. Both milk production and milk consumption remained fairly constant in OECD countries over the same period. The deficit between milk powder production and milk powder

consumption in non-OECD countries is quite marked in this case. Fortunately the forecasted surplus of milk powder produced in the OECD countries will go a long way to alleviate this deficit in the non-OECD countries, as have been found for most of the other commodities.

It is evident that the production of butter and milk powder is substantially lower in OECD countries, compared to their non-OECD counterparts. In contrast, cheese production is much higher in OECD countries. This trend is understandable if it is considered that cheese is a prestigious, high-value product.

Challenges

It needs to be considered that livestock production in developing regions is faced with a number of challenges to ensure sustainability [16, 17]. These challenges need to be overcome to ensure sustainable breeding programs. A broad subdivision can be considered as challenges imposed by the environment (or external challenges) and those related to infrastructure and capacity (indicated as internal challenges).

External Challenges

Production under Various Systems It should be considered that the natural and/or cultivated plant resources form the basis for all types of livestock production. The more industrialized livestock sector relies on feedstuffs (concentrates, and roughages for dairy cows) that are in many cases imported from elsewhere for the sustenance of farmed animals. In contrast, natural and cultivated pastures are particularly important for the grazing ruminants that are able to convert low-quality roughage to nutritious protein for human consumption. Owing to a lack of control over pasture conditions in farming systems reliant on natural precipitation, periods of nutrient undersupply may occur. Persistent droughts may occur from time to time, adding to the challenges faced by tropical livestock [18]. Moreover, tropical pastures are known to have a high lignin content, particularly at the end of the growing season [19].

These afore-mentioned factors may act as constraints to efficient livestock production in developing and tropical regions. Low-potential extensive natural rangeland sustains a large portion of the well-developed sheep sector in South Africa [8]. Seasonal and unprecedented longer-term droughts are the rule rather than the exception. According to Mirkena et al. [19], adaptation of farm animals to such periods of feed scarcity can be achieved in a number of ways. Animals may develop a reduced metabolic requirement, or an ability to slow down metabolism. Digestive efficiency could be improved, while an improved utilization of low-quality roughage could be enabled. An alternative strategy could be to deposit adipose body reserves to act as a safeguard against periods of inadequate nutrient supply. As pertaining to a reduction in metabolic requirement, Silanikova [20] demonstrated that desert Bedouin goats have lower energy requirements than suggested by their body size, while they are also able to utilize low-quality roughage with a high fiber content. The latter type of goat also tolerated intake levels of ~50% below ad lib intake, compared to ~20% in Saanen goats. Localized fat reserves are found in a number of species adapted to harsh environments. Tail fat reserves of Horro and Mentz lambs were proportionally more reduced in comparison to other fat depots during periods of food scarcity and resultant loss of body condition [21].

On the other hand, Fig. 13 clearly indicates that an increasingly large portion of per capita meat consumption is expected to be produced by poultry and pigs under more intensive production systems, also referred to as industrial systems [22]. This development leads to some challenges in itself. The intensification of animals on smaller areas is feared to lead to unprecedented spinoffs, like an increase in the transmission of diseases between animals and mankind [23]. This topic is dealt with in the next section, with a number of appropriate examples. However, it is important to note that some doubts exist about the governance of some countries in the developing world to adequately deal with this potential threat [23]. According to Gummow [23], this problem is compounded by a poor immune status in many countries because of diseases like HIV/AIDS. Additionally, child nutrition was found to be inadequate in many developing countries, leading to complications like stunting and retarded growth [6], as can also be inferred from Fig. 8.

Disease It is important to recognize that disease plays an important role in livestock production throughout the world, both in developing and developed regions. There is evidence that local, indigenous cattle developed tolerance to tsetse and trypanosomis challenge in parts of Africa infested by the tsetse fly [19]. A study by Van der Waaij [24] suggested that several quantitative trait loci (QTL) have a role to play in the tolerance of trypanosomis of cattle in the African tropics. Animals imported to these regions are not likely to survive, unless a high level of husbandry and the usage of appropriate chemical treatments are applied. Infestation of farm animals with ticks in developing countries often results in death owing to tick-borne diseases [25]. Local breeds of cattle, sheep, and goats are often tolerant to the challenge provided by such diseases [19]. In this respect, it has been shown that local Small East African goats were less likely to be affected by ticks and abscesses caused by ticks than imported Toggenburg goats in Tanzania [26]. Consistent differences in favor of the local Small East African goats were found for all three species of ticks that were considered in the study.

Analyses conducted on the national database of the Bonsmara breed in the South African National Beef Recording and Improvement Scheme indicated useful genetic variation in tick numbers, particularly when the data were structured to involve environments with a higher level of tick infestation [27]. Genetic variation on the underlying liability scale was also reported for the ability of Merino sheep to resist breech strike by the sheep blowfly, *Lucilia cuprina* [28–30]. The significant genetic variation was supported by distinct line differences between Merino lines divergently selected for their ability to rear multiple offspring [31]. The challenge of animals with breech strike is controversial from an ethical viewpoint, while the transient nature of breech strike makes an adequate natural challenge under all conditions infeasible. Alternatively, it has been suggested that indicator traits should receive some attention. Traits that are considered include breech fold score, dag score, breech cover score, and crutch cover score. A number of studies suggested that all these indicator traits show significant genetic variation [28, 29, 32, 33]. In general, the indicator traits were not unfavorably related to wool and fleece traits. There is also some evidence that dag score [28, 29], breech cover score [29], and breech fold score [30] are genetically related to breech strike. Earlier work also suggested a genetic basis for body strike in sheep, as reviewed by Morris [34]. Selection for combined resistance to body strike and fleece-rot also resulted in genetic gains that accorded with expectations [35]. Infestation with the sheep body louse, *Bovicola ovis*, was accordingly reported to be heritable in a New Zealand study [36]. However, lice infestation was not conclusively associated with susceptibility to gastrointestinal nematodes.

Most species of farmed livestock are also affected by internal parasites. In this respect, marked breed differences in resistance to *Haemonchus contortus* were reported between the indigenous Kenyan Red Maasai sheep compared to the Dorper breed, an import from South Africa. Indigenous Red Maasai sheep had lower parasite burdens (as reflected by fecal worm egg counts), higher packed cell volumes as well as an improved lamb survival compared to Dorpers [37]. A later study reported small breed differences in a more arid environment with an inherently lower parasite challenge [38]. The relative advantage of the Red Maasai became evident in an environment conducive to helminth infestation, as reflected by a threefold advantage in levels of production on Red Maasai sheep compared to Dorpers [38]. Nimbkar et al. [39] reported corresponding differences in crosses of the Garole breed with the Banmur and Deccani breeds in India. These breed differences are supported by ample evidence of genetic variation in fecal worm egg counts as a measure of resistance to gastrointestinal roundworms in sheep [40, 41], as well as realized genetic progress [34, 41, 42]. Selection for lower fecal worm egg counts resulted in lower outputs of larvae on the pasture by reproducing ewes [43] and concomitant economic gains [44].

Genetic parameters and progress in other diseases of sheep were reviewed by Morris [34]. Apart from four mycotoxic diseases, the review also considered bacterial diseases like mastitis, footrot, and pneumonia. All diseases have shown moderate genetic variation, and realized genetic gains were reported for facial eczema and ryegrass staggers. Mastitis and footrot also formed part of the review by Bishop [45], indicating how the epidemiology of transmittable diseases affects options to utilize genetic variation in disease resistance in a number of species.

In dairy cattle, improved modeling and revised trait definitions are being investigated for usage in the genetic improvement of resistance to mastitis on a national scale, as based on readily available somatic cell count data [46, 47]. Similar studies are underway as pertaining to bovine Johne's disease [48] and bovine tuberculosis [49].

Additionally, cognizance should be taken of new diseases of a noninfectious nature. Gummow [23] pointed out that increased industrialization and pollution also impacted on livestock farming, and listed chronic copper and vanadium overdose as an important source of livestock deaths in the Mpumalanga province of South Africa. Other examples of noninfectious conditions listed in the latter review were the impact of environmental contaminants on the life expectancy of humans in Russia as well as air pollution in the United States. These conditions need to be understood better, while pollution needs to be brought down to manageable levels [23].

The previous discussion dealt with the importance of disease, as well as heritable resistance to known pathogens. The complexity of selection for resistance to known pathogens, as reviewed by Bishop [45], is also recognized. The relevance of the above-mentioned to the eventual outcome of the chapter will become clear in the section on future directions.

It is important to note that intensification in the more industrialized livestock species (poultry, pigs, and dairy cows) are likely to be conducive to an increased risk of infection by some diseases [23]. Owing to close contact with mankind, the transmission of some animal diseases to humans (also referred to as zoonoses) places a further dimension on the importance of livestock disease. A number of recent and historic epidemics, resulting in loss of life among animals and humans alike, have been listed by Gummow [23]. The transmission of animal diseases to humans falls beyond the scope of this review, and will not be dealt with in detail. However, it is necessary to refer briefly to recent occurrences of Bovine Spongiform Encephalopathy (better known as BSE), foot and mouth disease, and Avian Influenza to get an indication of the impact of such diseases on mankind. Avian Influenza in particular has led to recent scares, associated with a loss of approximately 200 human lives [22]. An outbreak of Rift Valley Fever during the summer and autumn of 2010 similarly resulted in substantial livestock losses [50], as well as at least 17 human fatalities in South Africa during the past year [51]. This has resulted in the suspension of raw wool exports worth an estimated 1 billion South African Rand (ZAR) to the Chinese market on August 16, 2010 [52]. The impacts of such events on livestock, humans, and the economy should be clear from the foregoing.

Heat Stress and Water Requirements The climate can influence animal production in many ways. The impact of low and unreliable rainfall patterns already received attention previously. One of the other main stressors of livestock in the developing world, and particularly in the tropics, is heat [19]. Heat stress is reflected in increases in a number of physiological responses that result in impaired production and reproduction [53]. Heat stress is aggravated by an increased humidity [19]. According to Marai et al. [53], the following temperature humidity index (THI) can be an indication of the amount of heat stress experienced by animals:

$$\mathrm{THI} = \mathrm{db}^{\circ}\mathrm{C} = [(0.31 - 0.31\,\mathrm{RH})\mathrm{db}^{\circ}\mathrm{C} - 14.4]$$

With $\mathrm{db}^{\circ}\mathrm{C}$ = the dry bulb temperature in °C
RH = the relative humidity (RH%/100w)

Values below 22.2 suggest an absence of heat stress, a value from 22.2 to <23.3 is indicative to moderate heat stress, a value from 23.3 to <25.6 suggests severe heat stress and a value exceeding 25.6 reflects extreme heat stress. It is suggested that adapted animals are able to increase their sweating rate under adverse conditions in terms of heat stress, while they are able to control heart rate and rectal temperature better than their poorly adapted contemporaries.

A Brazilian study compared a number of physiological responses of five naturalized Brazilian cattle breeds (Curraleiro, Crioulo Lageano, Pantaneiro, Junqueira, and Mocho Nacional – the former four breeds from a *Bos taurus ibericus* origin and the latter from a *B taurus ibericus* x *B taurus aquitanicus* origin), as well as the commercially available Holstein (*B taurus taurus*) and Nellore (*B taurus indicus*) breeds [54]. Of the latter two breeds, it was thought that the Holstein would be poorly adapted to heat stress, while the Nellore was thought to be well adapted. Physiological traits measured on the animals are reported in Table 8.

Breeding in Developing Countries and Tropics. Table 8 Means for physiological traits of five naturalized Brazilian cattle breeds, as well as the Holstein and Nellore breeds

Breed	Physiological trait						
	RT	RR	HR	SR	Cort	PCV	TPP
Crioulo Lageano	38.7	33.8	64.4	242	14.8	32.1	7.34
Curraleiro	38.8	31.0	70.7	251	11.6	34.3	7.34
Junqueira	38.7	26.4	69.9	234	14.7	32.7	7.40
Mocho Nacional	38.8	38.8	70.6	259	13.6	35.0	7.23
Pantaneiro	38.8	33.3	69.9	252	15.9	36.8	7.50
Holstein	39.0	32.7	62.6	258	13.8	37.7	7.34
Nellore	38.6	27.7	68.9	225	12.0	33.1	6.99

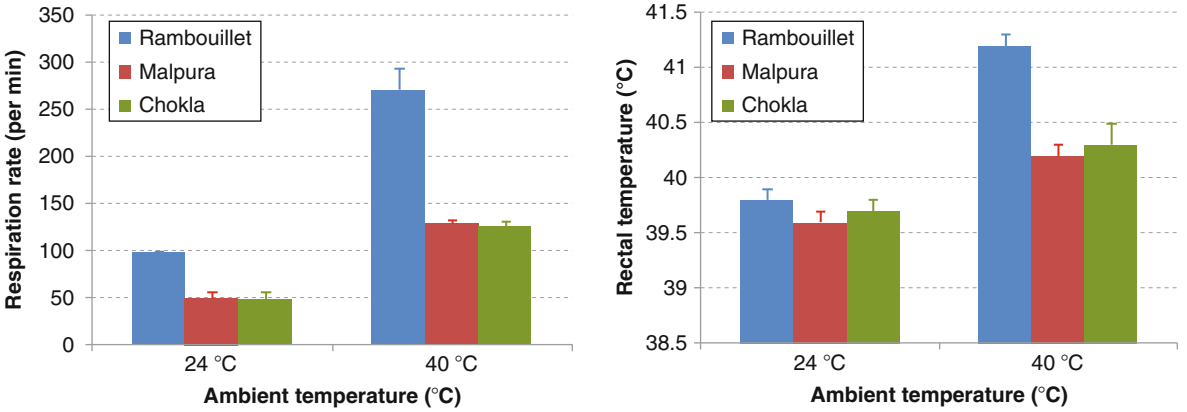
RT Rectal Temperature (°C), *RR* Respiration rate (movements/min), *HR* Heart rate (movements/min), *SR* Sweating rate (g/m/h), *Cort* Serum cortisol concentration (ng/mL), *PCV* Packed cell volume, *TPP* Total plasma protein
Source: Adapted from McManus et al. [54].

The temperatures were not extreme during the duration of the study. Maxima ranged from just above 20°C to just below 30°C, while minima ranged from ~12°C to ~22°C. Humidity ranged from ~50% to 90% in the mornings and from ~25% to ~58% in the afternoons. Although all physiological traits in Table 8 were within normal ranges for cattle, it is notable that Nellore cattle consistently had a lower rectal temperature, respiration rate, sweating rate, serum cortisol concentration, and packed cell volume compared to their Holstein contemporaries. Rectal temperature of Holstein cattle differed by 1.4°C from the morning to the afternoon, whereas all the other breeds differed by less than 1.1°C. The respiration rate of Holstein cattle also differed by 5.7 movements/min from the morning to the afternoon, compared to 0.4 movements/min in the Junqueira breed. Based on the packed cell volume and total plasma protein concentration, it was suggested that Holstein cattle were more dehydrated than the other breeds, and the Nellore breed in particular. The clear breed differences in Table 8 clearly suggest that the Holstein would be less adapted to heat than the Nellore breed, as anticipated. Of the naturalized breeds, the Junqueira seemed to be best adapted. In contrast, adaptation of the Mocho Nacional breed appeared to be the worst among the naturalized breeds.

The impact of heat stress on sheep was reviewed by Marai et al. [53]. Lambs borne by heat-stressed ewes had lower birth weight than those of ewes not subject to heat stress. The impact seems to be brought about by a reduction in embryo cell number and placentome size. Heat stress also depressed lamb growth, with solar radiation together with heat stress aggravating the situation. Exposure of sheep to heat stress conditions leads to impaired feed intake levels, as well as increases in respiration rate, body temperature, and water intake. The digestion of forage is also impaired by the exposure of sheep to heat stress conditions [53].

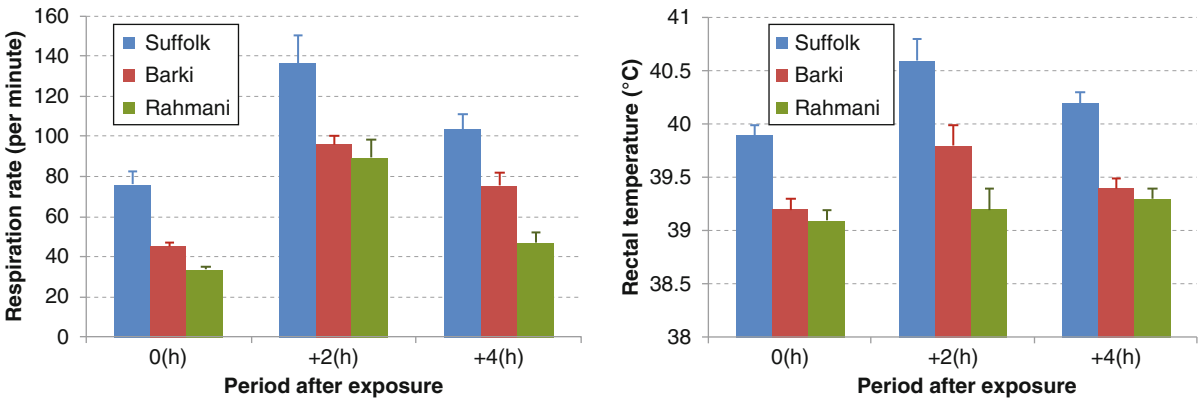
The physiological response of a temperate sheep breed (Rambouillet) was compared to those of two Indian breeds (Malpura and Chokla) at ambient temperatures of 24°C and 40°C in a study by Singh et al. [55]. The better adaptation of the Indian breeds to the ambient temperature of 40°C is evident in Fig. 17, as reflected by reduced respiration rates and rectal temperatures.

Very similar results were reported for Suffolk sheep, as representative of a temperate breed relative to local Egyptian breeds (the Barki and Rahmani) in the study of El-Sheikh et al. [56]. In this study, respiration rate and rectal temperature were studied at exposure to elevated temperatures (0 h), and after 2 and 4 h of exposure to high temperatures (respectively +2 h and +4 h).



Breeding in Developing Countries and Tropics. Figure 17

Means for respiration rate (*left*) and rectal temperature (*right*) of animals from the Rambouillet, Malpura, and Chokla sheep breeds at ambient temperatures of 24°C and 40°C (Adapted from Singh et al. [55])



Breeding in Developing Countries and Tropics. Figure 18

Means for respiration rate (*left*) and rectal temperature (*right*) of animals from the Suffolk, Barki, and Rahmani sheep breeds after 2 and 4 h of exposure to elevated temperatures (adapted from El-Sheik et al. [56])

The better adaptation of the two local breeds compared to the Suffolk is evident from Fig. 18.

The better adaptation of local breeds to conditions of excessive heat is evident from the foregoing. It could therefore be expected that animals from temperate breeds could find it difficult to adapt and thrive under such conditions. Menjo et al. [16] reported that 25% of Holstein-Friesian heifers born from artificial insemination in Kenya were lost to involuntary culling prior to their first calving. It is notable that the survival of heifers bred from semen of Kenyan, South African, and Israeli bulls had an improved survival relative to those bulls originating from Australia, New Zealand, the United States, and Canada. Conditions in terms of ambient temperature in the dairy producing areas of the latter countries are arguably cooler than those experienced in Kenya, while harsher conditions are expected in South Africa and Israel. Unfortunately, the relative milk yields of the heifers that originated from semen from the respective regions were not reported and could, thus, not be considered. Boonkum et al. [57] accordingly reported that days open were increased with an increased proportion of Holstein genes in Thai Holstein and Holstein cross cows.

The heritability of days open was slightly higher for summer calvings compared to late rainy season calvings. Susceptibility to heat stress increased with increasing parities, possibly leading to the observed high erosion rates of cows from first to third parity [58]. Whereas genetic trends for milk yield was favorable from first to third parity, second and third lactation cows became more susceptible to heat stress with time. These effects are expected to be aggravated with global warming. It is reassuring that statistical methods are sufficiently robust to rank animals for heat tolerance for selection purposes. Genomic selection is expected to improve the accuracy of evaluating young animals for selection purposes.

Many developing countries are in water-scarce areas of the world. It is therefore important to consider adaptation of livestock to water scarcity. Mirkena et al. [19] noted that breeds originating from arid countries can withstand water deprivation for longer periods than their counterparts from temperate countries. Camels are extremely well adapted in this sense, being able to withstand water deprivation for 17 days on dry feed [59] and for 30–60 days on green feed [60]. There are also donkey, goat, sheep, and some cattle breeds that are able to go without water for several days [61]. Black Bedouin and Barmer goats in the Middle East may go for 4 days without water [20]. Adapted breeds minimize water losses in urine and feces and are able to produce milk despite low water intakes. Because of the increasing strategic importance of water, production practices for the future should adopt water conservation practices [62].

The adaptation of local tropical breeds to extreme conditions was discussed in this section. The importance of this adaptation to breeding in the developing world will become clear in subsequent sections.

Internal Challenges

Infrastructure and Capacity Regions in the developing world were shown to lack infrastructure and capacity for the management of animal genetic resources (Table 9).

Between 71% and 100% of African countries had limited or no capacity in the seven categories that were considered. The situation in Asia was more variable. The central and southeastern parts had limited capacity, while conditions in the east and south were somewhat better. The capacity of the Southwest Pacific, Central America, and the Near and Middle East was also limited with 78–100% of the countries having limited or no capacity in the categories that were considered. The capacity of the South American and the Caribbean regions were intermediate in this respect, with between 30% and 70% of the countries having no or limited capacity in one or more of the categories under consideration. In contrast, the developed countries in Europe and the Caucasus and North America consistently had moderate to good capacities in 50% or more of the categories under consideration. The situation in North America in particular is good, with 100% of the countries having medium to good capacity in all categories except for the existence of laws and political programs.

The scenario set out in Table 9 led to an assessment by Brockhaus [63] that the strategic action as pertaining to genetic resource management has a sound basis in North America, Europe and the Caucasus, and, to a lesser extent, in Latin America and the Caribbean. Legislation in the former regions is well underway to regulate animal genetic resources. Weaknesses in the developing world are not only present at a strategic level but also at the basic operational and organizational levels. It thus seems that efforts to improve the vast and diversified livestock genetic resource of the developing world are constrained by several factors [64]. On the positive side, a growing level of awareness is present in the other regions [63]. This provides an opportunity to identify countries and stakeholders that may act as catalysts of development in other countries of the regions lagging behind. Local, regional, and international stakeholders that could play a role in this respect were listed by the latter literature source.

Structured Programs From Table 9 it is evident that the capacities to ensure structured livestock improvement may be lacking in most countries of the developing world. The emphasis placed on structured breeding programs for the livestock species of interest in the different regions must thus be considered next. The species most likely to be involved in structured breeding programs worldwide is cattle, followed by sheep, goats, pigs, and chickens (Table 10). Breeding of both

Breeding in Developing Countries and Tropics. Table 9 Assessment of regional capacities for the management of animal genetic resources for food production

Region	Physical infrastructure		Intellectual infrastructure		Policy development		
	Capacity	Participation	Research	Knowledge	Awareness	Laws	Implementation
Africa

The percentage of countries having no or limited capacities are listed with reference to physical infrastructure, intellectual infrastructure, and policy development. The balance of countries would have medium to high scores in these respects.

dairy and beef cattle is also considered as a priority by the largest number of countries. Regions with below 50% countries involved in structured cattle breeding programs are Africa (31%), the Near and Middle East (14%), the Caribbean and Central America (17%), and the Southwest Pacific (13%). Structured sheep and goat breeding is practiced less widely, with the only regions where programs are in place in 50% or more of the countries being Europe and the Caucasus, as well as North America in the developed world, and only the Near and Middle East in the developing World. The situation for structured goat breeding is much the same except for fewer than 50% of the countries in the Near and Middle East having programs in place. It is of interest that sheep and goat breeding was only considered as a priority in four African countries [65]. This situation is perplexing, as Africa is the continent with the third highest sheep population and the second largest goat population worldwide (Table 4). Structured pig breeding is basically only being practiced in the developed world countries in the Europe and Caucasus and North American regions. The North American region is basically the only region where structured poultry breeding is practiced by 50% of the countries. The lack of activity in pig and poultry breeding in most regions can be related to breeding in these species being mostly entrusted to international breeding companies with worldwide marketing capabilities.

Breeding in Developing Countries and Tropics. Table 10 Percentages of countries reporting structured livestock breeding programs per species in the regions of interest

World	14	47	33	27	27

Source: Adapted from Thieme [65].

Tools and Strategies in Livestock Breeding Breeding in pigs and poultry is mostly centralized and practiced at low levels in the developing world. These species will thus not be covered in this section.

There is clearly a lack of activities associated with animal genetic resource management of cattle in Africa, Asia, as well as in the Near and Middle East, when compared to the situation in the developed countries of Europe and the Caucasus (Table 11). Countries in Latin America and the Caribbean are well situated as far as identification, performance recording, and artificial insemination of cattle are concerned. However, most cattle breeds in this region lack a breeding goal and a breeding strategy.

Genetic resource management of sheep breeds in Africa, Asia, and the Near and Middle East is clearly hampered by a lack of identification of individuals and performance recording (Table 10). A third of Asian sheep breeds have a breeding goal and selection strategy in place. This is in contrast with Latin America and the Caribbean, where these aspects of animal resource management are lacking. However, the latter region performs better for the recording of individual animals, artificial insemination, and genetic evaluation. Artificial insemination and genetic evaluation of sheep are in fact better placed in Latin America and the Caribbean than in the developed regions of Europe and the Caucasus. About half the sheep breeds in these developed regions have breeding goals, selection strategies, as well as individual identification and recording in place.

The situation regarding goat breeds are quite similar to that in sheep, but with generally higher levels of uptake of genetic strategies and tools in African goat breeds (Table 11). In contrast, goat genetic resource management in the developed countries of Europe and the Caucasus are generally on lower levels compared to sheep. The lower uptake of artificial insemination in small ruminants compared to bovines is notable. This trend is probably related to the lack of a reliable trans-cervical insemination protocol in the small ruminant species.

The most important stakeholder in determining breeding goal definition was identified as research organizations in all regions [65]. The identification of individual animals also appears to be mostly driven by research institutions. The exception to this rule was in Europe and the Caucasus, where it was mostly driven by breeders and governments. Recording of animal performance is mostly driven by research organizations in Africa, by governments and breeders in Asia, by nongovernmental organizations in the Near and Middle East, and by breeders in Europe and the Caucasus. Genetic evaluation is seen as the responsibility of research organizations in all regions.

Breeding in Developing Countries and Tropics. Table 11 The percentage of cattle and sheep breeds applying tools integral to livestock breeding during the process of breed improvement

Region	Africa	Asia	Near and Middle East	Europe and the Caucasus	Latin America and the Caribbean
Cattle breeds with:					
Breeding goal	18	28	14	44	4
Strategy implemented	13	24	9	44	1
Individual identification	11	12	9	44	58

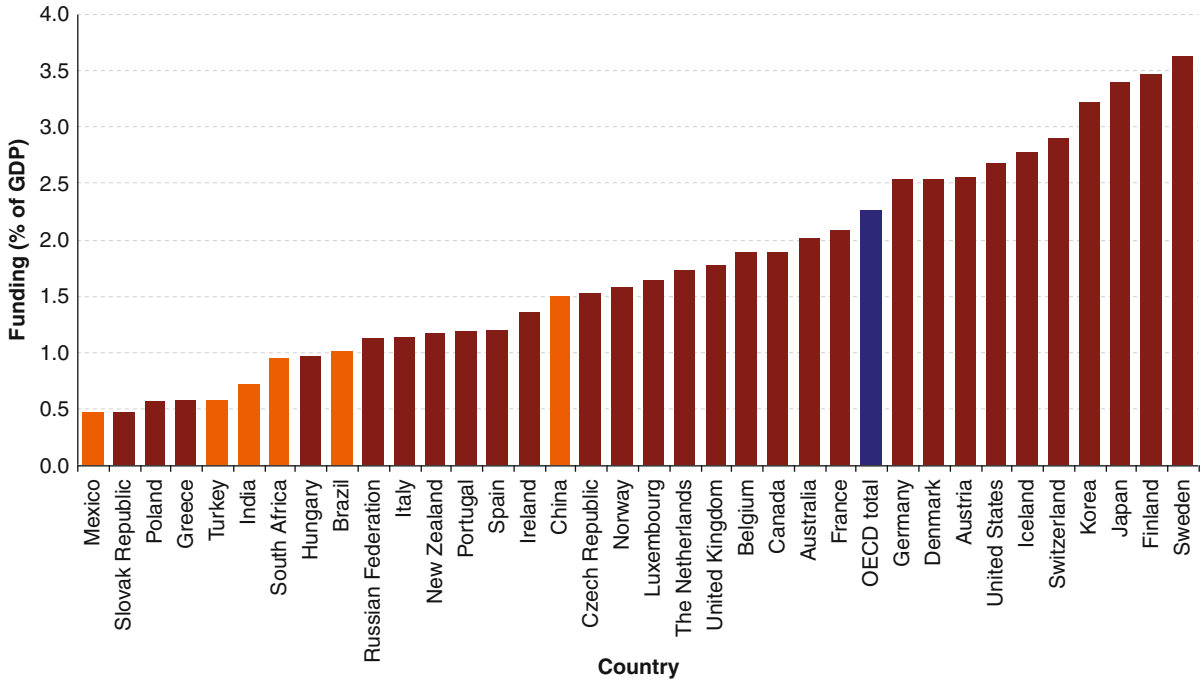
Artificial insemination	5	3	0	5	31
Genetic evaluation	16	3	0	10	27

Source: Adapted from Thieme [65].

Crossbreeding programs to complement pure-breeding efforts were reported in all species and all regions [65]. Crossbreeding seems to be more prevalent in cattle and goats compared to sheep.

Research Expenditure The importance of research organizations in the evaluation of animal genetic resources has been highlighted in the previous section. It is therefore relevant to consider the state of research funding in countries of the developing world and in the developed world (Fig. 19). The developing countries (orange bars) with the highest research expenditure in terms of gross domestic product (GDP) is China at 1.49%. Other developing countries are Brazil (1.02%), South Africa (0.95%), India (0.71%), Turkey (0.58%), and Mexico (0.46%). Research expenditure of countries in the developed world (dark red bars) ranged from 0.47% of the GDP for the Slovak Republic to 3.63% of the GDP for Sweden. The average research expenditure for OECD countries (blue bar) amounted to 2.26% of GDP.

Figure 19 provides information on research in general. Agricultural research is often not the area of scientific development attracting the highest level of



Breeding in Developing Countries and Tropics. Figure 19
Research funding expressed as a percentage of the gross domestic product (GDP) for a number of countries. Developed countries are depicted in dark red, developing countries in orange, while the blue bar depicts the average of the OECD countries (Source: OECD [66]).

funding. Information on South Africa as an example of a fairly prosperous developing economy is provided to demonstrate this point. Of a total research budget of ~ZAR 16.5 billion in 2006/2007, funding of research and development in Agricultural Sciences amounted to 6.9% [67]. This figure was substantially lower than those for Engineering Sciences (21%), Medical and Health Sciences (15%), Information, Computer and Communication Sciences (14%), Applied Sciences and Technologies (11%) and Social Sciences (9.4%). Of the ~ZAR 1.14 billion invested in Agricultural Sciences, only ~ZAR 0.34 billion are dedicated to research on animal production and animal primary products. This amounts to approximately 2% of the overall research and development budget.

During 2006/2007, the contribution of different sectors of the South African economy to agricultural research and development (the gross value of research and development is provided in Table 12) amounted 3.0% for the business sector, 16.7% for the governmental sector, 4.6% for the higher education sector, 8.1% for nonprofit organizations and 19.0% for science councils. Compared to 2004/2005 figures, research and development expenditure increased by 37% in the business sector, by 98% in the government sector, by 30% in the higher education sector, and by 38% for science councils. No consistent increase was evident in the research and development expenditure of nonprofit organizations. The share of agricultural research remained relatively stable in the business and higher education sectors as well as in the science councils. In contrast, the percentage of governmental research and development funds devoted to agricultural research halved over the same period (Table 12). The gross value of governmental research on animal production and animal primary products increased slightly from ZAR 0.058 billion during 2004/2005 to ZAR 0.067 billion during 2006/2007. However, the percentage of the total budget devoted to these study fields declined from 11.2% to 7.0% over the same period [67]. A modest increase in the share of agricultural research was recorded for nonprofit organizations. The

Breeding in Developing Countries and Tropics.

Table 12 Changes in South African research and development expenditure for Agricultural Sciences in the recent past, expressed relative to the total expenditure on research and development in the business, governmental, and higher education sectors, as well as nonprofit organizations and science councils

Sector and expenditure	Year		
	2004/2005	2005/2006	2006/2007
Business			
Total R&D (ZAR billion)	6.766	8.244	9.243
Agriculture (%)	2.8	3.1	3.0
Governmental

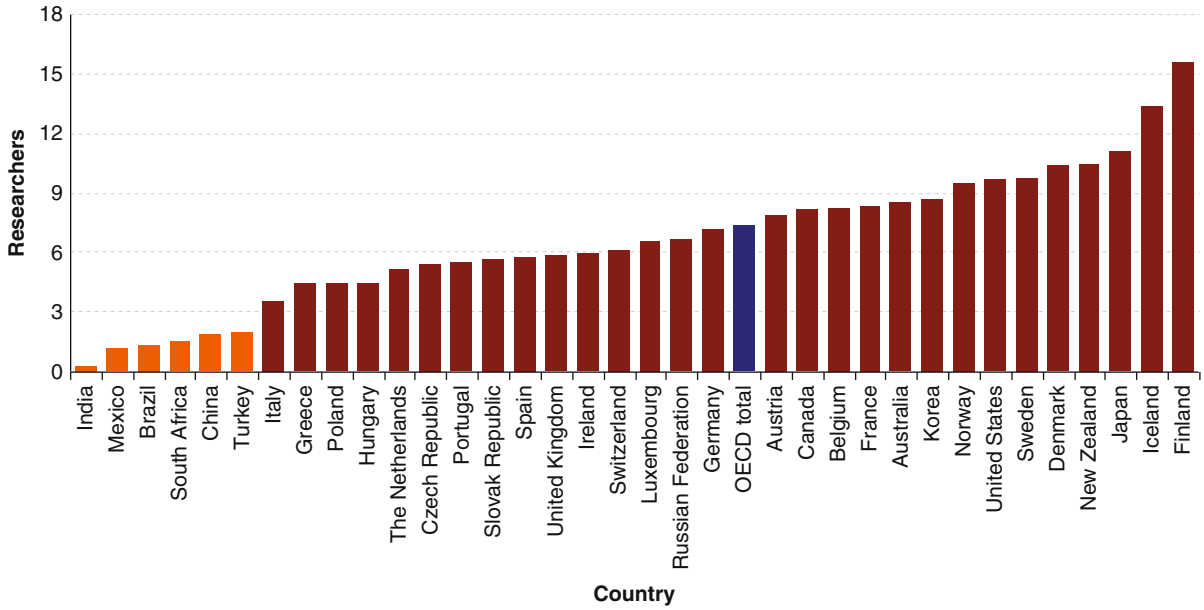
Source: Adapted from Anon [67].

contribution of this sector is probably not that important if it is considered that research by nonprofit organizations attract a relatively small fraction of the overall research funding (according to Table 12 only 1.2% of the overall research and development budget).

Given the importance of governments and other stakeholders in research in decision-making pertaining to livestock breeding [65], the reduction in the percentage of governmental funds allocated to agricultural research and development is disconcerting. If it is considered that South Africa has been identified as an emerging economy along with Brazil, Chile, China, India, Russia, and Ukraine [68], it is evident that the situation may be worse in other countries in the developing world. There thus seem to be a need for a concerted effort to consolidate funding for research pertaining to livestock genetic resources in the countries of the developing world.

Intellectual Capacity The previous heading was concerned with the funding of research in the developing world. Apart from the monetary needs, the functioning of all research organizations also depends on the number and quality of the researchers employed. The number of researchers per 1,000 members of the population in a number of developed and developing countries thus needs to be considered. It is clear that developing countries (orange bars) have substantially fewer researchers in employment per 1,000 population members when compared to developed countries (Fig. 20). The numbers of researchers per 1,000 population members in developing countries ranged from 0.3 in India to 1.9 in Turkey. In contrast, between 3.6 (Italy) and 15.7 (Finland) researchers were employed per 1,000 population members in the developed world, giving an average of 7.3 researchers per 1,000 population members for OECD member countries. The number of researchers per 1,000 population members in the developed world is thus substantially higher than in the developing world.

The discrepancy in the number of researchers per 1,000 population members is evident from Fig. 20. It is of interest to note the trend in the employment of researcher fulltime equivalents in a developing country like South Africa. Firstly, it is important to note that close to 50% of all the researcher fulltime equivalents in South Africa were employed by the business sector in 2006/2007 (Table 13). The higher education sector accounted for another 29%, science councils for 16%, the governmental sector for 6%, and nonprofit organizations for 1.6%. Overall, the number of researcher fulltime equivalents increased by 15% from 11,080 in 2004/2005 to 12,739 in 2006/2007 [67]. A similar increase was noted in the business sector, while the number of researcher fulltime equivalents in the governmental sector increased by a substantial 60%.



Breeding in Developing Countries and Tropics. Figure 20
The number of researchers expressed per 1,000 population members for a number of countries. Developed countries are depicted in dark red, developing countries in orange, while the blue bar depicts the average of the OECD countries (Source: OECD [66]).

The number of researcher fulltime equivalents in the higher education sector was fairly stable, while nonprofit organizations suffered a 13% decline in researcher fulltime equivalents. The number of researcher fulltime equivalents in science councils decreased by 15% from 2004/2005 to 2005/2006, but recovered to a level 28% higher than in 2004/2005 during 2006/2007. It is notable that researchers contributed about 50% to all research related personnel in the business sector (Table 13). Researchers formed a more commanding part of the personnel corps in the higher education sector (71–77%) and in nonprofit organizations (56–69%). In contrast, the support personnel appeared to have the lion's share of the personnel corps at the expense of researchers in the government sector (30–44%) and in science councils (31–40%). The latter similarity is not surprising, as the science councils are parastatal organizations receiving part of their budgets from the government coffers.

From the aforegoing, it can be deducted that scientists in the developed world are often faced with particular challenges relative to their counterparts in the developed world. One of these should be a heavier workload, to make up for the deficit in manpower as reflected in Fig. 20. It is therefore not surprising that South African professionals were found to spend longer times at the office compared to their colleagues in the United States, United Kingdom, and Australia in a survey conducted between June 2010 and July 2010 [69]. In 25% of the professionals interviewed, this situation was aggravated by inconsistent internet access. In view of South Africa's assessment as a developing economy [68], it is expected that the situation in many other developing countries could be worse.

It needs to be stated that the results provided in Fig. 19 and in Table 13 are for research in general and not for agricultural research in particular. Unfortunately, the information pertaining to researcher fulltime equivalents was not broken down to the level of research field as for the expenditure on research reported in Table 12. The increase in the number of researchers has to be viewed positively, noting that research and development in a country is needed for sustained growth and global competitiveness [67].

Breeding in Developing Countries and Tropics. Table 13 Changes in the number of South African researchers (expressed in full-time equivalents – FTE) in the recent past, expressed relative to the total number of FTE active within research and development (R&D) in the business, governmental, and higher education sectors, as well as nonprofit organizations and science councils

Sector and researcher fulltime equivalents	Year		
	2004/2005	2005/2006	2006/2007
Business			
Researcher fulltime equivalents (n)	5,300	5,896	6,111
Percent of personnel involved in R&D	46.9	48.2	48.5
Governmental			
Researcher fulltime equivalents (n)	491	651	784
% of personnel involved in R&D	29.5	43.9	37.9
Higher education			
Researcher fulltime equivalents (n)	3,506	3,555	3,658
Percent of personnel involved in R&D	77.1	72.1	70.8
Nonprofit organizations			
Researcher fulltime equivalents (n)	234	198	203
Percent of personnel involved in R&D	64.5	69.2	55.9
Science councils			
Researcher fulltime equivalents (n)	1,549	1,323	1,983
Percent of personnel involved in R&D	31.0	32.2	40.0

On the other hand, it has already been shown that the emerging economy of South Africa invested only 6.9% of the total research and development budget in agricultural research (Table 12). As high-level researchers are often attracted to better funding opportunities, it is likely that the agricultural sector could find it difficult to recruit and retain the most promising young scientists. Moreover, the increase in the number of researcher full time equivalents is unlikely to be met with immediate success, as its impact still needs to filter through with time.

Against this background, it is not surprising that animal resource management is suboptimal in most countries in the developing world, as depicted in Tables 9–11. Therefore it is important to consider ways to ensure that services with respect to animal resource management are delivered to producers in these regions, given the important contribution of livestock to food security and rural sustainability. In this process it is fitting to have a look at how the developing world contributes to the global science output.

The Contribution of Developing Countries to Global Science The recent 9th World Congress on Genetics Applied to Livestock Production (WCGALP) was held from August 1 to August 6, 2010, in Leipzig, Germany. WCGALP provides an opportunity to take stock of global research efforts involving livestock production every 4 years. The relative contribution that stemmed from scientists in the developing world can be assessed simultaneously. The country of origin of the first author of each abstract of oral contributions during concurrent sessions and of posters displayed during poster sessions was recorded and summarized in

Breeding in Developing Countries and Tropics. Table 14 Contributions to the concurrent paper or poster sessions of the 2010 World Congress on Genetics Applied to Livestock Production per topic, with the contributions from developing countries as percentage

Topic	Papers[a]		Posters[a]		Total[a]	
	N	%	*N*	%	*N*	%
Species breeding	164	11.0	181	49.2	345	31.0
Genetics of trait complexes	101	4.0	79	27.8	180	14.4
Methods and tools	90	4.4	46	30.4	136	13.2
Genetic improvement programs	96	12.5	52	32.7	148	19.6
Special topics	24	12.5	2	0	26	11.5

[a]Number of contributions within categories (*N*) and percentage contributed by the developing world (%).
Source: Adapted from WCGALP [70].

Table 14. None of the eight plenary lectures that were presented during the congress was by scientists or groups of scientists from the developing world. The contribution of the developing world to papers presented during concurrent sessions will be considered next. The contribution of scientists from the developing world ranged from 4% in the case of the topic "genetics of trait complexes" to 12.5% for the topics "genetic improvement programs" and "special topics" (Table 14). Cases where contributions from the developing world exceeded 10% of all contributions within subtopics will be noted subsequently. Within the topic of "species breeding," the developing world contributed most toward "small stock breeding" (33.3% of 21 papers), "poultry breeding" (20.0% of 20 papers), and "aquaculture" (18.8% of 16 papers). The contribution of scientist groups in the developing world to small stock breeding should probably be seen in context with the projected and current trends in sheep meat in Fig. 12. Pertaining to the topic "Genetics of trait complexes" one of nine papers on "behavior" (11.1%) was presented by scientists from the developing world. The developing world does not seem to be active on the topic "methods and tools" as no subtopic attracted 10% of more of the papers in this case. When the topic "genetic improvement programs" was considered, groups from the developing world contributed most papers to the subtopic "breeding objectives and economics of selection schemes" (40% of 10 papers), "management of genetic resources" (26.1% of 23 papers) and "selection for harsh environments (e.g., the tropics)" (11.1% of 9 papers). Given the location of most developing countries, it is somewhat surprising that the major contribution of the latter subtopic still seemed to originate from the developed world. A notable lack of activity was observed for the subtopics "advances in selection theory, including experimental demonstrations" (0 of 7 contributions), "selection using molecular information" (1 out of 39 contributions) and "design of selection schemes exploiting additive and/or nonadditive effects" (0 out of 8 contributions). Within the "special topics" category, scientists from developing countries contributed to the subtopics of "animal breeding and the environmental challenges" (22.2% of 9 contributions) and "education and training" (14.3% of 7 contributions). Overall scientist groups from the developing world contributed 41 out of 475 papers during concurrent sessions, or 8.6% of the total number of papers. Developing countries contributing three or more of these papers were Brazil (8), South Africa (5), Iran (4), Israel (4), and Kenya (3).

The contributions of scientist groups from the developing world to the poster sessions are much more evident (Table 14). About half of the posters on the topic "species breeding" originated in the developing world, while between 27.8% (genetics of trait complexes) and 32.7% (breeding objectives and economics of selection schemes) of contributions were made by scientist groups in the developing world. Both posters

on special topics were presented by scientist groups of the developed world.

Subtopics with more than 30% contributions from the developing world are listed next. The contribution of the developing world to posters on the topic of "species breeding" amounted to 73.7% for "poultry breeding" (of 19 contributions), 71.4% for "beef cattle breeding" (of 42 contributions), 62.5% for "small stock breeding" (of 16 contributions), 58.7% of "dairy cattle breeding" (of 46 contributions), and 38.5% for "aquaculture" (of 13 contributions). When the topic "genetics of trait complexes" was considered, it was found that posters originating from the developing world exceeded 30% for the subtopics "growth, development, feed intake and efficiency" (55.6% of 18 contributions), "lactation" (42.9% of 7 contributions), and "behavior" (33.3% of 3 contributions). Under the topic "methods and tools," the contributions of scientists from the developing world exceeded 30% for "functional genomics and systems biology" (37.5% of 8 contributions), "statistical methods – linear and nonlinear models" (33.3% of 15 contributions) and "software and bioinformatics" (33.3% of 6 contributions). When the topic of "genetic improvement programs was considered, contributions from developing world exceeded 30% for "breeding objectives and economics of selection schemes" (50% of 10 contributions) and "management of genetic resources" (33.3% of 15 contributions). It is evident that scientists from the developing world were more likely to make their contributions by the way of posters. It could be by own choice in many instances, while the available slots for oral presentations could simply have been filled by contributions from developed countries in other cases. Of the 142 posters presented by scientists from the developing world, five or more posters were contributed by Brazil (57), China (17), Mexico (14), South Africa (12), Iran (11), and Kenya (5). The overall contribution of developing countries thus ranged from 11.5% for the topic "special topics" to 31.0% for the topic "species breeding" (Table 14).

