downregulated after capsaicin or RTX treatment, the expression of an endogenous analgesic peptide galanin is increased. Moreover, increased neuronal nitric oxide synthase (nNOS) and cholecystokinin receptor-B (CCK-B) levels were observed in the RTX-treated animals (Burliński et al. 2011). Collectively, these changes were termed "vanilloid-induced messenger plasticity" (Szallasi and Blumberg 1999). It was postulated that vanilloid treatment alters the phenotype of sensory neurons from proinflammatory to analgesic/anti-inflammatory. Thus, vanilloid-induced messenger plasticity may represent a major mechanism of desensitization.

8 Vanilloids and Mitochondrial Dysfunction

In cultured DRG neurons, there is a clear separation between concentrations at which capsaicin activates TRPV1 (ED_{50}<100 nM) and at which it becomes neurotoxic (30–100 μM) (Chard et al. 1995; Wood et al. 1988). Moreover, capsaicin was reported to kill a variety of non-neuronal cells such as in human B-cells, mouse myeloid cell lines, and Jurkat T-cells as well as squamous cell carcinoma cell lines (Wolvetang et al. 1996; Macho et al. 1999; Lee and Surh. 1998; Hail and Lotan. 2002). Capsaicin-induced apoptosis was also described in rat thymocytes (Amantini et al. 2004). It is still hotly debated if these non-neuronal cells express functional TRPV1. For example, in dendritic cells, both the presence and absence of TRPV1 were reported (O'Connell et al. 2005; Tóth et al. 2009).

The effect of capsaicin on cell death seems to be either specific (TRPV1 mediated) or nonspecific (not mediated by TPV1) in nature. Capsaicin can cause apoptosis or necrosis depending on the dose applied. In cultured rat DRG cells, capsaicin causes apoptosis by increasing the intracellular Ca^{2+} concentration, enhancing mitochondrial Ca^{2+} accumulation, dissipation of the inner transmembrane potential ($\Delta\psi_m$), activation of Ca^{2+}-sensitive proteases, and DNA fragmentation (Dedov et al. 2001). Capsaicin evokes similar signalling events in transformed and mitogen-activated T-cells (Macho et al. 1999) and in human and rat glioblastoma cells (Bíró et al. 1998; Lee et al. 2000).

The intercellular Ca^{2+} homeostasis is maintained by Ca^{2+}-binding proteins present in cytoplasm, endoplasmic reticulum (ER), and mitochondria (Kostyuk and Verkhratsky 1994; Svichar et al 1997; Verkhratsky and Petersen 1998). The elevated intracellular Ca^{2+} triggered by capsaicin leads to activation of Ca^{2+}-dependent enzymes such as different phospholipases, proteases, and endonucleases that can cause apoptosis in neuronal cells as well as non-neuronal cells (McConkey and Orrenius 1996; Wood et al. 1988). Though in general mitochondria are able to sequester intracellular Ca^{2+}, excess Ca^{2+}-influx into mitochondria causes membrane permeability transition (MPT) pore in mitochondrial membrane (Wong et al. 2012). This is considered as prototypical inducing factor. This MPT allows water and other small molecules to infiltrate inside the mitochondrial matrix which leads to osmotic swelling of mitochondria and may cause physical rupture of mitochondrial membrane (Green and Reed 1998; Bernardi 1992; Crompton 1999; Kroemer and Reed 2000).

However, several reports suggest that vanilloids may exert effects which are independent of Ca^{2+}-influx and TRPV1 receptors. This is due to the fact that capsaicin has significant effects in biological systems that are much lower in the phylogenetic tree and do not contain TRPV1. For example, capsaicin acts as inhibitor for organisms such as *Paracoccus denitrificans*, *Escherichia coli*, and *Thermus thermophilus* HB-8 where it affects ubiquinone reduction by NADH (Yagi 1990). Not only pure capsaicin, other vanilloids such as dihydrocapsaicin and RTX can also act as inhibitor of NADH oxidase (Wolvetang et al. 1996). Indeed, these inhibitors are able to induce apoptosis in human B-cell and mouse myeloid cell line (Wolvetang et al. 1996). In contrast, it was shown that in organisms which do not have the energy transducing site, such as in *Saccharomyces cerevisiae* mitochondria and *Bacillus subtilis* membranes, capsaicin does not inhibit NADH-ubiquinone reductase, suggesting that mitochondria can be a potential target of capsaicin action (Yagi 1990). In addition to mitochondria, recently it has been shown that in hippocampal astrocytes capsaicin can act as an inhibitor of tyrosyl tRNA synthetase and by inhibiting this enzyme, it induces cell death (Cochereau et al. 1996, 1997).

The TRPV1-independent functions of capsaicin mostly indicate the deleterious effect of capsaicin on mitochondria. Earlier research suggests that after the systemic application of capsaicin in the Aβ-type sensory neuron of adult rat as well as neonatal rat leads to mitochondrial swelling and results in the formation of atypical hollow mitochondria (Joó et al. 1969; Szolcsányi et al. 1975; Jancsó et al. 1977; Jancsó and Király 1981; Szöke et al. 1998, 2002). However, the real molecular mechanism behind the formation of hollow mitochondria is not clear. In addition to the TRPV1 receptor-mediated effects, it seems that capsaicin can also exert receptor-independent effects on the mitochondria. Due to its structure, capsaicin can act as analog of coenzyme Q, a lipophilic mobile electron carrier present in plasma membrane and involved in maintaining the redox potential of membrane. Indeed, it has been reported that preincubation of human lymphoblastoid cells with coenzyme Q prevents capsaicin-induced apoptosis (Wolvetang et al. 1996; Macho et al. 2000). It suggests that capsaicin competes for coenzyme Q and alters the redox potential of plasma membrane. Apart from that it has been also reported in transformed and activated T-cells; capsaicin inhibits the plasma membrane NADH oxidoreductase (PMOR), an enzyme that transfers electrons from cytoplasmic NADH to external electron acceptors such as oxygen via coenzyme Q (ubiquinone) (Morré et al. 1995, 1996; Wolvetang et al. 1996; Macho et al. 2000). Capsaicin can also inhibit the NADH:coenzyme Q oxidoreductase (complex I) activity of the mitochondrial electron transport system (Shimomura et al. 1989; Yagi 1990) which causes alteration on the mitochondrial membrane structure and its function (Aranda et al. 1995; Tsuchiya 2001). In vitro experiments in transformed cells as well as in activated T-cells suggest that capsaicin treatment enhances the generation of reactive oxygen species (Macho et al. 1998, 1999; Garle et al. 2000) and depolarization of mitochondrial membrane (Dedov et al. 2001) and apoptosis. Capsaicin suppresses the growth of cancer cells by NF-kB inactivation, reactive oxygen species (ROS) generations, cell-cycle arrest, and modulating EGFR/HER-2

pathways (Hail 2003; Kang et al. 2003; Lee et al. 2004; Min et al. 2004; Surh 2002; Thoennissen et al. 2010). Similarly, RTX was also reported to inhibit the NADH oxidase located in plasma membranes, to generate reactive oxygen species, and to induce apoptosis in transformed cells (Wolvetang et al. 1996; Macho et al. 1999, 2000; Garle et al. 2000). The exact molecular mechanism by which capsaicin causes oxidative stress and apoptosis remains rudimentary (Pramanik et al. 2011).

9 Conclusion

Historically, capsaicin and RTX proved to be invaluable tools in defining a fundamental subdivision of the peripheral nervous system (Appendino and Szallasi 1997; Buck and Burks 1986). Capsaicin-sensitive neurons are peptidergic nociceptive (primary sensory) neurons that express the vanilloid (capsaicin) receptor TRPV1. The activation of these neurons not only transmits painful stimuli to the CNS but also initiates the neurogenic inflammatory response. In turn, neurogenic inflammation was postulated to play a pivotal role in the pathogenesis of diverse diseases states, ranging from migraine through asthma to irritable bowel disease.

What makes capsaicin unique among naturally occurring irritant agents is that the initial stimulation of these neurons is followed by a lasting but fully reversible refractory state (traditionally termed desensitization) or irreversible neurotoxicity. Desensitization to capsaicin has a clear therapeutic potential. Indeed, capsaicin-containing creams and patches have clinical application for decades for indications like diabetic polyneuropathy. Irreversible neurotoxicity can also be exploited for therapeutic purposes. Indeed, at present site-specific RTX injections are undergoing clinical trials to achieve permanent analgesia in cancer patients with chronic, intractable pain secondary to metastatic disease.

Despite the tremendous progress that has been made after the identification and molecular cloning of TRPV1 in understanding capsaicin mechanisms, several outstanding questions remain unsolved. Most important, the exact molecular mechanisms underlying reversible desensitization versus irreversible toxicity are yet to be established. At high concentrations, the specificity of vanilloids for TRPV1 is lost, and the distinction between specific (TRPV1-mediated) and nonspecific (non-TRPV1-mediated) vanilloid actions becomes problematic. As an added complication, the existence of functional TRPV1 receptors in cells other than capsaicin-sensitive primary sensory neurons remains controversial. For example, TRPV1 knockout mice show altered behavior (e.g., reduced fear response) and capsaicin causes extensive neurodegenerative changes in the rat brain; yet, reporter mice show essentially no TRPV1 expression in the brain (Cavanaugh et al. 2011; Marsch et al. 2007; Tóth et al. 2005; Roberts et al. 2004; Starowicz et al. 2008; Goswami et al. 2010). In this context it is worth to mention that involvement of TRPV1 in the regulation of spine morphology and synaptic transmission has been demonstrated (Goswami et al. 2010). Another puzzling example is the keratinocytes present in skin. Keratinocytes were reported to express TRPV1 (both mRNA and protein) and

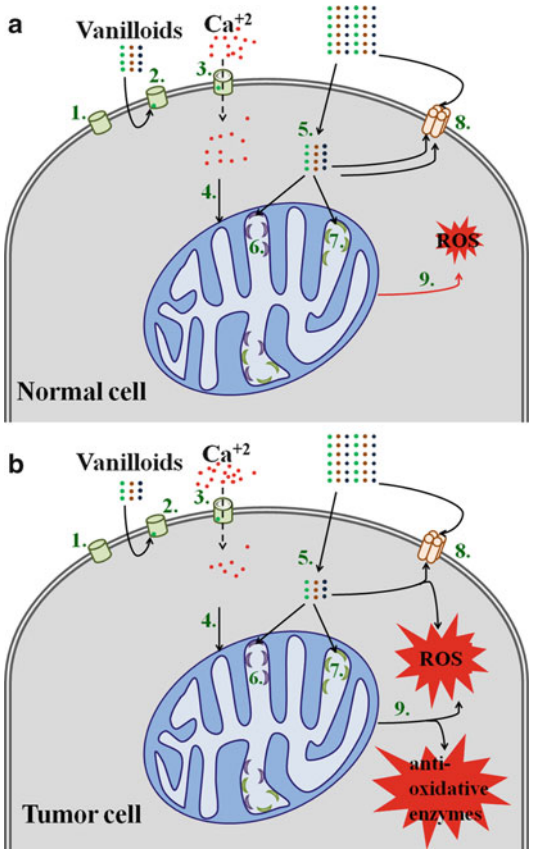

Fig. 1 TRPV1-dependent and TRPV1-independent vanilloid actions in normal cell (**a**) and tumor cell (**b**). TRPV1 present in the plasma membrane can be activated by different vanilloids with different affinities and binding kinetics (*Steps 1–2*). Potent vanilloids such as capsaicin or RTX activate TRPV1 at very low concentration and cause Ca^{2+} influx (*Step 3*). Vanilloids at much higher concentrations can cross plasma membrane and can also act on electron transport chain complex 1 (*ETC1*) and electron transport chain complex 3 (*ETC3*) (*Steps 5–7*). Vanilloids can also act on the coenzyme Q and PMOR (*Steps 8–9*). All these factors result in production of ROS (*Step 10*) relevant for neurotoxicity

respond to capsaicin with Ca^{2+}-uptake (Southall et al. 2003; Lee et al. 2008; Pecze et al. 2008). Yet, capsaicin evokes no responses in the rat skin after skin denervation (Fig. 1).

The mechanisms responsible for the marked species-related differences in vanilloid actions are only partially understood. It is now clear that birds do not respond to capsaicin because the avian TRPV1 receptor lacks the functional vanilloid-binding motif of mammalian TRPV1 receptors. However, it remains a mystery why the pulmonary chemoreflex is differentially regulated by RTX in rats (desensitization without prior excitation) and cats (repeatable excitation with no desensitization). However, much more and detailed studies are needed to characterize vanilloids for therapeutic applications in near future.

Abstract

Like many other diseases, Parkinson's disease (PD) requires preclinical models to understand the underlying molecular and cellular mechanisms that cause the disorder. Such models will also help to identify novel potential drug targets and to elucidate the effects of new drug candidates. The hydroxylated analogue of dopamine, 6-hydroxydopamine (6-OHDA), has been exploited as an experimental model to study PD. It also has been used extensively as a test system for novel symptomatic agents and for assessment of neuroprotective and neurorepair strategies. The 6-OHDA lesioned rat appears to be a good predictor for monitoring the efficacy of new dopaminergic drugs that enter phase II/III clinical trials. The aim of this chapter is the molecular and cellular mechanisms that are involved in the preclinical model of Parkinson's disease based on 6-OHDA. With special attention, we address the role of second messengers as the role of reactive oxygen species and the mitochondria as the headquarters of cell death. The role of molecular signaling pathways, for instance, the participation of Bcl-2 family members, will also be addressed.

List of Abbreviations

6-OHDA	6-hydroxydopamine
Bak	Bcl-2-antagonist/killer
Bax	X Bcl-2-associated protein
DA	Dopamine
GSH	Glutathione
MCC	Multiple conductance channel
MOMP	Permeabilization of the mitochondrial outer membrane
PD	Parkinson's disease
PTP	Permeability transition pore
ROS	Reactive oxygen species
$\Delta\Psi m$	Mitochondrial membrane potential

1 Introduction

6-Hydroxydopamine (6-OHDA), also known as oxidopamine, or 2,4,5-trihydroxyphenethylamine ($C_8H_{11}NO_3$) is a toxic oxidative metabolite of dopamine and is detected in the brains and urine of Parkinson's disease (PD) patients (Fig. 1). It has been applied broadly to generate experimental models of Parkinson's disease. 6-OHDA shares some structural similarities with dopamine and norepinephrine and exhibits high affinity for several catecholaminergic plasma membrane transporters, such as the dopamine and norepinephrine transporters. Consequently, 6-OHDA can enter both dopaminergic and noradrenergic neurons.

In this chapter we will focus on molecular and cellular mechanisms that are involved in neurodegenerative processes described in PD. We will discuss the preclinical model of Parkinson's disease (based on 6-OHDA), with special attention

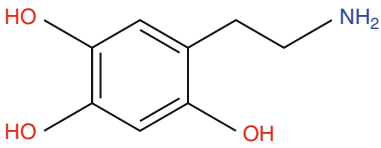

Fig. 1 Chemical structure of 6-OHDA

to the role of reactive oxygen species as second messengers and mitochondria as the headquarters of cell death. The role of molecular signaling pathways, for instance, the participation of Bcl-2 family members, will also be addressed.

2 In Vivo Experimental Animal Model

6-OHDA poorly crosses the blood–brain barrier, and, therefore, it does not accumulate within the brain parenchyma to meaningful neurotoxic concentrations following systemic injections. Thus, when 6-OHDA is administrated by systemic injection, it will not produce nigrostriatal lesions. Because of this, systemic injection is the preferred way of 6-OHDA administration to damage the peripheral nervous system and cause chemical sympathectomy. 6-OHDA has been found to deplete peripheral organs of noradrenaline (Porter et al. 1963; Laverty and Sharman 1965; Thoenen and Tranzer 1968). Former studies reported that 6-OHDA caused selective, acute degeneration of symptomatic nerve terminals in the peripheral nervous system (Malmfors and Sachs 1968; Thoenen and Tranzer 1968).

Already back in 1968, Thoenen et al. postulated that 6-OHDA can serve as a valuable tool for functional studies of the central nervous system (Thoenen and Tranzer 1968). The injection of 6-OHDA into the substantia nigra and the subsequent depletion of the nigro-neostriatal dopamine (DA) system were associated with marked motor asymmetry in the animals. This is in good agreement with data of Pottier et al. (1966). They found hypokinesia of the limbs ipsilateral to the depletion of striatal amines after the induction of lesions in monkeys. The same type of electrothermal lesion in rats also depleted natal DA (Hokfelt and Ungerstedt 1969). Moreover, it resulted in ipsilateral turning behavior, which is very similar to that found after nigral injection of 6-OHDA. Motor asymmetries were also reported upon removal of the corpus striatum and treatment with various drugs that interfere with catecholamine neurotransmission. Similar data to these were obtained after unilateral injection of DA into the nucleus caudatus putamen, which resulted in contralateral turning behavior (Ungerstedt 1968). From the results listed above, it seems probable that intracerebrally injected 6-OHDA is able to induce degeneration of catecholamine cell bodies, axons, and terminals in the vicinity of the site of injection. It thus offers the possibility of tracing these neuron systems in the brain, for instance, by studying the accumulation and disappearance of the transmitter after local injections of 6-OHDA into various cell groups, axon bundles, or terminal areas. Degeneration of the nigro-neostriatal DA neuron system, caused by 6-OHDA, produces marked motor disturbances, which are known to be associated with this system.

Several local sites of injection have been used to damage the central dopaminergic pathways, including intraventricular, intracisternal, and intracerebral tissues. For reviews on the animal model, see Bove et al. (2005), Cenci et al. (2002), and Duty and Jenner (2011).

3 In Vitro Experimental Cell Culture Models

There is accumulating evidence from in vitro and in vivo studies, implicating cell death in the etiology of the 6-OHDA model of PD. For instance, in neuronal (cerebellar granule cells, primary mesencephalic dopaminergic) and nonneuronal (mesencephalic-derived dopaminergic MN9D, NB41, SH-SY5Y, thymocytes, bovine chromaffin cells,) cell cultures, 6-OHDA induces characteristic biochemical, histochemical, and morphological changes that are characteristic for apoptosis (Blum et al. 2001). Furthermore, intracerebral injection of 6-OHDA causes apoptosis of dopaminergic neurons in the substantia nigra (Bove et al. 2005; Duty and Jenner 2011).

4 Cell Death Pathways Activated by 6-OHDA

4.1 Reactive Oxygen Species

Reactive oxygen species (ROS) are important for execution of physiological functions. However, excessive production of ROS is detrimental to the cell. Following an increase in ROS production, the cell's redox equilibrium is shifted to a more oxidized state, affecting both the structure and the function of different molecules. This may lead to specific toxic processes, which compromise the redox status of the cell and can cause cell death. Due to high levels of polyunsaturated fatty acids in their membranes and the relatively low activity of endogenous antioxidant enzymes, cells in the brain are particularly susceptible to oxidative damage. Increased oxidative stress together with a decline in endogenous antioxidants is an important determinant to develop PD. In our model, 6-OHDA initiates neurodegeneration through a combination of oxidative stress and mitochondrial respiratory dysfunction (Fig. 2).

Under physiological conditions, 6-OHDA is rapidly and nonenzymatically oxidized by molecular oxygen to form 1,4-para-quinone and its degradation products (Gee and Davison 1989), along with production of ROS such as hydrogen peroxide (H_2O_2), superoxide radical ($\bullet O_2^-$), and hydroxyl radical ($\bullet OH^-$). Quinones react with nucleotic groups of macromolecules, leading to inactive or destroyed quinoproteins. These do not seem to contribute significantly to the observed cytotoxic effects of 6-OHDA. H_2O_2 can enter the cells and reacts with trace metals to form highly reactive $\bullet OH^-$ (Koppenol 2001), which can oxidatively damage proteins, lipids, and DNA (Beckman and Ames 1997). We have shown that 6-OHDA concentrations that were nontoxic to cell cultures did not significantly

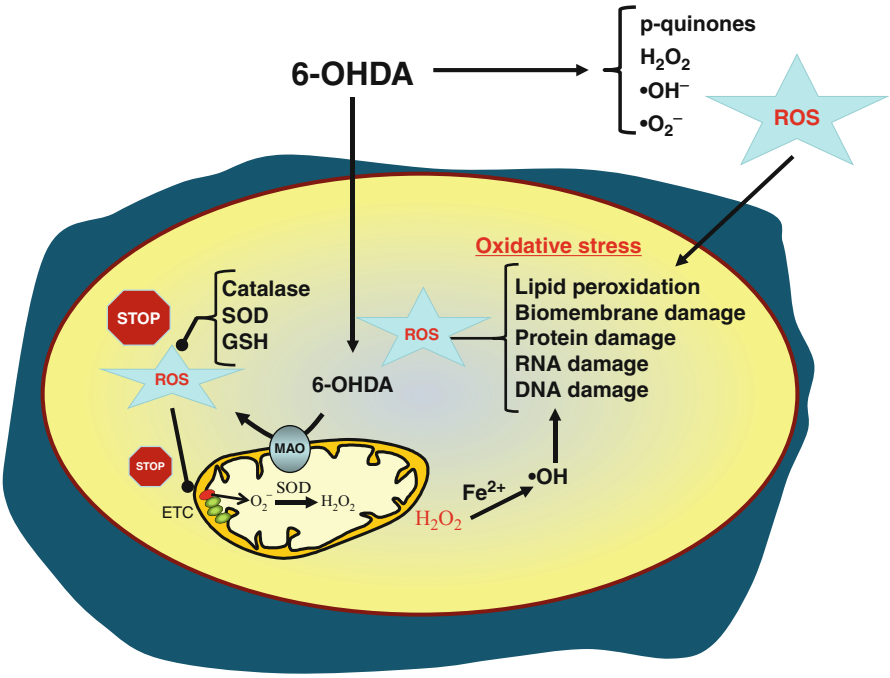

Fig. 2 6-OHDA initiates neurodegeneration through oxidative stress

increase H_2O_2 production (Galindo et al. 2003). Moreover, H_2O_2 addition to cultures produced a pattern of cell death similar to 6-OHDA.

In addition to the nonenzymatic self-auto-oxidation process, microinjection of 6-OHDA into the striatum may lead to the generation of H_2O_2 via a mitochondrial enzymatic oxidation process. Inhibition of complex I of the electron transport chain also stimulated mitochondrial production of superoxide radicals. These superoxide radicals were then catalyzed to H_2O_2 by superoxide dismutase, and, subsequently, •OH^- may arise from the breakdown of H_2O_2. This may be associated with the mitochondrial dysfunction seen in our experiments, because •OH^- rapidly attacks other biological molecules. The radicals produced in molecules such as lipids and proteins may also interact with mitochondrial enzymes to cause degradation.

4.2 Mitochondrial Dysfunction

Mitochondrial dysfunction is associated with many brain diseases including Parkinson's disease, Alzheimer's disease, and brain ischemia (Galindo et al. 2010; Jordan et al. 2011). However, the enzymatic basis for mitochondrial dysfunction remains largely unknown. Mitochondrial dysfunction in PD has been demonstrated as a reduction in complex I activity in the brains of patients (Mizuno et al. 1989; Schapira et al. 1989) and laboratory animals (Dabbeni-Sala et al. 2001).

Increased lipid peroxidation in the substantia nigra is typical of patients with PD (Dexter et al. 1989). This suggests that ROS are produced in excess, resulting in chronic local oxidative stress, which may cause progressive degeneration of the nigral dopaminergic neurons. Normally, ROS are probably produced in large quantities in the substantia nigra of humans, since there is an abundance of detoxifying enzymes, such as superoxide dismutase in dopaminergic neurons (Ceballos et al. 1990) and glutathione peroxidase in glial cells. In parkinsonian patients, the activity of these enzymes is not by definition abnormal (Marttila et al. 1988). However, decreased concentrations of glutathione (Perry et al. 1982) and increased activity of mitochondrial superoxide dismutase (Saggu et al. 1989) indicate that an excess of free radicals may be produced. Importantly, 6-OHDA readily reduces striatal levels of antioxidant enzymes (total glutathione (GSH) or superoxide dismutase) (Kunikowska and Jenner 2001; Perumal et al. 1992) to interact directly with complexes I and V of the mitochondrial respiratory chain. This leads to subsequent respiratory inhibition and further oxidative stress. Many of these effects are thought to mirror events that occur during PD in the brain, and this strongly supports the validity of the 6-OHDA model.

The oxidant H_2O_2 elicits the suppression of thiol-dependent electron transport, which appears to be related to the inhibition of complex I (nicotinamide adenine dinucleotide coenzyme Q reductase) in the respiratory chain (Mizuno et al. 1989). A 1-chloro-2,4-dinitrobenzene reductase in the mitochondrial matrix has been shown to be a thioredoxin reductase that reduces glutathione disulfide to glutathione (Lenartowicz and Wudarczyk 1995). 6-OHDA induced thiol oxidation in brain mitochondria, which was diminished by antioxidant enzymes. DA toxicity on neuronal cells is inhibited by thiol compounds and is potentiated by mitochondrial function inhibitors. Consequently, we and others have observed protection against 6-OHDA-induced toxicity in cell cultures by treatment with different antioxidant compounds (Galindo et al. 2003).

4.3 Mitochondria as Central Regulators of 6-OHDA Neurotoxicity

Mitochondria play critical roles in regulating cellular viability and show characteristic vulnerability to injury. Disruption of mitochondrial Ca^{2+} homeostasis may be involved in neuronal cell death. Mitochondria exposed to oxidative stress show enhanced Ca^{2+} uptake and increased formation of ROS. 6-OHDA slightly enhanced the Ca^{2+} uptake by mitochondria and apparently stimulated ruthenium red-induced Ca^{2+} release. The inhibitory effect of antioxidant enzymes indicates that ROS may be involved in the mitochondrial Ca^{2+} elevation induced by catecholamines.

Mitochondria can be considered as headquarters where the cell controls signaling pathways that under some circumstances can lead to cell death (Jordan et al. 2003a, 2011). Mitochondrial membrane permeabilization is a critical event during apoptosis and represents the point of no return of this lethal process (Galluzzi et al. 2009). Permeabilization of the mitochondrial outer membrane (MOMP) is a crucial

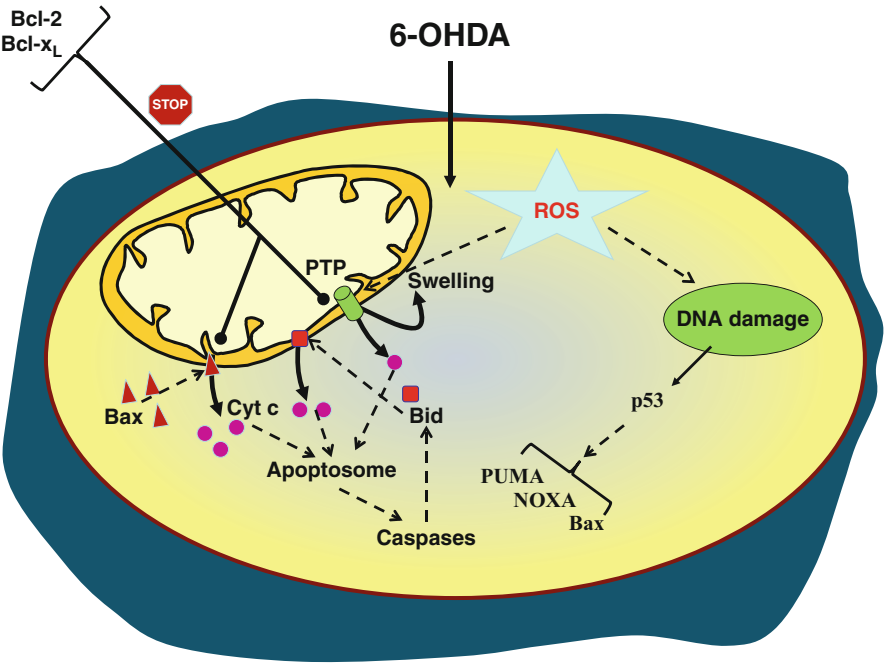

Fig. 3 Hypothetical mechanisms of 6-OHDA-induced MOMP

step both in apoptosis and necrosis. This phenomenon allows the release of mitochondrial death factors, which facilitates or triggers different signaling cascades. Ultimately this causes the execution of the cell involving release of cytochrome *c*. Treatment with 6-OHDA induced the release of cytochrome *c* from brain mitochondria (Gomez-Lazaro et al. 2008b).

MOMP is regulated either by the formation of the permeability transition pore (PTP) or by the insertion of Bcl-2 family members into the MOM (Fig. 3). There is some controversy about the role of the PTP in the 6-OHDA model. The PTP is a nonspecific large proteinaceous pore, spanning both mitochondrial membranes. It allows the passage of ions and substrates, in cost of loss of mitochondrial membrane potential. This leads to ATP depletion and energetic collapse and thus contributes to cell death (Qian et al. 1999). Onset of a PTP is such a severe perturbation of mitochondrial function that it basically assures cell death.

The PTP has been proposed to be another target of DA oxidation products in mitochondria. The oxidation of DA to dopamine quinone causes a significant increase in the swelling of brain and liver mitochondria. The effect of dopamine and 6-OHDA on mitochondrial membrane permeability has not been clearly elucidated. We have demonstrated that 6-OHDA did not induce PTP formation (Gomez-Lazaro et al. 2008b). First, 6-OHDA did not decrease the levels of mitochondrial calcein fluorescence, a hallmark of PTP opening. Second, 6-OHDA-induced

mitochondrial cytochrome c release was not inhibited in cell cultures that were pretreated with the PTP inhibitor cyclosporine A. Third, a mitochondria suspension isolated from brain did not readily undergo swelling upon exposure to 6-OHDA.

6-OHDA is also able to activate the multiple conductance channel (MCC), which is located in the inner membrane of mitochondria (Jordan et al. 2004). Normally, under physiological conditions, the MCC is closed, but it can be activated by different stimuli, such as Ca^{2+} at millimolar concentrations. Activation of the MCC leads to a multitude of changes in mitochondria, including mitochondrial membrane potential ($\Delta\Psi m$) dissipation.

6-OHDA induces profound mitochondrial fission in SH-SY5Y cell cultures, an event that precedes collapse of the $\Delta\Psi m$ and cytochrome *c* release (Gomez-Lazaro et al. 2008a). Mitochondria form a highly dynamic semi-tubular network, the morphology of which is regulated by frequent fission and fusion events as well as by movements along the cytoskeleton (Hoppins et al. 2007). Although the physiological significance of mitochondrial dynamics is not fully understood, growing evidence indicates that maintaining correct mitochondrial morphology through fission and fusion is critical for cell function (Chand et al. 2006; Chen and Chan 2006; Hoppins et al. 2007; Kiefel et al. 2006; Rouiller 1960). A reduction of the mitochondrial volume has been observed in pathological tissue (Arbustini et al. 1998; Nishino et al. 1998).

4.4 Bcl-2 Family Participation

Alternatively, MOMP may be initiated by insertion of the proto-oncogene Bcl-2 family into the MOM. The Bcl-2 family is composed of about 25 key regulators of apoptotic processes. These proteins are structural and functional homologs of the nematode protein CED-9 and are localized in the mitochondrial membrane. They contain up to four regions with a high homology to Bcl-2 (regions BH 1 to 4). Members containing only the BH3 region are proapoptotic proteins, and among them are Bax (X Bcl-2-associated protein), Bak (Bcl-2-antagonist/killer), BIM, and BID. How these proteins modulate changes in mitochondrial permeability is still an enigma. Inactive Bax resides in the cytosol or is anchored to the laxly face of the membranes of various organelles (Wolter et al. 1997). After a cell death signal, the Bax protein acquires a homo-oligomeric shape and is incorporated into the outer mitochondrial membrane. Postmortem studies indicated that the presence of Bax and its translocation to the outer mitochondrial membrane may contribute to the death of dopaminergic neurons in PD (Hartmann et al. 2001).

The protein BID is another Bcl-2 family member that migrates to mitochondria during processes of cell death. This protein is activated by caspase-8 and gives rise to a spoofed form t-bid, which is able to migrate to mitochondria, thereby altering their permeability. This migration is considered as the link between apoptotic caspase-8, triggered by signals of cell death, and downstream signaling cascades. On the other hand, some members of the Bcl-2 family have been proposed to modulate PTP formation. One example is Bcl-2, which inhibits the formation

of the PTP. Bcl-2 stabilizes the mitochondrial membrane, increases the buffering capacity of Ca^{2+}, and protects the $\Delta\Psi m$ to various stimuli. Yamada et al. have demonstrated that injection of a Bcl-2-producing vector into the substantia nigra 1 week prior to 6-OHDA injection increased neuronal survival in this tissue after the lesion (Yamada et al. 1999).

A potent induction of the BH3-only protein PUMA has been observed in response to 6-OHDA at both mRNA and protein levels (Gomez-Lazaro et al. 2008b). PUMA is thought to mediate the majority of the proapoptotic effects of p53 activity, which correlates with neuronal death in neurodegenerative diseases (Gomez-Lazaro et al. 2004; Gomez-Lazaro et al. 2005; Jordan et al. 2003b; Steffan et al. 2000; Tieu et al. 2001) including PD (Duan et al. 2002; Mandir et al. 2002).

Bcl-xL also belongs to the Bcl-2 family of proteins. Bcl-xL is able to protect cells from apoptosis induced by various stimuli, including serum deprivation, heat shock, malonate, and chemotherapeutic drugs (Fernandez-Gomez et al. 2005; Tsujimoto 1989). This suggests that the ability of Bcl-xL to prevent apoptosis is achieved by blocking a common cell death pathway. Our data indicate that Bcl-xL might prevent 6-OHDA effects by inhibiting MCC activation by the toxin (Jordan et al. 2004). TAT-Bcl-xL further reduces the number of cells that contain fragmented DNA or are caspase-3-reactive and increases the number of viable neurons in the striatum (Cao et al. 2002).

4.5 Caspases

Finally, the caspase family of proteases comprises fundamental components of many apoptotics signaling pathways. The percentage of active caspase-3-positive neurons among dopaminergic neurons was significantly higher in PD patients than in controls (Hartmann et al. 2000). Electron microscopy analysis of the human brain and in vitro data suggest that caspase-3 activation precedes and is not a consequence of apoptotic cell death in PD. Activation of caspase-3 was also demonstrated in 6-OHDA-induced apoptosis of SH-SY5Y cells (Gomez-Lazaro et al. 2008b). Pretreatment with caspase inhibitors prevented 6-OHDA-induced apoptosis (Hartmann et al. 2000; Takai et al. 1998). In human PD brain studies, a significantly higher percentage of dopaminergic substantia nigra neurons displayed activation of caspase-1, caspase-3, caspase-8, and caspase-9 (Hartmann et al. 2000; Mogi et al. 2000).

5 Flaws of the Model

However, the predictive validity of this model remains uncertain; strategies that reduced nigral dopaminergic cell loss in experimental animals so far have not been translated to the clinic. This can be due to the fact that the 6-OHDA model does not capture all features of PD. For example, it cannot exclude that PD pathological changes may occur in many brain areas outside of the basal ganglia locus coeruleus

and raphe nuclei, and this is not incorporated in the 6-OHDA model. Moreover, in the 6-OHDA model cell death occurs far more rapidly than in PD. Nevertheless, as long as these limitations are understood and accounted for when interpreting effects, the 6-OHDA model will remain at the forefront of preclinical drug discovery for PD.

Abstract

There is significant interest in using stem cells as a cell source for treatment against Parkinson's and other diseases due to the limited self-repair ability of the central nervous system and the lack of a pharmacological treatment to replace lost

neurons. Parkinson's disease is one of the main neurodegenerative disorders, and it is characterized by the degeneration of the nigrostriatal pathway caused by loss of ventral midbrain dopaminergic neurons in the substantia nigra pars compacta. Currently, there are no treatments to halt disease progress; the treatments merely ameliorate motor symptoms for a time, but the treatments are often followed by severe side effects. Cell-replacement therapy has been proposed as a treatment to replace damaged neurons and protect the remaining cells. Preliminary studies have utilized adult tissues, embryonic/fetal tissues, and embryonic stem cells as a source of dopaminergic cells. However, the ethical issues related to this type of procedure, the high quantity of required cells, the risk of tumor formation, and the immunological rejection associated with it have prevented this technique from being an effective treatment against Parkinson's disease. Researchers have been challenged to focus on new cell-replacement alternatives. In 2006, researchers found that only four transcription factors were necessary to reprogram an adult somatic cell to an induced pluripotent stem cell. This breakthrough revolutionized the scientific community, as this technique would allow scientists to obtain specific cells from the patient, avoiding rejection problems from non-autologous grafts and avoiding ethical problems. In addition, a large number of cells could be obtained. Although induced pluripotent stem (iPS) cells have great potential as a treatment against this disease, there are some obstacles for its clinical use such as the lack of standardized protocols that result in a dopaminergic cell phenotype that grafts without undifferentiated cells and without a risk of tumor formation. Currently, the iPS cell system is an ideal model of study for many other diseases besides Parkinson's, and the system is also good for drug screening. Recently, the direct reprogramming of somatic cells to induce neuronal (iN) cells without generating a pluripotent stage could be the solution to avoiding tumor formation risk. However, as a result of the low quantity of cells obtained, more investigations are necessary to convert this technique into an efficient cell-replacement therapy. If we overcome these obstacles, the use of iPS and iN cells could be, without a doubt, a promising therapy in the near future.

Keywords

Dopaminergic neurons • Induced neuronal cells • Induced pluripotent stem cells • Parkinson's disease • Pluripotency • Reprogramming • Stem cell • Therapy

List of Abbreviations

ASCs	Adult stem cells
ATRA	All-trans-retinoic acid
BDNF	Brain-derived neurotrophic factor
bFGF	Basic fibroblast growth factor
CB-SCs	Cord blood-derived multipotent stem cells
CNS	Central nervous system
DA	Dopamine
EGF	Epidermal growth factor

ESCs	Embryonic stem cells
FGF2	Fibroblast growth factor 2
FGF20	Fibroblast growth factor 20
FGF8	Fibroblast growth factor 8
GDNF	Glial cell line-derived neurotrophic factor
GSK-3	Glycogen synthase kinase 3
hESCs	Human embryonic stem cells
HGF	Hepatocyte growth factor
HSCs	Hematopoietic stem cells
HUVMSCs	Human umbilical vein mesenchymal stem cells
ICM	Inner cell mass
iN	Induced neuronal
iPSCs	Induced pluripotent stem cells
MSCs	Mesenchymal stem cells
NP	Neural progenitor
NPSCs	Neural progenitor stem cells
NSCs	Neural stem cells
NSPCs	Neural stem cell and neural progenitor cell
PD	Parkinson's disease
PGCs	Primordial germ cells
SCC	Stem cell coactivator complex
SDF1α	Stromal cell-derived factor-1α
SDIA	Stromal cell-derived inducing activity
sFRP1	Secreted frizzled-related protein 1
SHH	Sonic hedgehog
SNpc	Substantia nigra pars compacta
STEMCCA	Single excisable polycistronic lentiviral stem cell cassette
SVZ	Subventricular zone
VEGFD	Vascular endothelial growth factor D

1 Stem Cells

The human body consists of different cell types organized into tissues and organs. In the adult state, tissues are maintained because of the proliferative ability of stem cells (SCs). However, not all tissues have the same potential for renewal.

Different adult tissues differ in terms of the proportion of proliferative cells. For example, proliferative cells were discovered in the pancreas that have been described as being different from stem cells (Dor et al. 2004; Zhao et al. 2008). In the pancreas, the cells were able to renew constantly. Normally, the proliferative capacity of tissue is maintained by stem cells that have not only extensive renewal capacity, but also the ability to generate daughter cells capable of differentiating. These cells are called adult stem cells (ASCs) (Watt and Driskell 2010).

1.1 Characteristics

Stem cells are unspecialized cells in an undifferentiated state that have an extraordinary capacity to proliferate indefinitely without differentiating. However, stem cells are capable of differentiating into one or more specialized cell types. A stem cell divides to generate one daughter stem cell and one progenitor cell during self-renewal; later, the progenitor cell achieves a fully differentiated state.

The stem cells can also be categorized by their ability to divide and produce differentiated cells. These cells can be classified as totipotent, pluripotent, and multipotent cells. Totipotent cells are those that give rise to all cells of an organism including germ cells, as in a zygote. Pluripotent cells generate all cell types in an embryo except the cells of the embryonic membrane such as the placenta. The cells of the inner cell mass (ICM) are pluripotent cells that generate three embryonic germ layers. Unlike those cells, multipotent cells are adult stem cells that, despite the fact that they can give rise to different cell types, only generate a given cell lineage. Adult stem cells can differentiate into more than one mature cell. Examples of these adult stem cells are hematopoietic stem cells, mesenchymal stem cells, and neural stem cells (NSCs).

The stem cells present with different types of differentiation: (i) direct differentiation, where a specific cell type develops in a unidirectional pathway; (ii) transdifferentiation, where a direct conversion occurs from one cell type to another, different, cell type; and (iii) dedifferentiation, where a unipotent stem cell generates a multipotent one. Moreover, a stem cell can also fuse with a somatic cell resulting in another lineage (Nadig 2010; Lunn et al. 2011).

1.2 Classification

Stem cells can also be classified according to their origin: embryonic stem cells (ESCs) and adult stem cells (postnatal stem cells/somatic stem cells). ESCs can be obtained from blastocyst, epiblast, and primordial germ cells. These cells have been described as pluripotent because they are able to generate all cell types of the three primary germ layers (ectoderm, mesoderm, and endoderm). Initially, embryonic stem cells were isolated from preimplantation mouse embryos in the blastocyst state (Evans and Kaufman 1981; Martin 1981). In the year 1998, it was reported that stem cells could also be derived from human blastocysts (Thomson et al. 1998). Pluripotent ESCs can be obtained from the post-implantation epiblasts of the mouse embryo (Brons et al. 2007; Tesar et al. 2007). In this case, ESCs were isolated from 12-day-old embryos called epiblasts. Likewise, pluripotent ESCs can be obtained from primordial germ cells, which are progenitors of adult gametes (Kerr et al. 2006). The use of embryonic tissue in research and clinical fields generates cultural disagreement, as cells are generally obtained from "stored" in vitro fertilization embryos. Ethical and cultural matters make the clinical practice with stem cell-based therapies difficult (Watt and Driskell 2010).

In contrast, ASCs are found in most adult tissues. Unlike ESCs, ASCs are not pluripotent cells but rather multipotent cells. ASCs have the ability to differentiate into more than one cell type but not all cell types, as a pluripotent cell does. Examples of such cells are hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs). Hematopoietic stem cells can be obtained from cord or peripheral blood. These stem cells have been widely used in the treatment of several diseases such as leukemia, immunodeficiency, metabolic disorders, and tumors (Reimann et al. 2009; Perl et al. 2010). Mesenchymal stem cells originate in the stromal component of the bone marrow, although it is also possible to derive them from peripheral and umbilical cord blood (Perl et al. 2010). Mesenchymal stem cells are found in the bone marrow and hepatic, dermal, orofacial, and adult dental pulp tissues, among others (Gronthos et al. 2000; Nadig 2009; Nesti et al. 2011). Consequently, the use of MSCs as a treatment has been investigated for several diseases (Mundra et al. 2013; Morigi and Benigni 2012; Vawda and Fehlings 2012). Likewise, the role of MSCs in the contribution to tumor growth and progression has also been studied (Yang et al. 2013).

Currently, several human stem cell lines have been characterized that exhibit similar expression patterns for several pluripotency and lineage markers. However, these lines also present differences mainly due to the techniques used for their derivation and maintenance. Consequently, epigenetic factors and intrinsic genetic variations are important factors inherent to human samples, which could contribute to these variations and thus affect gene expression patterns (Adewumi et al. 2007).

1.3 Generation of Pluripotency

In the past, it was believed that only ESCs are pluripotent. However, further investigations have shown that not only are ESCs pluripotent, but adult cells can, in some circumstances, also produce progeny that differentiate across the three primary germ layers (ectoderm, mesoderm, and endoderm), which makes them pluripotent. A mechanism of reprogramming an adult cell to a pluripotent state is the transference of an adult nucleus into the cytoplasm of an oocyte (Gurdon et al. 1958; Gurdon and Melton 2008). An example of this technique is the creation of Dolly the sheep (Wilmut et al. 1997). Likewise, another mechanism to generate pluripotent cells is the fusion of adult cells with a pluripotent cell (Miller and Ruddle 1976). As described above, a pluripotent state can be generated through somatic nuclear transfer. Adult cells can also be reprogrammed to a pluripotent state by the transfection of only four transcription factors: Oct4, Sox2, Klf4, and Myc (Takahashi and Yamanaka 2006).

1.4 Markers of Pluripotency

During early embryonic development, cells change their gene expression profile. Some pluripotent state-related genes are expressed, whereas those related to

differentiation should be transcriptionally silenced. Many studies have identified the diverse pluripotency factors that are expressed in both embryos and stem cells.

Several methods have allowed for the identification of pluripotency factors. Studies performed in embryos, cell lines, and ESCs have relied on candidate gene analysis. Phenotypes resulting from specific knockdown, RNAi screens (Chambers et al. 2003; Rodda et al. 2005; Ivanova et al. 2006), gene expression profiles (Voutila et al. 2012; Zheng and Hu 2012), epigenetic profiles (Tomkins et al. 2012; Seisenberger et al. 2012; Al-Khtib et al. 2012), and protein expression profiles (Loh et al. 2006; Walker et al. 2007) have extended our knowledge of the genes and molecules associated with pluripotency.

These studies have allowed for the description of the role of the transcription factors Oct4, Sox2, Klf4, c-Myc, and Nanog for the establishment and/or maintenance of the pluripotent state.

However, a substantial amount remains to be learned regarding the changes in gene expression that occur during embryo development. Such changes are responsible for the pluripotent stem cell state and later to cell differentiation. In addition, it is crucial to understand the role of exogenous and endogenous factors for stem cell maintenance and how, through signaling pathways, gene expression levels are impacted.

These studies have helped determine a list of pluripotency-related genes that might be possible candidates for cellular reprogramming. However, the studies have not clarified the differential expression of genes leading to the pluripotent stem cell state nor how these genes determine the maintenance of the pluripotent state. It is important to emphasize that signaling pathways controlling pluripotency are extensively complex.

2 Stem Cells and Parkinson's Disease

2.1 Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative disorder that affects approximately 1 % of the population over 65 years of age worldwide (Twelves et al. 2003). However, the prevalence of this disease increases with the age. Studies performed in the USA have shown that PD incidence varies among Whites, Blacks, and Asians, and PD is substantially more common in Whites (Wright Willis et al. 2010). PD was described for the first time by Dr. James Parkinson in the year 1817. Although the disease etiology remains unknown, several factors are believed to be involved in PD development. This disease involves widespread dysfunction and cell degeneration that is characterized mainly by the gradual degeneration of ventral midbrain dopaminergic neurons in the substantia nigra pars compacta (SNpc), causing nigrostriatal pathway dysfunction. This degeneration leads to concomitant depletion dopamine (DA) in the striatum corpus, mostly in the caudate and putamen areas (Olanow 2004). This nigrostriatal pathway is related to controlling movement and gait. It should be noted that many patients suffering from

Parkinson's disease experience not only motor symptoms but also non-motor ones (Storch et al. 2013).

Parkinson's disease is mainly diagnosed by the motor clinical manifestations presented by patients. Unfortunately, the first motor symptoms are normally observed when more than 60 % of the dopaminergic neurons have died (Bernheimer et al. 1973). Currently, strong evidence shows the presence of non-motor symptoms such as olfactory dysfunction, sleep abnormalities, cardiac sympathetic denervation, depression, and pain long before the presence of motor symptoms (O'Sullivan et al. 2008; Obeso et al. 2010; Storch et al. 2013). These findings are particularly encouraging because they could aid in disease diagnosis at an early stage and thus result in therapies to halt its progress.

Currently, there are no effective treatments to cure this disease, and pharmacological therapies with dopaminergic drugs or functional neurosurgery merely improves the motor symptoms. The pharmacological treatments include dopamine precursors or dopamine agonists. It has been noted that treatment with L-dopa, the precursor of dopamine, may alleviate symptoms for only a few years. Moreover, long-term treatment with L-dopa is not satisfactory because the remaining dopaminergic neurons continue degenerating (Marsden 1994). In addition, chronic drug use is related to a variety of adverse effects such as L-dopa-induced dyskinesias (Politis et al. 2003; Fisone and Bezard 2011). Likewise, deep brain stimulation directed to the subthalamic nucleus or globus pallidus also may relieve symptoms in some patients (Odekerken et al. 2013). Current treatment options are oriented to reverse motors features of this disease such as tremor, rigidity, and bradykinesia/akinesia; however, these treatments do not halt PD progress. As the main cause of symptoms is ongoing degeneration, new treatments should, in the future, focus on halting dopaminergic neuron degeneration using neuroprotective agents or cell therapies to replace the degenerated neurons. Therefore, replacement therapy with stem cells or fetal tissue might be the best approach (Pawitan 2011), although many issues remain to be resolved before this technique can be used therapeutically. Transplanted cell survival is a major obstacle for the development of cell therapies for PD.

2.2 Stem Cell Therapy for Parkinson's Disease

Currently, PD patients are treated with various drugs including L-dopa, dopaminergic agonists, and inhibitors of dopamine-degrading enzymes. Likewise, deep brain stimulation has been utilized in numerous patients. While these treatments are effective early on to ameliorate the motor symptoms, the treatments do not halt the disease course. In recent decades, research efforts have focused on replacing the dopaminergic neurons that are lost in PD patients. To this end, cellular therapies that replace degenerated cells are the main interest focus today. These therapies involve the use of tissue transplants such as fetal, embryonic, or adult tissues as a source of dopaminergic cells or neural progenitor cells (Lunn et al. 2011). Over time, investigations included not only transplants from the same species but also

used autotransplantation and xenotransplantation between different species such as rats, mice, monkeys, pigs, and humans (Huffaker et al. 1989; Bankiewicz et al. 1990; Freed et al. 1990; Galpern et al. 1996; Hara et al. 1997; Molenaar et al. 1997; Barinaga 2000; Yurek and Fletcher-Turner 2004; Puschban et al. 2005; Arias-Carrión and Yuan 2009). Furthermore, investigations have performed the direct transplantation of SC-derived dopaminergic cells such as those derived from ESCs, induced pluripotent stem cells (iPSCs), fetal brain NSCs, and bone marrow-derived SC (Kim 2011). As recently described, other cell types, different from stem cells, may also be suitable for cell therapy. These cells include the induced neuronal (iN) cells, which are derived from somatic cells (Caiazzo et al. 2011; Politis and Lindvall 2012; Lévêque et al. 2012). Moreover, innovative therapies have emerged involving transplantation with genetically modified neuronal or nonneuronal cells. In some cases, the cells were genetically manipulated by introducing genes such as tyrosine hydroxylase, Bcl2, Nurr1, or neurotrophic factors (Holm et al. 2001; Torres et al. 2005; Shim et al. 2007; Ramos-Moreno et al. 2012).

One of the first transplantation studies was performed using a brain tissue graft containing dopamine-secreting cells in the rat striatum. The results were encouraging because the motor abnormalities present in these rats were significantly reduced after the fetal brain tissue graft (Perlow et al. 1979). Subsequent studies proceeded with searching for new sources of donor dopaminergic cells; some studies were very promising but others had poor results. The adrenal medulla, fetal or embryonic mesencephalic tissue, and the carotid body have been used as a source of dopamine-secreting cells (Strömberg et al. 1986; Espejo et al. 1998). Transplantation of human adrenal chromaffin cells or sympathetic neurons from the cervical ganglion was not effective (Yong et al. 1989). Adrenal medulla transplants also showed inconsistent results. Despite the fact that co-transplantation of peripheral nerves and the adrenal medulla in patients with Parkinson's disease can promote long-term improvement, other studies performed in patients showed that the adrenal medullary transplants do not survive long-term (López-Lozano et al. 2000; Kompoliti et al. 2007). On the other hand, the transplantation of mesencephalic dopaminergic neurons or the intrastriatal transplantation of carotid body tissues show more promise as future therapies for this disease (Mendez et al. 2005; Mínguez-Castellanos et al. 2007; Pardal and López-Barneo 2012).

The carotid body consists of adult tissue that contains dopamine-secreting cells and expresses high levels of glial cell line-derived neurotrophic factor GDNF (Toledo-Aral et al. 2003; Porzionato et al. 2008). Studies have shown that intrastriatal autotransplantation of carotid tissues induced functional recovery in parkinsonian rats and monkeys and in some patients with advanced PD (Espejo et al. 1998; Luquin et al. 1999; Arjona et al. 2003). More recently, a population of neural progenitor stem cells (NPSCs) was discovered in this organ (Pardal et al. 2007). Hence, not only is the transplantation of dopaminergic cells necessary for cell therapy, but also the presence of neurotrophic factors as a neuroprotection mechanism. These studies suggest the use of neurotrophic factors as a new experimental approach to combat this disease (Minguez-Castellanos and Escamilla-Sevilla 2005). There is concern because the grafted cells not only

produce dopamine, but also deliver neurotrophic factors that protect nigrostriatal neurons. Thus, the trophic factors would be capable of promoting restoration of the nigrostriatal pathway. In this regard, patient-specific adult stem cells derived from the carotid body could be an interesting candidate for PD treatment that avoids human embryonic/fetal tissue or embryonic stem cell use. The cells derived from adult tissues could also be expanded and differentiated into DA precursor cells in vitro (Pardal and López-Barneo 2012). More recently, studies of co-grafts of a cell suspension of rat dopaminergic neuroblasts with carotid body cells increased survival of dopaminergic neurons in rats with total unilateral dopaminergic denervation (Rodriguez-Pallares et al. 2012).

In spite of the fact that cell therapies with carotid tissues appeared to be effective in animal models and patients, the amount of tissue necessary for obtaining significant clinical benefit is one of the main factors limiting their use clinically. Although we are able to develop optimized protocols that could improve the safety and efficacy of these procedures, a major constraint is the availability of tissue for these grafts.

In this respect, progress in stem cell research appears to be the future for cell therapy against Parkinson's disease. Due to the self-renewal capacity and multilineage plasticity of stem cells, stem cells can generate numerous cell types needed for cell therapy. As mentioned previously, several types of stem cells have been isolated from many sources such as embryonic tissues, peripheral blood, umbilical cord blood, bone marrow, and the olfactory bulb. Stem cells have also been obtained from somatic cells; these stem cells comprise the ESCs, iPSCs, NSCs, and MSCs.

2.2.1 Embryonic/Fetal Tissue Cell Therapy for Parkinson's Disease

In the year 1988, Brundin and collaborators performed the first transplantation of human fetal mesencephalic neurons. The results were promising, showing that patients can effectively restore dopaminergic neurotransmission (Brundin et al. 1988). Because the utilization of human fetal tissue as source of dopamine cells is not easy, xenografting of the pig ventral mesencephalon may be an appropriate alternative to the use of human fetal tissue as a PD therapy. These studies showed how implants could survive and mediate functional recovery in animal model of PD and also in some patients, although immunological rejection is the main limitation in humans (Huffaker et al. 1989; Bankiewicz et al. 1990; Galpern et al. 1996; Molenaar et al. 1997; Schumacher et al. 2000; Larsson and Widner 2000).

One of the most commonly used therapies has been the intrastriatal transplantation of embryonic or fetal mesencephalic neurons, which have produced the best clinical results (Madrazo et al. 1990; Freed et al. 1990, 1992, 2001; Sirinathsinghji et al. 1990; Lindvall et al. 1994; Wenning et al. 1997; Piccini et al. 1999). Although in some cases the implanted neuron can survive many years, this phenomenon was not observed in all patients (Piccini et al. 1999). Thus, one of the main difficulties observed with these grafts is the low survival of implanted neurons (Piccini et al. 1999; Emgård et al. 1999; Kaminski Schierle et al. 1999). For this reason, further therapies were oriented to the application of neurotrophic factors as

a neuroprotective mechanism of neuronal degeneration (Kupsch et al. 1995; Ballagi et al. 1994; Collier et al. 1999). On the other hand, to improve transplant efficiency, new alternatives emerged including double grafts, either sequentially transplanted or co-grafted (Mendez et al. 1996; Sortwell et al. 1998; Hagell et al. 1999; Kaddis et al. 2000). Simultaneous intrastriatal and intranigral neuronal transplants in rat lesions contribute to striatal reinnervation and reestablishment of the nigrostriatal circuitry (Mendez et al. 1996). Moreover, sequential transplantation of human embryonic mesencephalic tissue in PD patients showed restoring of fluorodopa uptake without affecting graft survival (Hagell et al. 1999). Interestingly, co-grafts of DA neurons with Schwann cells, muscle cells with mesencephalic tissue, or mesencephalic tissue with striatal cell suspensions increase the survival and outgrowth of the DA neurons present in mesencephalic tissue. These effects were related to the neurotrophic factors delivered by the Schwann, skeletal muscle, and striatal cells (Sortwell et al. 1998; Collier et al. 1999; Kaddis et al. 2000). An interesting study performed in 250 patients with advanced PD showed how transplanted embryonic neuronal grafts survive and induce significant therapeutic effects (Björklund and Lindvall 1999).

All investigations performed in animals and humans have contributed to establishing the requirements of the transplanted cells to be used as a cell therapy for Parkinson's disease. Therefore, some important points to consider regarding establishing transplanted cells as possible cell therapy are the following: the presence of functional and morphological characteristics similar to dopaminergic neurons; the existence of the capacity to reestablish nigrostriatal circuitry; the presence of greater cell survival in tissue; the absence of adverse effects such as transplant-associated dyskinesias, transplant rejection, or tumor formation; and the reversion of motor symptoms in PD patients and animal models. On the other hand, difficulties in obtaining fetal tissue have added to the adverse effects caused by transplantation (the graft-induced dyskinesias in some patients), and the low survival of grafted cells makes this technique unsuitable for practice in numerous patients and cannot be recommended as a PD therapy (Freed et al. 2001; Olanow et al. 2003). In this regard, other neuronal cell sources such as embryonic stem cells could be an alternative cell therapy for PD.

2.2.2 Embryonic Stem Cell Therapy for Parkinson's Disease

Embryonic stem cells can be derived from different embryonic developmental states such as blastocyst, epiblast, and also primordial germ cells (Evans and Kaufman 1981; Martin 1981; Thomson et al. 1998; Kerr et al. 2006; Brons et al. 2007). These ESCs possess a self-renewal ability and retain pluripotency over prolonged periods of expansion in culture without differentiation (Dushnik-Levinson and Benvenisty 1995; Amit et al. 2000). Unlike other cell types, ESCs have a higher plasticity and the capacity to differentiate into any cell type including dopamine neurons (Park et al. 2004; Zeng et al. 2004; Yan et al. 2005; Datta et al. 2013). One of the main limitations of using ESCs for transplantation in PD patients is the pluripotent state of these cells because under these conditions, the cells could form tumors once grafted, hindering their clinical application. To avoid adverse

effects, an early study showed that an enriched population of midbrain NSCs could be derived from ESCs. Thus, the dopamine neurons obtained from neural SCs are suitable for transplantation (Kim et al. 2002). A recent report showed that dopamine neurons derived from human ESCs efficiently survive after transplantation in animal PD models without forming tumors (Kriks et al. 2011).

The decreased survival of grafted cells after transplantation is one of the main obstacles for this surgery. One procedure involves the injection of adenoviral vectors into the dopamine-depleted striatum of hemiparkinsonian rats to deliver the differentiation factor sonic hedgehog (SHH) or the glial cell line-derived neurotrophic factor (GDNF) to dopamine-rich grafts. Later, embryonic ventral mesencephalic cells were implanted in the striatum. Both trophic and differentiation factors enhanced the yield of dopamine neurons in the ventral mesencephalic grafts (Torres et al. 2005).

2.2.3 MSCs as Cell Therapy for Parkinson's Disease

Mesenchymal stem cells are multipotent stem cells with the capacity for differentiation into various cell types including neurons (MacKenzie & Flake 2002; Choi et al. 2012). These cells can be obtained from human umbilical cord, bone marrow, or adipose tissue (Fu et al. 2002; Kestendjieva et al. 2008; Li et al. 2010; Włodarski et al. 2012). Autotransplantation is possible for cell therapy because the cells can be obtained from the same patient. One interesting immunosuppressive property of these cells is the prevention of an inflammatory response, thus avoiding transplanted cell rejection (Guo et al. 2006; Mathew et al. 2003). Other interesting properties of these cells are their neuroprotective capacity mediated by the delivery of neurotrophic factors (Wilkins et al. 2009; Whone et al. 2012). Several studies have shown that the presence of neurotrophic factors protects the transplanted neurons and favors NSC proliferation and differentiation (Park et al. 2008). These features make MSCs good candidates for cell-replacement therapy in PD. Bone marrow-derived MSCs can be induced to secrete neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF). When these neurotrophic factor-secreting cells were transplanted into the lesioned brain of a Parkinson's disease rat model, regeneration of the damaged dopaminergic nerve terminal in the striatum was observed (Sadan et al. 2009). On the other hand, Li and colleagues differentiated human umbilical vein mesenchymal stem cells (HUVMSCs) into dopaminergic-like cells. Utilizing a rat model of PD, the authors observed that the transplanted cells together with NGF administration considerably increased grafted cell survival (Li et al. 2010).

2.2.4 Neural Stem/Progenitor Cells

The transplantation of fetal or embryonic tissue has significant limitations for use as a cell-replacement therapy such as ethical issues due to the use of human fetal/embryonic tissue, deleterious immune reactions by the central nervous system after intracerebral transplantation, and the high quantity of cells necessary for an efficient transplantation. In addition, this treatment could have side effects such as dyskinesia and a risk of tumor formation. Consequently, researchers have focused

their efforts on isolating and differentiating in vitro neural stem cells before performing the transplantation. Therefore, NSCs would be obtained first and, later, dopaminergic cells. Thus, fetal brain neural SC-derived dopaminergic cells were observed to have little risk of tumor formation and immune rejection in contrast to stem cells. In addition, neural stem/progenitor cells (NSPCs) are an alternative cell source for neural transplantation because they display important neuroprotective and immunomodulator features that favor survival of the remaining or transplanted neurons (Bonnamain et al. 2012).

Stem cell differentiation generates progenitors of a specific lineage cell such as NSCs. Neural stem cells are multipotent cells with the capacity to proliferate and give rise to cell types with restricted neural lineages (Bai et al. 2007). NSCs differentiate into neural progenitor cells (NPCs) and finally into dopaminergic neurons (Riaz et al. 2002). Although NSCs have a more restricted self-renewal potential, they proliferate in culture forming neurospheres and may be differentiated either before or after transplantation. Both neural stem cell and neural progenitor cells (NSPCs) are present in neurospheres. It has been discussed whether the term NSCs, neural precursor cells, or NPCs are the same cells. However, it is not clear which exact cell types are present within the neurospheres. Recently, it was demonstrated that neurospheres can be maintained in a culture with different cell populations (Narayanan et al. 2012). Currently, it is believed that the cell identities present in neurospheres might differ between species (Steffenhagen et al. 2011).

The NSPCs can be derived from embryonic nerve tissue, adult nerve tissue such as the subventricular zone or carotid body, or from differentiated embryonic/fetal stem cells (Okabe et al. 1996; Pardal et al. 2007; Ara et al. 2010). Autologous transplantation of NSCs derived from adult tissue is an attractive cell therapy against Parkinson's disease (Arias-Carrión and Yuan 2009). The intrastriatal transplantation of NSCs isolated from the developing human CNS in adult rats with unilateral dopaminergic lesions partially ameliorated lesion-induced behavioral deficits in some animals (Svendsen et al. 1997). Pre-differentiated neural progenitor cells are more effective in enhancing the therapeutic potency for PD (Wang et al. 2004). Others studies have shown that transplanted NSCs survive into the substantia nigra pars compacta or striatum in PD rat models (Zhu et al. 2009).

NSCs were isolated from the adult pig subventricular zone, maintaining their capacities for proliferation, self-renewal, and multipotency. Because the pig is immunologically closest to humans, pigs can be an efficient source for cell therapy (Liard et al. 2009). Interestingly, the use of xenografts of porcine neural precursor cell in a rat model of Parkinson's disease showed long-term survival of grafts in the host brain (Harrower et al. 2006).

2.2.5 Other Stem Cell Sources

From bone marrow, it is possible to obtain various types of stem cells such as MSCs and hematopoietic stem cells. One study showed that bone marrow-derived stem cells transfected with tyrosine hydroxylase and a GFP-containing plasmid can be later differentiated to neurons. Injection of these cells into the brain of a Parkinson's disease model rat showed favorable results (Zou et al. 2010). On the other hand,

stem cells can be isolated either from the dermis or hair follicles. Both cell types, dermis-derived neural crest-related and epidermal neural crest stem cells, can be differentiated into cells with distinct cell lineages including dopaminergic neuron-like cells. Transplanting these cells into Parkinson's disease model rats showed encouraging results (Kubo et al. 2009). In addition, implantation of epidermal neural crest stem cells into a brain injury rat model leads to cell differentiation into immature astrocytes, which secrete neurotrophic factors (Jackson et al. 2010).

2.3 Other Cell Sources for Parkinson's Disease Therapy

Although the tremendous potential of stem cells as an effective cell therapy in Parkinson's disease is well established, cells other than stem cells have also been investigated as alternative sources for cell therapy. These cells may be appropriate for use as supportive or replacement cells for neurons. Among these are amniotic epithelial cells, retinal pigment epithelium (RPE) cells, and fetal dopamine neurons (Sheng et al. 1993; Mendez et al. 2005; Yang et al. 2009; Kakishita et al. 2000). The ability of some cells to secrete neurotrophic factors, differentiate into dopamine-secreting cells in vitro, survive in the striatum in vivo, and increase dopaminergic marker expression levels in Parkinson's disease model rats makes them an excellent candidate for cell therapy against Parkinson's disease (Mendez et al. 2005; Stover and Watts 2008; Yang et al. 2009). The clinical results obtained from the transplant of fetal dopamine neurons in patients with Parkinson's disease were very interesting. When these neurons were transplanted into the striatum or both the striatum and substantia nigra, they presented as functional dopaminergic neurons at the transplantation sites. Likewise, postmortem analyses showed the survival of the transplanted dopaminergic neurons (Mendez et al. 2005).

Despite the progress achieved in this field, numerous complications have prevented the practical application of stem cell-based therapy: ethical problems of fetal and embryonic tissue use, low safety due to teratoma formation risk (Kuroda et al. 2013), and rejection issues and little efficacy caused by very low cell survival. Before the clinical application of cell therapy for patients with Parkinson's disease, safety and efficacy studies, standardized protocols that utilize animal compound-free defined media for culture in vitro, and differentiation procedures that allow us to isolate primarily dopaminergic neurons are required.

2.4 Differentiation of Stem Cells into NSCs and Dopaminergic Neurons

It is essential to increase our knowledge on nervous system development and to understand how numerous factors participate in the intrinsic and extrinsic signaling pathways inducing cell differentiation. As a result of these advances, we can design more efficient strategies for cell differentiation in vitro in the future.

The differentiation of stem cells involves the formation of neural precursor cells or neural progenitor cells, which can be expanded in vitro. Later, these cells are differentiated further into dopaminergic neurons (Cho et al. 2008). During the differentiation process, neuroepithelial rosette structures are formed (Zhang & Zhang 2010). It was found that not only are stem cells potentially tumorigenic, but neuroepithelial rosettes are as well. An efficient protocol for neuronal differentiation that eliminates ESCs and neuroepithelial rosettes is necessary to avoid risk of tumors or teratoma formation before transplantation. Although some studies performed in rats have shown that multipassage neural precursor cells do not form tumors, low survival and loss of the dopaminergic neuronal phenotype make them unsuitable for replacement therapies (Ko et al. 2009; Jo et al. 2009; Pawitan 2011).

In general, numerous protocols have been described to differentiate stem cells into dopaminergic neurons or dopaminergic-like cells. These protocols have presented with different degrees of efficiency (Hwang et al. 2010). Some protocols utilized a co-culture with PA6 or MS5 mouse stromal cells, and others used chemically defined media or the specific activation of an intrinsic pathway (Momčilović et al. 2012; Watmuff et al. 2012). Currently, there is notable heterogeneity in the yield of tyrosine hydroxylase (TH)-positive cells (Hwang et al. 2010). Although iPSCs and ESCs can be differentiated using the same transcriptional network with same set of morphogens, the differentiation occurs with reduced efficiency and increased variability (Hu et al. 2010). Derivation of only one cell population and increased efficiency during this process are important factors to consider.

Stromal feeder cell-based differentiation protocols have been described by several authors (Perrier et al. 2004; Sonntag et al. 2007). Stromal cells are a source of stromal cell-derived inducing activity (SDIA). Recent work has identified stromal candidate factors inducing the neuronal differentiation of hiPSCs such as hepatocyte growth factor (HGF), stromal cell-derived factor-1α (SDF1α), secreted frizzled-related protein 1 (sFRP1), and vascular endothelial growth factor D (VEGFD) (Schwartz et al. 2012).

Recent evidence has shown that Lmx1a overexpression generates enriched populations of human A9-subtype ventral midbrain DA neurons from hESC or hiPSCs, which should be suitable for cell-replacement strategies (Sánchez-Danés et al. 2012a). Similarly, other studies have shown how overexpression of the nuclear receptor Nurr1 (a transcriptional factor specific to midbrain dopamine (DA) neuronal development) in NPCs isolated from the subventricular zone (SVZ) could induce a DA neuron phenotype (Shim et al. 2007).

As a consequence of the progress in this area, it has been determined that a diverse combination of growth factors and molecules contributes to the expansion and/or differentiation of either stem cells or neural progenitor cells. Among those described include basic fibroblast growth factor (bFGF), fibroblast growth factor 2 (FGF2), fibroblast growth factor 8 (FGF8), fibroblast growth factor 20 (FGF20), docosahexaenoic acid, all-trans-retinoic acid (ATRA), sonic hedgehog (SHH), transcription factor Nato3, a 3 % oxygen level, and ascorbic acid (Volpicelli et al. 2004; Correia et al. 2007; Cooper et al. 2010; Morizane et al. 2010; Chang et al. 2012; Stacpoole et al. 2011; Li et al. 2012; Nissim-Eliraz et al. 2012; Wang et al. 2013).

Similarly, several studies have shown how the bone morphogenic protein antagonist noggin, sonic hedgehog (SHH), FGF8, and Wnt5a promote the differentiation, survival, and functional integration of stem cell-derived DA neurons in vivo (Jensen et al. 2008; Parish et al. 2008; Chiba et al. 2008). Likewise, the BMP, TGF-β, and Wnt signaling pathways are involved in midbrain dopamine differentiation. The BMP and TGF-β pathway members participate how upstream regulators of the Wnt signaling pathway during midbrain dopamine differentiation of human pluripotent stem cells (Cai et al. 2013). Likewise, another study showed that BDNF contributes to NSC proliferation and differentiation through the activation of the Wnt/β-catenin signaling pathway (Chen et al. 2013). Wnts, a family of secreted proteins, are involved in stem cell differentiation (Prakash and Wurst 2007). It was reported that loss of Wnt1 generates the loss of Lmx1a and Ngn2 expression, affecting the formation of DA neurons in the midbrain floor plate (Andersson et al. 2013). In addition, it has been observed that the Wnt signaling pathway leads to the inhibition of glycogen synthase kinase 3 (GSK-3). GSK-3 inhibition in the presence of epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF) increases hiPSC-NP proliferation. However, an absence of these growth factors generates a switch to neuronal differentiation and a dopaminergic fate (Esfandiari et al. 2012).

The effect of retinoic acid in the neuronal differentiation has been described. It was shown that retinoic acid induced neuronal differentiation of NTERA2 cells through the modulation of Sox2 and Sox3 gene expression. The authors showed downregulation of Sox2 and upregulation of the Sox3 gene (Stevanovic 2003).

Utilizing different stem cell types, it is possible to give rise to dopamine neurons. Recently, Li and colleagues were able to derive dopamine neurons from human cord blood-derived multipotent stem cells (CB-SCs) before treatment with all-trans-retinoic acid (ATRA) (Li et al. 2012). Similarly, the isolation and differentiation of MSCs from the umbilical cord matrix tissue alleviate Parkinsonian symptoms in a rodent model in vivo (Shetty et al. 2013).

On the other hand, iPSCs may also become an important source of dopaminergic neurons. Several differentiation protocols performed in embryonic stem cells were applicable to iPSCs. Thus, it was observed that docosahexaenoic acid stimulated the differentiation of murine iPSCs into dopaminergic neurons (Chang et al. 2012). The neurons obtained from reprogrammed fibroblasts improved symptoms in a rat model of Parkinson's disease (Wernig et al. 2008). Likewise, differentiated Parkinson patient-derived iPSCs reduce motor asymmetry in parkinsonian rats (Hargus et al. 2010).

3 Induced Pluripotent Stem Cells (iPSCs)

Although most of our tissues contain adult stem cells that differentiate into any cell type when required, including different tissues (Abdanipour et al. 2011; Darabi et al. 2013), the ability for renewing damaged cells is limited. Over time, the amount of adult stem cells decreases and, thus, the ability to regenerate damaged tissues also decreases. A greater understanding of the molecular mechanisms

and signaling pathways involved in the maintenance and division of these adult stem cells could help design strategies to maintain the tissue regenerative capacity. Certainly, this strategy could be the solution to many diseases involving cell loss. Unfortunately, knowledge in this field remains scarce (Beltrami et al. 2007).

Currently, global research efforts have focused on designing strategies to develop stem cells from different sources. In previous work, different technologies to develop patient-specific stem cells, such as somatic cell nuclear transfer or cell fusion, have been described. In these methodologies, either the somatic nuclear content is transferred to an oocyte or ES cells are fused with somatic cells (Wilmut et al. 1997; Tada et al. 2001; Cowan et al. 2005). Unfortunately, both methods involve technical and ethical considerations that hinder the technology. Likewise, the isolation of adult or embryonic stem cells is not easy to realize, mainly due to technical difficulties and cultural issues. Currently, iPSC technology is a new tool for increasing our understanding of the molecular mechanisms involved in the development of several disorders. Thus, there is great interest in researching the possible use of iPSCs, not just as model of PD but also in future clinical applications (Sun et al. 2010; Stadtfeld and Hochedlinger 2010; Ebben et al. 2011; Han et al. 2011). Currently, these technologies have generated several PD patient-derived iPSC lines (Sánchez-Danés et al. 2012b; Byers et al. 2012). These iPSC lines will certainly help our understanding of the molecular mechanisms of PD and help us to design patient-specific stem cell treatments.

3.1 History

In the year 2006, a remarkable finding was reported by Takahashi and Yamanaka in the Yamanaka group in Japan. They showed, for the first time, that an adult somatic cell could be reprogrammed into the pluripotent state by reproducing the ESC signaling pathways (Takahashi and Yamanaka 2006). To define the transcription factors necessary for inducing the reprogramming of somatic cells, the Yamanaka group initially selected a total of 24 separate genes. Previous experience suggested that these genes could play a role in ESC identity development and maintenance (Schöler et al. 1989; Avilion et al. 2003; Rizzino 2009). Thus, they determined a final "cocktail" of transcription factors required to induce pluripotent cell development. A number of these genes are involved in rapid cell proliferation, and some are considered oncogenes. After the analysis of different transcription factor combinations, the authors found that only four factors are essential to reprogram an adult somatic cell to the undifferentiated state, a so-called induced pluripotent stem cell (iPSC). Thus, the authors developed iPSCs by inducing overexpression through the retroviral transduction of Oct4, Sox2, Klf4, and c-Myc in mouse embryonic and adult fibroblasts and subsequent selection for Fbx15 expression (Takahashi and Yamanaka 2006). Shortly after, these studies were successfully confirmed by Wernig and colleagues (Wernig et al. 2007). Subsequently, new selection markers were reviewed for identifying iPSC colonies. The authors showed that selection for

Nanog expression generates a germline-competent iPSCs with characteristics similar to ESCs. Under these conditions, they found that the four transgenes (Oct3/4, Sox2, c-Myc, and Klf4) are silenced in Nanog iPSCs (Okita et al. 2007).

Due to the rapid progress in iPSC research, the Yamanaka and Thomson groups reported in 2007 the generation of iPSCs from human cells. These findings are particularly interesting because the contribution of pluripotent cells to disease modeling, drug development, or regenerative medicine was surprising. The Yamanaka group generated iPSCs from adult human dermal fibroblasts using the same four factors: Oct3/4, Sox2, Klf4, and c-Myc (Takahashi et al. 2007). Tumor development is linked with the reactivation of the c-Myc transgene, which is present in the reprogramming cocktail. The presence of this gene could increase tumorigenicity in both the chimeras and progeny mice, which is a serious hurdle for the therapeutic application of iPSCs technology. However, the Thomson group reported that four factors (Oct4, Sox2, Nanog, and Lin28) are sufficient for reprogramming human somatic cells to pluripotent stem cells. Interestingly, Klf4 and c-Myc were not included in the reprogramming cocktail, and the technical limitations that generate viral integration were also eliminated (Yu et al. 2007). Furthermore, new investigations were able to generate human iPSCs from adult dermal fibroblasts without c-Myc (Yu et al. 2007; Nakagawa et al. 2008).

In accordance with the previous descriptions from the Yamanaka, Jaenisch, or Thomson groups, the reprogramming process involved simultaneous overexpression of four transcription factors. In early studies, the authors utilized Oct4, Sox2, Klf4, and c-Myc as pluripotency factors (Takahashi and Yamanaka 2006; Takahashi et al. 2007; Wernig et al. 2007). Thereafter, the Thompson group achieved reprogramming using different pluripotent factors such as Nanog and Lin28 (Yu et al. 2007). Later, reprogramming was also obtained using a fewer number of transcription factors related to stem cell pluripotency (Patel and Yang 2010; Stadtfeld and Hochedlinger 2010; Robinton and Daley 2012). Moreover, some researchers achieved reprogramming including only one or two factors (Grinnell et al. 2007; Kim et al. 2008, 2009a, b, c).

On the other hand, iPSCs have been generated from cells of numerous origins and different species. First, iPSCs were obtained from mice and humans; later, they were generated from other species: rat, pig, rhesus monkey, marmoset, canine, sheep, and snow leopard (Stadtfeld and Hochedlinger 2010; Verma et al. 2012; Sumer et al. 2011; Piedrahita et al. 2011). Certainly, the reprogramming technology offers powerful new opportunities for research not only in the biomedical area. Similarly, iPSCs have been derived from different somatic cell types such as embryonic fibroblasts, adult fibroblasts, hepatocytes, epithelial cells, keratinocytes, melanocytes, mature B cells, mature T cells, pancreatic B cells, and the hepatic endoderm (Nakagawa et al. 2008; Shi et al. 2008; Silva et al. 2008; Stadtfeld et al. 2008a; Guo et al. 2009). Undifferentiated cells have also been useful for reprogramming to iPSCs. These cells include neural stem cells, myeloid progenitor cells, hematopoietic stem cells, adipose-derived stem cells, and cord blood stem cells (Stadtfeld and Hochedlinger 2010). Because the iPS cells can be differentiated into any type of cell with three germ layers, they can be

a cell source relevant for replacement therapy for several disorders. Low transformation efficiency has been a main problem in obtaining these cells.

These findings were startling and altered our knowledge of the epigenetic landscape. Although there has been extensive research to understand how these factors induce changes in gene expression profiles and chromatin modifications through global epigenetic changes, the molecular mechanisms involved in these dedifferentiation processes are incompletely understood (Bernstein et al. 2006).

3.1.1 Oct3/4

The octamer-binding transcription factor POU5F1 (also known as Oct3, Oct4, Oct3/4) is encoded by the POU5F1 gene and expressed during early mouse embryogenesis (Schöler et al. 1989; Palmieri et al. 1994). Oct3/4 has been described as a crucial regulator maintaining pluripotency, which in conjunction with other transcription factors such as Nanog and Sox2, forms a transcription factor molecular network that regulates ESC pluripotency (Boyer et al. 2005; Niwa 2007). Previous studies have shown that Oct3/4 at later stages is expressed in adult stem cells and is considered a pluripotent cell marker (Tai et al. 2005). However, Oct3/4 expression is not limited to stem cells, as differentiated cells also express it (Zangrossi et al. 2007). The differential expression of the isoforms Oct3/4 as Oct3/4A and Oct3/4B may correlate with different processes such as proliferation and differentiation. In fact, a recent study showed that the isoform Oct3/4A is expressed in the nucleus, whereas Oct3/4B is expressed in the cytoplasm in the developing tooth germ (Nakagawa et al. 2012).

Oct3/4 is an essential reprogramming factor, allowing mature somatic cells to return to a pluripotent state as observed in stem cells (Takahashi and Yamanaka 2006; Yu et al. 2007; Nakagawa et al. 2008). Interestingly, their extraordinary ability to reprogram somatic cells into pluripotent cells can be achieved either alone or in collaboration with other factors (Kim et al. 2008, 2009a, b; Li et al. 2011). Currently, a recent study has demonstrated that transcriptional activation of specific genes by Oct3/4 without the gene repression required for differentiation is sufficient for promoting pluripotency (Hammachi et al. 2012). These results contradict those previously reported by researchers who described that the repression of genes required for differentiation is an essential role of Oct3/4 (Boyer et al. 2006; Bilodeau et al. 2009). Oct3/4 does not appear to be required for somatic stem cell self-renewal (Berg and Goodell 2007; Lengner et al. 2007). Moreover, it was observed that Oct3/4 prevents the differentiation and expansion of progenitor cells when overexpressed in adult epithelia (Hochedlinger et al. 2005). Oct3/4 cooperates with a wide set of cofactors. Together with Sox2, Oct3/4 can form a protein-DNA ternary complex that is able to promote the transcriptional activation of fibroblast growth factor 4 (FGF4) (Yuan et al. 1995). Moreover, an interaction between Oct4 and Sox2 might promote expression of itself (Okumura-Nakanishi et al. 2005) and other factors such as Nanog (Kuroda et al. 2005). More recently, Oct3/4 together with Sox2 interacts with a multi-subunit stem cell coactivator complex (SCC) that affects Nanog and Oct4 gene expression as well as genomic regions occupied by Oct4 and Sox2 (Fong et al. 2011).

3.1.2 Sox2

The Sox genes consist of a family of transcriptional regulators involved in the control of nervous system development. Among these is the protein Sox2, an HMG box transcription factor, which is predominantly expressed in undifferentiated cells such as ESCs and is required for the maintaining pluripotency and/or self-renewal (Rizzino 2009).

Studies have shown that Sox2 can form a ternary complex with Oct3 on the FGF4 enhancer DNA sequences promoting FGF4 gene and Nanog gene transcriptional activation. FGF4 is one protein expressed in early embryonic development (Yuan et al. 1995; Kuroda et al. 2005). Likewise, a Sox2 regulatory region, which is also under the control of this Oct3/4-Sox2 complex, was identified (Tomioka et al. 2002). It is believed that the Oct3/4 and Sox2 expression levels are maintained by the Oct4/Sox2 complex in pluripotent cells by a reciprocal transcriptional regulation mechanism (Chew et al. 2005). It has been proposed that the major role of Sox2 is to regulate multiple transcription factors that affect Oct3/4 expression, thus maintaining Oct3/4 expression in pluripotent cells (Masui et al. 2007). Importantly, the transcription factor Sox2 and Oct3/4 have been implicated in early lineage decisions. While both factors cooperate to suppress trophoblast fates in ESCs, they also establish the three lineages present at implantation (Avilion et al. 2003; Li et al. 2007). Sox2 is highly expressed in dividing neural progenitor cells throughout the central nervous system (CNS) (Ellis et al. 2004; Ferri et al. 2004; Komitova and Eriksson 2004). Thus, Sox2 is expressed in embryonic early neural precursors of the ventricular zone and in the ependymal of adult cells. Sox2 is also expressed in lower proportions in differentiated neurons. An important role for Sox2 in neuron maintenance has been described (Ferri et al. 2004). Indeed, Sox2 expression is characteristic of NSCs in the adult brain; however, not all NSCs have the capability to differentiate into all neural cell types in vivo (Brazel et al. 2005). An interesting difference in Sox2 gene expression levels between human and mouse has been described. Mouse primordial germ cells (PGCs) express Oct3/4, Nanog, and Sox2, whereas human PGCs express Oct3/4 and Nanog but not Sox2 (Perrett et al. 2008; De Jong et al. 2008). Sox2 is considered a neural stem cell marker for ICM stem cells. Sox2 has been used as a key transcription factor for reprogramming somatic cells into induced pluripotent cells, but it was not considered essential (Kim et al. 2008, 2009a). Reprogramming neural progenitor cells into iPSCs can be achieved by the combination of factors necessary for reprogramming. Depending on the cellular context, exogenous Sox2 expression is not necessary if cells already express high levels of Sox2 (Eminli et al. 2008). Likewise, Sox2 is not absolutely necessary for neural stem cell self-renewal or multipotency (Miyagi et al. 2008). On the other hand, Sox2 has also been shown to be implicated in tumorigenesis in various organs (Lengerke et al. 2011). These observations indicate that there is a relationship between pluripotency and tumor development (Bernhardt et al. 2012).

3.1.3 Nanog

The transcription factor Nanog plays a key role during lineage specification and in the maintenance of pluripotency in both ICM and ESCs. Nanog in conjunction with other pluripotent factors such as Oct3/4 and Sox2 controls expression of target genes that

possess important functions in pluripotency development. Thus, it was found that Nanog-deficient ESCs lost their ability to self-renew (Cavaleri and Schöler 2003; Mitsui et al. 2003). High levels of Nanog can allow for ESC self-renewal and prevent differentiation in the absence of cytokine LIF or feeder layers (Pan and Thomson 2007). These key transcription factors form a complex regulatory network affecting the expression levels of different target genes related to pluripotency or differentiation (Wang et al. 2006). It was observed that Oct3/4 and Sox2 binding to the Nanog promoter is essential for Nanog transcription in mouse and human embryonic stem cells (Rodda et al. 2005). Moreover, it was observed that Nanog regulates downstream genes necessary for both pluripotency and the differentiation of stem cells through two distinct transactivation domains (Pan and Pei 2003). Other studies described that Nanog dimerization is necessary for interaction with several proteins that promote stem cell pluripotency (Wang et al. 2008). In fact, Nanog is a transcriptional activator for Rex-1, which is a marker for undifferentiated ESCs (Shi et al. 2006). When embryonic stem cells are differentiated into primitive endoderm, Nanog is repressed. Thus, Nanog downregulation plays a crucial role in cell fate during the early embryonic development (Hamazaki et al. 2004). Several studies have shown that Nanog expression is not exclusive to pluripotent cells because it is also present in tumor cells and plays a novel role in tumor development (Jeter et al. 2009). While mouse Nanog expression is high in undifferentiated ESCs in the ICM of the blastocyst, germ cell tumor, and teratoma-derived cell lines, expression is low in several adult tissues (Hart et al. 2004; Hoei-Hansen et al. 2005). Thus, Nanog levels may act as a control mechanism to decide between cell self-renewal and differentiation. Moreover, the expression of pluripotent genes such as Nanog in both seminomas and breast carcinomas suggests a direct role in the progression of different types of carcinomas and could serve as an important marker of tumorigenesis (Ezeh et al. 2005). It was observed that many characteristics present in stem cells are also present in cancer cells. This suggests that any changes in the complex regulation mechanism existing in pluripotent cells could lead to tumor development. Furthermore, it was found that Nanog priming before full reprogramming may generate germ cell tumors (Grad et al. 2011). It is fundamental to discriminate both cell types correctly. On the other hand, regulation of the pluripotent state involves the participation of various factors. Thus, many endogenous noncoding RNA molecules, polycomb complexes, and DNA methylation may play a role in regulating the pluripotent state (Kashyap et al. 2009). Tay and colleagues described how different microRNAs targeting Nanog, Oct4, and Sox2 coding regions participate in embryonic stem cell differentiation (Tay et al. 2008). Likewise, the identification of conserved lncRNA-encoding genes such as lncRNAs, AK028326, and AK141205 was described as direct targets of Oct4 and Nanog (Sheik Mohamed et al. 2010).

3.2 Delivery Systems into Donor Cell

Certainly, the main problem in generating iPS cells is an extremely inefficient transformation process. Thus, iPSCs reprogramming is influenced by numerous

variables that must be considered before choosing a reprogramming method. In fact, reproducibility and the quality of the resulting iPSCs are also affected by the delivery system.

Currently, there are several strategies to generate iPS cells, as rapid progress has been made in this field. These methods utilize several mechanisms for factor delivery as non-integrating vectors, excisable vectors, retrovirus, adenovirus, microRNA, and even soluble proteins, and each has different reprogramming efficiencies (Okita et al. 2008; Stadtfeld et al. 2008b; Kaji et al. 2009; Soldner et al. 2009; Woltjen et al. 2009; Zhou and Freed 2009). Several systems have been described to deliver transgenes into donor cells including integrative and non-integrative delivery systems. Integrative methods have been described such as viral delivery vectors, lentiviral delivery vectors, transfection of linear DNA, and the piggyBac transposon (González et al. 2011; Robinton and Daley 2012; Bellin et al. 2012). Wide variations in the efficiency of reprogramming were observed if reprogramming was performed in cells at different differentiation states. Less differentiated cells as progenitor cells can be reprogrammed more easily. Moreover, less differentiated cells may require fewer transcription factors to achieve reprogramming (Stadtfeld and Hochedlinger 2010).

The firsts iPSCs were obtained by retroviral transduction using pMX-based retroviral vectors (Takahashi and Yamanaka 2006; Takahashi et al. 2007; Okita et al. 2007; Nakagawa et al. 2008). In this case, the retroviruses expressing each gene separately showed an iPSC generation efficiency of less than 0.02 % when either mouse or human fibroblasts were reprogrammed (Stadtfeld and Hochedlinger 2010). Likewise, polycistronic vectors were designed resulting in the simultaneous, almost stoichiometric, expression of transcription factors encoded by the polycistron.

Later, other groups utilized effective lentiviral vectors as delivery systems of reprogramming factors (Yu et al. 2007). In contrast to other retroviruses, lentiviral vectors have a higher infection efficiency, allowing for the infection of both dividing and nondividing cells. Moreover, the development of new lentiviral vectors such as Tet-inducible reprogramming lentiviruses or the STEMCCA lentiviral vector permits the successful ectopic expression of reprogramming factors (Major et al. 2011; Sommer et al. 2012). However, there are several limitations to the safe use of lentiviral vectors for reprogramming. Viral integration into the genome can be random, thus affecting expression of tumor suppressor genes or oncogenes. Therefore, the possibility that viral transgenes can ultimately be spontaneously reactivated increases the risk of tumor formation (Okita et al. 2007).

To avoid viral integration, new alternatives have emerged for factor delivery through a non-integrative method. Adenoviral reprogramming of mouse fibroblasts or liver cells to iPSCs has been described (Stadtfeld et al. 2008b; Okita et al. 2008). Likewise, human iPS cells were derived using a non-integrating episomal vector. Because of the removal of the episoma, the human iPSCs were free of vector and transgene sequences (Yu et al. 2009; Chou et al. 2011). Human iPSCs were also derived using non-viral minicircle DNA vectors (Okita et al. 2010). The major

advantage of these technologies is the lack of genomic integration. One of the main issues in obtaining iPSCs is not just the lower reprogramming efficiency, but also choosing a method that does not change the genomic DNA. Other interesting reprogramming methods involve the use of proteins (Zhou et al. 2009). Although the technique has been described as having a very low reprogramming efficiency, multiple hiPSC lines have been derived through protein-based reprogramming. These cells rescued motor deficits in a PD model (Rhee et al. 2011).

One of the methods that have been proposed to significantly increase reprogramming efficiency is the use of RNA and certain molecules (Warren et al. 2010; Wang et al. 2012).

4 Direct Reprogramming into Neurons

One of the problems with the use of induced pluripotent stem cells is that they can generate tumors. Recently, different groups of researchers have shown that only a few transcription factors were sufficient to generate the direct conversion of fibroblasts to functional neurons without generating a pluripotent stem cell stage (Kim et al. 2011). These cells were less likely to form tumors, avoiding much of the carcinogenic risks of pluripotent cells; they are called induced neuronal (iN) cells. Vierbuchen and colleagues analyzed a pool of 19 neural-lineage-specific transcription factors as possible candidates for direct reprogramming. They showed that the combination of three factors, Ascl1, Brn2, and Myt1l, is able to transform mouse embryonic and postnatal fibroblasts into functional neurons in vitro. The iN cells generated expressed neuronal markers such as GABA (Vierbuchen et al. 2010). They were also capable of converting fetal and postnatal human fibroblasts into iN cells in the presence of the basic helix-loop-helix transcription factor NeuroD1 (Pang et al. 2011). Functional neurons were also obtained from adult human fibroblasts (Pfisterer et al. 2011). Similarly, Caiazzo and collaborates identified three other transcription factors, Mash1, Nurr1, and Lmx1a, that also can be utilized to induce the reprogramming of mouse and human fibroblasts into dopaminergic neurons (Caiazzo et al. 2011). On the other hand, another group of investigators found that the combination of five transcriptional factors, Mash1, Ngn2, Sox2, Nurr1, and Pitx3, were capable of reprogramming human fibroblasts into DA neuron-like cells (Liu et al. 2012).

One of the major disadvantages of this technology in cell-replacement therapy is the low number of cells generated. A new procedure that directly reprograms mouse fibroblasts into neural progenitor cells could avoid this problem. Unlike iN cells, these cells can be expanded in vitro (Kim et al. 2011).

Furthermore, before being used for cell transplantation, the cells must survive at the transplantation site in addition to being effective in the animal model. However, this tool is an attractive option for other cell types for generating patient- and disease-specific neurons to be used in a cell disease models.

5 Conclusion

In recent decades, research efforts have focused on replacing dopaminergic neurons that are lost in patients with Parkinson's disease. To this end, cellular therapies that replace degenerated cells have been the major focus and may be promising therapeutic options in patients with Parkinson's disease in the future. Preliminary studies have utilized adult tissue, embryonic/fetal tissue, and embryonic stem cells as a source of dopaminergic cells. However, safety issues such as the risk of tumor formation and immunological rejection have prevented this type of technique from being an effective treatment against Parkinson's disease. Advances in iPSC research have allowed scientists to obtain specific cells from the same patient, avoiding rejection problems. However, obstacles remain for its clinical use such as the lack of standardized protocols that result in a dopaminergic cell phenotype that grafts without undifferentiated cells and without a risk of tumor formation. Direct reprogramming of somatic cells into induced neuronal (iN) cells without generating a pluripotent stage could be a solution that avoids tumor risk. However, as a result of the low quantity of cells obtained, more investigations are necessary to turn this technique into an efficient cell-replacement therapy. If we overcome these obstacles, iPS and iN cells may be, without a doubt, a very promising therapy in the near future.

Alpha Synuclein in Parkinson's Disease

Christine Lund Kragh, Marina Romero-Ramos, Glenda Halliday, and Poul Henning Jensen

Contents

Abstract

The perception of Parkinson's disease (PD) as a disease centered on dopaminergic striatonigral neurodegeneration has changed fundamentally since 1997 when the first mutation in the SNCA gene (PARK1) encoding α-synuclein was discovered (Polymeropoulos et al. 1997). This discovery formed the basis for a new description of brain pathology characterized by the presence of α-synuclein

1 Introduction

The perception of Parkinson's disease (PD) as a disease centered on dopaminergic striatonigral neurodegeneration has changed fundamentally since 1997 when the first mutation in the SNCA gene (PARK1) encoding α-synuclein was discovered (Polymeropoulos et al. 1997). This discovery formed the basis for a new description of brain pathology characterized by the presence of α-synuclein aggregates in brain cell inclusions that are the hallmarks of PD and other synucleinopathies: dementia with Lewy bodies (DLB) and multiple system atrophy (MSA). This field has been thoroughly covered by many reviews during the last decade (Gai et al. 1998; Spillantini and Goedert 2000; Huang et al. 2004; Ubhi et al. 2011). This review will briefly highlight the historical breakthroughs but focus on recent developments in concepts and hypotheses.

2 Genetics

Missense mutations in the SNCA gene substituting single amino acids (A30P, E46K, and A53T) cause early-onset autosomal dominant PD and DLB (Polymeropoulos et al. 1997; Kruger et al. 1998; Zarranz et al. 2004). Additionally, genomic multiplications of the SNCA gene have been found in patients with early-onset PD and DLB (Singleton et al. 2003) demonstrating that simple overexpression and perhaps developmentally dysregulated expression of the normal protein is sufficient to initiate disease development. The discovery of these rare cases was essential because they causally tie α-synuclein to the development of a PD syndrome, leading to the widely accepted hypothesis that a gain of function in α-synuclein contributes to the pathogenesis of PD. A possible role for α-synuclein in sporadic PD is corroborated by a series of genome-wide association studies carried out on ethnically diverse populations of PD patients. The single-nucleotide

polymorphisms conferring the strongest risk are in the SNCA gene (Simon-Sanchez et al. 2009). Although SNCA is the strongest risk gene, polymorphisms within this gene only increase the risk 2–3 times above the low prevalence of about 0.14 % but serve to corroborate a mechanistic link between the development of sporadic PD and α-synuclein.

3 Structure of α-Synuclein

α-Synuclein is a small 140-amino acid protein, which was first identified as associated with purified synaptic vesicles from the electric ray *Torpedo californica* (Maroteaux et al. 1988). It is one of three synuclein family members (α, β, and γ) identified in humans. The α-synuclein protein can be divided into two regions: (i) the N-terminal region (residues 1–95), which contains seven imperfect repeats with a highly conserved hexameric motif (KTKEGV) and the aggregation-prone non-amyloid component (NAC) sequence (residues 60–95), and (ii) the unstructured C-terminal region (96–140), which is rich in acidic residues (Ueda et al. 1993; George et al. 1995).

The heat-stable nature of human α-synuclein was already described in 1994 (Jakes et al. 1994), and it was ascribed to its natively unfolded structure that possesses an ability to form α-helical structures in apolar solvents (Weinreb et al. 1996) and upon interactions with acidic phospholipid membranes (Clayton and George 1998). When analyzed by gel filtration, the unfolded structure caused the 14.4 kDa α-synuclein peptide to elute corresponding to an approximately 55 kDa globular protein. Moreover, certain dimers appearing on denaturing SDS-polyacrylamide gels were due to misincorporation of a cysteine residue in some preparations of bacterially expressed human α-synuclein (Masuda et al. 2006). Despite its unfolded nature, purified α-synuclein has been demonstrated to exhibit dynamic long-range interactions between the C-terminus and the central NAC domain and even further toward the N-terminus (Cho et al. 2009). Moreover, it undergoes a dramatic structural change upon binding to acidic liposomes where the N-terminal repeat regions fold into two α-helices (Bussell and Eliezer 2003; Chandra et al. 2003).

α-Synuclein aggregates into amyloid fibrils by a nucleation-dependent mechanism and the disease-causing mutations as well as C-terminal truncations favor the consumption of monomers into aggregates. The transformation from a monomeric state to an amyloid state proceeds through soluble oligomeric intermediates (Wood et al. 1999). Several lines of evidence suggest that the oligomers are the most toxic species. First, the disease-causing A30P mutation accelerates the initial oligomerization of α-synuclein in vitro, whereas it retards the formation of mature filamentous aggregates (Conway et al. 2000). Second, α-synuclein oligomers bind synthetic vesicles and cause transient permeabilization representing a potential mechanism of neurotoxicity (Lashuel et al. 2002). This was corroborated when oligomeric forms of α-synuclein applied extracellularly were shown to trigger

calcium entry and toxicity in a neuronal cell line (Danzer et al. 2007). Third, cytotoxicity in cellular models is usually seen without heavily aggregated α-synuclein (Xu et al. 2002; Outeiro et al. 2008; Tetzlaff et al. 2008; Kragh et al. 2009). The protofibrils formed in vitro from purified α-synuclein represent a diverse group generated from simple aggregation of monomers in buffer to induction by various agents and conditions, e.g., apolar solvents, lyophilization, and oxidative cross-linking by, e.g., metals and oxidation products from lipid peroxidation (Sharon et al. 2001; Nasstrom et al. 2011). Immunological characterization of α-synuclein oligomers has been feasible using two different antibodies: the pan-oligomeric A11 antibody recognizing soluble precursors of many types of amyloid-type fibrils (Kayed et al. 2007) and the FILA-1 antibody recognizing α-synuclein-specific epitopes shared between filaments and soluble oligomers. The FILA-1 antibody recognizes elevated levels of soluble α-synuclein aggregates in DLB brain extracts (Paleologou et al. 2009) indicating commonalities between in vitro-formed oligomers and those present in vivo. At present, the structural relation between in vitro-formed α-synuclein protofibrils and those found in cells and brain tissue is unclear and structure-specific imaging agents are in high demand.

Two recent reports challenge the dogma of α-synuclein as a natively unfolded protein and show evidence supporting native tetramers rich in α-helical structure. Both reports indicate that α-synuclein from red blood cells and recombinantly expressed in *Escherichia coli* with a short N-terminal extension can be purified as folded tetramers that irreversibly dissociate into monomers (Bartels et al. 2011; Wang et al. 2011). Interestingly, the tetramers are unable to aggregate and amyloid-type aggregation is only possible after dissociation into monomers. Importantly, the PD-causing missense mutations destabilize the tetramers and thus favor aggregation. These findings are controversial but potentially important as they hypothesize that a stabilization of the native tetrameric state could be a fruitful therapeutic strategy.

4 Posttranslational Modifications

α-Synuclein is subject to different posttranslational modifications. It can be phosphorylated at Ser87, Ser129, and Tyr125 (Ellis et al. 2001; Anderson et al. 2006; Paleologou et al. 2010) in human brain tissue. Though predominantly found in a non-phosphorylated state in vivo, α-synuclein is phosphorylated at Ser129 in inclusions in all α-synucleinopathies (Fujiwara et al. 2002; Anderson et al. 2006). Both Ser129-phosphorylation and ubiquitination are highly enriched in α-synuclein aggregates in diseased brain, whereas other less abundant modifications occur in both soluble and insoluble fractions.

The role of Ser129-phosphorylation in promoting toxic α-synuclein aggregation is unclear as in vitro phosphorylation of this residue has been demonstrated to prevent amyloid-type insoluble aggregation (Fujiwara et al. 2002;

Paleologou et al. 2008). α-Synuclein phosphorylation at Ser129 accelerates inclusion formation and/or toxicity in cell culture models (Smith et al. 2005b; Sugeno et al. 2008; Kragh et al. 2009) and correlates with pathology in transgenic *Drosophila* (Chen and Feany 2005). Studies in rats expressing the phosphomimic form of α-synuclein (S129D) using adeno-associated virus (AAV) have yielded conflicting results (see section on "Animal Models"). However, S129D may not be a suitable phosphomimicking variant of α-synuclein as it was demonstrated that S129D does not reproduce the effects of phosphorylation on structural and aggregation properties of α-synuclein in vitro (Paleologou et al. 2008). Mechanistically, Ser129-P may contribute functionally by conferring novel ligand-binding properties as demonstrated using a phosphopeptide co-immunoprecipitation approach (McFarland et al. 2008). Phosphorylation of tyrosines also occurs in α-synuclein (Ellis et al. 2001) and Tyr125-phosphorylation decreases with age in human brain tissue (Chen et al. 2009). Deletion of the tyrosine residues in α-synuclein increased toxicity in a *Drosophila* model (Chen et al. 2009) indicating a protective role for tyrosine phosphorylation that may be lost with aging. To fully understand the consequence of α-synuclein phosphorylation, it is important to identify the involved kinase(s). Casein kinase II, GRK2/5, and polo-like kinases 2/3 have been shown to phosphorylate α-synuclein in vitro, in cell culture, *Drosophila*, and mice (Pronin et al. 2000; Chen and Feany 2005; Arawaka et al. 2006; Inglis et al. 2009; Mbefo et al. 2010) (for a review see Oueslati et al. 2010).

Proteolytic C-terminal truncations after residues 115, 119, 122, 133, and 135 have been demonstrated in human brain tissue (Anderson et al. 2006), and such modifications increase α-synuclein aggregation in vitro (Crowther et al. 1998). Interestingly, α-synuclein is a substrate for cytoplasmic calpains, and cleaved α-synuclein is found in PD and DLB brain (Mishizen-Eberz et al. 2005; Kim et al. 2006; Dufty et al. 2007), suggesting that calpain may generate truncated toxic species of α-synuclein.

The early focus on dopaminergic neurons in substantia nigra in PD prior to the description of the Braak hypothesis and the use of L-dopa for therapy forms the basis for a large series of experiments on dopamine effects on α-synuclein and vice versa (for a review Leong et al. 2009). Key findings are that dopamine stimulates the formation of soluble off-pathway α-synuclein oligomers in vitro that do not aggregate into fibrils (Conway et al. 2001) and the dopamine oxidation product dopaminochrome promotes the formation of spherical oligomers (Norris et al. 2005). These observations were corroborated in cellular experiments where the dopamine level was modulated by expression of tyrosine hydroxylase (TH) forms (Mazzulli et al. 2006). In addition, α-synuclein has been related to different key proteins of the dopaminergic system. α-Synuclein influences dopamine synthesis by decreasing TH and/or aromatic amino acid decarboxylase activity via changes in the phosphorylation status of these two enzymes (Perez et al. 2002; Tehranian et al. 2006; Lou et al. 2010). Mutated α-synuclein A53T leads to low levels of VMAT2 and consequently to accumulation of dopamine in neurons (Lotharius et al. 2002). α-Synuclein levels have also been implicated in regulating the activity of the

dopamine transporter (DAT), although controversies exist. Hence, direct binding between transgenic hα-synuclein and DAT in cells enhanced dopamine uptake and dopamine-dependent cell death (Lee et al. 2001). However, a later study coexpressing the two proteins identified a negative effect on dopamine uptake (Wersinger and Sidhu 2003). Finally, using the opposite approach by silencing endogenously expressed α-synuclein showed a decreased sensitivity to the DAT-dependent toxin MPP+ and decreased dopamine uptake (Fountaine and Wade-Martins 2007). Hence, the definitive role of dopamine-dependent α-synuclein modifications in vivo and the effect of α-synuclein levels and modifications on dopamine metabolism are still enigmatic.

5 Cellular Metabolism

α-Synuclein is synthesized as a cytosolic protein but it can exist in various subcompartments, e.g., membrane associated or encapsulated with various post-translational modifications. Natively unmodified α-synuclein is readily degraded by the 20S proteasome (Liu et al. 2003) and by chaperone-mediated autophagy in lysosomes in vitro (Cuervo et al. 2004). How α-synuclein is degraded in the brain is less clear, and studies using cell lines and primary neuronal cultures have yielded different results (reviewed in (Xilouri and Stefanis 2011)). Neurons in culture appear to degrade the bulk of α-synuclein by chaperone-mediated autophagy and macroautophagy (Vogiatzi et al. 2008). A recent study using transgenic mice expressing human α-synuclein or α-synuclein-eGFP analyzed the levels of α-synuclein after topical application of inhibitors of the 20S proteasome and the autophagy-lysosome pathway (Ebrahimi-Fakhari et al. 2011). Using cranial window access to the brain surface combined with live imaging and tissue extraction, it was elegantly demonstrated that the basal α-synuclein turnover is mediated by the proteasome system and this process appears even more important with aging. Upon stress mediated by increased α-synuclein expression or compromised proteasomal activity, the autophagy-lysosome pathway is activated (Ebrahimi-Fakhari et al. 2011). The importance of lysosomal dysfunction in relation to Lewy body (LB) formation has been corroborated by the presence of LB pathology in Gaucher disease that is caused by dysfunctional lysosomal hydrolases (Vitner et al. 2010). Exocytosis of vesicle-bound α-synuclein was demonstrated in 2005 (Lee et al. 2005), and direct neuron-neuron transfer of α-synuclein was later confirmed using cell transplantation (Desplats et al. 2009). This formed the important experimental frame for testing whether α-synuclein by a prion-like mechanism causes the neurodegenerative progression described by the Braak hypothesis (Braak et al. 2004) ranging from development of LBs in fetal human dopaminergic neurons transplanted into PD patients (Kordower et al. 2008; Li et al. 2008) to Lewy-like pathology ascending to the brainstem after oral toxin-based generation of α-synuclein pathology in the gut (Pan-Montojo et al. 2010) and to neuronal uptake of preformed α-synuclein aggregates in vitro (Volpicelli-Daley et al. 2011).

6 Normal Functions

The normal function of α-synuclein has been difficult to pinpoint although its effective axonal transport (Jensen et al. 1999) and selective localization in nerve terminals (Maroteaux et al. 1988) suggest a function in this structure. Although it is expressed at high levels in the brain, it is also found in other tissues, e.g., hematopoietic cells (Miller et al. 2004). Reduction of α-synuclein in cultured neurons reduced the distal pool of synaptic vesicles (Murphy et al. 2000), and knockout mice corroborated a presynaptic function as evidenced by reduced striatal dopamine content and an increased neurotransmitter release upon paired stimuli (Abeliovich et al. 2000). However, the phenotype was surprisingly mild with the most striking feature being a resistance to the toxin MPTP (Dauer et al. 2002). Although knockout of α-synuclein alone or α-synuclein and β-synuclein together has minimal effects on neuronal function (Chandra et al. 2004), triple knockout mice lacking all synuclein members demonstrate a robust phenotype with gross reduction in presynaptic size and premature death (Greten-Harrison et al. 2010). These mice display deficits in assembly of SNARE complexes that are required for fusion of synaptic vesicles to the plasma membrane. Interestingly, it was recently shown that the synucleins act as chaperones for presynaptic SNARE proteins (Burre et al. 2010).

Transgenic expression of α-synuclein has been considered a rational approach for most studies of pathological α-synuclein effects because of the dominant inheritance of PD and DLB associated to mutations in the SNCA gene. Hence, wild-type and mutated human α-synuclein has been expressed in a range of cell lines, primary brain cells, yeast cells, and organisms ranging from *Caenorhabditis elegans* and *Drosophila* to mice, rats, and monkeys with variable results. Initially the criteria for success were generation of a LB-like structure and this frustrated many researchers. End points have later changed toward neuronal degeneration and cell death because it was realized that LBs may take months to years to develop in human neurons.

7 Pathogenic Functions

Mechanisms by which abnormal accumulation of α-synuclein disrupts cellular functions have been investigated intensively in several different model systems. Yeast studies have demonstrated that α-synuclein accumulation leads to a blockade of vesicular transport from the endoplasmatic reticulum to the Golgi apparatus and hereby inhibits the viability of the cells (Cooper et al. 2006). Moreover, activation of an unfolded protein response has been demonstrated in SHSY5Y cells overexpressing α-synuclein (Sugeno et al. 2008) and in postmortem brain tissue from PD patients (Hoozemans et al. 2007). However, it became clear in the yeast study that the toxic response was dependent on the α-synuclein dose as revealed by comparing high and low expressers (Su et al. 2010). A different approach has been

taken in mammalian cells that tolerate expression of α-synuclein but where cytotoxicity was induced by coexpressing proteins known to stimulate α-synuclein aggregation like p25α and synphilin-1 (Engelender et al. 1999; Kragh et al. 2009). Using this approach it was demonstrated that p25α induced cellular degeneration that could be attenuated by inhibitors of α-synuclein aggregation as well as of Ser129-phosphorylation (Kragh et al. 2009). The approach of including inhibitors of α-synuclein aggregation may be readily applicable to other models and thereby allow phenotypes caused by mere overexpression of α-synuclein to be more clearly distinguished from those forming aggregations.

It has previously been difficult to identify soluble α-synuclein aggregates in cellular models. Nevertheless, they have been detected by Western blotting in mesencephalic neurons exposed to polyunsaturated fatty acids (Sharon et al. 2003) and in a dopaminergic cell line overexpressing A53T α-synuclein (Zhou and Freed 2005). Moreover, a fluorescence lifetime imaging-based technique to probe the organization of α-synuclein within the cell has demonstrated the formation of small oligomers (Klucken et al. 2006). Toxic effects have also been demonstrated by applying α-synuclein from culture media to cells, but the toxic pathways elicited by internal versus external α-synuclein are still unclear. An elegant approach was used to test whether mature aggregates or insoluble protofibrils are responsible for toxic effects caused by overexpression of α-synuclein. In this study, α-synuclein mutants designed to favor generation of soluble protofibrils exhibited increased toxic potential compared to wild-type α-synuclein in cell and animal models (Karpinar et al. 2009).

Several lines of evidence implicate a dysfunction of the ubiquitin-proteasome system in the pathogenesis of α-synucleinopathies. Studies show that LBs contain ubiquitinated proteins (Chung et al. 2001; McNaught and Jenner 2001) and that the proteasomal activity is decreased in the substantia nigra of PD patients (McNaught and Jenner 2001; McNaught et al. 2003). Moreover, aggregated α-synuclein has been demonstrated to inhibit the activity of the proteasome in vitro (Snyder et al. 2003; Lindersson et al. 2004; Emmanouilidou et al. 2010), and this may have significant effects on proteasomal-dependent degradation of short-lived proteins.

Mitochondrial dysfunction as a consequence of α-synuclein accumulation has also been a major area of interest. Abnormalities of mitochondrial function and increased free radical-mediated damage were described in PD brain before the first PD-associated gene mutations were discovered. α-Synuclein can localize to mitochondria (Hsu et al. 2000; Tanaka et al. 2001; Smith et al. 2005a) and α-synuclein expression increases cellular sensitivity to rotenone, a mitochondrial complex I inhibitor (Orth et al. 2003; Ved et al. 2005). α-Synuclein has also been shown to reduce ATP synthesis and mitochondrial membrane potential (Kamp et al. 2010). Moreover, structural abnormalities of mitochondria have been observed in transgenic mice overexpressing mutant α-synuclein (Martin et al. 2006).

The existence of cellular α-synuclein excretion and uptake by neighboring neurons as previously described may form a path for spreading of the disease process in the nervous system. The potential of such mechanisms has been corroborated by the dramatic neuronal spread of α-synuclein pathology in transgenic mice

expressing human A53T mutant α-synuclein (Luk et al. 2012). Unilateral injection of homogenates from old symptomatic M83 mice into the brains of young mice caused a rapid propagation of aggregated and hyperphosphorylated α-synuclein ranging from the olfactory bulb to the spinal cord that also traversed the corpus callosum to the contralateral hemisphere. The propagation required the recruitment of endogenous mouse α-synuclein. Surprisingly, similar pathology was induced upon injection of in vitro-formed insoluble aggregates of a fusion protein consisting of C-terminally truncated human α-synuclein (1–120) and a Myc epitope tag that lacked the S129 phosphorylation site. Hence, insoluble α-synuclein aggregates may possess "prion-like" seeding activity (Luk et al. 2012).

8 Human Pathology

PD is diagnosed by two separate abnormalities in the absence of sufficient neuropathology for an alternative neurodegenerative disorder (Dickson et al. 2009). A moderate to substantial loss of the dopaminergic neurons in the substantia nigra is required, a finding that also occurs in the majority of movement disorders, and the presence of hallmark neuronal LBs in brainstem predilection sites is also required (Fig. 1a). LBs are also the hallmark pathology of DLB with the two conditions separated mainly on clinical rather than pathological grounds, particularly at end stage (McKeith et al. 2005). PD patients have a dominant slowly progressive movement disorder with cognitive impairment often intervening very late in the disease when LBs infiltrate into the cortex (Dickson et al. 2009). DLB patients have a dominant more rapidly progressive dementia disorder and have cortical LBs often with coexisting Alzheimer's disease (Halliday et al. 2011a). Although α-synuclein forms abnormal aggregates in all synucleinopathies, neuronal LBs only occur in PD and DLB with α-synuclein inclusions in alternate cell types (oligodendroglia) or cellular locations (axonal spheroids) in other synucleinopathies (Halliday et al. 2011a). The reason for the different locations and mechanisms of neurodegeneration involving α-synuclein remain largely unexplored.

In addition to PD and DLB, LBs occur in a small proportion of asymptomatic elderly, a finding which has allowed the development of a hypothesized pathological staging scheme for PD (Braak et al. 2003) and one for both PD and DLB (Beach et al. 2009). Braak hypothesis for the progression of pathology in PD states that the pathology starts peripherally in the olfactory and autonomic nervous systems and progresses through connected regions into the spinal cord and medulla oblongata (stage 1), progressing over time to the pons (stage 2) and midbrain (stage 3), to the basal ganglia (stage 4) and limbic systems (stage 5), and finally to association cortices (stage 6), largely sparing the somatosensory and motor system (Braak et al. 2003) (Fig. 1b). The alternate hypothesis for the progression of LB pathology across PD and DLB by Beach and colleagues (Beach et al. 2009) states that pathology begins in the olfactory bulb (stage 1) and then progresses in two different directions depending on clinical phenotype – for the motor phenotype (PD) LBs

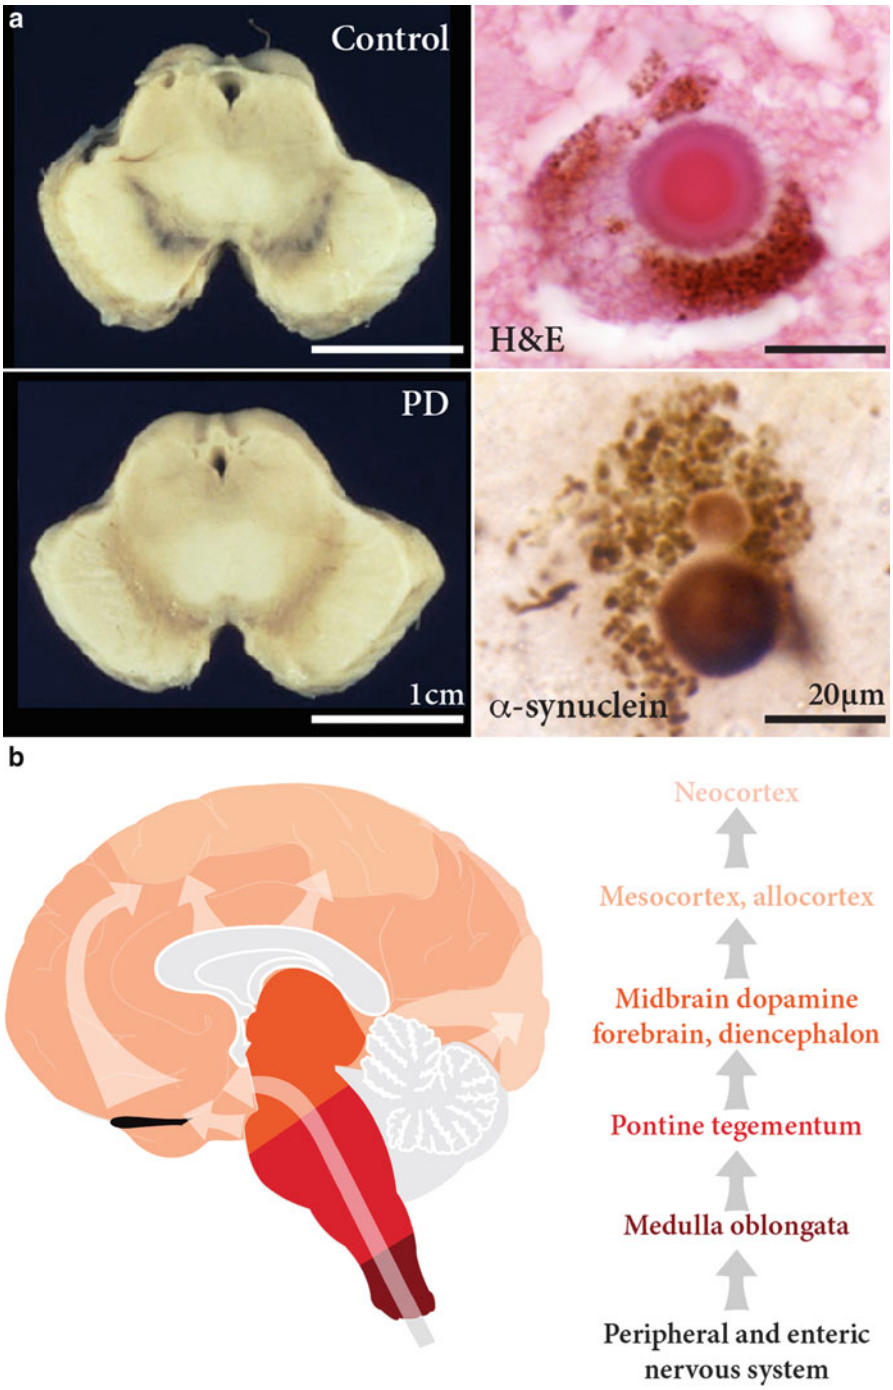

Fig. 1 (continued)

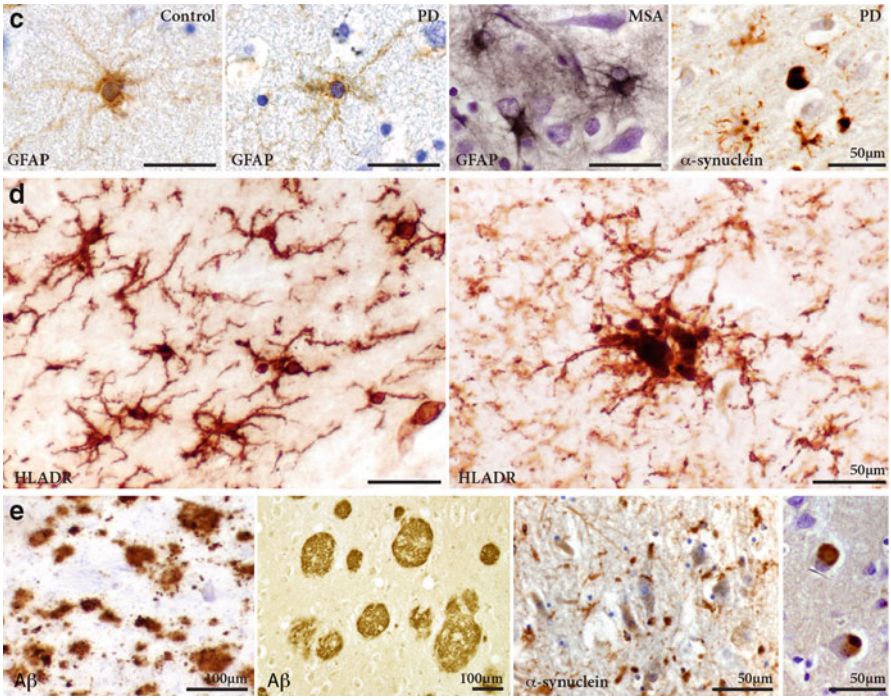

Fig. 1 Neuropathology found in patients with α-synucleinopathies. (**a**) The two diagnostic pathologies required for PD are the loss of pigmented dopaminergic neurons in the midbrain substantia nigra (shown macroscopically at *left*) and LB formation in remaining brainstem pigmented neurons (shown at *right*). Macroscopic photos of transverse sections through the midbrain from a control and a patient with PD demonstrate the loss of the dark neuromelanin pigment in the ventral midbrain. LBs within remaining pigmented neurons in patients with PD can be visualized as large round intracellular inclusions observed with hematoxylin and eosin (H&E) or α-synuclein immunohistochemistry. (**b**) Diagrammatic representation of the Braak staging scheme for the progression of PD from the olfactory and peripheral nervous systems to invade the brain in a slow hierarchical fashion from the lower brainstem to the upper brainstem and forebrain to the cortex. (**c**) Photomicrographs of the typical astrocytic changes that occur in PD versus MSA. While reactive astrogliosis is typical in MSA (observed as an increase in GFAP and hypertrophy of their cell bodies compared to controls), this reaction is not typically observed in end-stage cases of PD. Rather, in PD a large number of astrocytes abnormally accumulate α-synuclein throughout their cytoplasm, a finding associated with the formation of the large round intracytoplasmic LBs in nearby neurons. (**d**) Photomicrographs of the microglial changes observed in PD. Amoebic, phagocytic microglia aggregate only in regions with neuronal loss like substantia nigra (*right*), while in areas abnormally accumulating α-synuclein, the microglia display more HLA-DR reactivity in association with an increased branching morphology (*left*). (**e**) Pathologies associated with each other in patients with the more rapidly progressing DLB and later onset PD with early dementia. The density of amyloid plaques in both the striatum (*left*) and cortex (*middle left*) is related to each other and to the severity of dementia in these patients. Lewy neurites in the hippocampus (*middle right*) are also related to the severity of plaque and LB pathology (at *right*) in such cases

infiltrate the brainstem (stage 2a) and for the dementia phenotype (DLB) LBs infiltrate the limbic system (stage 2b). Finally, for both phenotypes, LBs are found in both the brainstem and limbic system (stage 3) prior to infiltrating cortical regions (stage 4) (Beach et al. 2009).

The Braak staging of PD pathology has been controversial due to discrepancies in a number of validation studies and also due to some conceptual difficulties, while the alternate staging scheme has not been independently evaluated. However, it should be noted that the majority of longitudinally followed cases with motor-dominant PD fit the Braak staging [see review (Halliday and McCann 2010)]. The most obvious difficulty with the Braak staging scheme is using asymptomatic cases with LBs to only stage the progression of PD and not DLB. The more restricted number of stages in the alternate hypothesis incorporating DLB makes this staging scheme of limited current utility. It should be noted that in ~10 % of asymptomatic elderly, LBs occur only in cortical regions (Zaccai et al. 2008). Additionally, the clinical progression of PD relates to the severity of dopaminergic cell loss (Greffard et al. 2006). This may not be surprising if LBs mark neurons destined to die with all LB debris removed following cell death. However, if this was the case, then as the disease progresses, there should be a reduction of LB pathology as cell death is enhanced and affects more regions, rather than the concept of pathology progressing to accumulate in more and more neurons and cells still viable in the brain. Empirical data shows that even in regions thought to be heavily affected with pathology, only 4–5 % of neurons contain LBs in PD (Harding et al. 2002; Greffard et al. 2010). Furthermore, there is no widespread brain tissue loss in PD (Weintraub et al. 2011), and the pattern and severity of cell loss does not reflect the demonstrated pattern and severity of LB formation. Definitive proof of the progression of LB pathology will only occur with the development of biomarkers capable of identifying this pathology.