Of the 837 contributions presented in concurrent sessions or as posters during WCGALP, 183 (or 21.9%) originated from the developing world. Most of these contributions were from Brazil (65), China (19), South Africa (17), Iran (15), Mexico (14), and Kenya (8). In total, 1,382 delegates from 60 countries attended the Congress. Of these, 229 delegates (or 16.6%) were from 32 developing countries. Developing countries represented by more than 10 delegates were Brazil (67), China (39), South Africa (19), and Mexico (19). It is notable that the average number of contributions per delegate were 183/229 = 0.799 for the developing world and 654/1,153 = 0.567 for the developed world. It thus seemed as if the scientists from the developing world were at least as willing to contribute to the scientific program as their peers from developed countries. Alternatively, a contribution at the congress could be a prerequisite for attendance for many of these scientists, given the limited funds that are available for these scientists (see Fig. 19).

From the aforegoing it is evident that the quantity and depth of research in the developing world make it difficult for scientists from these countries to compete with peers in the developed world. Kahi [64] also noted that studies from the developing world were underrepresented at the WCGALP. The fact that science groups in the developing world were much less likely to contribute papers on molecular genetics and genomic selection was also highlighted in the latter paper. More than a third of contributions at the WCGALP reported results of genomic selection [71]. The trend toward an increased investment in genomic selection is discussed later under the section "The technological age." However, the role of scientists in the developing world is anticipated to decline if they are not able to become involved in this study field. As noted before, the disparity in research funding and the availability of high-quality manpower (Fig. 20) doubtlessly contribute to this finding. However, it is also clear that a number of dedicated scientists from the developing world (based on the average number of contributions per delegate) still present their research findings at international forums. The capacity for change thus exists with such scientists acting as catalysts for the application of sound scientific applications in the developing world.

The Case for Conserving Animal Genetic Resources

It is estimated that 190 of approximately 7,600 livestock breeds became extinct over the past 15 years [72]. Roughly 60 breeds of cattle, goats, pigs, horses, and poultry were lost in the past 5 years. This section asks whether this should be a cause of concern or not.

Moreover, it should be debated whether the livestock breeds of the developed world should be treated as a strategic resource, and if so, why?

As an initial comment, it needs to be stated that the share of the developing world in global animal genetic resources trading is minimal [73]. Detailed records were available for trade flows of cattle semen, live cattle, and live pigs. Data for poultry, small ruminants, and aquaculture species are unfortunately scant. The bovine semen trade is dominated by OECD countries. Bovine semen is mostly exported by the United States (32.6% of the trade), Canada (31.5%), the Netherlands (7.4%), France (6.2%), Germany (5.6%), the United Kingdom (3.8%), Italy (2.5%), and other OECD countries (9.2%). In contrast, the share of developing countries in bovine semen exports is minimal at just over 1% of global trade. Developing countries exporting bovine semen are South Africa (0.5%), Argentina (0.3%), Brazil (0.3%), and others (0.2%). Much the same situation is in place for live cattle for breeding, where the contribution of the developing world amounts to only 7.5% of the global trade [73]. The contribution of the developing world to the trade of live pigs for breeding amounts to approximately 5%. The bulk of gene flow in farm animal genetic resources takes place between developed countries (60–70%). The rationale is that farming in these countries developed to depend on high-performance operations, operating at high levels of intensity and accuracy and at a reduced environmental variability [73]. It is argued that farm animal genetic resources from these systems should be adaptable to production systems worldwide. Based on this assumption, it is not surprising that gene flow from the developed countries to the developing countries constitutes the second most important trade pathways, accounting for between 20% and 33% in the trade of farm animal genetic resources. The exportation of genetic material from the developing world to the developed world constitutes between 1% and 2% of the global trade. There is also modest trade in farm animal genetic resources among developing countries, particularly with reference to low-input production systems [73].

A number of instances where genetic material from developing countries has been introduced to developed countries were reviewed by Blackburn and Gollin [74]. Neither Chinese Meishan pigs nor Zimbabwean Tuli cattle were able to penetrate the commercial livestock market in the United States. Although the Meishan pigs were prolific, unwanted growth and body composition traits led to a realization among pig geneticists in the United States that they could select for prolificacy within local pig breeds, without a need to cater for the unwanted characteristics of the Meishan. Tuli cattle similarly did not perform satisfactorily in terms of growth and feedlot performance, despite a good ranking for biological efficiency compared to Angus/Hereford cows. Interest in the breed thus dwindled, with only 150 registrations in 2000. In contrast, the South African Boer goat gained a foothold in the commercial goat market based on an improved body size, faster growth rate, and an improved conformation compared to local Spanish goats, which formed the basis of United States chevron production prior to the importation of Boer goats [74]. Adoption of the breed is supported by ~45,000 registrations in 2005, but Boer does were found to have a lower reproduction capacity than Spanish and Kiko does [75].

Against this background, it does not seem as if farm animal genetic resources of the developing world have a major role to play in the high-output production systems of the developed world. It even seems worthwhile to consider replacing the relatively low output farm animals of the developing world with more productive genotypes from the developed world. However, it has clearly been shown that these genotypes do not always perform according to expectations because of susceptibility to heat conditions [53–56], and typical diseases [24, 26, 37, 38] in the developing world. The often unpredictable environmental conditions inherent to farming systems in the developing world also contribute to a lack of adaptation of exotic genotypes [16, 19] under typical farming conditions in the developing regions. Samdup et al. [76] recently established that the crossing of indigenous dairy cattle in Bhutan with high-yielding Jersey cattle, as well as purebred Jersey cattle, resulted in a milk off-take of 2.4–4.6 times that achieved by local cows. However, the higher production levels of Jersey and Jersey crossbreds were offset by poor survival as well as low reproduction rates. Although crossbreeding contributed to higher livestock gross margins in the intensive areas, it has not yet resulted in meeting the demand for dairy products in Bhutan.

The downside of uncontrolled crossbreeding in farm animal genetic resources in the developing world is that the valuable adaptation traits like disease resistance may be lost. Based on the analysis of microsatellites, there is evidence that the genetic basis of the gastrointestinal nematode–tolerant Red Maasai breed is being eroded by crossing, predominantly with the exogenous Dorper breed [17, 77]. Based on the results of Baker et al. [37, 38], the ability of the Red Maasai to tolerate internal parasites may be lost in this way. Urgent intervention to halt the process has been advocated by Ole Kwallah et al. [77]. Fortunately, a nucleus flock under governmental control is still available to use in this process [17]. When Scholtz et al. [78] surveyed the South African beef cattle population in the communal sector, a high percentage (35%) of bulls that were used for breeding purposes were classified as nondescript or crossbred. This classification included the highest percentage of bulls, followed by the Nguni (22.5%), Brahman (18.2%), Afrikaner (9.9%), Bonsmara (5.1%), Drakensberger (2.8%), Simmentaler (2.1%), and various other breeds (4.4%). This observation also draws attention to a possible loss of genetic diversity because of random crossbreeding in the communal resource herds.

In this context, it is important to draw attention to fears that global livestock biodiversity will be compromised by the present animal breeding practices. These fears are supported by many breeds in different parts of the world with a lack of complete population data, as summarized in Table 15. It is clear that population data are not available for many breeds in the developing regions. Among the developing countries, information for Asia does not lag as far behind the developed world as for other developing regions, like Latin America and the Caribbean. The implication of this is that conservation status of many breeds is doubtful, simply because there is no information. According to Cardellino and Boyazoglu [79], the risk of extinction is not known for 30.0% of cattle breeds, 33.8% of goat breeds, 30.4% of pig breeds, and 29.6% of sheep breeds. Between 3.1% (goat) and 18.9% (pig) of breeds in all these species are already extinct, while between 12.7% (sheep) and 18.0% (pig) breeds are classified as at risk. The classification of no risk applies to 38.1% of cattle breeds, 49.5% of goat breeds, 32.6% of pig breeds, and 44.9% of sheep breeds. Against the background of these realities, it is important to consider ex situ conservation in the form of embryos and semen in some cases [80, 81]. The Brazilian animal germplasm bank has 60,000 doses of semen, more than 250 embryos, as well as over 700 DNA samples at present [81].

Breeding in Developing Countries and Tropics.

Table 15 The percentage of breeds with population data in the respective world regions according to class (*Mammalia* or *Aves*), and in total

Region	*Mammalia*	*Aves*	Total
Africa	32.5	21.4	30.5
Asia	55.9	41.4	52.5
Europe and the Caucasus	67.2	58.4	64.6
Latin America and the Caribbean	12.9	13.7	13.1
Near and Middle East	42.5	23.3	39.3

Southwest Pacific	22.1	15.2	20.4
World	**47.2**	**44.2**	**46.5**

Source: Adapted from Cardellino and Boyazoglu [79].

It is hypothesized that biodiversity in farm animal genetic resources is needed to ensure that it is possible to react to major changes possibly brought about by major events, like global warming. Against this background, a plan was drawn up to conserve the existing animal genetic resources, and to ensure that adapted genetic resources remain available for the smallholder systems typical of the developing world [82]. In accordance with this quest, Villanueva et al. [83] developed an indicator of farm animal biodiversity. The system was applied to British sheep and cattle breeds, and allowed inferences that the biodiversity in cattle at least actually increased from 2001 to 2008. A similar trend in sheep was negated somewhat by an increased variability in the data. It has also been reported by Djemali et al. [84] that the Sicilo-Sarde Tunisian dairy sheep breed has actually been resurrected in the recent past, after having been on the verge of extinction.

These arguments lead to the important topic of conserving farm animal genetic resources in the

developing world. According to Cardellino and Boyazoglu [79], such efforts should incorporate the recording of phenotypic performance in local breeds. According to the latter authors, the use of molecular information has possibly been overemphasized in conservation efforts of genetic resources in the developing world in the past. The role that molecular characterization may play in the conservation of farm animal genetic resources is well understood, and described by Toro et al. [85]. The point made by Cardellino and Boyazoglu [79], however, is that efforts for animal breeding for the genetic improvement of populations have been compromised to some extent. The basic principles of recording phenotypic data and pedigree information in livestock production systems have been known for a long time [86], so there is no need to elaborate on this. However, this is not done on a routine basis in the developing world. While major gains have been achieved in livestock production systems in the developed world, the same cannot be said for the developing world. Aspects like routine recording of phenotypes and pedigrees become a major effort under communal and smallholder production systems [79]. This results in little genetic gain being achieved. This may be a blessing in disguise, as there are many burning questions in this respect that still need to be answered [79]. Some of these questions pertain to the following:

- Standard interventions aimed at improving production may be counterproductive.
- Genetic and environmental effects may not be adequately researched in harsh environments.
- The magnitude and direction of genotype by environment interactions in unfavorable environment may differ from those in good environments.
- All the crucial adaptive traits may not be recognized.
- Selection could move populations off their adaptation equilibrium and make matters worse.

These challenges should be addressed before major interventions are applied. There are thus a number of research opportunities to address these challenges in future [79]. Before these can be addressed, however, it is necessary to have a closer look at the successes and failures of programs that were implemented in developing countries in the past.

Animal Breeding in the Developing World: Successes and Failures This section summarizes existing breeding programs, and what could be learned from them. It was attempted to cite most examples from the developing regions, but comparisons with the developed world are unavoidable. Readers will notice that this section is biased toward experience with farm animal genetic resources in South Africa. The reason for this is that a well-developed commercial sector exists in South Africa alongside low-input systems with communal land use. With a producer support estimate of approximately 4% in comparison to the range of estimates from below 5% (in Australia and New Zealand) to more than 70% (in Iceland, Norway, and Switzerland) in OECD countries [8], the South African commercial livestock industry is relatively efficient and in many ways comparable to livestock industries in the developed world.

As a point of departure, it has been established that animal breeding in developed countries has resulted in major and verifiable contributions in improved livestock production, resulting in the demands of consumers being met in a cost effective and sustainable manner [87]. Genetic advances in the more intensive pig, poultry, and dairy industries are often cited as examples of what can be achieved by a structured breeding program for well-defined selection objectives. Recent results pertaining to the well-established Sheep Genetics Australia scheme indicated that participants make progress at an average rate that is comparable to what is attainable in theory in the dual-purpose and terminal sire schemes [88]. Wool sheep farmers are less successful and are progressing at a rate of ~30% of what is attainable in theory. Advances such as those reported by Swan et al. [88] for dual-purpose and terminal sire sheep breeds have led to selection objectives in developed countries having changed from production traits to traits associated with animal welfare, product safety, and preferences by consumers [65].

It is evident from the foregoing discussion that such advances have not been realized in the developing world. However, there are examples of animal improvement schemes in developing countries that are benchmarked with international schemes. An example is the South African dairy cattle scheme participating in Multiple Across-Country Evaluations (MACE). Test-day databases for the South African Ayrshire, Guernsey,

Holstein, and Jersey breeds were harmonized with those of other participating countries [89, 90], to allow participation of the local dairy industry in MACE. Bovine semen produced in South Africa has a small international market share of 0.5% [73].

In contrast, dairy contributed only about 10% to the reason why emerging and communal farmers keep cattle [91]. Communal farmers mostly milked nondairy breeds like the Nguni (34%), Brahman (22%), Afrikaner (20%), and Bonsmara (10%) under free-ranging conditions. Traditional dairy breeds like Friesians and Jerseys only contributed 3% to communal cattle used for milk production. Herd size averaged 6 for dairy cattle and 11 for dual-purpose breeds. At 16%, the percentage of traditional dairy cows was somewhat higher for emerging farmers, but most of the cows milked were still from nondairy breeds. Herd size averaged 39 head for dairy cattle and 42 head for dual-purpose cattle in this sector [91]. Details of levels of production were not provided but it is assumed to be fairly low. In this respect, McDermott et al. [2] identified the dairy and small stock enterprises in small-scale farming systems as amenable to intensification.

There is evidence that breeding decisions peculiar to regions and managerial capacity of farmers may hold advantages in the dairy production enterprises of developing countries. In this respect, it was demonstrated that the continuous importation of semen may not be economically viable in the Kenyan dairy production system, where smallholders living below the poverty line own 70% of the dairy cattle [92]. Systems where semen from local bulls was used were consistently more profitable than those relying predominantly on imported semen. Arguably this effects could result from better adaptation to environmental conditions, as more daughters of Kenyan, Israeli, and South African artificial insemination bulls survived involuntary culling under Kenyan conditions [16], as discussed previously. Based on the parameters of the mechanistic lactation functions, it was contended that lower-yielding Ayrshire cows were better adapted to low- and medium-input systems in Kenya than Holstein-Friesian cows [93]. In contrast, the latter breed would have distinct advantages in high-input production systems where the levels of management and husbandry were high. Finally, it should be noted than India became the world's largest producer of milk, mostly through smallholding systems [94]. It is thus clear that substantial quantities of milk could be produced by small-scale farmers. This appears to be the case particularly in countries like Kenya and India, where there is also substantial private sector involvement [94].

The bulk of agricultural land in South Africa is not arable. Large areas are thus suitable only for extensive grazing, mostly by beef cattle in the north-eastern part and by sheep in the southwestern part [8]. The commercial breeding sector of the South African beef industry is serviced by the National Beef Recording and Improvement Scheme managed by the Agricultural Research Council (ARC), as described by Bergh [95]. After a peak of ~450,000 weights in the mid-1980s, this Scheme annually recorded between ~170,000 and ~260,000 weights since 1992. Breeding values for a range of growth/production, size, and reproduction traits are available to breeders [96]. Additional reproduction traits have been developed for inclusion in the Scheme recently [97], indicative of continuous development according to consumer specifications. It is estimated that nine beef breeds (Afrikaner, Beefmaster, Bonsmara, Braford, Charolais, Drakensberger, Gelbvieh, Angus, and Sussex) have at least 80% of the available females participating in the recording scheme [78]. As for other schemes managed by the ARC, real-time information to producers is available on the Internet [95]. Other beef breeds in South Africa are being provided by similar services by Breedplan® International [98], providing a link to international genetics. At 0.8%, South Africa controls a small portion of the international trade in live cattle exports for breeding [73], placing the country in the third position after Panama (4.1%) and Lithuania (1.0%) among developing countries.

At 47%, the sale of live animals and beef was listed as the most important reason for keeping cattle in the communal cattle sector of South Africa [78]. Cattle were also listed as being important for investment (15.4%) and cultural and ceremonial practices (13.3%), while the production of milk (10.2%), draft power (4.1%), and other reasons (4.5%) were of secondary importance. The average herd size in the communal/emerging sector was 19 head, as compared to 413 head in the commercial sector [78]. The most important attributes looked for a bull by communal farmers were size (33.1%), followed by conformation

(22.0%) and performance (18.9%). When ranked by emerging farmers, the attributes were ranked somewhat differently, being performance (30.3%), size (23.5%), and conformation (19.3%). Corresponding attributes in the commercial sector were performance (33.2%), conformation (11.1%), and temperament (9.8%). Only 1.9% of communal and 36.8% of emerging farmers used a controlled mating season, compared to 88.6% in the commercial sector. Artificial insemination was used by 0.1% of communal farmers, 6.3% of emerging farmers, and 21.9% of commercial farmers [78]. Guidelines for the participation of communal farmers to the National Beef Recording and Improvement Scheme are available [99], but uptake is low.

In sheep, across flock genetic evaluation results have been reported for the South African Dorper breed [100], the South African Merino breed [101], and the South African Dohne Merino breed [102]. The South African Small Stock Scheme has recently been compared to the evaluation scheme provided by Sheep Genetics Australia to Australian livestock producers [8]. The schemes do not differ appreciably for the basic production traits (live weights, wool and fiber traits, as well as for reproduction), which are recorded on farm by livestock producers. Differences between the schemes involve traits associated with disease resistance (fecal worm egg counts and traits associated with blowfly challenge) and carcass quality traits (ultrasonic muscle and fat dimensions) which are recorded on a national basis in Australia, but not in South Africa. The personnel to record these traits are not available in the South African scheme [8], and it is therefore only recorded in experimental flocks. The shortage in qualified personnel is not unexpected if the trend in terms of researchers are compared (Fig. 20 and Table 13). Australia boasts 8.5 researchers per 1,000 community members, compared to 1.5 researchers in South Africa. With almost a sixfold advantage it is not surprising that the former country has the capacity to allow the recording of the additional traits on a national basis. Moreover, if it is considered that the investment in research on animal production and animal primary products constitutes only 2% of the national research budget in South Africa [67], it is clear that scientists in South Africa are under immense pressure to deliver services comparable to that in developed countries like Australia.

Still there is reason for positive thinking. Overall, the South African scheme recorded ~81,000 weights and ~33,000 wool records (including a fleece testing service) for 2006-born animals with four professional staff and 10 auxiliary staff [103]. It was also shown that the recording of weights increased by about 50% from 2003 to 2006 in the scheme. These records were derived from 13 breeds, but slightly more than half came from the two major wool breeds (Merino – 31.4% and Dohne Merino – 23.9%) and a further quarter from the Dorper meat breed (24.2%) [8].

Sustained improvements in the relative economic value of breeding animals have been reported in the South African Merino breed [101] and in other South African breeds [103]. Leading studs in almost all breeds showed additive genetic gains comparable to those achieved elsewhere in the world. It is important to note that similar sheep breeding schemes are operative elsewhere in the developing world. Across-flock breeding values are thus available on the Internet for several sheep-producing countries in South America (see review by Cardellino and Mueller [104]). Similar reports were forthcoming from developing countries in South America, Western Africa, and India [105]. Kosgey et al. [18] reviewed a number of small stock projects in the tropics. Objectives strived for mostly involved growth, live weight, disease resistance, and traits associated with reproduction. An Indian project that was highlighted, involved the introgression of the fecundity gene from the Garole breed into the Deccani breed. Failed programs mostly lacked farmer participation [18]. Predicted rates of genetic gain from simulations in Ethiopian sheep breeds were generally in good agreement with actual responses in on-station research [106]. These predictions are in the process of being validated in four communities from different Ethiopian agroecological systems, based on community participation. Traditional Brazilian sheep breeding systems generally used appearance as the main criterion for selection. Recently a recording and genetic evaluation scheme named Ovigol® was launched to provide progressive breeders with the option of selection for traits linked to the profitability of their operations [107]. Uptake during the first 18 months was good, with records of 5,195 performance recorded animals of 13 breeders having been entered into the system.

Breeding in Developing Countries and Tropics. Table 16 Relative performance of commercial and communal rams on properties in the commercial and communal areas of South Africa

Trait	Commercial properties		Communal properties	
	Commercial rams	Communal rams	Commercial rams	Communal rams
Clean fleece weight (kg)	2.8 (100)	2.4 (86)	2.0 (100)	1.7 (85)
Fiber diameter (μm)	18.4 (100)	20.0 (109)	19.4 (100)	20.5 (107)
Clean yield (%)	76.3 (100)	68.5 (90)	66.9 (100)	60.5 (90)
Wool income (ZAR/head)	92.67 (100)	60.09 (65)	54.87 (100)	37.53 (68)

Source: Adapted from Marais [108].
Figures in brackets are expressed as a percentage of performance of commercial rams.

The genetic merit of rams from the South African commercial sheep breeding sector was compared to that of the communal sector on commercial and communal properties [108]. Fleece weight of progeny from commercial rams exceeded that of communal rams by about 15%, while the fiber diameter of lambs sired by communal rams was between 7% and 9% broader than that of commercial rams (Table 16). This resulted in wool income from the progeny of commercial rams being about 35% higher than that of lambs sired by communal rams. This trend was fairly consistent at both localities, with performance at the commercial properties being improved relative to that at communal properties.

In another study, Marais [109] studied the reproduction of ~1,200 communal ewes on four locations either mated to commercial or communal rams under communal production conditions. Reproduction was low, with the lambing percentages (lambs born per 100 ewes mated) being 30% and 47% for ewes mated to commercial and communal rams respectively. The corresponding means for weaning percentage (lambs weaned per 100 ewes mated) were 27% and 37% respectively, while lamb survival (lambs weaned per 100 lambs born) averaged 88% and 79% respectively. It is clear that reproduction of ewes mated to communal rams were substantially better than that of ewes mated to commercial rams, while the progeny of commercial rams had a slight advantage in terms of survival. The poor mating performance of commercial rams possibly suggest that they were not adequately adapted to the low-input communal conditions. The progeny of commercial rams were 7.2% heavier than those of communal rams at an age of 7 months. Lambs marketed per 100 ewes mated averaged 34.2% in a Western Cape study on properties of emerging farmers, with ranges between 9.5% and 56.7% [110]. In contrast, lamb marketing percentage ranged from 90% to 116% in a study where five commercial Merino-type ewe lines were mated to Dormer or Suffolk rams in a terminal crossbreeding experiment [111]. Even if it is considered that no replacements were kept in the latter study (ewe replacements need to be bought in) the improvement is evident. Additionally, the percentage of lambs docked per 100 ewes mated (range in brackets) on commercial properties in the Western Cape amounted to 88% for Merinos (63–103%), 93% for Dohne Merinos (76–113%), and 113% for South African Mutton Merinos (105–124%) in the study of Fourie and Cloete [112]. Even if losses between docking and marketing are considered, it is evident that reproduction on commercial properties would be superior to that on communal properties.

Based on the above information, the South African wool industry embarked on a program to improve conditions in the communal small stock production areas in the Eastern Cape in the early 2000s. The dual focus was on the upgrading of existing communal shearing sheds as well as the genetic improvement of the local animal resources [113]. Approximately 20,000 breeding rams have been introduced from the commencement of the program in 2003. It was furthermore independently established that 28% of such communal sheds realized prices of better or equal to the national

average in 2008/2009, compared to 9% in 2005/2006. Socioeconomic studies also indicated that undernutrition of children in the region was reduced from 43% in 2004 to 28% in 2009. This change results from an improved product (meat and wool) income, which initially contributed 47% to total household income compared to 65% at present.

As pertaining to substitution of animals from a local population with animals from the same breed but from another region to ensure a higher output, it was shown that Turkish Awassi dairy sheep had an improved milk yield compared to local Awassi ewes maintained in Syria [114]. Crossbreeding with and substitution by Turkish breeding stock were thus advocated as avenues for the improvement of Syrian dairy sheep breeding stock. Selection based on performance in the current flock also resulted in immediate gains, demonstrating that these principles are robust for extension to the Syrian environment.

The performance testing of meat and dairy goats in South Africa and other regions were reviewed by Olivier et al. [115]. The bulk of meat goat weaning weight data was derived from the Boer goat breed, with 11,679 records. The vast majority of dairy goat lactations were derived from the Saanen breed, with 14,688 out of a total of 16,148 lactation records. Data from these two breeds (Boer and Saanen) combine pedigree information and performance and form part of the National Livestock Improvement Scheme in South Africa. A study of small-scale goat keepers revealed that uncontrolled mating practices were followed by 98.3% of communal farmers and 92.3% of emerging farmers, at respective doe to buck ratios of 11:1 and 30:1 [116]. The reasons for keeping goats in the communal sector were for cash or investment (43.0%), products (37.6%), and cultural purposes (18.7%). Corresponding figures for emerging goat farmers were, respectively, 34.4%, 40.7%, and 24.8%. Communal farmers mostly kept unimproved veld goats (53.3%), Angora goats (28.3%), and Boer goats (15.4%). Emerging farmers had a lower percentage of unimproved veld goats (1.0%), and more Angora and Boer goats (62.8% and 36.1% respectively). Flock sizes ranged from 9 to 29 in the communal sector and from 18 to 91 in the emerging sector. High mortality of kids and females was listed as a major constraint to goat farming in these sectors [116].

The South African commercial poultry industry is highly industrialized, with little information on performance in the public domain. It would suffice to say that approximately 16 billion ZAR out of a total livestock income of 37 billion ZAR was derived from this sector in 2005/2006 [8]. In contrast, the communal sector kept an average of 10.9 chickens per household, with a range from 9.7 to 17.0 [117]. The number of hens per household averaged 6.1, with ranges from 5.4 to 8.4. Chicks per household amounted to 1.3, with ranges from 1.0 to 2.3. Egg output was estimated at between 35 and 45 eggs per hen per year. Chickens were mostly kept for household meat (89.8% of cases) and eggs for home consumption (64.2% of cases). Minor reasons for keeping chickens were for selling to other parties, ceremonies, culture, and manure [117]. Indigenous chicken production is considered important throughout Africa, despite relatively low levels of output [118]. However, the latter reference still demonstrated significant genetic variation in egg weight and body weights to be exploited in well-designed breeding programs. Genetic progress can thus be achieved, even though production conditions are less than optimal.

Based upon arguments presented under the previous headings, it was expected that animal improvement in most of the developing countries will be constrained by a lack of capacity. However, success in the commercial livestock sector of South Africa and in other developing countries has been reported above. Relative information on small-scale farming operations in South Africa is also reported for comparison. The latter production systems are comparable with small-scale production elsewhere. However, it is clear that commercial successes are not common in such systems. Production is mostly focused on home consumption, while levels of production are relatively poor. Yet successes have been reported throughout the world, as reviewed by Kahi et al. [119]. Moreover, socioeconomic drivers leading to success in these case studies were listed by the latter study. These guidelines could be used as a blueprint for future schemes wanting to embark on successful breeding programs in the communal livestock resource.

From the foregoing it seems that sustainable animal genetic resource management is feasible in the developing world. Strategies to operate within the constraints imposed by capacity problems and other limitations in this region need to be considered, while

the improvement of production in small-scale, low-input systems should receive serious attention. It is suggested that this will be easier to achieve in the presence of a strong commercial sector.

The Technological Age

It is common knowledge that the available technology improved rapidly over the past couple of decades. Analyses on animal breeding and genetics data that required a mainframe computer 20 years ago for a series of single-trait analyses are now routinely run as a single multi-trait analysis on a laptop computer.

Data Capturing, Analysis, and Dissemination

Computing power and data storage capacities increased markedly over the past few years. Software for the on-farm capture of animal records is readily available. This software enables operators with only basic computer skills to effectively collect data for entrance in national or regional databases. The recording system can easily be managed to use open-source software for routine data entry, data editing, and genetic analyses [120, 121]. Custom-made software for a specific enterprise can also be used for routine recordings [122]. Moreover, excellent research tools for data manipulation, the assessment of environmental effects, genetic parameter estimation, as well as the computation of animal solutions are readily available [123–126]. It seems quite feasible to adapt existing software used for breeding value estimation to include a genomic relationship matrix for the estimation of genomic breeding values in a single step approach [127, 128]. The available software packages allow for the analysis of various traits, which could consist of normally distributed linear data or traits with more challenging distributions (for instance, binary traits or discrete scores with multiple thresholds) in single- or multiple-trait analyses. The partitioning of random effects in direct and maternal genetic components as well as maternal permanent environmental effects have also become commonplace, while standard genotype by environment interactions is easily modeled. Analyses of longitudinal data, for example, growth data, lactation test-day records or reaction-norm analyses to model genotype by environment interactions, by using random regression methods have also become routine [129–132]. Interactive systems, where participants can access information on their animals directly from the Internet, have also become commonplace [95, 104, 121]. As this process takes place in real time, delays are effectively dealt with. This infrastructure is at the disposal of all livestock producers, including those of the emerging/communal sectors, provided that all relevant information is recorded.

Genomic Selection

If progress can be considered as rapid in computer support systems and specialist software for genetic analysis, this probably applies in the superlative to progress in DNA-based marker systems and marker-assisted selection. The bovine genome has recently been completely mapped and allows the study of the genetic structure of cattle breeds worldwide [133]. High-density Single Nucleotide Polymorphism (SNP) chips of thousands of SNP markers evenly spaced across the genome are readily available for pigs [134, 135], sheep [136, 137], cattle [138–140], and poultry [141, 142]. It has indeed been suggested that full genome information may become as commonplace as SNP technology at the next WCGALP to be held in Vancouver in 2014 [143]. The utilization of the genomic information linked to phenotypes has recently been reviewed by Goddard et al. [144], to give an overview of methods and the future of the technology. Information on SNPs was used in a BLUP or BayesA framework to attain genomic breeding values for Australian progeny testing sires [145]. Compared to the tradition sire pathway EBV, the BLUP-based system improved the accuracy of selecting dairy sires for progeny testing from 0.38 to 0.44 for the Australian selection index, from 0.35 to 0.53 for the Australian profit ranking, from 0.28 to 0.45 for protein yield, from 0.20 to 0.29 for protein percentage, and from 0.16 to 0.18 for fertility. The BayesA method resulted in further improvements of 0.04, 0.02, 0.03, 0.05, and −0.04, respectively [145]. There is consensus among analysts that genomic information can greatly enhance genetic progress in dairy cattle breeding [144, 146–148]. However, it needs to be stated that price considerations at present will only allow males and elite females to be genotyped [147]. Naturally, this may change in future as the technology becomes more affordable.

The above advances will have a marked impact on animal breeding in the developed world. The question remains if it will become sufficiently affordable for routine use in the countries of the developing world, given the financial constraints in these countries (Fig. 19). The human capacity needed to make full use of these innovations is another topic that needs to be debated, given the dearth of people with adequate scientific training in these countries (Fig. 20). These and other issues will be debated in the next section.

Future Directions

Future of Livestock Breeding in the Developing Regions and Tropics

Breeding Objectives Given the environmental challenges faced by animals in the developing world and the tropics, there is little doubt that elements of adaptability, robustness, and fitness should form part of the selection objective in those areas. Fitness and/or adaptability can be defined in many ways as was reviewed by Barker [149], but a definition like "a measure of the ability of an organism to survive and reproduce in a particular environment" is probably a good compromise. Naturally, the concept includes stressors that are inherent to the particular environment maintaining the animals, for instance, climatic conditions and disease. As the prospects of breeding for resistance to disease as well as adaptation to stressful environments in terms of heat, water scarcity, and a variable food supply have already been discussed, they will not be revisited here. It is, however, important to mention that records pertaining to susceptibility to a disease are highly incidence dependent [150], which should be considered during analysis. The importance of assessing the genetic resources from the developing world and the tropics for disease resistance has been highlighted by Gauly et al. [151], while some guidelines as to how to proceed with the process were also presented. Bath and Van Wyk [152] recently proposed a practical check for helminth infestation of small ruminants, which was easily applied by both commercial and small-scale farmers. It was suggested that this check can be used to guide decisions pertaining to the selective treatment of animals for internal parasites.

The remaining elements of fitness are therefore survival and reproduction, as was defined by Goddard [153]. According to the latter author, these elements of fitness have largely been ignored during selection of farm animals, despite obvious economic value. Arguments against reproduction and survival are a low heritability, while it was also considered difficult to record. Reproduction is also sex-limited and usually assessed later in the life of animals than other production traits. The omission of including fitness traits in the breeding objective led to a general decline of fitness in those farm animals that were intensely selected for (say) milk production. Yet the genetic coefficient of variation of 6-week pregnancy rate in dairy cattle equals that of milk yield [153]. The latter author suggests that the correct way to handle this situation would thus be to include fitness traits together with the traits of interest for a particular livestock species in a selection index, with appropriate economic weights.

It is also appropriate to consider selection for reproduction and survivability in a number of livestock species farmed with in developing countries. A number of indicators of reproduction (days from calving to first service, days open, artificial inseminations per conception, and pregnancy rate) in South African Holstein cattle of 14 herds were considered by Muller et al. [154]. Heritability estimates ranged from 0.06 to 0.08, as was also reported by other authors from developed countries. Selection for number of lambs weaned per ewe mated of South African Merino ewes (a trait with a similar low heritability as that quoted above) resulted in a genetic response of ~2% per annum, which is of the same magnitude as is expected for other traits of economic importance [155]. This realized improvement was consistent with expectations based on the review of Snowder and Fogarty [156]. Stayability of South African Angus cattle was similarly shown to be heritable [157]. From these results from the developing world it is evident that selection for reproduction and herd life in farm animals should be attainable, should it be desired. Appreciable progress has in fact been demonstrated in the national analysis of the South African Merino breed [101]. Total weight of lamb weaned per ewe mated (as measure of reproduction) improved at a rate of 0.73% per annum in the best performing flock, while the average flock gained at 0.14% per annum. At the same time, fiber diameter was reduced by 0.48% per annum in the best flock and by 0.42% per annum in the national flock. During the same period, relative

economic values increased by 2.80 ZAR per annum in the best performing flock ($R^2 = 0.94$) and by 1.17 ZAR per annum in the national flock ($R^2 = 0.98$).

How to Achieve the Objective of Improving Fitness and Adaptability Having discussed the state of animal agriculture in the developing world, as well as successes and failures of projects in that region, the issue remains whether the capacity to allow sustained improvement in those regions exists. It needs to be stated that research priorities for this venture has been clearly outlined by Cardellino and Boyazoglu [79]. The proposed needs are summarized in Table 17 and include the development of suitable information systems, the characterization of resources, as well as a sound knowledge of genetic diversity, functional genetics, and animal breeding. The collection of phenotypic data is a prerequisite for the system to be successful. If these data could be linked to pedigrees it would be an added bonus. This objective may seem nearly unattainable at present. However, traceability based on individual identification is increasingly seen as a good agricultural practice for the assurance of safety and quality in global trade [158]. It is foreseen that the developing world will in future have to comply with such prerequisites for continued market access. It should thus not be seen as far-fetched to start to apply a principle like individual identification in the near future. Data containing phenotypes linked to pedigree information can initially be used for routine genetic improvement.

Breeding in Developing Countries and Tropics. Table 17 Research priorities to enable the breeding of livestock in developing regions to increasingly contribute to local food security and poverty relief

Area	Specific needs
Information systems	Upgrading of the existing farm animal genetic resources (FAnGR) information system
	Acquisition of data on population size and structure
	The geographical referencing of FAnGR
Characterization	Define traits and record adaptation and performance of indigenous populations
	Describe the environment to evaluate genotype x environment interactions
Genetic diversity	Define and determine the risk of extinction for FAnGR
	Adopt measures to halt the decline of genetic diversity
	Assess genetic diversity by using molecular markers
	Integrate data on phenotypes with molecular information
	Acquire global information on specific markers associated with production and fitness
Functional genetics	Ensure that the genetic basis of adaptation traits are properly understood, including disease resistance, fitness, and adaptability to challenging environments
	Apply the most recent tools for conventional genetic improvement and marker-assisted selection (MAS)
Animal breeding	Assess impact of selection under low-input conditions
	Study the consequences of introducing exotic breeds
	Devise breeding structures for a low impact environment where little or no organizational structure exists
	Research stable crossbreeding systems with a role for indigenous breeds
	Implement MAS selection where applicable, that is, in the case of disease resistance
	Gain insight in genetics of adaptation to systems with a low and variable nutrient supply

Source: Adapted from Cardellino and Boyazoglu [79].

If it is affordable it could also be linked to genomic information in future. Goddard et al. [144] stressed the importance of being able to link genomic information to phenotypes for the accurate prediction of genomic breeding values. It should be noted that recommendations on animal welfare have been left out from Table 17 as it will be dealt with separately at a later stage.

The challenges of such a venture will be enormous. The requirements and structure of performance recording and genetic evaluation for low-input agriculture have been well documented [159] but their application in practice is lagging behind. Open nucleus breeding systems have often been advocated as a solution to the lack of sustainable genetic improvement in the developing regions [18, 160]. This solution will only be feasible if the nucleus herds/flocks are under central control of accomplished scientists at a governmental, academic, or parastatal research institution. Having said this, it is equally important to have the support of the stockowners at grassroots level. Failure of livestock breeding projects in the developing world has commonly been attributed to a lack of community involvement [18], whereas successful efforts generally benefitted from community involvement [119]. The importance of close involvement with the community stems from the multifunctional role of livestock in communities in the developing world [94]. Broad stakeholder involvement has been suggested, with collaboration of local committees, researchers and development practitioners [161]. Close interaction of these diverse partners are considered to be critical for success. The importance of participatory development approaches was also stressed by Nesamvuni et al. [162]. According to the latter authors, the integration of coexisting research and development programs is highly preferable to research and development programs operating in isolation.

Using the Kenyan Boran breed as an example, Rewe et al. [163] assessed open and closed nucleus systems of registered breeders with or without gene influx from commercial breeders to ensure that adaptation traits (mainly disease tolerance) are not compromised. The introduction of germplasm from the commercial breeders was profitable in both schemes. The study demonstrated that the success of a breeding program depended on the production system, and that adaptation could be introduced from the indigenous herd, as was suggested in Table 17.

It will be a bonus if a strong commercial sector, operating on par with conditions in the developing world, can be included in the genetic evaluation system. The successful establishment of public–private partnerships to enable the system to work is a further prerequisite for success. This blueprint seems to be effective in the South African small stock sector, as was described previously. It also appears to be relevant to dairy production in Kenya [94]. The real success with it will, however, only become known with the passage of time.

It needs to be stressed that this whole process can be orchestrated with existing tools for quantitative genetics, using known theory for the sustained genetic improvement of livestock. The emphasis on fitness traits may depart slightly from what has been practiced traditionally. Yet the approach to select for adaptation and fitness would be fairly similar to what has been proposed by Goddard [153] for general application across the globe.

Table 17 also refers to the possible role that crossing with indigenous livestock may play in commercial production. The benefits of well-planned crossbreeding systems in terms of direct and maternal heterosis are well known [164]. Structured studies are needed to apply these to livestock breeds in the developing world, where it needs to be balanced with the need to conserve the indigenous genetic resources. The substantial differences between breeds that form part of the genetic resource, as well as the relative advantage of crossbred ewes under challenging conditions in France compared to purebreds was confirmed in the literature [165, 166]. More structured research on this topic is needed for the optimal utilization of local, adapted farm animal genetic resources in the developing world. The role of cortisol and the functioning of the hypothalamic-pituitary-adrenocortical axis in breeding for an increased robustness have been highlighted recently [167]. Future studies should thus focus on the underlying causes of genetic variation at this level.

It is also important to consider the role that molecular genetics and marker-assisted selection may play in this process [167]. Constraints in monetary resources, infrastructure, and suitably qualified scientists place immediate earth-shattering breakthroughs beyond the ability of developing countries at present. Further

issues like intellectual property rights also complicate immediate application on a wide scale in the developing world [168, 169]. However, scientists in the developing world should take cognizance of progress in the application of marker-assisted selection in the developed world. The rapid development of technology may allow for inputs from this part of the world in future, as the technology becomes more affordable. Fitness traits like disease resistance and reproduction, which need to be selected for in the emerging regions, is particularly well suited to marker-assisted selection [168, 170]. The provision here is that sufficient monetary investment in the genotyping of animals should be available at that stage. Therefore it is also recommended that DNA samples from phenotyped animals in the nucleus flocks/herds be collected and stored for possible future usage. The general concept has been applied in the Australian Information Nucleus flock [171–173], which has already produced a number of outcomes [174]. Scientists in the developing world are well aware of the importance of combining genetic and environmental information for selection decisions [64]. It should thus be feasible for these scientists to adapt to the requirements listed above, should the opportunity arise.

Readers will notice that most of the examples listed in this section involved grazing ruminants. It is conceded that pigs and poultry played an important role in the production of protein in both the developing and developed world, and will continue to do so in the future (see Fig. 13). However, these industrialized livestock systems are in many cases served by multinational breeding companies, as stated previously. Moreover, the prospects of selecting for "robustness" or "fitness" in poultry and pigs have been covered in some detail in other entries in this encyclopedia [175, 176]. The issues dealt with in the latter entries are complex, and it would have been impossible to deal with them comprehensively in this entry.

Finally, it is clear that the system that is proposed would not only need monetary inputs, but also the human capacity to successfully orchestrate the flocks/herds [119]. In case of severe threat to some genetic resources, the option of ex situ conservation should also be an option [80, 81]. The need for collaboration across institutional and national boundaries, to ensure that the various forms of information generated in this way are optimally utilized, cannot be overstressed [168, 169]. It is therefore appropriate to ensure that the intellectual capacity to drive all the processes is available, as discussed under the following heading.

Broadening the Knowledge Base It is evident that the objectives above are unlikely to be achieved without a sound knowledge base. Based on the disadvantage of developing countries in terms of human capacity (Fig. 20), it is obvious that the people active on research and development of farm animal genetic resources should be well-trained. The limitation in human resources results in several challenges for scientists in this region, such as an increased workload in terms of teaching, and a reduced capacity for conducting research [177]. Sustainable farming and the improved use of farm animal genetic resources were targeted in a joint venture between the International Livestock Research Institute (ILRI) and the Swedish University of Agricultural Sciences. Training by the project team reached 137 university lecturers and researchers in developing countries so far [177]. Agriculture is not a favored study direction, as it is associated with poverty and an inability to improve the livelihood of families. A typical curriculum for students in animal science in South Africa (as an example of a developing country) was provided by Casey [178]. The intention with the training of students is to prepare them for a professional career in animal production, with appropriate registration. It is also noted that Sub-Saharan Africa has many universities that teach animal production. However, there is a lack of communication and collaboration between these role players [178]. In contrast, six European universities joined hands to form the 2-year European Master of Science program in Animal Breeding and Genetics [179]. The intention of the course is to assist in increasing livestock and fish production, development of sustainable animal breeding programs, the improvement of health and welfare, and the preservation of natural resources. The program also draws students from developing countries, but with ~20 scholarships per year, the impact is limited. Of students starting the program between 2007 and 2009, 46% were from Asia, 31% from Africa, 9% from the Americas, and 13% from within Europe. In Latin America, two universities from Peru, Bolivia, Mexico, and Spain each collaborate with universities

in Argentina and Austria to present a master degree in Animal Science [180]. Original assessment indicates that there is heterogeneity in the curricula, grading systems, and duration. A program for harmonization has been proposed.

In view of the challenges listed above, steps need to be taken to rectify the situation in the developing world. The obvious prerequisite is to ensure a skilled and motivated core of senior mentors, to pass on knowledge to the next generation. This will be facilitated by closer collaboration between role-players, both among institutions in the developing world and with institutions in developed countries [64, 119, 168, 169, 177]. Joint appointments of senior researchers at science and technology institutions at higher education institutes could also benefit training in farm animal genetic resources, by making better use of expertise [181]. To assist in these quests, there is a wealth of Internet-based training modules that can easily be accessed [182–184]. Collaboration between research groups and those involved in training is also proposed [177]. This approach will ensure that the studies embarked upon will be relevant. It is also important to attempt to recruit and retain well-qualified and dynamic persons for careers in animal agriculture, both in training and research. The so-called brain-drain from developing countries needs to be stopped and preferably turned around. This will only become feasible if scientists see a future for themselves in animal agriculture in developing countries, both in monetary terms and in job satisfaction. Alternatively, well-trained international scientists could be used as trainers when they return to their home countries for holiday or familial responsibilities [177]. There ought to be opportunities for improving the local knowledge base in developing countries when all these avenues are fully exploited.