In addition to the cell loss and LB pathology required for diagnosis, glial changes are obvious in PD (Halliday and Stevens 2011). Astrocytes in PD disengage from neurons leaving the neuronal membranes more exposed (Knott et al. 1999). They undergo PD-specific changes in that they accumulate non-fibrillar α-synuclein and lack the typical reactive astrogliosis that usually accompanies neurodegeneration (Song et al. 2009) (Fig. 1c). In particular, there is often no obvious hypertrophy of astrocytes or upregulation of their glial fibrillary acidic protein (GFAP) or any substantial proliferation, a finding that differs significantly from reactive astrogliosis observed in MSA (Song et al. 2009) (Fig. 1c). This may suggest that any reactive trigger resolves or is removed over time in PD, possibly by cellular uptake. In contrast, the astrocytes in patients with MSA do not accumulate α-synuclein but have the typical reactivity observed in chronic neurodegenerative conditions with obvious cell hypertrophy and upregulation of GFAP (Song et al. 2009) (Fig. 1c), changes that are associated with long-lasting reorganization of tissue architecture. The accumulation of α-synuclein in astrocytes in PD is related to the severity of LB infiltration and synaptic degeneration (Braak et al. 2007),

affecting more astrocytes (~45 %; (Song et al. 2009)) compared with neurons (~4–5 %; Harding et al. 2002; Greffard et al. 2010).

α-Synuclein in astrocytes causes an upregulation of inflammatory mediators (Klegeris et al. 2006; Lee et al. 2010) as well as neuroprotective factors (Power et al. 2002; Ishida et al. 2006; Durrenberger et al. 2009; Michael et al. 2011). The increase in α-synuclein deposition also correlates with an increase in activation of microglia (Croisier et al. 2005), and with the removal of astroglial processes from neurons, the vacated perineuronal space becomes occupied by amoeboid phagocytic microglia (Knott et al. 1999) (Fig. 1d). While activated microglia are well described as a feature of PD (see review Hirsch et al. 2012), phagocytic microglia are only found in regions of cell loss and express scavenger and high-affinity IgG receptor Fcγ (Orr et al. 2005) as well as macrophage markers (Croisier et al. 2005). These data suggest that the relatively large number of astrocytes affected by α-synuclein plays a significant role in the disease process.

PD is one of the age-associated neurodegenerative conditions and occurs often in association with other age-related neuropathologies (Compta et al. 2011). In particular, the pathology most often associated with age-related dementia is amyloid plaque accumulation (Matthews et al. 2009), which also contributes to dementia in older cases of PD (Compta et al. 2011) (Fig. 1e). It should be noted that patients with dementia and sufficient neurofibrillary tangle pathology for a diagnosis of Alzheimer's disease are not considered to have a LB syndrome that contributes to their dementia, due to their substantially greater Alzheimer-type pathology (Dickson et al. 2009). However, amyloid plaque pathology is known to occur in nearly all patients with DLB, being much less frequent in younger PD patients, even those with dementia (Halliday et al. 2011b). This confirms in vivo PiB imaging studies in patients with PD (Gomperts et al. 2008) and suggests that, in such typical patients, the α-synuclein cortical LB pathology is sufficient for their late end-stage dementia. Therefore, there is considerable clinical heterogeneity in patients with LBs that associates with other age-related pathologies – patients with a younger onset often have a slow disease course and more pure LB pathology at end stage, while patients with an older onset are more likely to have additional age-related pathologies and a more rapid and complex clinical course, the most rapid course occurring in patients with DLB (Compta et al. 2011).

9 α-Synuclein in Human Fluids as a Biomarker for PD Progression

Aggregated α-synuclein accumulates in degenerating neurons in PD making measurements of α-synuclein levels a rational biomarker for diagnosis and prediction of disease susceptibility. α-Synuclein has been detected in blood, CSF, and saliva at low nanogram/ml levels (e.g., (Fjorback et al. 2007; Devic et al. 2011; Shi et al. 2011)). Most investigations have focused on detecting the total amount of

α-synuclein but have also investigated the presence of polymers using identical monoclonal anti-α-synuclein antibodies as catching and detecting antibody (Tokuda et al. 2010). Future developments will likely aim at detecting specific α-synuclein isoforms, e.g., misfolded species as detected in brain extracts, and specific phosphorylations to allow for better stratification. For a review on α-synuclein in CSF, please see (Mollenhauer et al. 2010).

10 Modeling PD

Different organisms from flies and worms to rodents and primates have been used to model PD based on expression of wild-type or mutated human α-synuclein. In this section, we will highlight the discoveries related to mammals and refer readers to a recent review about other approaches (Pienaar et al. 2010). There are numerous human α-synuclein transgenic mice although the associated phenotypes are not always consistent probably due to the varying levels and areas of transgene expression as a consequence of the promoters used (for further reading see (Magen and Chesselet 2010; Chesselet and Richter 2011)). Disease modeling has focused on the following points: neurodegeneration in general and dopaminergic neurodegeneration in particular, basal ganglia-associated motor behavior and signs of abnormal α-synuclein folding and handling (see Table 1 for overview).

10.1 Dopaminergic Neurodegeneration

Mice lines using the dopaminergic TH promoter have been rather disappointing in modeling PD (Matsuoka et al. 2001; Rathke-Hartlieb et al. 2001) and only double-mutated α-synuclein (A30P and A53T; a condition not found in humans) has been able to induce dopaminergic failure (Richfield et al. 2002), and this was even obtained with the pan-neuronal Thy1 promoter (Ono et al. 2009). Interestingly, expressing C-terminal-truncated α-synuclein (1–120 or 1–130 α-synuclein) under the TH promoter induced dopaminergic cell death, although not progressively and related to developmental defects (Tofaris et al. 2006; Wakamatsu et al. 2007; Wakamatsu et al. 2008). Using the rat AAV model, the ability of truncated α-synuclein to promote pathological accumulation of wild-type α-synuclein was corroborated (Ulusoy et al. 2010). More widely expressing promoters like Thy1 and PDGF have also been used to model dopaminergic degeneration and subtle phenotypes have been obtained (Masliah et al. 2000; Rockenstein et al. 2002; Lam et al. 2011).

An alternative to the classic transgenic mice lines is adult transgenesis using viral vectors to induce overexpression of wild-type or mutated forms of α-synuclein in nigrostriatal neurons. This leads to progressive and selective neurodegeneration and dopaminergic loss in the basal ganglia (Kirik et al. 2002; Lo Bianco et al. 2002; Yamada et al. 2004; Maingay et al. 2006). These models have shown characteristics of α-synuclein misfolding (Lo Bianco et al. 2004;

Eslamboli et al. 2007), markers of dysfunctional synapses, and neuroinflammation (Theodore et al. 2008; Chung et al. 2009; Sanchez-Guajardo et al. 2010). So far, this is the only approach that has allowed transgenesis in nonhuman primates to successfully model several of the cardinal symptoms of the disease (Eslamboli et al. 2007; Yasuda et al. 2007).

10.2 Non-dopaminergic Neurodegeneration and Braak

The Braak hypothesis posits that α-synuclein degeneration also occurs in non-dopaminergic neurons (Fig. 1b). Indeed enteric nervous system anomalies and colonic problems have been demonstrated in α-synuclein mice (Wang et al. 2008; Kuo et al. 2010). Olfactory problems being early symptoms in the disease have also been observed early in mice along with concomitant α-synuclein pathology in the olfactory bulb (Fleming et al. 2004, 2008; Wang et al. 2008). Very pronounced brainstem and spinal cord degeneration has been observed in the lines using the prion promoter (Giasson et al. 2002; Lee et al. 2002) with up to 75 % of motor neuron cell death (Gispert et al. 2003).

10.3 Pathological α-Synuclein In Vivo

Several α-synuclein transgenic mice models have shown ubiquitin-positive intracellular inclusions (Masliah et al. 2000; Kahle et al. 2001; Lee et al. 2002; Eslamboli et al. 2007; Zhou et al. 2008) and characteristics of aggregation, like resistance to proteinase K treatment (Magen and Chesselet 2010). Early dysfunctional or plastic changes have been observed in the tissue before pathological deposition of α-synuclein can be detected that appears to correlate over time with the severity of neurodegeneration (Gispert et al. 2003). The putative role of α-synuclein Ser129-phosphorylation has been seen in different models (Magen and Chesselet 2010). Phosphorylation of Ser129 is a prerequisite for dopaminergic cell death in *Drosophila* (Chen and Feany 2005), but this has not been corroborated in mammalian models. Three studies have been conducted comparing the neurotoxicity of expressing wild-type and pseudo-phosphorylated S129D mutant human α-synuclein. In two studies wild-type α-synuclein was more toxic than S129D, while the third reported no difference between the two α-synuclein species (Gorbatyuk et al. 2008; Azeredo da Silveira et al. 2009; McFarland et al. 2009). However, it should be kept in mind that S129D α-synuclein structurally is a poor mimic of Ser129-phosphorylated α-synuclein (Paleologou et al. 2008). Indirect approaches for increasing Ser129-phosphorylation using overexpression of phosphoprotein phosphatase 2A activity in a Thy1 transgenic mice line (Lee et al. 2011) or the α-synuclein directed kinase GRK6 using viral vectors in rats (Sato et al. 2011) report increased toxicity, but these approaches also affect the phosphorylation status of other proteins. Noteworthy, phosphorylation at Ser129 is not necessary for α-synuclein

transgene-dependent cell death to occur, as demonstrated in animals overexpressing α-synuclein C-terminally truncated before the Ser129 residue (Wakamatsu et al. 2008; Ulusoy et al. 2010).

10.4 Inflammation and Microglia in the Disease

Microglia activation and neuroinflammation in PD is recapitulated in several models: changes in microglia numbers or morphology, the cytokine pattern, or the gene expression (van der Putten et al. 2000; Neumann et al. 2002; Gomez-Isla et al. 2003; Tofaris et al. 2006; Su et al. 2008; Emmer et al. 2011). The microglial activation patterns correlate with the degree of α-synuclein-dependent neuropathology in the rat viral vector PD model (Sanchez-Guajardo et al. 2010), and pro-degenerative synergism exists between the proinflammatory environment induced by local or peripheral LPS treatment and α-synuclein in transgenic models (Gao et al. 2008; Gao et al. 2011). Neuroprotection observed by both passive and active vaccination in an α-synuclein transgenic mice line demonstrates that the peripheral immune system may be harnessed therapeutically and such an approach is already in a Phase 1 trial (Masliah et al. 2005; Haggerty et al. 2011).

10.5 Interactions with Other Brain Disease-Related Genes

Regarding the possible interactions with other proteins and genes associated with PD, coexpression of A53T α-synuclein and LRRK2 (wild-type, mutated G2019S, or KD) resulted in synergistic toxicity enhancing and accelerating the α-synuclein-induced neurodegeneration (Lin et al. 2009). However, no difference in toxicity was observed in A53T α-synuclein transgenic mice when crossed with DJ1-deficient (Ramsey et al. 2010) or parkin null mice (von Coelln et al. 2006). Transgenic lines coexpressing wild-type α-synuclein and β-amyloid peptides showed more severe anomalies than single transgenics, suggesting a shared pathogenic event between both proteins (Masliah et al. 2001). In parallel, the role of α-synuclein in Huntington's disease has also been highlighted by a decrease in neurodegenerative changes in a knock-in mouse model of Huntington's disease with an α-synuclein knockout background (Tomas-Zapico et al. 2011).

11 Conclusion

There is still considerable doubt over the species of α-synuclein that contributes most to neurotoxicity (Fig. 2). Currently there is a huge gap between data obtained through in vitro versus in vivo methods. This is highlighted by recent data that suggests the native state of α-synuclein is a folded tetramer (Bartels et al. 2011; Wang et al. 2011). If this concept proves true, it has fundamental

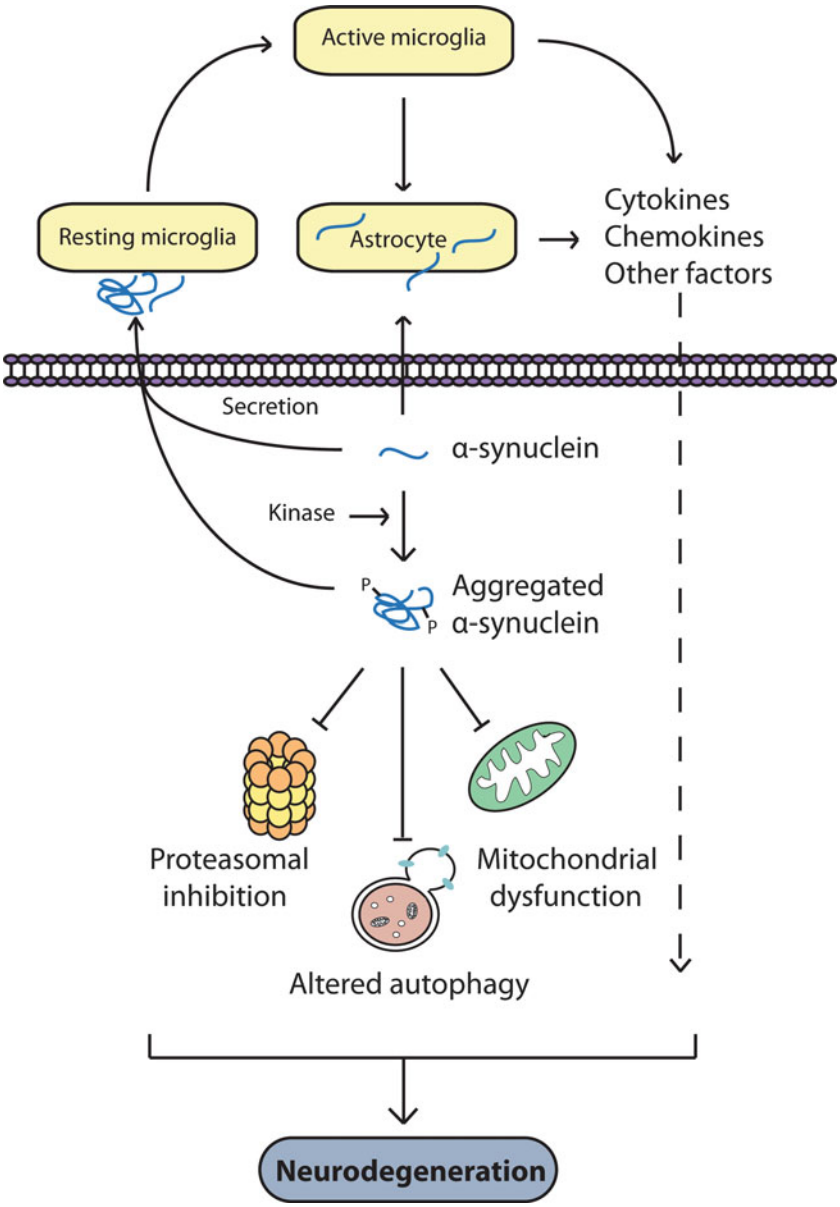

Fig. 2 Proposed mechanisms of neurodegeneration in PD. There are multiple potential pathways of neurodegeneration in PD. α-Synuclein aggregation and accumulation (e.g., of phosphorylated α-synuclein) can cause proteasomal, lysosomal, and mitochondrial impairment leading to neurodegeneration. In addition, α-synuclein can be secreted from neurons and taken up by microglia and astrocytes. Proinflammatory mediators such as cytokines and chemokines produced by activated microglia activate astrocytes, and the products released by activated microglia and astrocytes may exert neurotoxic effects

implications for conceptualizing the potential molecular mechanisms involved in α-synucleinopathies. How Ser129-phosphorylation contributes to these structures or to pathogenesis needs to be determined, as Ser129-phosphorylation is tightly linked to human pathological lesions. To date the functional significance of Ser129-phosphorylation in cell and in vivo models has been inconclusive, findings that may be related to its structural state. Development of novel structure-specific imaging tools, like antibodies and small molecules, is likely to assist with understanding of both the structural and posttranslational changes in α-synuclein that occur in α-synucleinopathies. It is important to clarify the significance of Ser129-phosphorylation of different α-synuclein structural species to determine their role in disease initiation and progression because kinases hold great potential as drug targets.

The novel hypothesis that the disease is spread through the uptake of extracellular α-synuclein has significant implications currently driving considerable research activity. The observation that astrocytes seem to be more prone to such uptake in PD now needs to be understood fully. Particularly, the functional significance of the early and pervasive astrocytic accumulation of α-synuclein needs to be determined. Does such behavior play a paralytic role in the neurodegeneration in PD? Regarding uptake of extracellular α-synuclein, research questions currently pursued include the following: How is α-synuclein externalized during aging and disease and in which forms? How does external α-synuclein affect cells at the cell surface and upon internalization? The answers to these questions will be important for the further development of the currently promising in vivo α-synuclein immunotherapies, as externalized α-synuclein is more amenable to such therapies. Whether there are specific α-synuclein species and/or cell types that are optimal for antibody-dependent targeting needs to be determined. Furthermore, any immunotherapy successes require replication in multiple models.

Aging is known to be the greatest risk factor for PD and LB pathology, but the mechanisms affected by aging still need to be identified. While the importance of mitochondrial function with aging needs to be considered, the specificity that mitochondrial aging precipitates only α-synucleinopathies and not other neurodegenerative conditions requires further explanation. Although speculative, Tyr125-phosphorylation may represent a α-synuclein-dependent cytoprotective mechanism associated with tetramer stability that is lost upon aging. The identification of the toxic species of α-synuclein and changes with aging will be important to determine. The identification that α-synuclein can be catabolized through autophagy and recent in vivo modeling suggests that disruption in the cross talk between proteasomal and autophagic α-synuclein catabolism may be important, particularly as the catabolism of α-synuclein changes during brain development and aging. Another significant factor may be the coexisting pathologies that accumulate with aging. Cellular defenses against misfolded proteins have been characterized in model organisms, and their role in PD needs to be clarified. Whether concentrating on α-synuclein therapeutic interventions alone is the best strategy needs to be clarified.

Abstract

Autophagy is responsible for the degradation and recycling of intracellular material including organelles, cytosolic proteins, and accumulated misfolded proteins. Increasing evidence implicates autophagy dysfunction in several neurodegenerative disorders including Parkinson's disease (PD). In this chapter, we analyze recent studies that provide new links between genes associated to PD and the autophagy process. Mutations in PD-associated proteins like α-synuclein, parkin, PINK1, LRRK2, DJ-1, UCH-L1, ATP12A3, and GBA have been recently directly or indirectly linked to alterations in the autophagic system, thereby contributing to the understanding of the role of this system in the pathogenesis of Parkinson's disease.

Keywords

α-synuclein • ATP12A3 • Autophagy • DJ-1 • GBA • LRRK2 • Parkin • Parkinson's disease • PINK1 • UCH-L1

List of Abbreviations

AD	Alzheimer's disease
ALS	Amyotrophic lateral sclerosis
CMA	Chaperone-mediated autophagy
GBase	Glucocerebrosidase protein
GD	Gaucher's disease
HD	Huntington's disease
LB	Lewy bodies
LIR	LC3-interacting region
LMP	Lysosomal membrane permeabilization
LSD	Lysosomal storage disorders
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MTOC	Microtubule-organizing center
PD	Parkinson's disease
ROS	Reactive oxygen species
SNpc	Substantia nigra pars compacta
UBA domain	Ubiquitin-associated domain
UPS	Ubiquitin-proteasome system
WT	Wild type

1 Introduction

In the last few years, autophagy malfunction had been profusely linked to a growing number of human disorders (Levine and Kroemer 2008; Mizushima et al. 2008), including several neurodegenerative diseases such as Parkinson's disease (Crews et al. 2010; Dagda et al. 2009; Levine and Kroemer 2008;

Narendra et al. 2008; Pan et al. 2008a; Stefanis et al. 2001; Vives-Bauza et al. 2009; Webb et al. 2003; Dehay et al. 2010; Vila et al. 2011), Alzheimer's disease (AD) (Boland et al. 2008; Ling and Salvaterra 2009; Nixon et al. 2005; Pickford et al. 2008), Huntington's disease (HD) (Kegel et al. 2000; Nagata et al. 2004; Petersen et al. 2001; Ravikumar et al. 2004), and amyotrophic lateral sclerosis (ALS) (Morimoto et al. 2007).

The first evidence that the lysosomal system could be altered in neurodegenerative disorders came from the observed accumulation of autophagosomes in brain samples from patients and animal models of these diseases (Anglade et al. 1997; Kegel et al. 2000; Nixon et al. 2005; Sapp et al. 1997; Dehay et al. 2010). This increase in autophagosomes was originally attributed to an activation of the autophagic process aimed at eliminating the abnormal accumulation of proteins occurring in these diseases. However, now we know that accumulation of autophagosomes can also be secondary to a failure in the completion of the autophagic process. After some years of abundant research in the field, a better understanding of the role of autophagy in the intracellular quality control system, particularly in neurons, is now providing new evidences to identify the specific autophagic pathways and steps affected in each of the neurodegenerative pathologies. All the accumulated information may provide new therapeutic approaches aimed at modulating autophagy to attenuate, halt, or prevent neurodegeneration.

2 Types of Autophagy

Autophagy, from the Greek "auto" (self) and "phagy" (eating), refers to the delivery of intracellular components to *lysosomes* for degradation. Lysosomes are intracellular organelles which contain acid hydrolases able to break up all type of intracellular and extracellular components and macromolecules (Bohley and Seglen 1992; Dice 2000; Mullins and Bonifacino 2001). In mammalian cells, there are various types of autophagy (Fig. 1) – macroautophagy, microautophagy, and chaperone-mediated autophagy (CMA) – differing in their mechanisms, their specificity of the substrate to be degraded, their regulation, and their function (Cuervo 2006; He and Klionsky 2006; Klionsky 2005; Levine and Kroemer 2008). Although each type of autophagy displays particular features, they all share some common components and are highly interconnected, resulting in a cross talk between the different autophagic mechanisms as well as between other non-lysosomal proteolytic systems, such as the ubiquitin-proteasome system (UPS). This connection between the different proteolytic systems in the cell allows the activation of compensatory mechanisms, when necessary (Kaushik et al. 2008; Massey et al. 2006a; Nedelsky et al. 2008; Pandey et al. 2007).

In *chaperone-mediated autophagy* (CMA), specific cytosolic proteins are directly translocated into the lysosomes through the lysosomal membrane without any vesicular trafficking (Cuervo and Dice 1996; Majeski and Dice 2004; Massey et al. 2004) (Fig. 1). All CMA substrates contain a sequence biochemically related to the pentapeptide KFERQ (Dice 1990), which targets the substrate to the

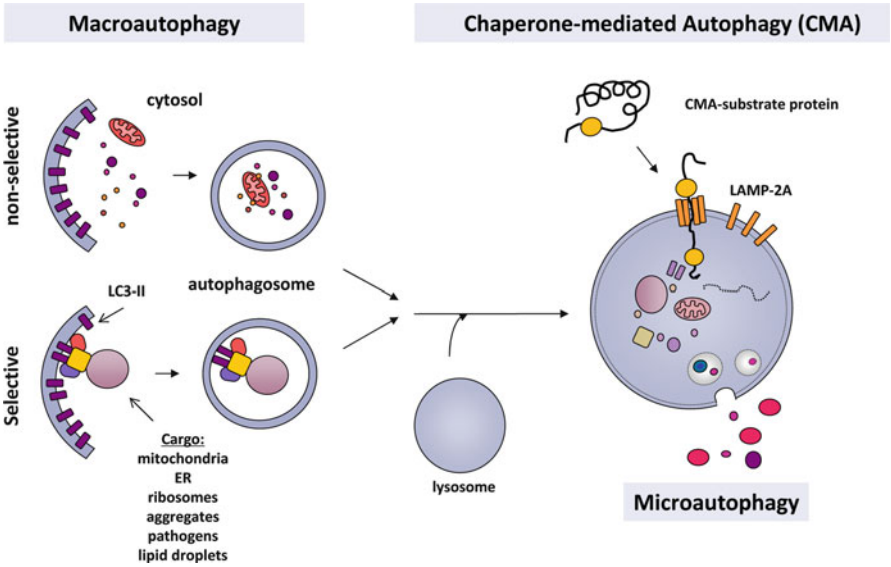

Fig. 1 *Autophagy pathways*. Three types of autophagy occur in mammalian cells. In chaperone-mediated autophagy (CMA), specific cytosolic proteins containing the CMA-targeting motif are recognized by a chaperone complex and sent to lysosome where they bind the membrane receptor LAMP-2A and directly are translocated into the lysosomes for degradation. Microautophagy involves the sequestration and degradation of complete regions of the cytosol (including proteins and organelles) through invaginations and tubulations of the lysosomal membrane. In macroautophagy intracellular components are enclosed in a double-membrane vesicle called autophagosome. This vesicle is then fused with lysosomes, which provides the hydrolytic enzymes required for the total degradation of the sequestered material. Macroautophagy can be a nonselective process engulfing in-bulk portions of the cytosol but also can be a selective mechanism where specific substrates are recognized by different autophagic adapters and sent selectively to degradation

lysosome membrane with the help of some cytosolic chaperones and binding to receptor membrane protein LAMP-2A (Agarraberes and Dice 2001; Cuervo and Dice 1996). The substrate protein is then translocated into the lysosomal matrix where it is rapidly degraded by the hydrolytic enzymes. CMA is activated by nutrient stress (Cuervo et al. 1995) but also in response to some other stress conditions like oxidative stress or exposure to toxic compounds (Kiffin et al. 2004).

Microautophagy involves the sequestration and degradation of complete regions of the cytosol by the lysosomal system, including cytosolic proteins and organelles, through the engulfment of the lysosomal membrane itself (Ahlberg and Glaumann 1985; Marzella et al. 1982; Mortimore et al. 1988; Sakai et al. 1998). The lysosomal membrane can form invaginations or fingerlike protrusions to form vesicles loaded with cytoplasmic components. Once the vesicle is inside the lysosome, the membrane disappears and the sequestered material is degraded (Fig. 1). To date, the mechanisms of induction or regulation of microautophagy in mammalian cells remain unknown, and it is assumed that microautophagy participates in the continuous basal turnover of cellular components under normal cellular conditions.

Macroautophagy is the best-characterized form of autophagy and is frequently referred just as "autophagy." Macroautophagy is responsible for the degradation of most intracellular components as a major mechanism to maintain cellular homeostasis and appropriate balance between protein synthesis and degradation. During macroautophagy, a portion of cytosol, including entire organelles, is surrounded by an intracellular membrane to form a double-membrane organelle called *autophagosome*, which contains the sequestered components (Wang and Klionsky 2003). This vesicle fusions later with lysosomes, which provides the hydrolytic enzymes required for the total degradation of the sequestered material (Fig. 1). Under stress conditions, autophagy can be activated as part of the cellular stress-response mechanism, as it occurs, for instance, in early stages of nutrient deprivation in order to provide amino acids and other essential basic elements (He and Klionsky 2009; Ravikumar et al. 2010). In addition to this well-known role of autophagy, this pathway also participates in other cell functions such as cell differentiation, tissue remodeling, development, host-to-pathogen response, and removal of toxic or abnormal intracellular components (Mizushima et al. 2008).

The demand for autophagy activity varies among different tissues and cell types. In most tissues, macroautophagy is mainly induced upon stress conditions. Consequently, a failure in macroautophagy can result in an increased cell susceptibility to stress, since the cell is no longer able to respond properly to stress situations, but under basal conditions cell survival may not be compromised. In contrast, postmitotic cells like neurons require an effective and constitutive macroautophagy activity to maintain cell homeostasis. Consequently, any disruption of autophagy in neurons results in an accumulation of abnormal proteins within the cell and leads to neurodegeneration, even in the absence of any aggravating event such as the presence of mutant or prone-to-aggregate proteins (Hara et al. 2006; Komatsu et al. 2006; Wang and Klionsky 2003).

Macroautophagy is a complex mechanism that can be divided into different steps: induction, elongation of the limiting membrane or phagophore, cargo recognition of the substrate to be degraded, fusion of the autophagosome with lysosomes, and clearance of the cargo (Fig. 1). While macroautophagy was originally described as a nonselective step in the autophagy process, recent studies demonstrated the selectivity of the autophagic degradation process. As a result, new types of autophagy have been described according to the selective substrate involved, including *mitophagy* (i.e., selective degradation of mitochondria by autophagy) (Kim et al. 2007), pexophagy (i.e., selective degradation of peroxisomes by autophagy) (Dunn et al. 2005; Sakai et al. 1998), reticulophagy (i.e., selective degradation of endoplasmic reticulum portions by autophagy) (Bernales et al. 2007), ribophagy (i.e., selective degradation of ribosomes by autophagy) (Kraft et al. 2008), lipomacrophagy (i.e., selective degradation of lipid droplets portions by autophagy) (Singh et al. 2009), xenophagy (i.e., selective degradation of intracellular pathogens by autophagy) (Levine 2005), and aggregophagy (i.e., selective autophagic degradation of ubiquitinated aggregates).

The intraneuronal accumulation of autophagosomes and aberrant or misfolded proteins that eventually aggregate forming inclusion bodies is observed in affected

brain regions of several neurodegenerative disorders and represent one of the hallmarks of these diseases, thus emphasizing the role of the autophagy system in the pathogenesis of these disorders. However, in each neurodegenerative disorders, autophagy can be affected at different step/s of the process, and therefore, the potential therapeutic approaches aimed to reestablish normal degradation activity in these diseases should differ depending on the autophagy step that is impaired.

3 Role of Autophagy in Neurodegenerative Disorders

Growing evidence indicates a role of autophagy failure in neurodegenerative disorders (Martinez-Vicente and Cuervo 2007; Mizushima et al. 2008; Wong and Cuervo 2010). When the intracellular degradative systems become compromised, the protein quality control of the cell fails, and as a consequence, many altered proteins (including mutant, posttranslational modified, or damaged proteins) often have the tendency to organize into complex structures like oligomers, protofibrils, and small aggregates that may be toxic to the cells. As part of the protein quality control system, cells have developed mechanisms to fight against protein misfolding, first trying to identify and repair altered proteins with chaperones (Voisine et al. 2010) and then, if necessary, eliminating the aberrant misfolded proteins through UPS or autophagy. Defects in either molecular chaperones or proteolytic systems have been identified in different neurodegenerative disorders, which have been proposed to contribute to the pathogenesis of these diseases. A failure in macroautophagy, in particular, can be dramatic for the cell since it is the only degradative mechanism able to eliminate the toxic protofibrils and aggregates once these have become insoluble. Furthermore, autophagy also contributes to the selective turnover of organelles, such as mitochondria, through the selective macroautophagy machinery. Therefore, an impairment in autophagy like the one observed in some neurodegenerative disease can lead to the accumulation of old or damaged mitochondria that become a new source of reactive oxygen species (ROS), thereby contributing to oxidative stress and aggravating the consequences of the pathologic process. Further supporting a role for autophagy in neurodegeneration, it has been reported that pharmacological or genetic inhibition of autophagy worsens the pathology and increases the number of aggregates in different cellular and animal models of neurodegeneration, while activation of macroautophagy with drugs like rapamycin can reduce the number of intracellular aggregates and ameliorates the neurodegenerative process in these experimental systems (Bove et al. 2011).

4 Autophagy and Parkinson's Disease

Parkinson's disease is a common neurodegenerative disorder of unknown origin mainly characterized by the loss of dopaminergic neurons from the substantia nigra pars compacta (SNpc) and the presence, in the affected brain

regions, of ubiquitinated intraneuronal proteinaceous cytoplasmic inclusions called *Lewy bodies* (LB). The presence of Lewy bodies in PD suggests that defective protein handling may contribute to the pathogenesis of the disease. The first evidence linking autophagy with PD involved the observation of accumulated autophagosomes in the SNpc of postmortem brain samples from PD patients (Anglade et al. 1997; Voisine et al. 2010; Zhu et al. 2003). Recent studies confirmed this observation (Chu et al. 2009; Dehay et al. 2010). More recently, a pathogenic autophagy impairment was observed in the MPTP mouse model of PD. MPTP-treated mice exhibit accumulations of undegraded autophagosomes and reductions in the number of functional lysosomes in SNpc dopaminergic neurons that precede cell death in this model. Lysosomal deficiency in this model was attributed to abnormal lysosomal membrane permeabilization (LMP) mediated by mitochondria-derived oxidative attack. Following LMP, the release of hydrolytic lysosomal enzymes to the cytosol can, among other consequences, abolish the lysosomal capacity of the cell, which results in an accumulation of undegraded autophagosomes that cannot be cleared by dysfunctional lysosomes (Dehay et al. 2010). Pharmacological reactivation of lysosomal-mediated degradation by *rapamycin* in MPTP-treated mice can restore autophagosome clearance and attenuate SNpc dopaminergic cell death in this model of PD (Dehay et al. 2010). Rapamycin also provides neuroprotection in other in vivo models of PD, such as 6-OHDA-treated mice (Santini et al. 2009), lactacystin-microinjected mice (Pan et al. 2008b), transgenic mice overexpressing wild-type (WT) α-synuclein (Crews et al. 2010), or paraquat-treated drosophila (Bjedov et al. 2010). The neuroprotective effects of rapamycin in all these models were attributed, at least in part, to the activation of autophagy.

5 PD-Related Proteins Involved in Autophagy

Genetic studies have provided important insights into the pathological mechanism underlying PD. Among all the genes linked to familial forms of PD, many of them appear now related to autophagy pathways, thereby providing new evidences and mechanisms to potentially explain the link between autophagic failure and PD. In this section, we will discuss some of the findings linking PD-related genes/proteins with the autophagy system.

5.1 α-Synuclein

α-*Synuclein* is a small protein encoded by the SNCA gene. Three missense point mutations have been linked to autosomal dominant forms of PD (A30P, A53T, and E46K), as well as duplications and triplications of the gene (Chartier-Harlin et al. 2004; Ibanez et al. 2004; Kruger et al. 1998; Polymeropoulos et al. 1997; Singleton et al. 2003; Zarranz et al. 2004). α-Synuclein is mostly found in neuronal presynaptic terminals, and although its exact functions remain unknown, it has

been proposed to be involved in the regulation of synaptic vesicles, neurotransmitter release, molecular chaperone activity in the SNARE complexes, and vesicle trafficking (Bonini and Giasson 2005; Burre et al. 2010; Cooper et al. 2006). α-Synuclein is a major component of LB and is normally degraded by different proteolytic systems, including the UPS (Bennett et al. 1999; Imai et al. 2003), macroautophagy, and CMA (Cuervo et al. 2004; Vogiatzi et al. 2008; Webb et al. 2003; Xilouri et al. 2009). As PD progresses, alterations in UPS and autophagy systems may impair the capacity of the cell to properly handle and execute α-synuclein turnover and thus contribute to the formation of protein inclusions like LB. The presence of aberrant or mutated forms of α-synuclein can induce the failure of one of these proteolytic pathways and interfere with the rest of proteolytic mechanisms, given the important cross talk between all the proteolytic systems of the cell.

α-Synuclein contains the CMA-targeting motif needed for the recognition by the hsc70 chaperone, which delivers the substrate to the lysosomal membrane receptor LAMP-2A in order to be translocated into the lysosomal lumen for its degradation. The two main point mutations in the α-synuclein gene (A30P and A53T) that lead to familial forms of PD can affect CMA activity. When one of these α-synuclein mutants is recognized through its CMA-motif, it is targeted to lysosomes and binds LAMP-2A receptor with higher affinity than the WT protein. However, the translocation of mutant α-synuclein inside the lysosome is impaired, and therefore, it cannot be degraded by CMA. In addition, mutant α-synuclein remains bound to the CMA translocation complex, thereby blocking not only their own degradation but also the degradation of other CMA substrates (Cuervo et al. 2004). The pathogenic effect of mutant α-synuclein on CMA activity was also observed in neuronal cell cultures (Vogiatzi et al. 2008; Xilouri et al. 2009). Additionally, CMA failure linked to α-synuclein pathogenic mutations is followed by a compensatory induction of macroautophagy, as it has been observed in other situations (Massey et al. 2006b).

Abnormal high levels of WT α-synuclein are also associated with PD. In cellular models, overexpression of WT α-synuclein impairs CMA activity and contributes to cell death through an effect on CMA-substrate MEF2D (Yang et al. 2009). MEF2D is a transcriptional factor required for neuronal survival that is shuttled from the neuronal nucleus to the cytoplasm, where it interacts with chaperone protein hsc70 before being targeted to lysosomes for degradation. High levels of α-synuclein (like those observed in PD patients with triplications of the α-synuclein gene) in α-synuclein-overexpressing cellular and animal models impair CMA-mediated degradation of MEF2D, leading to the accumulation of MEF2D in the cytoplasm and subsequent neuronal death (Yang et al. 2009).

In addition to the rare α-synuclein mutations and duplications/triplications of the gene (which occur in less than 2 % of patients from familial PD), the most common posttranslational modifications of α-synuclein have been described in sporadic PD patients and experimental PD models (Anderson et al. 2006; McFarlane et al. 2005; Paxinou et al. 2001; Smith et al. 2005; Uversky et al. 2005; Volles and Lansbury 2003). These modifications include phosphorylation, ubiquitination, nitration, and

oxidation of α-synuclein, as well as α-synuclein modifications caused by its interaction with oxidized dopamine (Norris et al. 2005). Some of these posttranslational modifications of WT α-synuclein can promote the formation of oligomeric protofibril intermediates, which usually evolve into insoluble α-synuclein fibrils, the main component of LB (Chen and Feany 2005; Conway et al. 2000; Rochet et al. 2004; Uversky et al. 2005). The ability of the modified α-synuclein forms to be degraded by CMA depends on the type of modification (Martinez-Vicente et al. 2008). For instance, phosphorylation, nitration, and oxidation of α-synuclein decrease the capacity of α-synuclein to be translocated and eliminated through the CMA pathway, thereby increasing the amount of these α-synuclein soluble forms into the cytosol and thus the possibility to interact with other molecules and become oligomers or aggregates. In contrast, dopamine-modified α-synuclein behaves as the A30P and A53T mutant α-synuclein, thereby remaining bound to the CMA translocation complex and blocking the degradation of other CMA substrates. The origin of this blockage seems to reside in the ability of dopamine-modified α-synuclein to form oligomers on the lysosomal surface after binding as a monomer to the CMA translocation complex. The formation of these clusters on the lysosomal membrane seems to prevent the binding and translocation of other proteins. The consequences of this inability to degrade modified forms of α-synuclein result in increased cytosolic concentrations of the protein, thus favoring its oligomerization. On the other hand, normal substrate proteins for CMA can no longer be turned over through this pathway and also end up accumulating inside the affected cells.

Overexpression of WT α-synuclein can also inhibit macroautophagy activity, as it has been recently showed in PD models (Winslow et al. 2010). In particular, the overexpression of α-synuclein causes the loss of function of Rab1, a protein involved in secretory pathways. Inhibition of Rab1a activity, in turn, causes mislocalization of Atg9, an autophagy protein essential for autophagosome formation. As a consequence, autophagosome formation is impaired, thereby resulting in an accumulation of autophagic substrates.

5.2 LRRK2

*LRRK*2 is a large protein with several domains including, among others, a ROC domain (with GTPase activity), a COR (C-terminal of ROC) domain, a leucine-rich repeat domain (LRR), and a serine/threonine kinase domain (Gloeckner et al. 2006; Greggio et al. 2006, 2008; Greggio and Cookson 2009; Smith et al. 2006; West et al. 2005). Several mutations in this protein cause an autosomal dominant form of PD (Paisan-Ruiz et al. 2004) with pathological and clinical features very similar to late-onset sporadic PD, including the presence, in most cases, of LB. The majority of these pathological mutations are localized in the GTPase or the kinase domain, being G2019S the most common mutation present in PD cases (Dachsel et al. 2010; Paisan-Ruiz et al. 2004, 2008; Zimprich et al. 2004). Many different physiological roles for LRRK2 have been proposed, but the putative substrate/s that LRRK2

might phosphorylate in vivo remains controversial. So far, it is known that the kinase activity is required for its GTPase activity and this kinase activity depends on the formation of LRRK2 dimers. It has also been shown that LRRK2 kinase activity is required for neurodegeneration, and therefore, inhibition of its kinase activity has neuroprotective effects in PD models (Greggio et al. 2006; Smith et al. 2006).

In the last few years, LRRK2 has been suggested to play a role in numerous different cellular mechanisms. Some of the suggested functions of LRRK2 include modulation of protein translation through the direct phosphorylation of the translation initiation factor 4E-BP1 (Imai et al. 2008) and the interaction with microRNAs that regulate protein translation (Gehrke et al. 2010). In cellular models, apoptosis also seems to be regulated by LRRK2 through the direct interaction of LRRK2 with the death adaptor FADD (Ho et al. 2009). Different groups have shown that LRRK2 can also be involved in neuronal morphogenesis (MacLeod et al. 2006; Parisiadou et al. 2009; Plowey et al. 2008; Wang et al. 2008). Relevant to this chapter, other authors have implicated LRRK2 in autophagy and the lysosomal system.

While the role of LRRK2 on autophagy is not fully understood, some authors propose that this function could be due, in part, to the role of LRRK2 on cytoskeleton dynamics and its interaction with tubulins, microtubules, and other proteins involved in trafficking and endocytosis. LRRK2 loss-of-function mutations would impair the trafficking and the cytoskeleton dynamics, thereby affecting, among other mechanisms, the lysosomal system (Dzamko et al. 2010; Gandhi et al. 2008; Gillardon 2009a, b; Sakaguchi-Nakashima et al. 2007; Shin et al. 2008). At the same time, other authors used different cellular models expressing mutant LRRK2 or LRRK2 knockdown animals to confirm the hypothesis that LRRK2 is involved in the autophagy process. These cellular and animal models exhibited an LRRK2-dependent impairment of the autophagy process, thereby confirming the role of this protein in the correct functioning of autophagy (Alegre-Abarrategui et al. 2009; Ferree et al. 2011; Gomez-Suaga et al. 2012; Ramonet et al. 2011; Tong et al. 2010, 2012). More recently, a novel PD cellular model based on the generation of dopaminergic neurons derived from induced pluripotent stem cells (iPSC) obtained from fibroblasts of patients carrying the G2019S LRRK2 mutation exhibited the typical autophagic alterations observed in postmortem brain samples from PD patients, such as an accumulation of autophagic vacuoles and defects in autophagosome clearance (Sanchez-Danes et al. 2012). Taken together, these data confirm the implication of LRRK2 in the autophagy process. However, the mechanisms underlying this effect and the consequences of PD-linked mutations of LRRK2 on this function remain unknown.

5.3 Parkin and PINK1

Autophagic failure in PD has recently been confirmed through the newly identified roles of parkin and *PINK*1 proteins in maintaining mitochondria homeostasis by mediating mitochondrial trafficking and autophagic clearance of dysfunctional

mitochondria. *Parkin* is a component of a multiprotein E3 ubiquitin ligase and PINK1 is a serine/threonine protein kinase that localizes in the mitochondria and is involved in stress-induced mitochondrial dysfunction. Recently, both proteins have been proposed to belong to the mitochondrial quality control system, working together to promote degradation of dysfunctional mitochondria by mitophagy (Dagda et al. 2009; Narendra et al. 2008; Vives-Bauza et al. 2009; Whitworth and Pallanck 2009).

Loss-of-function mutations in PINK1 or parkin are associated to autosomal recessive familial PD. These mutations result in mitochondrial dysfunction with impaired mitochondrial turnover that leads to cell death. Indeed, it has recently been shown that PD-linked mutations in parkin can cause defects in the mitophagy process (Geisler et al. 2010; Lee et al. 2010b; Matsuda et al. 2010; Narendra et al. 2010b; Vives-Bauza et al. 2010). In addition, PD-linked mutations in PINK1 cause defective parkin recruitment to mitochondria and, consequently, mitophagy efficiency is affected (Geisler et al. 2010; Narendra et al. 2010b; Ziviani and Whitworth 2010; Vives-Bauza et al. 2010). PINK1is localized in mitochondria where it is cleaved to a shorter form that is no longer retained in mitochondria and is released to the cytosol, resulting in low mitochondrial levels of full-length PINK. This PINK1 cleavage is membrane-voltage dependent, and after depolarization of the mitochondrial membrane, the cleavage is inhibited, resulting in an accumulation of full-length PINK1in the mitochondria (Narendra et al. 2010b) (Fig. 2). The retention of PINK1 in damaged mitochondria recruits parkin to mitochondria which, through its E3 ubiquitin ligase activity, can polyubiquitinate different membrane proteins like VDAC1 and mitofusin (Geisler et al. 2010; Narendra et al., 2010b; Ziviani et al. 2010; Gegg et al. 2010). Polyubiquitination of mitofusin inhibits mitochondrial fusion (Tanaka et al. 2010; Ziviani and Whitworth 2010), thereby preventing the fusion of damaged mitochondria with healthy ones, while polyubiquitination of VDAC1 is required for mitochondrial clearance by mitophagy (Fig. 2). After VDAC1 polyubiquitination by parkin, depolarized mitochondria is tagged and autophagic adapters can bind the mitochondria to be sent to the autophagosome, where it will be degraded after fusion with lysosomes. A potential role for the autophagic adapter *p*62 in this parkin-mediated mitophagy process is still controversial. p62 can bind both ubiquitin proteins, by its ubiquitin-associated (UBA) domain, and also *LC*3, through its LC3-interacting region (LIR) domain, thus acting as a recruiter of ubiquitin-tagged substrates that are sent to autophagic limiting membrane, where LC3 is one of the main components (Pankiv et al. 2007). The autophagosome is then formed and the substrate is eliminated by macroautophagy. Some authors have reported that this PINK/parkin-mediated process is p62-dependent and that the damaged mitochondria tagged by ubiquitination requires the binding of p62 to be eliminated (Ding et al. 2010; Geisler et al. 2010; Okatsu et al. 2010). However, other studies have found that mitophagy is not p62-dependent and probably other autophagic adapters can display this function (Lee et al. 2010a; Narendra et al. 2010a; Okatsu et al. 2010).

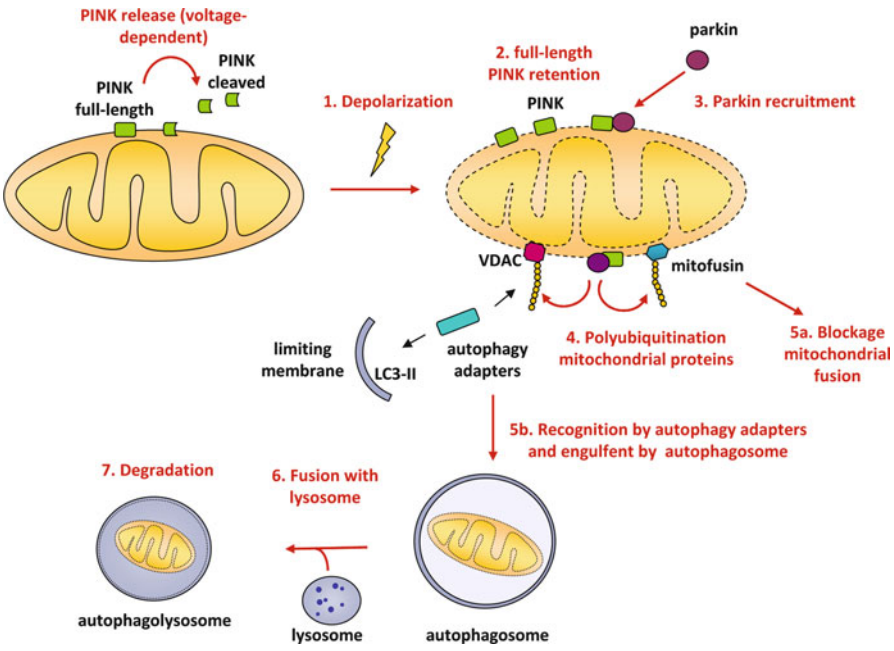

Fig. 2 *PINK/parkin-mediated mitophagy*. Upon mitochondria membrane depolarization, PINK1 full-length protein is retained in mitochondria membrane and recruits parkin protein. Once parkin is localized in the mitochondria membrane, they can polyubiquitinate different membrane proteins like VDAC1 and mitofusin. Polyubiquitinization of mitofusin inhibits future mitochondrial fusion with other healthy mitochondria, while polyubiquitinization of VDAC allows the interaction with autophagic adapters that will trigger the engulfment of the depolarized mitochondria by the autophagosome and its subsequent degradation inside the lysosomes

5.4 DJ-1

Mutations in the *DJ-1* gene result in a rare cause of autosomal recessive PD (Bonifati et al. 2003; Wong and Cuervo 2010). The physiological role of DJ-1 is still not fully understood, but it has been implicated in different biological functions like maintaining mitochondria integrity and acts as a redox-sensitive chaperone with antioxidant properties (Blackinton et al. 2009; Canet-Aviles et al. 2004; Irrcher et al. 2010; Junn et al. 2009; Kim et al. 2005; Meulener et al. 2005; Taira et al. 2004; Wong and Cuervo 2010). Most of these studies were performed in experimental in vivo and in vitro models of DJ-1 knockdown and showed that loss of DJ-1 function is linked to mitochondria depolarization and fragmentation, hypersensitivity to oxidative stress, and reduction of basal autophagy (Krebiehl et al. 2010). Recently, DJ-1 has also been linked to mitophagy by working together with parkin and PINK1 in the elimination of damaged mitochondria after oxidative stress (Thomas et al. 2011). The mechanism of action of DJ-1 on mitophagy remains unclear, but deficiency in DJ-1 leads to a similar mitochondrial phenotype as the one observed in

PINK1- and parkin-deficiency models (Thomas et al. 2011). In addition, DJ-1 overexpression is able to protect against oxidative stress in PINK1-deficient cells (Thomas et al. 2011). Overexpression of parkin or PINK1 can rescue the mitochondrial alterations occurring in DJ-1-knockdown cells, thus suggesting a potential role for DJ-1 in PINK1/parkin-mediated mitophagy.

5.5 UCH-L1

Another potential link between PD pathogenesis and autophagy is the role of UCH-L1 protein in the CMA pathway. *UCH-L1* (ubiquitin C-terminal hydrolase L1) is expressed in neurons and is associated with familial PD forms. This protein physically interacts with CMA receptor LAMP-2A at the lysosomal membrane. When the UCH-L1 protein carries the PD-linked mutation I93M or a posttranslational carbonyl modification reported in sporadic forms of PD, the interaction of the protein with the CMA translocation complex is increased, thereby preventing the CMA-mediated degradation of other substrates, as previously observed with some forms of α-synuclein (Kabuta et al. 2008). Interestingly, the UCH-L1 polymorphism S18Y may have opposite effects, being protective against the development of sporadic PD (Satoh and Kuroda 2001; Elbaz et al. 2003; Carmine et al. 2007). Experimental in vitro and in vivo PD models experimentally confirmed a neuroprotective effect of the S18Y polymorphism (Kyratzi et al. 2008; Xilouri et al. 2012). While the basis for this neuroprotective effect is still controversial, it may involve the antioxidant function of this UCH-L1 variant.

5.6 ATP13A2

The *ATP13A2*/*PARK9* gene encodes the protein *ATP13A2*, a lysosomal type 5 P-type ATPase present in lysosomal membranes, that is linked to autosomal recessive, levodopa responsive, nigrostriatal-pallidal-pyramidal neurodegeneration (Kufor-Rakeb Syndrome) as well as to some juvenile and young-onset forms of PD parkinsonism (Di Fonzo et al. 2007). The exact mechanism underlying the cellular functions of human ATP13A2 remains unknown, as well as its role in PD. Recently, it was shown that mutations/loss of ATP13A2 in human fibroblasts from patients with Kufor-Rakeb syndrome or in mouse primary neurons and dopaminergic cell lines leads to impaired lysosomal degradation capacity (Dehay et al. 2012; Usenovic et al. 2012a). ATP13A2 protein plays an important role in lysosomal membrane integrity, and mutations present in the *ATP13A2*/*PARK9* gene cause instability of the lysosomal membrane, impaired lysosomal acidification, decreased proteolytic capacity, and diminished lysosomal-mediated clearance of autophagosomes (Dehay et al. 2012). This lysosomal dysfunction results in accumulation of α-synuclein and toxicity in primary cortical neurons (Usenovic et al. 2012a). In addition, silencing of endogenous α-synuclein attenuated the toxicity in ATP13A2-depleted neurons, suggesting that loss of ATP13A2

mediates neurotoxicity at least in part via the accumulation of α-synuclein (Usenovic et al. 2012a). Identification of ATP13A2-interacting proteins by yeast two-hybrid system provide insights into ATP13A2 function and suggest a role in vesicular trafficking and fusion (Usenovic et al. 2012b). Loss of function of this protein could mediate α-synuclein aggregation and toxicity and explain the link between ATP13A2 mutations observed in patients with Kufor-Rakeb syndrome and neurodegeneration. In addition, loss of ATP13A2 function in cellular models was reported to disrupt autophagy activity and affect, in particular, mitochondrial quality control, thereby leading to impairment of mitochondrial turnover and increase of ROS production (Gusdon et al. 2012).

5.7 Glucocerebrosidase (GBA)

Loss-of-function mutations in the *GBA* gene are associated to *Gaucher's disease* (GD) and are also linked to an increased risk of PD and other related α-synucleinopathies (Neumann et al. 2009). *Glucocerebrosidase* protein (GCase) is a lysosomal enzyme responsible for the breakdown of the glycolipid glucocerebrosidase into glucose and ceramide inside lysosomes. GD is an autosomal recessive lysosomal storage disease caused by loss-of-function mutations of the GCase enzyme that results in accumulation of GCase substrates inside the lysosomes, especially in macrophages. GD is clinically classified in three groups: type 1 or non-neuropathic, type 2 or acute neuropathic, and type 3 or chronic neuropathic. Interestingly, patients with GD type 1, the non-neuropathic variant, have increased propensity to develop PD or related LB diseases (DePaolo et al. 2009). In turn, patients with PD have increased frequency of GBA mutations (DePaolo et al. 2009).

Although the mechanism underlying the association of GBA with PD remains unknown, several groups have proposed that impaired autophagy, aggregate formation, and α-synuclein metabolism may link GBA mutations with the pathogenesis of PD (Westbroek et al. 2011). In particular, some studies propose that alterations in the lysosomal system secondary to the presence of mutant GCase might connect PD and GD (Sun et al. 2010; Vitner et al. 2010). In cell culture models, the GBA mutants with gain-of-toxic function promote α-synuclein accumulation, an effect that can be reverted by autophagy induction with rapamycin (Cullen et al. 2011). Furthermore, patients with GD and PD exhibit LB positive for GCase, which suggests that α-synuclein oligomers may sequester mutant misfolded GCase within LB during the progression of the disease (Cullen et al. 2011). These results indicate that loss of GBA creates a positive feedback loop of reduced lysosomal function and α-synuclein accumulation that ultimately leads to neurodegeneration (Dawson and Dawson 2011; Mazzulli et al. 2011; Sardi et al. 2011).

Additional work is necessary to further identify the mechanisms underlying the connection between PD and GD, as other not-yet-identified factors or proteins may probably play a role since only a small percentage of GD patients and carriers with GBA mutations actually develop PD.

6 Conclusion

Mounting evidence indicate a role for autophagy dysfunction in neurodegenerative diseases, including PD. The potential involvement of autophagy alterations in PD has been reinforced in recent years by the finding that many of the mutated nuclear genes associated with familial forms of PD either directly or indirectly affect the normal activity of autophagy pathways. These findings might help to explain the pathogenesis of these diseases and most importantly lay the ground for the development of new therapeutic strategies based on the modulation of autophagy pathways for this group of devastating, currently incurable, diseases.

Abstract

The discovery of dopamine as a brain neurotransmitter by Arvid Carlsson and colleagues about 50 years ago contributed to better understand some of the brain diseases. Some of the drugs that are most widely used in neurologic and psychiatry illnesses, such as levodopa and antipsychotic drugs, act on dopaminergic mechanism. The discovery that the motor impairments of Parkinson's disease patients improved after restoring the physiological levels of striatal dopamine with levodopa attracted the attention of the neuroscience community for the role of this neurotransmitter in motor and brain functions. In the last decades, the knowledge has also been challenged by evidence that Parkinson's disease also affects cognitive and affective functions. Shortly after the introduction of levodopa as a therapy, a complex set of secondary phenomena such as dyskinesia was observed following repeated administration of the dopamine precursor. Information of dopaminergic cells and circuits has been enriched by findings obtained with several and highly sensitive technology in cellular biology, with sophisticated behavioral analyses of transgenic animals and functional neuroimaging. The present chapter attempts to review results reported in different clinical studies and animal models to provide a comprehensive picture of the role of dopamine in Parkinson's disease. Treatments have successfully been translated from preclinical to pharmacotherapeutic arsenal increasing clinical settings.

Keywords

Basal ganglia • Dopamine • Dopamine receptors • Dopaminergic drugs • Levodopa • Mesocortical system • Mesolimbic system • Nigrostriatal system • Nitric oxide • Parkinson's disease

List of Abbreviations

3-OMD	3-*O*-methyldopa
6-OHDA	6-hydroxydopamine
AIMs	Abnormal involuntary movements
AS	Alpha-synuclein
CNS	Central nervous system
COMT	Catechol-*O*-methyltransferase
DARPP-32	Dopamine- and cAMP-regulated phosphoprotein, Mr 32 kDa
DAT	Dopamine transporter
DLB	Dementia with Lewy body
DMV	Dorsal motor nucleus of vagus
DYN	Dynorphin
ENK	Enkephalin
FS	Fast spiking
GPCRs	G protein-coupled receptors
GPe	External segment of the globus pallidus
GPi	Internal segment of the globus pallidus

iLBP	Incident Lewy body pathology
IrtZ	Intermediate reticular zone
i.v.	Intravenous
LB	Lewy bodies
LC	Locus coeruleus
L-DOPA	L-3,4-dihydroxyphenylalanine
LN	Lewy neurites
LTS	Low-threshold spiking
MAO-B	Monoamine oxidase-B
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MSN	Medium spiny neuron
NPY	Neuropeptide Y
PD	Parkinson's disease
PET	Positive emission tomography
PV	Parvalbumin
SN	Substantia nigra
SNc	Substantia nigra pars compacta
SNr	Substantia nigra pars reticulata
SOM	Somatostatin
SP	Substance P
SPECT	Single-photon emission computed tomography
STN	Subthalamic nucleus
TH	Tyrosine hydroxylase
VMAT2	Vesicular monoamine transporter 2
VTA	Ventral tegmental area

1 Introduction

At the beginning of the nineteenth century, when James Parkinson published the book entitled "*Essay on the Shaking Palsy*" (Parkinson 2002), life expectation was no longer than 45 years old. The "shaking palsy," later named Parkinson's disease (PD) by Charcot, affects mainly aged people. Nowadays, the prevalence of PD in industrialized countries is generally estimated at 0.3 % of the entire population and about 1 % in people over 60 years of age (Nussbaum and Ellis 2003). Age disease incidence ranges from 110 to 330 per 100,000 individuals over 50 years old, and its incidence increases with increasing age throughout the life span (Mayeux 2003). Now, in the beginning of the twenty-first century, life expectancy is near 80 years old, and the incidence rate of PD increases to 400–500 individuals per 100,000 annually (Mayeux 2003). Therefore, there are much more parkinsonian patients nowadays than two centuries ago, and with the increasing age of the general population, the prevalence of PD will rise constantly in the future.

PD is characterized clinically by bradykinesia, rest tremor, muscle rigidity, and postural reflex impairment. The discovery that the motor impairments of PD patients improved after restoring the physiological levels of striatal dopamine with levodopa attracted the attention of the neuroscience community for the role of this neurotransmitter in motor functions (Olanow and Tatton 1999). Since dopamine is the main modulator of the basal ganglia, their components have long been seen as part of the motor system (Graybiel et al. 1994). In the last decades, this view has been challenged by evidence that PD also affects cognitive and affective functions (Dubois and Pillon 1997; Chaudhuri et al. 2006; Da Cunha et al. 2009). In addition, dysfunction of dopamine neurotransmission has been implicated in many other psychiatric and neurological diseases, such as attention deficit hyperactivity disorder (ADHD), drug addiction, Tourette syndrome, schizophrenia, and obsessive-compulsive syndrome. Furthermore, a growing body of evidence has been accumulated supporting the view that some kinds of cognitive processes, such as instrumental learning, decision-making, and other executive functions, depend critically on the dopamine signaling (see Da Cunha et al. 2009).

The present chapter attempts to review results reported in different clinical studies and animal models to provide a comprehensive picture of the role of dopamine signaling in PD.

2 Dopamine Neurotransmission System: Pathways, Receptors, and Signaling

A detailed review of the history and neurobiology of the dopamine signaling is beyond the scope of this chapter and can be found in very interesting reviews by Hornykiewicz (2002), Iversen and Iversen (2007), and Fahn (2008). The neurotransmitter dopamine plays a crucial role in motor, motivational, and reward-related functions of the central nervous system (CNS). Our understanding of neuropsychiatric illnesses and the modern psychopharmacology was greatly influenced by the discovery of dopamine as a neurotransmitter in the brain by Arvid Carlsson and colleagues about 50 years ago. Some of the drugs that are most widely used in the treatment of neurologic and psychiatry illnesses, such as levodopa, methylphenidate, and antipsychotic drugs, act on dopaminergic mechanisms. Therefore, dopamine neurotransmitter system has been one of the major and fertile fields of behavioral neuroscience and its research culminated in the award of the Nobel Prize in 2000 to three scientists, Carlsson, Greengard, and Kandel, for their important contributions to this field.

Dopamine was the last catecholamine discovered, and Sir Henry Dale, in 1952, suggested dopamine as the current name of 3,4-dihydroxyphenethylamine, also known as 3-hydroxytyramine. Its biosynthesis begins with dietary amino acid tyrosine actively transported into the brain. Tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine synthesis, is regulated by multiple mechanisms

(Molinoff and Axelrod 1971). Rapid activation of TH activity occurs via its phosphorylation by several protein kinases, including protein kinase A, Ca^{2+}/calmodulin-dependent protein kinase II, and protein kinase C. Possibly, its phosphorylation induces conformational change that results in a lower affinity of TH for catecholamines that trigger end-product inhibition of this enzyme. The end result is an increase of TH catalytic activity (Nestler et al. 2009). Several drugs can up- or downregulate TH expression, and extracellular stimuli may induce longer-term changes in TH activity through transcriptional regulation of its gene.

Dopamine is synthesized in the cytosol and transported into synaptic vesicles via the vesicular monoamine transporter 2 (VMAT2). From the synaptic vesicles, dopamine is released in a quantal manner when a nerve impulse traveling down the axon reaches the nerve terminal. Once in the synaptic cleft, dopamine can act on both postsynaptic and presynaptic dopamine receptors. Dopamine could be metabolized to homovanillic acid (HVA); 3,4-dihydroxyphenylacetic acid (DOPAC) via monoamine oxidase (MAO), an enzyme considered to be mostly intraneuronal; and 3-methoxytyramine (3-MT) via catechol-*O*-methyltransferase (COMT), an enzyme considered mostly extraneuronal. Entacapone and tolcapone are reversible COMT inhibitors which have been approved for clinical use in patients with PD as adjuvant to levodopa, significantly improving the clinical benefits of this therapy (Bonifácio et al. 2007).