"New" Issues

Finally, it is necessary to give attention to issues that have not previously impacted on animal agriculture in the developing world. Both topics are specialized study fields, worthy of an exhaustive discussion in their own right. However, this chapter will only briefly deal with the new challenges, within the developing world context.

Climate Change There is consensus that the global temperatures are on the increase, and that it is probably related to higher atmospheric concentrations of the so-called greenhouse gases. It is expected that global warming will affect extensive pasture systems to a greater extent than intensive, industrialized systems [62]. This implies that animal production in the developing world will be more vulnerable than in the developed world [4]. The carbon dioxide emissions of the developing world, in particular, are modest compared to emissions in the developed world [2]. Hoffman [80] pointed out that livestock production is contributing to global warming, but also that it will be affected by the consequences of the phenomenon. It is estimated that agriculture produces between 10% and 12% of the total global anthropogenic greenhouse gas emissions [185]. Between 50% and 60% of methane and nitrous oxide could be derived from livestock activities. The review by Eckard et al. [185] focuses on the possibility to reduce greenhouse gas emissions by ruminants through the manipulation of the animals, their diet, and their rumen microbes. Manipulation of animals is centered about breeding (the focus of this entry) and on changing managerial systems. Eckard et al. [185] cited sources that quoted differences between animals in methane production, hinting at possible genetic differences. These allegations were substantiated by Robinson et al. [186], reporting that methane production in sheep were repeatable (0.47) and heritable (0.30). Adjustment for live weight resulted in these parameters being reduced to respectively 0.32 and 0.13. Adjustment for live weight also eliminated the effect of sire breed upon methane production, while correlations with rumen volatile fatty acids did not support a contention that the latter could be used as a proxy for methane production. Cassandro et al. [187] predicted methane production of dairy cows from dry matter intake, and derived a heritability of 0.12, with upper and lower confidence limits of respectively 0.03 and 0.28. Genetic correlations of methane production with milk yield and butterfat content were high (respectively 0.92 and 0.67), but protein content and somatic cell count were not genetically correlated to predicted methane production (0.14 in both instances).

Alternatively, selection for an improved efficiency would also indirectly benefit methane excretions per

unit product from ruminants, as reviewed by Eckhard et al. [185], Hegarty and McEwan [188], and Herrero et al. [189], as would improvements in feed conversion and residual feed intake. Lamb production systems based on crossbreeding would be more effective in terms of methane produced per unit product than a wool and hogget production system [188]. Alternatively, methane emissions per unit product could also be reduced by an improved reproduction rate, the early disposal of unproductive animals and the longer retention of productive animals in flocks or herds. As dairy products are produced at lower levels of greenhouse gas emissions than beef, there may be a shift to dairy in a situation where greenhouse gasses need to be reduced [80].

Possibly more relevant to conditions in the developing world is the adaptation of animals to higher ambient temperatures and to more frequent severe climatic events, which are predicted to be a consequence of climate change [80]. The possible genetic improvement of adaptability, robustness, and heat tolerance has already been discussed and will not be reiterated here. Unforeseen catastrophic climatic episodes like floods, droughts, and heat waves could have a major and unpredictable impact on local farm animal genetic resources. For instance a heat wave in 1995 in the Midwestern United States resulted in an economic loss of $31 million in the state of Iowa alone [62]. Such events should be managed when they occur, as it is impossible to plan for them. However, the need for a disaster strategy to be in place in areas likely to be affected cannot be overemphasized. Thornton and Gerber [4] suggested that up-to-date weather information will play a role in mitigating the effects of climate change. State-supported schemes reminiscent of a sort of insurance scheme may have a role to play in disastrous events, while species substitution toward more hardy animals may be contemplated (i.e., from cattle to camels in dry parts of Kenya).

Animal Welfare Pressure on output traits, particularly regarding the more intensive livestock industries, resulted in the welfare of farm animals being compromised [189]. This topic is also extensively covered by Knap [175] in this issue, and interested readers are also referred to this paper. Because of this, discerning consumers have ensured that animal welfare is among the important considerations in production systems in developed countries, like Europe [190, 191]. Welfare in farm animals are usually defined as freedom from hunger, thirst, discomfort, pain, injury, fear, and distress, as well as an ability to express normal behavior [189]. Several routine husbandry procedures are considered to infringe on these fundamental freedoms, for example, the Mules operation in Australia [28, 30]. In this case, popular opinion has prevailed that the pain, fear, and distress of the operation outweighs the possible later advantages in terms of better resistance of animals to breech strike. This has resulted in pressure on Australian livestock producers to phase out the procedure. The same reasoning applies to tail docking of lambs. An alternative genetic solution was thus sought to enable the abolishment of this practice in the Netherlands in the two sheep breeds where conditional approval to dock tails are still granted [192]. Genetic variation seems to exist for tail length and selection for shorter tails may thus be possible. Issues in the developed world mostly involve the quality of life of farm animals in more intensive systems [193]. Aspects like survival, adequate nutrition, and protection against intense cold or heat are more important under extensive conditions. Sørenson and Fraser [193] proposed a self-regulatory process of auditing livestock operations for animal welfare, agreed on by all role-players.

Aspects of importance to this discussion are the impact breeding for welfare traits could have on genetic gains in other traits. First of all, it is fair to say that animals, where welfare is compromised, will in many cases not be capable of high levels of production. Because of the emphasis of herd health in dairy cattle selection schemes in Norway along with production traits, cows are much more likely to reconceive than in European countries. In response to this, longevity as well as health and fertility became much more important in the United Kingdom dairy indexes as well [189, 190]. Impaired mobility of dairy cattle because of poor claw health also leads to direct and indirect costs. Claw health traits of Finnish Ayrshire cows were lowly heritable [194]. Some leg conformation traits had favorable genetic correlations with claw health, and could serve as indicator traits.

A simulation study on outdoor pig production indicated that genetic gains had to be compromised

when welfare traits (leg conformation, mothering ability, and longevity) were included in the selection index [195]. Apart from a slightly slower growth rate and a reduced fat depth, free-range pigs performed as well as pigs in a conventional housing system [196]. The former system produced pork of a similar quality as that observed in a conventional system. Observations made at lambing were evaluated as possible indicators of ovine lamb survival by Brien et al. [174] and Lemmon et al. [197]. Although some observations were favorably related to survival, none were obvious candidates for immediate industry application in the former study. The latter study suggested that alternative methods of improving lamb survival should be investigated. It is however, notable that divergent selection for the ability of sheep to rear multiple offspring led to divergence in age-specific lamb survival in South Africa [198]. Hatcher et al. [199] also reported scope for the improvement of lamb survival by selection, although low direct and maternal heritability estimates were derived.

Animal welfare of the mostly free-ranging animals in the developing world is probably not compromised to the same extent as those animals in more industrialized systems. The exceptions are probably freedom of hunger and thirst, which cannot be guaranteed. It is nonetheless important for scientists in developing countries to take cognizance of the emphasis on welfare, and ensure that information on the impact of the selection strategies for livestock (that were previously discussed) on animal welfare are also considered. Intuitively, selection for adaptability, robustness, and fitness is unlikely to compromise welfare. However, challenge of animals by environmental stressors (heat, parasites, and uncertain food supply) typical of the developing world may lead to some ethical concerns. It is reassuring that the need to ensure a value system throughout the entire production chain is also recognized in the developing world [200].

Conclusion and Recommendations

From the foregoing it is evident that livestock industries in the developing world are faced by numerous challenges involving the environment, infrastructure, funding, and the availability of a sufficient number of well-trained scientists specializing in breeding and farm animal genetic resources. Despite these drawbacks, scientists in the developing world seem to be willing to contribute to the advancement of science in the region in spite of the considerable odds against them.

Within the constraints in terms of funding and manpower, it is proposed that major efforts should be put into obtaining phenotypic records from the farm animal genetic resource managed in the developing world. Wherever possible these records should be linked to pedigree information, which could follow on from the identification of animals for traceability purposes. Should this vision prove to be impossible to implement on a wider scale, it should be applied to genetic resources maintained by governmental, academic, and parastatal institutions within the developing world. The decision as pertaining to broader community involvement will largely be determined by local conditions, and need to be considered with care on the grassroots level. A prerequisite is that supportive institutional research actions should be conducted in environments conforming to those used by those resource-poor stockkeepers standing to benefit from it. Secondly, it has to be ensured that all initiatives involving the latter groups must have their full support for the intended projects to be successful. This structure will form the basis for simple animal recording and genetic evaluation schemes under communal and emerging farm systems. These schemes are highly unlikely to be cost effective and need to be subsidized from funds supplied by local government, higher education institutions or external sources. However, such evaluation is integral for local food security, sustainable development, and rural stability, thereby increasing leverage for the acquisition of funds dedicated to this cause. Should the envisaged scheme become successful and gather momentum, it would be easy to integrate into existing livestock improvement schemes for commercial agriculture, should the infrastructure exist.

Being in the developing world and the tropics, breeding should focus on traits associated with fitness and adaptability. However, traditional production and product quality traits should also be recorded, to monitor the impact of selection decisions on these traits.

It is not foreseen that genomic selection will change the way animal genetic resources in the developing world are selected in a drastic way in the immediate

future. However, it is advised that samples for the extraction of DNA are acquired for as many animals with phenotypes as possible in the system. After the extraction of DNA, these samples should be kept under safe conditions for possible future use. Given the appreciable advances in the technology, it may be possible to utilize DNA-based methods for the evaluation and selection of farm animal genetic resources in the developing world in the foreseeable future. Should this vision become a reality, the scene should be set for the immediate application of this technology on a broader basis. The need for adequate phenotypic data to link to genomic information cannot be overemphasized.

Finally, it is conceded that new issues such as global warming and the insistence of customers on assurance of traceable and welfare-based production systems are likely to affect animal breeding and genetics in the developing world in future. The animal breeding sector in developing countries should preempt these possible challenges, and react to it in a constructive way. Modern societies embrace change. Animal breeders in the developing world thus need to ensure that the challenges imposed by these issues are turned into opportunities.

Article Outline

Glossary

Animal model (AM) Statistical models that are used for evaluation of breeding values of all individuals in the population of interest.

Best linear unbiased prediction (BLUP) Standard statistical method for estimating breeding values in populations. BLUP adjusts for systematic fixed environmental effects and accounts for genetic relationships among animals.

Breeding value (BV) Mean additive genetic value of an individual relative to all members of the (base) population.

Effective population size (N_e) Number of individuals that would give rise to calculated sampling variance, or rate of inbreeding, if they bred in the manner of the idealized population with complete random mating, no selection, no migration, and no mutations.

Estimated breeding value (EBV) Estimate of the mean additive genetic value of an individual for a quantitative trait.

Generation interval (L) Average age of the parents when their progenies that will replace them in breeding are born.

Heritability (h^2) Measures the extent to which the phenotypes are determined by genetic factors. It is expressed as the ratio between additive genetic variance and the total phenotypic variance.

Inbreeding coefficient (F) Measure of the probability that two genes at any locus in an individual are identical by descent. It refers to an individual and expresses the degree of genetic relationship between the individual's parents.

Riding horse The narrow definition of riding horse or sport horse refers to horses of "Warmblood" breeds or Thoroughbred crosses, which compete in the classical equestrian sporting events of dressage, show jumping, and eventing. However, the broad definition of a riding horse refers to a horse used for any type of riding and will be used here.

Selection Any natural or artificial process favoring the survival and propagation of certain individuals in a population.

Selection intensity (i) Function of the proportion of animals selected for breeding relative to the total number of animals available for selection. The smaller the proportion selected, the higher the selection intensity.

Timeform handicap ratings An estimate of racing capacity of Thoroughbred horses (in Great Britain). Express racing merit as weights in pounds that the compiler believes the horse should carry in an average free handicap race.

Trotter A horse trained for harness racing. The horse races in trot, which is a two-beat springing gait with a suspension phase (no ground contact) between two diagonal supporting pair of legs.

Definition of the Subject

Animal breeding can be defined as a human activity with the deliberate purpose to change existing populations of animals in some desired directions, so that future generations of these animals become more valuable in some sense. A prerequisite for successful animal breeding is that there is a genetic variation in the population in the traits one want to improve in future generations. Other requirements are: clear definitions of the breeding goals, good pedigree files, valid measures of the desired traits, methods of genetic evaluations that can combine information from the pedigree and the measured trait, and finally effective selection of breeding animals with high estimated genetic values (BV = breeding values) and therefore

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

presumably with relatively large proportion of valuable genes affecting the desired traits.

The selected parents will transmit their genes to the next generation, and depending on the amount of genetic variation in the traits, accuracy of estimated genetic evaluations, and the selection intensity, the average level of the offspring generation will be raised as compared with the parent generation.

All general principles and methods of animal breeding obviously apply equally to the breeding of horses. There are however few structural and demographic characteristics specific to horse breeding that should be highlighted:

- Thorough registration of pedigree files
- Low rate of reproduction
- Long generation intervals
- Important traits are recorded on both males and females
- Wide overlapping of age groups among breeding candidates
- Considerable nonrandom mating practiced
- Extremely large differences in economic value depending on assumed genetic merit

All these factors support the use of methods for genetic evaluations that combine all pedigree information in an optimal way. In particular, the use of animal models (AMs) to obtain best linear unbiased predictions (BLUP) for genetic evaluation of breeding animals has become an important tool in modern horse breeding.

Introduction

Humans began to breed horses when the horse was domesticated some 6,000 years ago. Tamable animals were then selected from wild flocks and broken in. Stallions and mares with suitable temperament and desired characteristics were spared and got offspring in their new environment. The fitness measure of natural selection in the wild life was replaced by a selective value in the new role of serving humans. This artificial, and to lesser degree natural selection, of horses over 6,000 years has resulted in gradual genetic changes and subdivision into breeds adapted to different purposes [1, 2].

Throughout the history horses have been used for variety of purposes, such as riding, driving, carrying packs, and pulling agricultural equipments. Horses were also for a long time the most important means of transport in wars and have played a great role in the political and social development of many civilizations and even for the conquest of whole continents. Horses have also played a major role in the mythology of many religions but have as well been kept for their grace and were commonly used as a symbol of material status. The Vikings even used stallions for fighting contests. In many cultures, horses have been used for milk and meat production. The life of nomads in central Asia, of cowboys grazing and driving big herds of cattle, and of Indians hunting wild buffalos on the savannas in North America would have been impossible without horses. In brief, the human history would have been very much different without the company of the horse [3].

Today there are about 60 million horses in the world [4]. While horses are still used for agricultural work and transportation in many parts of the world, the main role of horses in modern societies is to serve humans as pleasure or sport companions. The economic and social impact of the worldwide horse sector is tremendous and often underrated. In Europe, three to six horses (varies between countries) create full employment for one person. So within the European Union alone, with almost six million horses, about one million people are directly or indirectly employed in horse-related activities. About 4% of European agricultural land is dedicated to horse breeding [5].

Horses are used and will undoubtedly be used in the future for various competitive performance events, sport events, and pleasure riding or driving. Modern knowledge of animal breeding, genetics, statistics, reproduction technology, and computer science will certainly be used for adapting the different horse populations of the world to their intended purpose.

Horse Breeding

Breeds

Horses are members of *Equus ferus caballus*. In fact, there is no strict scientific definition of the term breed, but the elusive concept of breed as a definition of a population of "purebred" animals is commonly used among horse breeders. The classic definition of a autochthonous breed refer to a distinctive set of

animals associated with a restricted geographical area in which it was developed to meet human needs under particular local conditions [6]. Often horse breeds are defined by breeding societies or registries that record pedigrees and maintain a studbook for a selected subset of horses based on geographical origin, phenotype, or function [3]. New synthetic horse breeds have been created by genetic selection according to a common breeding goal across several older horse breeds. As an example, many European Warmblood breeds have evolved this way. At the Web site "Breeds of Livestock: Horse Breeds" (http://www.ansi.okstate.edu/breeds/horses) detailed description on over 300 different horse breeds all over the world can be accessed.

Breeding Goals

Horse breeding, as all animal breeding, starts with a clear definition of breeding goals that usually includes many traits. The breeding objectives are a statement of the relative values of genetic change in all the desired traits that are included in a breeding plan. The overall objective (aggregate genotype) can be expressed as $H = \alpha_1 A_1 + \alpha_2 A_2 + \ldots + \alpha_n A_n$, where α_i is the relative (economic) weight and A_i is the animal's breeding value for the ith trait. The α_i values are often linear or nonlinear functions of the profit (return – cost) [7, 8]. Horse breeders often have a rather clear idea as to which traits they want to improve by genetic selection. However, the exact definitions of the relative weights on the different traits included in the breeding goal are often vague and determined by preferences of the individual breeder. Meanwhile, it is important that breeders should be provided with genetic evaluations for all the major traits that might be included in the breeding goal [9].

Registration of Pedigree Files

Unique identification of all members of a population has become a prerequisite for all rational breeding schemes using modern animal breeding methodology. The same identification number must refer to the same horse anywhere in the comprehensive pedigree files and in all files containing the registered traits. As horse breeding becomes increasingly more internationalized, the communication between horse registers in different countries is vital for successful breeding schemes. It is important that the identification number given to a newborn foal follow the individual animal throughout its entire life, even if the animal is exported to, or competes in, another country. It should contain codes for the country of birth, year of birth, and possibly the sex of the animal. The Web-based "universal equine life number" (UELN) system (www.ueln.net) offers a solution to this problem.

Measured Traits and Estimation of Genetic Parameters

An important part of a horse breeding scheme is to develop and use measures with good correlations with the traits in the breeding goal. The measurements need to be collected on a large or a random part of the population to be used in the selection and breeding process. Most traits that are important in breeding of horses are governed by a large number of genes and many environmental factors. They may therefore be analyzed with genetic and statistical methods that apply to quantitative traits [10]. Measurements of performance traits in horses are often not normally distributed and need to be transformed to approach the normal distribution. Sometimes conversion to ranks is more favorable [11]. Measures of performance in racing and other equine competition sport events are frequently based on functions of earnings, ranks, or racing times. Occasionally, the measures are summarized in handicap ratings or cumulated competition points.

In many populations, the recorded traits are scored on a linear scale, often by subjective judgment, in special field or station tests. These traits may involve measurements of conformational details, temperament, performance in special gaits, or performance at various ranch tasks.

Before the registered traits can be used as a basis for genetic evaluations, the genetic parameters (variation, heritability, genetic correlations, and environmental correlations) among the traits must be estimated. The methods used for estimating genetic parameters in horse populations are usually based on maximum likelihood techniques for mixed animal models [12, 13]. In some recent cases, Bayesian Markov Chain Monte Carlo (MCMC) methods have been applied [14, 15].

Heritability of racing performance traits based on earnings and rank functions have frequently been estimated in the range of 0.3–0.4. Time measures in trotter races and shorter gallop races generally show heritability estimates of nearly the same magnitude (0.2–0.4), while heritability estimates of racing time in longer Thoroughbred races are usually considerably lower or in the region 0.1–0.2 [12, 13].

Heritability estimates of competition variables for jumping and dressage performance in riding horses have been found to be lower than in racing or about 0.1, on average. Data on competition results in riding horses is often subjected to strong preselection, which can be the main reason for the low heritability estimates [13].

The average heritability estimates for field test traits measuring gaiting ability and free jumping in riding horses are in the range of 0.2–0.3. Corresponding average heritability estimates of traits registered at station tests for stallions are generally much higher or in the range of 0.4–0.6 [13].

Heritability estimates of sport competition scores in Icelandic horses were found to be around 0.2–0.3, while heritability of field test traits within the same breed was estimated in the range 0.2–0.4 with the average value of 0.34 [16, 17].

Heritability of cutting performance in Western riding competitions has been estimated in the range of 0.04–0.19 [18].

This brief summary confirms that genetic variation and thus scope for genetic improvement has been found in the most important traits in many horse breeds.

Genetic Evaluations and Selection

Traditionally, selection of horses was for a long time based on phenotypic observations on performance and body conformation in combination with subjective evaluation of the pedigree. Since mid-1980s, the BLUP method with animal model (AM) has gained popularity as a superior and standard method for combining information from phenotypic observations and pedigree [19]. Estimated breeding values (EBVs) obtained by AM-BLUP are now used as the main selection criteria in many horse populations.

Estimation of breeding values in a population begins with definition of a linear statistical model. The model should fit the data as well as possible but it should also include as few parameters as possible. The model should account for all major factors affecting variation in the data in a systematic way. In the simplest form, the model may be written for a single trait as

$$y_{ij} = \mu + b_i + a_j + e_{ij}$$

where y_{ij} is the phenotypic observation on the jth horse belonging to the ith class of fixed (systematic) effects affecting the trait; μ represents the overall mean of the (base) population; b_i represents the deviation from the population mean caused by the ith class of fixed effects; and a_j represents the breeding value of the jth horse. The breeding values are random normally distributed deviations from the genetic mean of the base population and have the variance $\mathbf{A}\sigma_A{}^2$, where $\mathbf{A}$ is the additive genetic relationship matrix. Finally e_{ij} denotes the remainder of the model, which is assumed to include independent and randomly distributed environmental effects pertaining to the jth horse.

Practical application of AM-BLUP in horse populations are usually based on far more complicated models than that shown above. They often include many fixed environmental factors, which affect systematically the variation in phenotypic records. As the breeding goal usually includes many correlated traits, multiple trait (MT) AM-BLUP procedures are commonly used for genetic evaluation of horses. Sometimes additional random factors are included in the model. This may be for genetic evaluation of repeated records on the same trait, or in other cases for better estimation and adjustment of genetic or environmental effects. As an example, the model may include both permanent environmental and genetic effects of the dam (maternal effects), or permanent environmental effects of riders, drivers, or trainers. Random regression models as an alternative to repeatability models for genetic evaluation of traits of longitudinal nature have good prospect in horse breeding [20, 21]. The trajectories may for example represent age development, racing distance, or competition classes.

Important traits in horse breeding are commonly scored on an ordered categorical scale. If there are at least several categorical classes and histograms of the

distribution show good approximation to the normal distribution then the data can be analyzed by linear models without any significant loss in precision. If, however, there are as few as 2–4 classes, then nonlinear threshold models may be more appropriate. This particularly applies to binary traits with low or variable frequency across the fixed effect classes of the model. But sometimes linear models (AM-BLUP) are used in such cases in large data, since the computations in the linear models are much simpler.

With the AM-BLUP method, the effects of fixed factors and the breeding values are estimated simultaneously by solving a large set of mixed model equations (MME) with equally as many unknown solutions as there are equations. The estimated breeding values become adjusted for fixed effects that are correspondingly adjusted for differences in breeding values of the horses with records in the various fixed effect subclasses. The use of the additive genetic relationship matrix inverse ($\mathbf{A}^{-1}$), computed from the pedigree list, ensures that sharing of genes between related animals is correctly accounted for in the model. In addition, the EBVs of animals that are parents of recorded animals are adjusted for in the EBVs of the mate. That is a very important property in horse breeding where the allocation of mares to breeding stallions is generally far from random in terms of genetic merit.

The pedigree file used as data for computing $\mathbf{A}^{-1}$ is a list of all registered animals in the population. Each row consists of unique identification number of the individual animal and both parents. First, the inbreeding coefficients are calculated for all animals with one of the several efficient algorithms (e.g., [22, 23]) that have been developed from the original algorithm of Quuas [24]. Then the elements of $\mathbf{A}^{-1}$ are build up by simple rules depending on the number of identified parents of each animal [25]. Animals without identified parents build the base population. In most horse populations, pedigrees are well filled and the pedigree of the youngest animals can be traced back through many generations. In such situations, one common base population can reasonably be assumed. Sometimes horse populations are either: mixtures from many base populations (e.g., synthetic breeds), or there is importation of breeding stock from other countries or populations, or there are many animals with incomplete pedigrees. In such cases, an appropriate genetic grouping by creating several base populations becomes essential [26].

The AM-BLUP method has been applied for genetic evaluations in many horse breeds throughout the world. Most applications have been within Europe, where AM-BLUP methods are routinely used for genetic evaluations in riding horses, trotters, Icelandic horses, and Thoroughbreds in many countries. In some breeds, the method has been in practical application for up to more than 2 decades. The published index values for the most important traits of the breeding goals have been widely used by breeding organizations, and by individual breeders, for facilitating their selection decisions. In many cases, the breeders have access to Web applications where BLUP indices can be searched and listed in various ways. These have become valuable tools for the breeders and a large help in their mating plans. Analysis of genetic trends in these populations have invariably shown that the rate of genetic progress have been boosted by the introduction of the AM-BLUP method.

As an alternative to the BLUP method, Ricard [13] has developed a nonlinear approximate Bayesian animal model method for genetic evaluation of horses based on ranks in competitions. The method provides estimated breeding values for an underlying normally distributed liability variable from the likelihood of ranking according to some phenotypic observations in any single race or competition event. The estimated breeding values are obtained as the mean (or mode) of the marginal joint posterior density of the combined prior information and the likelihood function according to Bayesian principles. A statistical inference drawn from the resulting EBVs can be given by probability statements in Bayesian fashion. The method adjusts the likelihood for systematic environmental effects and utilizes additive genetic relationship between animals in the same way as the AM-BLUP method does. The method has only been applied for genetic evaluation of trotters and riding horses in France [27, 28]. The method is computationally demanding and general software for the method is not yet readily available. Developments of the concept of ranks (Thurstonian model) into full Bayesian analyses using MCMC Gibbs sampler methods have

recently been proposed [29, 30]. The development of this methodology and modeling will continue and seems to have great potential in horse breeding.

Genetic evaluations of horses are often biased due to censoring of records [31, 32]. Horses are frequently preselected before they enter races, riding competitions, or field testing events. Information on the preselection criterion is usually lacking. However, in horse populations pedigree information is generally available on all horses, even on those without records. Therefore, the trait racing-status or test-status can be defined as an all-or-non trait, with the value one for tested animals and zero for culled or non-tested horses. Test-status has been confirmed a highly heritable trait in several horse populations (e.g., [32–34]). Environmental correlations between test-status and the recorded traits are not estimable because all animals with test-status equal to zero lack phenotypic records on the tested traits. However, genetic correlations between test-status and the recorded traits can be estimated if environmental covariances are constrained to some predefined values (e.g., zero). Indications of moderate to high genetic correlations between test-status and performance traits in horses have been confirmed in some populations [32, 33]. Inclusion of test-status in a multiple trait AM-BLUP framework was shown to increase the accuracy of selection and increase the rate of genetic progress in Swedish trotters, where the procedure has been routinely applied for a long time [33]. Ignorance of the problem with censoring of records results undoubtedly in bias in genetic evaluations and substantial loss of genetic progress in many horse populations.

International Genetic Evaluations

Breeding of sport horses has become a big global industry. Many breeding organizations of Warmblood riding horses in Europe have implemented modern methods for genetic evaluation of breeding horses on a national scale. The increased international trade with valuable breeding horses has led to important exchange of genetic material across populations having similar breeding goals.

The Interstallion project (http://www.interstallion.org) was established in 1998 to harmonize and improve exchange of information between Warmblood breeding organizations within Europe. The main aims have been to: (a) describe breeding objectives, test procedures, and genetic evaluation methods, (b) recommend improvements of national genetic evaluation systems, and (c) study methods of comparing genetic evaluations across countries. The project has resulted in several publications on these subjects [35–40].

Genetic evaluations for the global population of the Icelandic horse are computed regularly and published on the Internet (http://www.worldfengur.com) [41].

Selection and Genetic Progress

Factors Affecting Genetic Progress

The rate of genetic improvement by genetic selection in horse populations depends on:

1. Additive genetic variability in the selected traits (σ_A)
2. Intensity of selection (i)
3. Accuracy of selection (correlation between the true and the estimated breeding value, R_{TI})
4. Generation interval (L)
5. Inbreeding depression (d)

The genetic improvement per year can be expressed as

$$\Delta G/\text{year} = \sigma_A i R_{TI}/L - \Delta d$$

Increased intensity and accuracy of selection will increase the rate of genetic improvement if it is not leading to longer generation intervals nor increased homozygosity in loci affecting the traits and the general vigor (inbreeding depression). Generation intervals are generally very long in horse breeding (8–12 years). Shortening of the generation interval often means reduction in the accuracy in genetic evaluations (R_{TI}) but the selection intensity is usually affected in positive direction. The selection intensity, generation interval, and accuracy of selection are often different for stallions and mares. Therefore, the formula above is often modified to include two or four paths [42].

Multistage Selection in Horses

In horse breeding, large increase in the rate of response to selection can often be gained by an effective scheme for genetic evaluation of young horses that is based on pedigree information and early performance testing [43, 44]. The selection of stallions and usage for

breeding is usually of a multistage nature as they are selected repeatedly within the same generation [45]. The first step in stallion selection is based on pedigree information (ancestry and collateral relatives) and determines which colts get performance tested and thus undergo the second and the most important selection step for traits having medium to high heritability. Selection intensity should be high at the second selection stage, but unfortunately testing capacity is often limited, especially for riding horses. The cost and labor of keeping stallions instead of geldings is usually high and many colts are castrated at a young age before they can express their abilities. The third and final selection step is based on EBVs when the offspring results provide the main source of information. The value of the progeny information increases for traits with low heritability.

Effect of Selection on Effective Population Size and Inbreeding

Several generations of constant directional selection, in large populations with moderate selection intensity, will lead to a measurable reduction (10–30%) in the genetic variability (σ_A), which thereafter is assumed to stay reasonably constant due to an equilibrium between the reduction in genetic variance and the variation rebuilt by recombination [46]. Therefore, in large populations with negligible inbreeding, selection is expected to be effective for changing the population mean in the desired direction over many generations.

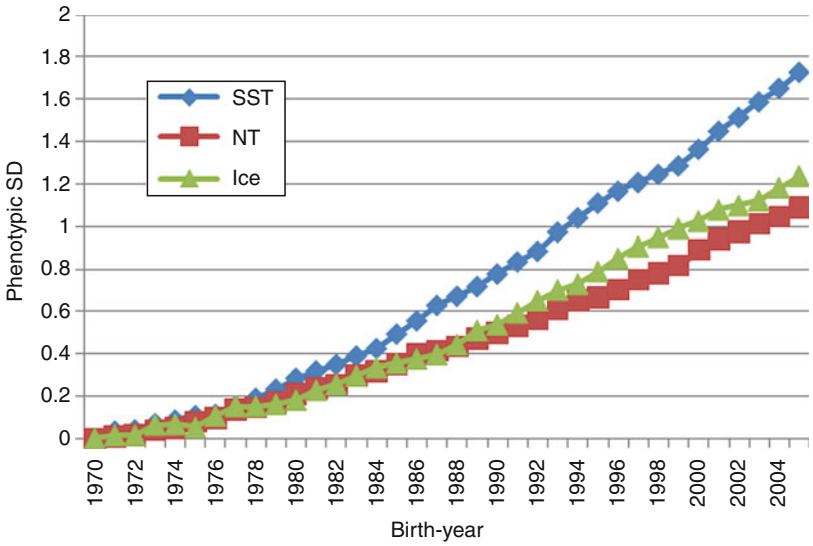
Intense selection in closed populations (no migration) will build up increased relationship among the future members of the population. That corresponds to reduction in the effective population size (N_e) and leads to mating of related individuals, which is defined as inbreeding. Small N_e and consequently heavy inbreeding results in random change in gene frequencies across generations and a general reduction in the Mendelian sampling variance term and thus decreased genetic variability (σ_A). Accumulation of inbreeding (Δd) in small closed populations will reduce the scope for genetic improvement in the selected traits. In addition, increased homozygosity in many loci in the population will presumably affect fitness traits negatively (fertility, health, vigor, etc.) and increase frequency of genetic diseases in the population [10].

Many horse populations are at risk of getting small effective population size, due to small actual population size, intensive selection on EBVs alone, and large variation in family size. In such populations, the risk of reduced genetic variability and inbreeding depression should not be ignored and the breeding schemes should aim at sustainable long-term progress, where breeding animals are to be selected in an optimum way such that genetic improvement in the breeding goal traits and effects on future inbreeding are simultaneously considered [47–49]. Sustainable breeding plans aiming at maintenance of genetic variation should direct the selection such that future inbreeding is avoided at the cost of some loss in short-term genetic progress.

Obtainable and Observed Genetic Progress in Horse Populations

The rate of genetic response in large horse populations depends mainly on how accurately the traits reflecting the breeding goal can be measured (heritability), the amount of variation in the aggregate genotypes (genetic variability), the quality of the method used for genetic evaluation (accuracy of selection), the testing capacity (selection intensity), and the age when the trait comes to an expression and can be measured (generation interval) [10].

In horse populations with onset of testing or racing performance at 3–6 years of age, and a conventional breeding scheme, the generation intervals are normally about 8–10 years for males and 10–12 years for the females. The selection intensity could correspond to ca 5% (1–10%) for males and ca 60% (40–80%) for females. When the selection criteria are EBVs that are obtained from the AM-BLUP method, then the source of information is a combination of pedigree, own performance, and offspring results. The average accuracy of selection on the male side (R_{TI}) could be about 0.8 for trait with $h^2 = 0.2$ and about 0.9 for trait with $h^2 = 0.4$. Higher accuracy would normally require more emphasis on progeny performance, which would prolong the generation interval. The accuracy of selection on the female side depends heavily on how large proportion of mares is tested for their own performance. A reasonable assumption could be $R_{TI} = 0.45$ for trait with $h^2 = 0.2$ and $R_{TI} = 0.63$ for $h^2 = 0.4$.



Breeding in Horses. Figure 1

Realized progress in the aggregate genotype, expressed in phenotypic standard deviation (σ_P) units, in three horse populations (*SST* Swedish Standardbred Trotter, *NT* Nordic Trotter, Ice Icelandic horse)

Given the assumptions above, the annual genetic progress in horse populations could correspond to 4–4.5% of the phenotypic standard deviation for traits (or combination of traits) with $h^2 = 0.2$ and to 6.5–7.5% for traits with the higher heritability of $h^2 = 0.4$. For readers interested in evaluation of different combinations of factors affecting the genetic progress in large populations, where inbreeding is ignored, a Java applet is available free at the following link: www.ihbc.se/web/contents/ihbcWebApplets/GenResponseApplet.html.

Estimates of genetic trend have been reported in several horse populations. The estimated annual genetic gain has been ranging from zero up to 6% of the phenotypic standard deviation of selected traits. Estimates of genetic trend in three different horse populations may serve as examples (Fig. 1). The Swedish Standardbred Trotter (SST) is a synthetic breed originating from imported American Standardbred Trotters and French Trotters. About 5,000 foals are born annually in the SST breed. The Nordic Trotter (NT) is a heavier type (cold-blood) originating from Norway and northern part of Sweden. About 1,300 Nordic Trotter foals are born annually (850 in Norway, 450 in Sweden). The Icelandic Horse is a closed population of small, compact, and strong horses that has been purebred in Iceland for more than thousand years. It is the only horse breed in Iceland where about 7,000 foals are born annually. Both the trotter breeds are used for harness racing and the breeding goal consists of several traits expressing racing performance ability and sustainability. The Icelandic Horse is used for riding and is known for its gaiting abilities, willingness, good character, and hardiness. The breeding goal for the Icelandic Horse consists of a linear function of 16 traits (8 conformation traits and 8 traits measuring riding ability [gaits and temperament]). The traits are registered at special field tests.

Genetic evaluations based on BLUP methods have been available as a guide for selection in these three breeds since mid-1980s. Between 1970 and 2005, the mean of the aggregate genotype (weighted mean of EBVs for several racing variables) in the SST population has been raised by 1.73 σ_P units, corresponding to the average annual ΔG/year = 0.049 over the entire period. The rate of genetic gain has increased gradually over the period as seen by the increased steepness in the slope showing the trend. For the last 10 years, the rate of genetic gain has been ΔG/year = 0.062, or 6.2% of the phenotypic standard deviation. In the smaller population of Nordic Trotter, the population average level

has lifted 1.09 σ_P units since 1970. That corresponds to ΔG/year = 0.031 over the entire period and to ΔG/year = 0.042 for the last 10 years. The population mean of Icelandic horses has been raised to 1.73 σ_P units over the 35-year period or by 3.5% σ_P per year. The average rate of response over the last decade has increased by 1% of the phenotypic standard deviation, or to 4.5% σ_P per year.

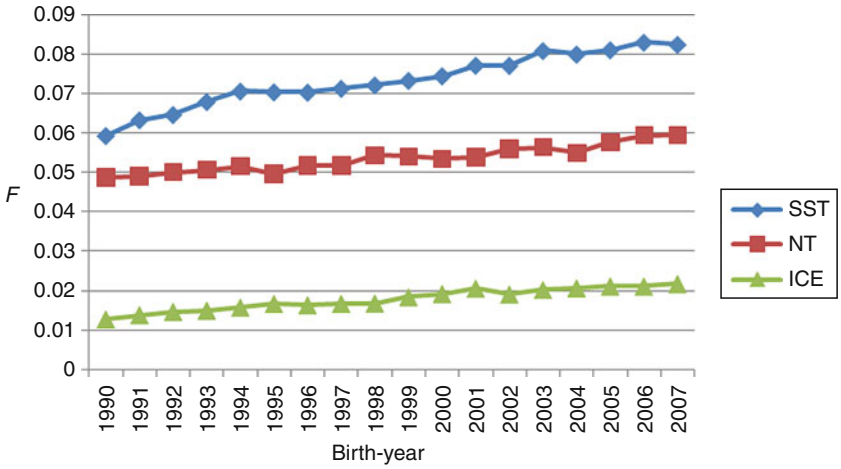
In the comparison of the three breeds, the efficiency of the selection has apparently been largest in the Standardbred Trotter. This larger genetic progress can mainly been attributed to higher selection intensity, particularly on the male side, where relatively few stallions are selected on the basis of results from races where many colts compete. The high selection intensity in SST is obtained by high testing capacity (races), widespread use of artificial insemination so that each selected stallion is able to cover more mares, and excessive use of information on results and pedigree. This is clearly reflected in the larger short-term response. However, the long-term sustainability of the breeding plan in the SST breed may be questioned as explained below when considering inbreeding and effective population size.

Long-Term Genetic Progress

An important aspect of sustainable animal breeding plans aiming at long-term genetic progress is to maintain genetic diversity (i.e., variation) within the population. In closed populations, gene frequencies fluctuate randomly from one generation to another as a result of the finite sampling of gametes. This phenomenon, called genetic drift, is quantified by the term effective population size, N_e [10, 50]. In a closed population, with no migration, the N_e is dependent on the number of parents in each generation, the variance of parental family sizes and selection. One way to estimate N_e is to measure the rate of increase of inbreeding over the different generations: $1/2N_e = \Delta F = (F_t - F_{t-1})/(1 - F_{t-1})$, where F_t is the mean coefficient of inbreeding for generation t (e.g., [10]).

The development of inbreeding in the three horse populations shows different levels that have evolved since the respective base populations (Fig. 2). The figure demonstrates difference in the rate of increase of inbreeding over time across the populations and thus gives a measure of their effective population sizes. According to the rate of inbreeding and the corresponding generation intervals, the effective population size (N_e) is approximately 40 for the Swedish Standardbred Trotter (SST), 50 for the Nordic Trotter (NT), and 100 for the Icelandic horse (Ice). The rate of inbreeding per generation, ΔF, is 1.3% in SST, 1.0% in NT, and 0.5% in Ice. In guidelines from FAO [51], the minimum recommended N_e is 50 corresponding to ΔF = 1.0% in livestock populations. Otherwise there is a great risk of loss in genetic variation, which will suppress long-term genetic progress and increase the risk for homozygosity of deleterious alleles, thus affecting health and fitness traits negatively. The SST breed is not only showing alarmingly high level of inbreeding (F ≈8%), but clearly surpassing the recommended rate of inbreeding per generation. The genetic constitution of the current generation of the SST breed is 94% of American Standardbred Trotter origin, while the remaining 6% can be traced to French Trotter base animals [33]. The American Standardbred Trotter is highly inbred with average inbreeding coefficient above 10%. The inbreeding in American Standardbred trotters and pacers is mainly due to remote inbreeding, where the horses are connected to one another by numerous paths through a small number of remote common ancestors. At the same time, breeders have deliberately avoided close consanguineous mating [52, 53]. Swedish breeders of Standardbred trotters have followed the same strategy. The average relationship among SST born in 2000 was R = 16.4% with a standard deviation of 5.2% [54]. Random mating within the population will result in average inbreeding coefficient above 8%. In order to reduce the rate of increase in inbreeding in the future, the variation in relationship among breeding candidates must be utilized in the mating strategy. Criteria for selection of breeding animals that involve EBVs modified such that the average relationship between selected animals is restricted have been proposed [47–49]. Increased migration of genetic material of French origin is also a recommended option for the breeders of Standardbred trotters in Sweden.

Breeders of the Nordic trotters have become increasingly aware of the risks associated with inbreeding in small closed populations. Negative effects of inbreeding (inbreeding depression) have been confirmed for reproductive traits, health traits, and racing



Breeding in Horses. Figure 2
Trend and level of inbreeding coefficients (*F*) in three horse populations (*SST* Swedish Standardbred Trotter, *NT* Nordic Trotter, Ice Icelandic horse)

performance in the Nordic trotter [55, 56]. Quotas for maximum number of mares that can be mated to each stallion have been put into effect and the rate of increase in inbreeding has reduced considerably compared with the period of 1970–1990, when the rate of inbreeding corresponded to $N_e = 32$ [57].

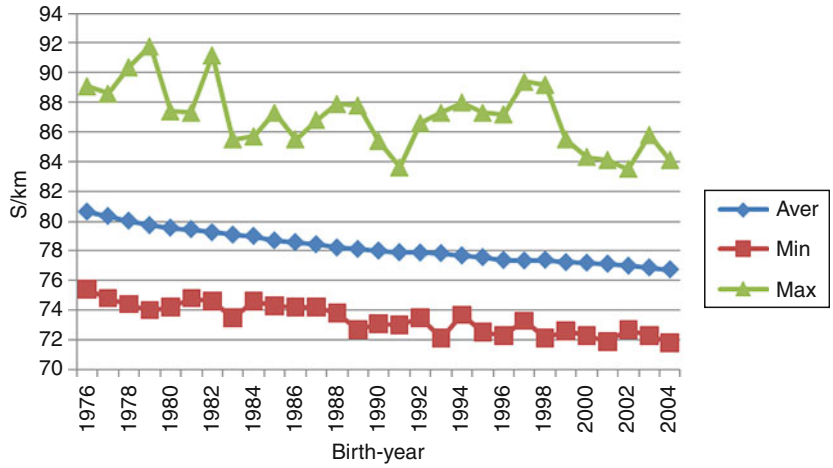
The inbreeding in the Icelandic horse is still at a low level and the rate of increase in the rate of inbreeding (ΔF) is yet not alarming. The breeding goal is broad as it includes very many traits, which helps keeping broad genetic variation among selected breeding individuals. However, awareness of the importance of maintaining low average genetic relationship among the selected parents is vital for the future of this breed, since import of genetic material to the closed horse population in Iceland is not a feasible option.

Genetic Progress in Racing Speed

One of the most interesting and debated questions concerning horse breeding is the "paradoxical" lack of improvement in winning times in the classical races for Thoroughbred horses over the last 50 years, in spite of significant genetic variation in racing performance variables and intense selection on racing performance [58–65].

The wild ancestors of modern horses were grazing flight animals and natural selection for speed and ability to traverse long distances were certainly important factors for the survival of the fittest. The Thoroughbred horses were founded by English and African horses screened for galloping speed and have been subject to an intense artificial selection on racing performance for over three centuries (30 horse generations). As a consequence, Thoroughbred horses are the fastest racehorses in the world galloping over distances of 1 to 2 miles. The breeding animals have not been selected directly on racing speed or racing time. Rather they have been selected on some function of ranks in races and special weight has been put on the ability to win races. Thoroughbred horses racing in the classical races all belong to the fastest segment of horses in the population.

Gaffney and Cunningham [61] estimated genetic change in Timeform handicap ratings of Thoroughbred horses in Great Britain. They confirmed effective selection on Timeform ratings and estimated annual genetic gain corresponding to almost 5% of the phenotypic standard deviation of 3-year-old Timeform ratings. This genetic progress is not reflected in winning times of the classic races, but the authors concluded that correlated genetic improvement in speed had been achieved in the Thoroughbred population as a whole but the fastest individuals in the population had reached the physiological limits for racing speed over the distance of the classic races. This conclusion assumes asymmetry in the distribution of racing speed.



Breeding in Horses. Figure 3

Observed trend in best average racing time records as 3–5-year-olds over 1 km for the average (aver), fastest (min), and slowest (max) Standardbred male trotters born in Sweden

The genetic evaluations of the Swedish Standardbred Trotter involve several variables that are functions of ranks in races (earnings, order at finish in the race) and racing time. As ranks in races are measures of racing performance that are relative to contemporaries racing at the same time, a genetic progress in these variables cannot be projected to any observable scale with clear physical meaning. On the other hand, the genetic progress in racing performance should be reflected in faster racing times. The best average racing time over 1 km has indeed improved continuously for the Swedish Standardbred Totter since recording started for the horses born in 1976 (Fig. 3). The limits for racing speed in trotters have apparently not been reached yet. However on the observed untransformed scale (s/km), the rate of improvement has slightly reduced over time and it seems increasingly harder to break the records. The dispersion of the slowest and fastest racing time records in the population around the average is also apparently asymmetrical. Arnason [66, 67] has previously argued that genetic evaluation of racing time records should be based on scaled logarithmic transformation of racing time records as $y^*_i = \ln(y_i - x)$, where y_i is the observed racing time record on the ith horse in s/km units, x is the asymptotic physiological limits for trotting racing speed in s/km in races over the traditional distance of 1 mile. When x is equal to 68.2 the distribution of y^*_i is almost perfectly normal in the population of Swedish Standardbred male trotters and the trend in average log transformed racing time records is linear.

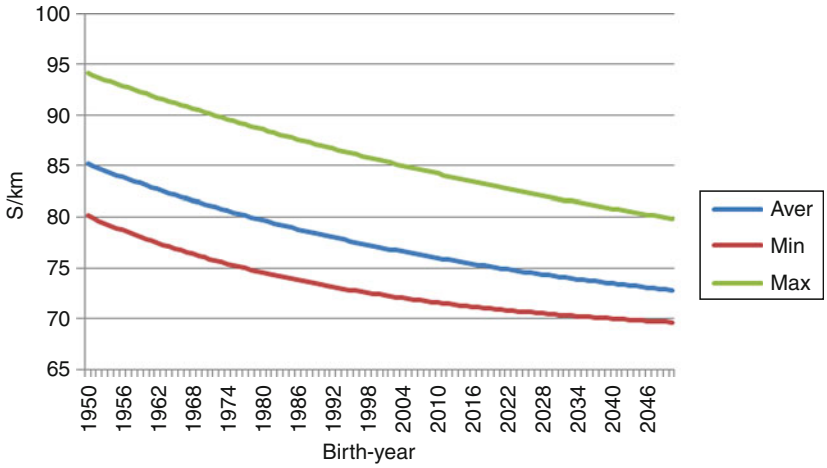
The trend in statistics (mean, minimum (fastest), maximum (slowest)) of fastest racing time records of 3–5-year-old males in the population of Swedish Standardbred Trotter can be described with the expression: $\text{s/km} = x\,(1 + e^{-pt})$, where x is the ultimate asymptotic limit for the fastest racing time records in the population as defined above, p is a positive constant, and t = birth-year – z, where z is a time scaling constant [67]. The constants p and z were estimated from recent data on racing results in the population of SST leading to the following equations for prediction of the development of the trend in the average, fastest, and slowest racing times in the population:

$$\text{s/km}_{(\text{aver})} = 68.2\left(1 + e^{(-0.013(\text{birth}-\text{year}-1843)}\right)$$

$$\text{s/km}_{(\text{min})} = 68.2\left(1 + e^{(-0.021(\text{birth}-\text{year}-1867)}\right)$$

$$\text{s/km}_{(\text{max})} = 68.2\left(1 + e^{(-0.008(\text{birth}-\text{year}-1829)}\right)$$

The predicted trend is revealed in Fig. 4. The racing time records in the population are expected to improve (become faster) at a linear rate on the logarithmic transformed scale, but at a diminishing rate on the untransformed linear scale of racing time (s/km). The presented racing times refer to "volt start," which is



Breeding in Horses. Figure 4

Predicted trend in best average racing time records as 3–5-year-olds over 1 km for the average (aver), fastest (min), and slowest (max) Standardbred male trotters born in Sweden

the most common starting procedure for trotting races in Sweden. Records from the flying "auto start" are adjusted by adding 2 s to the racing time.

The history of selection for trotting racing performance in Standardbred trotters is much shorter than that of selection for gallop racing performance in Thoroughbreds, and probably reflects a difference of at least 20 generations. If genetic variation can be maintained in the trotter population and the selection for trotting racing performance will be continued in the same manner over the next 200 years, the prediction equations above give the following estimates: Average racing time record for males born 2210 = 68.78 s/km; fastest racing time = 68.25 s/km; and slowest racing time = 71.44 s/km. This can be compared with the corresponding observed average, minimum, and maximum racing times of males born 2004 in the SST population: 76.74, 71.8, and 84.1 s/km. A parallel between this expected scenery for the development of racing speed in trotters and that already observed in Thoroughbreds is highly tempting. The average records (and the slowest) will continue to improve, however at ever decreasing rate, far after an apparent stagnation in the improvement of the fastest records. A slight improvement of the best records will be increasingly harder to identify due to the inappropriate scale. The small difference in racing speed between the fastest horses becomes less important as relative to fighting spirit and the mental and physical ability of the horse to react to the signals of the driver (or jockey) and to variations in speed at different phases of the race.

If there are some asymptotic limits to racing speed, they must relate to a nonlinear accumulation of biological and physical constraints on racing performance. Such factors might be: energy supply, energy transport rate, neural functions, oxygen supply, oxidative enzyme activity, accumulation of lactic acid in the blood, exponential increase in energy requirement for overcoming air resistance, and generally a nonlinear risk of stress on the locomotion (tendons, bones and ligaments), respiratory and cardiovascular systems, with increasing racing speed [13, 68].

Hypothetically, an insertion of a gene with positive effect on racing performance on an inferior racing horse would be likely to have more marked effect on its racing performance than if the same gene was inserted into an outstanding racer, which would already carry many genes with positive effects on racing performance. Such scale effects can often be removed by appropriate transformation and traditional quantitative genetic analysis methods may apply. Alternatively, a nonlinear polynomial genetic model for finite number of independent loci (geometric progression) might be attempted [66, 67]. The geometric progression model assumes constantly diminishing marginal substitution effects of the alleles affecting the trait.

In conclusion, the fact that racing times in classic Thoroughbred races have not improved markedly in more than a half century in spite of available genetic variation and selection is not necessarily a "paradox." It could merely be a result of the use of improper scale for measuring racing times in horses approaching their biological limits.

Future Directions

Methods of organized animal breeding using BLUP animal models and selection on EBV for important traits have proved useful in many horse populations worldwide. Genetic progress at the annual rate of 3–6% of the phenotypic standard deviation has been reported in several populations. Sustainable breeding schemes yielding this rate of constant response over a long period and at the same time maintaining sufficient genetic variability in the population can be accomplished with established knowledge and relatively cheap technical equipments.

In many parts of the world are rational and organized breeding plans still lacking in large and locally important horse breeds. In some societies, this can be explained by poverty and lack of higher level of education. In others is the social culture, including reluctant conservatism, a hindrance to the introduction of new technique and scientific influence on the traditional horsemanship and "horse culture." This will certainly change and introduction of new and modern organized breeding plans for horses will undoubtedly be seen in many countries in near future.

The increased international trade with valuable breeding horses and exchange of genetic material across horse populations has created need for international genetic evaluations, where EBVs can be fairly compared across countries. The need for international genetic evaluations will certainly grow in the near future.

Methodological developments in genetic evaluation procedures and statistical models will undoubtedly enhance future breeding in horses. Of particular foreseen interest is genetic evaluation of ranks in competitions based on Bayesian Thurstonian models [29, 30] and use of random regression models for evaluation of traits with repeated measurements [20, 21].

Recently, the horse genome has been fully sequenced and the results are available to the scientific community [69, 70]. This has created optimism that genomic selection, which is selection on genomic breeding values (GEBVs), might revolutionize future horse breeding. The GEBV are calculated as the sum of the effects of dense genetic markers across the entire genome on the trait of interest. The genetic (DNA) markers are in the form of a large collection of chromosome fragments, so-called SNP (single nucleotide polymorphism) chips. Since GEBV can be obtained already in young foals, the possibility to shorten the long generation intervals in traditional horse breeding and to hinder castration of genetically valuable individuals is obvious. Genomic selection has the most potential for genetic improvement of traits that are manifested late in life and of traits with low heritability. Breeding for performance traits in sport horses, longevity, and various health traits in horses could benefit enormously if genomic selection can be practiced in a cost-effective way.

More methodological as well as technical development is required before genomic selection can gain widespread practical application in horse breeding. The first step is the development of a sufficient number of high-density SNPs across the entire horse genome and the second step is to genotype large reference populations in different horse breeds with phenotypic records so that the effects of the markers on the phenotypes can be analyzed. In subsequent generations, a large number of horses will need to be genotyped for the markers to determine which chromosome segments they carry. Then the estimated effects of the segments can be summed across the whole genome to predict the GEBV [71]. This new technology is already revolutionizing dairy cattle breeding in several countries [72, 73] and an efficient algorithm for computing the relationship matrix by use of genomic information has been invented [74]. A combination of a traditional selection on EBVs and a selection on GEBVs is likely to be adapted soon in the most valuable sport and racing populations, where the cost of genotyping is little in relation to the value of the breeding animals and organized breeding plans with registration of data on phenotypes and pedigrees are already in function. As a dramatic reduction in the cost of genotyping can be anticipated in the future, a practical and widespread use of genomic selection may become reality in

breeding of horses throughout the world sooner than expected in the light of current status and prizes. An important challenge will be to meet unforeseeable snags that may rise from the use of the new technique and difficulties in managing future genetic variation and long-term genetic gain.

Article Outline

Glossary

Dynamic models Models that incorporate a time-varying element. Such models may have no spatial dimension or extend to modeling spatial variation in all three dimensions.

Integrated multi-trophic aquaculture (IMTA) Cocultivation of aquatic species at different trophic levels, such as salmon, mussels, and kelp or scallop and sea cucumber, in order to maximize yield and minimize the environmental footprint.

Modeling framework Models are a representation of reality, which they aim to reproduce in terms of generality, realism, accuracy, and simplicity. As a rule, generality and simplicity are maximized. A model framework usually consists of two or more models, which are combined to address different levels of complexity.

Research models Models that are more detailed, usually complex to develop, implement, and apply. Aimed mainly at the scientist, rather than the manager.

Screening models Models that use a limited set of inputs, and provide highly aggregated outputs, such as an index of suitability or an environmental score card.

Virtual technology for aquaculture Any artificial representation of ecosystems that support aquaculture, whether directly or indirectly. Such representations, exemplified by mathematical models, are designed to help measure, understand, and predict the underlying variables and processes, in order to inform an Ecosystem Approach to Aquaculture.

Definition of the Subject and Its Importance

Aquaculture, defined simply as the cultivation of aquatic organisms, has many similarities to agriculture, most notably that it is based on the interaction between humans and other elements of the natural system, converting the latter (at least in part) into a *managed* system.

In parts of the world, such as Southeast Asia, the distinction between the two types of cultivation becomes increasingly fuzzy, especially if they take place on land. Cocultivation of rice and tilapia in paddy fields [1] or the combination of penaeid shrimp (e.g., the whiteleg shrimp *Penaeus vannamei*) and water spinach (*Ipomoea aquatica*) in earthen ponds is common, as are many other combinations (Fig. 1). Carrying capacity in such intensive systems, whether in monoculture or in integrated multi-trophic aquaculture (IMTA), might at first glance seem equivalent to assimilative capacity.

Aquaculture in open water, whether in reservoirs, lakes, or coastal systems, must take into account the complexities of water circulation, together with the harmonization of different uses. In the context of organically extractive open-water culture, Bacher et al. [2] and Smaal et al. [3] defined carrying capacity as:

The standing stock at which the annual production of the marketable cohort is maximized.

Although this definition was proposed for bivalve shellfish culture, it is sufficiently broad to be relevant for production in open freshwater, coastal, and offshore environments, as well as in land-based systems using ponds or raceways. However, production carrying capacity needs to be further qualified, because in

economic terms the maximization of annual production is not the objective function, and brings with it increased environmental costs. Commercial production must seek to achieve optimal *profit*, well before the inflection point in the production function, where total physical product (TPP) maximizes *income* (e.g., [4, 5]).

This production-oriented view of carrying capacity for aquaculture, whether in terms of assimilative capacity for fed aquaculture such as finfish or shrimp or with respect to food depletion in the case of shellfish such as oysters, clams, or abalone, has been expanded over the last decade into a four pillar approach based on physical, production, ecological, and social carrying capacity [6, 7]. These pillars encompass the three elements of sustainability, viz., planet, people, and profit.

The terms carrying capacity and assimilative capacity are frequently associated with models of aquaculture impacts. Because these terms attempt to define the limits of sustainable aquaculture, predictive capability is highly sought (Fig. 2).

This chapter reviews the state of the art in modeling frameworks that assist with that prediction and support proactive management of aquaculture.

Introduction

The establishment of aquaculture activities in different geographical areas has historically been a bottom-up process, without any systemic planning or definition of a zoning framework. This is seen throughout the world, from the development of salmon cage culture in Scottish lochs to the incremental destruction of mangroves for construction of shrimp farms (Fig. 3).

This approach to licensing (or in many cases just to development) has been based on space availability and limits to production rather than on any environmental criteria, and has led to undesirable ecosystem effects, including habitat destruction both on land and in open waters, coastal eutrophication through increased nutrient loading from land, organic enrichment of sediments, loss of benthic biodiversity, and major outbreaks of disease.

In the last decade, better regulatory frameworks have led to a more stringent approach to licensing, most notably in the European Union, the United States, and Canada. The European Union's Marine Strategy Framework Directive (EU MSFD – EC [80]), together with guidelines for an Ecosystem Approach to Aquaculture (EAA – [8]), highlights the ecological component and aims to optimize production without compromising ecosystem services. Part of the challenge of determining carrying capacity is the quantification of negative externalities as a first step toward improved management.

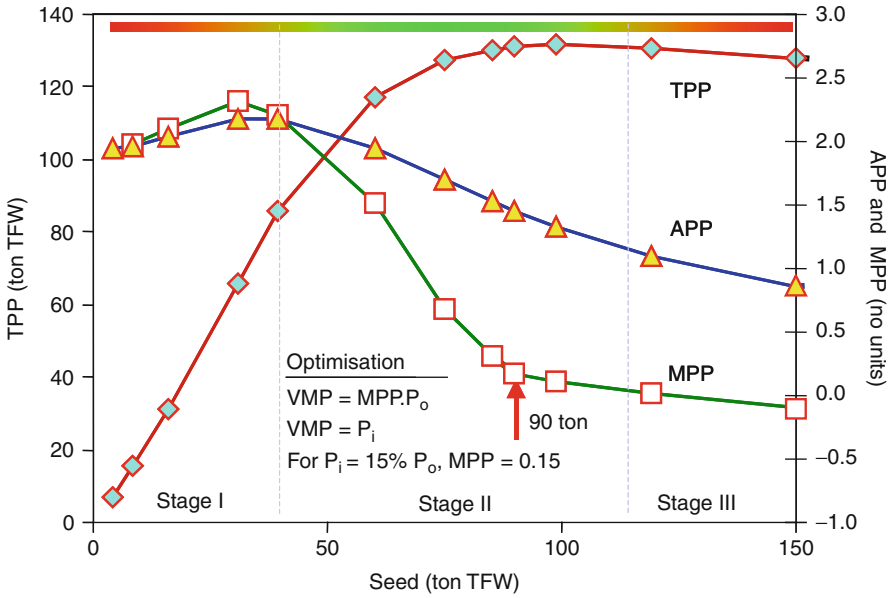
In Brazil, for instance, where aquaculture has grown very rapidly over the past decade (Fig. 4), environmental permitting of new tilapia farms in reservoirs is determined through the application of the Dillon and Rigler [9] phosphorus loading model, a rather simplistic view of carrying capacity.

A maximum limit of 30 μg L^{-1} of P has been established for reservoir waters, 5 μg L^{-1} of which is reserved for fish farming, to allow for multiple uses including cattle ranching, sugar cane production, urban discharges, and the natural background.

Fish farms are licensed sequentially, based on the contribution to P loading of their declared production.

Although this approach does address carrying capacity at the system scale (i.e., $\Delta P = 5$ μg L^{-1}), it does not consider any spatial or temporal variation, nor does it account for factors such as organic enrichment, disease, or impacts on biodiversity – all of which may be linked.

Whereas production and social (e.g., tourism) impacts are often local, ecological impacts *of* aquaculture can have far broader scales, as can large-scale effects *on* aquaculture, such as advection of harmful algae from offshore [10]. Sustainability is "easier to plan than to retrofit," [10] which makes a case for the



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 2
Marginal analysis indicates that the seed that provides maximum profit (*red arrow*) falls well to the left of the maximum production, shown by the *dotted line*. Production beyond the optimal profit point adds no value and potentially increases environmental pressure (Results from the FARM model, Adapted from [4])

analysis of carrying capacity at the system scale (e.g., Nobre et al. [11]), i.e., defining and quantifying the overall potential for different types of aquaculture prior to local-scale assessment (e.g., [12]) of new operations. Simulation models of varying degrees of complexity must play a role in the determination of carrying capacity for aquaculture, often combined as model frameworks, given the range of time and space scales and the number of processes involved.

Over the next decades, the growth of aquaculture will take place in developing nations [13–15], which makes it paramount that the digital divide, which is already considerable (as is the legal divide; see [16]), does not become wider.

Simulation technology that can support planning should be close to the production centers and be able to deal with data-poor environments and limited computational access and skills.

Modeling Frameworks for Carrying Capacity

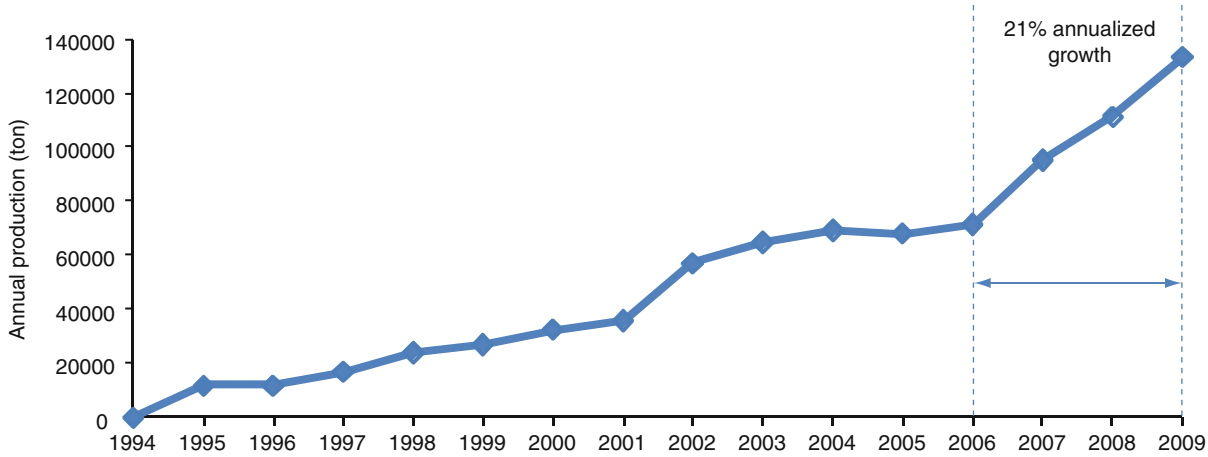
The concept of carrying capacity in aquaculture, based on four pillars of sustainability, has been adapted in Fig. 5 to include governance [16, 17]. This is considered more relevant than the physical element, which in many respects is encapsulated in the production pillar. Governance, on the other hand, is clearly missing from the original model of Inglis et al. [6], and the quality of balanced regulation, stakeholder involvement, and community-based management [18] often constitutes the difference between sustainable aquaculture and an environmental time bomb.

The social (here used in the context of social opposition to visual or other impacts of aquaculture development, such as conflict with leisure areas) pillar is at the forefront of decision-making for aquaculture in the EU, the US, and Canada and can frequently be identified as the single most important criterion for carrying capacity assessment and site selection (Fig. 5). By contrast, in Asia and other parts of the world where food production is the paramount concern, licensing criteria are more frequently based on the production pillar, with ecological considerations assuming less relevance. In China and Southeast Asia, the social component acts as a driver for increased aquaculture, for reasons of economy and food security. Governance is not usually

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 3
Expansion of shrimp ponds over a 13-year period in Estero Real, Nicaragua [83]

limited by a lack of legal instruments [16] but often by their adequacy and acceptance by stakeholders.

Two of the pillars illustrated in Fig. 5, production and ecology, are amenable to mathematical modeling, and two are not. This does not mean that those mathematical models will be entirely successful in describing growth, environmental effects, and particularly ecosystem responses, but they do make a significant contribution to the improved evaluation of carrying capacity. Part of the difficulty lies with our understanding of the relevant processes, parameters, and rates, part with other factors, such as the lack of a paradigm in ecology to support prediction. For instance, in the EU MSFD, as in other legal instruments, there are complex descriptors of ecosystem health such as biodiversity, and the scientific community struggles to establish meaningful classification systems and their relationship to anthropogenic pressures.



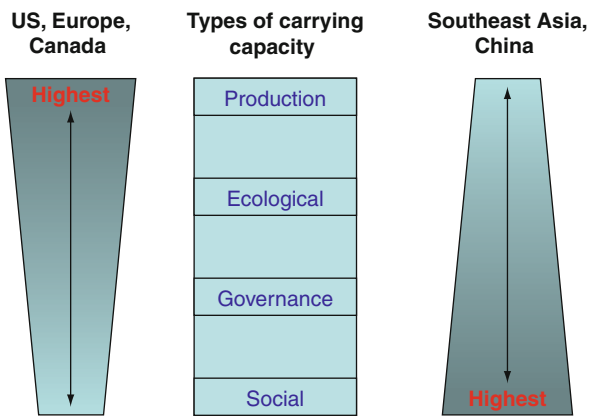
Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 4
Production of farmed tilapia in Brazil (MPA, personal communication, 2011)

There are also interactions with the human component of cultivation that constitute simulation challenges. Culture practice, for instance, is widely variable and can generally only be modeled in average terms [19].

Issues related to disease, which fall squarely between production and ecology and are extremely difficult to model, are a huge challenge in aquaculture and often include a significant element of poor governance, such as relaying of infected animals to hitherto uncontaminated areas.

Rearing large numbers of animals of the same species in close proximity to each other favors the establishment and spread of infectious diseases within those farmed populations [84]. Disease can affect both survival and growth of animals. Outbreaks of highly virulent bacterial and viral diseases can result in high mortality of an affected farm stock. For example, outbreaks of white spot syndrome virus (WSSV) in farmed whiteleg shrimp can result in greater than 60% mortality, with an attendant dramatic impact on the farms and regions dependent on farming this species.

Additionally, with ever increasing demands from consumers for high-quality products, the effects that disease can have on product quality are of increasing importance. For example, tilapia that have survived outbreaks of *Francisella* often have unsightly lesions in the fillets. There are also examples of diseases, such as Red Mark Syndrome in rainbow trout [85], that do not result in any significant mortality or morbidity, but still result in the product being downgraded or rejected by processors after harvest, imposing significant economic costs on the farmer.



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 5
The relative importance of the four pillars of carrying capacity (Adapted from [17])

The ecological effects of disease in aquaculture can also be profound. This includes spread of pathogens from farmed fish to wild fish and vice versa [86]. Disease agents that affect aquaculture species generally have their origins in wild aquatic animals [86]. Many systems (e.g., salmonid netcage and bivalve culture)

involve rearing the farmed animals in relatively open systems where the reared animals are in direct contact or close proximity with wild animals. Water is an ideal medium for the dissemination of many pathogens, leading to a high risk of transfer. For instance, in Norway and Scotland, exchange of sea lice *Lepeophtheirus salmonis* between farmed Atlantic salmon and wild salmonids has been implicated in causing significant declines in populations of wild Atlantic salmon and sea trout.

In order to examine modeling frameworks, the following sections review the definitions of, and distinctions between, the pillars of carrying capacity that are more amenable to mathematical modeling.

Assimilative Capacity and Carrying Capacity

Assimilative capacity is sometimes considered a subclass of the more general term carrying capacity, but other more specific definitions have been applied. We make a distinction as detailed below. Assimilative capacity refers to the ability of biological systems in the water column or sediments to process organic matter, nutrients, therapeutants, or contaminants without alteration of ecosystem state or function.

Carrying capacity refers to the biomass of cultured organisms that can be supported without altering system state or function measured by water or sediment quality standards and processes [20, 21]. The latter is thus determined by aquacultured biomass [22], where the former is independent of aquaculture and determined by biological properties of the habitat.

The application of standards to models of impact takes two forms:

1. Absolute criteria determined by regulatory bodies such as the Water Framework Directive of the EU (EU WFD – EC [79])
2. Relative standards compared to reference conditions or the range of variation observed in the environment

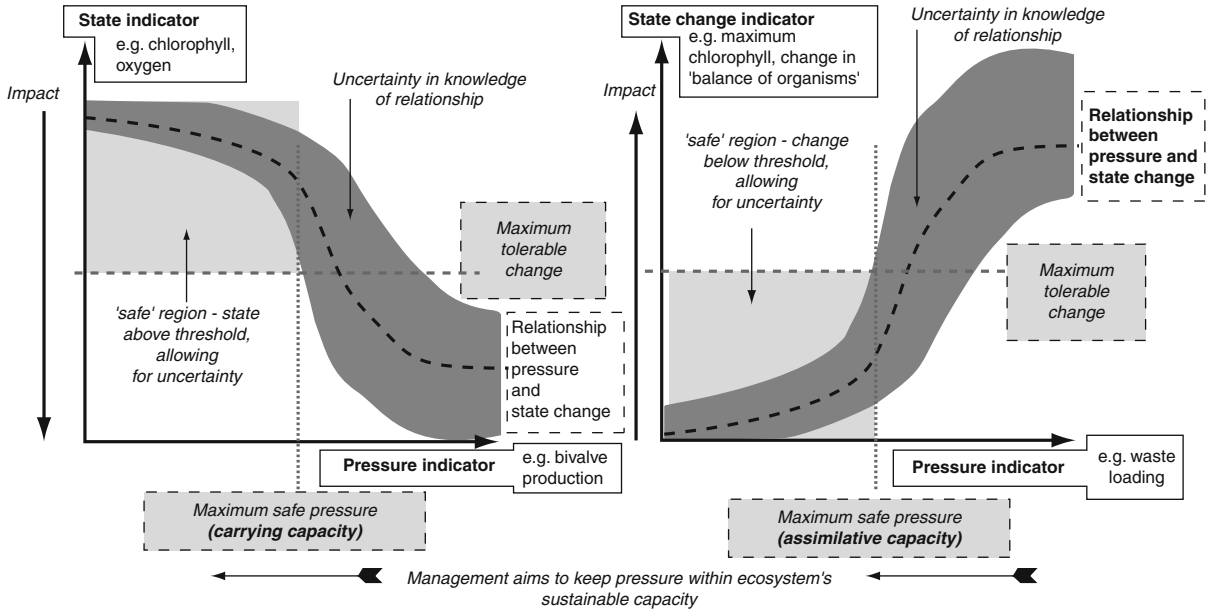
In both cases, there is an attempt to use these values as sustainability criteria. In the case of absolute standards, the background of the environmental conditions is not considered. For example, naturally eutrophic waters may show higher nutrient levels, with no relationship to aquaculture. This is particularly true of chlorophyll impacted by shellfish depletion. It may be more realistic to consider depletion in the context of the range of values observed in the environment as a means of establishing whether aquaculture signals can be detected against background noise. This type of standard has been applied to shellfish depletion of chlorophyll by Filgueira and Grant [20] and to shellfish biodeposits by Grant et al. [23].

Tett et al. [22] formalize both carrying capacity and assimilative capacity as the result of dose–response curves, couched in the terminology of DPSIR (Drivers-Pressure-State-Impact-Response; see also [24]; Fig. 6), where pressure is the farmed biomass and state is the system response modeled as a water quality standard. By comparing physical and geochemical rate processes, a net balance is determined, whereby the quantity of interest displays an increase (e.g., ammonia) or decrease (e.g., dissolved oxygen) relative to a water quality standard. When two of these processes are balanced, an index is created, constituting some of the earliest models in this research area, sometimes referred to as screening models.

A further distinction is that assimilative capacity be a function only of biological processing. Tett et al. [22] use the net results of water quality models which include advection–diffusion as well as biological processing to define assimilative capacity. Following bioenergetic lexicon, assimilation is a metabolic process involving digestion and/or decomposition, but excluding physical exchange.

There has been some decoupling of the measurements used to characterize aquaculture impacts in sediments (redox, sulfides; [25]) with models that are based on oxygen fluxes. Brigolin et al. [26] used a more classical early diagenesis model to examine coupled redox reactions at fish farm sites. This is one of the few cases where the field measurements used in regulation could be compared to model output including total sulfides and seabed oxygen consumption.

In terms of benthic impacts, assimilative capacity as the ability of sediments to accept some degree of organic enrichment without generating anoxic crises is well grounded conceptually. A comparison of benthic carbon supply via fish feed and fecal input to oxygen demand of the sediment forms the basis of some the original models of benthic impact [27] including the long-standing Norwegian MOM approach [21].



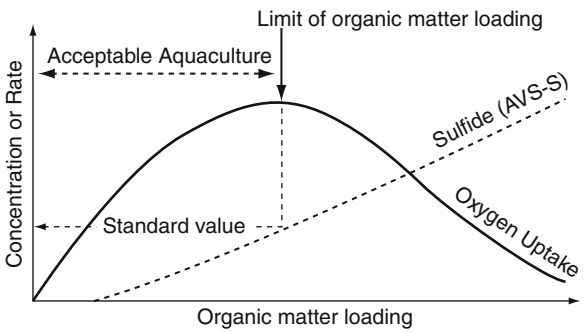
Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 6
Conceptual framework of assimilative and carrying capacities [22]

This concept was widely applied to multiple salmon sites by Morrisey et al. [28]. De Gaetano et al. [78] produced a more sophisticated version of the model for Mediterranean fish culture.

The intermediate disturbance hypothesis (e.g., [29]) provides a functional form to the model by suggesting a parabolic response of benthic diversity and activity to organic loading. Stimulation of aerobic demand occurs at low enrichment, peaking at intermediate levels and declining at high levels (Fig. 7; [30]).

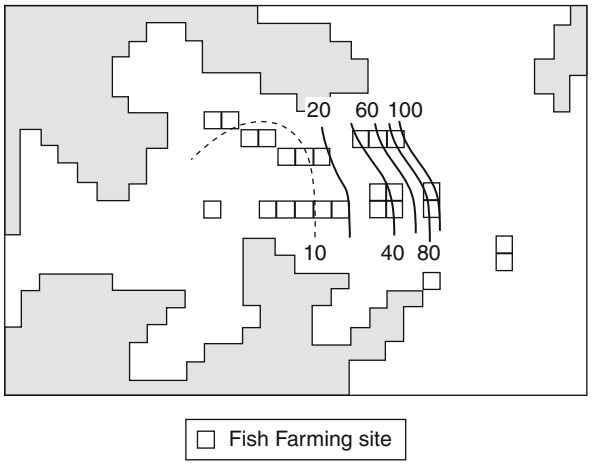
The latter authors define "acceptable aquaculture" as keeping sediment oxygen demand at or below the peak. They produced a numerical model which included a 3D circulation component, organic deposition, and decomposition based on a sediment diagenesis model using oxygen fluxes and anaerobic processes. Output is in the form of mapped values of organic loading based on fish stocking density that produces maximum aerobic oxygen concentration (Fig. 8).

The map shows that farms within the inner parts of the inlet have less permissible organic sedimentation due to reduced flushing. We suggest that this example is the appropriate approach to assimilative capacity since it models system function and its response to organic



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 7
Acceptable limits for organic matter loading from fish farms and the relationship to benthic oxygen uptake and sediment sulfide content [30]

loading based on the capacity of the benthos to absorb organic matter while maintaining oxic conditions. In addition, inclusion of a spatial diffusion–advection model allows incorporation of nonlocal processes and provides mapped output. Results are inherently inclusive of far-field effects and include interaction of multiple farms. Although the paper did not have the



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 8
Isopleths of the limit values of the organic matter loading rate ($\mu molO_2/cm^2/day$) in Gokasho Bay, estimated by a numerical model [30]

context of marine spatial planning, it is clearly applicable in terms of both the approach and the results. The comprehensive nature of this study and its faithfulness to the concept of assimilative capacity make it noteworthy in the literature.

Models of assimilative capacity, like those for shellfish carrying capacity, differ in spatial resolution. The original index models are 1-box, 0D models treating any body of water as a single basin. Physical exchange is thus averaged over the entire domain. This is often problematic since estuaries or other embayments are places with strong gradients in flushing. In addition, aquaculture sites are averaged in this scheme, so no questions regarding optimal location can be addressed.

One hybrid approach which solves some of these problems is the use of a full circulation model whose output is applied to local models. In this case, at least the physics is location specific, and subregions of the system may be considered without the 0D averaging.

Lee et al. [31] applied this approach to yellowtail culture in Hong Kong Harbour by comparing oxygen delivery to fish oxygen consumption and determining net oxygen concentration relative to water quality standards for different levels of stocked biomass. Similar schemes have been used for finfish culture in Scotland [22].

Models for Finfish, Shrimp, and Bivalve Culture

Models for Open Water Culture Models for organic loading by finfish include submodels of circulation, particle transport, and benthic response [21]. Models may also include a phytoplankton-nutrients-zooplankton (PNZ) component, simulating trophodynamics in the water column. This may be necessary due to the importance of phytoplankton and the microbial loop as nutrient processors [22]. For either finfish or shellfish, some version of a farm production or bioenergetics model is essential to estimate waste outputs from cultured animals. Benthic models applied to aquaculture are typically diagenetic, aimed at resolving sediment decomposition and nutrient regeneration [78].

For finfish, benthic deposition of farm wastes and consequent impacts are the primary emphasis; since fish are not dependent on the environment for food, trophodynamics are less relevant. Similarly, the models are usually localized since much of the waste material remains near the cage site (e.g., DEPOMOD). Nonetheless, there is concern that wastes reach the far field and produce negative benthic impacts. Despite this potential, far-field models of finfish cage culture are uncommon. Some early examples used 3D circulation models to examine waste dispersal over kilometer scales [87].

In a more recent example, Symonds [32] compared near-field models such as DEPOMOD to a far-field model based on a 3D circulation. He found that the dependence of near-field models on limited current meter observations was subject to the noise and uncertainty inherent in those measurements. In addition, the far-field model had the potential for bidirectional transport of waste, whereas the near-field model had permanent escape from its limited domain causing potential underestimation of benthic impacts. In addition, the far-field model allows consideration of multiple farms and their interaction. Skogen et al. [33] used a 3D circulation model coupled to a full ecosystem model to study the effects of fish farms on far-field oxygen, nutrients, and primary production, concluding that eutrophication in the far field of a Norwegian fjord was not enhanced by the farm.

The goal of most bivalve shellfish models is to understand seston depletion as a limiting food resource

for farmed animals. This requires a trophodynamic model which includes primary production, bivalve grazing, and advection–diffusion. Because farmed shellfish feed on phytoplankton from distant sources, recent examples involve models which include the far field. Nevertheless, there are many examples of 1-box, 0D models in which the physics and biology are averaged over the basin. Environmental impact of biodeposition to the benthos has been considered in several models including spatial examples [30, 34], but this is less frequently addressed compared to seston depletion. The opposite is true for field studies where benthic impacts are emphasized, and seston depletion is rarely addressed due to the difficulty in observing it. Because seston depletion occurs first at a farm scale, models of the depletion process have also been created at the local scale, prominently the FARM model [4]. Far-field models of seston depletion are increasingly common [20, 35].

It may be concluded that models of finfish aquaculture impacts would benefit from more spatial realism and far-field content, as well as further emphasis on assimilative capacity. Similarly, shellfish models would benefit from inclusion of benthic impact prediction in association with existing focus on seston depletion. The development of assimilative capacity models would be identical for both finfish and shellfish culture. This also places the context to that of ecosystem function. The present context of faunal indices based on carbon deposition in local models is important [36, 37], but is predicted on the basis of somewhat tenuous empirical relationships which are a departure from the more quantitative nature of the models.

Models for Land-Based Culture Models that simulate land-based culture taking place in ponds, tanks, or raceways use many of the biogeochemical features described above, but the physics is simplified to a reactor type of system and serves to determine water exchange and effluent loading to adjacent water bodies. Such models are cheaper to develop and implement than the examples given for open waters (here including lakes and estuaries, where water circulation should also be accounted for). According to the latest figures from FAO, over 70% of freshwater aquaculture in China takes place in ponds, corresponding to an area the size of New Jersey and an annual production of over 15 million tons [88].

This number is triple the total aquaculture production of America, Europe, and Africa combined, which suggests that substantial emphasis should be placed on models that can assist with site selection, optimization of carrying capacity, and evaluation of negative environmental externalities of pond culture.

Various examples of this type of approach exist (e.g., [38, 77]. Figure 9 shows mass balance results obtained with the Pond Aquaculture Management and Development (POND) model [39], which simulates the production and environmental effects of shrimp, fish, and bivalves cultivated in ponds, in monoculture or IMTA.

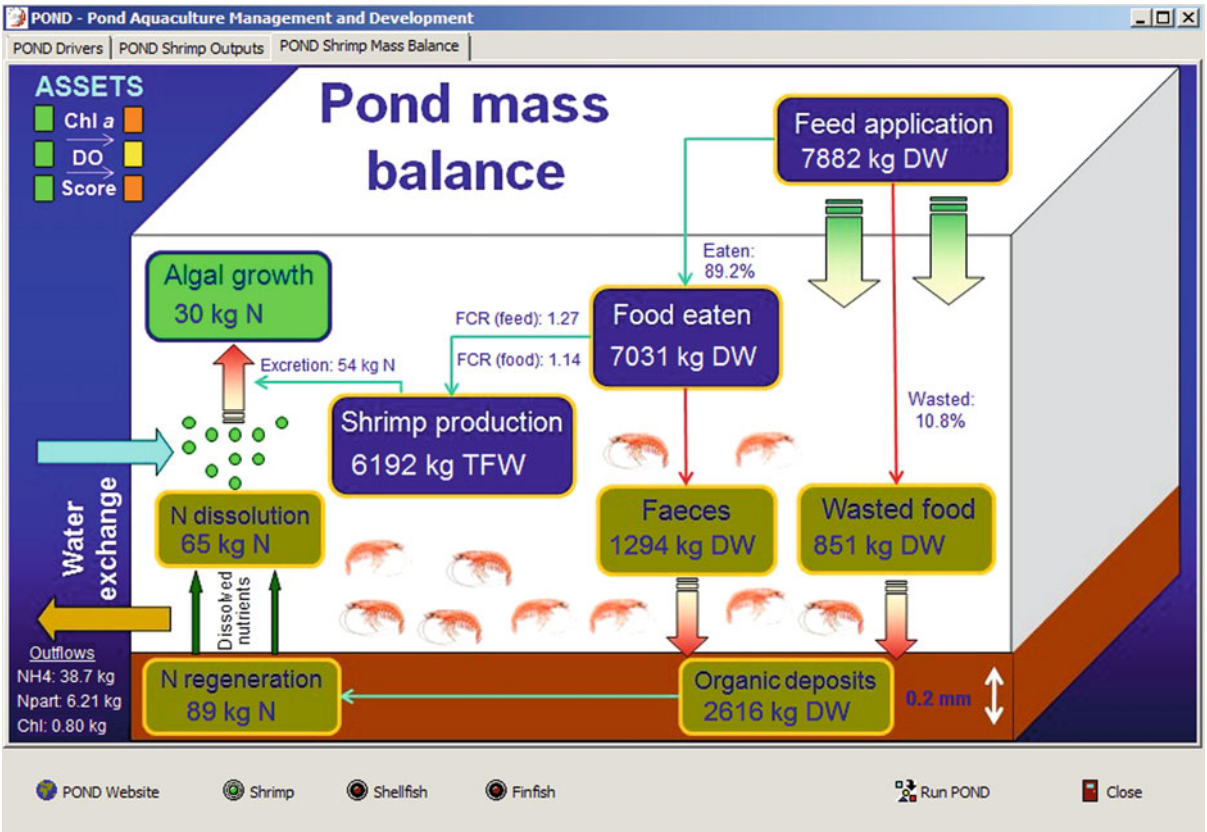
The model was run for a site at 23°N, with a daily water renewal of 3% of the pond volume, and estimates an environmental discharge of about 45 kg of nitrogen (mostly dissolved, but also as algae), roughly 14 population equivalents (PEQ) per year for the 90-day cultivation cycle. The cost of offsetting these emissions is over 500 USD [40]. In developing countries, these waste costs are not internalized but rather imposed on to the environment, contradicting the first principle of the ecosystem approach to aquaculture [8] that:

- Aquaculture should be developed in the context of ecosystem functions and services (including biodiversity) with no degradation of these beyond their resilience.

By contrast, pond production in the United States already requires a National Pollutant Discharge Elimination System (NPDES) permit [41]. Often, this means that large agro-industrial companies from developed countries price-leverage the lack of environmental regulation and/or implementation in the developing world.

Models of this kind can be coupled with a range of other models to provide a decision support framework. POND uses the well-tested Assessment of Estuarine Trophic Status (ASSETS) model [42], providing a color-coded assessment (Fig. 9) of the degradation of water quality over the culture cycle.

Models for Integrated Multi-trophic Aquaculture IMTA has been practised in Asia for thousands of



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 9
Mass balance of whiteleg shrimp (*Penaeus vannamei*) culture, including production and environmental externalities for a 1-ha pond

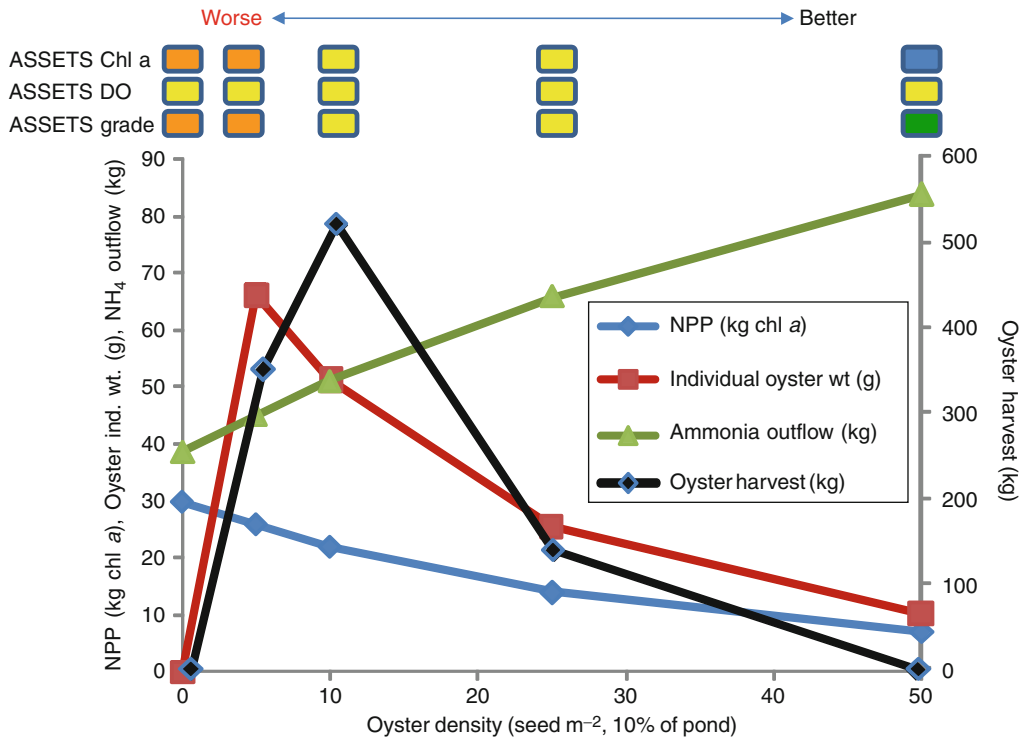
years. In the fifth century B.C., the Chinese aquaculturalist Fan Lee [81] wrote:

- You construct a pond out of six mou of land. In the pond you build nine islands. Place into the pond plenty of aquatic plants that are folded over several times. Then collect twenty gravid carp that are three chih in length and four male carp that are also three chih in length. Introduce these carp into the pond during the early part of the second moon of the year. Leave the water undisturbed, and the fish will spawn. During the fourth moon, introduce into the pond one turtle, during the sixth moon, two turtles: during the eighth moon, three turtles. The turtles are heavenly guards, guarding against the invasion of flying predators.

A substantial proportion of Asian aquaculture currently takes place in cocultivation, improving production, optimizing resources, and reducing environmental waste [14]. Despite this oriental wisdom, multi-trophic aquaculture is still rare in North America and Europe, although commercial interest is growing rapidly. This is reflected in research (e.g., [43, 44]), with the annual number of scientific publications on IMTA doubling from 2007 to 2010 (SCOPUS).

The combinations of species, relevant proportions, and culture practice are key to successful IMTA. There is traditional knowledge in China and other parts of Asia on what works best, but advances in mathematical modeling can make a substantial contribution by quantifying energy flows, production, and environmental externalities ([45], Nobre et al. [11], [16]).

Figure 10 shows a simulation of IMTA for a shrimp farm, with cocultivation of the Pacific oyster *Crassostrea gigas* at different densities, using the POND model. As the oyster density in the ponds increases,



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 10
Analysis of IMTA production and externalities by means of the POND model

the net primary production (NPP) of phytoplankton is reduced due to top-down control, although NH_4^+ increases due to bivalve excretion. The model is not simulating macroalgae or other aquatic plants, which if added would significantly reduce the output of ammonia.