Dopamine signal ends by spontaneous amine diffusion, local enzymatic degradation, and amine reuptake in the presynaptic neurons by dopamine transporter (DAT) (Cragg and Rice 2004; Nestler et al. 2009; Eriksen et al. 2010). This dopamine transporter seemingly play a key role in the dopamine transmission if we consider the behavioral consequences of their inhibition with blocking agents known to be powerful psychostimulants or drugs of abuse, as amphetamine or cocaine (see Nestler et al. 2009; Fig. 1).

Due to their diverse anatomy and disparate functions, different populations of dopamine neurons have been specifically implicated in a variety of neurological disorders. Biochemical characterization of dopamine in the brain revealed two families of dopamine receptors: D1-like receptors that also comprises D5 receptor and are able to stimulate adenylyl cyclase and increase cAMP production and D2-like receptors that comprises D3 and D4 receptors and are negatively coupled to adenylyl cyclase activity and inhibit cAMP production. In mammals, all of these receptors belong to the superfamily of GPCRs with seven transmembrane domains. D1 family is coupled to stimulatory G_s or the related G_{olf}, and the D2 family is coupled to inhibitory G_i/G_o (for review, see Herve and Girault 2005). D1 receptor activation stimulates the cAMP increase leading to the activation of protein kinase that have a broad array of cellular targets, including transcription factors, voltage-dependent ion channels, and glutamate receptors (Svenningsson et al. 2004).

Dopaminergic neurons and pathways were first described using classical histofluorescence techniques during the 1960s and 1970s (Carlsson et al. 1962). Knowledge of dopaminergic cells and circuits has been enriched by findings

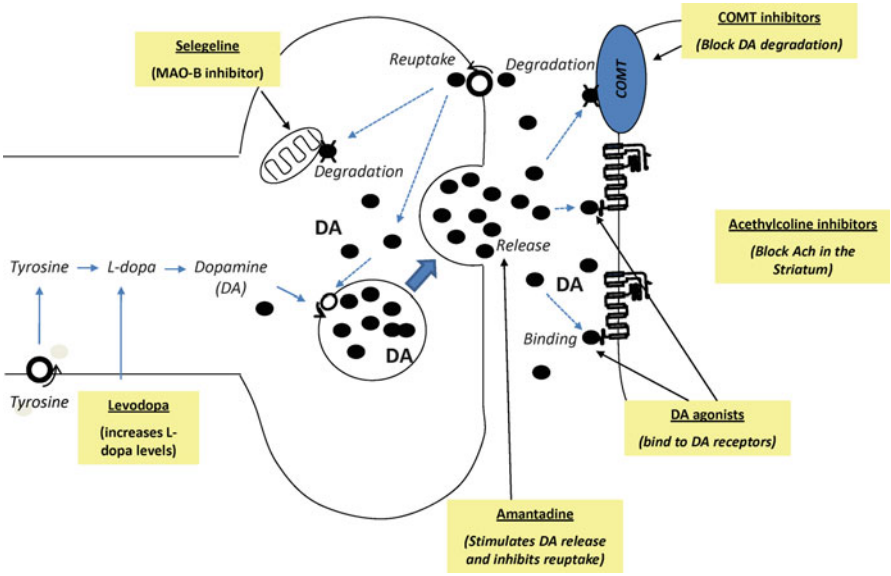

Fig. 1 *Dopamine synthesis, release, signaling, and reuptake and pharmacological approaches currently available for Parkinson's disease*. Dopamine synthesis originates from the amino acid tyrosine, which is converted to DOPA by the enzyme tyrosine hydroxylase (*TH*) (a rate-limiting enzyme). Subsequently, DOPA is decarboxylated, by the enzyme L-aromatic amino acid decarboxylase (DOPA decarboxylase), to form dopamine. L-dopa that is used in the Parkinson's disease treatment bypasses the rate-limiting enzymatic step and is decarboxylated by DOPA decarboxylase to form dopamine. The most significant mechanism by which the synaptic actions of dopamine is terminated is the reuptake into the nerve terminal via specific dopamine transporter (*DAT*) expressed on the membrane of presynaptic terminal. Dopamine is also catabolized by the enzymes monoamine oxidase (*MAO*) and catechol-*O*-methyltransferase (*COMT*). Possibly, MAO exists in mitochondria within dopaminergic nerve terminals, on extracellular space, and also in glia proximate to dopamine synapses. After its synthesis, dopamine acts on pre- and postsynaptic receptors from D1 or D2 dopamine receptor families, which, respectively, activates Gs protein and increases cAMP production or Gi protein and decreases cAMP production. Generally drugs including L-DOPA, carbidopa, amantadine, and COMT and MAO-B inhibitors revert temporarily the dopamine dysfunction caused by dopaminergic neurodegeneration in the basal ganglia of Parkinson's disease patients

obtained with several and highly-sensitive techniques, as immunohistochemistry (mainly to dopamine essential synthetic enzyme TH), cellular biology, transgenic mice or conditional mutants, functional anatomy, electrophysiological studies, sophisticated behavioral analyses, and functional neuroimaging. Altogether, these studies have also led to new concepts of healthy and pathological functions of dopaminergic circuits at the molecular and more integrated levels (Björklund and Dunnett 2007).

In the ventral mesencephalic tegmentum, dopaminergic cell bodies are very well organized in the following groups: the substantia nigra pars compacta (SNc) (A9),

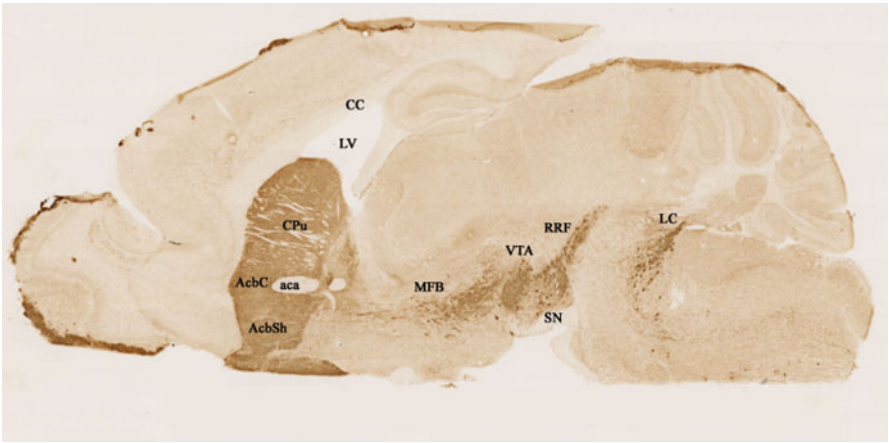

Fig. 2 Rat brain sagittal view (adult, *Wistar*) of the tyrosine hydroxylase immunocytochemistry showing the distribution of dopaminergic neurons. Abbreviations: *aca* anterior comm, anterior part, *AcbC* accumbens nucleus, core, *AcbSh* accumbens nucleus, shell, *cc* corpus callosum, *CPu* caudate putamen (striatum), *LC* locus coeruleus, *LV* lateral ventricle, *MFB* medial forebrain bundle, *RRF* retrorubral field, *SN* substantia nigra, *VTA* ventral tegmental area

the ventral tegmental area (VTA-A10), and the retrorubral area (A8) (Fig. 2). Dahlström and Fuxe (1964) defined the nomenclature of dopaminergic system in the rat midbrain: A8, A9 (substantia nigra), and A10 cell groups. The classification is nonetheless widely used.

Ascending dopaminergic pathways in the mammalian CNS can be simplified divided into three major systems. The two largest groups are located in the midbrain: the nigrostriatal system that originates in the substantia nigra (A9) and innervates predominantly the dorsal striatum and the mesocortical and mesolimbic systems that arise from the VTA and project to the cortical or several limbic areas (Bjorklund and Lindvall 1984; Krimer et al. 1997). The cell group of retrorubral area that forms a dorsal and caudal extension of the VTA contains cells that project to striatal, limbic, and cortical areas (Bentivoglio and Morelli 2005).

2.1 Nigrostriatal System

Since the first detailed studies of the SN by Cajal (1911), two main subdivisions were recognized. The SNc is characterized by densely packed neurons, and the substantia nigra *pars reticulata* (SNr) is marked by sparse dopaminergic cells, enmeshed in dopaminergic dendrites (Fig. 3). Most of the properties of dopamine neurotransmission in vivo are known from studies of the nigrostriatal dopamine pathway extending from the SNc to the dorsal striatum through the median

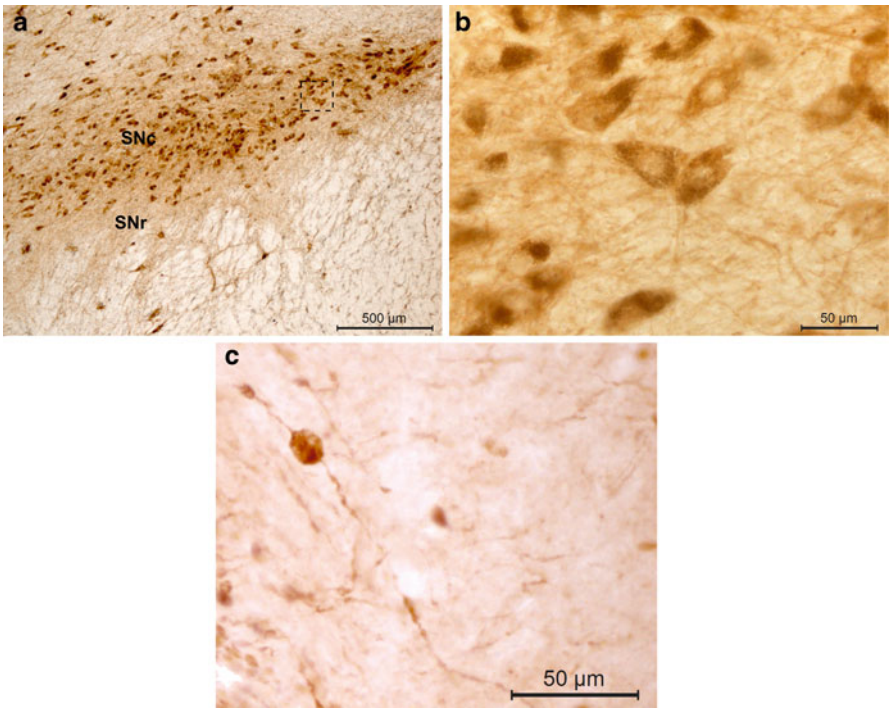

Fig. 3 Tyrosine hydroxylase immunocytochemistry of the regions of the human brain presenting positive reaction in the substantia nigra *compacta* (**a**, **b**; SNc), *reticulata* (**a** SNr,), and the striatum (**c**; caudate). Observe a high density of TH-positive neurons in the SNc, in contrast to sparse distribution in the SNr. TH- positive neurons are detected in the human and non human -primate striatum and and also in mice

forebrain bundle. Somato-dendritic release of dopamine in the SNc and axonal dopamine release in the dorsal striatum are both necessary for the expression of basal ganglia-mediated motor behaviors and various cognitive functions. In both rat and monkey, the striatal dopamine innervation is derived not only from SNc but also from cells located in the lateral VTA and retrorubral area. For this reason, the term "mesostriatal dopamine pathway" sometimes is used to include all components of the midbrain dopamine system projecting to the striatum (Björklund and Dunnett 2007).

The identification of cells of the SN as dopaminergic and of the dopaminergic innervation of the striatum through the nigrostriatal tract is inseparably intertwined with methodological achievements in experimental and chemical neuroanatomy in the 1960s and 1970s. These discoveries were intrinsically correlated to the histopathology of the midbrain dopaminergic system in PD in the 1960s (Bentivoglio and Morelli 2005).

2.2 Mesocortical and Mesolimbic Systems

Both of these systems connect the ventral tegmental dopamine cells (A8, A10) to prefrontal and cingulate cortex or to nucleus accumbens, amygdaloid complex, hippocampus, and piriform cortex. Ventral tegmental dopaminergic neurons play a critical role in motivation, reward-related behavior, attention, and multiple forms of memory (Nestler et al. 2009).

A third population of midbrain dopamine neurons resides in the retrorubral field and projects primarily to the dorsal striatum and the pontomedullary reticular formation; it is thought to play a role in orofacial movements. There are also connections between the retrorubral field and SN/VTA dopamine neurons. There are at least four groups of dopamine neurons in the hypothalamus that are intimately involved in neuroendocrine, hormonal, and arousal processes. Finally, there are populations of dopaminergic amacrine cells in the retina that contribute to neural adaptation to light and also some dopamine cells in the olfactory bulb (Nestler et al. 2009).

The striatum receives input from a number of regions, including the motor, sensory, and frontal cortex, integrates this information under the modulatory influence of dopamine, and uses this information to guide motor behavior. A cardinal feature of the striatum – the main integrator of cortical and thalamic information reaching the basal ganglia – is its dense dopamine innervation, which arises from the midbrain nigrostriatal pathway. Nigrostriatal dopaminergic neurons form highly branched networks within their striatal targets. The full extent of this arborization was elegantly demonstrated by Matsuda and colleagues (2009). A single dopaminergic neuron innervated up to 5.7 % of the neostriatum, while adjacent input dopaminergic neurons showed high degrees of overlapping with targets. It was calculated that a single postsynaptic medium spiny neuron (MSN) could be influenced by up to 194 dopaminergic inputs. As a result of this redundancy, clinical signs of PD only develop after up to 70 % of SNc neurons are lost. Each striatal MSN receives input from several thousand different cortical neurons on its spines. The input from each synapse is weak and many inputs are needed to discharge the neuron (Rothwell 2011).

Anatomically, striatal cells fall into two main classes: (a) spiny projection neurons and (b) aspiny interneurons. Spiny projection neurons, also known as medium spiny neurons (MSNs), represent the vast majority of striatal neurons. MSNs receive glutamatergic inputs from cortex and thalamus that terminate predominantly on spines (Kemp and Powell 1971). In addition, they are a main target of midbrain dopaminergic neuron axons that form synapses on MSN dendrites and spine necks (Smith et al. 1994).

One of the major targets of this innervation is the principal neuron of the striatum: GABAergic spiny projection neurons. Spiny projection neurons constitute as much as 90 % of the striatal neuron population. They can be divided into two approximately equally sized populations based on axonal projections. One population – **direct pathway spiny projection neurons** – projects axons to the nuclei at the interface between the basal ganglia and the rest of the brain,

whereas the other population, **indirect pathway spiny projection neurons**, projects only indirectly to the interface nuclei. The dopamine D1 receptor is expressed selectively by direct pathway spiny projection neurons. Also, **direct pathway** spiny projection neurons express high levels of substance P (SP) and dynorphin (DYN). The dopamine D2 receptor is expressed by **indirect pathway** spiny projection neurons, which also express enkephalin (ENK). These two G protein-coupled receptors (GPCRs) have distinctive intracellular signaling cascades and targets, leading to fundamentally different cellular responses to extracellular dopamine (see below).

There are four well-characterized classes of striatal interneuron: cholinergic interneuron, parvalbumin-expressing GABAergic interneuron, calretinin-expressing GABAergic interneuron, and neuropeptide Y (NPY)/nitric oxide-expressing GABAergic interneuron (Tepper et al. 2008). Together, these interneurons constitute 5–10 % of all striatal neurons. One of them, the cholinergic interneuron, co expresses dopamine D2 and D5 receptors (Bergson et al. 1995) and modulates both spiny projection neurons populations through muscarinic receptors (Yan and Surmeier 1996). Two other prominent interneurons, the somatostatin (SOM)/NPY-expressing GABAergic interneuron and the parvalbumin (PV) GABAergic interneuron, express dopamine D5 receptors (Centonze et al. 2003). The PV interneuron is strongly innervated by globus pallidus neurons that express dopamine D2 receptors (Bevan et al. 1998), creating a microcircuit that is influenced by both dopamine D1 and D2 receptors.

According to the classic model of basal ganglia function (see Fig. 4; DeLong 1990), movements occur during pauses in the tonic inhibitory activity of the basal ganglia output interface, generated by activity in the **direct pathway**. This model had its origins in neurophysiologic studies showing that corticostriatal activation of the direct striatonigral pathway results in pauses of the tonic activity of GABAergic neurons in the SNr (Chevalier et al. 1985). The opposing role of the **indirect pathway** in suppressing movements was originally proposed on the basis of studies in animal models of PD. Mink (2003) reviewed the classic model, proposing that the activity of direct and indirect pathways is coordinated to select particular motor programs and to inhibit competing motor programs. This model predicts that during ongoing behavior, there will be increased activity in neuronal ensembles that are part of direct and indirect pathway circuits, rather than one or the other. The execution of a movement sequence would then generate a complex pattern of activity in specific neuronal ensembles. Recent work using optogenetic or genetic approaches supports the general tenets of the model (Hikida et al. 2010; Kravitz et al. 2010). Although this model has proven to be of considerable clinical value, it fails to account for the great diversity and complexity of the decision-making process in action selection (Cisek and Kalaska 2010).

Dopamine acted by stimulating the MSNs of the direct and inhibiting those of the indirect pathway (Albin et al. 1989; Gerfen et al. 1990; Gerfen and Surmeier 2011). These opposing effects were suggested to depend on the expression of dopamine D1 receptors in the MSNs of the direct pathway and of dopamine D2 receptors in the MSNs of the indirect pathway. These receptors have distinctive

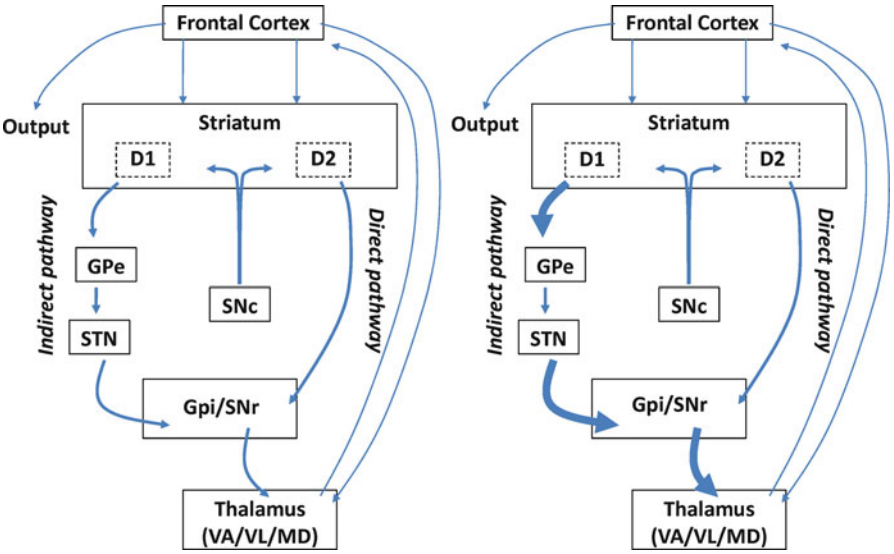

Fig. 4 *Overview of schematic representation of the main basal ganglia-thalamocortical circuits* (*left*). Normal status: the two output routes ("indirect" and "direct") are in balance at the level of the output structures (the GPi and the SNr) (*right*). Neurodegenerative changes in the central nervous system in Parkinson's disease (*PD*): depletion of dopamine in the striatum leads to imbalance in the two output routes and suppression of thalamocortical activity. The thickness of the *arrows i*ndicates the level of activity in the pathways. For some time, the symptoms of PD have been described as a loss of balance between the direct and indirect striatal output pathways. The indirect pathway is attenuated primarily by D2 receptor stimulation, whereas the direct pathway is activated via D1 receptor stimulation. With normal tonic/phasic balance, cortical activation of the indirect pathway (attenuated by tonic D2 stimulation) is in balance with other presumably motor cortical inputs influencing the direct pathway (augmented by phasic D1 stimulation). However, in PD, this balance is disrupted, with the loss of DA resulting in hyperactivity (with akinesia) in the indirect pathway and depression (with loss of voluntary movement) within the direct pathway. The model predicts that neuronal firing in the STN and GPi is increased in the parkinsonian state, leading to excessive inhibition of brain stem and thalamocortical neurons with the development of parkinsonian motor features. In contrast, the model proposes that dyskinesia is related to the decreased firing in the STN and GPi, with reduced inhibition of thalamic and cortical motor regions. Abbreviations: *D* dopamine, *GPe* external segment of globus pallidus, *GPi* internal segment of globus pallidus, *MD* mediodorsal nucleus, *SNr* reticular part of the substantia nigra, *SNc pars compacta* of the substantia nigra, *STN* subthalamic nucleus, *VA/VL* ventral anterior/ventral lateral thalamic nuclei (Modified from Hauser 2009)

intracellular signaling cascades and targets, leading to fundamentally different cellular responses to extracellular dopamine (Gerfen and Surmeier 2011). Also, direct pathway expresses high levels of substance P and dynorphin, whereas indirect pathway expresses enkephalin. Direct and indirect pathways are representing on Fig. 4.

Dopamine stimulation of D1 receptors acts via cAMP and protein kinase A to phosphorylate dopamine- and cAMP-regulated phosphoprotein, Mr 32 kDa

(DARPP-32), an important mediator of cAMP signaling and striatal excitability. The DARPP-32 signaling pathway has a central role in mediating signal transduction within MSNs in the striatum, and the function of this phosphoprotein depends on its relative state of phosphorylation at two main regulatory sites, threonine 34 (T34) and threonine T75 (T75). When DARPP-32 is phosphorylated at T34 by protein kinase A, it becomes a potent inhibitor of protein phosphatase 1, which in turn regulates the phosphorylation state of several classes of effector proteins, including transcription factors, ionotropic receptors, and ion channels (Greengard et al. 1999; Grace 2002). It has been shown that DARPP-32 is also present in other non-D1-containing neurons as well, including the enkephalin-containing striatal neurons (Langley et al. 1997). In this case, in contrast, stimulation of dopamine D2 receptors causes a dephosphorylation of DARPP-32 via calcineurin activation by calcium influx (Grace 2002).

Dopamine release appears to occur via two functionally distinct components. One is known as phasic component of dopamine release and is believed to underlie most of the behavioral indices of this transmitter. Phasic dopamine release occurs in a high-amplitude, brief pulsatile manner by means of action potentials and then is rapidly removed from the synaptic cleft via reuptake (Grace 1991, 2002). The other component is known as tonic dopamine release that occurs in very low concentration but is sufficient to activate extrasynaptic receptors, including dopamine terminal autoreceptors. D2 and D3 receptors act as inhibitory presynaptic autoreceptors and as postsynaptic receptors. In addition, D2 receptors have two splice variants, $D2_{short}$ and $D2_{long}$ (Nestler et al. 2009). Autoreceptors can exist on most portions of dopamine cells including the soma, dendrites, and nerve terminals. Stimulation of dopamine autoreceptors slows or inhibits dopamine synthesis or release. Thus, autoreceptors are supposed to exert a tonic downregulation of dopamine neuron activity, maintaining their firing within a stable range of activity (Harden and Grace 1995).

3 Dopamine-Related Disease: Parkinson's Disease

Several important diseases of the CNS are associated with dysfunctions of the dopamine system, ranging from PD to schizophrenia and drug addiction. In this review, we shall focus only the Parkinson's disease and some consequences for human beings. The discovery of mechanism of action of several drugs that act on dopamine synapses really improved the knowledge about the dopaminergic system and its related diseases.

PD is characterized by complex motor symptomatology, including tremor at rest, bradykinesia, rigidity, postural instability, stooped posture, and freezing that occur by hypofunctional dopamine states when nigrostriatal pathway is degenerated. Dopamine became clinically relevant when dopamine depletion in the caudate nucleus of patients with PD was discovered, whereas intravenous (i.v.) administration of L-dihydroxyphenylalanine (L-DOPA), the amino acid precursor of dopamine,

dramatically and rapidly alleviated parkinsonian symptoms (Hornykiewicz 2010). Studies with animal models of PD provided the first clear indication of the dichotomy in the regulation of the direct and indirect pathways, suggesting that their excitability shifts in opposite directions following the loss of dopamine, creating an imbalance in the regulation of the motor thalamus favoring suppression of movement (Albin et al. 1989). Specifically, direct pathway was suggested to spike less in the PD state, whereas indirect pathway was thought to spike more (Gerfen and Surmeier 2011).

Besides motor symptoms, dopaminergic-related non-motor symptoms, as depression, apathy, and sleep disorders, are part of the clinical spectrum of PD. There is increasing evidence that such symptoms are treatable, at least in part, with various dopaminergic agents (Chaudhuri and Schapira 2009).

One current drawback of dopaminergic therapy is that it cannot be targeted to a specific subpopulation of dopamine neurons. A consequence of this is significant dopamine-related side effects, such as hallucinations or compulsive gambling during treatment for PD or extrapyramidal and sexual side effects caused by antipsychotics. In addition, from the standpoint of pathogenesis, it is clear that dopaminergic neurotransmission is not the sole dysfunction in this neurological disease.

4 Dopamine Signaling in Parkinson's Disease

4.1 The Neuropathology of Parkinson's Disease: A Brief Historical Overview

The association of PD with the mesencephalic dopaminergic zone was hypothesized by Edouard Brissaud in 1893, based on an autopsy case of unilateral Parkinsonism associated with a tumor confined in the SN (see Parent and Parent 2010). The hypothesis was validated by Konstantin Tretiakoff in 1919, in his doctoral thesis, reporting the marked loss of neurons in the SNc and the presence of intracytoplasmic inclusions which he called "*corps de Lewy*" (reference to Friedrich Lewy's description of these pathological findings) in the surviving neurons of PD patients (Lees et al. 2008), after confirmed by Hassler in 1938, which found a constant cell loss in the SNc of 10 PD patients (Hassler 1938). Just on the beginning of 1960, Hornykiewicz described the presence of dopamine in SN and that it is reduced in the midbrain and in the striatum of parkinsonian patients, suggesting the possible existence of a link between SN and the corpus striatum (Hornykiewicz 1963).

Using new fluorescence techniques, Dahlström and Fuxe (1964) described firstly, in rat, the occurrence of catecholaminergic cell in the midbrain and lower brain stem, and Andén et al. (1964) noticed that lesions of SNc caused a substantial loss of the catecholaminergic fluorescence in the striatum, helping the acceptance of the existence of a nigrostriatal fiber system originating from dopaminergic midbrain neurons. The utilization of immunohistochemistry labeling of enzymes

participating in the metabolism was very useful to study the catecholaminergic neurons of midbrain, and Hökfelt et al. (1973) were the first to identify dopaminergic neurons in midbrain using antibodies to aromatic acid decarboxylase, followed by the immunohistochemical revelation of the rate-limiting enzyme of dopamine synthesis, the TH, done by Ljungdahl et al. (1975), confirming the dopaminergic nature of nigrostriatal pathway and starting a new era for basal ganglia research.

Jakes and co-workers described two proteins of synuclein family, the alpha- and beta-synuclein, in human brain (Jakes et al. 1994). After some descriptions of familial cases of PD associated with mutation on alpha-synuclein (AS) (Polymeropoulos et al. 1997; Goedert 1997), Spillantini et al. (1997) reported, for the first time, the strong immunolabeling of Lewy bodies (LB) and neurites (LN) with AS in PD and dementia with Lewy body (DLB), followed by several publications which reinforced the relevance of AS on PD pathogenesis.

4.2 The Topographic Braak Staging of Parkinson's Disease

After the recent observations on relationship of AS and PD, Del Tredici et al. (2002) evaluated the presence of AS in brain stem of subjects without history of neurologic or psychiatric disease. They described that all patients with AS inclusions in dorsal motor nucleus of vagus (DMV) and in intermediate reticular zone (IRtZ) presented also AS-immunoreactivity in other brain stem nuclei, as the locus coeruleus (LC) and the SN, suggesting that the pathological progression of PD could begin in the medulla and spread to the whole brain. The absence of clinical signs of PD in these individuals, even with AS pathology, can be explained by the existence of a presymptomatic phase before the onset of motor dysfunction.

The study of Braak et al. (2003) changed the classic concepts of an essentially dopaminergic dysfunction in PD. Using the same methods of Del Tredici et al. (2002) in 3 groups of (1) 41 individuals with clinical diagnosis of PD, (2) 69 individuals without neurological or psychiatric disease but with AS brain pathology, and (3) 58 individuals without neurological or psychiatric disease nor AS pathology, they showed that LB and LN marked with AS were present in nigral and extranigral areas, with a particular vulnerability and independent of neurotransmitter produced by the neurons, which became involved at different times in the progression of the disease, in a pattern of topographical caudorostral progression, as follows:

- Stage 1: The presence of LN and LB was detected in two major nuclei: DMV and the IRtZ. At this stage LN was observed first than LB; however, in advanced cases, the LN outnumbers the LB in these areas. This pattern was seen at all stages of disease progression. Some neuromelanin-laden nerve cells in these nuclei do not show LB/LN. The anterior olfactory structures (olfactory bulb/stalk and the anterior olfactory nucleus) are also affected by AS inclusions. This stage of pathology spares the pontine melanized neurons, as the LC.

- Stage 2: The more accentuated presence of LB/LN in DMV and IRtZ and the loss of neurons are seen at this stage. Furthermore, the pathological LB/LN appears in pontine areas of caudal raphe nuclei, the gigantocellular reticular nucleus and the coeruleus-subcoeruleus complex, but the latter nucleus has unaffected neurons. The midbrain nuclei remain uninvolved.
- Stage 3: There is worsening of lesions on affected nuclei in medulla and pons, and the LB/LN is seen in midbrain structures and nuclei from the basal forebrain. In the midbrain, the presence of LB/LN in SN is observed initially in melanized projection neurons of posterolateral and posteromedial subnuclei, without macroscopically detectable depigmentation. The compact portion of pedunculopontine tegmental nucleus is affected only by LN in stage 3. The magnocellular nuclei of the basal forebrain (medial septal nucleus, interstitial nucleus of diagonal band, basal nucleus of Meynert) develop only a network of LN. There is no pathological alteration in temporal mesocortex or neocortex, but LNs are seen in anterior olfactory nucleus and second sector of Ammon's horn (CA2) (for a wide review about extranigral brain stem nuclei affected by AS pathology, see Grinberg et al. 2010).
- Stage 4: The midbrain shows accentuated involvement of neuromelanin-laden neurons of SNc, more significant in posterior region of pars compacta; the depigmentation is macroscopically seen at this stage and is observed in the extracellular melanin granules in SNc. Other mesencephalic regions are affected, such as the paranigral and parabrachial nucleus, and the compact portion of pedunculopontine tegmental nucleus (PPN) is more affected by LB and LN. The basal forebrain becomes severely involved, and areas as stria terminalis, central nucleus of amygdala, and ventral claustrum show LB. The anterior olfactory nucleus is much damaged. This stage is characterized by AS accumulation in the anteromedial temporal mesocortex, with outer layers developing networks of LN and LB within inner layers.
- Stage 5: The last two stages indicate diffuse AS immunolabeling, including the neocortex. The SN is almost without melanin, and LB develops in melanized nerve cells as DMV and reticular formation. The network of LN in CA2 extends into adjacent sectors, comprising large portions of hippocampus. From the anteromedial temporal mesocortex (the periallocortical transentorhinal region and the proneocortical entorhinal area), the pathological progression moves toward the sensory association areas, anterior cingulate cortex, and prefrontal area, with LB in infragranular layers and LN in supragranular layers. The primary neocortical areas are spared.
- Stage 6: The final stage encloses the entire neocortex, but the pathological changes on premotor area, primary motor field, and primary sensory area are mild.

The authors of this study suggested that this staging model permits the distinction of clinically manifested cases, even as non-motor initial PD patients, as REM sleep disorders, psychiatric diseases, intestinal constipation, olfactory dysfunctions, and dysautonomia. The Braak hypothesis shows a correlation among pathological and clinical phenotypes. Jellinger (2003) observed that some individuals from

Braak's study had stages 3–4 PD pathology, but no motor symptoms were diagnosed, in which he called incident Lewy body pathology (iLBP). Furthermore, as noticed by Parkkinen et al. (2003) and Ishizawa et al. 2003, other diseases as DLB and AD showed LB with AS-immunoreactivity in the brain, reducing the specificity of Braak scheme for PD. After the publication of those works, the Braak staging model had gained acceptance rapidly. However, there are no conclusive proofs confirming a caudal-to-rostral temporal progression in PD pathology. Additional studies are required to elucidate these questions.

4.3 The Human Midbrain Dopaminergic System and Parkinson's Disease

Classically, the bradykinesia, rigidity, and tremor in parkinsonian syndromes are attributed to mesencephalic dysfunctions, and diseases as strokes and tumors localized in SN can cause a rigid-akinetic phenotype (Garcia de Yebenes et al. 1982; Akyol et al. 2006; Orta Daniel and Ulises 2008). PD is modernly considered as a multisystem neurodegenerative illness, affecting dopaminergic and non-dopaminergic neurons (serotoninergic, glutamatergic, cholinergic, nitrergic) as seen on Braak hypothesis. However, the major motor symptoms (bradykinesia and rigidity) and the motor complications (dyskinesia, wearing off phenomenon) are associated to dopaminergic transmission, justifying the special attention given to the nigrostriatal degeneration. There are other dopamine-rich areas in CNS, as the hypothalamus and retina, but its involvement in PD is controversial (for review see Archibald et al. 2009).

Based on the immunoreactivity to calbindin, the midbrain dopaminergic system can be divided into two tiers: the dorsal and the ventral tier. The dorsal tier encompasses the retrorubral groups and the VTA, its neurons are calbindin-positive, and they have horizontal orientation and low expression of DAT and D2 receptors. The ventral tier is composed by SNc, with calbindin-negative and ventrally oriented neurons, showing high amounts of DAT and D2 receptors. This cytochemical phenotypic classification has a practical application: the ventral tier is particularly vulnerable to the neurodegeneration of PD but with selective sparing of the dorsal tier (Haber and Gdowski 2004). However, the neuromelanin-laden neuron loss in SNc is not necessarily uniform (Ma et al. 1996).

Fearnley and Lees (1991) studied the micro-architecture of SN and the rates of neuron loss in normal aging and parkinsonian syndromes, and there was a linear reduction of pigmented neurons in advancing aging, more affected in dorsal tier. In opposite pattern, the PD individuals had 45 % of neuron loss in the first decade of disease, being greatest in the lateral ventral tier (average loss 91 %), followed by the medial ventral tier (71 %) and the dorsal tier (56 %). These results show a specific pattern of nerve cell loss in SNc on PD (Fearnley and Lees 1991). Ma et al. (1996) performed a morphometric analysis of SNc in PD individuals, and they described a marked reduction in pigmented neuron area, perimeter, diameter, and number in PD cases.

Damier et al. (1999a, b) developed a new method to analyze the SNc, based in immunolabeling to calbindin, identifying calbindin-rich regions ("matrix") and calbindin-poor islands ("nigrosomes"), and these pocket zone patterns were recognized in all brain as five nigrosomes. The nigrosome 1, localized in the ventral third and the lateral two-thirds of the calbindin-rich neuropil, corresponds to the ventral tier (Damier et al. 1999a). In another study (Damier et al. 1999b), the same authors used this SN analysis in PD subjects, and the neuronal depletion was maximum (98 %) in nigrosome 1, corroborating the findings of Fearnley and Lees (1991). A spatiotemporal progression of cell loss on PD was suggested, beginning in nigrosome 1, after spreading to other nigrosomes and to the matrix.

Another method used for analysis of dopamine depletion in parkinsonian syndromes is the radionuclide imaging with positive emission tomography (PET) and single-photon emission computed tomography (SPECT), applied as biomarkers for early disease and study of disease progression, mostly the presynaptic dopamine function, of the nigrostriatal pathway. There are four major ways to examine the dopaminergic terminals function: (1) the ^{18}F-dopa in SPECT and ^{11}C-dopa in PET, measuring the DOPA-decarboxylase activity; (2) molecules as ^{11}C or ^{18}F (for PET), or ^{123}I or ^{99m}Tc (for SPECT, as ^{99m}Tc-TRODAT-1) quantify the availability of DATs; (3) 11C-dihydrotetrabenazine or its 18F-labeled analogue measures the VMAT2 density; and (4) the ability of dopaminergic terminals to release dopamine after pharmacological stimuli (e.g., amphetamine) can be evaluated by changes in dopamine D2 receptor availability with ^{11}C-raclopride PET or ^{123}I-iodobenzamide SPECT (Brooks 2007; Stoessl et al. 2011).

It is known that ^{18}F-dopa uptake has correlation with nigral dopaminergic cell counts and dopamine concentrations in striatum of humans and nonhuman primates (Pate et al. 1993; Snow et al. 1993). In unilateral Hoehn & Yahr stage 1 PD patients, the dorsal posterior putamen ^{18}F-dopa uptake is first reduced, even contralateral to the asymptomatic limb, corresponding to the evidences that ventrolateral nigral dopaminergic projections to the dorsal putamen are more affected in the onset of clinical phase of PD (Kish et al. 1988).

The subsequent PD progression does not reduce the ^{18}F-dopa uptake in the first 2 years (Whone et al. 2003), but after that the functional loss occurs more rapidly in PD than aged controls (Brooks 2003), and the initial posterior-anterior gradient of striatal involvement is substituted by similar rates of decline in the whole striatum. Furthermore, the PET/SPECT measures show inverse correlation with severity of rigidity and bradykinesia in PD but poorly with tremor, suggesting the parkinsonian tremor may be associated with extranigral mechanisms (Vingerhoets et al. 1997; Benamer et al. 2000). Another finding is the increase of ^{18}F-dopa uptake into the internal globus pallidus in initial PD as a possible compensatory action, but this phenomenon vanishes with disease progression, simultaneously with onset of fluctuating responses to levodopa (Whone et al. 2003).

The motor complications on PD are also associated with radioimaging changes. PD patients with fluctuating responses to levodopa present 20 % reduction in ^{18}F-dopa uptake than those with sustained therapeutic responses (de la Fuente-Fernandez et al. 2000), and the ^{11}C-raclopride binding shows a mean 10 % fall in

posterior putamen of advanced PD subjects compared with early-stage patients (Torstenson et al. 1997). Nevertheless, PET studies with dyskinetic individuals show similar levels of striatal dopamine D1 and D2 receptor availability (Turjanski et al. 1997). The dementia in PD, a frequent non-motor complication of advanced stages, shows a reduction in ^{18}F-dopa uptake in cingulate and medial prefrontal areas, suggesting the involvement of the mesocortical dopaminergic pathway on cognitive decline in PD (Ito et al. 2002).

In conclusion, the major importance of midbrain dopaminergic neuronal degeneration on symptomatic progression of PD is unquestionable. However, it must be emphasized that there are several other non-dopaminergic neurons involved in its pathogenesis, as shown by Braak hypothesis, and the AS aggregation and accumulation can be the common link between these vulnerable nerve cells.

4.4 Dopamine-Related Treatments of Parkinson's Disease

The treatment of PD is very complex due to the progressive nature of the disease and the array of motor and non-motor features combined with early and late side effects associated with therapeutic interventions. While no treatments have yet been shown conclusively to slow the progression of the disease, a growing number of symptomatic pharmacologic therapies are available, as well as several forms of surgery and numerous non-pharmacological approaches.

Among dopaminergic drugs, L-DOPA standard and controlled-release formulations are marketed as fixed associations with a DOPA-decarboxylase inhibitor carbidopa or benzeraside. There are several dopamine agonists, with different receptor binding, pharmacokinetic profiles, and routes of administration and two types of indirect dopamine transmission enhancers, monoamine oxidase-B (MAO-B) and COMT inhibitors. Among non-dopaminergic medications, there are several anticholinergics, although amantadine is the only drug widely available for anti-glutamatergic effects. Functional neurosurgery for PD attempts to restore functional balance in basal ganglia relays. There are currently three targets: the ventral intermediate nucleus of the thalamus, the internal segment of the globus pallidus, and the subthalamic nucleus. Either CNS lesions (thalamotomy, pallidotomy, or subthalamic nucleus lesions) or implants of chronic stimulating electrodes at these sites (deep brain stimulation) can be used. Reconstructive surgery involves the implantation of human fetal mesencephalic cells (fetal transplant) or other dopamine-producing cells into the striatum. Rehabilitation for PD (speech, occupational, and physical therapies) has been applied empirically based on its accepted use in other chronic disorders.

It is important to consider that while drug treatments available for PD increased in the last 30 years, the first dopaminergic drug L-DOPA remains the more effective. Actually, the more recent drugs refined the treatment but they do not alter the clinical aspect and the evolution of the disease, and everyone can only temporary control and ameliorate the motor symptoms. The increasing evidences that cognitive dysfunctions, depression, constipation, pain, and nocturnal incapacity can play

Table 1 US Food and Drug Administration (FDA) approved medications for Parkinson's disease

Medication	Adverse effects	Indications and comments
Anticholinergics	Dry mouth, dry eyes, constipation, hypotension, cognitive impairment, urinary retention	Useful for symptomatic control of Parkinson's disease (benefits are mild to moderate); associated with more adverse effects than other drugs
Benztropine trihexyphenidyl		
Carbidopa/ levodopa	Nausea, somnolence, dyskinesia, hypotension, hallucinations	Levodopa is the most effective medication and remains the primary treatment for symptomatic Parkinson's disease; no added benefit for motor complications with sustained-release versus immediate-release preparations
Immediate- and sustained-release carbidopa/levodopa		
COMT inhibitors	Diarrhea; exacerbates levodopa adverse effects; bright orange urine	Useful for managing motor fluctuations ("wearing off" effect) in patients taking levodopa; levodopa dose may need to be reduced
Entacapone		
Tolcapone	Diarrhea; exacerbates levodopa adverse effects if dyskinesia appears; rare liver failure (liver function monitoring needed)	
Dopamine agonists	Nausea, headache, dizziness	Useful for early and advanced disease
Bromocriptine Pergolide	Somnolence; hallucinations; nausea; edema; fibrosis of cardiac valves, lung, and retroperitoneum; retroperitoneal and pulmonary fibrosis	Useful for the initial treatment of parkinsonism and as adjunct therapy in patients taking levodopa
Pramipexole Ropinirole	Nausea, sleep attacks, edema, hallucinations, hypotension	Useful for early disease and in patients with Parkinson's disease and motor fluctuations
MAO-B inhibitors	Nausea, insomnia, drug interactions with other MAO inhibitors/tyramine	Useful for symptomatic control of Parkinson's disease (benefits are mild to moderate) and as adjuvant therapy for patients with Parkinson's disease and motor fluctuations
Selegiline		
Rasagaline	Weight loss, hypotension, dry mouth, drug interactions with other MAO inhibitors/tyramine	
NMDA receptor inhibitor	Nausea, hypotension, hallucinations, confusion, edema	Useful for treating akinesia, rigidity, tremor, dyskinesia
Amantadine		

Abbreviations: *FDA* US Food and Drug Administration, *COMT* catechol-O-methyltransferase, *MAO-B* monoamine oxidase-B, *NMDA N*-methyl-d-aspartate. Based on information from Goetz et al. (2005)

important role in the quality of life of patients and the benefits of any new treatment should be evaluated in their impact in the well-bearing, mental health, and others deficiencies of the patients. A summarized review of the pharmacological approaches currently available for PD is illustrated in Table 1.

All the dopaminergic therapies are based in the pathway of catecholamine synthesis in the body, as presented in Fig. 1. Since most parkinsonian motor

symptoms occur as a consequence of dopamine depletion in the basal ganglia, dopamine replacement strategies represent the main therapeutic approach used to counteract PD motor impairment.

4.4.1 3,4-Dihydroxyphenylalanine (L-DOPA)

Since its introduction in the routine treatment of PD at the beginning of the 1970s (Cotzias 1971), L-DOPA (L-3,4-dihydroxyphenylalanine), a dopamine metabolic precursor, still remains as the most effective treatment for the treatment of the classical motor parkinsonian signs. L-DOPA, the naturally occurring isomer of the amino acid 3,4-dihydroxyphenylalanine, was first isolated in 1913 from legumes (seedlings of *Vicia faba*) by Marcus Guggenheim (Hauser 2009). Already 2 years earlier, Casimir Funk had synthesized D,L-DOPA in the laboratory (Hauser 2009). Funk and Guggenheim considered the amino acid as a possible parent compound of adrenaline. The discovery by Peter Holtz (1959) of an enzyme, DOPA decarboxylase, in mammalian tissue (kidney) extracts that converted L-DOPA to the corresponding – biologically active – amine, that is, dopamine, represented a turning point in catecholamine research (Hauser 2009). After the discovery of dopamine occurrence in the body, many biochemical studies were performed in an attempt to provide experimental support for the proposed biosynthesis of the catecholamines, mainly dopamine, from the amino acid L-DOPA (Hornykiewicz 2002).

The introduction of high dosage of L-DOPA by George Cotzias revolutionized the treatment of PD (Singh et al. 2007). As a prodrug of dopamine, L-DOPA crosses the blood-brain barrier, and it is decarboxylated to dopamine in the nigrostriatal pathways by brain enzymes Nowadays, L-DOPA is always given with carbidopa or benserazide, peripheral DOPA-decarboxylase inhibitors, which prevents peripheral metabolism of L-DOPA and allows a higher percentage of a dose to cross the blood-brain barrier. Primarily, they block L-DOPA metabolism in the periphery, thereby reducing the rate of the first-pass metabolism, and slowing the plasma clearance of L-DOPA; however, the enzyme inhibitors do not cross the blood-brain barrier.

The effects of the dopamine replacement therapy are predictable (as are the side effects), and none of the more recently introduced synthetic dopamine agonists has surpassed the clinical benefit derived from L-DOPA. L-DOPA has a long-duration response in early disease that enables adequate symptomatic control with dosage schedules (Table 1). This is a consequence of the ability of the nigrostriatal system to convert L-DOPA to dopamine, store it in presynaptic vesicles, and release it in response to physiological stimuli. However, as the disease progresses, the conversion of L-DOPA to dopamine in dopaminergic neurons becomes limited.

4.4.2 L-DOPA and Dyskinesia

Although the precise mechanisms of dyskinesia have remained elusive, three main risk factors for this side effect have been conclusively identified in clinical studies, namely, a young age at disease onset, disease severity (reflecting the extent of putaminal dopamine denervation), and high doses of L-DOPA (Jenner 2008; Stocchi 2009; see a recent review of Huot et al. 2013). These risk factors are

reproduced in both nonhuman primate and rodent species by applying neurotoxic lesions to the nigrostriatal dopamine pathway, followed by daily administration of L-DOPA at a sufficient dosage.

Although initially effective, dopaminergic therapies are eventually complicated by motor fluctuations, including off-time (periods of return of PD symptoms when medication effect wears off) and dyskinesia (drug-induced involuntary movements including chorea and dystonia) in most patients (Jenner 2008; Stocchi 2009). The mechanisms by which dyskinesia develop are not completely understood, but pulsatile stimulation of dopamine receptors by short-acting agents as L-DOPA and the degree of striatal denervation have been implicated (Obeso et al. 2000; Stocchi 2009). Dyskinesia may occur at the time of maximal clinical benefit and peak concentration of L-DOPA (peak-dose dyskinesia) or may appear at the beginning and/or at the end of the L-DOPA effect (diphasic dyskinesia, off-dystonia, off-dyskinesia). The progressive reduction in the duration of the clinical effect is called "wearing off." This change in the response to L-DOPA is more related to the disease progression and loss of buffering capacity of the presynaptic terminals to keep constant the levels of dopamine in the striatum (Chase 1998). When wearing off begins, it required modification of dosage and/or dose frequency of L-DOPA or the introduction of additional therapies. Interestingly, at this stage of the disease, so long as the plasma L-DOPA concentration is kept constant, the clinical response will persist (Mouradian et al. 1990; Schapira et al. 2009) and "wearing off" does not occur if the drug is given by continuous infusion (Nutt et al. 1989; Schapira et al. 2009). Motor complications can be an important source of disability for some patients who cycle between "on" periods, which are complicated by dyskinesia and "off" periods in which they suffer severe motor disability (Schapira et al. 2009).

Nonhuman primates have been used to produce models of L-DOPA-induced dyskinesia since the late 1980s (Crossman 1987). Following 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) lesion and subsequent treatment with L-DOPA, nonhuman primates (and macaques in particular) exhibit choreiform and dystonic movements that look very similar to those seen in dyskinetic PD patients. These models have been extensively used to define the basic pharmacological features of L-DOPA-induced dyskinesia (Jenner 2003; Cenci et al. 2009). Rats with 6-hydroxydopamine (6-OHDA) lesions have been the most widely used animal model of PD since the 1970s, but the idea that these animals can exhibit L-DOPA-induced dyskinesia has become accepted only recently (Henry et al. 1998; Cenci et al. 2009). For many years, drug-induced rotation remained the only available method to study motor effects of dopaminergic therapies in this animal model. When given to unilaterally 6-OHDA-lesioned rats, L-DOPA or dopamine receptor agonists induce the animals to turn in the direction contralateral to the lesion, a behavior traditionally regarded as a correlate of the antiparkinsonian activity of these drugs. Later on, it was realized that contralateral rotation shows sensitization during chronic dopaminergic treatment (Henry et al. 1998) – a feature reminiscent of the priming for dyskinesia described in nonhuman primates and supposed to occur in PD patients. About 10 years ago came the first reports that 6-OHDA-lesioned rats treated with L-DOPA exhibit movements with dystonic and

hyperkinetic features engaging the forelimb contralateral to the lesion, as well as axial and orofacial muscles (Lundblad et al. 2002; Winkler et al. 2002). These movements interfere with the rat's physiological motor activities, and they are reduced by treatments that have antidyskinetic efficacy in nonhuman primates and PD patients. Rating scales for rodent abnormal involuntary movements (AIMs) were developed to reflect the topographic distribution, frequency, duration, and amplitude of dyskinetic behaviors induced by L-DOPA (Dekundy et al. 2007; Cenci et al. 2009). Producing and validating an animal model is a fundamental task for investigators involved in translational PD research.

Nevertheless, it must be emphasized that L-DOPA remains the "gold standard" medication in the treatment of PD. The use of other dopaminergic drugs at the beginning of the treatment helps to delay the onset of the motor complications in patients with PD. However, at some time when the disability of the patient increases, L-DOPA needs to be introduced (Olanow et al. 2009b). L-DOPA use is appropriate when all other reasonable strategies fail to produce adequate control of symptoms or when patient's symptoms pose an imminent danger to them (e.g., loss of postural reflexes with high risk for falling).

Recently, there was a growing discussion about a possible neurotoxic effect of L-DOPA that could increase the disease progression, and many patients and doctors became afraid to use the drug and delayed its use at the most (Kurlan 2005). However, a critical evaluation of older and most recent studies fails to describe a deleterious effect of L-DOPA in the evolution of the degenerative process (Olanow et al. 2004). In contrast our work showed that chronic L-DOPA treatment to partial 6-OHDA-lesioned rats induces partial recovery of the dopaminergic system suggesting their trophic effect which was confirmed by the increase of the trophic factor pleiotrophin (Murer et al. 1998; Ferrario et al. 2004).

Therefore, in the initial stages of the disease, L-DOPA therapy is the most effective for improving motor symptoms in PD. However, long-term treatment is accompanied by fluctuations in motor performance, dyskinesia, and neuropsychiatric complications. Furthermore, as PD progresses, patients develop features that do not respond well to L-DOPA therapy, such as freezing episodes, autonomic dysfunction, falling, and dementia. The increasingly diverse possibilities in the therapy of PD, and the many side effects and complications of therapy, require the formulation of reliable standards for patient care that are based on current scientific knowledge.

4.4.3 Catechol-O-Methyltransferase Inhibitors (COMT)

L-DOPA is usually combined with a DOPA-decarboxylase inhibitor (carbidopa or benserazide) to improve absorption and reduce peripheral metabolism (Schapira et al. 2009). However, the majority of L-DOPA is still metabolized in the gut and liver by COMT to form 3-*O*-methyldopa (3-OMD). 3-OMD accumulates and may interfere with the brain penetration of L-DOPA. COMT inhibitors reduce the metabolism of L-DOPA, extending its plasma half-life by 30 % and prolonging the clinical effect of each L-DOPA dose. This effect was suspected to be of enough magnitude to produce more stable L-DOPA plasma levels if a COMT inhibitor was

used with each dose of L-DOPA. The hypothesis was that this combined therapy could delay the appearance of motor complications because of producing more continuous dopaminergic stimulation. However, clinical studies were unable to show this positive effect, and in opposition, the combined therapy led to earlier appearance of dyskinesia (Klivenyi and Vecsei 2010). This unexpected effect may be explained by the potentializing effect of the COMT inhibitors in the L-DOPA effect, since its dosage, or effect, is associated with earlier beginning of motor complications.

Entacapone and tolcapone are the two selective COMT inhibitors currently in use for the treatment of PD (see Table 1), while newer molecules are now in clinical evaluation. Both COMT inhibitors only have observable clinical effects when used in association to L-DOPA. The most significant clinical effect is the reduction in the daily off-time, by small prolongation in the time of L-DOPA effect (Olanow et al. 2004; Jankovic and Stacy 2007). The COMT inhibitors also potentialize the effect of L-DOPA, and they can be used to achieve a stronger symptomatic effect (Gallagher and Schrag 2008). Tolcapone is a central and peripheral COMT inhibitor and is apparently more efficacious than entacapone that only inhibits peripheral metabolism, but there are some concerns about its safety and in particular to its potential hepatotoxicity (Assal et al. 1998). Entacapone is much more widely used and appears to be less hepatotoxic (Gershanik et al. 2003; Schrag 2005). The main adverse effects are related to its potentializing dopaminergic effects and include dyskinesia, orthostatic hypotension, nausea, vomiting, and confusion. Other important side effects are the occurrence of diarrhea and urinary discoloration. The control of hepatic enzymes is always indicated during the use of tolcapone and eventually during the use of entacapone. The association of entacapone in a single tablet with L-DOPA and carbidopa is now available. Another effect of the COMT inhibitor is the reduction in the systemic levels of 3-OMD that was supposed to interfere with L-DOPA metabolism in the central nervous system. However, any clinical benefit could be proved to be due to this property (Muller and Kuhn 2006). Another systemic effect of the COMT inhibitors is the reduction in the blood levels of homocysteine in treated PD patients (Muller and Kuhn 2006; Muller and Muhlack 2009). This could be a hypothetical benefit in the long term, since homocysteine could mediate the progression of neuronal degeneration and increase the risk for development of dementia, vascular disease, and polyneuropathy in levodopa-treated PD patients (Muller and Muhlack 2009).

Recently, it was established that a continuous duodenal L-DOPA infusion may be an efficient strategy to obtain continuous dopaminergic stimulation and to decrease the complications of the therapy (Clarke et al. 2009). Other ways to obtain a stable plasma level of L-DOPA were under research and include the development of new controlled-release tablets and cutaneous patches of the drug.

4.4.4 Monoamine Oxidase Isoenzyme Type B (MAO-B) Inhibitor

Substantial experimental evidences indicate that the oxidative stress is an important pathogenic mechanism in PD (Yacoubian and Standaert 2009). There are many possible mechanisms associated to the generation of free radicals in PD. The own

dopamine metabolism produces free radicals in excess. Blocking the first step of dopamine metabolism by inactivating MAO-B reduces the production of free radicals. Selegiline and rasagiline are selective MAO-B inhibitors currently in clinical use (see Table 1). MAO-B inhibition may increase the concentration of dopamine in the synaptic cleft due to the inhibition in the dopamine degradations and also produce an antiparkinsonian effect (Wu et al. 2000). Unlike selegiline, rasagiline is not metabolized to amphetamine and has no sympathomimetic activity. Rasagiline has also shown neuroprotective effects in in vitro and in vivo models of PD (Jenner 2004).

Selective MAO inhibitors become nonselective at doses greater than those recommended. In this condition, selegiline and rasagiline may increase the risk of a hypertensive crisis if used in combination with tyramine-containing foods (e.g., fermented cheese, aged meats) or amine-containing medications (e.g., over-the-counter cough/cold medicines). Serotoninergic crisis also has been associated with the use of MAO-B inhibitors in association with antidepressive drugs, since they can increase brain serotonin levels. The motor symptomatic effect of the MAO-B inhibitors is only modest, and these drugs are most commonly used to treat patients at the earlier stage of the disease. However, the MAO-B inhibitors may also be used at the later stages to increase the daily on-time. Despite recent clinical studies with rasagiline suggested that the drug may also have a neuroprotective effect (Olanow et al. 2009a), this is still a matter of controversy (see Ahlskog and Uitti 2010).

4.4.5 Dopamine Receptor Agonists

Dopamine agonists directly stimulate dopamine receptors. Of the nine dopamine agonists marketed for the treatment of PD, five were ergot derivatives (bromocriptine, cabergoline, dihydroergocryptine, lisuride, and pergolide) and four are non-ergot derivatives (apomorphine, piribedil, pramipexole, and ropinirole) (see Table 1). Pergolide was retired of the market of most countries due to tendency to induce cardiac valvar fibrosis; however, the use of ergot-derived dopamine agonists (pergolide and cabergoline) in patients with PD was associated with increased risk of cardiac valvar regurgitation (Steiger et al. 2009). The acute side effects of dopamine agonists are similar to those observed with L-DOPA and include nausea, vomiting, and postural hypotension. It is generally accepted that the shared D2-like receptor agonistic activity produces the antiparkinsonian effect. This D2 effect also explains peripheral (gastrointestinal nausea and vomiting), cardiovascular (orthostatic hypotension), and neuropsychiatric (somnolence, psychosis, and hallucinations) side effects. Even at lower doses, patients experience orthostatic hypotension, constipation, dyskinesia, confusion, and excessive somnolence with these agents (Wong et al. 2003). These adverse effects tend to occur with the initiation of treatment and to abate as tolerance develops usually over the ensuing days to weeks. Other problems related to the use of dopamine agonists include weight gain (possibly related to overeating) and edema (especially in the lower extremities). More recently, attention has been focused on the association of dopamine agonist treatment with the development of pathologic gambling, hypersexuality, and compulsive eating and shopping. This has attracted

considerable scientific interest because of the known relationship between dopamine and reward (Obeso et al. 2000).

Almost all currently used dopamine agonists are able to protect dopamine neurons from death in many in vitro and in vivo experiments. This neuroprotective effect may be the result of different mechanisms: antioxidation, scavenging of free radicals, suppression of lipid peroxidation, and inhibition of apoptosis. Dopamine agonists have a significant clinical effect in the motor parkinsonian signs, but most of them were not comparable to that observed with L-DOPA. The use of dopamine agonists at the beginning of the treatment of PD to spare L-DOPA is indicated specially for younger patients. The monotherapy with this class of drugs is associated with lower incidence of dyskinesia and wearing off but with a lower antiparkinsonian effect than L-DOPA (Hitzeman and Rafii 2009). One explanation for their lower risk to induce motor complications may be due to the long half-life of these drugs in relation to the L-DOPA. One exception for this is apomorphine that has a pharmacokinetic curve very similar to the L-DOPA and is the only dopamine agonist which a similar symptomatic effect to it. The main limitation for the clinical use of this drug is the administration route that must be subcutaneous. In some countries apomorphine is infused subcutaneously and continuously by a pump mechanism in patients with PD. The clinical effect is significant and persistent (Clarke et al. 2009). This is now recognized as a potential continuous dopaminergic stimulation strategy and reduces functional impairment and motor complications.

New delivery ways for dopamine agonist molecule are in development. Subcutaneous patches of rotigotine seem to be efficient and may produce more continuous dopaminergic stimulation (Chen et al. 2009). Long-release tablets of non-ergot dopamine agonists are now in evaluation and may be useful to increase adherence of the patient to the therapeutics.

4.4.6 Is There Nitric Oxide Inhibition Utility in the Dopamine Replacement Therapy?

Notwithstanding recent advances in the management of PD, L-DOPA-induced dyskinesia continues to be a clinical and therapeutic challenge (Cenci and Lindgren 2007; Jenner 2008; Santini et al. 2008). However, many other neurotransmitters may play a central role in the neurobiology and management of L-DOPA-induced dyskinesia. Nitric oxide is a free radical that can also act as an atypical neurotransmitter and influence dopamine-mediated neurotransmission. Nitric oxide also regulates synaptic and neural plasticity being enrolled in the regulation of motor activity (Pierucci et al. 2011; Del Bel et al. 2005, 2011). There is evidence whereby communication between nitrergic and dopaminergic systems plays an essential role in the control of the nigrostriatal pathway. The dual localization of immunoreactivity for nitric oxide synthase (NOS) and tyrosine hydroxylase, enzymes responsible for the synthesis of nitric oxide and dopamine, respectively, proposes a close anatomical link between the two neurotransmitters (Mitkovski et al. 2012).

Recently, our group (Padovan-Neto et al. 2009, 2011; Novaretti et al. 2010; Del Bel et al. 2011) and other laboratories (Takuma et al. 2012; Yuste et al. 2011)

described that nitric oxide synthase inhibitors are able to decrease the motor changes related to prolonged administration of L-DOPA in rodent models of PD. Similar results were described, in latest meeting communication, for nonhuman primates by Iravani et al. (2008) and Yuste et al. (2011). Postmortem studies in human brain of patients with Parkinson's disease have greatly contributed to figure out the disease. In spite of this, few human brain studies have focused on the relationship between the development of dyskinesia and biochemical changes in the human brain. It limits the possible understanding of the nitric oxide system in the treatment of Parkinson's disease. But Parkinsonian patients presented in serum a marked rise of the production of the nitric oxide second messenger cyclic guanosine monophosphate (cGMP) levels (Chalimoniuk et al. 2004) induced by L-DOPA. Similar result was described in the cerebellum (Gumulka et al. 1976). Comparable result was described in animals (Itokawa et al. 2006). In mice, cGMP is regulated by L-DOPA (Chalimoniuk and Langfort 2007). In addition, Sanchez and cols. (2002) showed that nitric oxide stimulates L-DOPA release in the striatum in a time- and concentration-dependent manner.

A role for nitrergic neurotransmission in the pathophysiology of dyskinesia and as a potential drug target for new therapeutic has been proposed also by others (Iravani and Jenner 2011; Pierucci et al. 2011; Huot et al. 2013). NOS inhibitor treatment was able to prevent abnormal involuntary movements without significantly changing normal motor (Padovan-Neto et al. 2009). Different from the cataleptic effects of these drugs, there was no tolerance to the antidyskinetic effects of NOS inhibitors (Novaretti et al. 2010). The antidyskinetic effects of 7-nitroindazole, a preferential neuronal nitric oxide synthase (nNOS) inhibitor, seem to involve reduction in gene and protein expression in denervated striatal neurons (Padovan-Neto et al. 2011). L-DOPA increased nNOS mRNA levels in the contra- and ipsilateral side to the dopamine lesion of the frontal cortex but did not produce any further increases of nNOS protein in the striatum compared to the 6-OHDA-induced increase (Padovan-Neto et al. 2011).

Despite promising studies, efforts in synthesizing highly selective nNOS inhibitors have been difficult and have limited the development of such drugs (Hobbs et al. 1999; Vallance and Leiper 2002). To date, clinical studies of NOS inhibitors have been limited by the small number of potent and selective drugs that are safe for human administration (Vallance 2003; Petros et al. 1994: Rees 1995; Ashina et al. 1999). The recent discovery that multiple subunits of NOS exist, with apparent unique anatomic distribution and functional and pharmacological diversity (for review see Garthwaite 2008), holds considerable therapeutic potential. One novel therapeutic approach could be to manipulate the levels of endogenous NOS inhibitors. NOS inhibitors are also likely synthesized within the body. L-NMMA (NG-monomethylarginine) and asymmetric dimethylarginine are synthesized by methylation of arginine residues in proteins (Leiper and Vallance 1999). Once the proteins are broken down, the free methylarginines are released into the cell cytosol and act as competitive inhibitors of all NOS isoforms. They are metabolized to citrulline by the action of dimethylarginine dimethylaminohydrolase (Leiper and Vallance 1999; MacAllister et al. 1996). Inhibition of this enzyme leads to

the accumulation of methylarginines and thereby blocks nitric oxide production. Antagonists might be developed to target-specific pathways within the basal ganglia.

A novel class of drugs named membrane-associated guanylate kinase inhibitors has recently been proposed in treatment of excitotoxicity (Lau and Tymianski 2010; Doucet et al. 2012). These peptides are competitive antagonists designed to bind postsynaptic scaffolding proteins (as, e.g., PSD-95, postsynaptic density 95 kDa), aimed at dissociating the spatial relationship between nNOS and NMDA (*N*-methyl-d-aspartate) receptors (NMDA/PSD-95/nNOS receptor complex) (Zhou et al. 2010; Doucet et al. 2012). The association of nNOS with NMDARs, via PSD-95 (Christopherson et al. 1999), plays an important role in a range of normal neuronal functions including synaptic plasticity (Garthwaite et al. 1988; Steinert et al. 2010) as well as pathophysiological disorders of the brain (Aarts et al. 2002; Sun et al. 2008; Zhou et al. 2010; Doucet et al. 2012). Since (a) NMDARs couple to nNOS and (b) NMDAR antagonists (amantadine) and nNOS inhibitors possess antidyskinetic properties, the disruption of the NMDAR/PSD-95/nNOS complex may possibly represent an alternative approach to specifically block nitrergic signaling coupled to NMDA receptor activity. It may prevent the problems associated general reduction of NMDA or nNOS function. To date, PDZ-based interactions represent a drug target that still remains largely unused (Dev 2004). They are however currently undergoing phase II clinical trials (Lau and Tymianski 2010).

The reduction in L-DOPA-induced dyskinesia in rodents and primates treated with NOS inhibitors suggests the involvement of nitric oxide in this altered behavior. These preclinical findings suggest that nitric oxide is a promising therapeutic target for the reduction of L-DOPA-induced dyskinesia.

5 Conclusion

The discoveries of dopamine as a neurotransmitter in the brain, its depletion in patients with PD, and its replacement with L-DOPA therapy were major revolutionary events in the rise to effective therapy for patients with PD. However, although drugs that act on the dopaminergic system provide effective symptomatic control for the classic parkinsonian motor features, the patients' quality of life continues to deteriorate as a consequence of gait and balance difficulties, autonomic dysfunction, and cognitive impairment. L-DOPA remains at present the most powerful symptomatic drug for the treatment of this condition. However, motor complications of chronic L-DOPA treatment have emerged as a major limitation of this therapy. Nonetheless, the importance of dopamine neurotransmitter system in a broad array of human disorders ranging from PD to schizophrenia has driven an intensive array of investigations oriented toward increasing our understanding of this complex system in normal conditions as well as disease states. Knowledge of dopaminergic cells and circuits has been enriched by findings obtained with several and highly sensitive techniques, as immunohistochemistry, cellular biology, transgenic mice or conditional mutants, functional anatomy,

electrophysiological studies, sophisticated behavioral analyses, and functional neuroimaging. Altogether, these studies have also led to new concepts of healthy and pathological functions of dopaminergic circuits at the molecular and system levels.

Abstract

Iron plays essential roles in the development of early cognitive functions and in the maintenance of neuronal functions in the mature brain, so neurons have in place expeditious mechanisms to ensure a readily available supply of iron. However, iron is an intrinsic producer of reactive oxygen species (ROS), and increased levels of iron promote neurotoxicity because of hydroxyl radical formation, glutathione consumption, protein aggregation, lipid peroxidation, and nucleic acid modification. In this chapter, the components of iron homeostasis and the mechanisms by which iron homeostasis is lost in Parkinson's disease (PD) are discussed. In particular, it will be discussed the relevance of endogenous toxins such as aminochrome as mediators of mitochondrial dysfunction and of hepcidin as a mediator of inflammatory stimuli. A model is proposed that describes a positive feedback loop between changes in iron, glutathione, and ROS levels that ends in cell death.

Keywords

DMT1 • FPN1 • Glutathione • Hepcidin • Iron • Iron accumulation • Iron chelation • IRP1 • Mitochondrial complex I • Mitochondrial dysfunction • MPTP • NTBI • Parkinson's disease • Reactive oxygen species

List of Abbreviations

AC	Aminochrome
CDC14A	Dual specificity protein phosphatase
CNS	Central nervous system
CP	Ceruloplasmin
CSF	Cerebrospinal fluid
DAT	Dopamine transporter
Dcytb	Duodenal cytochrome b ferrireductase
DMT1	SLC11A2, divalent metal transporter 1
EMSA	Electrophoretic mobility shift assay
FPN1	SCL40A, ferroportin 1
GPAT	Glutamyl phosphoribosyltransferase
GSH	Glutathione
GSSG	Oxidized glutathione
HIF	Hypoxia-inducible factor
IFN-γ	Interferon gamma
iNOS	Inducible nitric oxide synthase
IRE	Iron regulatory element
IRP	Iron regulatory protein
L-DOPA	L-3,4-dihydroxyphenylalanine
LIMK1	LIM domain kinase 1
LIP	Labile iron pool
LPS	Lipopolysaccharide
MPP+	1-methyl-4-phenylpyridinium
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MRCKα	Myotonic dystrophy kinase-related Cdc42-binding kinase α

NFκB	Nuclear factor kappa B
NMDA	N-methyl-D-aspartate
NO	Nitric oxide
NTBI	Non-transferrin-bound iron
PAP7	PKA-associated protein 7
PD	Parkinson's disease
PINK-1	PTEN-induced putative kinase 1
ROS	Reactive oxygen species
SDR2	Stromal cell-derived receptor 2
SN	Substantia nigra
Tf	Transferrin
TfR1	Transferrin receptor 1
TH	Tyrosine hydroxylase
TNF	Tumor necrosis factor
TNFR	TNF receptor
TRPC6	Transient receptor potential canonical 6
XO	Xanthine oxidase
Zip 14	Zrt-, Irt-like protein 14

1 Introduction

Early observations in postmortem PD tissue showed decreased glutathione (GSH) and increased oxygen-mediated damage as detected by 4-hydroxynonenal protein adducts (Perry et al. 1982; Youdim et al. 1989; Jenner 1991). These findings established the evidence for the participation of oxidative damage in nigral neuronal death occurring in PD. At present, the causes for this deregulation remained obscure.

An important development in the study of the molecular mechanisms underlying the disease arose from the serendipitous discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) as a Parkinsonian agent (Langston et al. 1983). This initial finding was followed by the finding that the primary effect of MPTP, inhibition of mitochondria electron transport chain complex I, was a customary characteristic of Parkinsonian tissue (Schapira et al. 1990). Thus, it became fairly well established that mitochondrial dysfunction and the consequences therein are most probably germane to the development of the disease.

The finding of genetic mutations that induce familiar Parkinsonism has provided important insights into the cellular and molecular processes that go awry in PD (for a recent review see (Martin et al. 2011)). PINK1, parkin, DJ-1, and α-synuclein are proteins that interact with the mitochondrion and modulate its function. The fact that their loss of function results in familiar PD supports the notion that mitochondrial dysfunction is a central event to PD pathogenesis (Schapira and Gegg 2011).

There is abundant evidence showing iron accumulation in dopaminergic neurons of the SN pars compacta (Jellinger 1999; Bartzokis et al. 2000; Sayre et al. 2000; Perry et al. 2003; Zecca et al. 2004; Berg and Youdim 2006; Wilson 2006; Weinreb et al. 2011).

The observation that pharmacological agents with iron chelation capacity prevent neuronal death induced by Parkinsonian toxins (Zhu et al. 2007) highlights the pivotal role of iron in PD neuronal death. It is therefore important to understand the relationships between mitochondrial complex I dysfunction, oxidative stress, and iron accumulation and how the conjunction of these factors results in neuronal death. The pivotal role of iron in the events leading to nigral neuronal death is the subject of this chapter.

2 Iron Homeostasis and Dyshomeostasis: The Role of Iron Transporters on Iron Accumulation

2.1 The Iron Responsive Element: Iron Regulatory Protein (IRE/IRP) System. A Brief Description

In vertebrates, cellular iron levels are posttranscriptionally controlled by the activity of iron regulatory proteins (IRP1 and IRP2), cytoplasmic proteins that bind to structural elements called iron-responsive elements (IREs). IREs are found in the untranslated region of the mRNAs of the major proteins that regulate cellular iron homeostasis: the transferrin receptor, the iron transporter DMT1, involved in iron import, the iron-storage protein ferritin and the exo-transporter ferroportin 1, involved in decreasing the levels of cytosolic redox-active iron (for a recent review see (Wang and Pantopoulos 2011)).

The activities of both IRP1 and IRP2 respond to changes in cellular Fe status, although through different mechanisms. In iron-replete conditions, IRP1 has a 4S-4Fe cubane structure that renders the protein active as a cytoplasmic aconitase but inactive for IRE binding. Low levels of intracellular Fe induce disassembling of the 4S-4Fe cluster, which causes IRP1 to bind and stabilize TfR and DMT1 mRNA. Besides being regulated by iron levels, IRP1 is also regulated by effectors such as nitric oxide (Bouton 1999), hydrogen peroxide (H_2O_2) (Martins et al. 1995), hypoxia (Hanson et al. 1999), and phosphorylation (Schalinske and Eisenstein 1996). In contrast to IRP1, IRP2 activity is downregulated through iron-induced oxidative damage followed by ubiquitination and proteasome degradation (Guo et al. 1995). The genetic ablation of IRP2 revealed that IRP2−/− mice are born normal but develop in adulthood a movement disorder characterized by ataxia, bradykinesia, and tremor (LaVaute et al. 2001). In contrast, IRP1−/− mice are apparently normal during adulthood, with only slight misregulation of iron metabolism in the kidney and brown fat (Meyron-Holtz et al. 2004). Thus, IRP2 seems to dominate the physiological regulation of iron metabolism, whereas IRP1 seems to predominate in pathophysiological conditions.

A genome-wide search for IRE sequences resulted in 35 new target genes for IRPs (Campillos et al. 2010; Sanchez et al. 2011). Thus, the scope of the IRE/IRP system has lately gone from a restricted iron homeostasis system to a more global system, still undetermined, possibly linking iron homeostasis to a myriad of other cell functions (Fig. 1).

Newly found genes that contain an IRE motif include Hif-2α, which regulates the expression of proteins involved in erythropoiesis, angiogenesis, programmed

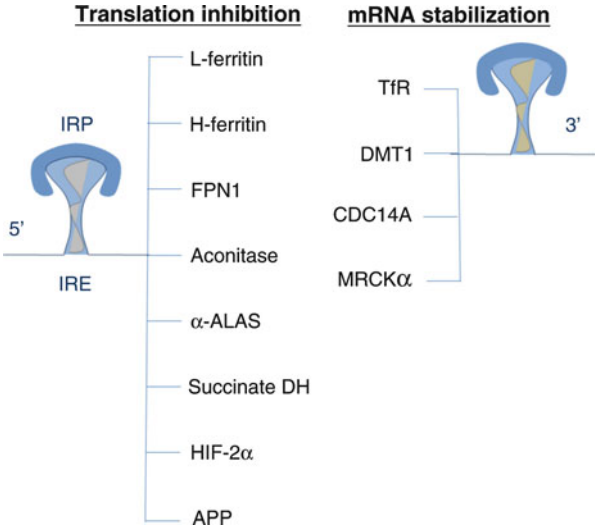

Fig. 1 Genes that contain an IRE motif in the untranslated regions of their mRNA

cell death, cancer, and ischemia (Patel and Simon 2008; Davis et al. 2011). Other prominent members are Cdc14, a tyrosine phosphatase involved in exit from mitosis and initiation of DNA replication. Cdc14 has been shown to dephosphorylate tumor suppressor protein p53, possibly regulating its function and MRCKα, a serine/threonine kinase regulated by Cdc42, a member of the Rho subfamily of small GTPases that regulate cytoskeletal organization. MRCKα also regulates myosin assembly by phosphorylation of the myosin-binding subunit of myosin light chain and phosphorylates LIMK1 and LIMK2, kinases that regulate actin assembly (Cmejla et al. 2010).

2.2 Cellular Components of Neuronal Iron Homeostasis

The components of neuronal iron homeostasis are shown in Fig. 2.

The scheme includes transferrin and transferrin receptor (TfR), inflow (DMT1; SLC11A2) and efflux (ferroportin 1, FPN1) iron transporters, the iron-storage protein ferritin, the ferrireductase Dcytb that reduces extracellular Fe^{3+} to Fe^{2+} prior to transport by DMT1, and the ferroxidase ceruloplasmin (CP) responsible for the oxidation of Fe^{2+} after transport by FPN1 and prior to the binding by apoTf. Transferrin-bound iron uptake starts with the binding of transferrin to surface receptors, followed by internalization into the endosomal system, release of iron mediated by the acidification of the endosome, reduction possibly mediated by Steap2, and transport into the cytoplasm by endosomal DMT1. Once in the cytoplasm, Fe^{2+} becomes part of the labile or reactive iron pool where it distributes to mitochondria, neuromelanin, and ferritin or engages in electron exchange reactions (Kakhlon and Cabantchik 2002; Kruszewski 2003). All the components described in Fig. 1 have been detected in the brain (Moos et al. 2007; Rouault et al. 2009; Haeger et al. 2010).

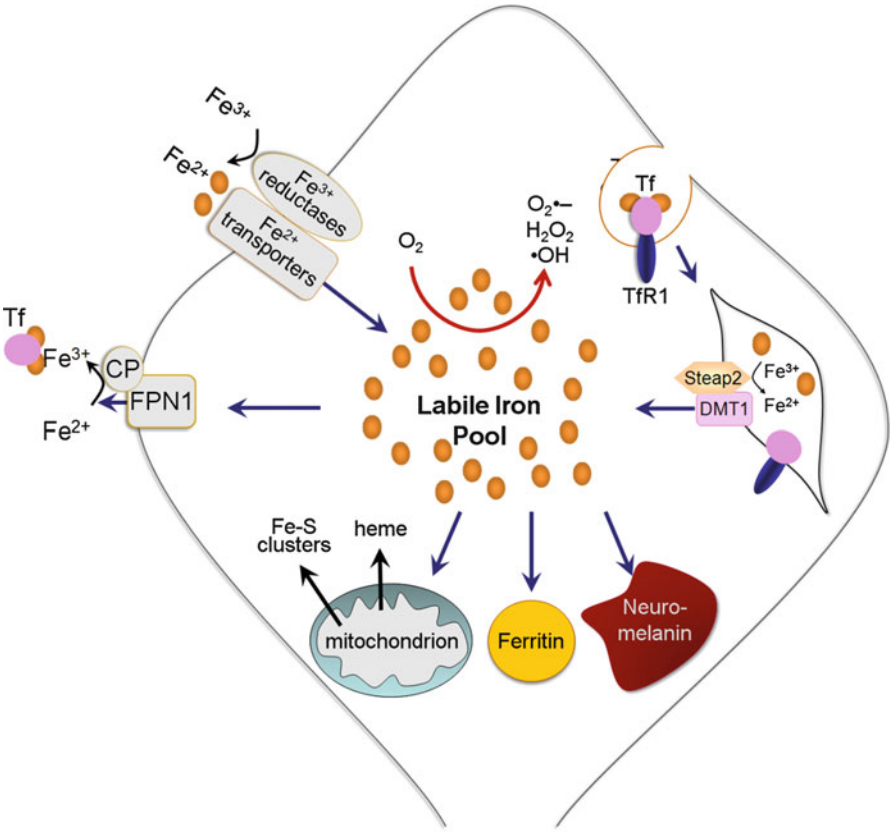

Fig. 2 Components of neuronal iron homeostasis. The molecular components comprise the transferrin–transferrin receptor complex; the ferrireductases Dcytb and/or SDR2, responsible for the reduction of Fe^{3+} prior to transport by DMT1; uptake (DMT1, TRPC6, VGCC, Zip14) and efflux (ferroportin 1, FPN1) iron transporters; the iron-storage protein ferritin; the ferrireductase Steap2, probably responsible for the reduction of Fe^{3+} prior to transport by DMT1 in endosomes in the brain; and the ferroxidase CP, responsible for the oxidation of Fe^{2+} after transport by FPN1 and prior to Fe^{3+} binding to apoTf. Once in the cytoplasm, iron forms part of the labile iron pool from where it distributes to mitochondria, ferritin, and neuromelanin, or it is exo-transported by FPN1. In the cellular environment, LIP iron is a net ROS producer. For simplicity, the molecular components of mitochondrial iron homeostasis were omitted (From Núñez et al. (2012) with permission from the publisher)

2.2.1 The Iron-Uptake Transporters

Iron concentration in cerebrospinal fluid (CSF) ranges between 0.2 and 1.1 μM, whereas transferrin concentration lies around 0.24 μM (Moos and Morgan 1998; Symons and Gutteridge 1998). Thus, CSF iron often exceeds the binding capacity of transferrin, and non-transferrin-bound iron (NTBI) uptake is expected to occur in neurons that express DMT1 or other iron-uptake transporters.

DMT1 (SLC11A2) is the paradigmatic transporter that brings iron inside cells (Gunshin et al. 1997). In the brain, DMT1 is expressed in hippocampal pyramidal

and granule cells, cerebella granule cells, pyramidal cells of the piriform cortex, SN and the ventral portion of the anterior olfactory nucleus, striatum, cerebellum, hippocampus and thalamus, as well as in vascular cells throughout the brain and ependymal cells in the third ventricle (Gunshin et al. 1997; Williams et al. 2000; Burdo et al. 2001). The pervasive presence of DMT1 in neurons suggests that DMT1 is necessary for their regular function (Hidalgo and Núñez 2007; Wright and Baccarelli 2007; Haeger et al. 2010; Pelizzoni et al. 2011).

The mammalian DMT1 gene undergoes alternative splicing generating four isoforms, all with similar activities for Fe^{2+} transport. The 1A and 1B mRNA DMT1 variants originate from alternative splicing at the 5′ end (exons 1A and 1B), while the +IRE or –IRE variants originate from splicing on the 3′ end (exons 16/16A and 17) (Hubert and Hentze 2002; Ludwiczek et al. 2007). The 1B isoforms are expressed in the brain (Haeger et al. 2010), whereas the 1A isoforms are almost exclusively expressed in the intestine (Hubert and Hentze 2002).

Given its crucial role on cell iron uptake, knowledge on the regulation of DMT1 expression is vital to understand pathological conditions in which iron accumulation is observed. It is generally accepted that the +IRE isoforms of DMT1 are regulated by the IRE/IRP system, which posttranscriptionally regulates the expression of iron homeostasis proteins such as transferrin receptor 1 (TfR1), DMT1, FPN1, and ferritin, in response to the concentration of reactive iron in the cytoplasm (Garrick and Garrick 2009). Knowledge on the regulation of DMT1(−IRE) mRNA levels through its 3′-UTR is scarce. Recently, its regulation by the levels of miRNA Let-7d was reported in developing erythroid cells (Andolfo et al. 2010). The authors demonstrated that when the levels of miRNA Let-7d increase, the expression of DMT1(−IRE) decreases, probably by inducing its degradation through binding to imperfect complementary sites within the 3′-UTR of its mRNA.

Understanding on the transcriptional regulation of DMT1 expression is emerging. The inflammatory cytokine NFκB and nuclear factor Y regulate DMT1(1B) expression in embryonic carcinoma cells (Paradkar and Roth 2006b), whereas hypoxia upregulates expression of the DMT1(1A) isoform, presumably through activation of HIF-1 (Lis et al. 2005; Wang et al. 2010a). HIF-1 also promotes the expression of the 1B isoform by binding to a putative hypoxia-response element sequence in DMT1 exon1B gene (Qian et al. 2011). Recently, upregulation of DMT1 mRNA by the endogenous neurotoxin aminochrome was reported (Aguirre et al. 2012). Micromolar concentrations of aminochrome induced increased DMT1(+IRE) expression coupled to decreased FPN1 expression, in a process blocked by the antioxidant N-acetyl cysteine. Thus, it is possible that an increase in the oxidative tone triggers, through an undefined mechanism, increased expression of DMT1.

2.2.2 The Iron Exo-transporter FPN1

FPN1 (SCL40A) is the only member of the SLC40 family of transporters and the first reported protein that mediates the exit of iron from cells (McKie et al. 2000). The protein is expressed mainly in enterocytes and macrophages, but its presence has also been described in neurons and astrocytes (Burdo et al. 2001).

In enterocytes, FPN1 is responsible for iron efflux during the process of intestinal iron absorption, while in Kupffer cells FPN1 mediates iron export for reutilization by the bone marrow (Devalia et al. 2002).

Knowledge on the regulation of FPN1 expression is incipient. Most probably, FPN1 expression is regulated at both transcriptional and translational levels (McKie et al. 2000; Knutson et al. 2003). There are two closely related isoforms of FPN, one (FPN1) that has an IRE motif in the 5′-UTR and another (FPN1B) that does not have it (Zhang et al. 2009). The 5′-UTR motif gives FPN1 a ferritin-like response to variations in cell iron, increasing its expression under elevated cell iron conditions (McKie et al. 2000; Yang et al. 2002; Aguirre et al. 2005). For the contrary, the 1A isoform, mainly expressed in enterocytes and erythroid precursor cells, responds to an iron challenge decreasing its expression (Zhang et al. 2009).

The expression of FPN1 in mouse brain is ubiquitous. It is present in oligodendrocytes, microglia, astrocytes, and neurons (Song et al. 2010). Space-temporal expression of FPN1 in neurons is variable (Moos and Rosengren 2006). In young brain high immunoreactivity is found in the neurons of the hippocampus and striatum (both in cell bodies and in projection fibers), a mild expression in the SN pars compacta and the superior colliculus and low expression in the SN pars reticulata (Boserup et al. 2011). In the adult brain, FPN1 immunoreactivity is lower in the projections of the striatum, but no differences have been found in neuronal cell bodies (Moos and Rosengren 2006).

2.2.3 TfR1

The TfR1 mediates the incorporation of iron into cells by binding the plasma iron-transport protein transferrin and undergoing recycling clathrin-mediated endocytosis (Harding et al. 1983). The presence of TfR in neurons, microglia, and astrocytes and its response to iron deficiency have been described (Han et al. 2003; Beard et al. 2005). Early studies by Faucheux et al. revealed that the density of ^{125}I-labeled transferrin binding sites were highest in the central gray substance, intermediate in the catecholaminergic cells of the superior colliculus and ventral tegmental area, and almost nonexistent in the SN (Faucheux et al. 1993).

As noted above, TfR1 is posttranscriptionally regulated by the IRE/IRP system. When cellular iron is low, IRPs bind to five IRE motifs in the 3′-UTR of TfR1 mRNA increasing its mRNA stability. TfR1 expression is transcriptionally regulated by hypoxia through HIF-1 (Tacchini et al. 1999). TfR1 expression is also regulated by inflammatory stimuli: LPS/IFN-γ treatment to mouse macrophages upregulates NF-κB, which in turn transiently activates HIF-1-dependent TfR1expression and iron uptake (Tacchini et al. 2008).

2.2.4 Ferritin

Ferritin, a multimeric protein formed by 24 subunits of H and L monomers, is the only well-characterized iron-storage protein in living organisms (Liu and Theil 2005). The 24 subunits in ferritin form a hollow cavity that can store as much as 4,500 Fe^{3+} atoms in the form of crystallized diferric oxo-hydroxyl complexes (Harrison and Arosio 1996). Ferritin plays a fundamental role in controlling the

size of the cytoplasmic redox-active iron pool (Salgado et al. 2010). Although ferritin is expected to reduce this pool by storing iron, there is a dynamic exchange of iron between its ferritin-bound form and a cytoplasmic form amenable to transport by FPN1 (De Domenico et al. 2006). In addition, ferritin contributes to the pool of redox-active iron every time it turns over (Mehlhase et al. 2005). H-ferritin, the subunit responsible for Fe^{2+} oxidation, is relatively poorly expressed in melanized dopaminergic neurons of the SN pars compacta, as compared to neurons in other parts of the brain, but is strongly expressed in oligodendrocytes (Snyder and Connor 2009).

2.2.5 The Ferrireductases and Ferroxidases

Fe^{2+} is the preferred species for transport, so ferrireductases must reduce Fe^{3+} prior to its transport into the cell. In contrast, Fe^{2+} transported from inside the cell to the extracellular milieu must be oxidized by ferroxidases to Fe^{3+} prior to transferrin binding. Three membrane ferroxidases have been described: Dcytb, its homologous cytochrome b561, and SDR2 (Vargas et al. 2003). Dcytb, initially described as the ferroxidase responsible for reduction of nonheme iron in the duodenal lumen (McKie et al. 2001), is the only member of the iron transport machinery that lacks an IRE in its mRNA. Recently, the upregulation of Dcytb by Hif-2α was reported (Latunde-Dada et al. 2011). As mentioned before, DMT1 and FPN1 exhibit transcriptional regulation by Hif-1. Thus, the control of iron acquisition through the upregulation of Dcytb and DMT1 by Hif-1, coupled to the downregulation of FPN1 by Hif-2α, results in a concerted response of increased iron accumulation under hypoxic conditions. The presence of Dcytb and SDR2 was recently reported in astrocytes, where they may have a limited role in iron accumulation by these cells (Tulpule et al. 2010), but there is no report on their presence in neurons. Maybe the high concentration of ascorbate in the CSF, which should keep NTBI in the 2+ state, makes unnecessary a membrane-bound iron reduction system in brain cells.

The Steap family of ferrireductases comprises the members Steap1, Steap2, Steap3, and Steap4 (Ohgami et al. 2006). Steap3 was described in endosomes of erythroid precursor cells, catalyzing the reduction of Fe^{3+} to Fe^{2+} prior to transport by DMT1 (Ohgami et al. 2005). In situ hybridization studies show that Steap2 is expressed in the brain (Ohgami et al. 2006). Whether Steap2 or other member of the Steap family has a role in iron uptake by neurons remains speculative.

Two multi-copper ferroxidases, ceruloplasmin (CP) and hephaestin (Heph), are involved in iron export from the cell. CP seems to be required for iron release from most tissues in the body. Although the liver is the predominant source of serum ceruloplasmin, ceruloplasmin gene expression has also been demonstrated in many tissues including spleen, lung, testis, and brain (Hellman and Gitlin 2002). The scope of action of the membrane-bound CP homolog Heph is restricted to the small intestine, where it is required for efficient iron absorption (Vulpe et al. 1999).

2.2.6 Neuromelanin

Neuromelanin is a polymer formed by oxidized metabolites of dopamine, containing a peptide component of about 15 % (Zecca et al. 2002). Neuromelanin

avidly binds iron in its +3 form, presenting high- and low-affinity binding sites (Double et al. 2003). Given the low expression of ferritin, neuromelanin is the main iron-storage moiety in SN pars compacta neurons. It is believed that the high-affinity sites are protective as they sequester iron in a redox-inactive form, whereas iron in the low-affinity sites is redox active (Gerlach et al. 2008). Thus, when iron concentration increases above the high-affinity binding capacity of neuromelanin, the neurons become prone to oxidative damage.

3 Iron Accumulation and Glutathione Depletion in PD

Iron is an intrinsic ROS producer. When one or more of its six ligand binding sites are not tightly bound, iron engages in one-electron exchange reactions, producing free radicals (Graf et al. 1984) through the Haber-Weiss and Fenton reactions. The thermodynamic balance of these reactions indicates that in the reductive environment of the cell, iron, in the presence of oxygen, catalyzes the consumption of GSH and the production of the hydroxyl radical ($^{\bullet}OH$) (Núñez et al. 2012).

In dopaminergic cells, another source of free radicals derives from the nonenzymatic oxidation of dopamine mediated by redox-active iron, resulting in semiquinones and H_2O_2 production (Zoccarato et al. 2005). Thus, redox-active iron, both through the Fenton reaction or via dopamine oxidation, is a dangerous prooxidant agent.

3.1 Iron Accumulation in PD

Overwhelming evidence indicates that iron accumulation is a common feature of a number of neurodegenerative disorders of the central nervous system that include Huntington's disease, Alzheimer's disease, Friedreich's ataxia, amyotrophic lateral sclerosis, and Parkinson's disease (Jellinger 1999; Bartzokis et al. 2000; Sayre et al. 2000; Perry et al. 2003; Zecca et al. 2004; Berg and Youdim 2006; Wilson 2006; Weinreb et al. 2011). Indeed, the autocatalytic production of hydroxyl radicals because of iron accumulation has been proposed as the unifying mechanism of cell death in neurodegenerative diseases (Kell 2010).

Iron accumulation has been demonstrated in the dopaminergic neurons of the SN pars compacta (Youdim et al. 1989; Hirsch et al. 1991; Gorell et al. 1995; Vymazal et al. 1999). Interestingly, MPTP, a drug that causes experimental Parkinson's disease, upregulates DMT1(+IRE) protein expression in mice ventral mesencephalon, where it increases neuronal death presumably through abnormal increases in cellular iron content (Salazar et al. 2008; Jiang et al. 2010). Additionally, DMT1(−IRE) mediates L-DOPA neurotoxicity in primary cortical neurons (Du et al. 2009).

The contribution of iron dyshomeostasis to the progression of events leading to neuronal death is likely, since iron accumulation has been detected in brain tissue from patients who have died, after the final steps of the pathology. Since neuronal

death caused by MPTP or 6-hydroxydopamine intoxication is blocked by pharmacologic or genetic chelation of iron (Kaur et al. 2003; Shachar et al. 2004; Youdim et al. 2004; Youdim and Buccafusco 2005; Zheng et al. 2010) or by dysfunction of the iron transporter DMT1 (Salazar et al. 2008), it is possible that iron dyshomeostasis takes place in the late stages of the disease as part of a vicious cycle resulting in uncontrolled oxidative damage and cell death. A recent study in mesencephalic dopaminergic neurons shows that low (0.25–0.5 μM) concentrations of 1-methyl-4-phenylpyridinium (MPP+), the active metabolite of MPTP, induce neuritic tree collapse without loss of cell viability (Gómez et al. 2010). This collapse was effectively prevented by decreasing iron supply or by the addition of antioxidants. Thus, it seems plausible that increased intracellular iron and ROS are involved in the early steps of dopaminergic neuron dysfunction, prior to cell death. Later, a vicious cycle of further iron accumulation, complex I dysfunction, and ROS increase may result in uncontrolled oxidative damage and cell death.

Iron toxicity is not restricted to dopaminergic neurons. Neurotoxic concentrations of NMDA induce the NO-Dexras1-PAP7 signaling cascade in glutamatergic PC12 cells. Upon activation, PAP7 binds to intracellular DMT1 and relocates it to the plasma membrane, increasing intracellular iron and the production of hydroxyl radicals. Thus, the DMT1-iron-uptake-hydroxyl radical signaling pathway appears to mediate NMDA neurotoxicity (Cheah et al. 2006).

3.2 Glutathione (GSH) Metabolism in PD

The tripeptide GSH (γ-L-glutamyl-L-cysteinylglycine) is the most abundant and the main antioxidant agent in the central nervous system, where it reaches mM concentrations in the cytoplasm (Meister and Anderson 1983; Dringen et al. 2000). In its redox cycling, glutathione is present either in its reduced (GSH) form or its oxidized disulfide (GSSG) form, the ratio GSH:GSSG being faithful reflection of the redox state of the cell (Schafer and Buettner 2001).

Early postmortem studies revealed decreased levels of GSH in degenerating SN of PD patients (Perry et al. 1982; Sofic et al. 1988; Sian et al. 1994), the observation implicating that GSH depletion may play a major role in the neurodegenerative process. The question arises whether GSH depletion is an early event during the progression of the disease or a reflection of increased oxidative stress resulting, for example, from mitochondrial complex I inhibition and/or iron accumulation.

Chronic submaximal inhibition of GSH synthesis in N27 dopaminergic cells results in about 50 % inhibition of mitochondrial electron transport chain complex I without ensuing cell death (Chinta and Andersen 2006). Thus, increased oxidative stress generated by complex I inhibition should result in decreased GSH levels and further inhibition of complex I. Conversely, a decrease in GSH levels, provoked by unknown causes, could result in inhibition of complex I activity.

Iron induces the consumption of GSH. After exposure to increasing concentrations of iron, SH-SY5Y dopaminergic cells undergo sustained iron accumulation and a biphasic change in intracellular GSH levels, increasing at low (1–5 μM) iron

concentrations and decreasing thereafter. Indeed, cell exposure to high iron concentrations (20–80 μM) markedly decreases the GSH:GSSG molar ratio and the GSH half-cell reduction potential, with the associated loss of cell viability (Núñez et al. 2004).

It is therefore possible that a decrease in GSH levels is a consequence of the increased oxidative load produced by the increased intracellular iron. Nevertheless, increased iron and decreased GSH may be intertwined in a positive feedback loop, since in dopaminergic neurons the pharmacological reduction of GSH levels results in increased levels of TfR and an increased labile iron pool (Kaur et al. 2009). Thus, the question remains as to which of the three processes initiates the oxidative spiral, but a reasonable assumption is that if one of them develops, the others will follow.

4 Mitochondrial Dysfunction in Parkinson's Disease

Mitochondrial dysfunction is another event involved in Parkinson pathogenesis. Evidence of mitochondrial dysfunction in PD began in the 1980s, when, after an intravenous injection of illicit drugs, four people developed a marked Parkinsonism. Further analysis of the substances injected revealed the existence of MPTP, a potent inhibitor of complex I of the mitochondrial respiratory chain (Langston et al. 1983). Since its discovery, mice and monkeys intoxicated with MPTP have been used as experimental models of PD.

MPTP crosses the blood–brain barrier and it is oxidized by astrocytes to the active metabolite MPP+. Subsequently, MPP+ is selectively taken up by dopaminergic neurons through the dopamine transporter DAT (Gainetdinov et al. 1997). Inside neurons MPP+ inhibits mitochondrial complex I (Mizuno et al. 1987). Among the effects of this inhibition are decreased levels of ATP (Scotcher et al. 1990) and increased production of free radicals and oxidative stress (Wong et al. 1999).

Decreased activity of mitochondrial complex I, found in postmortem tissue of PD patients (Schapira et al. 1990; Tretter et al. 2004; Banerjee et al. 2009; Hattingen et al. 2009), is probably a founding event in neuronal death. The association between complex I inhibition and PD is further supported by the observation that rats intoxicated with rotenone, a selective inhibitor of complex I, develop a syndrome similar to PD, characterized by neuronal degeneration and the formation of inclusion bodies rich in alpha-synuclein (Betarbet et al. 2000). Likewise, inhibition of glutaredoxin 2, an enzyme involved in mitochondrial Fe–S synthesis, produces an alteration in iron metabolism in a model of Parkinson's disease (Lee et al. 2009). Additionally, the fact that mutations in mitochondrial proteins PINK-1, a putative serine/threonine kinase involved in mitochondrial response to oxidative stress (Valente et al. 2004), and DJ-1, an antioxidant protein that relocalizes to mitochondria under conditions of oxidative stress (Blackinton et al. 2005), result in a genetic form of PD lends further support for an important role of mitochondria in PD neurodegeneration.

ROS seem to have a negative effect on complex I activity. Experiments with isolated synaptosomal mitochondria revealed that low concentrations of H_2O_2 decrease complex I activity by 10 %. This relatively minor effect of H_2O_2 was additive to partial inhibition of complex I induced by low concentrations (5 nM–1 μM) of rotenone (Chinopoulos and Adam-Vizi 2001). Similarly, submitochondrial particles exposed to $O_2^{\bullet-}$, H_2O_2, or $^{\bullet}OH$ present decreased activity of NADH dehydrogenase, a marker of complex I activity (Zhang et al. 1990). Thus, an initial inhibition of complex I could generate a positive loop between ROS generation and further complex I inhibition.

5 Fe–S Cluster Synthesis and Its Relevance to PD

5.1 Fe–S Cluster Biogenesis

Iron–sulfur (Fe–S) clusters are small inorganic cofactors formed by tetrahedral coordination of iron atoms with sulfur groups. The Fe–S clusters most commonly found in eukaryotes are 2Fe–2S and 4Fe–4S. Fe–S clusters are cofactors for proteins that are involved in many cellular processes, including electron transport, enzymatic catalysis and regulation, and DNA synthesis (Lill and Muhlenhoff 2008). The proteins that contain Fe–S clusters in eukaryotes are present in mitochondria, endoplasmic reticulum, cytoplasm, and nucleus (Lill et al. 2006; Sheftel et al. 2010).

The mitochondrion plays a central role in the generation and biology of Fe–S clusters since it holds the assembly machinery responsible for their synthesis (Lill et al. 2006). Fe–S cluster synthesis also occurs in the cytoplasm, albeit at a minor scale (Ye and Rouault 2010). In eukaryotes, the Fe–S cluster assembly machinery of mitochondria comprises the cysteine desulfurase, Nfs1, which provides sulfur and Isu1, a protein that serves as a molecular scaffold for the assembly of the Fe–S cluster. Synthesis of the transiently bound Fe–S cluster on the Isu scaffold proteins requires reduced (ferrous) iron and the input of electrons, presumably to generate sulfide (S^{2-}) from cysteine (Ye and Rouault 2010). Finally, synthesized Fe–S clusters either are transferred to mitochondrial apoproteins or are exported into the cytoplasm by the Fe–S cluster export machinery. This machinery involves the ABCB7 transporter, the antioxidant GSH, and the sulfhydryl oxidase Erv1, which is also involved in protein import (Lill et al. 2006; Sheftel et al. 2010). Iron is transported inside the mitochondria by the transporter mitoferrin (Shaw et al. 2006).

5.2 Biological Functions of Iron–Sulfur Clusters

Mitochondria contain numerous Fe–S proteins essential for its function. Complex I has eight Fe–S clusters, succinate dehydrogenase (complex II) has three Fe–S clusters, and ubiquinone cytochrome c oxidoreductase (complex III) has one 2Fe–2S cluster. Additionally, mitochondrial aconitase contains a 4Fe–4S cluster in its catalysis center (Beinert et al. 1983). Proteins involved in purine metabolism in the

cytoplasm like xanthine oxidase and phosphoribosylpyrophosphate amidotransferase (GPAT) contain two 2Fe–2S and one 4Fe–4S cluster, respectively (Unciuleac et al. 2004; Martelli et al. 2007). As mentioned above, disassembly of the 4Fe–4S cluster in IRP1 alters the active site accessibility and determines IRP1 binding to target mRNAs (Wallander et al. 2006; Cairo and Recalcati 2007). In the nucleus, proteins involved in DNA repair and replication contain Fe–S clusters (Sheftel et al. 2010). For a compendium of Fe–S clusters, see the Prosthetic Groups and Metal Ions in Protein Active Sites (PROMISE) http://metallo.scripps.edu/promise/MAIN.html.

5.3 IRP1: A Link Between Fe–S Clusters and Iron Homeostasis

Recent data indicate that inhibition of complex I by rotenone results in decreased synthesis of Fe–S clusters, as shown by the decreased activity of the Fe–S cluster-containing enzymes cytoplasmic aconitase, mitochondrial aconitase, xanthine oxidase (XO), and GPAT, as well as the activation of cytoplasmic IRP1 (Mena et al. 2011) (Fig. 3).

It is considered that decreased activity of complex I results, via decreased Fe–S cluster synthesis and the consequent activation of IRP1, in a false "low iron" signal that activates the iron-uptake system. In consequence, diminished Fe–S cluster synthesis could play a fundamental role in the accumulation of iron observed in Parkinson's disease. Future research is needed to evaluate its participation in neurodegenerative diseases in which iron accumulation is observed.

6 Aminochrome: An Inhibitor of Complex I of the Mitochondrial Electron Transport Chain

The causes for complex I dysfunction in sporadic PD are a matter of active research. Exogenous toxins can be of relevance, given the existing correlation between PD and exposure to toxins such as MPTP, rotenone, paraquat, fenazaquin, annonacin, and Guadeloupe PSP-PDC (reviewed in Schapira (2010)). Endogenous toxins could also cause mitochondrial dysfunction, as is the case for nitric oxide (Clementi et al. 1998; Broom et al. 2011), 4-hydroxynonenal (Humphries et al. 1998; Castellani et al. 2002), and advanced glycosylated end products (Munch et al. 2000; Remor et al. 2011).

An endogenous source of free radicals proper to dopaminergic neurons derives from the nonenzymatic oxidation of dopaminoquinone to dopamine o-quinone that at physiological pH spontaneously cycles to o-quinone *aminochrome* (Arriagada et al. 2004; Zoccarato et al. 2005). A one-electron gain by aminochrome results in the highly reactive leukoaminochrome o-semiquinone radical that reacts with oxygen to generate $O_2^{\bullet -}$ (Segura-Aguilar et al. 1998). Moreover, aminochrome seems to mediate the transfer of electrons from respiration-active complex I into oxygen, thus increasing the production of $O_2^{\bullet -}$ and H_2O_2 (Zoccarato et al. 2005). The increase in reactive oxygen species has direct

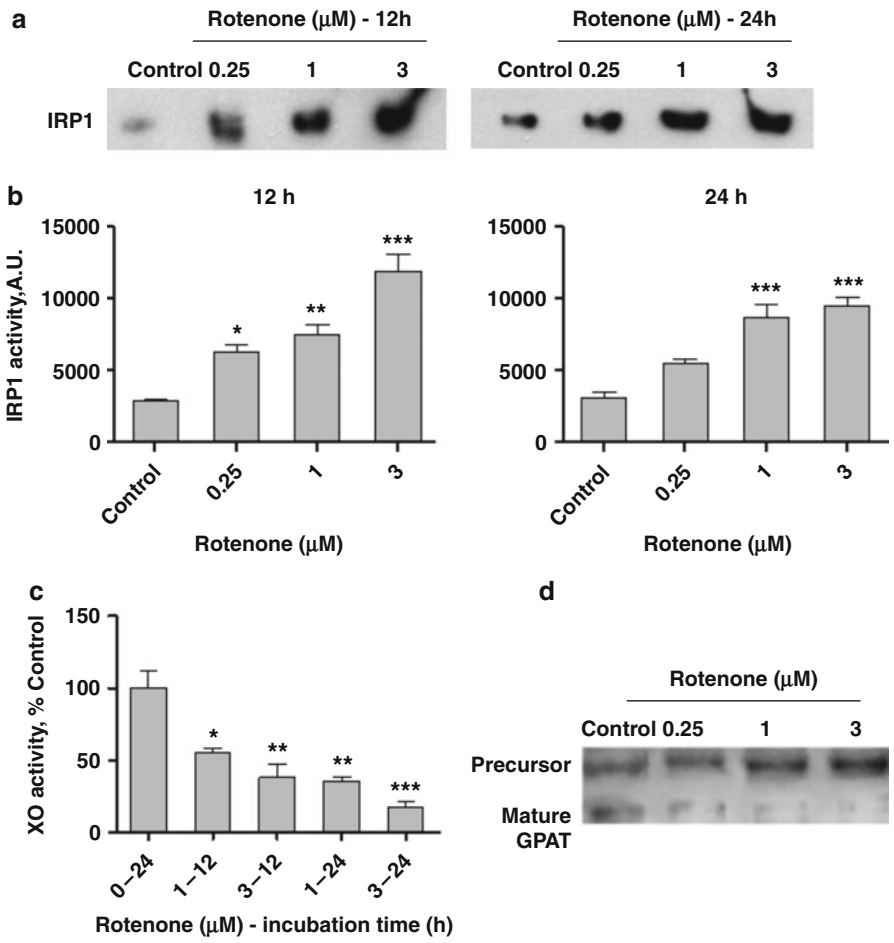

Fig. 3 Complex I inhibition affects IRP activity, XO activity, and Fe–S cluster content of GPAT. (**a**) EMSA for IRP activity. Cells were treated for 24 h with 0.25, 1, or 3 μM rotenone. Subsequently, the cytosolic extracts were probed with an IRE sequence tagged with biotin. (**b**) Densitometric quantification of data in A. Data represent mean ± SEM; n = 3. (**c**) XO activity of cells treated for 12 or 24 h with 0.25, 1, or 3 μM rotenone. Data represent mean ± SEM; n = 3. (**d**) Cells were treated for 24 h with 0.25, 1, or 3 μM rotenone. Subsequently, the holo and apo forms of GPAT were detected by Western blot. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$ compared with the control condition (Modified from Mena et al. (2011) with permission from the publisher)

consequences on the mitochondrial electron transport chain since both H_2O_2 and the $^{\bullet}OH$ inhibit complex I activity and decrease ATP production (Zhang et al. 1990; Bautista et al. 2000; Sims et al. 2000; Chinopoulos and Adam-Vizi 2001).

Recent work from our laboratory has established that aminochrome inhibits complex I and ATP production in SH-SY5Y neuroblastoma cells differentiated into a dopaminergic phenotype (Fig. 4) (Aguirre et al. 2012).

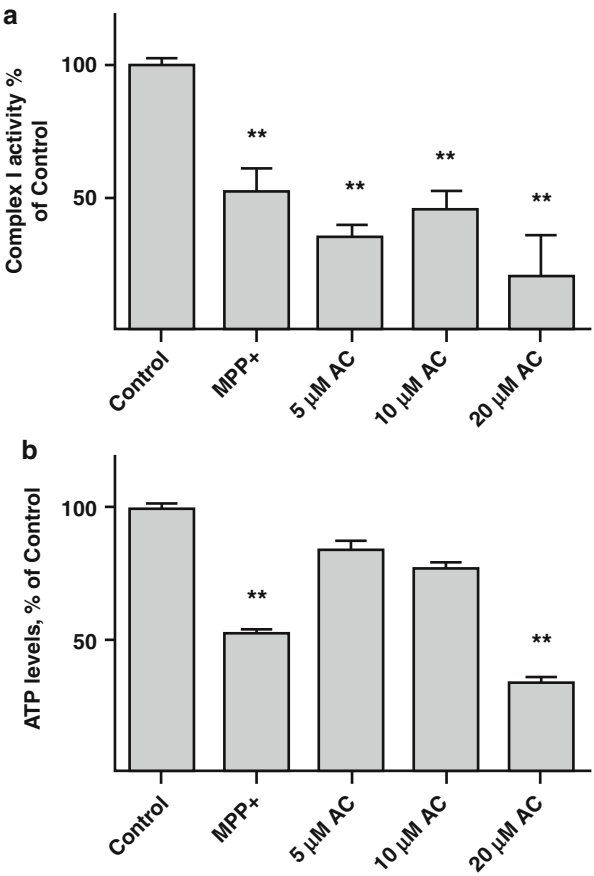

Fig. 4 Aminochrome inhibits complex I activity. SH-SY5Y cells differentiated to a dopaminergic phenotype were treated with 5–20 μM aminochrome or 100 μM MPP+ for 20 h prior to determination of complex I activity as described (Mena et al. 2011). (**a**) Complex I activity (nmoles/min/mg) normalized to the untreated (Control) condition. (**b**) Determination of ATP levels in cells treated as above. Results represent mean ± SEM of three independent experiments. ** $P < 0.01$ compared with the control condition (Modified from Aguirre et al. (2012) with permission from the publisher)

The inhibition is apparently direct on the mitochondria and not secondary to other process since it was replicated in isolated mitochondria. Additionally, overnight treatment with low micromolar concentrations of aminochrome induced increased expression of the iron import transporter DMT1 and a decrease in the export transporter FPN1. Both changes resulted in increased iron uptake. These results strongly suggest that aminochrome promotes complex I inhibition and increased iron accumulation that ends up in cell death. Therefore, aminochrome should be considered an endogenous toxin that, if uncontrolled, can induce deregulation of iron homeostasis.

7 Inflammation, Hepcidin, and PD

In addition to iron accumulation, another event strongly associated with neuronal death in PD and other neurodegenerative disorders is the presence of inflammatory processes characterized by the occurrence of reactive microglia and massive production of pro-inflammatory cytokines. Both phenomena have been studied as

independent events leading to the progression of the disease, but, as discussed above, the expression of iron homeostasis proteins such as ferritin, DMT1, and Dcytb is regulated by inflammatory cytokines. Moreover, the recent identification of hepcidin in the central nervous system reinforces the idea that in PD a chronic inflammation state and deregulation of iron homeostasis are intimately related.

7.1 Hepcidin, the Master Regulator of Iron Homeostasis

Hepcidin is a 25-amino acids cationic peptide of secreted into bloodstream by the liver. Initially, hepcidin was described as a peptide with antimicrobial activity (Krause et al. 2000); however, further studies revealed that it also acts as a major regulator of circulating iron levels (Nicolas et al. 2001; Pigeon et al. 2001). Two processes contribute to blood iron levels: the recycling of senescent red blood cells (RBC) and intestinal iron absorption. The recycling by spleen macrophages of heme iron from senescent RBC is the main contributor of iron to the circulation, providing about 95 % of daily turnover. The recycling of RBC iron comprises the phagocytosis of senescent RBC, the release of iron contained in the heme moiety of hemoglobin by heme oxygenase-1, and the subsequent iron release into the blood mediated by FPN1 (De Domenico et al. 2008; Kovtunovych et al. 2010).

The physiological function of hepcidin is to reduce the levels of circulating iron by downregulation of the iron exo-transporter FPN1 in macrophages. The binding of hepcidin to FPN1 present in the plasma membrane of splenic macrophages induces the endocytosis of the complex and the subsequent lysosomal degradation of FPN1 (Nemeth et al. 2004). The decreased levels of FPN1 lead to the accumulation of iron in macrophages and the decrease of circulating iron.

Hepcidin synthesis is regulated by multiple stimuli that have an effect in the regulation of circulating iron levels. Erythropoietin, a hormone that stimulates red blood cell production, and hypoxia downregulate the synthesis of hepcidin, increasing circulating levels of iron as required for the production of new RBCs (Peyssonnaux et al. 2007; Pinto et al. 2008). On the contrary, increased plasma iron levels and inflammatory cytokines stimulate hepcidin synthesis, which results in reduced levels of plasma iron and its accumulation in cells (Lee et al. 2005; Wrighting and Andrews 2006; Gnana-Prakasam et al. 2008; Frazier et al. 2011).

7.2 Hepcidin Expression in the CNS

Hepcidin shows a wide distribution in the CNS, most notably in the midbrain, with a clear presence in the superior colliculus, the geniculate nucleus, some fiber bundles of the SN pars reticulata, the SN pars compacta, and the striatum (Zechel et al. 2006) (Wang et al. 2010b). Hepcidin is expressed mainly in glial cells, as well as in endothelial cells of the choroid plexus (Zechel et al. 2006; Marques et al. 2009). Hepcidin expression changes with age: increased mRNA levels of hepcidin in cortex, striatum, and hippocampus have been observed with aging (Wang et al. 2010b).

As stated above, hepcidin synthesis is induced by inflammatory stimuli. Bacterial lipopolysaccharide (LPS) induces liver hepcidin expression. LPS also increases hepcidin expression in the brain. After an intraventricular injection of LPS, a transient transcription of the gene for hepcidin ensues in the choroid plexus, which correlates with increased levels of pro-hepcidin in the cerebrospinal fluid (Marques et al. 2009). The highest hepcidin expression was observed at 3 h, returning to baseline levels 24 h after the injection. Interestingly, LPS treatment induced a tenfold increase in hepcidin expression in the SN (Wang et al. 2008), which correlates with a marked increase in iron levels observed in this region in PD. Recently, it was reported that in ischemic brain there is an increase in hepcidin expression in cerebral cortex, hippocampus, and corpus striatum, in parallel with increased levels of free iron and ferritin (Ding et al. 2011). These data suggest that hepcidin could be an important contributor to iron accumulation in the brain.

7.3 FPN1–Hepcidin Interactions in the CNS

As described above, the iron transporter FPN1 is a receptor for hepcidin. An interesting fact is that the spatial distribution of FPN1 and hepcidin is similar. Although the effects of hepcidin on FPN1 levels differ according to cell type (Chaston et al. 2008), the injection of hepcidin in mice lateral cerebral ventricle causes a decrease in the levels of FPN1 in the cerebral cortex, hippocampus, and striatum (Wang et al. 2010b). These results suggest that in the brain, hepcidin generates the same response as that observed in macrophages, that is, iron retention inside the cells. This conclusion is strengthened by the fact that high doses of hepcidin produce an increase in the iron-storage protein ferritin, thus indicating increased cellular iron concentration in these brain areas. Unexpected for a high cell iron situation, treatment with hepcidin induces the decrease of both FPN1 protein and mRNA and an increase in total DMT1 in the hippocampus and cortex of rats (Li et al. 2011), a situation that should drive further iron accumulation. Hippocampal neurons in culture treated with hepcidin also show a decrease in the expression of FPN1, which is reflected in a reduction of the iron released from these cells (Wang et al. 2010b). In astrocytes, one study recently reported that treatment with hepcidin significantly reduces iron uptake (both Tf-Fe and NTBI) and iron release, accompanied by decreased expressions of TfR1, DMT1, and FPN1 (Du et al. 2011).

7.4 Hepcidin: A Nexus Between Inflammation and Iron Accumulation in PD

Many cases of PD are accompanied by general inflammation of the brain, with a dramatic proliferation of reactive amoeboid macrophages and microglia in the SN (McGeer et al. 1988). In the striatum, macrophage proliferation is accompanied by high expression of pro-inflammatory cytokines such as TNF-α, IL-1β, IFN-γ, and

IL-6 by glial cells (Mogi et al. 1994; Hirsch et al. 1998; Muller et al. 1998). The increase of many of these cytokines has also been observed in cerebrospinal fluid and the basal ganglia of patients with PD (Nagatsu 2002). The aforementioned characteristics are also observed in several animal models of PD, such as those injected with 6-hydroxydopamine, MPTP, rotenone, or LPS (Herrera et al. 2000; Barnum and Tansey 2010).

The induction of hepcidin synthesis by cytokines suggests that in PD high brain hepcidin levels may mediate iron accumulation. For example, an increase in hepcidin secretion in PD triggered by inflammatory stimuli could be responsible for the decrease of FPN1 observed in this neurodegenerative condition and the subsequent accumulation of iron in neurons and glia (Lv et al. 2011).

7.5 Hepcidin-Independent Relationships Between Iron Accumulation and the Inflammatory Response

Inflammatory cytokines modulate the activity of IRP1 and IRP2 through nitric oxide-dependent and nitric oxide-independent mechanisms, thus influencing iron homeostasis (Mulero and Brock 1999). Stimulation of macrophages with IFN-γ, TNF-α, and LPS produces an increase in IRE-binding activity of IRP1 and IRP2, reducing FPN1 and increasing DMT1 mRNA expression. Interestingly, pretreatment with the anti-inflammatory cytokine IL-10 reverts this response (Wardrop and Richardson 2000; Yang et al. 2002; Ludwiczek et al. 2003; Wang et al. 2005). In addition, DMT1 expression is transcriptionally enhanced by the transcription factor NFκB (Paradkar and Roth 2006a), whose activation is downstream of many cytokine receptors such as TNF receptor (TNFR) and IL-1 receptor (IL-1R). Activation of NFκB by inflammatory stimuli may play a significant role in iron accumulation by dopaminergic neurons of the SN, which express high levels of TNFR (Boka et al. 1994). Interestingly, an increase in the nuclear immunoreactivity of NFκB has been observed in PD brains or in animal models for this disease (Hunot et al. 1997), so it is possible that activation of NFκB contributes to iron accumulation in PD.

Finally, the iron transporter Zip14 could be important in the regulation of brain iron homeostasis. Highly expressed in the brain (Girijashanker et al. 2008) and upregulated by inflammatory mediators (Liuzzi et al. 2005; Lichten et al. 2009), Zip 14 could additionally contribute to iron accumulation in dopaminergic neurons of PD brains.

8 A Positive Feedback Loop in the Death of Neurons

It is proposed that inhibition of mitochondrial complex I by endogenous and/or exogenous toxins and inflammatory processes produced by trauma or other causes result in a vicious cycle of increased oxidative stress, increased iron accumulation, and decreased GSH content (Fig. 5).

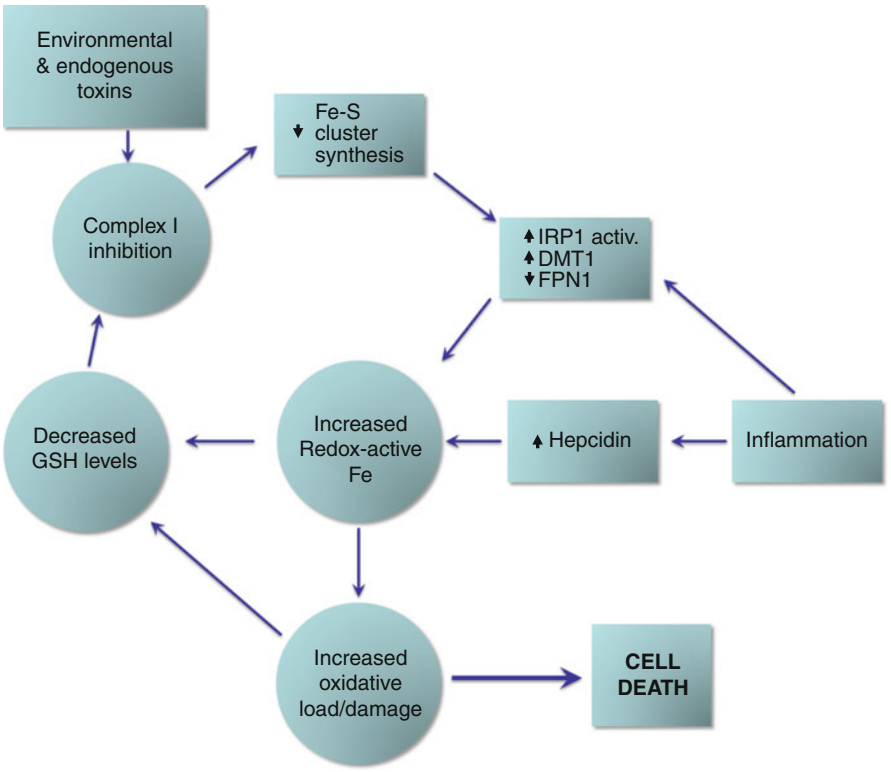

Fig. 5 A positive feedback loop resulting in uncontrolled oxidative load. Complex I inhibition by endogenous or exogenous toxins results in decreased Fe–S cluster synthesis (see text). Decreased Fe–S cluster synthesis leads to the activation of IRP1 that needs a 4Fe–4S cluster to acquire its inactive state. Increased IRP1 activity results in increased DMT1 and decreased FPN1 synthesis, which produce increased iron accumulation. Increased iron induces increased oxidative stress and increased GSH consumption. Decreased GSH produces further complex I inhibition (From Núñez et al. (2012) with permission from the publisher)

In this scheme, neuronal death linked to complex I dysfunction is brought about by a positive feedback loop in which complex I inhibition results in decreased Fe–S cluster synthesis, IRP1 activation, increased DMT1 and TfR expression, and iron accumulation. Complex I dysfunction and increased cellular iron result in decreased GSH levels. Both increased oxidative stress and low GSH levels further inhibit complex I activity. Another input to this cycle is contributed by inflammatory cytokines that induce hepcidin synthesis, which by inducing FPN1 degradation results in increased neuronal iron content. Inflammatory cytokines also transcriptionally regulate DMT1, FPN1, and Zip 14 synthesis and activate IRPs (see text). Central to this scheme is the deregulation of iron homeostasis since iron chelators effectively block cell death and prevent early events in neurodegeneration such as neuritic tree shortening (Zhu et al. 2007; Gómez et al. 2010).

9 Conclusion

Diminished activity of mitochondrial complex I, iron accumulation, oxidative stress, and inflammation are pathognomonic signs of sporadic PD. It is possible that the initiation of any one of these processes will initiate and enhance the others through the generation of a positive feedback loop that will produce apoptotic neuronal death. Intervention of this positive loop should result in prolonged life of the affected neurons. Still unanswered is the question of why SN pars compacta neurons are so particular prone to this deregulation.

Contents

Abstract

Parkinson's disease (PD) is currently regarded as the most common degenerative disorder of the aging brain after Alzheimer's dementia. Much progress has been made in identifying the genes involved in familial, or inherited, PD. However,

the majority of cases are sporadic (not inherited) and their origin(s) still remain largely undetermined. The environment is a key contributor to human health and disease. Epidemiological evidence suggests that environmental factors play a role in the etiology of neurodegenerative diseases. Particularly, paraquat (PQ) has been largely demonstrated to induce cell death in a variety of cell types and tissues associated with PD. The study of PQ-induced neurotoxicity has provided valuable insight into the mechanisms regulating neuronal cell death by environmental toxicants. However, to date, the molecular mechanisms involved in neuronal cell death by PQ have not been completely identified. This article presents a comprehensive review of the published epidemiologic and toxicologic literature and critically evaluates whether a relationship exists between PQ exposure and PD.

List of Abbreviations

ARE	Antioxidant responsive element
ASK1	Apoptosis signal-regulating kinase 1
CMA	Chaperone-mediated autophagy
DA	Dopamine
DOPAC	3,4-Dihydroxyphenylacetic acid
DβHB	D-β-hydroxybutyrate
ER	Endoplasmic reticulum
ERK	Extracellular signal-regulated kinase
GSH	Glutathione
HVA	Homovanillic acid
IRE1	Inositol-requiring enzyme 1
JNK	c-Jun NH_2-terminal kinase
LAMP-2A	Lysosomal-associated membrane protein-2A
LD	Lethal dose
MAO-B	Monoamine oxidase B
Mn^{2+}-EB-DTC	Mn^{2+}-ethylene-bis-dithiocarbamate
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
Nrf2	Nuclear factor (erythroid-derived 2)-like 2
PD	Parkinson's disease
PEG 400	Polyethylene glycol 400
PKC	Protein kinase C
PQ	Paraquat
REP1	Dinucleotide repeat sequence
ROS	Reactive oxygen species
SAPK	Stress-activated protein kinase
SOD	Superoxide dismutase
TH	Tyrosine hydroxylase
Trx	Thioredoxin
WT	Wild-type

1 Introduction

Paraquat (PQ, methyl viologen), 1,1′-dimethyl-4,4′-bipyridinium (Fig. 1), is a widely used potent herbicide. It was first synthesized in 1882 by Weidel and Russo, as recorded by Haley in his review (Haley 1979). Its redox properties were discovered by Michaelis and Hill in 1933 (Haley 1979). At first, it was used as an indicator of oxidation reduction, since, in the absence of molecular oxygen, donating an electron to PQ ($PQ2^+$) generated a monocationically stable violet or blue form, and is, thus, commonly known as methyl viologen (Dinis-Oliveira et al. 2008). But its properties as a herbicide were not discovered until 1955 and, some years later, in 1962, it was actively introduced to the global markets. PQ is registered and used in approximately 100 countries worldwide, being the second most widely used herbicide in the world after glyphosate. Despite this, today, its use is banned in the European Union (EU), unlike the import of products from outside the EU that have been treated with PQ. In its recommended rating of "pesticides by risk," the OMS (World Health Organization) considers composite PQ to be moderately toxic (Category II). The ECB (European Chemicals Bureau) classifies PQ by the route of exposure, so it is considered very toxic (R26) by inhalation, toxic (R25) orally, and moderately toxic (R24) dermally. PQ is included in the family of herbicides known as bipyridines. It is a contact herbicide, non-selective, systemic, and does not act on the leaves of green plants. Among its advantages, it is rapidly absorbed by the leaves of plants that are sprayed, exerting its effect very quickly, as the clay soil, which makes it biologically inactive.