The ASSETS score is best at the higher oyster density, but at a density of 10 oysters m^{-2}, the shrimp culture cycle would yield a harvestable oyster biomass of over 500 kg to provide an annualized extra income of over 10,000 USD. The removal of algae and detritus by the filter-feeding bivalves corresponds to three PEQ per year, about 15% of the discharge. At the higher densities, the bivalves are performing a bioextractive function and do not reach market size in a short cycle due to food depletion. A more detailed analysis can be made by simulating oyster growth continuously over multiple cycles of shrimp culture. Such interactions can also be modeled for other combinations, for example, tilapia and shrimp or salmon and mussels.

Models for Disease Spread and Control In determining the carrying capacity of aquaculture operations, it is important to ensure aquaculture production practices and systems within a farm, managed region, or zone are resilient to the effects of disease. Modeling provides a means of investigating the interactions occurring among the four pillars and the spread and establishment of pathogens; however, to date, most models have ignored the influence of society on aquatic disease. Many different models have been derived to investigate the spread and impact of particular pathogens: In aquatic systems, two of the most common approaches are (1) compartment-based models and (2) network models.

Compartment-based models assume that individuals transition through a series of states from susceptible (S) to infected (I), and potentially back, or through a series of other states such as resistant (R). These models are often referred to as SIR models [46] and are usually based on continuous time, and therefore use differential equations; however, stochastic and

discrete time approaches are also used. SIR models do not track individuals but assume the population follows a set of behavior rules, and that at each point in time, a proportion of the population leaves one state to enter another according to these rules. In aquatic systems, these models are generally used to track disease through a population of animals, but they have also been applied to look at spread through a population of sites. Simple implementations are often analytically tractable, allowing conditions under which thresholds and equilibria occur to be found without the need to run simulations.

One of the key pieces of information that can be derived from these models is a maximum (susceptible) host carrying capacity for which a pathogen cannot persist. Such carrying capacities used in the context of pathogens are often referred to as a critical threshold (N_T) and may be useful to wildlife and farm managers when attempting to control or prevent disease. This threshold is however largely dependent on the assumptions made regarding the way a pathogen is transmitted, and obviously does not apply if transmission is not dependent on host density, but is frequency based (as is often assumed to be the case when modeling sexually transmitted infections). It is therefore important that the correct form of transmission is used in a disease model to avoid false inference. The most commonly used form of model assumes that transmission occurs by contact between animals or sites, that the number of contacts is density dependent, and that mixing between individuals occurs equally and at random. This is often referred to as a "density-dependent transmission" or "pseudo mass action" model [47, 48].

Under these assumptions, one method by which N_T can be derived is by determining the conditions under which the basic reproductive number, R0, is equal to 1. In simple terms, R0 is the number of secondary infections that arise if an infected individual enters a wholly susceptible population. If greater than 1, the pathogen will establish; if less than 1, it will die out. R0 is governed by the total population density, the period over which an infected animal sheds pathogen, and the transmission rate β (the rate of contacts between individuals and that the probability that given a contact, infection occurs). Both environmental conditions and management/husbandry decisions can influence this number, and therefore the critical threshold for establishment. Understanding the influence of each of the four pillars of carrying capacity on R0 is therefore critical in order to predict and manipulate N_T. Omori and Adams [49] illustrate the application of compartment-based models to assess the influence of the ecology and production pillars on the dynamics of Koi herpesvirus in farmed carp populations *(Cyprinus carpio)*. Their approach showed that temperature and on-farm production processes used in conjunction with this could be used to immunize a population, preventing clinical disease expression.

The assumption of random mixing of a population is often not reasonable, as in reality some individuals will be more social or isolated than others, and individuals tend to have discrete groups of contacts that may or may not be connected to other groups within a population. Under these circumstances, the assumption of random mixing can lead to substantial overprediction of the epidemic process. Social network analysis (SNA) and modeling approaches provide a means of incorporating the contacts that occur between individuals, and therefore the consequence this may have on pathogen spread. In the case of agriculture and aquaculture, these models tend to be based at the level of the site, rather than the animal in question.

A major advantage of this modeling approach is that much epidemiologically useful information can be obtained merely by examining the network properties, without parameterizing for a particular disease. For example, in order to develop generic surveillance and control strategies, it may be useful to identify:

- Clusters of connected individuals within the network and whether it is possible to make them epidemiologically distinct through the removal of a few connections.
- Long chains of connection that join the network throughout and thus allow disease spread.
- Super-spreaders, which are individuals that contact a high number of other individuals and can thus rapidly spread pathogens.
- Super-sinks, which are individuals that receive from a lot of other individuals. Though they may not

spread a pathogen, they are most likely to receive one and may therefore be useful for surveillance purposes.

Many statistics can be generated to summarize different properties of a network. Although R0 can also be estimated, other statistics such as the degree of centrality or clustering coefficient may provide more useful means of assessing the likelihood of spread through a network. Green et al. [50] demonstrated the application of such statistics using SNA applied to the Scottish network of trout and salmon farms. The analysis showed how much transmission was likely to occur in the network as it stood but also used a variety of methods to remove the most influential connections to reduce transmission.

In addition to examining the network properties, stochastic simulations can be run over the network. In such simulations, the network is randomly seeded with infected individuals and, at each subsequent time point, connected individuals change state from susceptible to infected at a given probability and given the likelihood of a contact. This approach is often useful when evaluating rates of spread and the effectiveness of control strategies but also has the potential to be used as a real-time tool during an outbreak, if it can be parameterized for the pathogen of interest. Further useful information may be gained from these models by making network models spatially explicit, as this facilitates the designations of control zones.

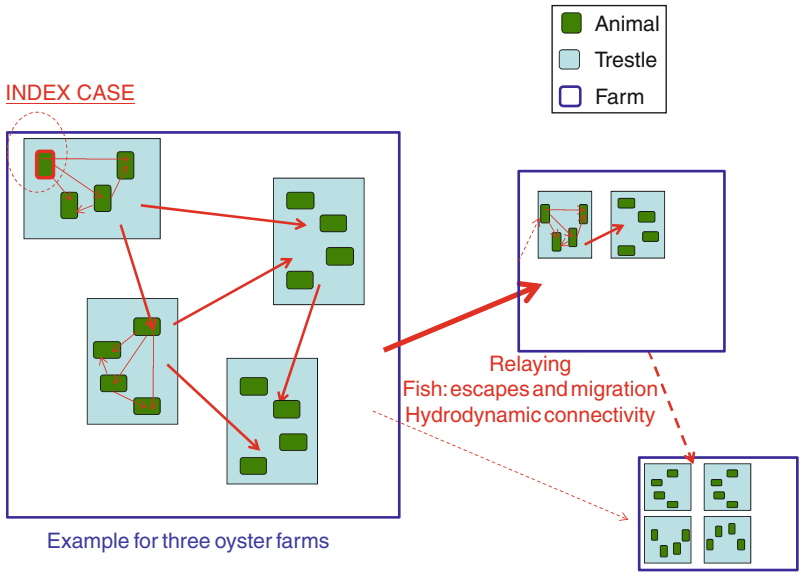
Werkman et al. [51] used stochastic network simulations to good effect to determine the efficacy of different fallowing strategies in eradicating disease from areas producing different amounts of fish. Thrush and Peeler [52] used a simulation of movements over the English and Welsh trout industry network to investigate the potential spread of *Gyrodactylus salaris*. This demonstrated that in 95% of the simulations run, less than 63 of 193 river catchments would be at risk of getting the pathogen in the 12 months following introduction. Jonkers et al. [53] developed this model further into a strategic tool that could be used to evaluate the effectiveness of different control and surveillance efforts on disease spread.

One of the major limitations of network approaches is that they rely on knowledge of the complete network of connections and assume that this remains stable over time. Missing connections or changes to the network with time could lead to misdirected efforts. For many aquatic systems, reliable network data are not available or are difficult to compile. Under these circumstances, simpler compartment-based approaches may still be of value in informing control policies. One such application was demonstrated by Taylor et al. [54] to evaluate the effectiveness of different control options in reducing the spread of Koi herpesvirus in the UK between sites holding carp.

Most models applied to aquatic systems to date tend to be based at either the level of the site or animal, with few attempting to combine the two approaches. There is, however, substantial scope to develop future models that incorporate multiple levels that account for transmission between individual animals in a unit, the influence this has on the transmission between units on a farm, and the subsequent effect on between-farm spread (Fig. 11).

Where attempts to link these two levels together have been made, useful results have been obtained. Hydrodynamic models have been applied to look at the spread of sea lice between Norwegian salmon cages in fjord systems [55]. These models track the number of lice generated and monitor their dispersal and decay over time and space to see whether they reach and infect other sites. Green [56] combined compartment-based and network approaches to incorporate the influence of within-site processes on network spread and found that differences in site biomass influenced the rate of between-site transmission if density-dependent transmission was assumed. One of the major advantages of models that link the within-site epidemic with between-site spread is that they allow for the consequences of different detection (or action) rates to be assessed, allowing more efficient resource planning.

The primary goal of all of the approaches described above is often to apply changes to the system to understand their influence on pathogen spread. In application to aquaculture systems, this may be conducted to establish how best to maximize N_T (either in the number of animals produced within a site or the number of sites in an area) and thus increase carrying capacity. Generally speaking, N_T can be increased by reducing the amount of connectivity between individuals (restrictions in movements), changing their susceptibility to disease (e.g., by vaccination) or reducing the



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 11
Network models working at different scales in time and space

period over which an individual is able to transmit a pathogen (e.g., through good surveillance and rapid culling). Other important disease management tools that have or could be evaluated by the modeling approaches described above include:

- The use of management areas in which aquaculture activities such as harvesting or treatment are coordinated between all farms in an area
- Fallowing of sites between production cycles to allow pathogens present to die out and potentially reduce the infection pressure other sites are exposed to
- Year class separation, where only one age class is present at a time causing all animals to be harvested prior to stocking new animals
- Removal of high-risk contacts between sites that are likely to spread disease widely
- Biomass limits to reduce the maximum amount of pathogen that could be discharged from a site
- Minimum distances between sites to reduce transmission via hydrographic connectivity

Building a Framework

Screening Models and Research Models The models reviewed above address different components of aquaculture carrying capacity, focusing mainly on production and environmental effects, including disease aspects. Additionally, they consider different scales in time and space and range from statistical models to spatially discrete representations, which may (e.g., hydrodynamic models) or may not (GIS) be time varying. It is useful in this context to distinguish between screening models and research models.

Screening models typically use a limited set of inputs and provide highly aggregated outputs, such as an index of suitability or an environmental scorecard. Examples include a comparison of ammonia excretion by caged salmon compared to tidal flushing [57] and the production of biodeposits compared to tidal removal for suspended mussel culture [23].

Models of this type (e.g., FARM, [4]; POND; Fig. 9) are easy to use by the management community and provide a quick diagnosis for a specific site, or a generic overview comparison for multiple areas.

Models that are complex to apply (and usually lengthy and complex to develop and implement) may be termed research models and are of limited practical use in day to day management. Partly, this is due to the knowledge required for parameterization, volumes of data involved, and substantial requirements in processing and interpreting results. This does not mean that the results of such models do not have

a clear application for management, but operating them may be beyond the scope of many institutions.

The concept of a single overarching model, able to provide answers across a range of space and time, has been shown repeatedly to be unsound. Just as software suffers from feature creep [58, 59], stand-alone models tend to become increasingly overparameterized, partly in an effort to better match reality and partly in an attempt to solve per se what should really be approached with a combination of models.

A more promising alternative is to combine GIS, dynamic models, network models, and remote sensing tools as appropriate to deal with questions that range from the impact of a HAB event on a salmon cage at the scale of days to the economic success of 10 years of mussel farming.

An increase in model complexity does not necessarily equate to increased accuracy [60], whether in physical or biological models. In both cases, the scale at which predictions may be made is limited by our incapacity to accurately predict the weather. As a consequence, model resolution and accuracy are limited by key drivers such as river flows, salinity patterns, and water and air temperature, which impact metabolic rates, algal blooms, turbidity, spawning, or larval dispersal.

Models in the Context of Integrated Coastal Zone Management Carrying capacity models for aquaculture are useful in their predictive capability and therefore in management of both cultured biomass as well as location. Spatially resolved models are particularly notable in this context. Within the catchment, this may be addressed by means of GIS (see, e.g., [61]) and can be enhanced through a combination of dynamic simulations and spatially resolved models.

Aguilar-Manjarrez and Nath [89] performed an extended analysis of the potential for fish aquaculture in Africa, based on GIS models, using a resolution of 3 arc minutes (25 km^2 at the equator). For small-scale operations, suitability was based on water requirements, soil and terrain, availability of feed inputs, and farmgate sales projections. This analysis was also carried out for larger, commercial farming and concluded that for the three species considered (Nile tilapia, African catfish, and carp), about 23% of the area of continental Africa scored very suitable for both types of farming. These authors did not explicitly consider environmental effects of fish farming, probably because that analysis is best performed regionally or locally, as part of detailed site selection, but the modeling tools for addressing these impacts are available today.

GIS models have also been combined with remote sensing to assess aquaculture opportunities, for example, for crab and shrimp in the Khulna region of Bangladesh [62]. In this case, the focus was on gross production, economic output, and employment, and discussed species suitability with respect to factors such as salinity distribution and freshwater availability. Once again, the environmental externalities of the different types of culture were not included but can be modeled to provide a more complete picture for decision support, including externality costs.

Figure 12 shows the Jaguaribe estuary, in the state of Ceará, northeast Brazil. As part of the application of the ASSETS model to determine the eutrophication status of the estuary (Eschrique and Braga, personal communication, 2011), the nitrogen loading from 1,200 ha of shrimp farms, located between the city of Aracati and the dunes fringing the beach, was determined using POND.

The contribution of shrimp farming to the nitrogen load was estimated to be of the order of 60 t year^{-1}, roughly equivalent to 20% of the total loading, or about 15,000 PEQ.

Screening models of this kind are simple to use and help water managers in developing countries to address the challenge of multiple uses and nutrient sources to the coastal zone and to make better decisions with respect to site selection and waste treatment. They can also be included in a more general catchment modeling approach, combining their outputs with hydrological models such as the Soil and Water Assessment Tool (SWAT) model (e.g., Nobre et al. [11]).

In open water, including semi-enclosed systems such as estuaries and bays, because spatially resolved models incorporate physical circulation, they are potentially useful for other aspects of coastal zone management.

There are of course a variety of possibly impactful activities in the coastal zone including eutrophication, fisheries and fish processing, contaminant input, resource extraction, and transportation. There are inevitably competing uses of the water and bottom,

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 12
The Jaguaribe estuary, in Ceará, NE Brazil. Shrimp farms occupy an area of about 12 km^2 and discharge the effluent into the estuary

and making predictions about aquaculture in isolation is insufficient. Water and sediment quality standards applied over large spatial scales help to apply objectives that may be seen as ecosystem-based management. The implementation of these objectives is achieved through marine spatial planning. The implication of planning is that predictions can be made to anticipate overlaps, conflicts, and cumulative impacts of various activities.

Although models exist for these other activities, particularly those acting through eutrophication, the models need to interact coherently, and their outputs should be tied together in a way that is useful for management decisions. Two essential features of this integration are physical models that unify the transport of materials common to almost every process in the ocean and GIS to maintain data layers. The physical model establishes the spatial domain which can be either conserved, collapsed, or expanded within the GIS. At present, models run within GIS are necessarily simple and based on averaged values. For example, the AKVAVIS tool developed in Norway [63] utilizes a GIS with calculation of shellfish growth as well as fish farm effects on water quality at any location based on an inline model using depth, temperature, and other spatially located characteristics within the GIS [63].

Tironi et al. [24] utilized an open source circulation model to predict far-field deposition for Chilean salmon culture. An essential feature of their work was a GIS interface used to depict other coastal activities in light of hydrodynamics and dispersal of farm waste. Nobre et al. [11]) combined models of watersheds, aquaculture, and eutrophication to look at mitigation strategies for improving nutrification in Chinese bays.

In marine systems with aquaculture but lacking other activities (e.g., some Norwegian fjords), the culture model may form the basis of the decision support system. In Lysefjord (southern Norway), a pump was used to transport water to depth where it enhanced diffusion of nutrient from below the thermocline to the euphotic zone [90]. The increase in primary production was used as a food source for cultured mussels. A model was employed to determine the best location for the upweller as well as the mussels in order to benefit from increased primary production, balancing the increase in new production with mussel removal to maintain chlorophyll within its natural limits. This example is of interest because the ecosystem was truly managed in terms of bottom-up nutrient supply, new production, grazing in terms of mussel culture, and marine spatial planning optimized for the extent and level of shellfish culture.

As more types of activities are added to decision support tools, one approach is to use GIS as a wrapper for model outputs produced as layers. Decision support comes from ancillary software with features such as portrayal of alternative land uses, exclusion of protected areas, weighting of valued features and habitats, and economic analyses. Several initiatives have been undertaken in this vein, with the incorporation of simulation models mostly in the initial stages of progress. Examples which have freely available ArcGIS extensions include NatureServe Vista (natureserve.org) and Marine InVEST (naturalcapitalproject.org). There are different emphases in the various projects, including conservation, community engagement, ecosystem services, and land use, in addition to water quality issues.

Among these, Marine InVEST seeks to maintain ecosystem services in the context of activities such as fisheries, aquaculture, renewable energy, and recreation [64]. Input information ranging from oceanographic data to species distribution is used in various models to consider outputs in terms of ecosystem services provided, traditional model results (e.g., water quality), and socioeconomic valuation (Fig. 13).

We note the importance of models other than those based on eutrophication and water quality. For example, some of the same spatial data used to model aquaculture impacts can be used to predict the location of sea grasses or species at risk [65, 66]. Protected areas or buffer zones may then become part of the plan. In this way, critical habitat and biodiversity are also considered along with aquaculture siting. Moreover, these decision-support frameworks can be used in public forums to incorporate community input, as has been done with protected area planning via MARXAN GIS [67]. In practice, these are few examples of models used to this extent, but it provides a very useful management shell in which to consider aquaculture submodels.

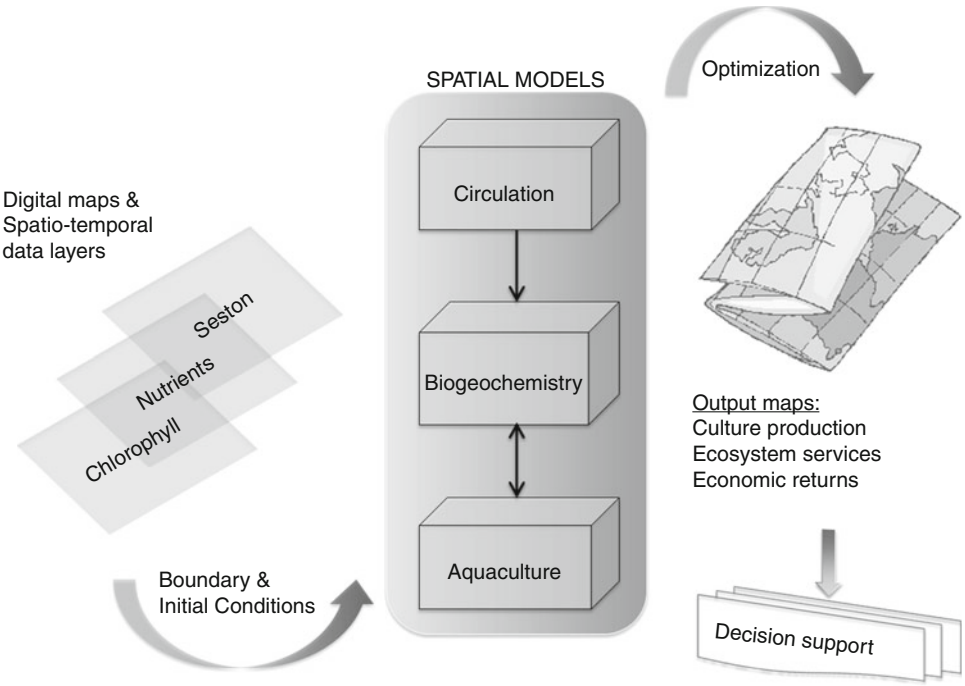
The Other 50% of the Problem At present, two major components of carrying capacity, the social and governance aspects, are not amenable to mathematical modeling (Fig. 5); they are nevertheless fundamental areas for aquaculture management.

The social pillar, from the perspective of social acceptance of aquaculture and, in particular, of the definition of limits to industry growth, has been discussed, for example, by Byron et al. [18]. Stakeholder dialogue, understanding of terms and concepts, and the simple fact that opinions can be voiced during the decision-making process are major contributors to generate consensus. The tools employed include questionnaires, meetings, and presentations of different sides of the issue. Simulation models can help inform those discussions by, for example, providing quantitative data on development scenarios but social positions often have a strong emotional component.

The governance pillar plays a major role in the assessment of carrying capacity. Table 1 shows key aspects of the human interaction in aquaculture and highlights the consequences of poor practices and governance.

The issues identified have consequences that vary in severity, from a reduction in revenue and profit to major outbreaks of disease and the loss of aquaculture resources across large areas.

Because the effects of human mismanagement can be so far reaching, it is important to discuss to what extent modeling frameworks can be used to assist the



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 13
Models for different purposes are linked through input data layers that are used to build scenarios about management actions (e.g., restoration of eelgrass, increase in aquaculture) and climate change (e.g., sea-level rise, water temperature)

farmer and the water manager. The eight topics in Table 1 fall under the heading of governance (here taken to include self-regulation by farmers and farmers' associations, as well as legal instruments, policy, and implementation), but only three (dark blue) can benefit directly from recommendations from simulation models, addressing stocking density and feeding practices.

Five of the issues identified introduce disease-related problems, and whereas procedures such as relaying, or seed import from contaminated sources, are strictly within the remit of good governance, models can to some extent assist in predicting the likelihood (i.e., risk), spread, and establishment of diseases, if present within an aquaculture area.

Regulations enacted to control spread of diseases can directly mandate what species and culture practices, stocking densities, etc., are permitted within a zone/region. Firstly, this would include planning applications assessments that would consider, among other factors, how siting a farm may potentially adversely affect other aquaculture operations located in that area, as well as potential effects on wild animal populations. In some cases, e.g., in Chile, regulations have been enacted that specify minimum distances between farms.

There is also an increasing move by some large-scale industries, as part of developing common codes of practice, to manage farms to minimize the effects of disease on production. These codes can include restricting stocking densities, production on farms, specifying minimum allowable distances between farms, and introduction of mandatory fallowing periods between production cycles. All these are measures that would theoretically constrain carrying capacity, at least in the short term, but might well increase the overall sustainability of the industry in the zone or region in the longer term. Although these may not be enforced by government regulations when first developed (e.g., they are often "voluntary codes"), those signing up may be entering legally binding agreements. These codes may then be used as the basis to develop more formal regulatory frameworks in the future at the local, national, and even supranational level.

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Table 1 Key issues in culture practice, time frames, and potential consequences (color coding reflects the extent to which models can be applied: *black* – substantial; *dark red* – reasonable; *light red* – inapplicable)

N°	Topic	Time frame	Issues/consequences	Examples
1.	Species selection	Prior to cultivation	Imported exotics, disease, proliferation	Pacific oyster, now considered invasive in the Netherlands; *Perkinsus* (dermo) and MSX, U.S. East Coast
2.	Seed purchase	Start of cultivation	Disease from imports, stable broodstock	Herpes virus spreading in oysters across Europe
3.	Relaying	Variable	Disease spread	Transmission of Herpes in oysters across Europe, ISA in Chilean salmon
4.	Stocking (farm or pond scale)	Critical periods	Overstocking can lead to: mass mortalities due to dissolved oxygen depletion, other environmental factors, and stress-related disease outbreaks	Whitespot Syndrome Virus (WSSV) in Penaeid shrimp, *Perkinsus* in clams
5.	System-wide carrying capacity	Months to years	If carrying capacity is significantly exceeded: harvest reductions, disease outbreaks, economic hardship, system collapse, long recovery cycles, long-term loss of resource	Marennes-Oléron, France, longer oyster culture cycles; Sacca di Goro, Italy, mass mortality of Manila clam; Qinshan, Fujian province, China, 50,000 fish cages (yellow croaker), mass mortality
6.	Feeding practice	Culture cycle	Ecologically damaging practices with ecosystem consequences, e.g., overfeeding of caged fish and benthic hypoxia	Fertilization of intertidal/subtidal areas in China to promote seaweed growth, increasing yields of commercial products (seaweed, gastropods); use of juvenile fish as fish meal for cage culture in parts of Asia
7.	Spatial distribution of culture	Culture cycle	If inappropriate, e.g., by combining year classes in shellfish, more labor-intensive, greater impacts on the ecosystem, e.g., through sediment reworking	Clam culture in southern Portugal
8.	Lease structure	–	Fragmented/inexistent lease structure, smallholdings governance issues, due to multiple stakeholders	Pond culture in Thailand (average freshwater pond: 0.28 ha); Clam culture in southern Portugal (average lease: 0.15–0.5 ha)

Regulation can also influence the carrying capacity of a zone or region both directly and indirectly. In particular, to help control the spread of diseases between countries, the OIE aquatic animal code [91] lists a number of infectious aquatic animal diseases that are generally considered untreatable, pose a significant threat to aquaculture and/or wild fish populations, and are not widely distributed (e.g., are exotic to most countries where the species they affect are farmed). Countries and regions also have laws and regulations to prevent the entry and, where pathogens do gain entry, specify measures for their control and eradication. For instance, Directive 2006/88/EC lays down, for European Member States, the required minimum animal health requirements, disease prevention, and control measures for aquaculture animals and products.

Eradication of a disease from a country or zone may involve extensive depopulation of affected farms and not restocking them until it is confirmed that the risk from disease is significantly reduced. This has obvious short- and long-term consequences on the carrying capacity of the affected species in the affected areas.

For example, following detection of the notifiable viral disease Infectious Salmon Anemia (ISA) on an Atlantic salmon farm in Chile in 2007, the disease spread throughout the salmon industry [92]. The effects were dramatic. It is estimated that salmon production in 2010 was little more than 98,000 t, down from 386,000 t in 2006 [93]. With the 1.5–2.5-year production cycle for salmon, these effects will be felt for years to come, with estimated smolt release in 2009 only 10% what it was in 2007 [94]. It is estimated that, compared to production in 2007, levels will be reduced cumulatively by at least 700,000 tons during the period 2009–2011, with their value reduced by more than two billion USD.

Disease controls can restrict the types of aquaculture activity that are permitted, or are practically possible, within a zone or region. Here, the constraints to carrying capacity are often opportunity costs, with fish not reared in a particular area because of potential disease risks. The effects can be quite subtle. For instance, in the UK, controls in place to restrict the spread of bacterial kidney disease are considered by some sectors of the rainbow trout farming industry to adversely affect their operations at the expense of the larger Atlantic salmon industry that has generally supported the maintenance of these controls. This would also include the effects of restrictions placed on the movements of live fish and ova between countries that limit the opportunities to farm those species in other countries.

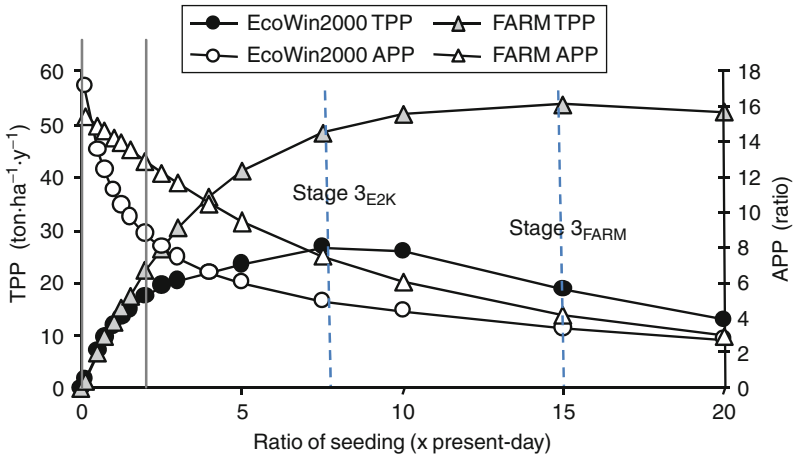
Finally, societal acceptance of aquaculture activities may be influenced by disease risk concerns, particularly to wild fish stocks. This is perhaps best illustrated by sea lice spread to wild fish. There is additional public concern as to the effects on the environment of use of chemical treatments. In particular, there is strong resistance to fish farming in many remote and pristine environments due to fears they may adversely affect local ecosystems. Increased public awareness of welfare issues in aquaculture may also lead to practices that reduce the incidence of disease as a consequence.

Blueprint for a Model System

There are considerable challenges in selecting and combining different types of models, each of which plays a particular role, for carrying capacity assessment. A number of models are available, many of which reviewed above, but the level of usability varies widely, as does the capacity of one model to "speak" to another. This comes about through the "one tool" syndrome: If your only tool is a hammer, all your problems are nails. One tool, i.e., one model, may be fine for a particular level of analysis, but it will be incapable of doing all the work.

For instance, a local-scale model such as DEPOMOD [36], MOM [68], or FARM [4] will need current velocity fields supplied either by field measurements or by other types of models. Equally, it will not provide a robust answer with respect to system-scale carrying capacity. Even at the farm scale, such models do not consider the interactions among farms, although the siting of a new farm in a region will inevitably affect environmental conditions and production in existing farms. These changes will then feed back, so that the original farm-scale assessment will change because the model input data will change.

Figure 14 illustrates this difference for mussel culture in Killary Harbour, Ireland, by comparing two models at differing scales [35]. EcoWin2000 (E2K) is an ecological model applied at the system scale, whereas FARM simulates production and environmental carrying capacity at the local scale. Both models can be used to perform a marginal analysis [4] to determine stocking densities that lead to optimal profitability. This is extremely useful for licensing purposes since farms often maximize income rather than profit (i.e., aim for the highest TPP). It can be seen that for a coastal or semi-enclosed system, there appear to be significant differences between the results for the system-scale model, where the dotted line indicating highest TPP (which exceeds the seeding density of maximum profit) occurs at a density 7–8 times greater than the present situation. FARM, however, which deals only with the local scale, determines the end of stage 2, i.e., highest TPP, as around X15 density. This is because (1) E2K runs multiple production cycles, typically for periods of 10–20 years, i.e., the ecosystem model reports what is actually harvested, whereas FARM reports what is harvestable over one cycle, and (2) FARM does not account for interactions among farms, whereas E2K considers the farms in the whole water body.



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 14
Impacts of different mussel-stocking densities on total physical product (TPP, harvestable biomass) and average physical product (APP, the ratio between seeded and harvested biomass) as simulated by EcoWin2000 (system scale, per unit of cultivated area) and FARM (single farm) for Killary Harbour, Ireland (Adapted from [35])

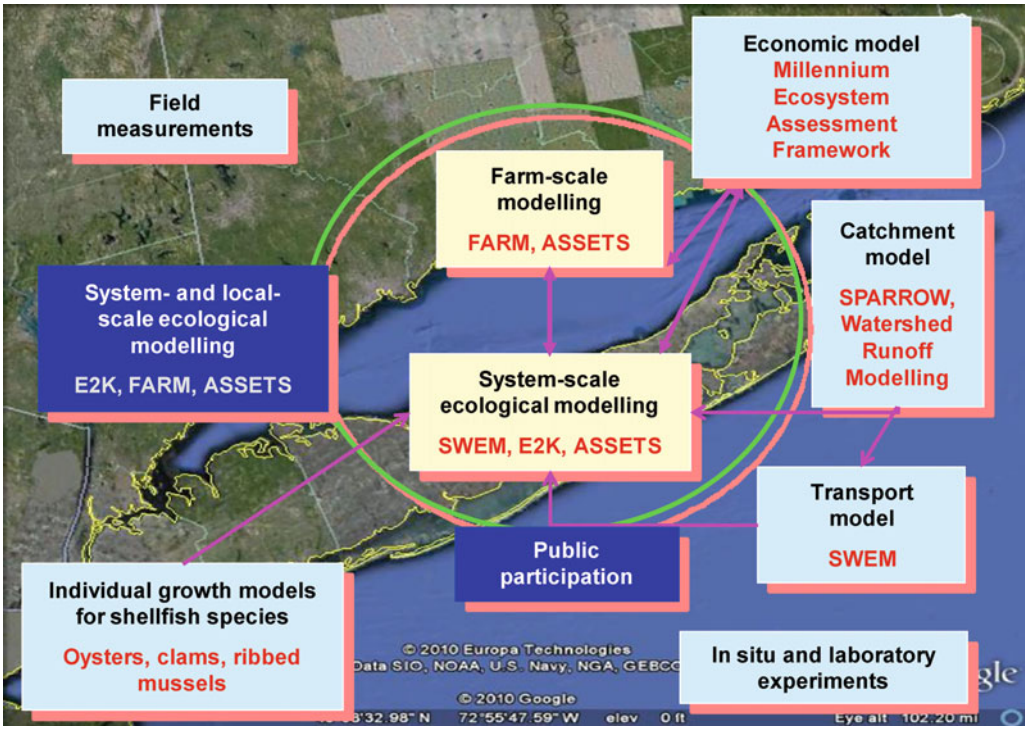
The following set of properties is desirable when assembling a modeling system to address aquaculture carrying capacity:

1. No single model solves all problems. Overparameterization and code bloat only make matters worse.
2. Models should only be as complex as the problem requires. In other words, as simple as possible. Increased computational power is no excuse for unnecessary complexity.
3. Models should be able to work independently, present value in doing so, and add further value when working in conjunction with other models.
4. Models should define exactly what problems they can address, as part of the overall questions for an ecosystem, rather than the opposite.
5. Any model in the system must be able to receive input from data or from other models and be able to supply outputs in a form that can be easily used by other models.
6. Different models are appropriate for different scales in space and time. Carrying capacity assessment may require scales as short as a tidal cycle (e.g., for intertidal culture of clams) and as long as a decade (e.g., for coupling ecological models with economic models).
7. Models share a challenge with field sampling with respect to the conversion of data (measured or modeled) into information that is useful for managers; the use of screening models, or other approaches that help to distil data into meaningful information, is a vital component of any system.

Figure 15 shows an example of such a multi-model framework for investigating the role of bioextraction by oysters, clams, and ribbed mussels as part of a nutrient control strategy for Long Island Sound. The various models chosen conform to the seven properties described above.

Previous applications of this kind of framework include the SMILE project in Northern Ireland [19] and the SPEAR project in China ([69], Nobre et al. [11]).

A different kind of multi-model framework has been developed by Kapetsky et al. [70], through the application of various types of remotely sensed data in a GIS system, incorporating variables such as sea surface temperature, current speed, and chlorophyll *a*. In the example shown in Fig. 16, current speeds of 0.1–1 m s^{-1} are combined with suitable depth ranges for fish cages and shellfish longlines. High current speeds are problematic for both culture structures, due to excessive hydrodynamism, and finfish production, due to higher metabolic costs and lower yields; very low current speeds may cause sediment organic enrichment and quality loss for certain species.



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 15
Modeling framework: the REServ shellfish bioextraction project, Long Island Sound, USA (NOAA/EPA REServ Project)

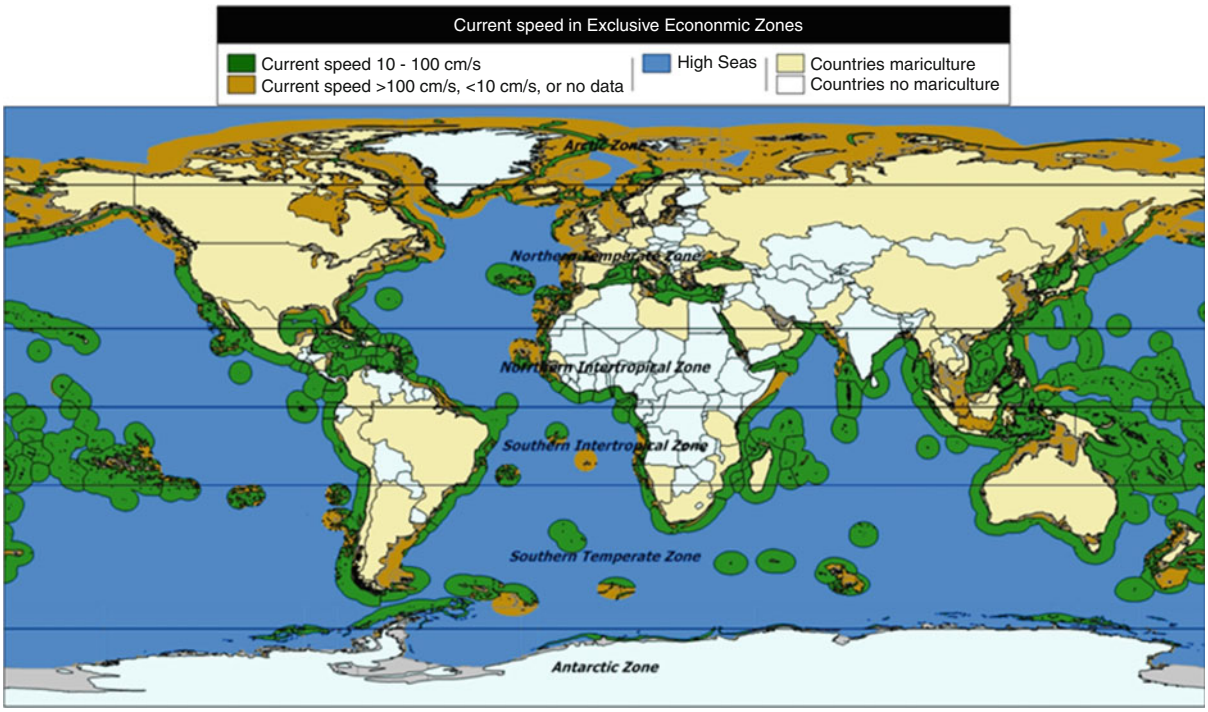
Quantification of suitable areas indicates that 123 countries have at least 100 km^2 within their exclusive economic zone that meet these criteria.

For an annual production of 1 kg m^{-2} $year^{-1}$, this corresponds to 10^7 t $year^{-1}$ of aquatic products. This analysis has been further refined by considering distance to port, a key economic consideration for offshore aquaculture, which will considerably reduce this estimate. The same applies to other factors, such as marine protected areas. An assessment of spatial potential (a component of *production* carrying capacity) was executed at a finer scale for selected areas in Canada, Chile, Ireland, and Norway (Fig. 17). For a number of specific locations (farms) in these four countries, the time required for growing an adult salmon was then determined using a dynamic model [71], forced by remotely sensed sea surface temperature. In this case, the model end point was a particular fish biomass, rather than a specific cultivation period.

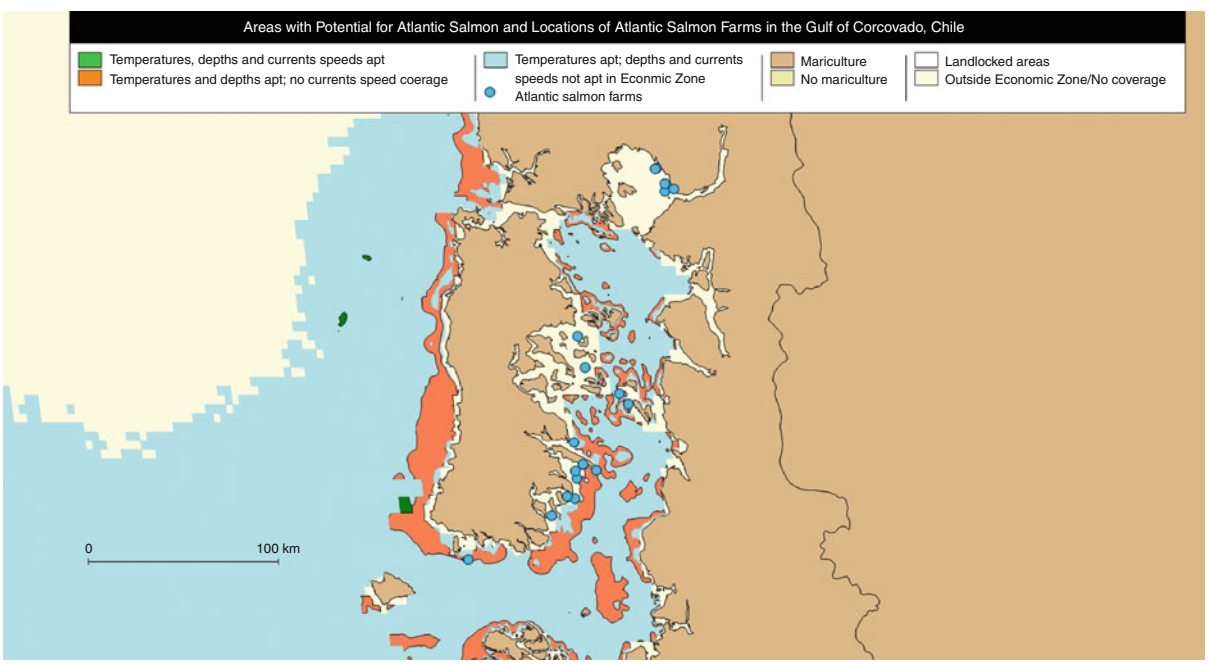
It is easy to see how this kind of coupling can be leveraged, for example, by introducing the effect of current speeds on metabolic requirements, using economic models to analyze the trade-offs between biomass and market price (lower yield, higher product quality), and using models such as FARM to quantify environmental effects, considering factors such as current speed and depth of site, both of which are readily available.

It is clear from this discussion that different modeling products and services are required for different markets. Water managers or planners may for instance be concerned with bay-scale carrying capacity, taking into account the multi-sectorial context of aquaculture, i.e., integrating ecological models with marine spatial planning. Those types of models will help inform decisions on the conservation of wild populations and biodiversity and also provide support for licensing, legislative compliance, and source apportionment for managing pressures.

On the other hand, a farmer will probably be more focused on optimization of production, improvement of feed conversion ratios, and business profits.



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 16
World ocean areas suitable for offshore aquaculture (From [70])



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 17
Areas in Chiloé Island, Chile, with temperature apt for Atlantic salmon mariculture (22–32°C) and depths (25–100 m) and current speeds (10–100 cm/s) apt for submerged cages (From [70])

But increasingly, the environmental footprint of the farm, together with potential positive impacts, such as the role of shellfish in reducing eutrophication symptoms, will be of interest. In the European Union, with legislative requirements for Good Ecological Status by 2015 in all EU water bodies and Good Environmental Status in all marine waters by 2020, some of the modeling approaches and tools described above will undoubtedly be in demand to perform self-assessments and to resolve conflicts.

As models of disease risks evolve, and become better integrated with other types of models, these too will be in demand for siting decisions.

Some of these models will be products, some will be services, and some will be a combination of both. The ways in which those markets develop and the future directions in which the science and technology may evolve will be discussed in the final section of this entry.

Future Directions

Support for an Ecosystem Approach to Aquaculture

Application of the EAA on a worldwide scale requires the harmonization of (1) environmental, (2) social, and (3) multi-sectorial planning objectives [8]. These three principles and their relative weights differ substantially across world regions, and it is not feasible from a social and political standpoint to establish uniform compliance with respect to limits and thresholds.

The only solution is to define appropriate approaches, which within particular world regions define a gradient in relative terms, assessing EAA in terms of the principles stated above. The three principles of EAA can be mapped onto the four pillars of carrying capacity and illustrated as the overlap of these [16]. The importance of each theme represented will vary regionally and will evolve through time based on societal cues.

It is clear that aquaculture in Europe and North America is more closely aligned with EAA, and the present effort in marine spatial planning will only reinforce that. It is also clear that aquaculture production in developed countries will grow little, and that consumer demand in these regions is satisfied in large part through imports (Fig. 18).

In the United States, 84% of aquatic products are presently imported, of which 50% are from aquaculture. This has resulted in a nine-billion-USD seafood trade deficit [82]. Table 2 presents a summary of the main issues that are presently considered in aquaculture carrying capacity and site selection, together with what may constitute future components for assessment. Models play a key role.

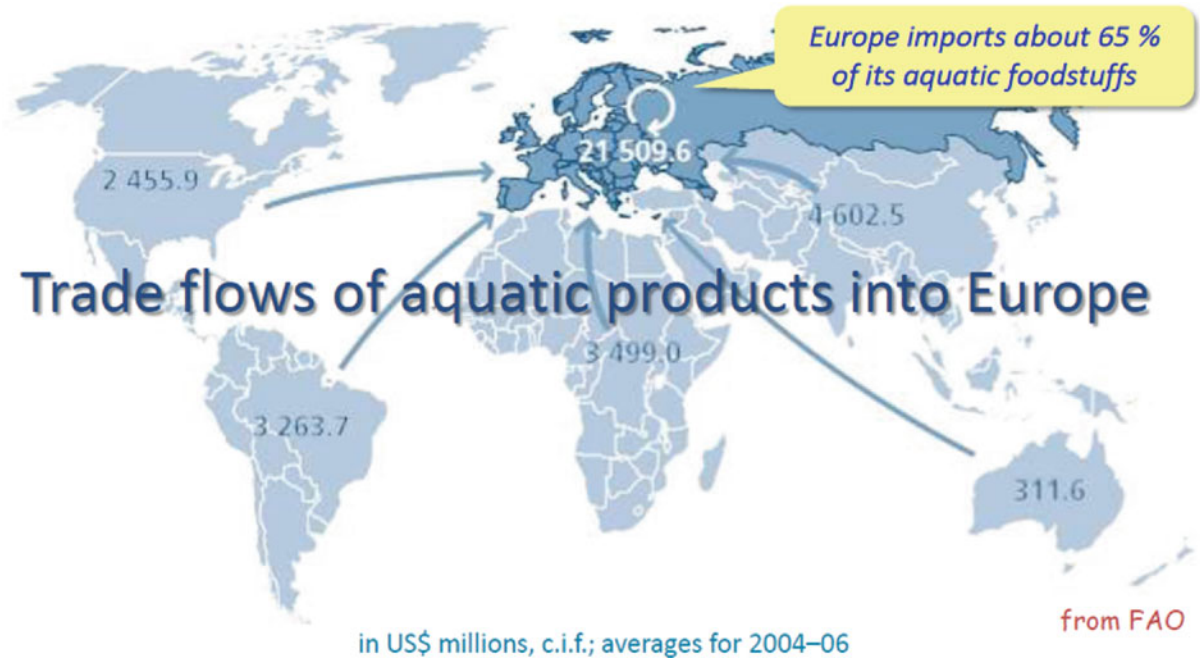
Since developing nations supply the bulk of farmed aquatic products, will continue to do so, and will probably increase their contribution, it is critical that state-of-the-art tools are available to ensure sustainability in the countries where they are most needed.