There is controversy surrounding the use of PQ in agriculture because, even though its herbicidal properties are excellent, otherwise, it has clear toxicity to humans and the environment, especially proper precautions are not taken. In this sense, the structural similarity between PQ and the active metabolite of the neurotoxin called MPTP (MPP^+, Fig. 1), widely accepted as a model of parkinsonism, together with some correlations observed in epidemiological studies between the use of PQ and the development of Parkinson's disease (PD) (Tanner et al. 2011), led to the postulation of the existence of a relationship between the pesticide and the origin of the disease (Costello et al. 2009; Di Monte et al. 1986; Hertzman et al. 1990;

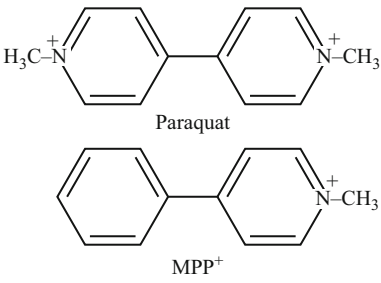

Fig. 1 Chemical structures of PQ and MPP^+

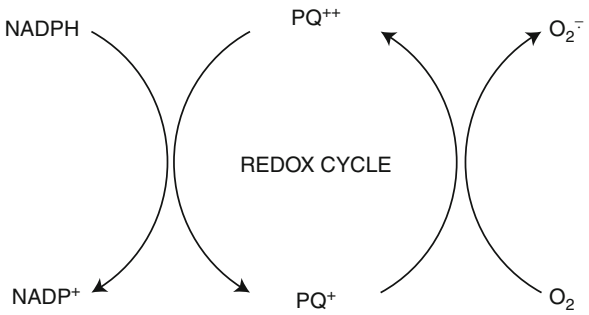

Fig. 2 Redox cycle of PQ

Liou et al. 1997). Both show neurotoxic effects based on the generation of oxidative stress, but by different routes (Richardson et al. 2005). PQ is currently considered as a valid model for studying neurotoxicity based on oxidative stress, as in the case of MPP^+, and investigations are ongoing concerning the relationship that may exist between application and exposure to this pesticide and the development of PD, which is a widely accepted fact in the case of MPP^+, leading to an accumulation of very strong and important evidence in the case of PQ, oxidative stress, and cell death. The same active ingredient that makes PQ a perfect herbicide also makes it a perfect toxic for any mammalian cell. The redox cycling of PQ (Fig. 2) on biological systems has two important implications: one is the generation of reactive oxygen species (ROS) and the other is the depletion of reducing equivalents (NADH, NADPH, etc.), which are necessary for the proper functioning thereof, affecting different cellular processes, such as the synthesis of fatty acids. Like inside plant cells, within the model's neurons, PQ needs a donor of electrons in order to be reduced. The potential standard reduction (E°) of a compound indicates the affinity of this structure to accept electrons. PQ has an E° of -0.45 V. The potential E° of the redox couples NAD^+/NADH and $NADP^+$/NADPH are -0.32 V and -0.324 V, respectively, which means that PQ, under physiological conditions and with the aid of diaphorase cells, could accept electrons from either of the reducing agents. The potential E° of MPP^+ is -1.18 V, which indicates that PQ has a greater ability to accept electrons than MPP^+ (Drechsel and Patel 2008). Among the cellular enzymes that can give electrons to PQ (PQ enzymes with diaphorase), those that can be highlighted are the following: mitochondrial complex I (NADH: ubiquinone reductase complex) (Fukushima et al. 1993), thioredoxin reductase (Gray et al. 2007), NADPH:ferredoxin oxidoreductase (Liochev et al. 1994), NADPH oxidase (Bonneh-Barkay et al. 2005), and NOS (Patel et al. 1996), as well as others. The mitochondria, therefore, becomes a major source of ROS generation within the PQ-induced mechanism, which may induce PQ-diaphorase activity at one or more points during the breathing cycle (Drechsel and Patel 2008). Once the PQ has been reduced, it can then be oxidized by a molecule of oxygen and generate a superoxide molecule ($O_2^{\bullet-}$), which occurs in cell oxidative stress and will switch to different routes that trigger cell damage in different components and

initiate the activation of different cellular mechanisms, such as apoptosis or autophagy. Apoptosis induced by PQ has been demonstrated to involve mainly the intrinsic mitochondrial pathway. The intrinsic pathway of apoptosis, also referred to as the mitochondrial pathway, is activated by a wide variety of cytotoxic stimuli or environmental stressors. Although the mechanisms by which these stimuli trigger apoptosis differ between them, they convey the release of pro-apoptotic proteins from the mitochondria, including cytochrome c. However, the exact mechanisms mediating cytochrome c release are still a matter of debate (Grimm and Brdiczka 2007; Ravagnan et al. 2002). In PD, cell death by apoptosis has been proposed to result from mitochondrial dysfunction, leading to an increase in oxidative stress and a decline in ATP production. PQ-induced cytotoxicity has been suggested to be mediated through the extrinsic pathway of apoptosis by activation of the Fas receptor (Vogt et al. 1998), but its relevance to the progression of PD remains unclear. On the other hand, in recent years, converging evidence suggests that the impairment of homeostasis mechanisms processing unwanted and misfolded proteins plays a central role in the pathogenesis of PD (Olanow 2007). Impairment of the autophagy-lysosomal pathway was related to the development of PD (Pan et al. 2008). The activation of autophagy was also identified within peripheral blood mononuclear cells from PD patients (Prigione et al. 2010). In this sense, PQ is able to also induce autophagy in dopaminergic cellular models (González-Polo et al. 2007b). Therefore, PQ is considered as one of the most useful models for studying neurotoxicity based on the generation of oxidative stress (such as PD), playing a key and fundamental role in the production of superoxide anions in the redox cycling of the herbicide, which can induce both apoptosis and autophagy processes.

2 Epidemiologic Evidence

As evidence emerges that several genes are involved in the pathogenesis of PD, the role of environmental chemicals in the etiology of this disease has become intensely debated. Many chemicals that are toxicologically or structurally similar to MPTP, an agent known to induce Parkinsonian symptoms in humans (Langston and Ballard 1983), could be a risk factor for PD. Several studies reported increased risk associated with exposure to either insecticides or herbicides (Butterfield et al. 1993; Firestone et al. 2005; Gorell et al. 2004; Semchuk et al. 1992) and organochloride, organophosphate, and carbamate insecticides (Seidler et al. 1996). The relationship between exposure duration and PD risk was investigated in several studies and showed a positive correlation with the duration of exposure to, and high doses of, herbicides and insecticides (Brown et al. 2006; Seidler et al. 1996). In these studies, PQ exposure was shown to be significantly associated with PD (Hertzman et al. 1990; Liou et al. 1997). A case–control study of environmental risk factors and PD in Taiwan reported evidence of a strong correlation between PD incidence and the level of PQ exposure (Liou et al. 1997). Another report from Dinis-Oliveira and coworkers showed that

occupational exposure to PQ was associated with parkinsonism in a study in British Columbia (Dinis-Oliveira et al. 2006).

PQ has been shown to interact synergistically with other pesticides and insecticides. It has been reported that exposure to a combination of maneb (a dithiocarbamate fungicide) and PQ increases PD risk, particularly in younger subjects and/or when exposure occurs at younger ages (Costello et al. 2009; Thiruchelvam et al. 2000). Combined exposure of rotenone and PQ has been linked experimentally to pathophysiological mechanisms implicated in human PD (Tanner et al. 2011). Another study in Central Valley, California, that combined ambient exposure to ziram and PQ as well as combined ambient exposure to maneb and PQ at both workplaces and places of residence showed substantially increased risk of PD. Those exposed to ziram, maneb, and PQ together experienced the greatest increase in PD risk (Wang et al. 2011).

Different groups of pesticides have also shown positive associations with PD. Case reports and post-mortem studies have described PD in persons exposed to organophosphate insecticides; organochlorine insecticides, including dieldrin; herbicides, including glyphosate and diquat; fungicides, including maneb and other dithiocarbamates (Corrigan et al. 1998; Firestone et al. 2005; Fleming et al. 1994; Kamel and Hoppin 2004; Wechsler et al. 1991). However, other studies have not found a significant association, although PD risk was still elevated (Firestone et al. 2005; Hertzman et al. 1990; Kamel and Hoppin 2004; Li et al. 2005a; Wirdefeldt et al. 2011). In addition, potential confounding factors include age, well-water consumption, farming, rural living, head trauma, smoking and caffeine intake, and infectious diseases such as nocardiosis, as all of these have been suggested to affect the incidence of PD (Berry et al. 2010). The Agricultural Health Study carried out a cohort investigation of over 79,500 agricultural workers from North Carolina and Iowa. The researchers considered various exposures, including acute poisoning episodes and chronic exposures, and took account of several confounding factors and the different farming practices. They found that the prevalence of neurological symptoms was associated with cumulative life-time exposure to pesticides, notably, organophosphates and organochlorines, and that this prevalence was mainly associated with chronic moderate exposure (Berry et al. 2010; Kamel et al. 2007).

3 Relation Between Environmental and Genetic Factors in Parkinson's Disease: The Paraquat and PARK Genes Connection

The etiology of PD is unknown, but it likely has a multifactorial origin, involving both genetic and environmental factors, such as exposure to PQ. The interaction of both factors is possibly responsible for the selective death of dopaminergic neurons observed in this disease. Outside of the studies that have identified human mutations as a basis for disease, the high number of individuals with sporadic PD have an unknown etiology. Although this interaction is not clear, there exist many studies with results that indicate the direct interaction of PQ with PARK genes (Table 1).

Table 1 Summary of genetic ("PARK") loci associated with a monogenetic form of PD

Gene	Locus	Protein name	Inheritance	Function
PARK 1/4	4q21.3-q22	α-synuclein	AD	LB component
PARK 2	6q25-27	Parkin	AR	E3 ubiquitin ligase
PARK 3	2p13	¿?	AD	¿?
PARK 5	4p14	UCHL-1	AD	Ubiquitin C-terminal hydrolase
PARK 6	1p35-36	PINK1	AR	Mitochondrial kinase
PARK 7	1p36	DJ-1	AR	Antioxidant protein
PARK 8	12q12	LRRK2	AD	Kinase, GTPase
PARK 9	1p36	ATP13A2	AR	ATPase, cationic transport
PARK 10	1p32	¿?	AD	¿?
PARK 11	2q36-q37	GIGYF2	AD	Receptor tyrosine kinase signaling
PARK 12	Xq21-q25	¿?	X-linked	¿?
PARK 13	2p13	HtrA2/Omi	AD	Serine protease
PARK 14	22q13.1	PLA2G6	AR	Phospholipase A2
PARK 15	22q11.2	FBXO7	AR	E3 ubiquitin ligase
PARK 16	1q32	RAB7L1	¿?	¿?
PARK 17	4p	VPS35 (2011)	¿?	¿?
PARK 18	6p	EIF4G1 (2011)	¿?	¿?

¿? - unknown

One of the most important genes related to PD is *PARK 1/4*, which codifies to α-synuclein and plays an important role in the LB formation, and could establish interactions with toxicants. In this sense, in 2001, Vladimir N. Uversky and colleagues (2001) showed how the presence of PQ produced the fibril formation of recombinant α-synuclein in vitro, being the first approach that linked pesticides with PD. Interestingly, this fact is accelerated in a dose-dependent manner and the exposure to PQ increased the α-synuclein levels in the ventral mesencephalon and frontal cortex of mice (Manning-Bog et al. 2002). Moreover, that laboratory provided evidence that the α-synuclein overexpression protects front dopaminergic cell PQ-dependent degeneration in transgenic mice, for both human WT α-synuclein and human Ala53Thr mutant α-synuclein (Manning-Bog et al. 2003). Furthermore, the PQ exposure leads to the nuclear localization of α-synuclein in mice midbrain, and it co-localizes with histone H3, and this event could be a mechanism to decrease the pool of free histones (Goers et al. 2003). Under macromolecular crowding conditions, the presence of PQ accelerates the α-synuclein fibrillation compared with only the addition of polymers, such as PEG 400 (Munishkina et al. 2004). In an in vivo study, Thiruchelvam and colleagues (Thiruchelvam et al. 2004) treated male mice over a period of 7 weeks with combined PQ and Mn^{2+}-ethylene-bis-dithiocarbamate (Mn^{2+}-EB-DTC), observing that the mice which expressed human doubly-mutated α-synuclein (A53T and A30P) presented a significant reduction in locomotor activity, dopamine (DA) levels, and TH+ neurons, as well as small decrease in

3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) levels, but the DA turnover was elevated relative to saline counterparts. In HEK293 cells, G209A mutant α-synuclein expressing cells were partially protected from the PQ oxidative stress, but less than that for WT α-synuclein cells (Orth et al. 2004). On the other hand, a report based in the nematode *C. elegans* (Ved et al. 2005) demonstrated that WT α-synuclein and A53T mutant showed no difference in terms of sensitivity to PQ compared with the nontransgenic line, and the co-treatment with PQ and probucol increased the survival levels, but not when using D-β-hydroxybutyrate (DβHB), indicating that the free radical generation contributes to PQ toxicity, and, in this model, it is independent of the complex I inhibition. In astrocytes, the expression of PEP-1–SOD fusion protein with Tat-α-synuclein increased the cell viability compared with cells pretreated with mutant proteins (A30P and A53T) after the PQ exposure, and the neuroprotective effect was synergistically higher than the expression of Tat–α-synuclein when measuring the SOD activity assay. Also, in that study, when PEP-1–SOD was cotransduced with WT Tat-α-synuclein, the number of TH^+ neurons and the Hsp70 protein levels were enhanced compared with PQ-treated cells, but not when they overexpressed A53T mutant Tat-α-synuclein (Choi et al. 2006). A study by Fernagut et al. (2007), using mice overexpressing human WT α-synuclein under the Thy-1 promoter (Thy1-αSYN), demonstrated how they had several impaired postural adjustments (such as errors per step, time to orient downward, etc.), which were unchanged after the PQ treatment. However, this herbicide induced a significant increase of the proteinase K-resistant α-synuclein inclusions in the substantia nigra of Thy1-αSYN mice, and their diameter were higher relative to the saline treatment. This fact could be due to an increased level of the protein or to the α-synuclein nitration, allowing its resistance to proteolysis (Uversky et al. 2005). Studies in human neuroblastoma SH-SY5Y cells (Chau et al. 2009) have shown that PQ produced similar cell death and free radical generation in control and WT α-synuclein cells; however, this rate is higher in cells overexpressing A53T mutant α-synuclein. Also, the caspase-3 activity was highest in the mutant cells, in line with the mitochondrial membrane potential reduction, indicating apoptosis mediated by PQ. Otherwise, the co-incubation with cabergoline (dopamine agonist) decreased this pattern of cell death, having better protection in A53T mutant cells. Another neuroprotector was used to prevent PQ toxicity (Chau et al. 2010), rasagiline (irreversible MAO-B oxidase inhibitor), demonstrating that it ameliorated the PQ cell death in SH-SY5Y cells overexpressing or not WT or A53T mutant α-synuclein, as well as decreasing the PQ-induced caspase-3 activation and free radical production. In the same way, the A53T mutant mice suffered a TH+ neuronal loss in a synergic manner with PQ, combined or not with iron, and this event is age-dependent, just as the increase of the protein oxidation levels. However, the dopaminergic neuronal death and the nitrated α-synuclein can be partly rescued using the antioxidant EUK-189 (Peng et al. 2010). A recent epidemiologic report showed an approach between α-synuclein and environmental factors, like PQ, because of the low risk of PD development in subjects who were either homozygous or heterozygous for the α-synuclein REP1 259 genotype, and subjects who were homozygous or

heterozygous for the REP1 263 genotype have a higher risk, but in PQ exposure areas, the protective effect of the shorter repeat REP1 could be lost, and the longer REP1 genotype may enhance this susceptibility and promote a higher risk in younger populations (Gatto et al. 2010). An important item could be if there is a mechanism to maintain the α-synuclein levels in the cell, and some studies (Mak et al. 2010) have shown how α-synuclein is associated with lysosomes in the midbrain of PQ-treated mice to uptake and internalize this protein for later clearance in this organelle via chaperone-mediated autophagy (CMA), because the PQ exposure increased the hsc70 and LAMP-2A levels and their interaction with α-synuclein. To establish a relationship between CMA and α-synuclein, the investigators used transgenic mice overexpressing mouse α-synuclein, observing higher levels of LAMP-2A and hsc70. A new report showed that lithium protects against neuronal cell death and prevents nitrated/oxidized α-synuclein accumulation in human A53T mutant-expressing mice chronically exposed to PQ/maneb in several brain regions (Kim et al. 2011).

Another gene involved in PD is *parkin* (*PARK2*), and several studies have demonstrated that the environmental stress also modulates the corresponding protein. In this way, a report by Pesah and colleagues showed how *parkin* mutant flies have enhanced sensitivity to PQ toxicity (Pesah et al. 2004), claiming that parkin could have a protective role. Also, PQ changes the parkin solubility and promotes the formation of intracellular parkin inclusions in SH-SY5Y cells expressing FLAG-parkin (Wang et al. 2005). In a previously cited study (Ved et al. 2005), in *C. elegans*, the *KO8E3.7*/*Parkin KO* did not show a higher sensitivity to the PQ treatment, and the same pattern was demonstrated in the co-treatment with probucol and DβHB as in the previous paragraph. In *parkin* mutant human fibroblasts, the treatment with PQ induced significant loss of mitochondrial membrane potential, slight increase in protein oxidation, and reduction of mitochondrial branching (Grünewald et al. 2010).

Following the above, *PINK1* (*PARK6*) is a gene that is strongly related to PD. In this case, in *PINK1* silenced cells, PQ generated an important reduction in cell viability and a higher rate of apoptosis cell death (Gegg et al. 2009). In primary fibroblasts cultures, the mitochondrial membrane potential was unaffected in control and mutant cells after PQ exposure, but the glutathione (GSH) levels were increased in missense culture to a greater extent (Grünewald et al. 2009). A report realized in *C. elegans* (Sämann et al. 2009) suggested a functional linkage between the *lrrk-1* and *pink-1* homologs of human *LRRK2* (*PARK8*) and *PINK1* genes, showing how the loss of *pink-1* function produced a higher sensitivity to PQ, whereas the genetic deletion of *lrrk-1* could compensate for both of these deficiencies.

Finally, DJ-1 (CAP1/RS/PARK7) is a protein related to early-onset PD, for which patients respond to treatment with dopamine (Bonifati et al. 2003). Although the function of DJ-1 is unclear, several studies suggest their possible involvement in the cellular response against oxidative stress, because DJ-1 has the capacity to eliminate ROS by auto-oxidation (Bonifati et al. 2003; Kinumi et al. 2004; Taira et al. 2004). It has been observed that, if DJ-1 shows mutations in C106, it is unable

to protect the cell under conditions of oxidative stress caused by MPP^+ (an inhibitor of mitochondrial complex I) (Canet-Avilés et al. 2004). These findings suggest that mutations in the DJ-1 protein can cause mitochondrial susceptibility against toxins such as MPP^+. There are many cellular and animal models available to investigate the combined effect of genetic and environmental factors involved in PD and to study the interaction between DJ-1 and the herbicide PQ. The idea that DJ-1 stimulates the autophagy response against PQ and reduces apoptotic cell death response could open the door to the development of new treatment strategies against PD (González-Polo et al. 2010).

4 Cellular Models in Paraquat Neurotoxicity

In PD, cell death by apoptosis has been proposed to result from mitochondrial dysfunction, leading to an increase in oxidative stress and a decline in ATP production. Some studies have shown that PQ induces cytochrome c release (Fei et al. 2008; González-Polo et al. 2004) and caspase-9 activation, which are preceded by the induction/activation of pro-apoptotic Bax and Bak (Fei et al. 2008; Yang and Tiffany-Castiglioni 2008). The evaluation of Bcl-2 family members showed that PQ induces high levels of Bak, Bid, BNip3, and Noxa (Fei et al. 2008). Interestingly, there are many works which demonstrate that, individually, PQ and maneb (and other pesticides related to PD) activate Bak, but, together, they trigger Bax-dependent cell death. Focusing on mechanisms responsible for this synergy, the study showed that maneb + PQ increases the expression of three strong Bak inhibitors, Bfl-1, Bcl-xL and Mcl-1, and, also, induces Bax activators that included Bik and Bim (Fei and Ethell 2008). The induction of pro-apoptotic Bax and apoptosis in response to PQ has also been reported to be dependent on p53 (Rossi et al. 2001; Yang and Tiffany-Castiglioni 2008). PQ neurotoxicity has also been reported to require the activation of stress-activated protein kinases (SAPKs) (Chun et al. 2001; Klintworth et al. 2007; Niso-Santano et al. 2006, 2010; Ramachandiran et al. 2007; Yang et al. 2009).

Although the mitochondrial pathway of apoptosis has been largely linked to PQ-induced cell death, other signaling pathways have also been implicated in PQ toxicity. Recently, PQ has been shown to induce DNA damage and endoplasmic reticulum (ER) stress. ER stress is associated with the activation of inositol-requiring enzyme 1 (IRE1), apoptosis signal-regulating kinase 1 (ASK1), and c-Jun NH_2-terminal kinase (JNK) (Niso-Santano et al. 2010; Yang et al. 2009). In this sense, PQ-induced oxidation of Trx has been reported as a possible mechanism for the activation of the ASK1/JNK signaling pathways (Niso-Santano et al. 2010; Ramachandiran et al. 2007; Yang et al. 2009). NF-E2-related factor-2 (Nrf2)-dependent regulation of antioxidant responsive element (ARE)-mediated gene expression has been shown to protect against PQ (Minelli et al. 2009). Accordingly, Nrf2-dependent regulation of Trx levels determines the sensitivity of PQ toxicity by the activation of ASK1/JNKp38 signaling (Niso-Santano et al. 2010). PQ-induced tyrosine nitration and lipid peroxidation have been

demonstrated (Schmuck et al. 2002). However, the molecular targets for these signaling events remain to be elucidated. It was recently demonstrated that oxidative stress induced by PQ generates protein aggregation of the plasma membrane Ca^{2+} -ATPase and its degradation by calpain (Zaidi et al. 2009).

Recent studies have demonstrated that low concentrations of PQ induce autophagy, which is followed by apoptosis (González-Polo et al. 2007a, b, 2009) and modulated by DJ-1. Because the inhibition of autophagy potentiated apoptosis induced by PQ, it was proposed that autophagy might be acting as a protective mechanism against cell death progression.

The fact that PQ induces the accumulation of autophagic vacuoles and increases the degradation of proteins in the cytoplasm of SH-SY5Y cells (González-Polo et al. 2007a) indicates that the increased oxidative stress can activate autophagy in the initial stages of mitochondrial dysfunction, having a protective role of PQ-induced cell death (González-Polo et al. 2007a, b). Moreover, it has been shown that PQ exposure induces an early ER (endoplasmic reticulum) stress response that is correlated with this adaptive activation of autophagy, with hallmarks such as the accumulation of autophagic vacuoles, activation of beclin-1, accumulation of LC3-II, p62 degradation, and mTOR dephosphorylation (González-Polo et al. 2007a, b; Niso-Santano et al. 2011). This response is accelerated in cells that overexpress WT of the ASK1 protein. The inhibition of autophagy caused, in this model, an exacerbation of the apoptosis induced by WT ASK1 overexpression with or without PQ. These results suggest that autophagy has an important role in the cell death/survival events produced by PQ and ASK1 that contribute to neuronal degeneration.

Therefore, increased autophagy might be a new strategy for the treatment of neurodegenerative diseases (Menzies et al. 2006). However, it is encouraging to consider enhancing autophagic capacity as a therapeutic strategy in the prevention of neurodegeneration because, as mentioned above, there is evidence showing that the abnormal regulation of autophagic pathways may lead to apoptosis and cell death (Walls et al. 2010).

Most of the studies regarding the molecular mechanisms of PQ-induced apoptosis and autophagy have been directed towards neuronal cell types (Table 2). However, it is obvious that the complexity of brain tissue organization is given by the interaction of different neurons with glial cell types. Compared to neurons, astrocytes have been demonstrated to be more resistant to PQ-induced oxidative stress by the responsive induction of a variety of antioxidant systems, including catalase and SODs (Olesen et al. 2008; Röhrdanz et al. 2001; Schmuck et al. 2002). Recent studies have demonstrated that microglial cells react to pro-oxidant conditions, suggesting that they can contribute to environmental stress-induced neurotoxicity (Vogt et al. 1998). PQ induces microglial activation, which seems to precede PD neurodegeneration (Purisai et al. 2007). Low PQ concentrations have recently been demonstrated to be toxic to neurons only in the presence of microglial cells. In this study, it was observed that, in neuron–microglia cultures exposed to PQ, microglia was a source of PQ-derived oxidative stress (Wu et al. 2005). Interestingly, NADPH oxidase from glial cells has been proposed to mediate the

generation of ROS (Kim et al. 2008; Purisai et al. 2007; Schmuck et al. 2002), which seems to be regulated by the activation of protein kinase C (PKC) and extracellular signal-regulated kinase (ERK) signaling pathways (Kim et al. 2008; Miller et al. 2007).

5 Animal Models in Paraquat Neurotoxicity

Animal models are an important tool for studying different human diseases, including PD. Animals do not develop PD spontaneously, but it is possible mimic the symptoms of this disease, either by surgery or the use of chemicals to damage the tissues of the body in a way that reflects the changing disease. Animal models allow scientists prove what is causing parkinsonism symptoms and to test different treatments that cannot be tested in people. Therefore, despite these models never being able to fully mimic the human model, they are vital in order to understand the molecular and biochemical features of PD (Orth and Tabrizi 2003).

Using drugs to alter the animals is the main method used in research on Parkinson's disease. MPTP, rotenone, or PQ are used to cause parkinsonian symptoms in different animal models. The animal models commonly used for PD investigations are monkey, rat, or mice, but animals like rabbits, fruit flies, dogs, nematodes, zebrafish, pigs, or guinea pigs are also used, although to a lesser extent.

These models have highlighted the possibility that environmental chemicals used in everyday situations may be responsible for contributing to the development of PD. Behavioral effects and loss of neurones in the substantia nigra were observed and the depletion of dopamine was reported in many, but not all, of these studies.

The following is a review of the different animal models used for the studies of parkinsonian symptoms associated with exposure to PQ.

5.1 Rat Animal Model

The use of a rat animal model to study parkinsonian symptoms is very common. Exposure to PQ in rats induces much damage at different levels in rats, and presents lung and renal toxicity and toxicity to the liver. At higher doses, observations include decreased body weight gain, clinical signs like dyspnea, increased respiratory sounds, swellings and sores in the genital area, hematological changes, and effects on organ weight, as well as increased mortality.

In addition, a large number of studies have been performed in rat brains to observe animal behavior after being treated with PQ. It has been shown that there are changes in behavior as well as neuropathological effects in rats which received both systemic and intrahippocampal injections of PQ dichloride (Corasaniti et al. 1992). After treatment with PQ by unilateral injection into the substantia nigra, there was loss of Nissl substance, glial reaction, and loss of neurones in the substantia nigra, and, neurochemically, there was dopamine depletion (Liou et al. 1996). The neuropathological findings in another study showed that PQ possesses marked neurotoxicity, with neuropathological lesions culminating in neuronal necrosis (Calò et al. 1990). Another study showed that PQ induces oxidative stress, neuronal loss in the substantia nigra region, and parkinsonism in adult rats (Somayajulu-Niţu et al. 2009) and lipid peroxidation in rat brains (Yumino et al. 2002). This neurodegeneration is observed after exposure to PQ, which might occur via an early inflammatory response in young adult animals (Cicchetti et al. 2005).

Therefore, in rats, it has been shown that PQ induces neuronal damage and changes in the behavior of these animals. Furthermore, this damage could be caused by oxidative stress, lipid peroxidation, and inflammatory responses after stimulation with PQ.

5.2 Mouse Animal Model

Many in vivo studies in mice have shown that acute PQ administration may elicit a distinct decrease in the level of dopamine and spontaneous motor activity in mice (Kang et al. 2009; Li et al. 2005b) and there are studies that relate directly the PQ exposure in mice with a decrease in motor activity (Brooks et al. 1999). However, equivocal results have been reported by studies investigating the effect of exposure to PQ on selective nigrostriatal degeneration in rodents. There are studies which show that PQ does not induce Parkinson's disease symptoms in mice (Rojo et al. 2007), but other works show that PQ administration triggers an apoptotic cell death program through oxidative stress-mediated activation of the JNK signaling pathway, suggesting a possible mechanism for selective dopaminergic neuron loss (Peng et al. 2004). There has been a study on C57BL/6 mice exposed to PQ, maneb, or a PQ + maneb mixture, a combination that produces PD symptoms in mice (Thiruchelvam et al. 2000).

With a better understanding of the genetic alterations involved in familial PD, several transgenic mouse models have been generated that can reproduce many features of parkinsonism. Animal models generated by mutations or deletions of the relevant Parkinson's-related genes have also been used to examine the effects of PQ; for example, studies have shown that the overexpression of α-synuclein protects against PQ toxicity (Manning-Bog et al. 2002, 2003).

5.3 Monkey Animal Model

Monkey species, like *Saimiri sciureus* or *Macaca fascicularis*, are normally used in studies with PQ treatments. There have been studies carried out to characterize and compare the toxicity, clinical syndromes, and pathology of PQ, using an LD_{50} in these animals of normally 50–70 mg/kg body weight. Many decades ago, there were studies indicating that the oral administration of PQ in this species induced clinical signs of intoxication, such as anorexia, adipsia, diarrhea, hyperpnea, dyspnea, and tachycardia, which depend on the duration of exposure and the concentration of PQ (Murray and Gibson 1972; Purser and Rose 1979). However, there are few studies of monkeys concerning the neuronal damage caused by PQ exposition, although recent studies on PQ administration in monkeys have demonstrated that it produces a depletion of dopamine in the striatum of these animals (O'Leary et al. 2008).

5.4 Fruit Fly Animal Model

Drosophila melanogaster is a popular study species in science. This particular species has become an invaluable tool to scientists, who have been studying this insect for over a century. The fruit fly *D. melanogaster* has a similar number of genes to humans and, therefore, it is often used in genetic changes in order to observe the effects on the progression of disease. A large number of human genes, including those implicated in PD such as parkin, UCH-L1, PINK1, DJ-1, and LRRK2, have highly conserved homologs in *D. melanogaster* (Whitworth et al. 2006).

The exists many models of fruit flies to study genetic changes, which has shown dysfunction of DA neurons, locomotor deficits, and retinal degeneration after treatment with PQ. The α-synuclein (Takahashi et al. 2003) or parkin models in flies show that PQ induces DA neuron loss, mitochondrial pathology, locomotor deficits, LB-like protein aggregates, and sensitivity to oxidative stress (Greene et al. 2005). Another study in flies indicates that DJ-1 plays a critical role in the survival of dopaminergic neurons and response to oxidative stress in PQ treatment (Menzies et al. 2005). In *D. melanogaster*, there are also studies that show damage at the level of oxidative stress which occurs with PQ exposure, along with neuronal damage that this entails (Rzezniczak et al. 2011).

5.5 Nematode Animal Model

Caenorhabditis elegans is a nematode animal model used commonly in scientific studies. *C. elegans* models have a well-characterized genome and the adult wild-type worm comprises 1,000 cells, about a third of which are neurons, exactly eight of which are dopaminergic neurons. It also has all the dopamine transmission mechanisms of a human model (Nass et al. 2001). These dopamine neurons of *C. elegans* are sensitive to neurotoxins and pesticides like 6-OHDA (Nass et al. 2002), MPP^+ (Braungart et al. 2004), and rotenone or PQ (Ved et al. 2005). This has led to a search for genetic patterns among nematodes of resistance to the toxicity of PQ in genes that seem to be involved in the function of chemosensory cilia (Fujii et al. 2004, 2005) or with antioxidant genes (Yanase et al. 2002).

5.6 Zebrafish Animal Model

The *Danio rerio* species is a 3–4-cm-long zebrafish used to study development and gene function as a potential model of PD. In zebrafish, dopaminergic neurons are anatomically comparable with the nigrostriatal tract in mammals. These neurons are sensitive to some of the classical PD model toxins, namely, 6-OHDA and MPTP, showing reduced brain levels of dopamine after treatment (Anichtchik et al. 2004).

A study among zebrafish with PQ showed that, in adult zebrafish, there was no induced effect after a long period of exposure to pesticide PQ, and in larval zebrafish, only a trend of reduction in diencephalic DA neurons was shown, which did not reach statistical significance (Bretaud et al. 2004).

5.7 Dog Animal Model

In many studies with dogs, principally the Beagle dog breed, the animals received PQ as a dietary supplement and the results indicate that levels of pulmonary capillary and pulmonary vascular resistance were increased, mean arterial pressure and cardiac output were decreased, while the total vascular resistance and pulmonary vascular resistance were increased (Sone et al. 1989). Another study showed the appearance of dyspnea, and, often, emaciation or inappetence, with some body weight loss. However, there are no conclusive studies on the neurological damage produced in dogs after exposure to PQ.

5.8 Rabbit Animal Model

Rabbits are another animal model used to probe the toxicity of PQ. After PQ exposition, damage by pneumonitis has been detected in the animals (Seidenfeld et al. 1985), as well as damage to the eyes, liver, kidneys, heart, and lungs (Hassan et al. 1989), but there exists no studies demonstrating damage at the neurological level.

5.9 Pig Animal Model

Pigs have been used on rare occasions for PQ toxicity studies, showing that high concentrations of and prolonged exposure to PQ may have deleterious effects on epidermal morphology in the absence of significant percutaneous absorption (Srikrishna et al. 1992), but there has been no study neuronal damage in these animal models.

6 Conclusion

Toxicologic studies have suggested that multiple genetic and environmental factors could be involved in the etiology of PD. Studies with transgenic mice suggest that the genetic background may also lead to increased vulnerability to the neurotoxic effects of pesticides such as PQ. The weight of evidence is sufficient to conclude that a generic association between PQ exposure and PD exists, but it is not sufficient to conclude that this is a causal relationship. In addition, the multifactorial etiology of PD hampers unequivocally establishment of the role of any individual contributory causal factor. Further research is needed in order to identify long-term biomarkers of exposure, improve methods for estimating pesticide exposure, and

undertake prospective cohort studies of PQ-exposed people. It is also necessary to increase the volume of studies on the molecular basis of PQ toxicity in order to establish a clear relationship between its neurotoxic effects and in vivo neuronal loss that leads to PD.

Abstract

Over the past years there has been considerable progress in our understanding of manganese (Mn)-induced neurotoxicity and its mechanisms. These studies led to changes in Mn safety assessment around the world. However, manganism continues to represent a health concern, especially considering the recent findings linking manganism to Parkinson's disease (PD). Animal models have been invaluable in these investigations. Findings from these studies are discussed in this chapter within the context of Mn-induced neurotoxicity mechanisms and its role in the etiology of parkinsonism.

Keywords

Dopamine • Manganese • Neurotoxicity • Parkinson's disease

1 Introduction

Over the past several decades, there has been considerable progress in our basic knowledge regarding the mechanisms and factors regulating Mn neurotoxicity. The disorder known as manganism is associated with the preferential accumulation of Mn in the globus pallidus of the basal ganglia, which is generally considered to be the major and initial site of injury. Because the area of the central nervous system (CNS) comprising the basal ganglia is complex and dependent on the precise functioning and balance between several neurotransmitters, it is not surprising that symptoms of manganism overlap with those of Parkinson's disease. The fact that neurological symptoms and onset of Mn toxicity are quite broad and can vary unpredictably probably reflects specific genetic variance of the physiological and biochemical makeup within the basal ganglia; however, there is evidence suggesting that persistent exposure can predispose individuals to acquire dystonic movements associated with Idiopathic Parkinson's disease (IPD). This chapter provides a review on Mn-induced neurotoxicity with specific focus on data using various animal models that provided some key findings in an attempt to unravel mechanisms that lead to these syndromes and what they have in common.

2 Manganese Essentiality

Mn is an essential nutrient necessary for a variety of metabolic functions including those involved in normal human development, activation of certain metalloenzymes, energy metabolism, immunological system function, nervous system function, reproductive hormone function, and in antioxidant enzymes that protects cells from damage due to free radicals (ATSDR 2000). In the brain, Mn is an important cofactor for a variety of enzymes, including those involved in neurotransmitter synthesis and metabolism (Erikson and Aschner 2003). The most important source of Mn is the diet, although there is no consensus regarding safe and adequate levels of this nutrient for various age groups.

Mn deficiencies, although not frequently reported, can result in several biochemical and structural defects in experimental animals (Keen et al. 1999). Thus, taking into account the variety of enzymatic processes which are dependent upon Mn, an inadequate daily supply of the metal may cause a variety of health repercussions, ranging from generalized growth impairment, birth defects, reduced fertility, and impaired bone formation to altered metabolism of lipids, proteins, and carbohydrates (Freeland-Graves and Lin 1991; Keen et al. 1999). Mn is a required cofactor for several enzymes; however, it can be replaced by iron, magnesium, or copper. Notably, the majority of Mn-dependent enzymes known are found in bacteria and plants. The well known Mn-dependent mammalian enzymes include arginase, glutamine synthetase, phosphoenolpyruvate decarboxylase, and manganese superoxide dismutase (MnSOD).

3 Manganese Toxicity

3.1 Sources of Manganese Exposure

There are many sources of Mn exposure which have been of interest in causing neurotoxicity. Table 1 summarizes the most important sources of Mn intoxication.

3.2 Main Routes of Manganese Exposure

3.2.1 Pulmonary Tract

Mn is readily absorbed by the pulmonary tract as it lacks the homeostatic control systems that are present in the GI tract. The bioavailability of the inspired Mn depends on several factors, such as the size, mass, and density of the particle, the site of Mn deposition, the composition of Mn within the particulate matter, and how efficiently the metal is solubilized by macrophages within the lung (Roth 2006). It is believed that, at least in part, three characteristics contribute to Mn's absorption via the pulmonary tract: (1) transport into the olfactory or trigeminal presynaptic nerve endings located in the nasal mucosa, (2) transport across the pulmonary epithelial lining fluid, and/or (3) mucociliary elevator for the lung clearance (Roth 2006).

3.2.2 Gastrointestinal (GI) Tract

Oral intake of Mn is the major physiological route of absorption, occurring mainly through the consumption of water, fruits, and vegetables (Khan et al. 2008). The mechanism by which Mn is absorbed by this route is not completely understood; however, it is believed that both passive and active transport are involved (Garcia-Aranda et al. 1983). In general, the concentration of Mn in the diet influences the amount absorbed through GI tract as well as the amount which is eliminated in the bile. When dietary Mn levels are high, adaptive changes include

Table 1 Sources containing Mn that may lead to intoxication

Source	Examples	Nontoxic doses	Reference
Water		<150 μg/L	Ljung and Vahter 2007; Wasserman et al. 2006
Diet	Teas, vegetables, dietary supplements	0.9–10 mg/day	Finley and Davis 1999; ATSDR 2000
Airborne	Welding fumes, MMT[a], steel foundries, ferromanganese production	<2 μg/day	Lynam et al. 1999; Roth 2009; Zayed et al. 1999
Milk and infant formulas		<105 mg/day	Stastny et al. 1984
Parenteral exposure	TPN[b], radiological contrast	100 μg/L	Bertinet et al. 2000; Ono et al. 1995
Pesticides	Maneb, Mancozeb		Aschner 2000
Drugs	Methcathinone		Sikk et al. 2011

[a]Methylcyclopentadienyl manganese tricarbonyl
[b]Total parenteral nutrition

reduced GI absorption, enhanced Mn liver metabolism, and increased biliary and pancreatic excretion of the metal (Dorman et al. 2001, 2006). Additionally, several factors can influence Mn absorption and retention. For example, dietary intake is influenced by the presence of other trace minerals, phytate, ascorbic acid, and other dietary constituents (Aschner and Gannon 1994; Davidsson et al. 1989).

3.3 Manganese Pharmacokinetics

3.3.1 Absorption

The major source of Mn in humans is via dietary ingestion (Au et al. 2009). Approximately 3–5 % of ingested Mn is absorbed through the intestinal wall, and the rest is excreted in feces, representing a precise homeostatic control over Mn absorption. Its uptake is tightly regulated and any excess of ingested Mn is readily excreted via the bile. In contrast, both pulmonary uptake and particulate transport via the olfactory bulb (Verity 1999; Zayed et al. 1999) can lead to Mn deposition in the striatum and cerebellum and inflammation of the nasal epithelium (Roth 2009).

Iron (Fe) has a strong influence on Mn homeostasis as both metals share physiological transporter [transferrin (Tf)], binding and uptake via the Tf transporter and the divalent metal transporter, DMT1/NRAMP2. In rodent models, Fe deficiency is associated with increased Mn absorption across the gastrointestinal tract, as well increased Mn deposition in the brain (Fitsanakis et al. 2008; Freeland-Graves and Lin 1991; Garcia et al. 2007).

3.3.2 Transport

The identity of the carrier(s) involved in Mn transport into the brain is still controversial. It is believed that at normal plasma concentrations,

Mn enters into the CNS primarily across the capillary endothelium, whereas at high plasma concentrations, transport across the choroid plexus predominates (Murphy et al. 1991). How and in what chemical form Mn is transported across the blood–brain barrier (BBB) has been addressed in series of studies. Mn is absorbed in the GI tract as Mn^{2+}, is oxidized to Mn^{3+} by liver and plasma ceruloplasmin, and transported by transferrin (Tf) (Aschner and Gannon 1994; Takeda et al. 1995). Tf-dependent Mn transport across the BBB has been documented (Aschner and Gannon 1994), but the majority of BBB Mn transport occurs via the DMT1.

A critical regulator of brain Mn levels is the divalent metal transporter, DMT-1/NRAMP-2. DMT-1 (also referred to as the DCT or divalent cation transporter) is known to shuttle both Mn and Fe ions in the (+2) valence, as well as other divalent metals. Mutations in *DMT-1* in the rat or mouse result in significantly lower brain levels and uptake of both Mn and Fe (Chua and Morgan 1997; Fleming et al. 1998). Notably, a recent study (Salazar et al. 2008) has shown that DMT-1 contributes to neurodegeneration in an experimental model of PD.

Additional brain Mn transporters include the Mn-citrate transporters (MCT) and the Mn-bicarbonate symporters (Crossgrove et al. 2003). However, the relevance of these genes to Mn transport in vivo is not completely understood. The Mn-bicarbonate symporters, ZIP-8 and ZIP-14, have been identified as members of the solute carrier-39 and are expressed on brain capillaries (He et al. 2006). These symporters utilize a HCO_3^- gradient as the driving force for Mn uptake across the plasma membrane.

Other possible mechanisms for Mn transport include dopamine transporters (DAT). It is believed that DAT facilitates Mn transport into dopaminergic striatal neurons and that Mn accumulates in the globus pallidus via axonal transport (Anderson et al. 2007). As a result, blockage of the DAT in the striatum attenuates Mn accumulation in striatal neurons and decreases Mn concentrations in the globus pallidus (Anderson et al. 2007). Finally, Mn transport via voltage-regulated channels (Lucaciu et al. 1997), store-operated channels (Riccio et al. 2002), ionotropic glutamate receptor channels (Kannurpatti et al. 2000) (all Ca^{2+} channels), and choline transporters (Lockman et al. 2001) has also been described.

3.3.3 Distribution

Under basal conditions, brain Mn concentrations are heterogeneous, with the highest values reported in the palladium and putamen in humans and in the hypothalamus in rats (Bird et al. 1984; Dorman et al. 2001). The basal ganglia accumulate the highest Mn levels upon excessive exposure to this metal, although the precise physiological basis for this result remains unclear. However, the high expression of DMT1 in several nuclei of the basal ganglia likely contributes to the propensity of Mn to accumulate in this particular region of the brain (Huang et al. 2004). Similarly, high levels of Mn within the olfactory bulb have been associated with the high expression of DMT1 in this region in rats (Fitsanakis et al. 2008). However, further characterization of the absorption and elimination kinetics, as well as Mn uptake and export pathways are necessary to better understand the basis of differential Mn accumulation

in different brain regions. It is worth noting that recent pharmacokinetic modeling of Mn accumulation in the rat required different diffusion constants between brain regions to account for the asymmetry in Mn levels across the brain (Nong et al. 2008).

It is noteworthy that no information exists on the putative extracellular transport mechanisms of Mn; thus, there is no knowledge regarding conditions that affect the removal of Mn from the brain. However, ferroportin-1 protein expression, the only known iron exporter, is induced by Mn exposure in HEK293T cells (and mouse brain), attenuating Mn accumulation and cytotoxicity and strongly suggesting that ferroportin-1 is a putative Mn exporter (Yin et al. 2010).

3.3.4 Excretion

The physiological half-life of Mn in the adult rat and primate brain is approximately 51–74 days (Cotzias et al. 1968; Newland et al. 1987; Takeda et al. 1995). The main excretion mechanism for Mn depends on normal liver function. Indeed, blood Mn concentrations are increased during the active phase of acute hepatitis as well as in post hepatic cirrhosis, and a significant correlation exists between blood Mn and the activities of liver enzymes in patients with hepatitis and cirrhosis (Spahr et al. 1996). Corroborating this hypothesis, magnetic resonance imaging (MRI) has consistently shown signal hyperintensity in the globus pallidus of at least 80 % of cirrhotic patients (Butterworth et al. 1995). Furthermore, direct measurements in pallidal samples obtained from the autopsies of cirrhotic patients revealed several-fold increases of Mn concentrations, and histopathologic evaluations showed Alzheimer's type II astrocytosis (Weissenborn et al. 1995). In fact, hepatic encephalopathy results in cognitive, psychiatric, and motor impairments, which could be related to manganism (Hazell and Butterworth 1999).

4 Manganese Neurotoxicity

It has been known for more than 150 years that Mn is a neurotoxic agent. Mn toxicity has been predominantly observed in occupational settings, following the accidental ingestion of large quantities or after chronic inhalation of high levels (Mergler et al. 1994). The brain is particularly susceptible to excess of this metal, but the mechanisms of toxicity are poorly understood. In humans, it has been postulated that there is a spectrum of neurobehavioral and neurophysiological effects associated with Mn toxicity, including both subclinical and clinical symptoms (Mergler et al. 1994).

Mn was first considered to be neurotoxic when five workers employed in grinding the black oxide of Mn developed an unsteady gait and muscular weakness (Couper 1837). Traditionally, Mn neurotoxicity has been most commonly associated with occupations such as Mn mining and smelting, battery manufacturing, and steel production (Santamaria et al. 2007). Nowadays industrial environments, occupations in battery production, welding operations, and mining represent the main sources of Mn exposure and intoxication (Huang et al. 1989; Roth 2009). Furthermore, non-occupational exposures from contaminated drinking water, milk and infant formulas, total parenteral nutrition (TPN) and air as a result of the combustion of the gasoline

additive, methylcyclopentadienyl manganese tricarbonyl (MMT), also present contemporary health concerns (Aschner and Dorman 2006; Aschner et al. 2009; Santamaria et al. 2007).

Mn neurotoxicity, or *locura manganica*, also referred to as manganism, is a neurologic disorder characterized by psychological and neurological abnormalities which resemble Parkinson's disease (PD) (Barbeau 1984; Huang et al. 1989; Mena et al. 1967), Mn also damages brain areas distinct from those that are affected in PD (Calne et al. 1994; Olanow 2004). The similarities between the clinical manifestations of PD and manganism include the presence of generalized bradykinesia and widespread rigidity, while dissimilarities include less frequent resting tremor, more frequent dystonia, symmetry of effects, a particular propensity to fall backward, a characteristic "cock-walk," in which patients walk on their toes with elbows flexed and spine erect (Calne et al. 1994). There are also differences with respect to treatment response – although there may be an initial response to levodopa, the primary treatment option for PD, there is typically a failure to achieve a sustained therapeutic response in patients with manganism (Aschner et al. 2009; Calne et al. 1994). The similarities between the two disorders can be partially explained by the fact that the basal ganglia accumulate most of the excess Mn compared with other brain regions in manganism, and dysfunction in the basal ganglia is involved in PD (Dobson et al. 2004). PD is primarily associated with the loss of dopaminergic neurons within the substantia nigra, allowing the caudate and putamen to become overly active and possibly cause continuous output of excitatory signals to the corticospinal motor control system (Dobson et al. 2004). The substantia nigra is spared in manganism, which is linked to the degeneration of GABAergic neurons within the globus pallidus in pathways postsynaptic to the nigrostriatal system (Pal et al. 1999).

The symptoms observed in Mn-exposed subjects are believed to be caused by the preferential accumulation of Mn in brain areas which are rich in dopaminergic neurons (DAergic) and are largely involved in motor control. Perturbation of striatal DA levels likely explains the biphasic syndrome experienced by manganism patients. Upon Mn intoxication, an initial phase of increased DA production is associated with psychotic episodes commonly observed in psychiatric patients (Aschner et al. 2009; Roth 2009). As Mn poisoning progresses, catecholamine levels decrease, most likely due to the loss of nigrostriatal DAergic neurons and, consequently, the parkinsonian-like symptoms ensue (Benedetto et al. 2009).

4.1 Manganese and Mitochondria

Different studies point to the mitochondria as the main cellular targets of Mn toxicity. Nominally, mitochondria have been posited to play a central role in the etiology of both Parkinson's disease (PD) and manganism. Due to transport mechanisms that favor the influx of Mn over its efflux, the metal accumulates in this organelle and thus can readily disturb its function (Gavin et al. 1990). Using

imaging techniques, Morello et al. (2008) reported that prior to any ultrastructural damage to neurons and astrocytes, the largest rate of Mn increase was noted in the mitochondrial cytoplasmic matrix of these cells (Morello et al. 2008).

Mn^{2+} is sequestered by mitochondria via the Ca^{2+} uniporter (Chance 1965). Once inside, Mn^{2+} can trigger mitochondrial dysfunction through several mechanisms, primarily involving oxidative stress. Oxidative stress can also occur as a consequence of mitochondrial dysfunction caused by Mn. Studies of postmortem PD brains show damage to the substantia nigra (SN) consistent with generation of reactive oxygen and nitrogen species (ROS, RNS), characterized by lipid peroxidation, protein oxidation, 3-nitrotyrosine formation, DNA oxidation, DNA breaks and a decrease in the activities of the ROS scavenging enzymes glutathione peroxidase and superoxide dismutase (Bowman et al. 2011). Mn can also impair mitochondrial function by inhibiting the mitochondrial electron transfer chain. Zhang et al. (2004) reported that Mn^{2+} affects the activity of respiratory chain enzymes, inhibiting complexes I–IV and interfering with oxidative phosphorylation (Zhang et al. 2004). Furthermore, it has been shown that Mn can bind to a specific Mg^{2+} site on the F1-ATPase, slowing its activity (Smith et al. 1985). Such effects result in a decline of ATP production, leading to increased leakage of electrons and increased O^{2-} production, thereby causing the eventual collapse of cellular function, which may be followed by cell death (Scholte 1988).

Mn also alters calcium homeostasis in mitochondria by inhibiting its efflux and increasing its levels in the organelle (Gavin et al. 1990). It has been widely reported that elevated calcium levels associated with ROS production result in the opening of the mitochondrial permeability transition pore (MPT), increasing the permeability to protons, ions and solutes (Zoratti and Szabo 1995). As a consequence, there is loss of the inner membrane potential ($\Delta\psi m$), leading to mitochondrial swelling, impairment of oxidative phosphorylation and ATP synthesis (Gunter and Pfeiffer 1990). Indeed, Mn has been found to decrease $\Delta\psi m$ in a concentration dependent manner, indicating that this calcium-dependent process may occur during Mn neurotoxicity (Gunter and Pfeiffer 1990; Milatovic et al. 2007; Yin et al. 2008).

Additionally, apoptotic mechanisms may be also related to Mn neurotoxicity. Calcium-induced MPT opening leads to the activation of the Bcl-2 family of proteins, especially Bax/Bac, culminating with the release of cytochrome c (Cyt c) (Green and Reed 1998; Korsmeyer et al. 2000). Cyt c activates, via the ERK pathway, the cysteine protease caspase-3, the executioner protein, which is responsible for mediating apoptosis, chromatin condensation and DNA fragmentation (Petit et al. 1996). Indeed, Yin et al. (2008) demonstrated that Mn exposure in astrocytes results in ERK and caspase-3 activation. Further, Malecki (2001) observed DNA strand breakage at Mn concentrations as low as 5 μM, reinforcing this mechanistic hypothesis.

In addition, the overexpression of wild-type human α-synuclein in *C. elegans* increases vulnerability to mitochondrial complex I inhibitors, such as rotenone, fenperoximate, pyridaben, and stigmatellin (Weissenborn et al. 1995). α-Synuclein overexpression has also been recently shown to enhance Mn-induced neurotoxicity via the NF-kB-mediated pathway (Hazell and Butterworth 1999) in a mesencephalic cell line (MES 23.5). Mn also induces the overexpression of α-synuclein in

PC12 cells via ERK activation (Zlotkin et al. 1995) and chronic exposure to Mn decreases striatal dopamine turnover in human α-synuclein transgenic mice (Butterworth et al. 1995).

4.2 Dopaminergic System

Dopamine (DA) is one of the most prevalent catecholamines within the brain; its signaling helps control locomotion, emotion and neuroendrocrine secretion (Cooper et al. 1996). In this regard, research conducted on Mn toxicity either focuses on the effect on the DA transporter (DAT) or the DA receptor. Postnatal Mn exposure causes a decline in presynaptic DAergic functioning, such as DAT protein expression and DA uptake in the striatum, and a long-term decrease in DA efflux (Huang et al. 2003; McDougall et al. 2008). In adult animal models, there is strong evidence to suggest that exposure to Mn can inhibit DA neurotransmission and deplete striatal DA (Chen et al. 2006; Pal et al. 1999; Reichel et al. 2006), thereby resulting in the observed motor deficits (see review, Guilarte 2010). Importantly, chronic exposure to Mn also decreases striatal DA turnover in human alpha-synuclein transgenic mice (Peneder et al. 2011).

The two main families of DA receptors responsible for DA regulation are D1- and D2-receptors. D1-receptors are G-protein-coupled receptors that stimulate adenylate cyclase activity, while D2-receptors inhibit adenylate cyclase activity (Baldessarini and Tarazi 1996; Hazelwood et al. 2008). A recent study has demonstrated that striatal D2-receptors are not affected by Mn intoxication in monkeys (Eriksson et al. 1992); nevertheless, other studies have shown that the density of D2-receptors is lowered in developing rats treated with Mn (Seth and Chandra 1984).

The direct interaction between Mn and DA is also noteworthy. Both Mn^{2+} and Mn^{3+} are known to react with DA via the Fenton‘s reaction, catalyzing the auto-oxidation of DA and generating reactive oxygen species (ROS), thereby leading to oxidative damage (Donaldson et al. 1981, 1982; Lloyd 1995; Stokes et al. 1999). Mn-induced DA auto-oxidation relies on various mechanisms involving semi-quinone and aminochrome intermediates, L-cysteine or copper (Cu) and NADH facilitation (Graumann et al. 2002; Lloyd 1995). Mn oxidant generation is believed to depend on its oxidation state, and oxidative damage is more pronounced for Mn^{3+} versus Mn^{2+} oxidation state (Reaney and Smith 2005).

5 Manganese and Parkinson’s Disease

Idiopathic Parkinson’s disease (IPD) is a progressive neurodegenerative disorder with a slow onset, and compared with the familial forms of the disease, it is associated with advanced age (>55 years old), tremors at rest, bradykinesia, rigidity, and postural instability (Jankovic 2008; Lees et al. 2009; Tolosa et al. 2006).

Molecular imaging is a useful strategy for the diagnosis of PD and has provided extensive evidence that PD patients exhibit decreased levels of presynaptic dopamine neuron terminal markers in the striatum (Felicio et al. 2009). This is consistent with the loss of DA terminals as a result of degeneration of neuronal cell bodies in the substantia nigra pars compacta. Single positron emission tomography studies have shown that PD patients exhibit decreased levels of DA transporters (DATs) and vesicular monoamine transporter type 2(VMAT2) and reduced activity of dopa decarboxylase as measured by the conversion of L-DOPA to dopamine in the striatum (Felicio et al. 2009).

As previously described in this chapter, Mn causes oxidative stress, mitochondrial dysfunction, DAergic degeneration, among other molecular damages, which culminate with an extrapyramidal syndrome called parkinsonism, because of the similarities with PD. While the underlying etiology of the majority of cases of IPD is unknown, there is evidence that exposure to Mn, even at relatively low levels, can result in a spectrum of neurologic impairment including parkinsonism and perhaps IPD itself (Meeker et al. 2007). Manganism like PD is associated with altered neurological dysfunction of the basal ganglia, and because symptoms often overlap between the two, incorrect diagnosis can occur. This is especially true in the latter stages of the disorder when it is feasible that manganism may actually manifest in more Parkinson's-like features in susceptible individuals (Roth 2009).

Characterization of this neurological disorder and investigation of the mechanisms was possible due to research of Mn neurotoxicity in different animal models. A suitable animal model for parkinsonism is histopathologically characterized by the progressive and significant loss of DA neurons and the loss of some non-DA neurons. Moreover, animal models readily mimic the clinical manifestations of the human descriptions.

5.1 Studies in *Drosophila melanogaster*

Drosophila has a relatively simple central nervous system, showing progressive degeneration of DAergic neurons, formation of Lewy bodies, and impairment of climbing activity in PD models (Barone et al. 2011; Feany and Bender 2000). There are about 200 DAergic neurons in the flies; however, they are responsible for modulating a wide range of behaviors ranging from sleep and locomotion to courtship and learning (Van Swinderen and Andretic 2011).

Under chronic Mn exposure, flies show reduced survival, life-span, and reduced locomotor activity, with Mn showing greater toxic effects than iron and copper (Bonilla-Ramirez et al. 2011). Mn accumulates in the head of the flies, and the number of DAergic neuronal clusters labeled with green fluorescent protein (GFP) is reduced upon Mn treatment (Bonilla-Ramirez et al. 2011). This study also showed that Mn-induced DAergic degeneration was associated with impairment in the climbing behavior and mobility shortage analogous to fly PD models.

5.2 Studies in *Caenorhabditis elegans*

The nematode *Caenorhabditis elegans* offers several advantages as a tool for studying neurotoxicity, including its relatively short life-span, lasting 20 days on average, and low costs in growing and maintaining large colonies (Link 2006). Genetic, genomic, and chemical mutant screens are more easily performed in *C. elegans* than in most other experimental species. Compound screening using *C. elegans* is also less time-consuming, due to fast reproduction and a high progeny number (Schmidt et al. 2007). The basic cell biology and biochemistry of nematodes overlap with mammals, including similar ion channels, neurotransmitters (e.g., DA, serotonin, acetylcholine, GABA), vesicular transporters, receptors, and synaptic components, particularly the ones that form the DAergic system (Bargmann 1998). The wiring diagram of the nematode nervous system consists of a defined set of 302 neurons, of which eight are dopaminergic (Gitler et al. 2009). Several worm behaviors are related to DAergic function which also enables to evaluate the effects of the degeneration in this model.

Mn exposure in worms has been associated with morphological alterations, reduced longevity, oxidative stress, and behavioral alterations, such as decreased head trash and body-bend frequencies (Au et al. 2009; Benedetto et al. 2010; Settivari et al. 2009; Wang and Xing 2008). Particularly, DAergic degenerations were observed after acute exposure to this metal (Benedetto et al. 2010; Settivari et al. 2009). Benedetto et al., making use of various genetic strains of *C. elegans* in conjunction with the fluorescent-tagging of different classes of neuron types, have demonstrated that Mn causes a dose-dependent and specific degeneration of DAergic neurons (Benedetto et al. 2010). This effect was absent in GABAergic, serotonergic, or glutamatergic neurons. A novel finding also showed that this Mn-induced degeneration requires the presence of the reuptake transporter, dopamine transporter 1 (DAT-1), as *dat-1* loss-of-function abolished the Mn-induced DAergic loss in the *dat-1*;Pdat-1::GFP worms (Benedetto et al. 2010). In addition, Mn toxicity was reduced by the loss of tyrosine hydroxylase (TH)/CAT-2 function in the double knockout strain, *cat-2(e1112);dat-1(ok157)*, establishing that proper DA synthesis is required for the DAT-1-dependent Mn-induced toxicity. Furthermore, the absence of vesicular monoamine transporter (VMAT2)/CAT-1 in the *cat-1(e1111)* mutants, where the DAergic neurons are unable to release DA at the synaptic cleft, resulted in increased tolerance to Mn exposure, indicating that extracellular, but not intracellular DA, is involved in mediating Mn-induced toxicity (Benedetto et al. 2010). Corroborating this finding, loss-of-function of the three DA receptors [*dop-1(vs100), dop-2(vs105)*, *dop-3(vs106)*] led to increase in extracellular DA, exacerbating Mn toxicity (Benedetto et al. 2010).

The ability of Mn to cause specific DAergic degeneration was linked to the presence in worms of orthologues of the mammalian divalent metal transporter-1 (DMT-1)/NRAMP2 (natural resistance-associated macrophage protein 2). Two of three gene orthologues in worms (*smf-1* and *smf-3)* are mostly localized in the digestive system but are also present in DAergic neurons (Au et al. 2009; Settivari et al. 2009). Decreased susceptibility to Mn and its accumulation in *smf-1* and *smf-3*

knockout worms demonstrated the involvement of SMF-1 and SMF-3 in Mn uptake in *C. elegans*. Work by Settivari et al. also indicated a role for *smf* in Mn neurotoxicity, demonstrating that genetic knockdown or deletion of *smf-1* and *smf-2* partially inhibits DAergic neuronal death (Settivari et al. 2009).

Pesticides containing Mn are also a source of exposure. Mancozeb (MZ), whose active ingredient is Mn/zinc (Zn)-ethylene-bis-dithiocarbamate (Mn/Zn-EBDC) caused mitochondrial dysfunction and GABAergic and DAergic degeneration in worms (Negga et al. 2011a, b). The use of MZ in the crops has been increasing, yet it has been linked to PD and parkinsonism in humans (Israeli et al. 1983).

5.3 Studies in Rodents

Knowledge regarding Mn neurotoxicity and its relation to IPD has been largely derived from rodent studies. A welding fume exposure in rats that corresponded to ~5 years for humans led to alterations in reduced tyrosine hydroxylase levels in the striatum and, more interestingly, to alterations in PD-related proteins expression (Sriram et al. 2010). For instance, there was decrease in the expression of Park5 and Park7. Park5 is involved in the ubiquitin-proteasome system and compromised function or reduced expression of this protein has been associated to IPD (Choi et al. 2004). Park7 mutations account for ~1–2 % of early onset cases of PD, and its reduction may be related to the decrease in mitochondrial integrity (Sriram et al. 2010).

Another PD-related gene that has been investigated is α-synuclein. The deposition of this small protein in Lewy bodies due to three point mutations in the α-synuclein gene is a molecular hallmark of familial PD (Ulmer and Bax 2005). It has been reported that Mn can induce overexpression of α-synuclein in PC12 cells, which reduces cellular viability (Cai et al. 2010). Furthermore, Mn exposure in rat-derived primary cerebellar neuron culture increased levels of α- synuclein associated to increased oxidative stress (Tong et al. 2009). Furthermore, rat mesencephalic cells expressing α-synuclein showed higher neurotoxicity to Mn, an effect that occurred through NF-κB pathway activation (Prabhakaran et al. 2011). Combined, these important studies link PD-related genes and manganism, indicating that Mn may increase susceptibility to PD-inherent mutations.

5.4 Studies in Nonhuman Primates

The use of nonhuman primates to study Mn-induced neurotoxicity is of great relevance, considering that they are closely related to humans in relation to genetics, biology, neurotransmission systems, and particularly, behavior. Historically, nonhuman primate studies can be divided into two categories. The studies from the 1960s to the early 1990s used Mn doses that were considerably higher than those used in studies from 1995 to 2008 (for a review, see Guilarte (2010)). Most studies before 1995 used cumulative doses >300 mg/kg body weight. These early studies did not use

neuroimaging techniques because of their more recent availability, with the exception of Newland and Weiss (1992), who administered very low doses of Mn and used T1-weighted magnetic resonance imaging (MRI) (Newland and Weiss 1992).

Administration of exceedingly high doses of Mn (approximately 300 mg/kg/day) caused loss of postural stability, excitability, hypoactivity, falling, muscular rigidity, tremors, unsteady gait and loss of power in limbs (Eriksson et al. 1992; Neff et al. 1969; Pentschew et al. 1963). Notably, chronic exposure to exceedingly high doses (10 and 15 mg/kg/day) of Mn for >272 days can also cause serious cognitive, behavioral, and motor impairments (Schneider et al. 2006). For instance, videotaped animals showed increased frequency in certain stereotyped behaviors, such as increase in grooming and licking fingers and decrease in climbing in the cage (Schneider et al. 2006).

Decreased DA levels in monkeys brains were usually described (Chandra et al. 1979; Dorman et al. 2006; Newland et al. 1987). However, depending on the exposure design and route of exposure, the areas of decreased dopamine vary from one report to another. Consistently, basal ganglia (especially striatum and globus pallidus) are the brain regions that are more often described as having decreased levels of the neurotransmitter (Bird et al. 1984; Chandra et al. 1979; Eriksson et al. 1987), associated with higher Mn accumulation (Dorman et al. 2006, 2008; Erikson et al. 2007).

5.5 Studies in Humans

As pointed out by Perl and Olanow, a very limited number of autopsy studies have been performed on workers who were exposed to Mn or on persons with other related conditions in which Mn would be increased in the brain (Perl and Olanow 2007). Recently, noninvasive imaging techniques to measure Mn effects in the brain have been tested with relative success. For instance, PET (positron emission tomography) scan imaging with 6-[(18)F]fluoro-l-dopa (FDOPA) showed that asymptomatic welders have presynaptic nigrostriatal dopaminergic dysfunction with different anatomical localization from the symptomatic IPD patients analyzed (Criswell et al. 2011). In addition, specific tests showed that these asymptomatic welders were showing motor impairment (Criswell et al. 2011).

Several other authors have proposed that occupational exposure to Mn is a risk factor for parkinsonism (Gorell et al. 1999; Kim et al. 1999; Racette et al. 2001, 2005). This is also verified in reports demonstrating increased frequency of parkinsonism in communities near these occupational sources, becoming an environmental issue. An epidemiological study investigated the risk of Parkinson's disease in the cities of Toronto and Hamilton, Canada, in relationship with industrial emissions of Mn as well as the use of MMT as a gasoline additive (Finkelstein and Jerrett 2007). Subjects were assessed based on residence location to traffic-generated air pollution and neighborhood levels of ambient Mn. Results of this study found an association between ambient levels of airborne Mn in Hamilton and the risk of physician-diagnosed Parkinson's disease. Their statistical modeling

suggests that exposure to ambient Mn correlates with early onset of parkinsonism, consistent with the premise that chronic exposure to Mn adds to the inherent loss of neurons triggered by the normal aging process. A more recent study by Lucchini et al. (2007) evaluated the incidence of Parkinson's disease in pre-Alps Valcamonica valley area adjacent to three ferroalloy plants (Lucchini et al. 2007). These authors indicate that the prevalence of parkinsonian disorders in this area was higher than elsewhere in Italy and Europe having a high crude (296/100,000) and sex- and age-standardized prevalence (407/100,000) when compared to other national and international data (overall prevalence of parkinsonism of 108–257/100,000 in Europe; 157.7/100,000 in Italy) (von Campenhausen et al. 2005).

Mn neurotoxicity is also of great concern. Case reports have been published on patients with hepatic diseases, such as cirrhosis and hepatitis. These patients develop encephalopathy and parkinsonian behavior (Dharmasaroja 2010; Mendieta Zeron et al. 2011; Olanow 2004), associated with reduced liver Mn clearance and increased Mn blood levels, as well as neuronal accumulation, as indicated by the increased t1-weighted signals in MRI (Chalela et al. 2011; Kulisevsky et al. 1993; Rivera-Mancia et al. 2011). Parenteral nutrition has also been linked to encephalopathy and extra-pyramidal symptoms, as the daily doses administered in these preparations are 5–6-fold higher than the required dose (Chalela et al. 2011; Hardy 2009).

6 Conclusion

Over the past few decades considerable progress has been made in understanding Mn neurotoxicity and its mechanisms. Given that Mn accumulates and affects neurons in the basal ganglia, it is not surprising that symptoms of Mn neurotoxicity overlap with those of PD. The studies reviewed herein illustrate that Mn can accelerate the onset of parkinsonism in exposed individuals and that the accumulated Mn in the basal ganglia, which includes both the globus pallidus and the substantia nigra, can lead to DAergic neuronal degeneration and parkinsonism. Furthermore, some subpopulations may display increased vulnerability to Mn-induced neurological deficits becoming most prevalent in late age. The question on whether chronic exposure to Mn directly leads to the development of IPD is difficult to resolve and will require additional studies.

Mechanisms of Dopamine Oxidation and Parkinson's Disease

Juan Segura-Aguilar and Irmgard Paris

Contents

Abstract

Dopamine's ability to oxidize to aminochrome explains why this molecule is both an essential neurotransmitter for movement control and a neurotoxic compound that induces toxicity and apoptosis in cell lines. Dopamine spontaneously

oxidizes to aminochrome in the presence of oxygen due to the protons on the dopamine hydroxyl groups that are dissociated when dopamine is in the cytosol (pH 7.4). Dopamine oxidation is prevented by vesicular monoaminergic transporter-2 (VMAT-2) that takes up dopamine into the monoaminergic synaptic vesicles where the low pH prevents dopamine oxidation. Dopamine in the cytosol can also be degraded by monoamine oxidase (MAO) and catechol *ortho*-methyltransferase (COMT) soluble isoform. However, under certain unknown conditions dopamine oxidize to aminochrome, the precursor of neuromelanin, since the neuromelanin pigment is found in the human substantia nigra. Aminochrome participates in two neurotoxic reactions: (i) the one-electron reduction of aminochrome, which is catalyzed by flavoenzymes that use NADH or NADPH as electron donors. This reaction produces leukoaminochrome *o*-semiquinone radical, which is extremely reactive with oxygen that autoxidizes, depleting both NADH and O_2 required for ATP synthesis when the flavoenzymes use NADH; and (ii) aminochrome forms adducts with proteins such as alpha-synuclein-inducing and alpha-synuclein-stabilizing neurotoxic protofibrils. In addition, aminochrome inactivate parkin an E3 ubiquitin ligase of proteasomal system, complexes I and III of electron transport chain, tyrosine hydroxylase, actin, and α- and β-tubulin. Aminochrome is also able to participate in three neuroprotective reactions such as (i) polymerization to neuromelanin, which is a pigment localized in substantia nigra and is present in normal subjects; (ii) aminochrome two-electron reduction to leukoaminochrome catalyzed by DT-diaphorase, which prevents aminochrome neurotoxic reactions; and (iii) glutathione conjugation of aminochrome catalyzed by glutathione *S*-transferase M2-2. The role of aminochrome in the degeneration of dopaminergic neurons in Parkinson's disease is discussed. Aminochrome may induce the focal neurodegeneration of dopaminergic neurons through mechanisms involving mitochondrial dysfunction, protein aggregation, oxidative stress, and protein degradation dysfunction.

Keywords

Alpha synuclein • Aminochrome • Aromatic amino acid decarboxylase • Catechol orto-methyl-transferase • Dopamine • DT-diaphorase (NQO1) • Free radicals • Glutathione-S-transferase M2-2 • Mitochondria complex I • Mono amine oxidase • Oxidation • Parkin • Parkinson's disease • Tyrosine hydroxylase • VMAT-2

List of Abbreviations

AADC	Aromatic amino acid decarboxylase
COMT	Catechol *ortho*-methyltransferase
GST M2-2	Glutathione *S*-transferase M2-2
L-dopa	L-dihydroxyphenylalanine
MAO	Monoamine oxidases
TH	Tyrosine hydroxylase
VMAT-2	Vesicular monoaminergic transporter-2

1 Dopamine

Dopaminergic neurons play a key role in motor activity. Dopamine is an essential neurotransmitter synthesized from the amino acid tyrosine. It is stored and transported in monoaminergic vesicles, released during neurotransmission, and is taken up by dopamine transporters from the intersynaptic space. Dopamine is synthesized in several steps. The first step involves the formation of L-dihydroxyphenylalanine (L-dopa) from tyrosine by the enzyme tyrosine hydroxylase (TH). The L-dopa is then decarboxylated by aromatic amino acid decarboxylase (AADC) to generate dopamine and CO_2. Dopamine has two hydroxyl groups that are dissociated in the cytosol at pH 7.4. This dissociation allows the oxidation of dopamine to *o*-quinones. However, dopamine accumulates in monoaminergic vesicles because TH and AADC are associated with the vesicular monoaminergic transporter-2 (VMAT-2). This transporter is present in the membranes of monoaminergic synaptic vesicles and generates a complex with the enzymes (Cartier et al. 2010). Thus, tyrosine is converted to L-dopa by TH and is immediately decarboxylated by ADDC to dopamine. The dopamine is then taken up by VMAT-2 into the monoaminergic synaptic vesicles. The uptake prevents free dopamine from accumulating in the cytosol and the oxidation of dopamine to *o*-quinone. The dopamine uptake mediated by VAMT-2 is associated with a vesicular ATPase that is translocated into the vessel as ATP is hydrolyzed to ADP, Pi, and one proton (H^+). This process creates a proton gradient (Fig. 1). The VMAT-2 transporter exports two protons as one molecule of dopamine is taken into the cell (Chaudhry et al. 2008; Knoth et al. 1981). The pH inside the monoaminergic synaptic vesicles has been estimated to be 2–2.4 pH units lower than the pH in the cytosol (Guillot and Miller 2009). The dopamine inside the monoaminergic synaptic vesicles is stable. It does not oxidize to *o*-quinone because it is well protonated. The free dopamine in the cytosol participates in three reactions. First, the dopamine can undergo deaminative oxidation to become dihydroxyphenylacetic acid. This reaction is catalyzed by monoamine oxidases. Second, the dopamine catechol structure can be oxidized to become the *o*-quinone aminochrome. Finally, dopamine can be methylated by *ortho* methyltransferases (Fig. 1).

2 Dopamine Degradation

2.1 The Oxidative Deamination of Dopamine

The monoamine oxidases (MAO, E.C. 1.4.3.4) degrade excess dopamine in the cytosol by catalyzing the oxidative deamination of the dopamine amino group to 3,4-dihydroxyphenylacetaldehyde. Ammonia and hydrogen peroxide are also produced in this reaction. 3,4-Dihydroxyphenylacetaldehyde is metabolized by aldehyde dehydrogenase to 3,4-dihydroxyphenylacetic acid (DOPAC) as NAD^+ is simultaneously reduced to NADH (Fig. 2). The MAO enzymes

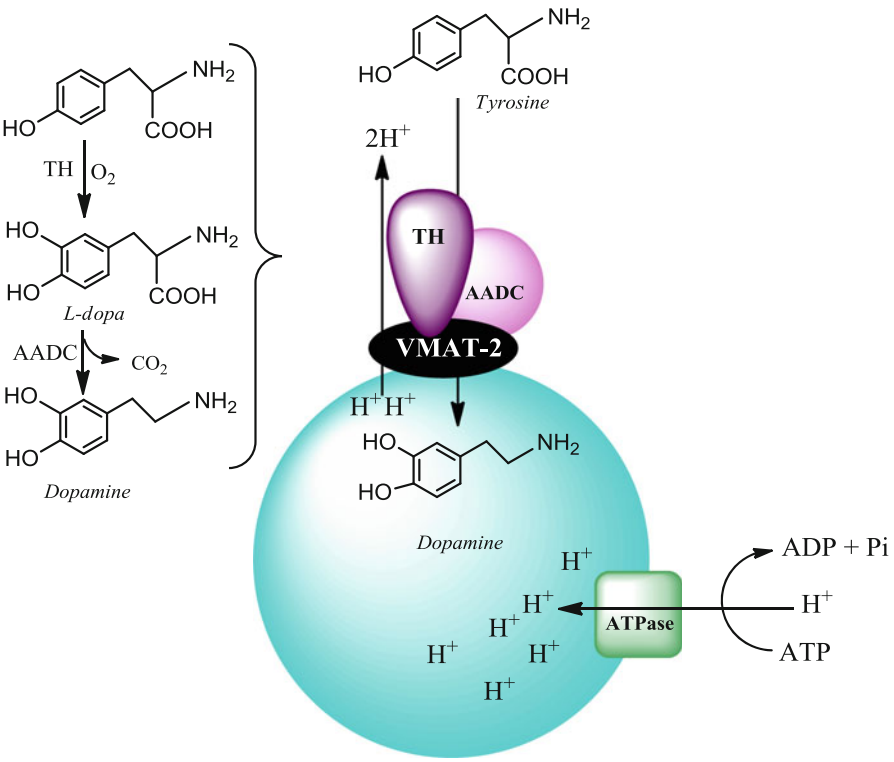

Fig. 1 Dopamine synthesis from tyrosine catalyzed by tyrosine hydroxylase (*TH*) and aromatic amino acid decarboxylase (*AADC*) and uptake into monoaminergic synaptic vesicles mediated by VMAT-2

are flavoenzymes with multiple isoforms. The isozymes are labeled A and B and share 70 % identity. These enzymes carry sequences specific to FAD (Bach et al. 1988) and are localized to the outer membranes of the mitochondria in neurons, glial cells, and other cell types (Weyler et al. 1990; Shih et al. 1997). MAO-A is mainly found in catecholaminergic neurons, whereas MAO-B is found in serotonergic and histaminergic neurons as well as in astrocytes (Westlund et al. 1988; Saura et al. 1994). MAO-A acts on mainly monoaminergic neurotransmitters such as serotonin, dopamine, noradrenaline, and adrenaline. In contrast, the substrates of MAO-B include trace amines such as tyramine and phenylethylamine (Strolin-Benedetti et al. 1992). The nonselective inhibitors of MAO-A and MAO-B include isocarboxazid¸ phenelzine, nialamide, iproniazid, iproclozide, and tranylcypromine. The selective inhibitors of MAO-A include clorgyline, brofaromine, moclobemide, toloxatone, linezolid, befloxatone, and cimoxatone. The selective inhibitors of MAO-B include selegiline and rasagiline (for review, see Bortolato et al. 2008). The MAO in dopaminergic neurons degrades dopamine to maintain low cytosolic concentrations and

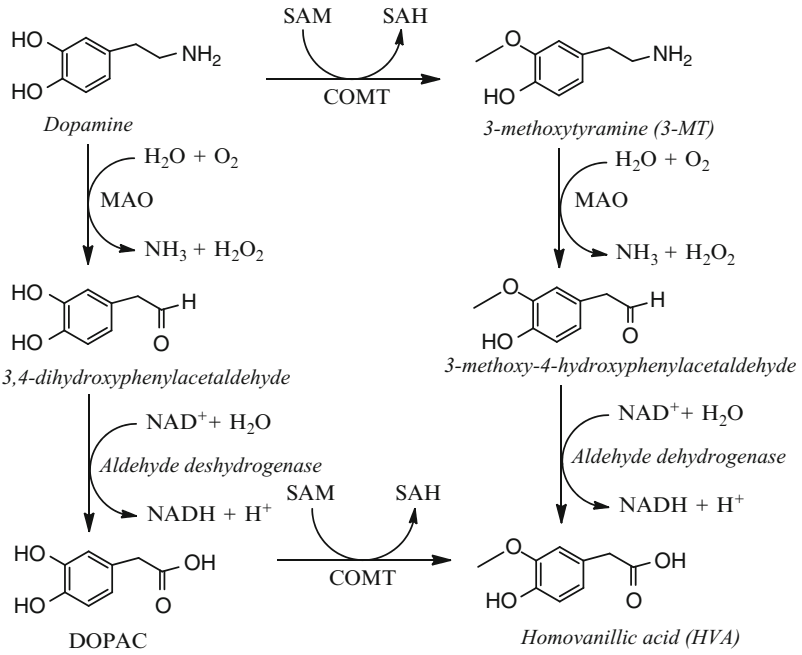

Fig. 2 Dopamine degradation catalyzed by monoamine oxidase (*MAO*) and catechol *ortho*-methyltransferase (*COMT*)

to prevent dopamine oxidation. However, MAO activity is associated with oxidative stress. This process is a result of hydrogen peroxide formation from the oxidative deamination of dopamine. Hydrogen peroxide is a precursor to the hydroxyl radical. Rasagiline may protect the brain in Parkinson's disease model systems by inhibiting the formation of reactive oxygen species derived from the deaminative oxidation of dopamine catalyzed by MAO-B (Weinreb et al. 2011).

2.2 *Ortho*-Methylation of Dopamine

Dopamine is also degraded by catechol *ortho*-methyltransferase (COMT; EC 2.1.1.6). This enzyme converts dopamine to 3-methoxytyramine, which is then metabolized to 3-methoxy-4-hydroxyphenylacetaldehyde by MAO. Finally, homovanillic acid is formed when aldehyde dehydrogenase catalyzes the oxidation of 3-methoxy-4-hydroxyphenylacetaldehyde (Fig. 2). NADH is also formed in this reaction. Homovanillic acid is also formed by COMT-mediated methylation of the hydroxyl group on DOPAC. Two isoforms of COMT have been discovered: The first is the soluble isoform S-COMT, and the second is the membrane-bound isoform MB-COMT. Both the S- and MB-COMT isoforms are found in microglial

and astroglial cells. COMT is present in pyramidal neurons, cerebellar Purkinje and granular cells, and striatal spiny neurons (Myöhänen et al. 2010). MB-COMT is localized to the cell body, axons, and dendrites of rat cortical neurons. The C-terminal catalytic domain of MB-COMT is in the extracellular space. This domain inactivates the synaptic and extrasynaptic dopamine in presynaptic and postsynaptic neurons (Chen et al. 2011). The downregulation of COMT by estrogen most severely affects the prefrontal cortex and kidneys, where COMT is physiologically important for dopamine metabolism (Schendzielorz et al. 2011). Entacapone has been applied to inhibit COMT in Parkinson's disease treatment. This inhibition prolongs the half-life of L-dopa and allows the delivery of continuous stimulation to the neuronal dopaminergic receptors (Marin and Obeso 2010). A single nucleotide polymorphism (1947) that controls COMT activity has been identified (Tan et al. 2005).

3 Dopamine Oxidation to *Ortho*-Quinones

3.1 Dopamine Oxidation to Aminochrome

The protons on the dopamine hydroxyl groups are dissociated when dopamine is in the cytosol (pH 7.4). Dopamine spontaneously oxidizes in the presence of oxygen, even in the absence of metal-ion catalysts (Linert et al. 1996). Dopamine oxidation can produce a dopamine *o*-semiquinone radical and a superoxide radical (reaction 1). Two dopamine *o*-semiquinone radicals can react in a disproportionation reaction to produce one molecule of dopamine *o*-quinone and one molecule of dopamine (reaction 2, Fig. 3). Alternatively, the dopamine *o*-semiquinone radical can be one-electron oxidized by oxygen to produce dopamine *o*-quinone and a superoxide radical (reaction 3, Fig. 3). Dopamine oxidation can also be catalyzed by metals. Manganese (III) oxidizes dopamine under aerobic and anaerobic conditions without forming superoxide radicals because manganese (III) catalyzes the formation of both dopamine *o*-semiquinone and dopamine *o*-quinone (Segura-Aguilar and Lind 1989). Copper sulfate (II) and iron chloride (III) oxidize dopamine by forming a complex with it (Paris et al. 2001, 2005a, b). Sodium metaperiodate also catalyzes dopamine oxidation (Graham et al. 1978). Further, prostaglandin H synthase, lactoperoxidase, cytochrome P450, xanthine oxidase, and dopamine β-monooxygenase catalyze dopamine oxidation through peroxidase activity (Galzigna et al. 2000; Thompson et al. 2000; Segura-Aguilar 1996; Foppoli et al. 1997; Hastings 1995). Tyrosinase can catalyze the two-electron oxidation of dopamine to dopamine *o*-quinone. This process does not form dopamine *o*-semiquinone radicals or consume oxygen (Segura-Aguilar et al. 1998; Jimenez et al. 1984).

Dopamine *o*-quinone is only stable at a pH below 2.0. Thus, this molecule is not stable at physiological pH (Segura-Aguilar and Lind 1989). The amino group of dopamine spontaneously rearranges and undergoes cyclization to become

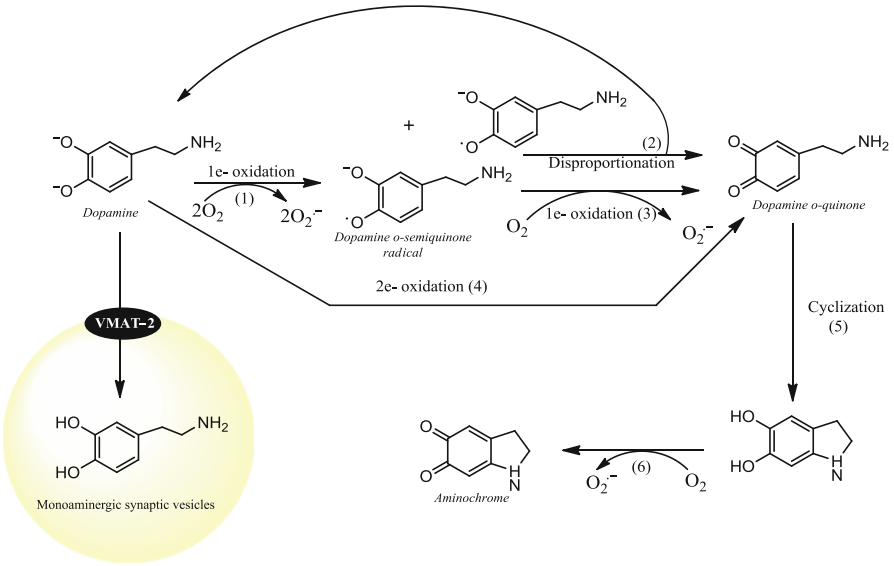

Fig. 3 Dopamine oxidation to aminochrome

leukoaminochrome (reaction 5). Leukoaminochrome undergoes oxidation to become aminochrome (reaction 6). Purified aminochrome (also called dopaminechrome) is stable for approximately 3 h (Paris et al. 2010). This timeframe suggests that aminochrome is the relevant end product of dopamine oxidation in neuromelanin-containing dopaminergic neurons.

Aminochrome formation is dependent on the presence of free cytosolic dopamine that can be oxidized. The efficient uptake of dopamine into monoaminergic vesicles is mediated by VMAT-2, and the degradation of free dopamine by MAO prevents the oxidation of dopamine to aminochrome. However, under certain conditions, free dopamine in the cytosol can oxidize to form aminochrome. The presence of neuromelanin in the substantia nigra of healthy controls suggests that dopamine oxidation occurs in vivo because aminochrome is the precursor of neuromelanin.

3.2 Aminochrome Tautomerization

Aminochrome is an unstable molecule that rearranges to 5,6-dihydroxyindole (reaction 1), which is then oxidized to become 5,6-indolequinone (Fig. 4, reaction 2) (Napolitano et al. 2011). However, tyrosinase-catalyzed dopamine oxidation in the absence of metals produces aminochrome that is stable for 3 h after purification (Paris et al. 2010). From a physiological point of view, 3 h is adequate for a molecule to be one- or two-electron reduced by flavoenzymes or to form adducts with proteins. The 5,6-indolequinone is in equilibrium with the quinone methide even though

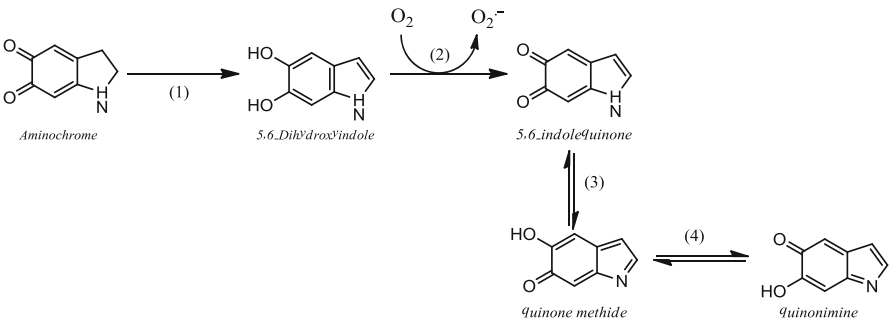

Fig. 4 Aminochrome tautomerization

the presence of transition metal cations favors the formation of the quinone methide (reaction 3). The quinone methide is also in equilibrium with quinonimine (reaction 4, Fig. 4; Pezzella et al. 2007).

4 Aminochrome Metabolism

4.1 Aminochrome Polymerization to Neuromelanin

Aminochrome is not completely stable. At high concentrations, it polymerizes to form a dark pigment called neuromelanin (Fig. 5). Neuromelanin formation appears to be a normal process because it is present in dopaminergic neurons of the substantia nigra in healthy subjects without Parkinson's disease. It accumulates with age (Zecca et al. 2002). Neuromelanin appears to have a neuroprotective function through the chelation of metals (Gerlach et al. 2003; Hong and Simon 2007) and the binding of such proteins as alpha-synuclein (Fasano et al. 2006). However, neuromelanin induces apoptosis in cell cultures (Naoi et al. 2008). Interestingly, extracellular neuromelanin also induces microglial activation in the substantia nigra. As a result of this process, superoxide radicals, nitric oxide, hydrogen peroxide, and pro-inflammatory factors are produced, and tyrosine hydroxylase-positive neurons are lost (Zhang et al. 2011). However, neuromelanin is normally stored in double-membrane vacuoles, and the possible neurotoxic effects described by Zhang are avoided.

4.2 Aminochrome Adducts with Proteins

Aminochrome forms adducts with proteins that may be involved in the pathogenesis of Parkinson's disease. Alpha-synuclein is hypothesized to cause damage through the generation of neurotoxic protofibrils and has been associated with familial Parkinson's disease. The role of alpha-synuclein in sporadic Parkinson's disease remains an open question. However, aminochrome forms adducts with alpha-synuclein (Fig. 6). This process induces the formation and stabilization of

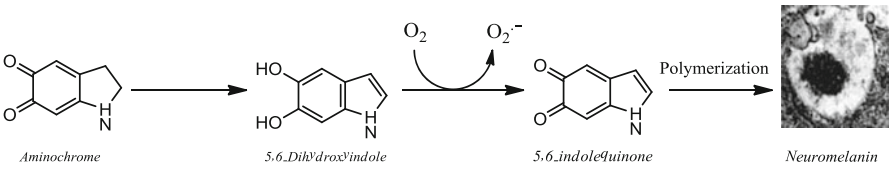

Fig. 5 Aminochrome as precursor of neuromelanin pigment

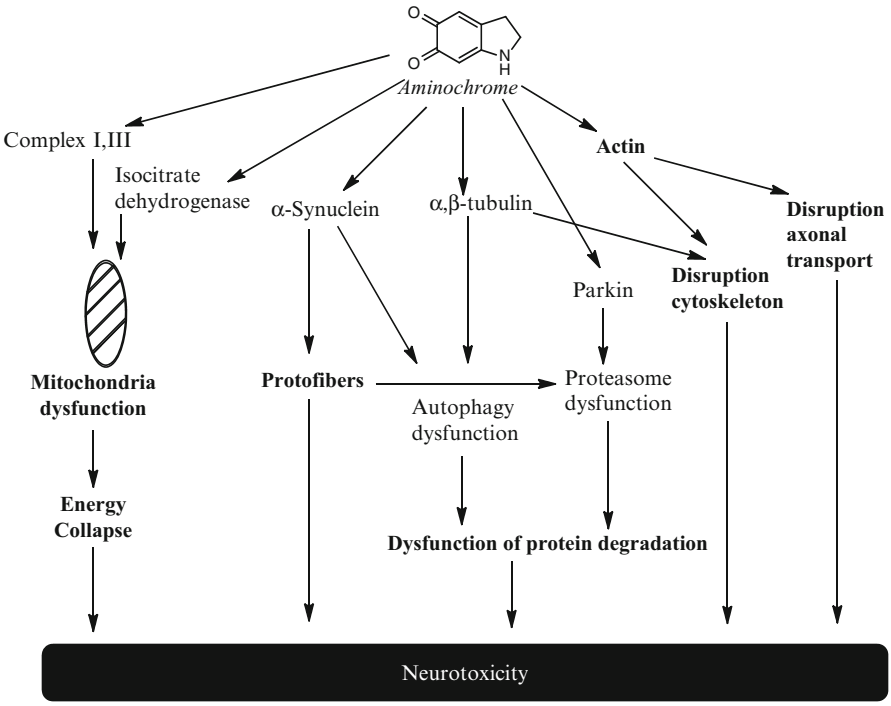

Fig. 6 Formation of aminochrome adducts with proteins

neurotoxic protofibrils that may play a key role in alpha-synuclein neurotoxicity (Conway et al. 2001; Norris et al. 2005). Therefore, aminochrome may be the link between alpha-synuclein and sporadic Parkinson's disease. In familial Parkinson's disease, the formation of neurotoxic protofibrils is dependent on the presence of a specific point mutation that changes alpha-synuclein properties (Polymeropoulos et al. 1997). In sporadic Parkinson's disease, however, the formation of neurotoxic protofibrils is dependent on the formation of aminochrome. The aminochrome forms adduct with other proteins such as actin and α- and β-tubulin and disrupt cytoskeletal architecture (Fig. 6; Paris et al. 2010). Dopamine o-quinone, a transient precursor of aminochrome at physiological pH, forms adducts with and inactivates parkin, a ubiquitin ligase of the proteasomal system (LaVoie et al. 2005).

This result suggests that aminochrome inactivates the proteasomal system, which is consistent with another report (Zafar et al. 2006). Interestingly, a mutation in the parkin gene has also been associated with a familial form of juvenile Parkinson's disease (Kitada et al. 1998). Aminochrome (dopamine o-quinone) forms adduct with the mitochondrial complex I (Van Laar et al. 2009) and induces energy collapse by inactivating mitochondrial electron transport and ATP production. Aminochrome (dopamine *o*-quinone) also forms adducts with and inactivates tyrosine hydroxylase, human dopamine transporter, and tryptophan hydroxylase (Xu et al. 1998; Whitehead et al. 2001; Kuhn and Arthur 1998).

4.3 Aminochrome One-Electron Reduction

The aminochrome quinone can be one-electron reduced to become a leukoaminochrome *o*-semiquinone radical. This process is catalyzed by flavoenzymes that transfer electrons from NADH or NADPH to aminochrome. The leukoaminochrome *o*-semiquinone radical is extremely reactive under aerobic conditions. It catalyzes the reduction of oxygen to superoxide and generates a redox cycle between the leukoaminochrome *o*-semiquinone radical and aminochrome (Baez et al. 1995; Segura-Aguilar et al. 1998).

The redox cycling between the leukoaminochrome *o*-semiquinone radical and aminochrome is important for aminochrome neurotoxicity. This process is catalyzed by flavoenzymes and transfers electrons from NADH or NADPH. NADH and oxygen depletion through redox cycling results in energy collapse because these molecules are no longer available for ATP synthesis in the mitochondria (Fig. 7). This effect is potentiated by the formation of superoxide radicals. These radicals spontaneously or enzymatically generate hydrogen peroxide, the precursor of hydroxyl radicals. NADPH can also be used as the electron donor in the reaction catalyzed by flavoenzymes. NADPH is involved in the reaction catalyzed by glutathione reductase that keeps GSH in the reduced state. As a result of NADPH depletion, GSH is unable to exert its antioxidant action, and oxidative stress is thereby increased. The one-electron reduction of aminochrome is neurotoxic in catecholaminergic cells (Paris et al. 2001, 2005a, b, 2009, 2010, 2011; Arriagada et al. 2004; Fuentes et al. 2007; Díaz-Véliz et al. 2008; Muñoz et al. 2012).

4.4 Aminochrome Two-Electron Reduction

DT-diaphorase (EC.1.6.99.2) is a flavoenzyme composed of two subunits and contains two molecules of FAD. This enzyme is unique among flavoenzymes because it catalyzes the two-electron reduction of quinones to hydroquinones. Both NADH and NADPH can be used as electron donators in this reaction. DT-diaphorase is mainly localized in the cytosol, but approximately 5 % of this enzyme is associated with the mitochondria and endoplasmic reticulum. It is found in

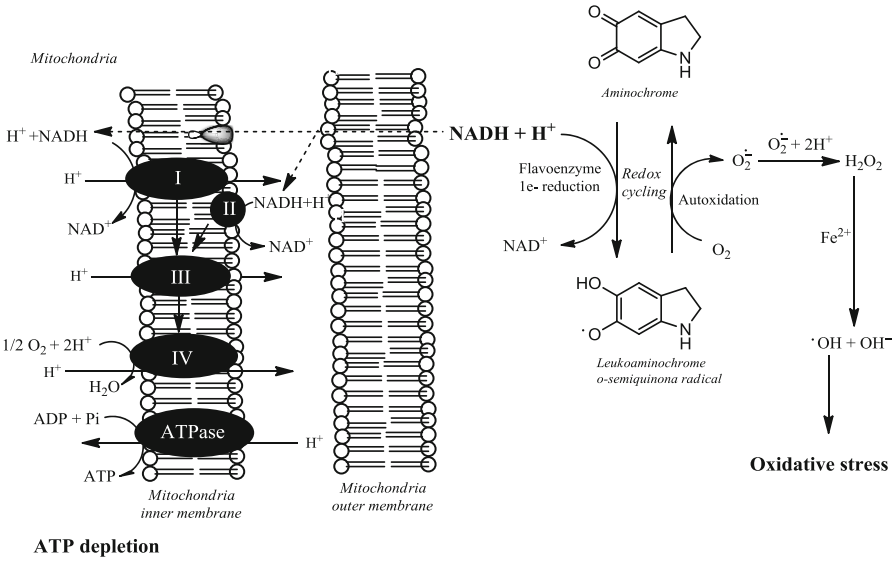

Fig. 7 One-electron reduction of aminochrome catalyzed by flavoenzymes that use NADH as electron donor

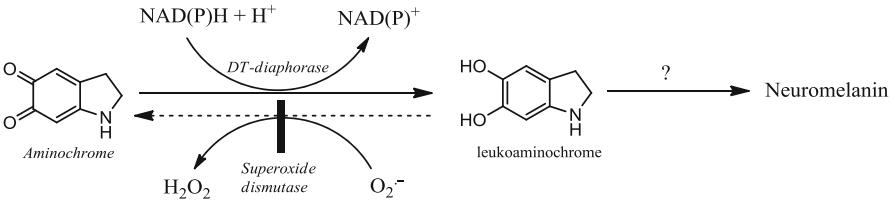

Fig. 8 DT-diaphorase catalyzes the two-electron reduction of aminochrome

different tissues and organs including the brain. DT-diaphorase immunoreactivity co-localizes with tyrosine hydroxylase-like immunoreactivity, suggesting that DT-diaphorase is expressed in the dopaminergic neurons of both the substantia nigra and ventral tegmental area. The dense network of the DT-diaphorase-immunoreactive fibers in the striatum and the dopaminergic innervations were simultaneously lost following a 6-hydroxydopamine lesion. It is important to mention that DT-diaphorase constitutes 97 % of the total cytosolic quinone reductase activity in the rat substantia nigra. DT-diaphorase immunoreactivity has also been found in Bergmann glia, astrocytes, and tanycytes (Schultzberg et al. 1988). DT-diaphorase catalyzes the reduction of aminochrome to leukoaminochrome (Segura-Aguilar and Lind 1989). Leukoaminochrome autoxidizes in the presence of superoxide radicals (Fig. 8). However, the presence of superoxide dismutase

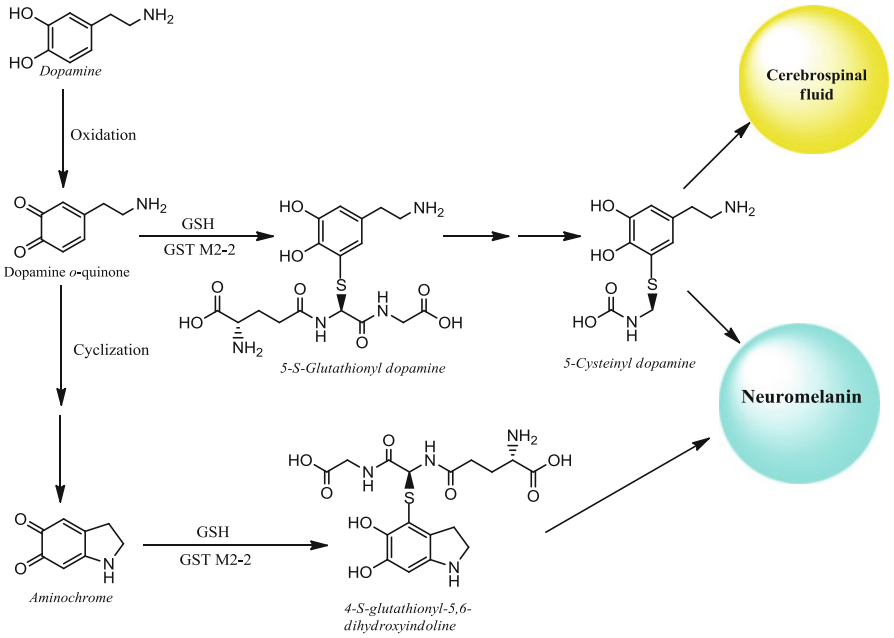

Fig. 9 Glutathione (*GSH*) conjugation of aminochrome and dopamine *o*-quinone catalyzed by glutathione *S*-transferase M2-2 (*GST M2-2*)

in the cytosol prevents leukoaminochrome autoxidation (Baez et al. 1995). These in vitro results suggest that DT-diaphorase may protect against aminochrome neurotoxicity. Cell culture studies support this idea: DT-diaphorase inhibition with dicoumarol or siRNA induces aminochrome neurotoxicity (Arriagada et al. 2004; Lozano et al. 2010; Paris et al. 2011; Muñoz et al. 2012). DT-diaphorase also prevents the formation of alpha-synuclein protofibrils (Segura-Aguilar et al. 2006; Cardenas et al. 2008) and the cytoskeletal disruption arising from adduct formation with actin and α- and β-tubulin (Paris et al. 2010).

4.5 Aminochrome Conjugation with Glutathione

Aminochrome can be conjugated with glutathione by glutathione *S*-transferase M2-2 (GST M2-2) to 4-*S*-glutathionyl-5,6-dihydroxyindoline (Fig. 9). The 4-*S*-glutathionyl-5,6-dihydroxyindoline molecule is stable in the presence of biological oxidizing agents such as oxygen, superoxide radicals, and hydrogen peroxide (Segura-Aguilar et al. 1997; Baez et al. 1997). This stability suggests that the molecule is a final elimination product. Interestingly, the precursor of aminochrome dopamine *o*-quinone is also conjugated by GST M2-2–5-glutathionyl-dopamine

(Fig. 9). This process prevents the formation of aminochrome (Dagnino-Subiabre et al. 2000). The tripeptide γ-L-Glu-L-Cys-Gly of all glutathione conjugates undergoes glutathione degradation to cysteine conjugation. Therefore, 5-glutathionyl-dopamine is ultimately converted to 5-S-cysteinyl-dopamine (Shen et al. 1996). Interestingly, 5-*S*-cysteinyl-dopamine has been detected in the cerebrospinal fluid of PD patients and in dopamine-rich brain regions such as the caudate nucleus, putamen, globus pallidus, and substantia nigra as well as in neuromelanin (Cheng et al. 1996, Rosengren et al. 1985, Carstam et al. 1991). GST M2-2 also catalyzes the conjugation of dopa *o*-quinone to 5-glutathionyl dopa. The tripeptide glutathione on 5-glutathionyl dopa undergoes degradation to generate 5-S-cysteinyl-dopa (Dagnino-Subiabre et al. 2000). Melanoma cells produce and release 5-S-cysteinyl-dopa, which is ultimately excreted through urine (Ito et al. 1984). Therefore, the conjugation of glutathione must be protective against aminochrome neurotoxicity.

4.6 Aminochrome and Parkinson's Disease

The discovery that Parkinson's disease patients show a loss of neuromelanin-containing dopaminergic neurons led to intensive research focused on understanding the mechanisms involved in the loss of dopaminergic neurons, which results in motor symptoms. Recently, the presymptomatic and symptomatic phases of Parkinson's disease were subdivided into six stages (Braak et al. 2004). The progressive loss of nigral neurons with Lewy bodies is considered to be an essential neuropathological feature. However, olfactory disturbances, sleep fragmentation, and depression precede the motor symptoms (Wolters and Braak 2006). The disease may initially affect the olfactory bulb, enteric plexus, and motor component of cranial nerve X (stage 1). It may progress to the locus coeruleus, caudal raphe, and magnocellular reticular formation (stage 2). Approximately 5 years before the manifestation of the motor symptoms, the substantia nigra, amygdala central subnucleus, Meynert's nucleus, and pedunculopontine tegmental nucleus are affected (stage 3). Approximately 4 years after the manifestation of motor symptoms, the transentorhinal cortex, CA2 plexus, and intralaminar thalamic nuclei are affected (stage 4). Approximately 10 years after the manifestation of motor symptoms, the prefrontal cortex and tertiary sensory association areas are affected (stage 5). Finally, the secondary and then the primary motor and sensory areas are affected (stage 6) (Hawkes et al. 2010).

Despite the therapeutic efficacy of L-dopa for Parkinson's disease, the role of substantia nigral neurodegeneration (stage 3) in the motor symptoms of the disease remains unclear. The association of the alpha-synuclein (Polymeropoulos et al. 1997) and parkin (Hattori et al. 1998; Abbas et al. 1999) genes with the familial form of Parkinson's disease was important in understanding possible mechanisms underlying the sporadic form of the disease. Several other genes have also been associated with familial Parkinson's disease

(for review, see Corti et al. 2011). Despite the enormous advances in the field, the neurotoxins and mechanisms involved in Parkinson's-related neurodegeneration still remain unclear. However, the mechanisms of dopaminergic neurodegeneration are generally thought to involve mitochondrial dysfunction, alpha-synuclein aggregation in neurotoxic protofibrils, protein degradation dysfunction, oxidative stress, and neuroinflammation (Schapira 2011; Conway et al. 2001; McNaught et al. 2004; Cuervo et al. 2010; Schapira and Jenner 2011).

The proposed timeline for Parkinson's disease (Hawkes et al. 2010) suggests that approximately 5 years elapse between the stage 3 damage to the substantia nigra and the appearance of motor symptoms (stage I in the Hoehn and Yahr scale). The progression of the disease after the manifestation of the motor symptoms is also very slow. It takes approximately 10 years to progress to stage III of the Hoehn and Yahr scale. These data refute the possibility that an exogenous neurotoxin is involved in the idiopathic degeneration of the dopaminergic neurons in the substantia nigra. This possibility is unlikely because MPTP induced severe parkinsonian motor symptoms in 3 days (Williams 1984). It is also important to note that the neuromelanin-containing dopaminergic neurons in the substantia nigra are lost, suggesting that the dopamine in the degenerative cells oxidizes to aminochrome, the precursor of neuromelanin.

We propose that aminochrome is the endogenous neurotoxin involved in the neurodegeneration of the neuromelanin-containing dopaminergic neurons in Parkinson's disease. This compound induces focal neurotoxic events in the years prior to the development of motor symptoms. The following evidence supports this idea: (i) Aminochrome induces mitochondrial dysfunction by forming adducts with complexes I and III in the electron transport chain as well as isocitrate dehydrogenase (Van Laar et al. 2009). The redox cycling induced by aminochrome one-electron reduction depletes NADH, thereby decreasing ATP production in cell culture (Muñoz et al. 2012). (ii) Aminochrome induces the formation and stabilization of alpha-synuclein protofibrils (Norris et al. 2005). (iii) Aminochrome induces protein degradation dysfunction by inactivating parkin (Xu et al. 1998), a ubiquitin ligase involved in the proteasomal system. In addition, alpha-synuclein protofibrils inhibit chaperone-mediated autophagy (Xilouri et al. 2009) and the 26S proteasomal system (Zhang et al. 2008). Aminochrome also induces the aggregation of α- and β-tubulin through forming adducts with these proteins (Paris et al. 2010). Tubulin aggregation prevents the microtubule formation required for the fusion of autophagocytic vacuoles and lysosomes (Monastyrska et al. 2009). (iv) Finally, aminochrome induces oxidative stress by undergoing one-electron reduction to become the leukoaminochrome *o*-semiquinone radical (Paris et al. 2001, 2005; Arriagada et al. 2004). Interestingly, aminochrome may play a role in four of the five mechanisms that are generally accepted as being involved in the degeneration of neuromelanin-containing dopaminergic neurons in Parkinson's disease.

Abstract

Parkinson's disease (PD) is characterized by a slow and progressive degeneration of dopaminergic neurons in the substantia nigra *pars compacta*. To date, despite an intensive research, the cause of the neuronal loss in PD is poorly understood. It has been postulated that neuroinflammatory mechanisms might contribute to the cascade of events leading to this neuronal degeneration. In this review, we describe the evidence for neuroinflammatory processes from *postmortem*, in vivo and in vitro studies in PD. We further identify the cellular types associated with neuroinflammation that are involved in the degeneration of dopaminergic neurons in animal models and PD patients. Overall, available data support the importance of non-cell-autonomous pathological mechanisms in PD, which are mostly mediated by activated glial and peripheral immune cells. This cellular response to neurodegeneration triggers deleterious events (e.g., oxidative stress and cytokine-receptor-mediated apoptosis), which might eventually lead to dopaminergic cell death and hence disease progression. Novel studies have also demonstrated that genetic markers could be implicated in neuroinflammation and even in the role of glucocorticoids in sustaining activated microglia in inflammatory processes. Finally, based on these evidences, we highlight possible therapeutic strategies aimed at downregulating these inflammatory processes that might be important to slow down the progression of PD.

Immunomodulatory therapy • Inflammation • Microglia • Neuroinflammation • Parkinson's disease

1 Introduction to Parkinson's Disease

1.1 Overview

Parkinson's disease (PD) is the second most common neurodegenerative disorder in developed countries and the most common neurodegenerative movement disorder (Calabrese 2007; Dorsey et al. 2007; Rochet et al. 2012; Schapira et al. 2009). It is an age-dependent disease with an average age of onset of 55 years of age, approximately 1 % of 65-year-olds are affected, and this rises to 4–5 % in 85-year-olds, while the risk for developing PD increases 5-fold by the age of 70 (Bauso et al. 2012; de Lau et al. 2004; de Rijk et al. 1997; Fahn 2003; Khedr et al. 2012). Two forms of the disease have been characterized: a sporadic form, which generally affects 95 % of all patients and whose etiology is unknown, and a familiar genetic form, which affects 7–10 % of all cases and is linked to mutations in a restricted number of genes (Dauer and Przedborski 2003; Kumar et al. 2012; Martin et al. 2011; Pastor 2012). However, during the last decades, genome-wide association studies (GWAS) have provided evident gains in interpreting the genetic of PD (Nalls et al. 2011; Satake et al. 2009; Simon-Sanchez et al. 2009), and recently, 9 of

the 11 postulated susceptibility single-nucleotide polymorphisms (SNPs) (Nalls et al. 2011) have been corroborated for PD (Sharma et al. 2012).

PD is characterized by motor symptoms like resting tremor, slowed movement, postural instability, and muscle rigidity (Reichmann 2010); however, there are other symptoms that may include olfactory dysfunctions, urinary problems, constipation, or sleep disruptions and which can halt or even slow down the progression of PD (Erro et al. 2012; Grinberg et al. 2010; Pastor 2012; Peeraully and Tan 2012). The motor symptoms can be treated with dopaminergic drugs; however, the effectiveness diminishes as the severity of the clinical symptoms increases due to progression of the underlying neurodegeneration (Schapira et al. 2009), and moreover, this treatment only improves the symptomatic motor dysfunction.

1.2 Etiology and Molecular Pathways of Neurodegeneration

PD is a neurodegenerative disorder with a complex, multifactorial etiology. In recent years, there has been increasing evidences to support a role for genetic factors in this cause. These evidences have come from twin and familiar studies, where a screening of the most potential susceptibility genes was done. Together with genetic factors, environmental factors may play a role in the disease progress; however, the most accepted theory for PD etiology is that there is a complex interplay between susceptible genes and environmental influences in the causation of PD (Kwok 2010; Soreq et al. 2012).

For non-familiar forms of PD, the dominate view is that multiple causes exist that are decisive in disease initiation and progression; among all of them the age, the genetic predisposition, and the exposition to environmental toxins are especially critical (Nagatsu and Sawada 2006). At the cellular level, three types of cellular alterations may be distinguished in the pathogenesis of PD: the production of reactive oxygen species, dysfunctions in mitochondrial respiratory chain, and an aberrant protein aggregation (Banerjee et al. 2009). Presently, mitochondrial complex I toxins, such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 1-1'-dimethyl-4-4'-bipyridinium (paraquat), and rotenone, are used for inducing nigrostriatal neuronal degeneration due to dopaminergic (DA) neurons that are specially susceptible to this substances (Meredith et al. 2008).

Following a histological point of view, within the brain the most striking pathological features are the severe loss of dopaminergic neurons in the substantia nigra (SN), the presence of proteinaceous inclusions principally composed of fibrillar α-synuclein, and ubiquitinated proteins within some remaining nigral neurons called Lewy bodies (LBs) or abnormal neurites called Lewy neurites (LNs) (Lees et al. 2009; Lewy 1912; Trétiakoff 1919). However, nowadays LBs and LNs stained with antibodies to ubiquitin, α-synuclein, and other biomarkers can be detected in other brain regions apart from the SN, like the locus coeruleus, amygdala, dorsal raphe nucleus, thalamus, and cerebral cortex (Braak et al. 2003; Halliday et al. 2011; McLean et al. 2012). This would explicate why PD debut in patients is associated not with motor dysfunctions but rather with a variety of

non-motor symptoms including those concerning the autonomic nervous system, a subset of which are prodromal and can antecede the motor symptoms by 10 years (Dubow 2007; Grinberg et al. 2010; Kaufmann et al. 2004; Poewe 2007; Tolosa and Pont-Sunyer 2011). According to Braak and Braak's *postmortem* anatomopathological studies, the first areas that are affected by the illness are the dorsal IX/X motor nucleus, medulla oblongata, and pontine tegmentum, and over time, LBs and LNs will affect midbrain regions as SN and finally neocortical regions (Braak et al. 2003). It is not until after reaching specifically the SN *pars compacta* (SNpc) (stage 3 of Braak and Braak classification) that clinical symptoms appear due to the deficits in dopamine release at the level of the striatum (Del Tredici et al. 2002; Picconi et al. 2012).

1.3 Pathogenesis of Parkinson's Disease

Among the environmental toxins, which have been postulated with the development and progression of PD, it has been suggested that pesticides (e.g., paraquat or rotenone), infectious agents (e.g., virus), and heavy metals could have a crucial role (Mizuno et al. 2001; Rohn and Catlin 2011). However, it is not important what insult initially provokes neurodegeneration, since parkinsonism animal models and the function of genes implicated in familial PD form suggest that the main culprits that trigger degeneration in SNpc dopaminergic neurons are the ubiquitin-proteasome pathway, mitochondrial dysfunction, and oxidative stress (Elstner et al. 2011; Kanthasamy et al. 2010). While the pathogenic mechanisms that ultimately cause PD are still unclear, because the key molecular and cellular events underlying development of PD are divergent, it is believed that the progressive nature of PD is characterized by the activation of neuroinflammatory pathways that over time trigger neurodegeneration (Dauer and Przedborski 2003; Gao and Hong 2008; Tansey and Goldberg 2010).

2 Neuroinflammation in the Pathogenesis of PD

Glial activation and inflammatory reactions play important roles in DA neuronal death in PD patients and animal models inducing microglial activation, disruption of the blood–brain barrier (BBB), and infiltration of peripheral immune cells (Block and Hong 2005; Choi et al. 2005; Panaro and Cianciulli 2012). However, all these changes are not exclusive of PD, since neuroinflammatory processes are also present in other neurodegenerative diseases such as Alzheimer's disease, Huntington's disease, and amyotrophic lateral sclerosis (Cunningham 2012; Hirsch and Hunot 2009). The purpose of this chapter is to describe the evidences of neuroinflammatory processes associated with the nigrostriatal DA neuronal degeneration not only in the brains of PD patients even more in animal models of parkinsonism. Finally, we will discuss the effectiveness of using specific targets on inflammatory pathways that could relent the progression of PD.

2.1 Hallmarks of Neuroinflammation

Neuroinflammation is the brain response to infections and injuries associated with most acute or chronic neurodegenerative diseases (Nencini et al. 2003; Schmidt et al. 2005). Neuropathological and neuroradiological studies have shown that prior to significant loss of neurons, a neuroinflammatory process characterized by an increase in glial activity often occurs (Frank-Cannon et al. 2009; Fuhrmann et al. 2010; Ratai et al. 2011). The dogma that the nervous and immune systems were isolated with litter interaction except during disease and/or trauma was based on the evidences that immune responses were blunted in the central nervous system (CNS) and that the blood–brain barrier (BBB) prevented infiltration of immune cells and molecules into the CNS (Prendergast and Anderton 2009). However, recently, the convergence of unexpected results from diverse fields has demonstrated a bidirectional communication between these systems. Firstly, it has been postulated for many years that the BBB was an impermeable barrier to immune cells and most diffusible factors produced in the periphery. However, last studies have clarified that, in response to insult, the permeability of BBB may increase or become dysregulated and also that cytokines produced by glial cells in the brain can cross the compromised BBB and activate immune cells (Deverman and Patterson 2009; Prat et al. 2001). In response to cytokine activity, blood-derived monocytes will migrate through the compromised BBB into the CNS and aid microglia in causing neural inflammation, degeneration, and cell death (Hakimi et al. 2011). Moreover, immune cell infiltration into the CNS is more common than previously believed. Indeed, many neurological diseases, including Alzheimer's and Parkinson's disease, are accompanied by neuroinflammation, and anti-inflammatory drugs reduce the risk for Alzheimer's and Parkinson's disease (Lucin and Wyss-Coray 2009). Secondly, there is now growing evidence that neural-immune cross talk may even occur in non-disease conditions, including in the healthy brain, where the permeability of the BBB can be regulated under normal conditions (Chung et al. 2010).

The terms neuroinflammation and neurodegeneration are intimately linked since neuroinflammation consists of an innate immune response which involves the activation of microglial cells which produces several products like cytokines, chemokines, complement cascade proteins, prostaglandins, and reactive oxygen species in response to a peripheral or central insult (Chung et al. 2010), and the term "neurodegenerative" disease, as PD and AD are, is based on the feature that it is primarily the death and dysfunction of neurons that cause disability, being, the activation of various components of the innate immune system, recognized as a feature of these "neurodegenerative" diseases (Tansey and Goldberg 2010). This association is very important under the clinical point of view because if the immune system, as it is supposed, plays any active role in a neurodegenerative disease, for better or for worse, then modifying it – enhancing favorable behaviors or suppressing harmful ones – may be capable of slowing the progression of the disease. The role of neuroinflammation in neurodegenerative diseases is still controversial, since neuroinflammatory response may exert protective but also

detrimental effects, the reason why it is suggested to be a "double-edged sword" (McGeer and McGeer 2004; Wyss-Coray and Mucke 2002).

2.2 Cell Types Involved in Neuroinflammation

In innate immunity, peripheral effectors are myeloid-derived blood monocytes that additionally give rise to macrophages and a specific type of antigen-presenting cells (APC) that are dendritic cells (DC) (Kurant 2011). The role of these macrophages/APC is performed by the brain microglia in the CNS, being the primary effectors of immune surveillance and self-renewing and arising from fetal myeloid progenitors (Eglitis and Mezey 1997). Microglia play a homeostatic role in the CNS and respond to environmental stresses and immunologic challenges by removing dying cells (Nakamura 2002), entering a state of chronic activation in which they release toxic factors resulting on ongoing damage to surrounding tissue (Ransohoff and Perry 2009). Although the key molecular and cellular events underlying development of neurodegenerative diseases are clearly divergent among them, one common way in which these divergent molecular or cellular events (e.g., aberrant protein misfoldings, peroxidations, mutations, aggregation) may all contribute over time to neuronal death is activating resident microglial populations in specific brain areas. In the case of genetic mutations or prolonged/repeated environmental exposures, where the initial stimulus that triggered microglial activation is not silenced/eliminated, a self-sustaining cycle of neuroinflammation can ensue, and such a chronic inflammatory environment is presumptive to cause neuronal dysfunctions and death of compromised neuronal populations.

Astrocytes, another member of the glial cell family, contribute to virtually every aspect of brain function, including ionic homeostasis, energy metabolism, and synaptic signalling, and play an important role in the stabilization of the permeability of the BBB (Zlokovic 2008). The varied and important roles of astrocytes have evolved to allow increasingly complex nervous systems to operate efficiently and with high fidelity. For example, astrocytes figure prominently in glutamatergic synaptic transmission, a basic event of brain function: high-affinity glutamate uptake into astrocytes meliorates the temporal and spatial fidelity of glutamatergic signalling, and astrocytes afterward move glutamine back to neurons for the synthesis of more glutamate (Hertz and Zielke 2004; Uwechue et al. 2012). Recent studies have demonstrated that the important and dynamic contributions of astrocytes to normal brain function demand that neuron and astrocyte relationship must be seen as an equal partner relation where this harmonious collaboration will produce a desired function (Ransom and Ransom 2012). So, it has to be discarded as the historical view of astrocytes as simple "scaffolding" cells; nowadays the most accurate view is to denominate astrocytes as "partner cells" (Ransom and Ransom 2012).

During past decades the role of peripheral immune cells in neuroinflammation was very controversial. Besides this controversy, increased accumulation of activated microglia and astrocytes and leukocytes adhering to postcapillary venules are

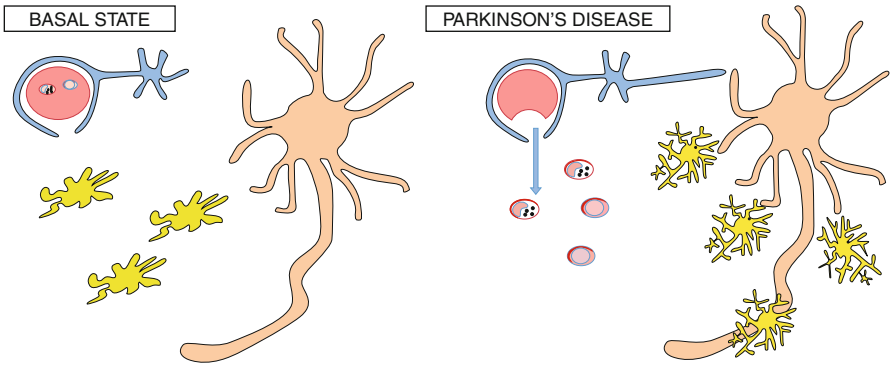

Fig. 1 Neuroinflammation triggers the activation of the peripheral immune system. Under neuroinflammatory conditions, there is a modification of the local microenvironment through early microglial activation that allows peripheral immune cell infiltration. Contributing to neuroinflammation, the presence of newly created vessels that have not likely developed the restrictive properties of the blood–brain barrier, failing to protect the parenchyma from peripheral immune cells and inflammatory factors in the peripheral circulation, has been shown

observed in the affected brain areas in neurodegenerative diseases, suggesting the presence of an ongoing inflammatory process (Casoli et al. 2010; Chung et al. 2010). As neuroinflammation triggers the activation of peripheral immune system, several studies implicated subsets of T cells taking part of the neurodegenerative processes. The mechanism related with this specific recruitment of T cells is still unknown, but it might involve a modification of the local microenvironment through early microglial activation and innate neuroinflammatory processes (Chung et al. 2010) (Fig. 1).

2.3 Evidence for a Role of Neuroinflammation in PD

2.3.1 Role of Microglia in PD

Data from postmortem studies provided the first evidence for a role of neuroinflammation in PD, since a massive microglial activity was detected in the brain of PD patients (McGeer et al. 1988b). Moreover, in postmortem investigations of humans exposed to MPTP, activated microglia have been detected 16 years after the last drug exposure (Langston et al. 1999). Since McGeer's initial observation (McGeer et al. 1988b), activated microglia have been identified in the putamen, hippocampus, transentorhinal cortex, cingulated cortex, and temporal cortex of PD brains (Imamura et al. 2003). However, since these are end-stage cases, whether this activation was a general consequence of neuronal death or the reflection of the active participation of microglia in the neurodegenerative process remains unclear (Graeber and Streit 2010).