Which developing countries and which types of culture should be priorities for the application of such models? From an EAA perspective, those that have the highest impact on the environment are the most promising candidates. Kapetsky et al. [73] used FAO production statistics at country environment level (freshwater, brackish water and marine) to estimate the intensity at which aquaculture was practised in each of those environments. A knowledge of the species being cultured can reveal the production systems and their associated impacts in a very general way. The approach outlined above can be refined to focus more closely on modeling needs by considering the potential impacts by species and culture systems in countries in which production data by species are reported.

Dissemination of models can be passive (e.g., packages freely accessible via the Internet) or active (training courses and workshops by region or by country). In both cases, it is essential to establish the technical capacity, level of interest, and financial commitment of the audience and the status of the Internet as a communications and data pipeline for technical support in each country. The focus should not be on developing countries alone because (1) virtual technology specialists in developed countries may be in a position to aid dissemination and (2) companies established in developed countries often have aquaculture operations in developing countries, and could therefore also help to bridge the gap.

Looking into the Crystal Ball

The Thematic Review "Virtual Tools for Aquaculture," presented at the FAO Global Aquaculture Conference



Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 18
Trade flows of aquatic products into Europe [72]

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Table 2 Novel management approaches (Adapted from [10])

Topic	Now	Tomorrow
Feed based (cage, pond)	Site selection based on holding capacity (cages), wastewater minimization (ponds)	Integrated model systems, risks, welfare, and disease. Holistic indicators
		LCA: inefficiencies and eco-labeling
		Mechanistic and statistical models
		Data assimilation models
Shellfish farming	Large areas	Economic sustainability, ecology and economics, disease
	Focus on production and social carrying capacity NIMBY, (Not in my backyard) NIMTO (Not in my term in office)	Coupled GIS expert systems including xenobiotics, HAB, etc.
		Model uncertainties in yield
		Early warning
Integrated multi-trophic aquaculture	Optimize production	Integrated coastal zone management
	Reduce negative externalities	Simulate species combinations
		Full economic assessment
		Combine GIS, remote sensing, and modeling

in 2010 [10], encapsulates much of our thought on the future of models in aquaculture. The final points in this entry are drawn from that review.

The aquaculture industry is going to be affected by many different issues and trends over the coming years, often operating concurrently, sometimes in unexpected ways, and producing changes in the industry that may be very rapid indeed. Mathematical models will play an important role in addressing many of these, particularly in the following areas:

1. Information exchange and networking are going to accelerate the use of virtual technology and decision-making for problem solving to support industry growth. Web-based access to real-time information will further accelerate this growth.
2. Links between industry and research centers will become more effective responding to objective-led demand for virtual technology-driven RTD.
3. Strategic alliances will need to be reinforced or created for the implementation of virtual technology for aquaculture in developing countries, for example, FAO and WorldFish Center are working in many of the same target countries, and this could facilitate the transfer of research outcomes on virtual technology to end users. The same applies to collaborative research with third countries mediated, for example, by the European Union, the United States of America, and Canada.
4. Many virtual technology tools will need to be more production and management oriented. And even if attractive and promising, these tools will have to be adapted to local realities and conditions to really become useful (and used) in the future. This requires a compromise with respect to ease of use, data requirements, and scientific complexity. Many such tools will evolve from service to product, requiring academic developers to accept a loss of control in conditions of application, as a natural trade-off (and inherent risk) of product maturity.

A number of key thematic and technical areas where models for aquaculture are currently incipient, and expected to develop strongly in the next decade or so, have been identified below. In all the examples, such models will contribute to an overall modeling framework, by integrating and complementing existing tools.

Disease Disease in cultivated aquatic species is a major source of concern, yet disease modeling is still relatively underutilized in these systems though its worth has clearly been demonstrated in several studies. However, while epidemiological theory predicts that host density thresholds may be an important part of host–parasite dynamics, clear empirical examples are rare, as much in aquaculture as in other studied agricultural systems. It is suggested that this is not evidence that host thresholds do not exist, rather that statistical difficulties arise with confounding factors or inadequate data. Evidence here is afforded from much better-understood and more data-rich systems, for example, human measles [95–97], where there is compelling evidence on the effects of host density on the likelihood of disease outbreaks taking place within populations.

One of the major limitations in aquatic systems, however, is that the routes by which pathogens are transmitted and their relative contributions to an epidemic are often not understood. If transmission is incorrectly specified, there can be substantial consequences to estimates of N_T. Additional experimental and field data are required to identify and quantify transmission routes for many aquatic animal pathogens, if prediction of the effects of host density on disease incidence is to be made through modeling. To facilitate this, increasing emphasis is required on the use of real-time data acquisition combined with models for real-time analysis and short-term prediction of animal welfare. It is expected that such systems will become cheaper and more generalized, and that some of the indicators and trends will find application at longer timescales, albeit by means of a probabilistic approach.

A further potential limitation of the models currently used is their inability to predict across and link scales from the processes occurring within a tank to the transmission across and then between sites. Methods of investigating disease processes through these metapopulation approaches should be investigated further.

To date, only a few models have been developed to simulate pathogenic infections of shellfish with respect to physiology, for example, Powell et al. (1996) for the American oyster *C. virginica*, but with widespread concerns about relaying, susceptibility, and mortality,

models focusing on a more mechanistic approach will undoubtedly appear over the next decade.

Harmful Algal Blooms This is another area where little predictive capacity exists, except in the short term through the use of operational oceanography, relying on bloom identification and tracking. Management is at present reactive, and modeling of appearance and development of such blooms is in its infancy, due to the lack of an appropriate paradigm. Sensors such as targeted RNA probes (e.g., [74]), integrating handheld devices, or potentially deployed in situ and used in a networked framework will both help in early detection and management and contribute to the understanding of the underlying triggers. Considerable developments are also expected in remote sensing algorithms able to discriminate (at least) between HAB and nontoxic blooms (S. Bernard, personal communication, 2010).

Certification and Traceability The arrays of sensors that can be deployed at the farm scale to enable coupled monitoring and modeling are important for both product certification and traceability. The number, reliability, and accuracy of underwater sensors will increase, and the cost will decrease, both with technological developments and market growth.

Real-time data acquisition and interpretation will make it possible for consumers to visualize the whole "cradle to grave" cycle of an aquaculture product. For instance, a batch of oysters may be "bar coded" to reveal the origin of seed and the entire environmental interaction over the culture period, including metadata and measured data on water quality, HAB events, condition (meat ratio) of the animals, and impact on their environment, for example, in terms of reduction of eutrophication symptoms through the indirect removal of nitrogen and phosphorus, or conversely the addition of particulate organic material due to biodeposition. Such sensors will typically be queried at a sub-hourly frequency, particularly if they are also used for welfare monitoring; this will easily allow importers, health inspectors, or consumers to perform verification and certification, and will provide an important contribution to both food safety and environmental awareness.

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 19
QR code for farmed shellfish, readable on any smart phone

For the farmer, the existence of this kind of integrated coding will also help improve various aspects of culture practice and increase attractiveness of the business model to the key sector of insurance. For the consumer, such data will need to be presented in a comprehensible format, for example, in the form of a few indicators (Fig. 19).

Modeling with Data Scarcity Good data are required to support acceptable model predictions. The acquisition of high-quality data, with appropriate spatial and temporal resolution, is expensive and often beyond the scope of developing countries, except on a fairly limited scale. This, together with an often fragmented approach to the study of interacting ecosystems, in many cases driven by institutional barriers, presents a challenge to the application of models.

Improved mechanisms for data access, particularly for remotely sensed data, together with models that deal with uncertainty and risk, will contribute to conversion of sparse data into more meaningful information – although such an approach may be considered unsuitable in parts of the developed world, in many countries it will be a much better basis for decisions

than the options that are presently used. In addition, it will promote a "virtuous cycle" toward more informed decision support and promote the use of better data and more sophisticated models, as the data become available to drive them.

A wide variety of models will benefit from this development because many models developed and tested for temperate systems need adjustment with respect to parameters, thresholds, and equations, when applied to tropical and subtropical systems.

Information Technology The last 5 years have seen a huge leap in various areas of distributed computing, all of which are expected to develop significantly in the coming years.

Three examples are presented here:

1. Web 2.0 now provides a large diversity of community- and corporation-based resources. Currently, over 7,000 items exist for aquaculture on YouTube – at the time of presentation of the VITAL Thematic Review [10] there were 1,800. For aquaculture modeling, that number has also quadrupled since 2010 and now stands at 75.
2. There is a strong trend toward the development and use of *Software as a Service* (SAAS), deployed on the web and competing with traditional desktop applications. This is incipient in the aquaculture world but can be seen, for example, in the WinShell application (http://longline.co.uk/winshell), which allows users to simulate individual shellfish growth on line. Central to the development of this kind of application are Rich Internet Applications (RIA), which provide a full user experience and are an area of rapid growth [75]
3. Mobile computing is increasingly ubiquitous, and it is now possible to use models on many handheld devices, as illustrated in Fig. 20, which shows a tide prediction model for Mumbai, India. This kind of model might be used to help predict the yield in intertidal culture of bivalve shellfish.

The trend toward the increasing use of such devices, including for various real-time applications in aquaculture management, will increase. In parallel, the stand-alone server is rapidly being replaced by cloud computing, which will tend to make the circulation of data both easier and cheaper. Both elements will contribute to bridge the information divide between richer and poorer nations.

Computer access, literacy, and internet connectivity are significant barriers to entry for the population in the rural areas in developing countries, where aquaculture takes place. Over the coming decade, many aquaculture farmers will have their first contact with the World Wide Web by means of smart phones.

Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of. Figure 20
Tidal prediction for the port of Mumbai using the Oceanus21 smart phone app (http://longline.co.uk/oceanus21). Ports can be automatically selected based on GPS coordinates and phone location

Cell phones are ubiquitous even in remote areas and are much better adapted to local language and alphabet, which constitute other barriers in accessing technology.

The future of aquaculture is promising. It needs to be, given the world population growth expected in the next decades. Simulation models, particularly when used within appropriate frameworks, show enormous potential to inform and guide the future development of aquaculture, toward a world which is more socially responsible, more equitable, and more sustainable.

Acknowledgments

We are grateful to the EU FP7 COEXIST project, and to FAO, for the opportunity to develop many of the ideas presented here. We would like to thank B. Costa-Pierce for the opportunity to contribute to this volume, all our coauthors in the Virtual Tools for Aquaculture FAO report presented at the FAO Global Aquaculture Conference 2010, E.S. Braga and S. Eschrique for data on the Jaguaribe estuary, Ceará, Brazil, and S.B. Bricker and L. Ramos for comments on the draft. We thank H. Mildmay-White for design work on figures.

Carrying Capacity for Sustainable Bivalve Aquaculture

Christopher W. McKindsey
Ocean and Environmental Sciences Division, Fisheries and Oceans Canada, Institut Maurice-Lamontagne Fisheries and Oceans Canada, Mont-Joli, Québec, Canada

Article Outline

Glossary

Benthic Pertaining to the sea floor.

Carrying capacity The intensity of a practice that a given environment can sustain indefinitely given the availability of various necessities in that environment and the various pressures on them.

Ecosystem approach to aquaculture (EAA) A strategy to integrate aquaculture into context of the wider ecosystem such that it promotes sustainable development, equity, and resilience of interlinked social and ecological systems.

Ecosystem-based management (EBM) A process that highlights the need to use the best available knowledge about the marine ecosystem to manage marine resources, with an emphasis on maintaining ecosystem service functions.

Integrated coastal zone management (ICZM) A process for managing coastal zones that uses an integrated approach and considers all aspects of the coastal zones, including biological, geographical, and political boundaries, to achieve sustainability.

Model A simplified description, conceptual or mathematical, of a system or process, to assist in calculations, predictions, and understanding.

Pelagic Pertaining to the water column.

Definition of the Subject

Bivalve aquaculture is one of the fastest growing sectors of the food industry, raising concerns about the influence of the activity on the environment. This is true at two levels: First, farmers must make sure that the bivalves that they raise do not deplete resources in a given area to such an extent that bivalve production is decreased. Second, society in general wishes that such activities have an acceptable impact on the environment and are sustainable. There is also intense competition for space and its use in many coastal zones, making siting of many farms contentious. Thus, many organizations have stressed the importance of determining the carrying capacity of different areas for bivalve culture. There are a number of ways that "carrying capacity" may be defined, including physical, production, ecological, and social, and the first three categories are to lesser or greater degrees related to social expectations and standards. A number of methods have been developed to calculate these different categories of carrying capacity for bivalve culture. This entry outlines some advances to estimate the different categories of carrying capacity and suggests a framework that may be followed to encourage the development of a sustainable bivalve aquaculture industry. An emphasis is placed on the latter two categories as these are the ones for which knowledge is the most lacking, are arguably the most complex, and for which advances are the most pressing.

Introduction

Aquaculture is the fastest growing sector of the food industry. Since the 1970s, production in the sector has increased at a rate of about 7% per year and by 2008 accounted for 43% of the total annual fisheries production of 160 million tons and projections by the UN [1] suggest that this production will increase greatly in the future. This increase in production has raised concerns about the impacts of the activity on local environments, (e.g., [2]) and much work has been focused on understanding the interactions between aquaculture and the ecosystem, (e.g., [3, 4]). Although concerns were initially largely directed at the influence of finfish cage culture on the environment (e.g., nutrient

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

loading, disease issues, and interactions due to escapes), concerns have also been raised about the influence of farmed bivalves.

As for aquaculture in general, production of farmed bivalves has increased greatly over the past few years and as of 2008, 11.7 million tons of the total 13.5 million tons of worldwide bivalve captures was from aquaculture production. This includes the culture of over 4 million tons each of clams and oysters and about 1.5 million tons each of scallops and mussels. The greatest concerns relating to farmed bivalves include enhanced localized biodeposition [5], food depletion in the water column due to bivalve grazing [6], alteration of nutrient and oxygen fluxes [7], and the transfer of disease and hitchhiking species [8]. Recent reviews on the environmental interactions associated with bivalve culture have been done for oysters [9], clams [10], and mussels [11].

Increasingly, regulators and other groups are looking to science to determine whether sites have reached their carrying capacity for bivalve culture. Moreover, a number of standards – performance standards, best management practices, certification standards, etc. – have been or are being developed to ensure that bivalve production is being done in a manner that is consistent with a global environmental ethic [12–14]. Some of these codes have been developed by industry groups and are voluntary in nature, some have been developed and are used by public authorities and regulatory agencies, and others are being developed by a variety of organizations (e.g., buyers, nongovernmental organizations, marketing groups) as a means of informing consumers about a product with the goal of influencing farm practices through consumer choice and market forces [15]. In all cases, the idea is that such criteria will encourage the development of a sustainable bivalve aquaculture industry such that the carrying capacity of a given area has not been exceeded and impacts are minimized. Recently, the National Research Council [15] suggested that performance standards based on the carrying capacity of sites be developed and implemented at the ecosystem level. Similarly, the FAO [16] has suggested that an Ecosystem Approach to Aquaculture (EAA) be followed to ensure the "integration of the activity within the wider ecosystem in such a way that it promotes sustainable development, equity, and resilience of interlinked social and ecological systems." Many advances have been made in the estimation of carrying capacity for bivalve culture over the past few years. The broad aim of this entry is thus to update an earlier paper on the subject [17] and to discuss a number of ideas that have been developed in the interim. It focuses on the outgrowing stage of bivalve culture as this stage is arguably the most important in terms of its interactions with the environment. Many other activities related to bivalve culture exist (see list below) and these are discussed by McKindsey et al. [17].

Abbreviated selection of activities related to bivalve culture that may influence the ecological carrying capacity of coastal areas. (Modified from McKindsey et al. [17].)

1. Seed collection
   - (a) Dredging
     - (i) Disturbance of benthic communities, especially the removal of long-living species
     - (ii) Removal of juveniles from wild populations of target species
     - (iii) Collection of non-target species
     - (iv) Suspension of sediments
     - (v) Depletion of food resources for other species
     - (vi) Release of H_2S and reduction of dissolved oxygen in the water due to oxygen-consuming substances, release of nutrients
   - (b) Artificial collectors
     - (i) Removal of juveniles from wild population of target species
     - (ii) Increasing target and non-target species recruitment success
     - (iii) Alteration of the hydrodynamic regimes
     - (iv) Acting as FAD
     - (v) Risk of entanglement for large vertebrates (e.g., marine mammals, sea birds, turtles, sharks)
     - (vi) Foci for nuisance species
   - (c) Hatcheries
     - (i) Chemical pollution (e.g., pharmaceuticals)
     - (ii) Genetic selection
     - (iii) Spread of diseases

(d) Importation
  (i) Introduction of alien species
  (ii) Genetic pollution
  (iii) Spread of diseases
2. Ongrowing
  (a) Effects common to all techniques
    (i) Organic enrichment of seafloor
    (ii) Providing reef-like structures
    (iii) Alteration of hydrodynamic regime (current speed, turbulence)
    (iv) Food web effects: competition with other filter feeders, increasing recycling speed of nutrients, removal of eggs and larvae of fish and benthic organisms
    (v) Spawning: release of mussel larvae
    (vi) Providing food for predators of bivalves
    (vii) Control of predators and pests
  (b) Bottom culture
    (i) Activities to prepare the culture plots, e.g., dredging for predator removal
    (ii) Placement of protective structures (netting, pipes)
    (iii) Removal of associated organisms by dredging and relaying
    (iv) Competition for space with wild benthos organisms
  (c) Artificial structures for suspended and off-bottom culture (trestles, poles, rafts, longlines)
    (i) Acting as artificial reef or FAD (attraction/displacement or enhancement of animals)
    (ii) Risk of entanglement for large vertebrates (e.g., marine mammals, sea birds, turtles, sharks)
    (iii) Foci for nuisance species
3. Harvesting
  (a) Effects common to all techniques
    (i) Removal of biomass, nutrients
    (ii) Removal of filtration capacity
    (iii) Removal of non-target species
    (iv) Competition with predators
  (b) Dredging
    (i) Disturbance of benthic communities, especially removal of long-living species
    (ii) Suspension of sediments
    (iii) Release of H_2S and decrease of dissolved oxygen in the water due to oxygen-consuming substances, release of nutrients
  (c) Collection of off-bottom structures
4. Processing
  (a) Dumping of by-catch
  (b) Relaying near auction houses
  (c) Depurating
  (d) Dumping of shells
  (e) Effluents from processing plant
  (f) Spread of alien species or diseases

As a first step, it is important to understand what is meant by "carrying capacity." A number of definitions have been suggested that consider a variety of physical, biological, and social criteria. In this entry, the four functional categories of "carrying capacity" as outlined by Inglis et al. [18] and McKindsey et al. [17] are used:

1. *Physical carrying capacity* – the total area of marine farms that can be accommodated in the available physical space.
2. *Production carrying capacity* – the stocking density of bivalves at which harvests are maximized.
3. *Ecological carrying capacity* – the stocking or farm density above which unacceptable ecological impacts become apparent.
4. *Social carrying capacity* – the level of farm development above which unacceptable social impacts are manifested.

The specific aims of this entry are to (1) provide an overview and update of different categories of carrying capacity, (2) give a more in-depth review of factors that could be considered for the determination of *ecological* and *social carrying capacity* as these categories are the least developed conceptually and in terms of modeling, (3) outline a decision framework for incorporating all four categories of bivalve carrying capacity into the determination of the overall carrying capacity of a given area for bivalve culture, and (4) outline research to address knowledge gaps for carrying capacity studies.

Functional Categories of "Carrying Capacity"

Physical Carrying Capacity

The physical carrying capacity of a site (embayment, inlet, offshore area, etc.) is simply the geographic area

in which conditions are suitable for the production of a given species using a given method. It is a function of the overlap of the requirements of the species being harvested and the physical resources (e.g., depth, substrate type, salinity, hydrodynamics) in the site. The physical carrying capacity of a site may differ greatly between species and culture methods being employed. For example, an embayment may have an extensive area that is suitable for on-bottom clam culture but relatively little area that is appropriate for suspended oyster culture. Likewise, modification of an area (e.g., by the addition of a species-specific appropriate substrate) may extend the physical carrying capacity of an area.

Traditionally, the physical carrying capacity of sites was determined by building knowledge of an area using hydrographic charts as the base layer, adding other appropriate layers (e.g., temperature and salinity) as available, and analyzing the layers using formal or *ad hoc* Geographic Information Systems (GIS), (e.g., [19, 20]). With the expansion of culture sites in more remote regions where such information may not be readily available, the use of remote sensing methods to estimate various physical parameters (e.g., depth, salinity, temperature, as well as chlorophyll levels and related biological parameters that are needed to estimate production carrying capacity – see further) may be used in combination with GIS to facilitate site selection [21]. Although more of a social factor (see further), an additional advantage of using GIS for aquaculture site selection is that it can be used within a coastal management framework to include other activities so as to avoid user conflicts [22, 23].

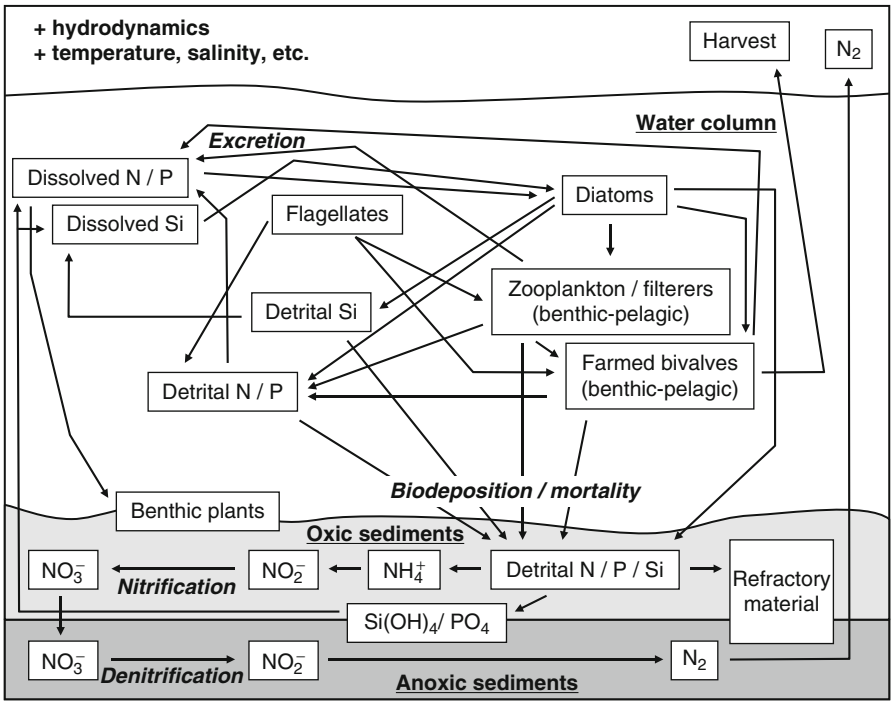
Production Carrying Capacity

The production carrying capacity of a site is the stocking density at which harvests are maximized. Given that trade-offs between bivalve growth rates, market tastes, and economic returns, etc., would likely encourage selection of a specific bivalve size and type (see further), production carrying capacity is often not necessarily the greatest biomass. This category of carrying capacity is what most people think about when they consider "carrying capacity" and is the best studied. The production carrying capacity of a given site is strongly related to hydrodynamic and food regimes and its physical carrying capacity. Indeed, various "habitat suitability models" have been developed that combine both categories of data to predict the best areas for bivalve production, (e.g., [24]). Models to predict production carrying capacity have three main components: (1) a hydrodynamic model that transports food, nutrients, and other wastes; (2) a biogeochemical component that describes processes that influence food production and consumption; and (3) a physiological component that determines the rate of food consumption and growth of the farmed bivalves [25].

Bivalve culture systems are hierarchical, with individual bivalves and their associated fouling organisms nested within culture units (socks, cages and stacks of cages, pearl nets and strings of pearl nets, etc.), these being nested within culture gear (longlines or rafts), which are nested within farms, and so on [26–28]. An understanding of processes operating at each scale as well as the relations between these scales is needed to predict hydrodynamics and how this influences biogeochemical and physiological processes within culture systems and to understand cascading effects on the greater ecosystem.

In its simplest form, the production carrying capacity of a given location is a function of the available food resources and the rate at which they are renewed via in situ production and/or flushing relative to their rate of removal (filtration) by the farmed bivalves. This type of approach has been developed for mussel culture in eastern Canada [29]. However, such models commonly under- or overestimate flushing and a number of authors have suggested that their use be avoided for production carrying capacity studies, (e.g., [30]). Despite this, a number of groups have advocated calculating the ratio of clearance time by farmed bivalves to flushing rate or water residence times (as calculated by such methods) to evaluate the sustainability of sites for bivalve culture [31] and as a rough first step in evaluating whether carrying capacity is potentially exceeded for ecological certification standards [32]. In the latter case, if the ratio between clearance and renewal times is less than unity, then further analyses based on primary productivity are required.

More encompassing approaches to calculating production carrying capacity based on hydrodynamic and mathematical models that include spatially and



Carrying Capacity for Sustainable Bivalve Aquaculture. Figure 1
Conceptual diagram of bivalve aquaculture interactions in coastal ecosystems considered in production carrying capacity estimations. Only main pathways are indicated

temporally explicit feedbacks between the farmed bivalves, phytoplankton, zooplankton, detritus, and physical (e.g., temperature, nutrients, see Fig. 1) parameters are becoming the standard. Models vary greatly in complexity. Although a simple box model for a location may be sufficient for some situations, it is likely unsuitable for embayments with some degree of environmental heterogeneity [33]. The next level of complexity is a simple 1-D hydrodynamic transport model, (e.g., [34]), which may be expanded upon to include vertical transport for suspended culture, (e.g., [35]). More complex models include multiple coupled boxes within an area driven by a 2-D hydrodynamic model (with tidal and meteorological forcings). The most complex models, fully refined 3-D finite-element hydrodynamic models, generally provide a much more accurate estimation of hydrodynamics and may be used to drive the biological models. Historically, computational power has limited the broad application of complex models [36] but this is no longer the case as powerful computers are now readily available [25]. However, increased development time and sampling requirements to validate more complex models make the use of simpler box models a good approximation for understanding the hydrodynamics of an area and slow ecological processes [37] and for carrying capacity modeling [38].

Production carrying capacity models require data on biogeochemical components which include a large number of variables related to the flux of nutrients and primary production and interactions between different food sources for the farmed bivalves. This includes nutrient fluxes due to excretion by the farmed bivalves and associated organisms and organic matter in trapped sediments in culture structures [39–41], nutrient uptake by and production of phytoplankton [42–44], zooplankton and detritus components, and a benthic component that includes biological and chemical processes [45–47]. This latter submodel is of particular importance in shallow areas [33]. Figure 1 gives an example of the types of processes that are included within such models.

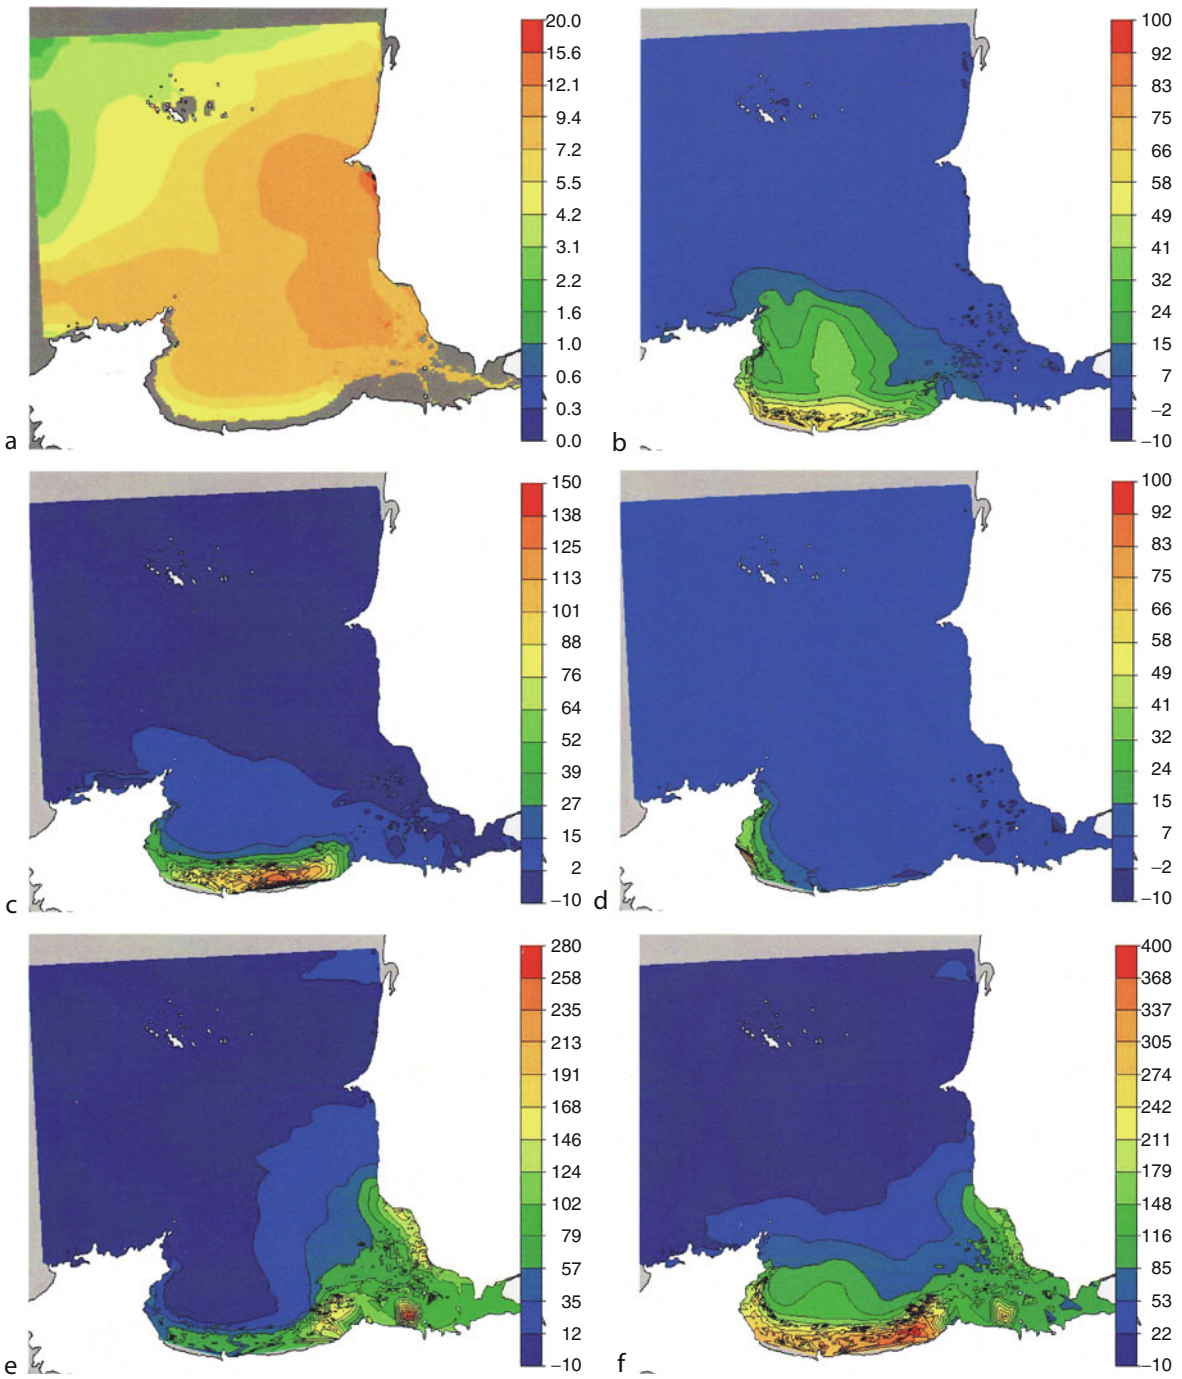
Bivalves graze on and may impact plankton and other suspended components in the water column [48]. These components and environmental factors (e.g., temperature) in turn greatly influence the growth of the farmed bivalves. Models to predict the physiological response and growth of bivalves vary greatly in their complexity. Models may be divided into statistical and more mechanistic approaches that include bioenergetics [49, 50]. Today, many studies use an approach based on dynamic energy budget (DEB) models that were developed by Kooijman, (e.g., [51–53]). In these models, energy budgets are partitioned into core processes: structural volume, reserves, and a reproductive buffer, and forced by food and physical parameters. Examples include work on a variety of bivalves, (e.g., [25, 54–56]) and have been incorporated into general models for bivalve production carrying capacity [35, 57]. A generalized set of DEB models for a few of the most commonly farmed bivalve species has been assembled and is available (http://www.shellsim.com). Production carrying capacity models based on this latter suite of components have been successfully used in a number of studies, (e.g., [35]). Although these types of models are attractive in that they include logical mechanistic processes, their complexity makes them difficult to apply at times and requires substantial ground truthing and simpler models will often yield acceptable results.

Ultimately, the different sub-models must be put together to estimate production carrying capacity. An important advance in modeling production carrying capacity is the development of Graphical User Interface (GUI) modeling environments that allow users to link different sub-models fairly easily through a visual environment rather than with text commands. An example of this is the use of object-oriented modeling environment, as promoted for the FARM model developed by Ferreira et al. [35, 57]. This model links together various components forced by a 1-D hydrodynamic model, or 1-D with horizontal mixing for off-bottom bivalve culture, to estimate production carrying capacity and eutrophication assessment (see further) at the farm-scale based on a limited number of parameters. It may also be used to guide the selection of growing sites, culture layouts, production densities, farmed species, and to maximize production or economic returns. The model has been shown to be useful in a number of locations and for a number of species [57] and is available as a client–server application (www.farmscale.org; www.longline.co.uk/winshell). Simile [58] is an object-based GUI modeling environment that has been used extensively by Grant and colleagues [25, 33, 38, 54, 59]. This environment is well suited to constructing carrying capacity models for bivalve culture because of its inherent ability to represent spatial elements and specify hydrodynamic connections between them and, because of its GUI environment, it is transferable to nonexperts [38].

Models for production carrying capacity usually consider only the farmed bivalves as consumers of plankton. However, in some situations, particularly shallow sites with large densities of natural bivalves, grazing by natural bivalves may also exert a large pressure on plankton communities [60–62]. Thus Sequeira et al. [63] have recently developed a model that includes natural benthic communities as a forcing function on plankton communities and suggest that these populations may significantly reduce production carrying capacity. Similarly, Cugier et al. [64] found that wild native and exotic filter-feeding organism had a greater effect on the control of primary productivity than did the farmed bivalves in Mont Saint Michel Bay, France (Fig. 2). The biomass of filter-feeding fouling organisms, particularly tunicates, on farmed bivalves and infrastructure may be considerable, at times greater than that of the farmed bivalves [65]. Given that they may have similar grazing rates to that of farmed bivalves [66], these should be included within production carrying capacity models where fouling is great. This has been attempted for the Thau Lagoon [67] and the Oosterschelde Estuary [68].

Ecological Carrying Capacity

The definition the "ecological carrying capacity" of a system is greatly dependent on social values as what is considered to be an "unacceptable" impact is dependent on the values of a given society. A society or their representatives must select which components (e.g., species or habitats) of a given area are important and set acceptable limits of change for each. Often, information on specific parameters may not be available and managers may choose to consider components



Carrying Capacity for Sustainable Bivalve Aquaculture. Figure 2

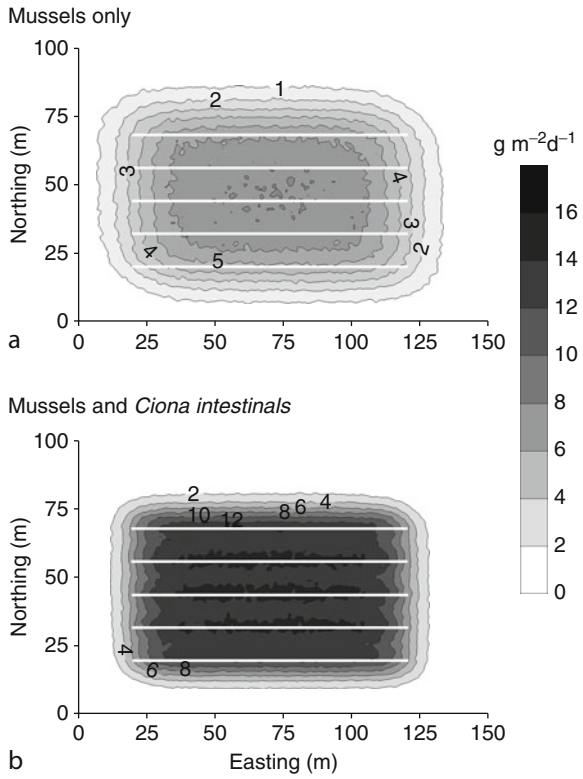
Simulated annual maximum chlorophyll a for the reference case (A – current situation with all filter feeders included) and differences with the reference case (in%) for five scenarios of with different filter feeders removed, (B – without exotic slipper-limpets, C – without farmed mussels, D – without farmed oysters, E – without native filter feeders, F – with no filter feeders in the bay). Because of the wide range of differences between the scenarios, the scale bar is not the same for each sub-figure (From Cugier et al. [64])

for which information is available or more easily obtained. As pointed out by McKindsey et al. [17], this may be a logical choice given that components that have a high societal value are also likely to have been studied.

While production carrying capacity focuses on the farmed bivalves themselves and the organisms that support their production, ecological carrying capacity also includes other organisms and habitats in the ecosystem. There are three main categories of ecological carrying capacity: (1) that related to the pelagic habitat; (2) that related to the benthic habitat; and (3) that which employs ecosystem function approaches. The first category is largely related to plankton depletion due to grazing by farmed bivalves. The second category is related to increased sedimentation within culture sites due to biodeposition by the farmed bivalves. The third category considers both these issues and changes in biomass and energy flow in a system. Ecological carrying capacity is strongly related to both the physical carrying capacity and the production carrying capacity of a site, particularly with respect to that related to the pelagic habitat.

Models to estimate the production carrying capacity of a site contribute to determining the ecological carrying capacity of a site for organisms that are dependent on the delivery of food from the water column. Presumably, if the farmed filter-feeding bivalves impact themselves by overgrazing the available resources, then they are also likely impacting other organisms that feed in a similar manner [69]. Indeed, some recent production carrying capacity models explicitly included benthic filter-feeding organisms [63, 64] and some work has suggested that overgrazing by farmed bivalves may impact other suspension feeders in the surrounding ecosystem [70]. The calculation of carrying capacity for other planktivores in the water column may be similarly evaluated. Sedimentation rates to the bottom are a function of the plankton communities in an area (e.g., [71]). Thus, as has been shown for natural systems with bivalves [72, 73], depletion of the water column via grazing by farmed bivalves may influence sedimentation rates within a given area and thereby benthic communities, potentially enhancing differences between benthic communities within and outside of culture sites [11].

With respect to the benthic habitat, research has largely focused on the impact of increased sedimentation due to biodeposit production by farmed bivalves on infaunal communities [9–11]. Research on the ecological carrying capacity of benthic habitats has likewise been focused on predicting how increased sedimentation due to biodeposit production by farmed bivalves influences infaunal communities. Grant et al. [74] predicted benthic loading rates from biodeposits from farmed mussels (*Mytilus edulis*) at a bay scale as a balance between biodeposit production, as calculated using a simple physiological model, and flushing, as calculated based on a simple tidal prism model (validated using a finite-element 2-D hydrodynamic model and field work). Although there was some variation between modeled and observed biodeposition for both studied bays, the authors suggest that the approach is valuable as a screening tool to develop relative ranking of different systems and identify potential issues. A number of approaches have also been evaluated that couple spatially explicit hydrodynamic-dependent particle tracking models to predict flux of biodeposits from farmed bivalves to the bottom to predict benthic loading footprints and associated benthic community changes. A simple approach is to modify the existing DEPOMOD model, which was developed to this end for finfish cage culture but for which individual bivalve culture structures (e.g., mussel longlines, see Fig. 3) or groups of structures in a system may be modeled [75]. However, this approach has a number of limitations. First, the model assumes a homogenous flow field, an assumption that is unlikely to be true for extensive culture sites. Second, the module for resuspension of sedimented biodeposits is not fully developed and remains one of the greatest sources of uncertainty for biodeposition/impact models [74]. Although resuspension may be negligible in areas with weak currents [75], Giles [76] used a more advanced hydrodynamic model to drive a biodeposit dispersion model and stressed the importance of this aspect for predicting the dispersal of biodeposits in areas with strong currents. A number of recent studies have started to address this issue and supply data to better parameterize this module, (e.g., [75, 77, 78]). Although general relationships exist for benthic organic loading and infaunal community structure [79], predictive dose-dependent relationships between organic loading from bivalve biodeposits and faunal responses are



Carrying Capacity for Sustainable Bivalve Aquaculture. Figure 3

Modeled biodeposition footprint (g m^{-2} d^{-1}) within an idealized suspended mussel farm with (**a**) mussels only and (**b**) mussels fouled with *Ciona intestinalis*. Biodeposition rates were modeled for five backlines (white lines in figure) measuring 100 m each based on currents measured during a 24 h period in St. Marys Bay, eastern Canada (Modified from McKindsey et al. [65])

largely lacking, making predictions difficult [80]. Similarly, there is no universal metric available to describe benthic responses although a large number of indices have been developed, some showing good relationships with aquaculture [81]. As noted above, the biomass of tunicates and other fouling organisms on farmed bivalves and infrastructure may be considerable, and these likely contribute greatly to organic loading to the sea bottom in some cases [65, see Fig. 3] and thus must be considered when determining the biodeposition-related ecological carrying capacity of an area for the benthic habitat.

Tenore et al. [82] used a mass-balance approach to examine the influence of bivalve culture as a part of a coastal ecosystem but specifically to predict ecological carrying capacity. Gibbs [83] used food web analysis to estimate the level of bivalve culture that could develop before it dominated the energy flow in a marine system and impacted fisheries resources. More recent work has used Ecopath with Ecosim [84] to determine the trophic functioning of various areas that include bivalve culture [85–88]. These models differ considerably in their complexity (i.e., number of trophic groups included) and have generally found that bivalve culture promotes short energy pathways with high trophic efficiency and energy cycling. However, the aim of these studies was not specifically to determine the ecological carrying capacities of the studied areas. Research [69] to evaluate the carrying capacity of an area for mussel culture in New Zealand using Ecopath found that the ecological carrying capacity of the area (defined as the level of culture that would not significantly change the major energy fluxes or structure of the food web) was much less than the production carrying capacity (defined as the level of production at which the ecosystem collapses down to a nutrient–phytoplankton–culture–detritus-dominated system) of the area. More recent research in the eastern United States based on the same approach but for coastal lagoons with oysters also found that the stocking density calculated for ecological carrying capacity was less than that calculated for production carrying capacity [89]. Although the original version of Ecopath was limited in its applicability because it could not be used to simulate changes to flows with time, the new version does not assume a steady state. Rather, it bases the parameterization on an assumption of mass balance over an arbitrary period, often a whole year, and biomasses of any given trophic group need not be at equilibrium. A component of Ecopath, Ecosim, accepts time series data for different trophic groups and may be appropriate to evaluate different management (i.e., stocking and harvesting) options. These approaches have some limitations. Perhaps the most important for bivalve culture is that the models are not spatially explicit. Thus, the model may not be used to identify near-field and far-field effects and exchanges between areas are assumed to be instantaneous. This is not logical in

complex coastal areas where most bivalve culture is done. This issue has been addressed to some extent with the development of Ecospace, a dynamic, spatial version of Ecopath that incorporates the key elements of Ecosim [84]. This review found no studies that use either Ecosim or Ecospace to estimate ecological carrying capacity for bivalve culture; information to do this is usually not available and when such spatially explicit temporal data are not available, Ecopath provides a standardized methodology for developing a model [89]. As it is, data on many specific biological variables (life history values, interactions, etc.) are lacking for most systems. If default values are used, these must not be simply accepted without critical evaluation [90]. Even when data is available to guide the determination of variable values, many must be adjusted to make the model balance [69]. Perhaps most importantly, Ecopath uses a largely top-down mass-balance approach and thus poorly represents bottom-up effects [91], a situation that will be problematic for bivalve culture given that it largely impacts nutrients and lower trophic levels.

In sum, most potential measures of ecological carrying capacity consider only a single or a restrained number of ecosystem components [92]. Little research has been directed at understanding the impact of biodeposition (of biodeposits and of farmed bivalves and associated organisms) on the productivity or sustainability of benthic infaunal communities or the communities of larger invertebrates and fishes that may prefer to associate with culture sites to profit from the biodeposition. Likewise, little research has addressed the impact of the modification/addition of physical structure associated with bivalve culture (i.e., both the infrastructure and the farmed product, as well as removal of seagrass, etc.) [11]. The addition of structure may attract and create suitable habitat for a large variety of organisms, such as fish and decapods, but also of fouling organisms that may otherwise not have appropriate habitat in a given area. In contrast, the removal of some features for bivalve culture may repel other organisms. Thus, flexible approaches to evaluating ecological carrying capacity need to be developed to incorporate our evolving understanding of the functioning of marine ecosystems and their interactions with bivalve culture [17, 89].

Social Carrying Capacity

The social carrying capacity of a site is the most complex of all types of carrying capacity to determine. It depends on not only the three above categories of carrying capacity but also on trade-offs between stakeholders to meet the demands of both the population (socioeconomic factors such as traditional fisheries, employment in other sectors, and recreational use) and the environment (protected habitats, species, etc.) [22, 31, 83, 93–95]. Moreover, social issues often inform other categories of carrying capacity (see further in "Decision Framework" section). This category is at the heart of Marine Ecosystem-Based Management (EBM) and Integrated Coastal Zone Management (ICZM) and must be fully developed so that responsible management decisions may be made [96]. That being said, the techniques for determining the social carrying capacity of a site are the least developed of all carrying capacity categories [97].

Despite these limitations, a number of criteria are common to each of the different methods: representativeness, independence, and involvement/buy-in of the groups involved in the process, and transparency [98].

One method that has been developed to manage natural resources is the concept of "limits of acceptable change," or LAC. Although originally developed to define the limit of recreational activities in terrestrial wilderness areas, it may also be applicable to a wider range of natural resource management issues [99, 100]. More recently, it has been applied to bivalve aquaculture in New Zealand [101]. It was recognized that LAC was not a tool to determine the level of bivalve culture that was ecologically sustainable. Rather, it provided an adaptive management framework to prevent significant negative effects due to the activity. Through a collaborative process, LAC provides a framework to identify indicators of change, setting levels of changes of indicators that are acceptable, and identifying management responses that are to be undertaken if these levels are exceeded. The selected indicators must be relevant and practical to measure. Although in the New Zealand example ecological indicators were selected (spatial extent of phytoplankton depletion, also done recently in eastern Canada [25]), the approach could also be used for other types of

indicators derived from other categories of carrying capacity evaluations. The important aspect is that the selected indicators are chosen in a collaborative way [102], including input and discussions with members of the public, environmental managers, scientists, members of the industry, groups with conflicting interests, etc. In addition to the process being representative, it must also be transparent and adaptive so that new information may be easily included in the decision-making process. Indeed, much work has shown that collaborative efforts between all stakeholders are essential to ensuring satisfaction in the consultation process and developing policy [103].

A recent example of this is the evaluation of the ecological carrying capacity of lagoons in Rhode Island, eastern United States, for oyster culture [97]. This involved the development of the Working Group on Aquaculture Regulations (WGAR), which guided and oversaw the development of a mass-balance modeling approach to calculate both the ecological and social carrying capacities of the area for oyster culture. Whereas it is usually left up to the modelers to determine what constitutes an acceptable or an unacceptable impact [97], it was considered that the process would be much more transparent and inclusive by including input from all stakeholders, following the criteria outlined by Soto et al. [104] stating that an ecosystem approach to aquaculture (EAA) should:

1. Be developed in the context of ecosystem functions and services with no degradation of these beyond their resilience capacity
2. Improve human well-being and equity for all relevant stakeholders
3. Be developed in the context of (and integrated to) other relevant sectors

The above strategies to evaluate the social carrying capacity of locations may be considered as social-ecological systems (SESs) where all of the potential stakeholders participate. Walker et al. [105] outline four general steps in the process:

1. Stakeholder-led development of a conceptual model of the system, including its history and preliminary assessments of the drivers of key ecosystem goods and services.
2. Identification of the range of drivers of the system, stakeholder visions for the future, and contrasting possible future policies, to identify a limited set of future scenarios.
3. Identify the resilience of the system by examining the results from i and ii. This is generally done through the development of models of the system's dynamics to identify important attributes that affect resilience.
4. Stakeholder evaluation of the process and outcomes in terms of policy and management implications.

Ostrom [106] recently developed a framework to evaluate the sustainability of management strategies for SESs. It is a nested approach with four first-level core subsystems. In bivalve culture systems, these may include (1) resources systems – a given embayment or other logical management area; (2) resource units – such as phytoplankton biomass or physical space; (3) governance systems – the specific rules related to culture activities that manage resource use; and (4) users – the various groups that use the resource for sustenance, recreation, etc. Each core subsystem is made up of a series of secondary subsystems and interacts with other core subsystems. One of the main findings was that, although many researchers have predicted that users of a system will not self-organize to create a sustainable SES and thus regulation by governments is needed, this prediction was not supported when stakeholders were enabled to discuss management options. Monitoring and enforcement were other key components that determined the success of the studied SESs.

A further method to determine the social carrying capacity of a site is by attaching a monetary value to the different categories of impact due to aquaculture [15]. However, this is a complex undertaking and must include both positive and negative effects of the operations [107]. Moreover, acceptability of different effects is quite variable among locations and groups, further complicating the goal of attaining consensus for different variables.

The use of fuzzy expert systems has also been advocated to determine the social carrying capacity of an area for bivalve culture [17]. This approach has been shown to be useful when data types are disparate and

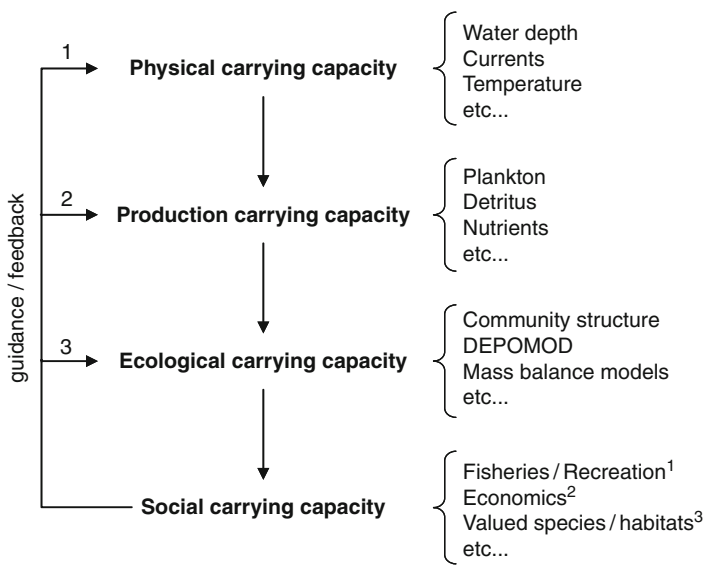
uncertainties are great or simply unknown. In short, instead of stating that a given level of production is acceptable or unacceptable, a given level is treated as being, say, 50% acceptable. It is rather more like dealing with varying shades of gray rather than cases that are black and white. This has the important effect of inducing less conflict between stakeholders on issues that may be contentious.

In sum, methods to determine social carrying capacity for bivalve culture remain poorly developed. In general, few methods have been developed specifically for aquaculture although methods developed for other sectors may be adapted. Analysis of the attempts to use SESs in other systems has shown that some approaches work; such approaches may be looked to for determining social carrying capacity for bivalve culture.

Decision Framework to Determine Carrying Capacity

A hierarchical approach to determine the carrying capacity of an area for bivalve culture is proposed (Fig. 4). The first level, the physical carrying capacity, relates to the available natural conditions and the needs of the operation and bivalves to be cultured. The second level, the production carrying capacity, is a function of the supply of food to the farmed bivalve in an area and is determined using modeling efforts. At the third level, the ecological carrying capacity of an area is estimated using modeling or by following a logical framework to evaluate the range of possible outcomes for production estimates varying between none (and/or the current level) and the maximum calculated production carrying capacity; there is little use to go beyond this point as it is assumed that this level will not be surpassed knowingly. Finally, managers weigh and balance the different scenarios based on the outcomes from each of the preceding categories of carrying capacity and make a decision as to what level of productivity is acceptable – the social carrying capacity.

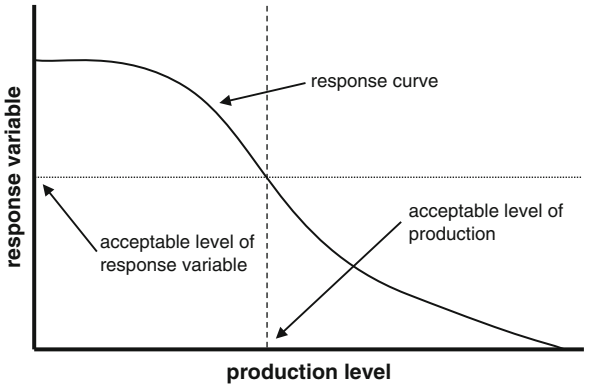
It must be understood that the three first categories of carrying capacity are a function of social values. For example, a given coastal area in which bivalve culture may be done is often valued for myriad competing activities, such as water quality, visual aesthetics,



Carrying Capacity for Sustainable Bivalve Aquaculture. Figure 4
Hierarchical structure to determine carrying capacity of a given area. Note that social carrying capacity provides guidance to choosing pertinent response variables and on establishing limits for these. Superscripts indicate examples of the type of information that informs the selection of response variables for other carrying capacity categories (Modified from McKindsey et al. [17])

competition for limited space, other species, etc. For the first category, physical carrying capacity, competition for physical space may be direct or indirect. For example, direct competition may result as there may be multiple demands to use the same area for different purposes, such as bivalve culture as well as fishing or recreational boating. Indirect competition may arise because of visual aesthetics or the not-in-my-backyard factor where waterfront owners or users do not want their views affected by aquaculture installations. Production carrying capacity is likely rarely maximized because of economic costs related to production. Thus, Nobre et al. [108] developed a modeling approach that considers both ecological and economic aspects and their interactions to maximize profit and EAA as focusing aquaculture management on maximizing output is likely economically inefficient and carries unnecessary ecological risks. In fact, this approach addresses all four categories of carrying capacity with an emphasis on maximizing economic returns. The ecological carrying capacity of an area is also clearly a function of social values as what is valued varies among populations (e.g., specific bird and fish populations, water clarity, eelgrass, or specific rare habitats).

Consultation with stakeholders throughout the process of defining the carrying capacity for a given area will identify the appropriate (given the social values of the population) response variables or indices to be examined [97]. Ideally, the scientists should then be able to select suitable tools from a toolbox (e.g., models, GIS, and comparisons with previous studies) to predict the form of the response curves of the selected response variables to a range of production-level scenarios. It is important to note that although it is the role of scientists to describe the form of the responses to a range of production-level scenarios (see Fig. 5), their role ends once they have done this. It is then up to managers, in consultation with the various stakeholders, to use all available scientific information to inform regulations and policy [17, 97]. Again, this should be done within the context of EBM and ICZM, given that there is likely a paucity of information about a number of factors that are needed to make informed judgments [96]. Thus managers will likely have to rely on instinct, local knowledge, extrapolation from studies done elsewhere, contributions from various stakeholders, etc., to make management and policy decisions. Even faced with an absence of some types of information, this does not remove the logic of the hierarchical nature of the decision framework outlined above. Indeed, it could be argued that this is precisely when the process is most useful and should be followed using all available information – so that an unbiased view of the situation may be formed and thus promoting appropriate management decisions. As pointed out by McKindsey et al. [17], failure to follow the process (e.g., by stating at the outset of the process that certain types of development or developments in certain areas are not permitted) will likely result in otherwise feasible bivalve culture installations not being initiated. It is also contrary to the notion of effective and transparent processes in the establishment of ICZM or EBM.



Carrying Capacity for Sustainable Bivalve Aquaculture. Figure 5

Hypothetical response curve of an environmental variable under the influence of varying levels of bivalve culture production. The dotted line indicates the level of the indicator that has been determined to be acceptable and the dashed line the corresponding level of production (Modified from McKindsey et al. [17])

Knowledge Gaps and Future Directions

This entry concludes with a brief discussion of knowledge gaps and directions for future research to better estimate the carrying capacity of areas for sustainable bivalve culture, except for the estimation of physical carrying capacity for which methods are fairly well developed and are currently used extensively to this end.

While it is generally true that "existing models must be made spatially explicit" [17], this is currently being done. However, models to this end require much information that is often not easily available. So, perhaps a better knowledge gap to address is to determine when such models are needed and when can general models be used.

Similarly to the first point, although temporal variation must be included in models to consider seeding and harvesting activities, some generalized models to this end have already been developed [35, 57, 108, 109]. These should be expanded upon and evaluated in several locations to fully assess their generality.

Far-field impacts for the benthic environment need to be evaluated. For example, is sedimentation outside of culture sites decreased due to grazing and, if so, what is the influence of this on the benthic environment? How does this influence our interpretation of "impacts" on the benthic environment within farm sites?

Work is needed on how nonlinear or unexpected results may be incorporated into carrying capacity models. For example, how can the provision of bivalve culture-related structure in the environment – which may increase the abundance of fouling organisms and thus filtration capacity or attract various other organisms – be included in carrying capacity estimates?

Methods need to be developed to include both "positive" and "negative" effects into the decision-making process. For example, while suspended bivalve culture may increase organic loading locally, it may also mitigate the effects of eutrophication (and models have been developed to assess this, e.g., 35) or increase the abundance of commercially important species locally [11].

Despite the growing prevalence of certification standards and ecolabeling for aquaculture products, it is not clear that such processes are improving conditions in the field [14]. Although such standards are often elaborated within a multi-stakeholder framework, it is not clear under which conditions they are necessary and how the three previous points are considered in their development or application.

Given that many groups promote including the notions of reversibility or resilience in the definition of carrying capacity, (e.g., [16]), surprisingly little work has actually addressed this for the benthic environment [but see 110]. Work on evaluating the resilience of benthic systems to bivalve culture is needed.

Appropriate management tools, such as methods for combining disparate data types, need to be developed to incorporate the information needed to estimate various aspects of carrying capacity to aid in decision making and policy development.

Article Outline

Glossary

Cartagena protocol on biosafety (CPB) The Cartagena Protocol on Biosafety to the Convention on Biological Diversity is an international agreement which aims to ensure the safe handling, transport, and use of living modified organisms resulting from modern biotechnology that may have adverse effects on biological diversity, taking also into account risks to human health. It was adopted on 29 January 2000 and entered into force on 11 September 2003 (for full text, see http://bch.cbd.int/protocol/text/).

Convention on biological diversity (CBD) The objectives of this Convention are the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding (for full text, see http://www.cbd.int/convention/text/).

Convention/protocol/treaty A treaty is an agreement in written form between nation-states (or international agencies, such as the United Nations, that have been given treaty-making capacity by the states that created them) that is intended to establish a relationship governed by International Law. It may be contained in a single instrument or in two or more related instruments such as an exchange of diplomatic notes. Various terms have been used for such an agreement, including treaty, convention, protocol, declaration, charter, covenant, pact, act, statute, exchange of notes, agreement, modus vivendi ("manner of living" or practical compromise), and understanding. The particular designation does not affect the agreement's legal character.

Genetically modified/genetically engineered/transgenic organisms Organisms, such as plants, animals, and microorganisms (with the exception of human beings), in which the genetic material (DNA) has been altered in such a way that does not occur naturally by mating and/or natural recombination (The terms "genetically modified" (GM), "transgenic," "genetically engineered" (GE), and "living modified" (LM) are used in different legal instruments around the world. It is useful (and deliberate) in this document to essentially use them interchangeably).

Living modified organism (LMO) Any living organism that possesses a novel combination of genetic material obtained through the use of modern biotechnology (according to the CPB).

Modern biotechnology The application of [1] in vitro nucleic acid techniques, including recombinant deoxyribonucleic acid (DNA) and direct introduction of nucleic acid into cells or organelles, or [2] fusion of cells beyond the taxonomic family, that overcome natural physiological reproductive or recombination barriers and that are not techniques used in traditional breeding and selection (according to the CPB).

Definition of the Subject

This contribution describes and compares the regulation of GMOs and the underpinning legislative frameworks in selected countries from around the world. It also includes a description of the relevant international agreements related to biosafety and a description of the main characteristics and attributes of a modern biosafety regulatory framework in this area.

Introduction

The rapid development and deployment of modern biotechnology in the last decades have made biosafety a critical issue. Although modern biotechnology has the potential of benefiting agricultural interests in developing countries as well as overall human welfare, living modified organisms (LMOs) resulting from modern biotechnology or genetically modified organisms (GMOs) remain a source of concern with regard to the conservation and sustainable use of biodiversity, as well as to human health. The perceived risks, which relate to the release of GMOs into the environment as well as the placement of GMOs onto the market, have as much to do with social values as scientific concerns. For example, social concerns may require the labeling of genetically modified (GM) food and feed, the mitigation of socioeconomic impacts, and the demonstrated potential for the co-existence of organic, conventional, and GM farming [1].

Global use of GM crops is growing rapidly, increasing approximately 87-fold from 1996 to 2010 to 148 million hectares under cultivation by 15.4 million farmers in 29 different countries [2]. Furthermore, the estimated value of the global GM crop market in 2010 grew to US$11.2 billion, while the value of harvested products was estimated at US$150 billion [2]. Although the majority (52%) of GM crops are still grown in industrialized countries, developing countries are rapidly approaching parity and, due to their high rates of adoption, are soon expected to grow the majority of GM crops [2]. By 2009, the major biotech crops had achieved high levels of market penetration: 77% of soybean, 49% of cotton, 26% of maize, and 21% of oilseed rape grown globally in 2009 were GM varieties [3].

Despite expected high benefit-cost ratios from biotechnology, only a few developing countries, such as Brazil and Argentina, have had high uptake rates (over 20 million hectares) [2] of GM crops, with uptake typically concentrated in crops that are exported to developed country markets. Few others (mainly India and China) have started exploring their own national research capability in biotechnology. In the vast majority of developing countries, both investment in biotechnology research and development and the transfer to farmers of transgenic crops already being marketed have been generally low. This in part reflects a lack of transparent regulatory capacity necessary in dealing with risks associated with biotechnology as well as in addressing the issues of property rights development and protection that are essential to promoting innovative research. This is particularly important because of the high cost of undertaking the initial research and development in biotechnology [4].

As GM technologies are very recent and fast developing, most governments are trying to keep pace by developing regulatory policies that reflect consumer demands and preferences affecting GM agricultural products. Almost all developed countries require products derived from GM sources to be assessed both for their safety as foods and for their environmental impacts. However, there are considerable differences in the approaches taken by different countries. In the United States, analysis and approval mechanisms for GM foods have been subsumed into existing regulations governing the release of new foods, plants, and pesticides, whereas in the European Union, regulation of GM products requires considerable separate scrutiny (see chapter "► Commercialisation of GM Crops: Comparison of Regulatory Frameworks" by Devos et al.). Countries worldwide are in different stages of policy development, with the majority of the developing countries still in the infant stage [4]. In setting up

domestic legislation, developing countries seem to be paying increasing attention to international trade concerns [5].

India along with Argentina, South Africa, and others constitute a group of developing countries that aspire to develop domestic biotechnology through national public R&D and/or by creating incentives for the participation of multinationals as sources of technology. They each have relatively liberal regulations as well as more explicit regulatory institutional arrangements [6]. Those developing countries with well-developed public agricultural research and extension systems (such as India) are well placed to benefit promptly from the new biotechnology by working in partnership or in parallel with private biotechnology and seed companies. Approving investments in those activities by the private sector – and the overall investment climate – will allow the process of adaptation and adoption to move forward. The experiences in India, China, and South Africa all indicate that rapid and widespread adoption is then possible, including by small farmers [7].

The biosafety frameworks of the described countries were selected based, primarily, on considering the following criteria: level of production and commercialization of GMOs, investments made and political commitment with the research and development particularly in the field of GMOs, regional leadership in the adoption of GMOs and in the elaboration and implementation of biosafety legal frameworks, and the existence of a functional biosafety framework in place.

Argentina

Argentina is a major producer of agricultural products and the third largest producer of soybeans. Initially, the harvested area of soybean was 36,000 ha (59,000 mt) in 1970, increasing to 5.98 million hectares in 1995/1996 (12.43 mmt). The country has historically been the earliest and most aggressive adopter of GM crops in Latin America, first planting glyphosate-tolerant soybeans in 1996, which sparked a further expansion of soy production and which is now in excess of 14 million hectares, of which at least 98% is GM [8]. This rate of adoption is far higher, and much faster, than that in the USA, which was the first country to introduce this technology [9]. In addition, Argentina also grows significant quantities of GM corn (Bt and glufosinate ammonium tolerant) and Bt cotton, comprising 40% and 20% of overall production in 2009 for these two crops, respectively [3, 10]. Available estimates place accumulated benefits (extra income which would have not been generated in the absence of the technology) until the year 2001/2002 at approximately US$5.2 billion in the case of soybeans, about US$400 million for Bt maize, and approximately US$40 million for Bt cotton [7]. Argentina is now third only to the United States and Brazil in terms of the area planted with transgenic crops (22.9 million hectares) [2] and is thus a very important player in the international arena. Notably, Argentina signed, but has yet to ratify, the Cartagena Protocol on Biosafety (CPB, hereinafter referred to as "the Protocol") of the Convention of Biological Diversity in May 2000. Argentina is currently undergoing a consultation process, analyzing and debating with all the involved sectors the position the country will take in this respect [8].

Regulatory Oversight in Argentina

Argentina was one of the first countries to establish a system of regulatory oversight for GMOs [11]. It has instituted regulatory measures for the safe development and application of biotechnology in general and GMOs in particular. It chose to develop the policy on biosafety within the context of trade-related issues [12] and as such has policies, procedures, and institutional arrangements to regulate the development, importation, and export of GMO products. The Argentine biosafety system is based on guidelines, not on legislation. Argentina's legislative framework for regulating GMOs is based on the existing agricultural regulatory system (e.g., for plant protection chemicals) supplemented with GM crop-specific regulations established to specify conditions for environmental release or to assess food safety. The non-statutory guidelines include standards for facilities and practices designed to prevent the unintended release of a GMO, conditions of isolation, monitoring field trials, and standards for risk assessment for conducting the environmental release. This approach gives the system flexibility and allows for changes needed to keep up with scientific advances. One disadvantage, however, is that compliance with guidelines is

not legally enforceable; there is no way to prosecute offenders in the rare cases of non-compliance that have occurred [13].

Similar to the USA and Canada (see below), Argentine biosafety regulation follows a product-based approach which results in several agencies, all within the Agriculture Directorate of the Secretariat of Agriculture, Livestock, Fisheries and Food (SAGPyA), mandated to regulate GM crops and products. The National Advisory Commission on Agricultural Biotechnology (CONABIA) is the lead agency in charge of regulating GM crops and was established in 1991 by Resolution 124/91 (later expanded by Resolution 669/93) of the SAGPyA to provide advice and oversee the implementation of biosafety regulations [14]. CONABIA's jurisdiction and procedures were established in Resolutions 656/92, 837/93, and 289/97 (later replaced with 39/03) [13]. Resolution 39/03 is part of the general regulatory system governing the existing agricultural regulations in Argentina related to plant protection (Decree-Law of Agricultural Production Health Defense 6704/66 and its amendments), seed and phytogenetic creations (Seed and Phytogenetic Creations Law 20.247/73 and its regulatory decree), and animal health (Law of Veterinarian Products, and Supervision of Creation and Commercialisation 13.636/49).

CONABIA is a multidisciplinary and interinstitutional organization with advisory duties and comprises representatives from the public sector, academia, and private sector organizations related to agricultural biotechnology. Its main responsibility is to assess the potential environmental impact of the introduction of GMOs in Argentine agriculture [8]. The Commission handles applications for laboratory and greenhouse testing, field trials, and governs the "flexibility status" of release conditions (unconfined release, usually large-scale, for regulatory purposes or off-season seed multiplication) of GM plants [13]. Resolution 60/2007 provides a differentiated treatment for the authorization of the breeding of parental material which contains transgenic events already approved for commercialization. Furthermore, it advises SAGPyA on the issuance of necessary licenses and authorizations for experimentation and/or environmental release of GM microorganisms, as well as GMO-derived or GMO-containing products (although the final decision is made by SAGPyA) [6]. In order to obtain the appropriate marketing license, varieties must also comply with requirements stipulated by the National Service of Health and Agrofood Quality (SENASA) [15]. SENASA's jurisdiction concerning the oversight of GMO-derived food was established in Resolution 289/87, while Resolution 511/98 including Annexes established the food-safety review criteria [13]. The latter was based on FAO and WHO documents, as well as on relevant regulations from Australia, Canada, the EU, Japan, and the US, but has since been replaced by Resolution 412/2002.

A key part of the GMO regulatory process consists of verifying that the commercial approval will not have a negative impact on Argentina's foreign trade. This specific assessment is carried out under Resolution 39/03 by the National Bureau of Agrifood Markets (NBMA), and it includes an analysis of the current status of regulatory systems and public acceptance in the importing countries. The National Seed Institute (ex-INASE) is responsible for ensuring that all the necessary requirements for registration in the National Registry of Cultivars have been established. Ex-INASE plays a further role in the biosafety system by receiving and logging applications for GMO field trials. Applications containing confidential business information are kept secure at INASE's offices. Agency personnel perform field test site inspections, checking for compliance with the biosafety requirements set by CONABIA [13].

During 2001, the SAGPyA actively cooperated with members of the Argentine Congress in drafting a biosafety law. This draft represented a major improvement on the current situation, since it clearly set forth a conceptual framework, as well as issues and instances to be considered as participants in risk analysis procedures. But due to the institutional and economic crisis that broke out on December 2001, the draft was never discussed in Congress, and there is no evidence that it will be discussed in the near future [8].

Commercialization of GM Crops: Argentine Approval Process

When an organization intends to obtain an authorization for commercialization of a GM crop in Argentina, it has to pass reviews by the three regulatory agencies. Briefly, CONABIA should determine that the environmental impact of the large-scale release of the GM crop

will not significantly differ from that of its non-modified counterpart; SENASA's Technical Advisory Committee on the Use of GMOs should determine that the derived foods are safe for human and animal consumption, and the DNMA should determine that the release will not have an undesired impact on the country's international trade [16].

The prerequisite for entering the commercial evaluation process is that authorizations for experimentation and/or release into the environment of the specific GM crop have been previously granted [16]. After at least one release into the environment has been approved and the safety of the GM crop has been demonstrated, the applicant can apply for a "flexibilization" permit which allows future releases by simply providing notification of the location, area, sowing date, and intended harvest date [11]. Flexibility status conditions are granted for the following purposes [13]:

- For providing testing material
- For export
- For off-season seed multiplication (not for use in Argentina)
- For tests, which need to be presented at later stage (e.g., variety registration)
- For pre-commercial seed multiplication for a pending variety registration

The deregulation of field testing conditions is dependent on the results of the biosafety assessment conducted by CONABIA with regard to the criteria laid down in Resolution 131/98. These include the characterization of the GMO (recipient organism, genetic modification, insert, donor organisms, phenotypic characterization, potential environmental interactions of GMO) and the impacts expected from the production of the GM crop at commercial scale (environmental effects and impact on human health) [16]. If SAGPyA, on the recommendation of CONABIA, authorizes "flexibility status" release conditions for the GM crop in question, the applicant only needs to submit information on the area to be sown, the date of sowing, the site of release and the harvest date [16]. The flexibility status of a GM crop allows large-scale planting, but not planting for commercial purpose.

The second step to commercialization is the evaluation of the safety of the GM crop for human consumption and feed. This evaluation is carried out by SENASA under Resolution 412/2002 [17]. In the third step of the commercialization process, the NBMA assesses the impact of the GM crop in question on export market security. It does this by analyzing the status (if any) of the specific event in the destination markets and, as a result, whether the addition of this event to Argentina's export supply might represent a potential barrier to the access to these markets.

After completion of all of the steps mentioned above, CONABIA's Office of Technical Coordination compiles all pertinent information and prepares a "Project of Resolution" on the basis of its own, SENASA's, and DNMA's assessments and submits it to the SAGPyA, which takes the final decision on approval or denial of the commercialization request [13]. Should the GM crop be authorized for open cultivation, it must also be registered in the National Registry of Cultivars, a process overseen by ex-INASE. For those GM crops expressing either herbicide tolerance or insect resistance, they require a pesticide approval from SENASA prior to their commercial use [13].

Canada

Regulatory Oversight in Canada

In line with a similar approach adopted in the United States (see below), the regulatory framework established in Canada is based on the extension of the existing regulations to GMOs [18]. However, in contrast to all other countries, Canada relies on the concept of novelty to trigger regulatory oversight, thereby enabling the regulation of a wider array of novel seeds or food [19], and includes those produced by conventional breeding, mutagenesis, or rDNA techniques. Directive 94–08, first published in 1994, defines these as "plants containing traits not present in plants of the same species already existing as a stable population" [20].

The Canadian Environmental Protection Act (CEPA) of 1988 formally recognizes biotechnology as a manufacturing process for products potentially posing environmental risks, and therefore, the act requires environmental assessments. CEPA, however, embraces a product-based approach to biotechnology, an approach explicitly defined in the 1993 Regulatory Framework for Biotechnology [21]. In accordance

with this framework, policy-makers proceeded to the amendment of a series of regulations (below) contiguous to the laws governing the products of biotechnology. These amendments were mostly aimed at inscribing a trigger (the novelty of the trait) launching the risk evaluation process for the products of biotechnology.

The Canadian approach is based on an agreement between the Canadian Federal agencies in 1993 that was renewed in 1998. The responsibility for regulating plants with novel traits (PNTs), including GM plants, is shared between the Canadian Food Inspection Agency (CFIA) and Health Canada [18]. The CFIA operates under the authority of the Seed Act, the Plant Protection Act, the Feeds Act, the Fertilizer Act, and the Health of Animals Act. It also shares some responsibilities with Environment Canada under the Canadian Environmental Protection Act, and with Health Canada under the Pest Control Products Act, and the Food and Drugs Act. The Canadian Environmental Protection Act is an umbrella legislation intended to serve as a regulatory "safety net" for any biotechnological products not currently regulated by another federal act. The Department of Fisheries and Oceans regulates aquatic organisms under the Fisheries Act.

In 1997, the CFIA took over the risk management of novel seeds and feeds from Agriculture and Agri-food Canada. The agency regulates novel plants following assessment criteria provided by Directive 94–08. In particular, the CFIA is responsible for the regulations and guidelines dealing with cultivating PNTs, assessing their impact on the environment and biodiversity. Canadian authorities state that "all plants derived through genetic engineering have been considered novel, and as such have undergone a full, comprehensive, and rigorous safety assessment prior to release into the environment" [22]. In addition, the agency is also in charge of ensuring livestock feed safety, along with the responsibility for the regulation of seeds, veterinary biologics, and fertilizers. Furthermore, the CFIA develops standards related to the packaging, labeling, and advertising of foods and handles all inspection and enforcement duties [23].

Many GM crops are destined, in whole or in specific parts, for the human food supply system. For this reason, they must not only obtain CFIA approval but must also be assessed by Health Canada. It is within the jurisdiction of Health Canada to regulate GM foods according to the Food and Drugs Act under Division 28 of Part B of Food and Drug Regulations (Novel Food). As with seeds, the trigger for pre-market safety assessments is novelty, and as such, Health Canada treats as novel food all those derived from GMOs "whether it is a micro-organism, a plant or an animal, such that it exhibits characteristics that were not previously observed, no longer fall within the anticipated range or no longer exhibits characteristics that were previously observed, for that plant, animal or micro-organism" [23].

Environment Canada is only responsible for the environmental assessment of GMOs used in industrial processes. Although the Canadian Environmental Act requires environmental risk assessments for GMOs, the responsibility for conducting assessments relevant to novel plants, feeds, and food rests with the CFIA, PMRA, and Health Canada. Notably, CFIA, as the agency most involved in the environmental risk assessment of GMOs, is the responsibility of the agriculture minister whose mandate is to promote agricultural development.

Commercialization of GM Crops: Canadian Approval Process

Before crops with novel traits may be authorized for unconfined release, they must be fully assessed for environmental safety by the CFIA. In meeting the extensive information requirements for these applications to the CFIA, applicants will have conducted experiments at the earlier confined release stage. These experiments are expected to contribute scientifically robust data to address the key criteria of environmental safety assessments. The applicant is required to provide the Plant Biosafety Office (PBO) at the CFIA with extensive high-quality, statistically sound data and/or valid scientific rationale to demonstrate the environmental safety of the PNT. This information initiates a review and decision for authorization of the release. CFIA officials also use pertinent information generated from the Agency's own research, either conducted in-house or contracted out, on specific key environmental areas [18].

The unconfined release assessment by the PBO focuses on real or potential interactions of the PNTs

with the wider agricultural and ecological environment, using "substantial equivalence" as the basis for these assessments. Evaluations consider the unique combination of species and traits, using standard descriptions of each species known as biology documents as a baseline for comparison. If the PBO concludes that there is minimal potential for significant negative environmental impact of the PNT relative to its unmodified counterpart, an unconfined environmental release may be authorized. In some cases, the PBO may authorize an unconfined release with conditions, such as a requirement that the applicant ensures that users of an insect-resistant PNT deploy methods to delay development of resistance among insect populations. Note that for species that may be used for food or feed, developers of PNTs must also seek approvals from Health Canada for human food use and from the CFIA Feed Section for livestock feed use [19]. The starting point for the safety assessment of novel foods is also based on "substantial equivalence," where the novel food is evaluated relative to conventional counterparts that have a history of safe use [23]. Health Canada has 45 days to decide whether the product is safe or to request additional information to pursue the risk analysis, even to the extent of involving experiments [23].

All imported PNTs (or products derived from them) require a prior import permit, being subject to the CFIA regulatory review under the Plant Protection Act and Regulations. Pest risk assessments (PRAs) are conducted by the Plant Health Division in order to evaluate the potential capability of PNTs to pose a pest risk to the agricultural and forestry environment. Those commodities determined not to pose a plant pest risk are now no longer required to have an import permit. Additional exempted commodities include: PNTs with prior approval; PNTs (or products derived from them) that are incapable of sexual or asexual propagation, i.e., have been processed in some way to render them non-viable, such as by grinding or freezing; and plants further developed from exempted PNTs, or considered substantially equivalent to them provided that the intended use is similar, and that the plants do not display any additional novel traits, do not contain novel genetic elements, and have not been subject to inter-specific breeding [24].

China

China has become one of the Asian leaders in biotechnology and has dedicated substantial economic, scientific, and technological resources to R&D. Since the 1980s, ministries and relevant government agencies in China have been investing significantly in agro-biotechnology research and have established more than 150 laboratories, resulting in the largest plant biotechnology capacity outside of North America [25]. The government has allocated research budgets to biosafety and management, and nearly all biotechnology research programs have expanded their scope into biosafety issues [5]. The commitment to sustain biosafety after project closure is demonstrated by its growing budget to support agricultural research in biosafety over the last few years. From an initial budget of slightly over US$ 80,000 in 1999, China now spends about US$ 3 million annually on agricultural biosafety-related activities [10].

A wide variety of crops and traits has passed through China's biosafety system and are now planted commercially, while many others remain at the field trial stage, including many varieties with adaptation-related traits developed by Chinese institutes and companies [26]. In contrast to the other countries described in this chapter, most of these crops have been developed predominantly by public sector laboratories in China. The biosafety regulatory system in China has also reviewed a large number of applications since it was formally set up in the late 1990s. The government received 1,044 applications for field trials or commercial release, and 777 of these were approved [27, 28]. These applications predominantly covered 60 crops, as well as several animals and a large number of microorganisms [28]. Varieties of cotton, tomatoes, phytase maize, insect-resistant rice, and sweet and chili peppers have all been approved for commercial planting [3].

Regulatory Oversight in China

China has adopted a policy that promotes research and development of biotechnology, while at the same time, retaining control over research in genetic engineering. In the early 1990s, China had already implemented a very pragmatic approach to GM crop regulation. Regulations were basically product-based with special attention given to the economic interest of a given

application. By 1993, China had already established its first biosafety regulation, namely the "Safety Administration Regulation on Genetic Engineering" issued by the Ministry of Science and Technology (MOST). This instrument required relevant ministries to draft and issue corresponding biosafety regulations on biological engineering (i.e., the Ministry of Agriculture (MOA) for agriculture and the Ministry of Public Health for food safety) and established general principles, safety categories, risk assessment and risk management procedures, application and approval mechanisms, and legal responsibilities [29]. It was followed in 1996 with the "Safety Administration Implementation Regulation on Agricultural Biological Genetic Engineering" by the MOA [12]. This was an explicit regulatory regime for the risk assessment and management of agricultural products of genetic engineering. Labeling was not part of this regulation, nor was any restriction imposed on imports or exports of GM products. The regulation did control GMOs for research and commercial production, as well as establishing the National Agricultural GMO Biosafety Committee (Biosafety Committee) to provide the MOA with expert advice on biosafety regulations.

Criticism of GM crops on environmental, food-safety, and ethical grounds, however, led to some significant changes in the Chinese legal framework on agro-biotechnology [5]. In 2001, the State Council decreed a new and general rule on biosafety, with the aim of protecting human, animal, and plant health and the environment. This new "Regulations on Safety of Agricultural Genetically Modified Organisms" replaced the 1993 Regulation issued by MOST. The 2001 regulations provide the MOA with overall national authority to oversee the use of GM crops, whereas the 31 provincial biosafety management offices are responsible for the supervision and administration of biosafety in their respective areas [30]. The 2001 regulations meet the generally accepted risk assessment procedures outlined in the relevant international instruments and also stipulate a comparative risk assessment approach, in which a GM crop is compared with the corresponding non-transgenic crop for environmental/ecological safety and food safety.

To implement this Regulation, the MOA issued three implementation regulations including Implementation Regulations on Safety Assessment of Agricultural Genetically Modified Organisms, which provided the legal basis and technical guidelines in GM crops risk assessment in China [31]. These new regulations primarily concerned Biosafety Evaluation, Import Safety, and Labeling and included several important changes to existing procedures and details of regulatory responsibilities after commercialization. The changes included an extra pre-production trial stage prior to commercial approval, new processing regulations for GM products, labeling requirements for marketing, new export and import regulations for GMOs and GMO products, and local and provincial-level GMO monitoring guidelines [29]. Specifically, the Regulation on Biosafety Evaluation establishes procedures for handling applications for GM cultivation and sets up an advisory body, the National Biosafety Committee (NBC), and a decision-making body, the Office of Agricultural Genetic Engineering Biosafety Administration (OGEBA), under the MOA to handle applications. Applicants must provide information on risk assessment, and GMOs are classified into four classes depending on their potential danger to human and animal health and to the environment. The Regulation establishes the requirements that should be met to obtain authorization to import GMOs and will vary according to the intended purposes of the imports, i.e., research, release into the environment, or processing. In response to representations from GM-producing countries, China agreed to allow trade to continue as normal until the new Regulation on Safety of Imports entered into force on 20 April 2004 [32, 34]. The Ministry of Public Health (MPH) is responsible for food-safety management of biotechnology products (processed products based on GMOs) and promulgated its first regulation on GMO food safety in April 2002, to take effect after July 2002.

China's policy on GM regulation is now under the responsibility of an agency which was established by the State Council, the name of which has been variously reported as either the Joint Monitoring and Management Commission [12] or the Allied Ministerial Meeting [29]. It has a multi-stakeholder membership comprising the highest representatives from ministries like Agriculture, Health, Commerce, Science and Technology, the National Development and Reform Commission, the National Inspection and Quarantine Agency, and the State Environmental Protection

Administration. It is responsible for the coordination of key issues related to the biosafety of agricultural GMOs, the examination and approval of the applications for GMO commercialization, determining the list of GMOs for labeling, and establishing import or export policies for agricultural GMOs and their products. In addition, under the new regulation, foreign investment in biotechnology has been prohibited [5].

The NBC remains the major player in the process of biosafety management. Currently, the NBC is composed of 56 members who come from different administrative departments, academic institutions, etc. They are experts in biological research, production, processing, inspection and quarantine, public health, and environmental protection with respect to agricultural GMOs [31]. The committee meets twice each year to evaluate all biosafety assessment applications related to experimental research, field trials, environmental release, pre-production trials, and commercialization of agricultural GMOs. It makes recommendations to the OGEBA based on the results of its biosafety assessments. OGEBA is responsible for the final approval of decisions, as well as handling routine work and daily operations [29]. In 2005, all 31 provinces in China established biosafety management offices. These biosafety management offices collect local statistics on and monitor the performance of research and commercialization of agricultural biotechnology in their provinces and assess and approve (or disapprove) all applications of GM-related research, field trials, and commercialization in their provinces. Only those cases that are approved by provincial biosafety management offices are submitted to the NBC for further assessment [29].

In May 2007, the National Development and Reform Commission in China announced that it had approved the establishment of a National Biosafety Research Centre. To be completed by 2009, the Centre will manage agricultural and biological-related issues. It is to house several research departments, including laboratories for high-risk plant pathogens, insects, and plants, as well as units for agriculture-related information analysis and quarantine facilities. The Centre will be supervised by the Plant Protection Institute of the Chinese Academy of Agricultural Sciences.

In 2009, a major development in China was the commercialization of transgenic Bt rice, which reached pre-production trials but was still pending final commercialization approval for several years. Influenced in part by opposition to the technology in Europe and to some extent Japan, the final approval of many crops stalled at the level of China's inter-ministerial committee even as research and field trials continued apace. The discovery by Greenpeace that some transgenic seed was planted by farmers without authorization caused international debates about China's biosafety system and may have contributed to regulatory approval delays [33].

Commercialization of GM Crops: Chinese Approval System

If the product is for cultivation, applications must be authorized before the first import of a specific GMO can take place and must be accompanied by a safety assessment carried out in the country of origin of the GM material [5]. For permanent approval of each imported GM product, compulsory field trials are carried out in China in order to re-assess safety within the Chinese context [35]. Generally, the practice in China is to use a comparative risk assessment approach, in which the transgenic crop is compared with the corresponding non-transgenic crop in ecological risk assessment and hazard identification in transgenic foods [36, 37]. Although there are no official guidelines in China for risk assessment on food derived from transgenic crops, the assessments carried out so far on nutrition, toxicity, and allergenicity generally followed the relevant Codex principles and guidelines [31].

In China, agricultural GMOs also need to satisfy the procedures governing the release of new seed varieties. These procedures are governed by the Seed Law in China. Only agricultural GMOs that have previously obtained a biosafety certificate are eligible to be classified as a new seed variety in accordance with the Seed Law and relevant regulations. After the GMO has passed seed variety testing and received the permission for production, it is eligible to enter into the chain of production and marketing [31].

India

In India, a wide variety of crops have been field trialed, but most have not yet been commercialized. The first approval for the commercial production of any GM crop in India occurred in March 2002 when the Indian

competent authority approved three varieties of *Bacillus thuringiensis* (Bt) cotton (MECH 12, MECH 162, and MECH 184 expressing the *cry1Ac* gene for insect resistance) amid widespread protests by anti-GM activists. This was followed by a significant increase in the availability of Bt cotton (currently 809 hybrid varieties) [38] better suited to Indian cultivation. By 2003, more than 34 genes were being tested in a wide variety of crops, including cotton, rice, mustard, maize, potatoes, eggplant, tomatoes, pigeon pea, and cabbage [29]. Most of the varieties initially introduced included insect-resistant cotton varieties as well as some crops modified with herbicide tolerance. Several Bt crop varieties have passed through the field trial stage and have received approval for commercial planting. The primary technology used in India originated in the Monsanto Company, which partnered with Maharashtra Hybrids Company (MAHYCO) to develop transgenic hybrid Bt cotton for sale in India. Once some Bt varieties had been approved for commercial planting, it was discovered that 800,000 ha of unapproved BT cotton had been planted, weakening confidence in the biosafety system [29]. The latest GM crop awaiting regulatory approval for commercial release is Bt brinjal (known also as aubergine or eggplant), which received positive assessments by the regulatory bodies based on years of field trials [3] but was refused authorization by the Environment Minister at the last stage of the commercialization process.

Regulatory Oversight in India

With the signing of the CPB in 2001, India became committed to introducing structures and procedures commensurate with the conditions laid down in the CPB agreement – one of the main guiding principles for India when dealing with products derived from agricultural biotechnology. This commitment provided India with the incentive to strengthen its biosafety capacity and have relevant institutional mechanisms at hand to enable the proficient dealing of GMOs. As the CPB places due importance to national legislations, provided it is developed in accordance with the former, the existing domestic policy on GMOs was required to be fine-tuned and amended wherever necessary. The goal of the Indian regulatory system is therefore to ensure that their GM crops pose no major risk to food safety, environmental safety, or agricultural production and that there are no adverse economic impacts on farmers [29]. As such, the Government of India has adopted a policy of careful assessment of the benefits and risks of GMOs at various stages of their development and field release to ensure biosafety [39].

The existing regulatory framework takes the form of rules and guidelines and is based upon three specific provisions of the Environment Protection Act of 1986 (EPA). These are sections 6, 8, and 25. While Section 6 of the Act empowers the Central Government to make rules on procedures, safeguards, prohibition, and restrictions for handling of hazardous substances, Section 8 of the Act prohibits a person from handling hazardous substances, except in accordance with procedures and after complying with safeguards. Section 25 of the EPA empowers the Central Government to lay down rules regarding procedures and safeguards for handling hazardous substances. Thus, the biosafety rules in India are statutory in nature as they originate from the EPA. These provisions of the EPA led to the adoption of the 1989 Rules for the Manufacture, Use, Import, Export and Storage of Hazardous Micro organisms Genetically Engineered Organisms or Cells ("1989 Rules") [39, 40].

In 1994, the Department of Biotechnology revised its earlier guidelines of 1990, entitled "Revised Guidelines for Safety in Biotechnology." These revised guidelines aimed at regulating large-scale production and the deliberate release of GMOs, plants, animals, and products into the environment and shipment and importation of GMOs for laboratory research [6]. By 2002, an array of legislation likely to impact biosafety regulations had come into existence. This included the National Biodiversity Act 2002 (NBA) and the Protection of Plant Varieties and Farmers' Rights Act 2001 (PPVFR), the latter of which derived from a broad-based consultation with a view to incorporate a form of farmers' rights into the national plant variety rights legislation. The biosafety rules have since been supplemented by the Biotechnology Safety Guidelines issued by the Department of Biotechnology (DBT). These guidelines have been issued in pursuance of Rule 4[2] of the Biosafety Rules, which require manuals of guidelines to be brought out by the Review Committee on Genetic Manipulation [40].

Therefore, the Indian biosafety regulatory framework, comprising the 1989 Rules and the 1990, 1994, and 1998 DBT guidelines, covers the entire spectrum of activities relating to GMOs. This includes "research involving GMOs, as well as genetic transformations of green plants, recombinant DNA (rDNA) technology in vaccine development, and large-scale production and deliberate/accidental release into the environment of organisms, plants, animals and products derived from rDNA technology." Production facilities such as distilleries and tanneries that use GMOs are also covered. In India, the risk assessment and regulatory approval for releases of GMOs and GM products are mandatory. The concept of "biosafety" used in the regulations is a broad one, covering the health safety of humans and livestock, environmental safety (ecology and biodiversity), and economic impact. The first two safety aspects dominate the regulations, while economic impact is given less prominence.

Two nodal agencies, the Ministry of Environment and Forests (MoEF) and the DBT at the Ministry of Science and Technology, are responsible for the implementation of the regulations [39]. The life cycle of a GM product features four domains, pre-research, research, release, and post-release, and is characterized by the presence of six competent authorities [41, 42]. The Recombinant DNA Advisory Committee (RDAC) is in the pre-research domain as it triggers research through its initial approval mechanisms. The Review Committee on Genetic Manipulation (RCGM) resides in the DBT and functions in the research domain, closely monitoring the process of research and experimental releases. It requests food biosafety, environmental impact, and agronomic data from applicants who wish to do research or conduct field trials and will give permits to import GM material for research. Pursuant to Rule 4 [2] of the 1989 "Rules," the RCGM is also required to produce manuals of guidelines. The RCGM is primarily made up of scientists (including agricultural scientists) and can request people with specialized knowledge to review cases. It has a Monitoring cum Evaluation Committee (MEC) that monitors limited and large-scale field trials of GM crops and is primarily made up of agricultural scientists. Commercial production of GM crops, large-scale field trials of GM crops, and the imports of GM commercial products and GM-derived products (e.g., foodstuffs, ingredients in foodstuffs, and additives including processing aids containing or consisting of GMOs) come under the authority of the Genetic Engineering Approval Committee (GEAC) at the MoEF. The committee members are primarily bureaucrats representing different ministries, and they draw on the scientific expertise of each ministry. Additional to these national committees are the State Biotechnology Coordination Committee (SBCC) and the District Level Biotechnology Committee (DLC), who, along with the MEC, basically occupy the post-release domain, although they also contribute to the research domain activities through data provisioning to the RCGM. Completing the regulatory apparatus are the Institutional Biosafety Committees (IBSC) which undertake the monitoring and implementation of safeguards at the R&D sites, under the close supervision of the RCGM, the SBCC, and the DLC. IBSCs must be established in any public or private institute using rDNA in their research and comprise scientists from their respective institutes and a member from the DBT. There are more than 230 IBCs in India, of which 70 deal with agricultural biotechnology. They can approve contained research at institutes unless the research uses a particularly hazardous gene or technique which will require specific approval from the RCGM [29]. In general, these authorities are vested with non-overlapping responsibilities [39, 43].

Under the Constitution of India, it is not the central Government of India but the state governments that exercise formal authority over agriculture. Thus, while the national government may take the initiative in the policy arena and formulate policies concerning agricultural biotechnology and GM crops (in R&D as well as commercialization), as well as being where the decision-making process resides, the agreement and active cooperation of state governments are indispensable for their implementation [44].

The multitude of rules and regulations underline the complexities involved in biosafety as it cuts across ministries and agencies and does not merely govern environmental issues. Most of these regulations deal with GMOs in seclusion without referring to a common agency or secretariat to deal with the risks that are associated with the organism [46], resulting in the biosafety regulations being subjected to criticism both by industry and civil society groups. While

industry associations consider these regulations as affecting their growth, civil society groups consider biosafety regulations as not being strong enough to check the introduction of potentially harmful biotechnology products. Since 2004, there have been serious discussions in India on re-engineering the structure of biosafety regulations. The primary objective of the exercise is to cut down red tape and ensure greater transparency in decision-making. Calls have come for the replacement of the present regulatory system (with its dispersed, unclear, and confusing mandates; responsibilities; and powers) by a new, single, integrated, and professionally led authority, the National Biotechnology Regulatory Authority (NBRA), with a comprehensive mandate and a wide range of responsibilities, with the power to implement the regulatory regime with speed and efficiency [40, 44] and to help the assessment of risks and benefits associated with GM crops in a credible and transparent manner [47]. In May 2007, it was announced that the NBRA will be fully functional in 2 years time and will be administered by the DBT to expedite the application of biotechnology in the agriculture, veterinary, and medicine sectors [48].

The current amendments or changes that have favored the industry relate to changes in the 1998 revised guidelines for research in transgenic plants, whereupon a relaxation was permitted regarding the concept of deliberate release. This amendment, by conferring powers to the RCGM to permit limited conduct of field trials in multi-locations, was at variance with the 1989 Rules that prohibited deliberate or unintentional release for experimental purposes, except where the GEAC approved it as a special case. The distinction between small-scale and large-scale releases brought about by the changed guidelines was unusual and was designed to ensure the control of the DBT and the RCGM over initial field testing of transgenic crops. An amendment was made by the DBT in September 1999 conferring rights to the RCGM to approve small experimental field trials for research, limited to a total area of 20 acres in multi-locations with any one location not exceeding 1 acre. Through this amendment, the DBT removed small experimental trials for research from the deliberate release clause of the 1989 Rules [40].

The changes that have been made to accommodate civil society concerns are basically twofold. The first relates to the formation of the MEC by the DBT in 1998 in order to closely and objectively monitor private sector biosafety data and through the mandatory involvement of state-level agricultural university scientists. The second change, which was induced by the Bt cotton controversy in India, has been the introduction of allergenicity tests of transgenic seeds, leaves, and vegetables on rodents, rabbits, guinea pigs, and goats in the 1998 version of the Biotechnology Safety Guidelines [42]. This precautionary step is viewed by the industry as having contributed to the delay in the regulatory approval for Bt cotton [40]. Additional regulations have recently been added to the PPVFR Act of 2001, requiring applicants to provide relevant GEAC clearances and approvals for registering transgenic varieties, as well as an affidavit stating that the "Terminator" Technology or the Genetic Use Restriction Technology is not involved [52]. Notably, the decision-making circle does not include the participation of industry, civil society, or consumer groups. While the 1989 Rules explicitly say that the RCGM, the GEAC, the SBCCs, and the DLCs may co-opt other members/experts as necessary, they neither include nor exclude representatives of NGOs and the private sector. In practice, however, these non-governmental stakeholders have been excluded [44]. However, following the "Terminator" controversy, the National Bureau of Plant Genetic Resources is now mandated by the government of India to develop probes to detect the presence of terminator genes in imported material, highlighting how the force of public opinion can still shape biosafety rules in India.

To keep up with the rapid pace of developments in plant biotechnology, especially GMOs, the Indian regulatory system revised its existing guidelines in 2008. These were to provide greater clarity on data requirements and include: Standard Operating Procedures (SOPs) for Confined Field Trials of Regulated, Genetically Engineered (GE) Plants [49], Guidelines for the Safety Assessment of Foods Derived from Genetically Engineered Plants [50], and Protocols for Food and Feed Safety Assessment of GE crops [51]. Guidelines for Institutional Biosafety Committees (IBSCs) are also currently under review.

While the overall regulatory system remains unchanged, a notable difference is the classification of all GM field trials into two categories, based on size.

The RCGM, operating in the DBT, is now the regulatory authority for Biosafety Research Level I (BRLI) trials. BRLI trials are limited in size to no more than 1 acre (0.4 ha) per location and a maximum cumulative total of 20 acres (8.1 ha) for all locations for each plant species/construct combination (e.g., one or more events originating from the transformation of a plant species with the same genetic construct), per applicant, per crop season. The GEAC, operating in the MoEF, is now the regulatory authority for Biosafety Research Level II (BRLII) trials. BRLII trials are limited in size to no more than 2.5 acres (1 ha) per location, and the number of locations is decided on a case-by-case basis for each plant species/construct combination, per applicant, per crop season.

Members of the MEC, SBCCs, and DLCs and monitoring teams of SAUs have the authority to inspect and monitor confined field trials at the time of planting, during the growing and harvesting season, and during the period of post-harvest land-use restriction for compliance with the terms and conditions of authorization.

Commercialization of GM Crops: Indian Approval Process

The approval process in India begins with the submission of an application regarding a new LMO event with potential benefits over the conventional variety/hybrid in terms of economic benefit to the farmer and/or the environment. The developer is required to follow a set procedure that involves providing all the necessary information specified by the regulatory body. Such an application is reviewed by the RCGM which, in the first instance, may recommend various limited contained or open field trials to be undertaken in order to generate specific biosafety data which may be lacking in the original submission. Once the full dossier of information from experiments undertaken under confined conditions is submitted, the RCGM will then ascertain as to whether the LMO presents any immediate adverse effects, either to humans, animals, and the environment (including the likely impact of large-scale cultivation on biodiversity). If considered as presenting minimal risk, the RCGM may permit large-scale open field trials to be conducted to generate data concerned with the agronomic performance of the LMO. Once more, possible adverse impacts on the environment, including on non-target organisms, are evaluated. The unconfined, open field trials are conducted either by the applicant or by the ICAR, involving their institutes/State Agriculture Universities, and are monitored by the MEC. The MEC reports their observations directly to the RCGM and the GEAC. Based on the biosafety data and the field performance, the RCGM may recommend the case to the GEAC for further evaluation. The GEAC will consider all the data provided and may ask the company to furnish additional data or repeat the trials in multi-locations during the next season. Based on the overall recorded benefits, the GEAC can approve the commercialization of the GM crop for a limited period and in a specified geographical zone. Data collected during this period will form the basis of the review undertaken by the GEAC for any extension or expansion to the set conditions of commercialization. Any adverse impact on human, animals, and environment derived from such large-scale cultivation is required to be immediately notified by any individual or organization directly to the GEAC.

All commercial authorizations are for a limited period, requiring renewal after the expiry period. Furthermore, approval is conditional upon the observing and collecting of relevant information on the risks, if any, arising from the commercial use of the GMOs and products thereof [42]. A key addition in the 1998 guidelines is the requirement to generate data on comparative economic benefits of a modified plant. Thus, the 1998 guidelines call for a demonstration that a transgenic crop is both "environmentally safe and economically viable." An agronomic evaluation of the transgenic crop to determine economic advantage to farmers is seen as an integral component of the transgenic crop approval process, along with the biosafety evaluation [42]. Thus, when the government granted permission for large-scale field testing of transgenic cotton in India in July 2000 (the first crop to receive such approval), mandatory data to be generated by the applicant included "cost of transgenic seed, projected demand, and the area to be covered under transgenic cotton cultivation" [45].

The Philippines

The Philippines' National Agenda for Sustainable Development for the twenty-first Century (PA 21)

provides the policy framework of the country's strategy for sustainable development. In 2001, the Presidential Policy Statement on Modern Biotechnology [53] reiterated the government policy of promoting the safe and responsible use of modern biotechnology and its products as one of several means to achieve and sustain food security, equitable access to health services, sustainable and safe environment, and industry development. The Philippine government formally funds biotechnology as part of the annual budget for agricultural R&D through legislation [54]. In December 2002, the Philippines became the first country in Asia to commercialize a GM crop for use as food, feed, or for processing [55] when the Department of Agriculture (DA) approved the Bt corn MON810 for import and propagation [56]. By summer 2005, the Philippines had approved 19 different LMOs for direct use as food, feed, or propagation [57], while in 2010, this had increased to 53 (when stacked events are also included).

Regulatory Oversight in the Philippines

The Filipino biotechnology regulatory system was established as a result of the recommendations from the scientists asking the national government to formulate a national policy on biosafety and create a technical body to draft guidelines to ensure that experiments using GMOs do not pose unacceptable risks to human health and the environment [12]. The Philippines has a body of policies aimed at regulating the development, importation, transfer, and use of GMOs. The first guidelines for biosafety were promulgated in October 1990 as Executive Order (EO) 430, which established the National Committee on Biosafety of the Philippines (NCBP). The NCBP was established to "oversee the compliance with policies and guidelines in all institutions, public or private, as well as to coordinate with the appropriate national bodies that have regulatory powers over any violations" [58]. At present, the NCBP is concerned with contained use (confined laboratory and greenhouse experiments on the regulated article), and its primary function is to identify and evaluate potential hazards involved in initiating genetic modification experiments and recommend measures to minimize risks [59]. Additional guidelines were developed and published by the NCBP and the Department of Science and Technology in 1991, 1998, and 2002 before being incorporated into the National Biosafety Framework, which was finalized in 2004 and issued as EO 514 in April 2006 [5, 12]. The rules and regulations for the import and release into the environment of plants and plant products derived from the use of modern biotechnology are set out in Administrative Order no. 8, Series of 2002 of the Philippine Department of Agriculture (AO 8) [35, 55]. The following year, the DA issued Memorandum Circular No. 8, which outlined the import requirements for biotech products. This was quickly followed by the issuance of Memorandum Circulars 11 and 12 in August 2003, which further clarified the import rules for biotech products for direct use as seed, food, feed, or for further processing [57]. Importers of GM plants for contained use, field testing, and propagation (or commercial planting), as well as GMOs for direct use as food, feed, and processing, are required to obtain an approval permit [15, 55] which stipulates that the performance of the GM crop and its effect on the environment as well as human and animal health have been positively assessed [11].

The decision-making process is vested in multiple national competent authorities (NCAs) after consultation with other agencies and/or with a multi-stakeholder advisory body. The Department of Agriculture (DA) is the competent national authority responsible for biosafety decisions concerning plants and plant products derived from modern biotechnology, fisheries and other aquatic resources, domesticated animals and biological products used for animal husbandry or veterinary purposes, and biological agents used for biocontrol. It is the government institution with mandatory responsibility for GM crop field releases and commercialization. Likewise, the Department of Science and Technology is responsible for research and development, the Department of Health for pharmaceuticals which are not addressed by other relevant international agreements or organizations, and the Department of Environment and Natural Resources concerning regulated organisms intended for bioremediation, the improvement of forest genetic resources, and wildlife genetic resources, and applications of modern biotechnology with potential impact on the conservation and sustainable use of biodiversity [12].

Commercialization of GM Crops: Filipino Approval Process

In consultation with the NCBP, the Bureau of Plant and Industry (BPI) of the DA is responsible for the granting of permits issued under AO 8 and are classified according to the intended use of the regulated article: (a) importation for contained use, (b) field testing, (c) release for propagation, and (d) importation for direct use as food or feed or for processing [61]. Applications for import must be accompanied by a certificate from the competent authority in the country of origin stating that the regulated article has been locally approved and a notification in accordance with international obligations. Local applications must be supported with the necessary technical and scientific dossiers, a public information sheet (PIS), and a certificate from the BPI stating that the regulated article has undergone satisfactory field testing in the Philippines. The AO 8 policy for commercial propagation stipulates that no regulated article will be released unless (a) field testing showed that the GM crop will not pose any significant risks to the environment, (b) food and/or feed safety studies showed that the GM crop will not pose any significant risks to human and animal health, and (c) a permit for propagation has been secured from the DA. If the GM crop has transgene-derived pesticidal properties, it must also be duly registered with the Fertilizer and Pesticide Authority (FPA) [61]. Upon receipt of an application, the BPI has 5 days to process and evaluate all of the documentation to ensure that it is sufficient in form and substance. If it is found to be defective, then the applicant is given a 60-day grace period to correct or provide further necessary information. Only a complete application will be accepted for evaluation by a multi-stakeholder advisory body, the results of which must be reported to the BPI within 30 days of acceptance. For the duration of the evaluation process, the reviewers remain anonymous to both the public and the BPI. The Scientific and Technical Review Panel (STRP) and the Bureau of Agriculture and Fisheries Products Standards (BAFPS) evaluate all applications; the STRP comprises of at least three experts from a roster of independent scientists and particularly evaluates the risk assessment and risk management strategies outlined by the applicant, whereas the BAFPS will make a determination of compliance with food-safety standards. Additionally, the Fertilizer and Pesticide Authority (FPA) and the Bureau of Animal Industry (BAI) will also evaluate applications of those regulated articles which are also pest-resistant plants or to be used as feed, respectively. Concurrently, the applicant must carry out a public consultation by publishing the PIS in two newspapers of general circulation and inviting the public to make comments directly to the BPI within 60 days of posting the notice. A decision, together with any agreed permit conditions, is made within 120 days of publication of the notice [62]. Approved products are then included in the registry for direct use maintained by the BPI. Once in the registry, for imported articles, the applicant is no longer required to secure an import permit for succeeding shipments. However, a notification of shipment to BPI is required within 15 days before its arrival at a Philippine port [57].

South Africa

South Africa is a biotechnology leader in Africa and is involved in sophisticated biotechnology activities, including those pertaining to the development and commercialization of GMOs [6, 63]. In 2000, the South African government began to focus on, and substantially increased, its research support for biotechnology. This led to the adoption of the 2001 National Biotechnology Strategy (NBS), a policy framework to create incentives for the biotechnology sector [63], involving several government departments [64]. The NBS commits more than US$300 million per year from government to finance a variety of biotechnology initiatives [6].

South Africa is among only three African countries in which GM crops are commercially grown [2]. In 2006, the commercial release of insect-resistant (Bt) cotton and maize; herbicide-tolerant (RR) soybeans, cotton, and maize; and cotton with the "stacked gene" (Bt and RR) had been approved. At the time, it was estimated that these GM crops accounted for the cultivation of 30.5% of yellow maize, 28.8% of white maize, 59% of soybean, and 90% of cotton in South Africa [65]. The total area of commercialized transgenic crops increased in 2010 to 2.2 million hectares [2], which is mostly due to white and yellow maize, followed by RR soybeans and insect-resistant cotton. Giving an insight

into potential future commercial releases, several varieties of these crops were also in field trials as of 2009, along with additional new crops. Between January and September 2009, the number of field trial permits issued totaled 267 [3]. Maize topped the list with 222 approvals, followed by 24 permits for cotton, 15 for vaccines, 3 for soybeans, and one each for sugar cane, sorghum, and table grapes. The traits associated in these approvals included drought tolerance and herbicide tolerance in maize, herbicide tolerance in cotton, biofortified sorghum, fungus resistance in table grape, alternative sugar production pathways in sugar cane, and cassava with altered starch content.

Regulatory Oversight in South Africa

Concerns regarding the commercial release of GMOs led to South Africa enacting legislation to regulate the development, importation, and application of GMOs. The Genetically Modified Organism Act 1997 (GMO Act) was passed in 1997, and it was subsequently modified in 2006 to bring it in line with the CPB [66]. Regulations for its implementation were initially adopted in 1999, and then, amended regulations took effect in February 2010. The formal structures for the implementation of this act include an Executive Council, which reviews applications for GMO work; a scientific advisory committee (South African Committee for Genetic Experimentation [SAGENE]); a registrar to administer the GMO Act; and an inspectorate to monitor function. According to the legislation, no person may import or export from South Africa, or develop, produce, use, release, or distribute any GMO in South Africa, other than under a permit for undertaking such an activity [67]. Such a permit is to be issued after a technical assessment and risk analysis report has been submitted by the applicant and has been approved by the Executive Council. This Council is responsible for making regulatory decisions and is comprised of ten members: one representative from each of eight government ministries (Agriculture, Science and Technology, Health, Environmental Affairs and Tourism, Trade and Industry, Labour, Water Affairs and Forestry, and the Department of Arts and Culture), the chair of SAGENE who provides scientific and technical analysis of risk assessment data, and the GMO Registrar [68]. The GMO Regulations provide that an applicant shall notify the public of any proposed release of GMOs prior to the application for a permit for such release. Public notifications shall be in the form of a standard notice published in the printed media informing the public of the intended release. It is worth noting, however, that the first field trials were allowed in 1994, and since 1997, several multinational companies have been permitted to grow and import GMOs even before the GMO Act was belatedly implemented in November 1999 [63, 69].

Commercialization of GM Crops: South African Approval Process

Commercial activities concerning GMOs all require a permit, including those for: import, export, contained use (including development, production, distribution, transport, but not those under containment levels 1 & 2, i.e., in the laboratory or growth chamber), deliberate release of GMOs into the environment (trial and general release), and commodity clearance [70]. All applications must be submitted to the GMO Registrar at the DA, along with a copy of the public notice and proof (newspaper clippings) in order for the application to be processed. The public notice allows interested parties to submit comments or objections in connection with the intended release to the Registrar within 30 days after the date of the notification [71]. The Registrar then undertakes an initial review of the application to determine compliance with the provisions of the GMO Act. If the application is not compliant, the application is referred back to the applicant. Once compliant, the application is forwarded to a committee (expertise nominated by SAGENE chairperson) formed under SAGENE to conduct a review of the proposed activity. The review includes an evaluation of the risk assessment data, including food safety (if applicable), submitted in the application. Conclusions of the assessment are detailed in a recommendation report, which is sent to the Registrar on completion of the review. At this stage, the application can be referred back to the applicant to address any concerns raised or to supply additional information, and the response returned to the committee. Once all concerns have been addressed, the committee makes a recommendation on the application. The recommendation document, public input, and a copy of

the application is forwarded to the Executive Council for consideration, who will also take into account the socioeconomical impact that the GMO may have. The Council then submits its decision in writing to the Registrar. Should the Council raise any concerns, the Registrar will once again refer the application back to the applicant for clarification. Based on the information received from the applicant and the assessment done by the Council, the application will be approved or rejected. If the application is approved, the Council authorizes the Registrar to issue a permit to the applicant. This permit will be accompanied by specific containment conditions as prescribed by the Council. If the application was rejected, the Registrar will communicate the decision back to the applicant with reasons for the rejection [70]. Regulations of the Department of Health of 2004 provides for the labeling of foodstuff with genetically modified ingredients that are significantly different to the non-GMO ingredients. The Consumer Protection Act of 2008 also addresses this issue.

United States of America (USA)

In the USA, GM crops have been sold since 1994 and in 2006 were already planted on 54.6 million hectares (soybean, maize, cotton, canola, squash, papaya, and alfalfa), confirming the USA's role as the world leader in agro-biotechnology [10]. The regulatory system in the USA relative to biotechnology products is rather different from the one put in place in the EU, and the discrepancies mainly reflecting the different approaches taken by the governmental authorities, citizens, and firms toward GMOs and GM food, especially in the initial years of the biotechnology revolution.

In the USA, agricultural biotechnology politics has been dominated by a strong and cohesive coalition of pro-biotechnology upstream and downstream producers and farmers. Lower public outrage has made mobilization of NGOs in the United States difficult and, in combination with a less-favorable institutional environment (notably, centralized regulatory policy-making), has resulted largely in their exclusion from agri-biotech policy-making [72].

Regulatory Oversight in the USA

Taking the approach that GM products are essentially an extension of conventional products, the US Government has made use of existing laws to ensure the safety of GM products [15]. US regulatory authorities operate under the assumption that the fact that a plant has been genetically modified is less important than the specific effects of the modification [4]; therefore, the regulation focuses on the characteristics of the products rather than the way in which the product was produced [35]. The current system was delineated by the White House Office of Science and Technology Policy under the 1986 Coordinated Framework for Regulation of Biotechnology [73]. It is still the key document for regulating gene technology in the United States and provides the basis for the regulation of crop varieties produced by rDNA techniques. Under the Framework, the US Department of Agriculture (USDA), the Food and Drug Agency (USFDA), and the Environmental Protection Agency (USEPA) that were responsible for regulatory oversight of certain product categories or for certain product uses are also responsible for evaluating those same kinds of products developed using genetic engineering techniques. Transportation, growing (including field testing), and propagation of GM crops are governed by the USDA's Animal and Plant Health Inspection Service (APHIS) under the Federal Plant Pest Act 1996 (FPPA) and the National Environmental Policy Act 1969. Specifically, the APHIS has two responsibilities: deciding on which GM seeds to oversee, so-called regulated articles, and which GM seeds are safe enough to be free from the agency's oversight, so-called deregulated articles. Deciding on GM seeds to be regulated depends on "familiarity," gained from direct experience through field testing under regulated conditions. Any eventual deregulation, that is, exempting a GMO from the oversight of APHIS, involves a petition process whereby an advertisement is published in the US Federal Register, and a period to comment is provided to the public [74].

If a GM plant is not intended for human consumption and is not modified to contain a pesticide, the USDA is the leading agency. For plants genetically modified to produce their own pest protection, APHIS coordinates its evaluation with the USEPA. Pest-resistant GM crops fall under the authority of the USEPA under the Federal Insecticide, Fungicide, and Rodenticide Act 1996 (FIFRA) and the Toxic Substances Control Act 1976. They are subject to a strict

testing regime, where producers must submit testing data to the USEPA who determines the quantity of pesticidal substances that may be present in food [75]. In fact, industry is required to obtain an Experimental Use Permit (EUP) from the USEPA to test any pest-resistant plant in a field larger than 10 acres. Once the permit is granted, firms are expected to consult the USEPA on the details of the field experiment. While the APHIS analyzes data on the source of the new gene, the nature of the pesticidal substance produced, differences with its natural equivalent, effects on non-target organisms, and environmental fate, the USEPA focuses on the toxicology, the digestive fate, and the potential allergenicity of the toxin. In line with the product-based approach, the USEPA does not assess the GM plant per se but the toxin produced by the plant. As for any pesticides, the USEPA subjects these toxins to a registration process. Pest-resistant plants whose toxin falls under this process are mostly of the Bt variety. Following this registration logic, if the toxin produced by a GM plant has been approved previously as a regular pesticide, a new registration is not required. The USEPA has been requesting for years new regulations to obtain a wider role in the assessment and the management of GM plants, but thus far with only limited success [11, 72, 74]. The US Food and Drug Administration (USFDA) regulates food applications of GM crops and relies on existing laws that hold food manufacturers responsible for food safety. Of the three agencies, the USFDA has had the most influence on biotechnology policy because most biotechnology products on the American market are health care or food products [72]. In 1999, public meetings were held by the agency with the aim of sharing its experience regarding GM foods and soliciting views on whether its policies and procedures should be modified. Public comments indicated considerable public support for a mandatory and more transparent process [4].

Commercialization of GM Crops: US Approval Process

The APHIS oversees the confined and unconfined release of transgenic plants as well as any importation and interstate movement under the FPPA. In addition to the FPPA, the USDA issued rules in 1987 for the "introduction of organisms and products altered or produced through genetic engineering which are plant pests or which there is reason to believe are plant pests" [76]. By these rules, the introduction of a crop produced by rDNA techniques into the environment is only legal with an authorization by the APHIS. The APHIS grants a release permit after preparing an environmental impact assessment and "Finding Of No Significant Impact" ("FONSI"). Exempt from these rules are experiments with plants produced by rDNA technology in a contained environment (e.g., laboratory, green house).

In 1997, the USDA simplified the procedure for the unconfined release of GM crops into the environment by allowing the applicant to petition the APHIS for a "determination of non-regulated status" [77]. When receiving a petition, the APHIS prepares an environmental impact assessment taking into account the following eligibility criteria:

- The crop must not be listed as noxious weed or weed.
- The introduced genetic material must be stable and characterized.
- The introduced genetic materials must not
  - Result in any plant disease
  - Confer an infectious entity or encode toxic substances to non-target organisms
  - Encode products intended for pharmaceutical use
- Any plant virus-derived sequences must not pose a significant risk for new plant virus creation.
- The GM crop must be free of known human and animal pathogens or allergens.

After a complete petition is filed, it is published in the Federal Register to solicit comments from the public. Thereafter, the APHIS reviews the data, taking into account public comments and takes a final decision, which is again announced in the Federal Register. The issuance of a "non-regulated" status for a transgenic crop means that it is deregulated and can be freely commercialized in the US (unconfined release, import, interstate movement), except if it contains a pesticidal substance. In that case, an additional "plant pesticide" approval by the USEPA is required.

The responsibility of the USEPA is to evaluate the risks of GM crops "producing their own pesticide" for

human consumption under the FIFRA. The evaluation process is held to the same standards as those for pesticides applied to plants. To be registered under the FIFRA, a pesticide must not cause "unreasonable adverse effects" on the environment and on human health [78]. Transgenic insect- and virus-resistant plants fall under the jurisdiction of the USEPA; however, viral coat proteins are normally exempted from the requirements as the USEPA considers these proteins as "low-risk applications" based on the principle of familiarity and their ubiquitous presence in the food supply. Today, Bt toxins, one viral coat protein, and the potato leaf roll virus protein are registered as pesticides and supervised by the USEPA. The agency evaluates the risks of these "plant-incorporated protectants" by taking into account the following criteria: toxicological effects, effects on non-target organisms, insect resistance management, and persistence of the substance in the environment. The evaluation process lasts approximately 1 year. If adverse effects of insect- or virus-resistant plants are observed after commercialization, the USEPA has the legal power to amend existing registrations. Moreover, the USEPA may impose new measures such as new pest resistance schemes [79].

Besides the pesticide registration under FIFRA, Section 408 of the FFDCA requires the USEPA to determine tolerance limits for substances used as pesticides on and in food and feed [78, 80]. "Nucleic acids that are part of a plant-incorporated protectant" are exempted from this requirement because the USEPA considers them as "safe" [80]. Once approvals from the APHIS, and from the USEPA when pesticidal substances are used, have been granted, it is legal to commercialize the GM plant or derived product in the USA. However, applicants normally engage in a voluntary consultation process with the USFDA before marketing of the GM plant or derived products. This policy is now under review.

International Obligations Relevant to the Biosafety Frameworks

Countries do not have complete discretion when deciding how to set up their biosafety regulatory system as there are several international treaties and agreements that relate to biosafety. If a country is bound by any or all of those international agreements, then their biosafety regulatory system must be compliant with those obligations [81].

Cartagena Protocol on Biosafety

The conclusion of the CPB was broadly recognized as a step forward in providing an international regulatory framework to reconcile trade with environmental protection by creating an enabling environment for the environmentally sound application of biotechnology [82]. The Convention on Biological Diversity (CBD) [83] in Article 19 [3] states that:

- The Parties shall consider the need for and modalities of a protocol setting out appropriate procedures, including, in particular, advance informed agreement, in the field of the safe transfer, handling and use of and living modified organism resulting from biotechnology that may have adverse effect on the conservation and sustainable use of biological diversity.

In 1995, the second Conference of the Parties (COP) to the CBD began the consideration of the need for and modalities of such a protocol. COP Decision II/5 commenced the negotiations for the protocol by launching an open-ended ad hoc Working Group on Biosafety [1]. Meeting six times between 1996 and 1999, the Working Group concluded its work with the submission of a draft protocol for consideration by the first extraordinary meeting of the COP, convened with the purpose of adopting a protocol on biosafety to the CBD. The result of this first extraordinary meeting, which took place in two separate meetings in 1999 and 2000, was the adoption of the Protocol [84]. In accordance with its Article 36, the Protocol was opened for signature by States and regional economic integration organizations from 15 to 26 May 2000 and remained open for signature from 5 June 2000 to 4 June 2001. By that date, the Protocol had received 103 signatures. The Protocol entered into force on 11 September 2003, 90 days after receipt of the 50th instrument of ratification [85]. There are presently 160 parties to the Protocol [86], with the COP to the CBD serving as the meeting of the Parties to the Protocol (COP-MOP), the Protocol's governing body. Since the coming into force of the Protocol, the COP-MOP has met five times. The fifth meeting of the

COP-MOP took place from 11 to 15 October 2010 in Nagoya, Japan, and it approved a Supplementary Protocol on Liability and Redress to the Cartagena Protocol on Biosafety [87].

The Protocol's scope is the "transboundary movement, transit, handling, and use of all living modified organisms that may have adverse effects on the conservation and sustainable use of biological diversity, taking also into account risks to human health" [82]. To ensure the safe transfer, handling, and use of GMOs, the Protocol sets up two separate procedures. The first time that a GMO is to be intentionally introduced into the environment, the Protocol sets up an Advance Informed Agreement (AIA) procedure. That procedure requires that the exporter of the GMO provides a notice with detailed information about the GMO to the importing country. The importing country then reviews the information, conducts a risk assessment, and decides, based on the risk assessment results, whether to approve or reject the GMO. The second procedure set up by the Protocol is for GMOs to be used for food or feed or for processing (such as corn, soybeans, wheat, or other grains that will be fed directly to humans or animals or used for processing). For those GMOs, the AIA procedure is not required. Instead, the Protocol establishes a simpler system that reflects the decreased likelihood that those GMOs will affect the importing country's biodiversity. Before the GMO can be exported to another country, the only requirement is that the safety decision in the exporting country is communicated to other countries through the Biosafety Clearing-House. For LMOs used for other purposes, such as LMOs used in the laboratory, the Protocol leaves any regulation to the discretion of the individual country. The Protocol also does not cover products derived from LMOs, such as processed foods that have ingredients that came from LMOs. Although the Protocol comprehensively covers many issues, there are a few remaining to be addressed by the individual Party when establishing their biosafety regulatory regime [81].

In addition to the CPB, other relevant international agreements exist. Under international law, countries shall comply with all treaties to which they are parties, provided that the provisions of these treaties are not contradictory (principle of accumulation of international obligations). According to the principle of integration contained in the Rio Declaration on Environment and Development (Principle 4) and the 2002 Plan of Implementation of the World Summit on Sustainable Development (Paragraph 92), environmental treaties and trade goals shall mutually support each other. In fact, the various agreements and instruments on the topic of the development and use of agrobiotechnology are all closely interrelated and need to be carefully considered in the decision-making process, both individually and collectively. This regulatory and public policy background consists of relevant international instruments and processes, such as: the entry into force of the CPB, the Codex Alimentarius Guidelines on Food Safety and Labelling of GMOs, and the World Trade Organization (WTO) Agreements on Sanitary and Phytosanitary Measures and Technical Barriers to Trade. Table 1 presents a summary of the main international instruments and processes of relevance for biosafety.

A Comparative Analysis of Regulatory Processes in All Study Countries

Attributes of a Modern Regulatory Biosafety System

Although the development of regulatory regimes is essentially based on national specific practices, legal systems, public management strategies, and local socioeconomic considerations, national regulatory biosafety frameworks will generally always consider the following elements [110–112]:

- Biosafety policy, occasionally as part of a broader biotechnology or biodiversity policy
- Regulatory policy
- A mechanism to handle requests and permits related to LMO use, in particular, notifications required by the CPB (i.e., an administrative system)
- A mechanism for monitoring and inspections
- A system that allows public participation and information

According to Jaffe [113]:

> The purposes of a national biosafety regulatory system are to scientifically assess the safety of genetically engineered (GE) organisms to humans and the environment, manage any potential risks, and authorize the development and marketing of safe GE organisms and

Commercialisation of GM Crops: Comparison of Regulatory Frameworks. Table 1 Relevant international instruments and processes (Taken from [88])

Agreement, declaration, or process	Content
Rio Declaration on Environment and Development	The precautionary principle is a fundamental instrument for the safe use of biotechnology. This principle is contained in Principle 15, which sets forth that: "*In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation*".
United Nations Environment Program – International Technical Guidelines for Safety in Biotechnology	Enacted in Cairo in 1995, these guidelines may assist governments, intergovernmental organizations, private organizations, and others to strengthen capacities and exchange biosafety information.
	The guidelines are based on the following principles: (a) identification of hazards; (b) risk assessment, taking into account the probability of any hazards arising and the potential consequences of such hazards; and (c) risk management, applying adequate management strategies which include developing procedures and methods to minimize risks and their consequences, or making decisions not to proceed. Such management strategies shall be proportional to the risk assessment results.
World Trade Organization (WTO) Agreement	The WTO Agreement recognizes the goal of sustainable development, considering that free trade shall protect and preserve the environment [89]. There are three WTO Agreements which can be associated with GMOs: The Agreement on the Application of Sanitary and Phytosanitary Measures (SPS; [90]), the Agreement on Technical Barriers to Trade (TBT; [91]), and the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS; [92]). It is also important to understand the regulations and procedures that govern Dispute Settlement Understanding (DSU) in the WTO context [93].
Agreement on Technical Barriers to Trade (TBT)	The TBT Agreement is relevant to biotechnological products as it applies to technical regulations and rules, including requirements for packaging and labeling [91]. The TBT Agreement recognizes that no country shall be prevented from taking necessary measures to ensure the quality of its exports, the prevention of deceptive practices, and the protection of the environment and human, animal, and plant life or health. However, such measures shall not be taken as means of arbitrary or unjustifiable discrimination between countries, where the same conditions prevail, or as disguised restrictions on international trade. Furthermore, such measures must otherwise comply with the provisions of the Agreement [91].
The Agreement on the Application of Sanitary and Phytosanitary Measures (SPS)	SPS rules are summarized in the following manner [90]: 1. Members have the right to take necessary sanitary and phytosanitary measures to protect human, animal, and plant life or health, provided that such measures are not inconsistent with the provisions of the Agreement. 2. Any sanitary or phytosanitary measures are applied only to the extent that is necessary to protect human, animal, and plant life or health, based on scientific principles. Furthermore, such measures cannot be maintained in the absence of sufficient scientific evidence of their necessity. 3. Members shall ensure that their sanitary and phytosanitary measures do not arbitrarily or unjustifiably discriminate between members among whom identical or similar conditions prevail. Moreover, sanitary and phytosanitary measures shall not be applied in a manner that would constitute a disguised restriction on international trade.

Commercialisation of GM Crops: Comparison of Regulatory Frameworks. Table 1 (Continued)

Agreement, declaration, or process	Content
	4. Sanitary or phytosanitary measures, which are taken in accordance with the relevant provisions of the Agreement, are presumed to comply with the members' obligations under GATT 1994, which relate to the use of sanitary or phytosanitary measures, in particular, the provisions of Article XX(b) [94]. 5. In principle, members shall base their sanitary or phytosanitary measures on international standards, guidelines, or recommendations, where these exist. 6. Sanitary or phytosanitary measures which comply with international standards, guidelines, or recommendations are deemed necessary to protect human, animal, and plant life or health and are presumed to be consistent with the relevant provisions of GATT 1994 [94] and the SPS Agreement [90]. 7. Members may introduce or maintain sanitary or phytosanitary measures which result in a higher level of sanitary or phytosanitary protection than the level that is required by the relevant international standards, guidelines, or recommendations, provided that there is a scientific justification to this heightened level of protection or that this level of protection is determined by a member country to be appropriate according to Article 5 of the SPS Agreement regarding risk assessment and adequate protection levels [90]. However, measures which result in a heightened level of sanitary or phytosanitary protection need not go against any other provisions in the Agreement. The above-mentioned standards, guidelines, and recommendations are defined as those established by international organizations, such as the Codex Alimentarius Commission, the Office International des Epizooties, and the Secretariat of the International Plant Protection Convention. As for other subjects that are not within the scope of the aforementioned organizations, they shall be regulated by "other international organizations" identified by the WTO Committee on Sanitary and Phytosanitary Measures as being open to the Parties' membership.
The Codex Alimentarius	Created by the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) of the United Nations, the Codex Alimentarius (http://www.codexalimentarius.net) is the organization which is in charge of establishing regulations related to food safety. Codex Alimentarius standards need to ensure fair trade practices in food trade, according to WTO rules. The Codex Alimentarius Commission established an Ad Hoc Intergovernmental Task Force on Food Derived from Biotechnology [95] to handle issues associated with food obtained through biotechnological processes, particularly food used for health and nutrition purposes. In July 2003, the Codex Alimentarius Commission held a meeting during which three risk assessment standards for food resulting from biotechnology were approved [96]. These standards establish risk assessment principles for food derived from modern biotechnology. The principles refer to the concept of "tracing," which is a risk assessment tool whose meaning is the subject of an important debate. In fact, the United States of America consider this concept to be different from traceability and limit themselves to following only the previous and subsequent link in the LMO movement chain. The approved standards are the following: – Principles for the Risk Analysis of Foods Derived from Modern Biotechnology [97] – Guideline for the Conduct of Food Safety Assessment of Foods Derived from – Recombinant-DNA Plants [98] – Guideline for the Conduct of Food Safety Assessment of Foods Produced Using Recombinant-DNA Micro-organisms [99]

Commercialisation of GM Crops: Comparison of Regulatory Frameworks. Table 1 (Continued)

Agreement, declaration, or process	Content
	In 2008, the Ad Hoc Intergovernmental Task Force on Food Derived from Biotechnology completed a Guideline for the Conduct of Food Safety Assessment of Foods Derived from Recombinant-DNA Animals [100]. At its 31st session, the Commission noted that the Task Force had completed its work, one year ahead of schedule, and agreed to its dissolution [101]. Likewise, the Codex Committee on Food Labelling is working on draft guidelines for the Labelling of Food and Food Ingredients Obtained through Certain Techniques of Genetic Modification/Genetic Engineering, as well as on a Draft Amendment to the General Standard for the Labelling of Pre-packaged Foods (in order to address the issue of genetically modified foods) [102]. Finally, in 2007, the Codex Alimentarius Commission adopted the "Working Principles for Risk Analysis for Food Safety for Application by Governments" that were proposed by the Codex Committee on General Principles [103]. These principles allude to the precautionary approach. For more information on Codex activities, see www.codexalimentarius.net.
International Plant Protection Convention (IPPC)	The IPPC (https://www.ippc.int/) aims to prevent the international spread and introduction of pests of plants and plant products and to promote appropriate measures for their control. The Convention was reviewed in 1997 and entered into force in 2005 [104]. A Commission Working Group studied plant pest risks associated to LMO issues and an international standard (ISPM No.11 pest risk analysis for quarantine pests, including analysis of environmental risk and LMOs) [105]. This text intends to protect plants and ecosystems from LMO-related risks. According to the text, such protection measures should be cost effective, nondiscriminatory, and feasible and should not limit basic trade needs.
World Organization for Animal Health (OIE)	The World Organization for Animal Health, also known as the Office International des Epizooties (OIE; http://www.oie.int/), is an intergovernmental organization created by the International Agreement signed on 25 January 1924. OIE's mission is to ensure the transparency of animal health conditions worldwide. Member countries promise to declare animal diseases detected on their territory. In addition, the OIE is in charge of safeguarding international trade through the elaboration of health regulations destined to be applied to international transboundary movements of animals and animal products. The WTO recognizes such regulations as international reference rules.
Regional International Organization for Plant Protection and Animal Health (OIRSA)	In 2000, the Regional International Organization for Plant Protection and Animal Health (OIRSA; http://www.oirsa.org) produced a Regional Guideline on the Safety of Plant Biotechnology [106]. In fact, the Guideline is based on the CPB and essentially regulates the same issues as the Protocol. However, in view of its nature, the guideline also aims to harmonize the various regional laws and practices pertaining to the issue of biosafety.
Central American Commission for Environment and Development (CCAD)	The Central American Commission for Environment and Development (CCAD), which is the environmental authority of the Central American Integration System (SICA), through its biodiversity program and territorial legal system, prepared a Central American Protocol on the Safety of Modern Biotechnology. A series of technical consultations was undertaken and led to the adoption of a draft Protocol, which was then approved by the Central American Ministries of Environment in 2002. Although the Central American Protocol is based on the CPB, some of its provisions go beyond the scope of the CPB. In fact, provisions regarding labeling, documentation, liability, contained use, and transit, as well as various biosafety principles, have been included in the Central American Protocol in an attempt to avoid the inconsistencies and ambiguities which resulted from the multilateral negotiations that lead up to the adoption of the CPB.