In order to elucidate the role of microglia activation in PD, several groups have studied several animal models using MPTP, rotenone, and 6-OHDA that exhibit levels of microglial activation similar to what is found in PD (Arai et al. 1999;

Barcia et al. 2003; Carvey et al. 2005; Cicchetti et al. 2002; Gao et al. 2002). However, recent studies have demonstrated that in the case of paraquat and rotenone, microglial activation are likely non-cell autonomous and may occur as a result of dopaminergic neuron damage or by factors released by neurons and/or other cells (Klintworth et al. 2009). Similar to what has been described in MPTP-intoxicated humans, an activated microglia and dopaminergic cell loss was also found in the SN of primates years after they were treated with MPTP (Arai et al. 1999; McGeer et al. 2003), even in those parkinsonian animals never treated neither with levodopa nor with dopaminergic agonists (Barcia et al. 2004), suggesting that microglia plays an active role in the pathology of PD and may indeed perpetuate the degeneration of dopaminergic neurons once activated.

Moreover, the presence of microglial activation participating in neuroinflammatory processes has also been confirmed on a molecular basis. Levels of proinflammatory mediators, including TNFα, IL-1β, IL-6, reactive oxygen species (ROS), and eicosanoids, are elevated in the brains and peripheral blood mononuclear cells (PBMC) of PD patients (McGeer et al. 1988b; Mogi et al. 1994; Nagatsu et al. 2000; Nagatsu and Sawada 2005).

Oxidative stress is caused by an imbalance between the production and destruction of reactive oxygen species (ROS) and reactive nitrogen species (RNS). The production of ROS/RNS under neuropathological conditions would be modulated by microglial NADPH oxidase and nitric oxidase synthase (NOS) (Paramo et al. 2010). Nitrite (as an indicator for nitric oxide free radicals) in the cerebrospinal fluid, as well as increased expression of inducible nitric oxide synthase (iNOS) within the SN, was also found in PD patients (Qureshi et al. 1995). Moreover, an association between Parkinson's disease and polymorphisms in the nNOS and iNOS genes has been described (Levecque et al. 2003). In the MPTP model of parkinsonism, NADPH oxidase and inducible nitric oxidase synthase (iNOS) are known to be major sources of ROS/RNS production where they mediate DA neuronal death in SN (Liberatore et al. 1999; Wu et al. 2002, 2003). Moreover, other in vivo and in vitro studies have demonstrated that microglia-derived NADPH oxidase/iNOS play a crucial role in the production of ROS/RNS and conduce to DA neuronal death following the oxidative stress pathway (Qin et al. 2005; Rodriguez-Pallares et al. 2007). Consequently, the vast majority of therapeutic attention directed at inflammation within the CNS in patients with PD has been directed toward microglial cell activity.

Numerous investigations have proposed a deleterious role of microglial activation in PD based on the vulnerability of dopaminergic neurons to various microglia-derived proinflammatory cytokines (De Lella Ezcurra et al. 2010; Ferrari et al. 2006; Stone et al. 2009), while α-synuclein can directly induce activation of microglia and release of proinflammatory cytokines, leading to dopaminergic neurodegeneration (Hirsch and Hunot 2009; Zhang et al. 2005). Using animal models, it has been shown that α-synuclein overexpression triggers an early microglial activation in the SN as well as elicits an increased expression of proinflammatory molecules such as IL-1β and TNFα, prior to dopaminergic neurodegeneration (Kachroo and Schwarzschild 2012; Mosharov et al. 2009;

Thiruchelvam et al. 2004). In addition, α-synuclein is released from cells in vitro and is capable of directly activating microglia (Jin et al. 2007; Maguire-Zeiss 2008; Zhang et al. 2005). Taken together, these observations place α-synuclein and microglial activation together as early players contributing to neuroinflammation that may mediate ulterior dopaminergic neurodegeneration (Gao et al. 2011).

However, it seems that the plasticity of microglia must be considered with regard to their contribution in PD, and their role (whether beneficial or detrimental) may depend on the stimuli present and the stage of disease (Li et al. 2007; Michelucci et al. 2009; Sanchez-Guajardo et al. 2010).

One approach that can connect microglial activation with PD pathogenesis involves in vivo imaging. Positron emission tomography (PET) imaging in combination with the isoquinoline ^{11}C-PK11195 BP_{ND}, which is a ligand of the peripheral binding site of benzodiazepine, is used to track microglial activation (Gerhard et al. 2006a; Ouchi et al. 2005). Although there was a controversy about the efficiency of this marker as a microglial detector, based on discrepancies between in vitro and in vivo experiments, nowadays it is accepted that PK11195 binds to the peripheral binding site of benzodiazepine on activated microglia and macrophages. A significant increase in this PK1195 marker, reflecting microglial activation, was reported in the midbrain and putamen of PD patients when compared to controls, and this activation positively correlated with the motor severity of PD (Bartels et al. 2010; Ouchi et al. 2005). These findings demonstrated the crucial pathogenic importance of early microglial activation for the progression of the disease which suggested that an early introduction of neuroprotective drug to slow down or inhibit microglial activation could be a suitable therapeutic target in PD. Additionally, PD patients exhibited significantly increased ^{11}C-PK11195 BP_{ND} in the basal ganglia, pons, and frontal and temporal cortical regions (Gerhard et al. 2006a). Gerhard and colleagues demonstrated that the increased microglial activation remained unchanged for 2 years, while the patients deteriorated clinically during this period (Gerhard et al. 2006a), similar to what had been described in MPTP-induced parkinsonian monkeys (Arai et al. 1999; Barcia et al. 2004). In relation with this sustained microglial activation, it has been recently described that IFN-γ signalling, associated with TNF-α expression, has a crucial and cell-specific role in stimulating and maintaining glial cell activation in parkinsonism (Barcia et al. 2011).

In sum, PET imaging and in vivo and in vitro studies support the hypothesis that microglial activation occurs early in PD where they remain activated for longer periods and possibly drive progression of the disease (Gerhard et al. 2006a, b) (Fig. 2).

2.3.2 Role of Astroglia and Oligodendroglia in PD

Astrocytes, the major glial components of the CNS, constitute up to 20–50 % of brain volume and provide the optimal microenvironment for neuronal function by exerting active control on the cerebral blood flow (Gordon et al. 2008; Mulligan and MacVicar 2004). Although the presence of reactive astrocytes is evident in the most affected brain areas of PD patients having a role in the progression of the disease (Forno et al. 1992; Teismann and Schulz 2004), the specific role of this cell type is still unclear. It was previously described that one of the main functions of astrocytes is to secrete neurotrophic factors in SN for inducing the survival of dopaminergic

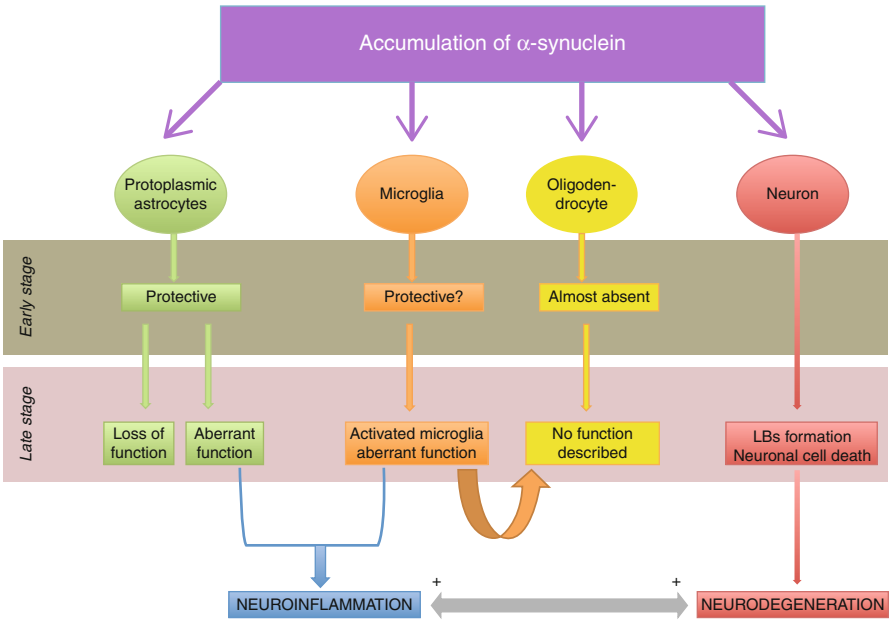

Fig. 2 Effect of α-synuclein accumulation on neuroinflammation associated with PD. Associated with PD, there is an accumulation of α-synuclein at different levels. During the early stages of neurodegeneration, astrocytes may quickly respond to α-synuclein released from degenerating neurons to protect against neurodegeneration. During the long time course of neurodegeneration, the activated astrocytes may lose their protective properties or might be aberrantly activated, leading to stimulation of neuroinflammation. On the other hand, microglia may be as well protective during the early stages of neurodegeneration, but at late stages of the disease, it would be aberrantly activated, contributing to neuroinflammation and perpetuate neurodegeneration. Concerning oligodendrocytes, the presence of α-synuclein deposits in oligodendroglial cells has been described, but its function is still not clear

neurons (McGeer and McGeer 2008). Although the relationship between reactive astrocytes and the release of neurotrophic factors is ambiguous, based on previous studies it was concluded that the decreased levels of astrocyte-derived neurotrophic factors are directly responsible for dopaminergic neurodegeneration in PD (Knott et al. 2002; Saavedra et al. 2006; Sandhu et al. 2009).

As it was previously described in this chapter, Lewy pathology follows a progressive pattern beginning in the anterior olfactory structures, dorsal motor nucleus of the vagal nerve, and portions of the enteric nervous system and evolving in caudo-rostral manner within the CNS (Braak and Del Tredici 2008). Unexpectedly, as PD progressed, α-synuclein-positive inclusions were also detected in astrocytes that were not known to produce α-synuclein (Wakabayashi et al. 2000). However, recent works have demonstrated, in cultured cells and α-synuclein overexpressed animal models, that α-synuclein proteins released from neuronal cells are taken up by astrocytes through endocytosis and form inclusion bodies, and this abnormal inclusions incite changes in astrocytic gene expression profiles reflective of

a proinflammatory response (Lee et al. 2010; Tousi et al. 2012). Finally, it was recently described that of the two main types of astrocytes, fibrous and protoplasmic, only protoplasmic astrocytes are involved in PD, where they become nonreactive and accumulate α-synuclein (Halliday and Stevens 2011). In sum, glial cells are responsible for the progression of PD and play an important role in initiating the early tissue response. In particular, early dysfunction and α-synuclein accumulation in astrocytes causes recruitment of phagocytic microglia that attack selected neurons in restricted brain regions causing the clinical symptoms of PD (Halliday and Stevens 2011) (Fig. 2).

In relation with oligodendrocytes, although neuroinflammation associated with PD has been attributed to activated microglia and astrocytes in both SN and striatum, the role of oligodendrocytes is unknown. Despite the presence of α-synuclein-positive filamentous inclusions in oligodendrocytes in the midbrain of PD patients, which was almost absent in PD patients with mild nigral degeneration (Khedr et al. 2012; Wakabayashi et al. 2000), the correlation between oligodendrocytes and parkinsonism has been barely explored (McGeer and McGeer 2008; Takagi et al. 2007). Recently our group has described in the MPTP model of parkinsonism that the loss of dopaminergic neurons and of their axons projecting to the striatum, in MPTP-induced parkinsonism in both mice and macaques, is accompanied by a prominent oligodendrogliosis along the nigrostriatal pathway, which significantly presents a negative correlation with striatal dopaminergic innervation (Annese et al. 2012). This exacerbation in oligodendroglial response could be induced by the cytokines released by both microglia and astrocytes involved in neuroinflammation (Arai et al. 1999; McGeer and McGeer 2008) (Fig. 3). However, the function and mechanisms triggered by oligodendrocytes and the importance of these α-synuclein deposits must be further investigated in both experimental models of parkinsonism and PD.

2.3.3 Role of T Cells in Mediating Neuroinflammation-Induced PD

A role of T cells in neuroinflammation associated with neurodegenerative diseases had been several times denied based on the idea that the CNS has traditionally been considered "immune privileged" due to the presence of innate microglia and the protection of the BBB, but recently numerous evidences have discarded this hypothesis. In relation with PD, a role for an adaptive immune response in the etiology of PD has been also demonstrated. For example, the presence of T lymphocytes in the midbrain of PD patients suggests that the potential role of infiltrated peripheral cells is related to PD pathogenesis (McGeer et al. 1988a). Even more, T cell infiltration has been found in CNS tissues of PD patients (Brochard et al. 2009; Miklossy et al. 2006), and a markedly increase in the density of IFN-γ–positive cells has been detected in brains of PD patients (Hunot et al. 1999). Moreover, there are reports indicating that nitrated α-synuclein activates peripheral leukocytes in draining lymphoid tissue and mediated adaptive immune responses in potentiating microglial activation and exacerbating neuronal death (Benner et al. 2008). However, whether this inflammation is the consequence or the cause of neuronal injury is still unclear. Recently, it was reported that $CD4^+$ T cells are cytotoxic in a MPTP parkinsonism model; therefore, invading $CD4^+$

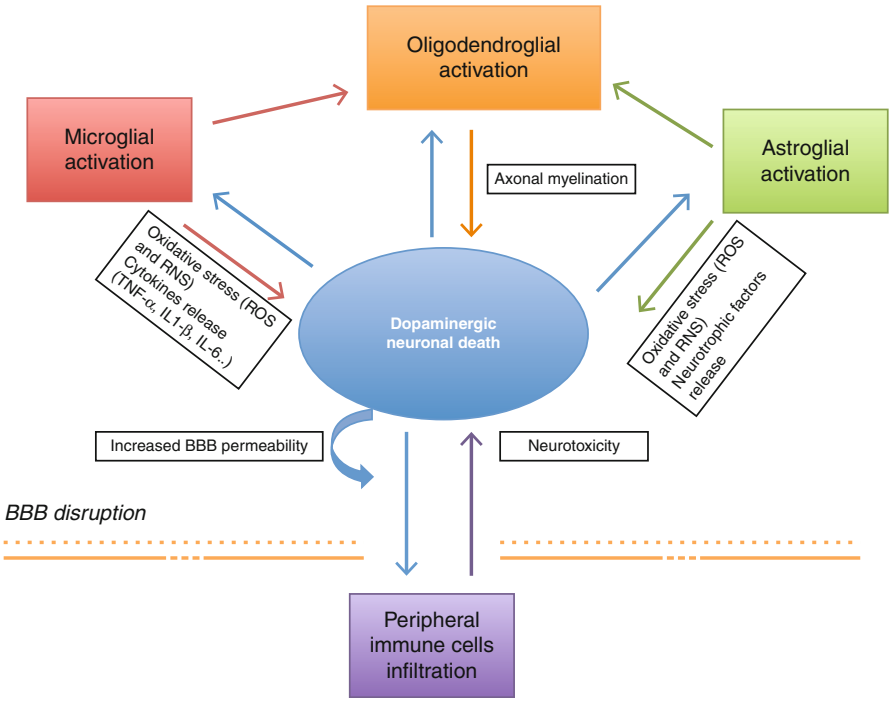

Fig. 3 Processes implicated in neuroinflammatory pathway associated with PD. Dopaminergic cell death induces microglial activation, a reactive astrocytic response, and also blood–brain barrier (BBB) disruption. Through the "hole" in the BBB, peripheral immune cells are allowed to infiltrate. This exacerbated neuroinflammation inducing increased neuronal death through the release of ROS/RNS oxidative products, cytokines, and neurotrophic factors

T cell-mediated immune response contributes to DA neurodegeneration through the Fas/FasL pathway (Brochard et al. 2009). These studies innovatively implicate the adaptive immune system, similar to the innate immune system, not only in the response to but also in an active participation in the pathogenesis of PD. However, more work needs to be done to determine if and how they will serve as a potential target for therapy in PD (Fig. 3).

2.4 Genetic Markers in PD

Numerous monogenic genes have been associated with familial forms of PD (Satake et al. 2009; Simon-Sanchez et al. 2009; Tan and Skipper 2007; Tan et al. 2007), but this accounts for only 10 % of the PD population, a reason why the relative contribution of genes and environmental factors in these cases of sporadic PD is still unclear (Tan and Skipper 2007). In the last years, a few common genetic risk variants could be associated with PD, but this is far to explain the etiology of all the cases (Hill-Burns et al. 2011; Tan et al. 2007). However, recent genome-wide

association studies have identified genetic markers linked to neuroinflammation, providing an open window to understand the pathophysiologic mechanism of PD (Hamza et al. 2010; Nalls et al. 2011; Satake et al. 2009; Simon-Sanchez et al. 2009). In the last decade, various studies suggested a possible influence of HLA alleles (HLA-DR and HLA-DQ) in PD (Hill-Burns et al. 2011; Montgomery et al. 2010; Stranger et al. 2007).

This hypothesis was demonstrated in anatomopathological studies, where PD brains exhibited upregulation of DR antigens and presence of DR-positive reactive microglia (McGeer and McGeer 2008), and in a genome-wide association study, which demonstrated a specially significant correlation between HLA-DR allele and late-onset PD (Hamza et al. 2010; Hill-Burns et al. 2011; Kumar et al. 2012). On the other hand, other studies have analyzed the relationship between a given genetic polymorphism in neuroinflammation-associated genes and the risk of PD. The most consistent genetic evidence implicates TNF in the initiation and progression of PD; a single polymorphism in the TNF promoter resulted in a higher TNF production especially overrepresented in early-onset sporadic PD (Nishimura et al. 2001; Wahner et al. 2007; Wu et al. 2007). On the contrary, TNF polymorphisms affecting its receptor 1 have been found to be significantly decreased in PD patients (Kruger et al. 2000). Other studies on single-nucleotide polymorphisms in the IL-1α and IL-1β families also corroborate the genetic role in the PD-associated neuroinflammation (Hirsch and Hunot 2009).

This genetic association between inflammatory genetic markers and PD suggests a strong influence of genes on the neuroinflammation process linked to PD and offers new targets for drug development and pharmacogenetics.

2.5 Glucocorticoids and PD

The human being is born with the ability to respond to stress, and the physiological stress response begins when the brain detects a homeostatic challenge and activates the sympathetic nervous system, which releases catecholamines, followed by the slower activation of the hypothalamic-pituitary-adrenal (HPA) axis: hypothalamic secretion of corticotropin-releasing hormone into the pituitary portal circulation activates pituitary secretion of adrenocorticotropic hormone, which then induces the glucocorticoids (GCs) that are secreted by the adrenals (Papadimitriou and Priftis 2009; Sorrells et al. 2009). Interestingly, the functioning of the HPA axis exhibits an enormous individual variability that aids to justify the considerable individual differences in vulnerability to stress-related disease, including psychiatric disorders and neurodegenerative diseases.

GC-GR responses to neuronal injury are complex, for instance, an excess of GCs (such as occurs in chronic stress) was found to aggravate neuronal injury in experimental ischemia (Sorrells et al. 2009), while an important neuronal survival effect of GR was presented in an acute lipopolysaccharide (LPS)-induced inflammatory lesion model (Nadeau and Rivest 2003). Several reports have proposed that the GC-GR responses might be crucially linked to PD pathogenesis. Thus, chronically high levels

of GCs were shown to exacerbate motor deficits in 6-hydroxy-DA-treated rats (Smith et al. 2008). This experimental observation corroborates clinical data showing that stress can trigger or worsen motor symptoms in PD patients (Smith et al. 2002). The involvement of GC-GR in DN survival after MPTP intoxication was suggested previously in adrenalectomized mice (Sugama et al. 2009) as well as in transgenic mice harboring antisense GR (Morale et al. 2004).

Recent studies by our group, linking neuroinflammation in PD pathogenesis and the mechanistic actions of GR, exposed that GR is associated with the p65 subunit of NF-κB in microglia nuclei and modulates the transactivation potential of NF-κB (Ros-Bernal et al. 2011). GC-GR system is altered in PD and this may adversely affect DN survival (Barcia et al. 2009). GR dysfunction in PD may result in a chronic inflammatory reaction, and further in-depth work on its glial actions might open innovative therapeutic perspectives.

3 Anti-inflammatory Therapy in PD

The hypothesis that neuroinflammation is extremely implicated in PD progression has become more and more convincing due to the accumulation of preclinical studies, imaging studies, and *postmortem* analysis studies that strongly implicate inflammatory processes in the progressive degeneration of the nigrostriatal pathway. Up to now, it has to be determined if anti-inflammatory therapy in humans could induce any beneficial alteration in PD progression.

Previous clinical trials with anti-inflammatory compounds have failed probably because of many reasons such as the advance stage of the patients enrolled, the dose regimen, or the wrong chosen compound. According to this, minocycline, which was successful in a phase II clinical trial, attenuating nigrostriatal DA neurodegeneration in an animal model (Du et al. 2001; Peng et al. 2006; Ravina et al. 2006), has been proved in a phase II clinical trial with controversial effects (Dodel et al. 2010). Therefore, we need more clinical studies before dismissing the effectiveness of long-term anti-inflammatory compounds. However, taking into account that the innate inflammatory response is not always detrimental, even beneficial (Wyss-Coray 2006), maybe the long-term inhibition of inflammatory response is detrimental for PD treatment (Kanthasamy et al. 2010; Wyss-Coray and Mucke 2002). Instead, more selective targets of inflammatory mediators and participants in cell-death pathways could be considered in future therapies to prevent neuronal loss in PD.

Recent studies have demonstrated that specific drug treatment does appear to reduce susceptibility to PD and immunomodulatory therapies are currently a major area in PD research (Appel et al. 2010; Li et al. 2011). Based on peripheral immune cell activation, immunomodulatory therapeutic strategies may develop vaccines for antigens to trigger cell-mediated anti-inflammatory responses (Benner et al. 2008; Brochard et al. 2009) as well as, once it is clear that BBB is altered in PD, to hamper the migration of immune cells across this BBB (Tan and Skipper 2007). Moreover, these immunomodulatory strategies may also be of

interest for cell transplantation therapies in order to induce a longer survival of grafted DNs which are affected by such an immune-related hostile microenvironment (Satake et al. 2009).

4 Conclusion

Neuroinflammation is widely considered to participate in the progression of PD (Table 1). Microglia-derived inflammatory factors such as TNF-α and IL-1β trigger harmful downstream signalling pathways and accelerate neuronal death in the SN. Activated microglia also increase the production of ROS that impose oxidative stress on the intra-neuronal antioxidant system, consequently exacerbating neurodegeneration in PD. But not only microglia, even astroglia and maybe

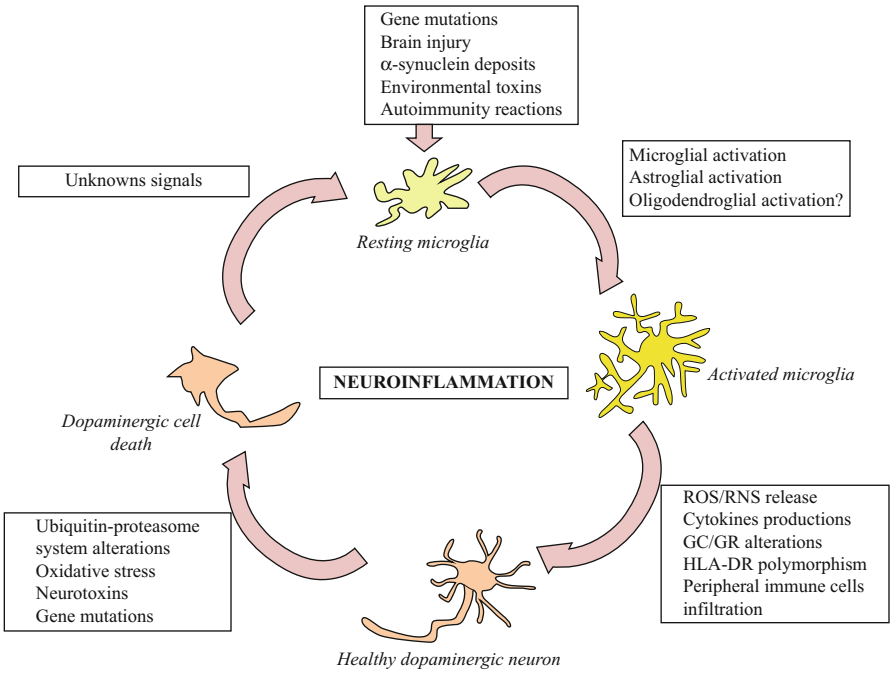

Fig. 4 Neuroinflammatory steps associated with dopaminergic cell death. Diverse initiation processes including gene mutations, brain injury, and alpha-synuclein deposits will activate immune cells in the CNS inducing microglial and astroglial activation, the production of cytokines (TNF-α, IFN-γ, etc.), and the release of oxidative species such as ROS and RNS. This neuroinflammatory response may also include the involvement of components of the peripheral immune system and the alteration of the GC/GR pathway. As a result of this neuroinflammatory process, an environment of sustained increase of inflammatory and oxidative stress in the SNpc would be created. Alternatively, a healthy neuron may become dysfunctional as a result of alterations in the ubiquitin-proteasome system, direct exposition to neurotoxins, and the general oxidative stress inducing the dopaminergic cell death. Finally, this dying/dead dopaminergic neuron would secrete unknown signals that would induce phagocytosis by activated microglia (Adapted from Tansey et al. 2007)

oligodendrocytes have a main role in controlling neuroinflammatory processes in PD. In relation to the sustained microglia activation, GC-GR system is misbalanced in PD and contributes to the neuroinflammatory processes, where some genetic markers such as HLA-DR could be the new targets for drug development and pharmacogenetics against neurodegeneration (Fig. 4).

In sum, the inflammatory component of PD is having significant attention among researchers, and it will probably be assumed in the clinical scenario in the coming years. To date, there are numerous preclinical trials testing the protective effects of anti-inflammatory drugs in animal models of parkinsonism, and we expect that hopefully some of them will soon be brought into phase I trials. However, further researches on novel targets are needed to understand the specific aspects of neuroinflammation in PD.

Neuromelanin and Parkinson's Disease

Giorgia Greco

Contents

Abstract

Dark pigmented organelles, present in catecholaminergic neurons in specific brain regions, are indicated with the term neuromelanin (NM). They are complex structures, mainly comprised by granules of melanin polymer, closely associated with peptide and lipid components. Although NM is present in several animals, it is considered as a unique feature of the man due to the extremely higher degree of pigmentation, even in comparison to other primates. For a long time NM was considered an inert cellular waste product of poor interest that in the absence of mechanism of removal accumulates during the entire lifespan. Just recently, NM has received renewed attention for its role in Parkinson's disease (PD), where a

selective death of the NM-containing neurons of the substantia nigra (SN) pars compacta is observed, while nonpigmented neurons are mostly spared. A physiological accumulation of NM seems to be a protective phenomenon, which prevents several neurotoxic processes. In particular, in dopaminergic neurons of SN, where no ferritin has been detected, NM appears to function as an iron storage system. However, in PD patients NM released by dying neurons can trigger a vicious circle of neuroinflammation and ensuing neuronal death. This chapter presents the structure, the production, and the development of NM, as well as the recent hypotheses about physiological NM role and its behavior in pathological conditions.

5,6-dihydroxyindole • 5-*S*-cyteinyldopamine • Benzothiazine • Casing model • Catecholaminergic neurons • Dolichol • Dopaminequinone • Dopaminochrome • Eumelanin • Ferritin • Melanin, peripheral • Microglia activation • Mixed melanogenesis • Neuromelanin • NM, age • NM casing model • NM, degradation products • NM, electron density • NM, enzymatic control • NM, iron binding sites • NM, iron level • NM, iron storage system • NM, lipid component • NM membrane • NM, metal chelator • NM, neuron selective death • NM organelle • NM, organic molecule interaction • NM, oxidation potential • NM, peptide component • NM pigment • Pheomelanin • Pigmented neurons

List of Abbreviations

4-AHPEA	4-amino-3-hydroxyphenylethylamine
AFM	Atomic force microscopy
DA	Dopamine
DAQ	Dopaminoquinone
DOPA	Dihydroxyphenylalanine
DQ	DOPA-quinone
FEL	Free-electron laser
NM	Neuromelanin
PD	Parkinson's disease
PDCA	Pyrrole-2,3-dicarboxylic acid
PEEM	Photoelectron emission microscopy
PTCA	Pyrrole-2,3,5-tricarboxylic acid
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SEM	Scanning electron microscopy
SN	Substantia nigra
TDCA	Thiazole-4,5-dicarboxylic acid
TTCA	Thiazole-2,4,5-tricarboxylic acid

1 Introduction

Neuromelanin (NM) is a natural brown-black polymeric pigment present in the highest concentration in the catecholaminergic neurons of substantia nigra (SN) and locus coeruleus of human brain.

This pigment belongs to the melanin family, which members include the peripheral melanins, responsible in the mammalian for the coloration of hair, skin, and iris (Prota 1992).

NM has stimulated the interest of numerous scientists for almost one century. Pigmented neurons were observed in man since the 1930s, and it was long assumed that the intense pigmentation of selected brain regions was a unique feature of the human being and did not occur even in other primates (Adler 1939; Foley and Baxter 1958). Some years later, the pigment was observed in SN of the adult gorilla (Adler 1942), chimpanzee, orangutan, gibbon, certain old-world monkeys and lemurs (Scherer 1939), cat and dog (Brown 1943), and horse (Gillilan 1943). On the basis of these results, Marsden (1961) investigated systematically the distribution of the pigment in SN of mammals in 49 species from 11 mammalian orders, founding that the dark granules were present in the nigral cells of the members of the Primates, the Rodentia, the Carnivora, the Perissodactyla, the Artiodactyla, the Xenarthra, and the Marsupialia. The pigmented cells varied from animal to animal only in regard to their number and intensity of the pigmentation. Interestingly, the SN cells of all the examined 16 species of the Primate order were pigmented and more intensely respect to the members of the other orders, reaching the highest degree of pigmentation in man. However, the presence of the pigment in such a wide variety of mammalian orders did not lead to any indication to its function in the brain.

Therefore, for a long time NM was considered an inert cellular waste product of poor interest. Just in recent years, NM has received renewed attention for its role in Parkinson's disease (PD), one of the most common neurodegenerative disorders with clinical features among which bradykinesia, rigidity, tremor, and postural instability (Calne et al. 1992; Gelb et al. 1999). These classic motor symptoms result from the progressive and selective death of the NM-containing neurons (NM, neuron selective death) of the SN pars compacta, which form an integral part of the basal ganglia motor circuit (Double 2012). The loss of the NM-containing neurons of SN is the main pathological process observed in PD, while nonpigmented neurons are mostly spared (Bush et al. 2006), and this is considered a criterion required for a confirmed diagnosis of PD (Braak et al. 2003).

Many questions about the significance of NM are still awaiting answers, despite it may be of primary importance for providing information to the etiology of PD. Until now no unambiguous physiological role has been defined for NM, as well as the relationship between the presence of NM and the neuronal susceptibility has not yet been clarified. In addition, NM biosynthesis, whether it is enzymatically controlled or results from an autoxidation pathway, is still object of investigation.

In this chapter, the distribution, the structure, the biosynthesis, and the development of NM in the human brain are presented. Moreover, the recent hypotheses about NM physiological role, also in relation to its architecture, and NM pathogenic action in the selective degeneration of pigmented neurons during PD are discussed.

2 Distribution and Appearance of Neuromelanin (NM)

In man NM is mainly found in the cytoplasm of the catecholaminergic neurons of the SN pars compacta of the midbrain and in the neurons of the locus coeruleus within the pons, where almost all the neurons are pigmented and a darkened area can be seen macroscopically (Fedorow et al. 2005a). Some pigmented neurons are also found in other regions of the pons and the midbrain, in the hypothalamus, and medulla oblongata (Bazelon et al. 1967; Rosengren et al. 1985), where, however, the number of NM-containing cells is around tenfold lower than those in SN (Bogerts 1981).

Only dopamine (DA) and noradrenaline neurons are reported to contain NM, while no NM is preset in adrenaline neurons. Interestingly, within the brain not all the DA and noradrenaline neurons produce NM. The pigment is found in 95 % of the DA neurons of SN, only in 50 % of the neurons of the ventral tegmental area, and other DA neurons, as, for example, those of the olfactory bulb do not produce the pigment at all (Double et al. 2008). This suggests that even though DA or noradrenaline is required for NM biosynthesis, their presence within the neurons does not ensure NM production.

Due to the number of pigmented neurons in human SN pars compacta and the high concentration of pigment inside the cells, NM isolated from SN is the most studied pigment. It has been evaluated that NM levels in a middle-aged man without any neurological disorders are around 2 μg/mg wet weight of SN (Zecca et al. 2002a).

Scanning electron microscopy (SEM) and atomic force microscopy (AFM) images of NM have revealed that the dark pigment is composed by granules with an average diameter of ∼350 nm, comprised of small spherical particles of ∼30 nm diameter (Bush et al. 2006). Similar morphological organization with substructures of spherical constituents with diameters on the order of 30 nm has been observed also for other members of the melanin family, among which the natural melanin from the ink sac of the cuttlefish *Sepia officinalis* and the melanin isolated from human hair and from bovine and human eyes (Liu and Simon 2003). Besides the natural occurring pigments, also SEM images of bioinspired synthetic melanin have revealed tightly aggregated globe-like nanosized particles with an average diameter of 39 ± 9 nm, resembling the architecture of the natural melanins (Greco et al. 2011).

Differently from the other members of the melanin family, NM pigment is naturally found as organelles (NM organelle) comprising three different electron-dense constituents (NM, electron density). The dark electron-dense component, identified as the melanin polymer itself, is closely associated with a component of intermediate electron density and an electron-lucent component, suggested to be

lipid (Duffy and Tennyson 1965; Moses et al. 1966). The question of whether NM is surrounded by a membrane or not is still debated. Early studies clearly showed that the organelles are membrane bound (Moses et al. 1966; Hirosawa 1968), whereas other works did not confirm this observation (Duffy and Tennyson 1965). Recently, NM synthesis was induced in rat SN neurons and cell cultures by exposure to DOPA (dihydroxyphenylalanine). These model organelles were surrounded by a double membrane separated by ~15 nm. NM isolated from human SN showed similar features, but no strong evidence for the existence of a double membrane was provided (Sulzer et al. 2000). The controversial information in several papers about NM membrane may be the consequence of different purification methodologies, which could alter the aspect of the granule. It has also been proposed that a lack of a clear evidence for a membrane enclosing the NM organelle may be due to the difficulties of preserving membranes in the human brain postmortem (Fedorow et al. 2005a). Further studies are necessary to clarify the presence of a membrane that may play an important role in moderating or even preventing the interaction of the pigment with other neuronal constituents.

A recent investigation has revealed the presence of dark pigmented areas in noncatecholaminergic neurons and in brain regions other than SN and locus coeruleus (Zecca et al. 2008). The organelles observed in neurons of the putamen, premotor cortex, and cerebellum exhibited three components of different electron density surrounded by a double membrane, resembling the NM of SN. The electron-dense component was comprised of substructures of 30 nm diameter and was identified as a member of the melanin family on the basis of its physical-chemical properties.

The pigment was termed NM too, even if it derives biosynthetically from the different precursor DOPA, instead of DA or noradrenaline. The study has shown that pigmented aggregates with common structure, behavior in aging, and interaction with metal ions and lipids, besides NM of SN and locus coeruleus, are ubiquitous within the human brain (Zecca et al. 2008). This result opens new and interesting questions about the function of melanin pigments in the human central nervous system. In particular, the peculiar NM architecture involving different constituents suggests that NM is not likely to be a waste product without significance, as considered until some years ago.

3 Structure of NM

The present information about NM structure derives prevalently from studies performed by several independent research groups on NM isolated from human SN. In addition to the dark melanin pigment, peptide and lipid components concur to form the NM structures of different electron density observed in electron micrographs. The peptide component is covalently bound to the melanin structure and corresponds to ~15 % of the NM weight, while lipids are adsorbed on the surface of the pigment and account for ~20 % of the NM weight (Zecca et al. 2000). In the following paragraphs, the melanin pigment, the peptide, and the lipid components of NM granule are discussed in detail.

3.1 The Melanin Pigment

NM pigment is considered a member of the melanin family, as similarly to the pigment of skin, eyes, and hair, it is a heterogeneous low soluble aromatic polymer, with a stable free radical and high affinity for transition metals (Bridelli et al. 1999).

Several experimental evidences support the common view that in vivo NM derives from oxidation of DA (Double et al. 2008). Two complementary strategies, also used for the coetaneous melanin, have been employed to study the structure of the pigment. Naturally occurring NM has been investigated by different chemical degradation methods and following analysis of the liberated products, while the polymer formation has been mimicked in vitro by oxidation of DA and isolation of intermediate compounds (Wakamatsu et al. 2003; Tse et al. 1976; Young and Babbitt 1983; Zhang and Dryhurst 1994). At the present, in vitro oxidation of DA is commonly used for the preparation of synthetic pigments, as models of NM (Double et al. 2000; Zareba et al. 1995). Both degradative and biosynthetic strategies have shown that NM comprises two distinct classes of polymers: eumelanin and pheomelanin. The pathway for NM biosynthesis has been suggested to be similar to that for the synthesis of peripheral melanins (Ito and Wakamatsu 2006). The first step is DA oxidation to dopamine quinone (DAQ) that for intramolecular cyclization and further oxidation is converted into dopaminochrome. This a reactive specie that can rearrange to 5,6-dihydroxyindole, which for polymeric oxidation leads to the eumelanin. Alternatively, DAQ conjugates to L-cysteine, with ensuing formation of isomeric cisteinly dopamine adducts, mainly 5-*S*-cyteinyldopamine. This adduct for oxidation, followed by intramolecular cyclization of the cysteine chain, gives rise to benzothiazine units, which polymerize leading to the pheomelanin (Zhang and Dryhurst 1994) (Fig. 1).

Peripheral eumelanin and pheomelanin pigmentation (Melanin, peripheral) has been more extensively studied. Both pigments derive from a common precursor, the DOPA-quinone (DQ). Eumelanin appears as a dark pigment responsible for the brown-black coloration of skin and hair, while pheomelanin determines the carroty to fire-red color of hair, commonly found in Celtic populations. Over the past 30 years, chemical analyses have been performed that enable the quantification of the amount of eumelanin and pheomelanin present in a naturally occurring sample of melanin. These works collectively reveal that more often than not, natural melanin pigments consist of both eumelanin and pheomelanin in varying ratios (Ito and Wakamatsu 2003; Thody et al. 1991). Recently, by the use of modern surface techniques, in particular photoelectron emission microscopy (PEEM) coupled to a free-electron laser (FEL), it has been shown that human black hair melanin has a surface oxidation potential of −0.2 V versus the normal hydrogen electrode, attributed to the eumelanin, while melanin form red hair has two surface oxidation potentials of −0.2 and +0.5 V, respectively. The negative potential has been ascribed to eumelanin pigment, whereas the positive to the pheomelanin one. This indicated that melanin from red hair has both types of melanin on or near their surface, and on the basis of the oxidation potential values, eumelanin is an antioxidant, while pheomelanin exhibits a prooxidant behavior (Ito 2006; Simon et al. 2009).

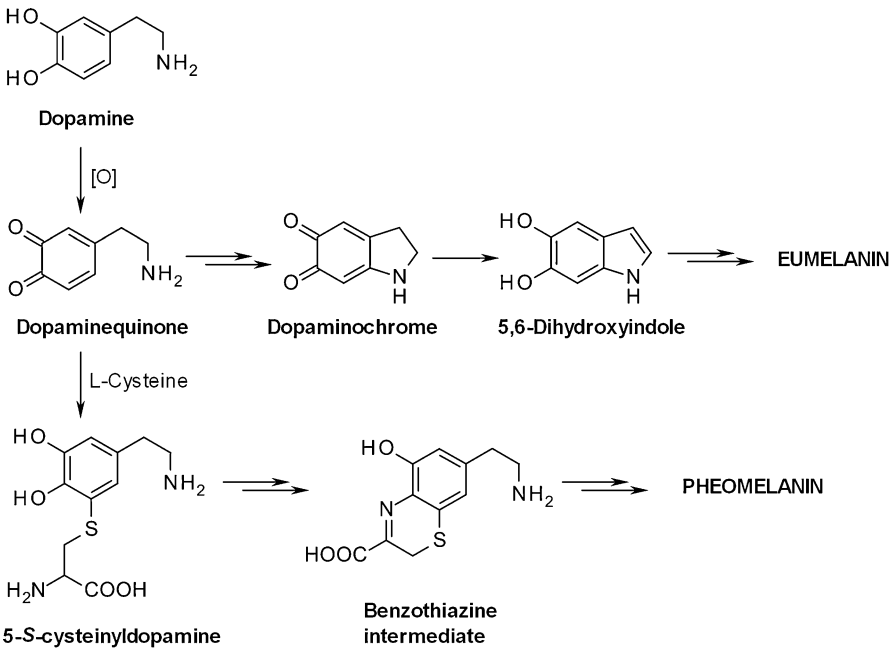

Fig. 1 Formation of indole and benzothiazine units from DA oxidation and their polymerization to eumelanin and pheomelanin pigment of NM granule

Supported by biochemical evidence, a casing model (NM casing model) with a pheomelanin core encased in a eumelanin shell was proposed in 1982 and since then it has been sustained by different other studies (Agrup et al. 1982; Simon and Peles 2010). On the basis of this model and on the eumelanin/pheomelanin ratios, the melanin granule from red hair results to have a tinier eumelanic coat, exposing the pheomelanin core. In the last years epidemiological and clinical data support the hypothesis that eumelanin is photoprotective, defending the tissues from UV-induced damages, whereas pheomelanin may be the main cause of the abnormal susceptibility to erythema and skin cancer, observed in red hair people (Bliss et al. 1995).

Two microanalytical methods, initially developed to quantify the amount of eumelanin and pheomelanin in cutaneous tissues and hair, have been applied to NM isolated from SN (Wakamatsu et al. 2003). The first method consists in the alkaline hydrogen peroxide oxidation of the sample, followed by quantification of pyrrole-2,3-dicarboxylic acid (PDCA) and pyrrole-2,3,5-tricarboxylic acid (PTCA), degradation products of eumelanin (NM, degradation products), and thiazole-4,5-dicarboxylic acid (TDCA) and thiazole-2,4,5-tricarboxylic acid (TTCA), degradation products of pheomelanin. The second method is specific for pheomelanin and it is based on the quantification of 4-amino-3-hydroxyphenylethylamine (4-AHPEA), arising from reductive hydrolysis of the pigment with hydriodic acid (Fig. 2).

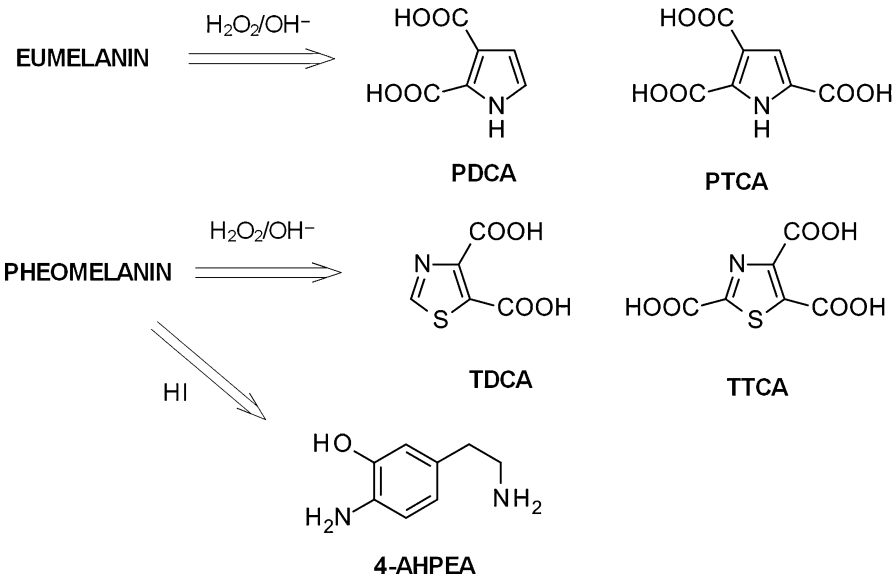

Fig. 2 Degradation products of eumelanin and pheomelanin pigment by treatment of NM granule with alkaline hydrogen peroxide or hydriodic acid

These methods showed in NM isolated from SN the presence of eumelanin and pheomelanin in a ratio of 3:4 (Wakamatsu et al. 2003). FEL–PEEM analysis has revealed for NM granules a single oxidation potential (−0.1 V) (NM, oxidation potential), indicating the presence of only eumelanin on the surface; no superficial pheomelanin have been detected (Bush et al. 2006). Therefore, the eumelanin surface is built up on the pheomelanin core according to the casing model (Fig. 3).

X-ray diffraction studies have shown that NM granule of SN, as other natural peripheral melanin, has a multilayer three-dimensional structure, composed by planar overlapped sheets at about 4.7 Å of distance (Zecca et al. 2008). Just recently the pheomelanin core is receiving attention. By X-ray absorption spectroscopy, the atomic structure around the atom of S in natural and synthetic NM has been investigated, revealing for the first time in a direct and nondegradative way the presence in human NM of heterocyclic S of the benzothiazine type (Crippa et al. 2010).

3.2 Peptide Component in NM

Whereas several efforts have been directed to the comprehension of the pigment structure, only recently the presence of other components in NM granule has been investigated. Zecca et al. (2000) showed a peptide component in NM (NM, peptide component), after treatment with different strong agents for protein removal.

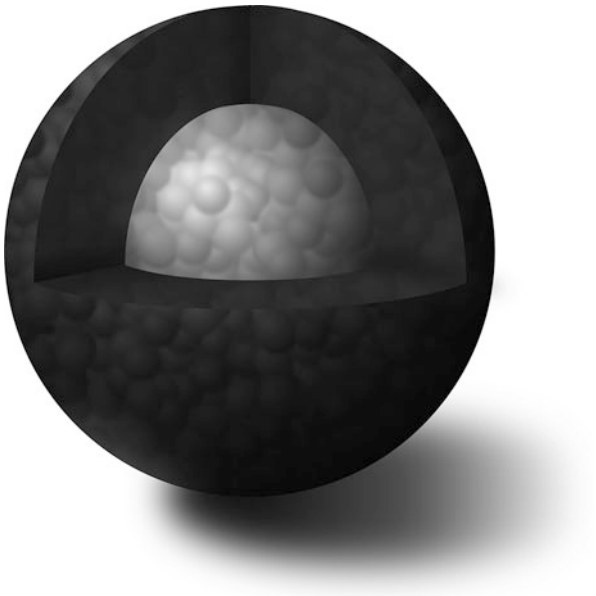

Fig. 3 Representation of NM pigment according to the casing model. A portion of the dark eumelanin surface is cut away to reveal the lighter inner pheomelanin core. Both melanin components are comprised of small spherical particles

The peptides resulted to be covalently bound to the melanin structure, as shown by comparison with a treatment for eliminating only noncovalently bound proteins. The peptide residues were present even after digestion with proteolytic enzymes, indicating that the peptide chains are in some way sterically protected by the melanin pigment. Furthermore, synthetic melanin incubated in brain homogenate showed the ability to bind peptides chemically.

The cysteine units in the intact bound peptide chain represent ~3 % of the entire amino acid content, and their amount is almost unchanged in the strongly bound peptide residues, suggesting that they are localized in proximity of the pigment. The association of melanin to peptide component may result from a direct reaction of catechol moieties of the indole units on the surface of NM granule with the cysteine residues of peptides. At support to this interpretation, a model study has shown the formation of protein-bound cysteinylcatechols by incubation of DA or norepinephrine with bovine serum albumin (Ito et al. 1988). Proteomics of NM granules (NM, proteomic) has allowed the identification of more than 70 proteins, occurring commonly in human brain tissues, mainly lysosomal proteins, sustaining the hypothesis of a genetic program for the formation of NM granules (Tribl et al. 2005).

3.3 Lipid Component in NM

The electron-lucent component comprises 35 % of the NM granule volume (Fedorow et al. 2006) and contains neutral lipids (NM, lipid component). A two-step washing of the granules with methanol and hexane has allowed a completed

removal of the lipid component, proving that they are adsorbed onto the surface of the granule and not chemically bound (Zecca et al. 2000). Interestingly the major lipid component of NM is the polyisoprenoid dolichol, which contains 17–23 isoprenoid units and accounts for approximately 12 % of NM weight (Fedorow et al. 2005b; Ward et al. 2007). Other lipids have been also found, as cholesterol, ubiquinone-10, α-tocopherol, and dolichyl esters, but they are present only in small quantity (Fedorow et al. 2005b).

Small amounts of dolichol are ubiquitously distributed in the body, generally located in cellular membranes, where it is supposed to have a role in the stabilization of the membrane itself. While the phosphorylated form of dolichol is involved in the formation of glycoproteins in the endoplasmatic reticulum (Varki et al. 1999), the function of free dolichol remains to be clarified.

Accumulation of dolichol is associated with neurodegeneration in disorders such as the neuronal ceroid lipofuscinoses (Kin et al. 1983). In NM granule, the presence of large dolichol deposits represents until now the first example of dolichol concentrated in intracellular inclusions in healthy tissue (Fedorow et al. 2006). The association of dolichol with NM results to be specific. Indeed cholesterol, which in all the other brain regions is typically 200-fold higher than dolichol on a mass basis (Andersson et al. 1987), is present at considerably lower concentration in NM lipid. Dolichol may play a structural function, as it can alter membrane lamellar bilayer into nonlamellar or hexagonal structure (Zhou and Troy 2004).

Recently, the influence of NM lipids in the aggregation of the granule has been investigated (Dedov et al. 2007). The removal of all NM lipids resulted in significantly larger granules than those present prior to lipid removal. Interestingly, selective removal of cholesterol by methanol extraction resulted in an eight- to tenfold enhancement in granule size, whereas the pro-aggregation effect of dolichol extraction using hexane was significantly smaller. These data showed that NM lipids, preventing the formation of large pigment aggregates, may be a factor regulating NM granule size in vivo (Dedov et al. 2007).

Under oxidative stress condition, lipid peroxidation appears to contribute to neurodegeneration in PD (Dexter et al. 1989). In this contest, dolichol may be a substrate of the lipid peroxidation, as in vitro studies have shown a time-dependent degradation of dolichol when incubated with a radical initiator (Dedov et al. 2007). These observations are just preliminary and further investigations are required for clarifying the structural and physiological role of NM lipids in normal and pathological conditions.

4 Biosynthesis of NM

The study of neuromelanogenesis is made more complicated than that of peripheral melanin biosynthesis, because NM is absent from all of the commonly used laboratory animals including rodents. A general understanding of the first steps of NM biosynthesis has been provided by investigation of the products arising from in vitro biomimetic oxidation of NM precursors and comparison with what is

known about peripheral melanins (Fig. 1). It is extensively debated whether the NM synthesis is enzymatically controlled (NM, enzymatic control), like all melanins in the periphery, or whether NM arises from a simple autoxidation of DA. Although DA cells in the midbrain express tyrosine hydroxylase, the rate-limiting enzyme for DA synthesis, there is no correlation between the degree of pigmentation and tyrosine hydroxylase immunoreactivity (Gaspar et al. 1983). The enzyme tyrosinase is a key enzyme in the synthesis of peripheral melanin, since it catalyzes the conversion of the amino acid tyrosine to DQ, the precursor of eu- and pheomelanin (Korner and Pawelek 1982). However, immunochemistry studies have no detected tyrosinase in human midbrain (Ikemoto et al. 1998). At support to that, albinos, who are characterized by absence of peripheral pigmentation due to a lack of functional tyrosinase, have normally pigmented neurons in SN (Foley and Baxter 1958). Also the enzyme peroxidase and macrophage migration inhibitory factor have been proposed for NM synthesis. However, their distribution in the brain does not correlate to NM distribution (Okun 1997; Matsunaga et al. 1999). Several other enzymes have been suggested to be associated with NM biosynthesis, but to date no likely candidate has been demonstrated to be involved in the neuromelanogenesis. In the absence of a convincing enzymatic route, for a long period NM has been regarded as a waste product of catecholamine metabolism (Bogerts 1981; Graham 1979; Mann and Yates 1983; Mann et al. 1977). Indeed, NM is not present at birth and increases over the lifespan, supporting the idea that the pigment is a cellular by-product of DA metabolism formed via autoxidation and, in the absence of any mechanism to remove it, accumulates intracellularly with age. However, several evidences are in contrast with this view. First of all, NM and DA do not have the same cellular distribution in human brain and the pigment seems to be a peculiar feature of the man, lacking or at least present in small amount in the midbrain of many other species (Fedorow et al. 2005a). In addition, PD patients treated with DOPA, which it is rapidly converted in DA by the enzyme aromatic acid decarboxylase, do not exhibit increased quantities of NM within their surviving SN neurons as might be expected to be the case if NM represents a product of pure DA autoxidation (Zecca et al. 2001a). Finally, the complex casing structure proposed for the NM pigment and its aggregation with specific protein and lipid components support the existence of a controlled process.

The casing model may be the consequence of a mixed melanogenesis regulated in some way by cysteine levels. In vitro studies on biosynthesis of peripheral melanin have clearly indicated that DQ conjugates to cysteine leading to pheomelanin production until cysteine concentration is above 1 μM. At lower cysteine levels DQ polymerizes in eumelanin (Ito 2003; Land et al. 2003). This favored production of pheomelanin over eumelanin suggests that the first step is the formation of the pheomelanin core, and then, when the cysteine is depleted, eumelanin production starts. In NM production, this casing process is further favored by the fact that DAQ cyclizes much more slowly than DQ, leading to a preferential production of cysteinyldopamines (Ito 2003). The construction of NM granule seems to be a regulated process in such a manner that DAQ is conjugated first with cysteine to form cysteinyldopamine isomers, which are further

oxidized to form a pheomelanic core. This step is followed by the production of a eumelanic surface (Ito 2006). Whereas it is not well understood how initially DA and later the cysteinyldopamines are oxidized for producing the pheomelanin pigment, the synthesis and the following deposition of eumelanin pigment onto the preformed pheomelanic core may be a spontaneous process, in part catalyzed by the prooxidant pheomelanin core, as observed in biomimetic studies (Greco et al. 2011).

5 Developmental Stages of NM

NM concentration in SN pars compacta increases similarly in men and women over the entire lifespan. In the first year of life, NM is in general not detectable. Between 10 and 20 years, the NM levels are 0.3–0.8 μg/mg of SN, between 20 and 50 years are 0.8–2.3 μg/mg SN, and between 50 and 90 are 2.3–3.7 μg/mg of SN (Zecca et al. 2002a) (NM, age).

In accordance with these quantitative analyses, light microscopy images have revealed that no NM is visible in SN neurons in the prenatal or infant brain. The pigment first appears within the cytoplasm of the DA neurons at around the age of 3 years as small granules, whose size and number increase until the age of 20. At this time NM fills, on average, 47 % of the cytoplasm. After the age of 20, the proportion of the cell occupied by the pigment remains stable, but the amount of pigment increases with age (Halliday et al. 2006). Over time the coloration and the appearance of NM change too. Initially, NM occurs as dusty yellow-brown granules, which progressively form dark denser clusters (Halliday et al. 2006). These data may represent a direct observation of the construction of the NM granule in vivo according to the casing model, where the fine yellow-brown pheomelanin is form first and then it is encased by the dark eumelanin shell. However, at the present no evidence of the pigment in the on-growing granule is available. In this contest, further works, leading to clarify the variation of eumelanin/pheomelanin levels with aging, will be a fundamental step in the study of neuromelanogenesis.

Interestingly, also brain dolichol levels increase over the human lifespan. At the age of 6 years, dolichol in human brain gray matter is around 18 μg/g wet weight, exceeding the 200 μg/g after the sixth decade of life (Pullarkat and Reha 1982).

6 Dual Role of NM

In contrast to peripheral melanin, whose main function in the body is to protect underlying tissues from harmful UV radiation (Ito 2006), much less is known about the role of NM.

No physiological function has been defined for NM and two different roles have been suggested, either protective or toxic with respect to the degeneration of catecholaminergic neurons depending on the cellular context.

An increasing number of new studies concord with the view that NM is a cellular protecting system in the normal brain. NM synthesis protects the neurons in the SN, because the melanin component is generated from cytosolic catechols which are not accumulated in synaptic vesicles (Zucca et al. 2004). Therefore, this mechanism ensures the removal of reactive/toxic quinones arising from DA oxidation that otherwise would cause neurotoxicity (Paris et al. 2010). Furthermore, NM can trap a variety of organic molecules, as drugs (e.g., chlorpromazine, haloperidol, imipramine), pesticides (e.g., paraquat), and toxic compounds (e.g., 1-methyl-4-phenylpyridinium (MPP^+), beta-carbolines), and immobilize them as stable adducts, thus protecting against toxicity (Salazar et al. 1978; Lindquist et al. 1988; Ostergren et al. 2004; D'Amato et al. 1986) (NM, organic molecule interaction).

Similar to peripheral melanin, NM is a strong chelator of metal cations such as iron, zinc, copper, manganese, chromium, cobalt, mercury, lead, and cadmium (Liu et al. 2004; Zecca and Swartz 1993; Zecca et al. 2002b) (NM, metal chelator). In NM isolated from SN, iron is the metal occurring at the highest concentration, with levels above 10 μg/mg NM (NM, iron level). In DA neurons of SN ferritin are not present, whereas it has been found in glial cells (Zecca et al. 2004; Moos 2000). Therefore, nowadays NM is the only well-documented storage system of iron in SN neurons (Zucca et al. 2004) (NM, iron storage system). In normal condition, NM can sequester iron ions, playing an important role in the protection the neurons from iron-induced oxidative stress (Zareba et al. 1995). NM contains both high- and low-affinity iron-binding sites, where the higher-affinity binding sites (NM, iron-binding sites) are particularly better able to sequester iron (Double et al. 2003). The pigment in vivo is suggested to be only partially saturated with iron, thus maintaining a residual chelating capacity to protect SN against iron toxicity (Shima et al. 1997). In the presence of high iron levels, NM accumulates iron in low-affinity binding sites, arranged in a ferritin-like oxyhydroxy iron clusters, where it can be redox active, producing free radicals and thus leading to neurotoxic consequences (Gerlach et al. 1995; Double et al. 2003; Zecca et al. 2001b). In parkinsonian subjects, where an abnormal loss of NM-containing neurons is observed, the NM levels are 1.2–1.5 μg/mg of SN pars compacta, which is less than 50 % with respect to the age-matched controls (Zecca et al. 2002a). At support to NM protective role, the levels of redox activity are significantly higher in PD patients (+69 %) and increase in patients with the most severe neuronal loss (Faucheux et al. 2003).

On the other hand, NM can be also toxic in PD patients when it is released by dying neurons of SN. Insoluble extracellular NM is phagocytosed by microglia with consequent induction of neurotoxicity by overactivation of microglia (microglia activation) and ensuing production of reactive oxygen species (ROS) and nitrogen species (RNS), and proinflammatory factors (Zhang et al. 2011). Recent epidemiological studies have suggested that neuroinflammation, in particular in a chronic state, is recognized to contribute to the pathogenesis of PD (Chen et al. 2003; Gao et al. 2011; Wu et al. 2002). An initial damage of pigmented neurons, independently if the factors are genetic or environmental, causes the release of NM, which could trigger a vicious circle of neuronal death that enhances the inflammation. Moreover, as ROS can degrade NM, the consequence may be that the neurons not only lose

a protective agent but also release iron and other cytotoxic metals and compounds, accelerating the neuronal death (Zucca et al. 2004; Shima et al. 1997).

In addition to these studies, there are strong evidences for an alteration of NM structure since the first stages of PD. In particular, it has been observed during the disease a decrease of the lipid component and an increase of the density of the pigment (Halliday et al. 2005). Investigations by magnetic spectroscopies of the pigment structure have revealed that the melanin component undergoes modification (Fasano et al. 2006). Other studies have also showed that α-synuclein protein, a primary component of Lewy bodies, aggregates on NM in SN in parkinsonian, but not in healthy control, brains (Halliday et al. 2005). Therefore, this interaction may explain the higher susceptibility during the disease process of highly pigmented brain regions, such as SN (Double 2012).

7 Implication of NM Architecture in Parkinson's Disease

The casing model reported for NM pigment is particularly intriguing and growing efforts are directed to the study of its formation and function in the brain.

In healthy conditions, the pheomelanin core of NM pigment may be the result of a detoxification process of DAQ through conjugation with cysteine. In fact, SN is the brain region with the highest levels of cysteinyldopamine isomers, the pheomelanin precursors (Spencer et al. 1998). The pheomelanin core may function as scaffold for the eumelanin pigment. Moreover, recent evidences suggest that it could also catalyze eumelanin formation (Greco et al. 2011). The eumelanin surface of NM granule is responsible for neuronal protection. Indeed, it is much more efficient than pheomelanin in binding drugs and metals ions (Mårs and Larsson 1999). In addition, the surface oxidation potential found for the eumelanin is not sufficiently to generate a high level of oxidative stress (Bush et al. 2006). On the other hand, any damage of the protective eumelanin surface by ROS, process that likely occurs in the human brain during PD, could expose the pheomelanin core. Pheomelanin, differently from eumelanin, has well-documented prooxidant property (Ye et al. 2006; Bush et al. 2006); therefore, the exposure of pheomelanin core may induce of a cascade of neurodegenerative events (Ito 2006).

At support to the fact that NM architecture may be involved in some way in the pathogenesis of PD, Gao et al. (2009) have recently reported an interesting correlation between the risk of PD and the hair color. They have shown that individuals with red hair have approximately a twofold higher risk for PD relative to those with black hair. It is known that the peripheral pigment granule of red hair individuals is characterized by a tiny eumelanin coat with consequent permanent exposure of the prooxidant pheomelanin core and this seems to be related to the higher incidence of melanoma in comparison to individuals with black hair (Samokhvalov et al. 2005; Vincensi et al. 1998). These findings should stimulate further researches directed to study of the NM architecture and the changing of melanin composition, in particular the eumelanin/pheomelanin ratio, with age and in pathological conditions.

8 Conclusion

Despites the recent progresses in the comprehension of NM biology, there are still many open questions. The future challenges are the clarification of the NM biosynthesis, its mechanism of turnover, and the role in heath individuals. Because of the complexity of NM granules, major insights into the chemical structure of the pigment, the peptide, and the lipid components would elucidate the possible interactions with other neuronal constituents. Moreover, a detailed understanding of NM structural and physiological changes in pathological conditions, in particular the contribution of NM to the oxidative stress and to neuronal vulnerability, would advance our knowledge of the underlying mechanisms that govern the progression of PD.

Neurotoxicity of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) as a Parkinson's Disease Model

H. Nakayama, T. Ito, Y. Shibui, T. Sai, K. Uchida, and X. J. He

Contents

Abstract

Administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to susceptible animals is the most popular means for modeling the destruction of the nigrostriatal dopaminergic neurons seen in Parkinson's disease (PD). MPTP causes a damage to the substantia nigra pars compacta (SNpc) dopaminergic neurons and depletes striatal dopamine secretion in nonhuman primates and rodents. MPTP passes through the blood–brain barrier (BBB) and is converted, mainly in glial cells, into its active form, 1-methyl-4-phenylpyridinium (MPP^+), by an enzyme, monoamine oxidase B (MAO-B). MPP^+ is selectively transported into dopaminergic nerve terminals through dopamine transporter (DAT) and finally induces dopaminergic cell loss. The selective neurotoxicity of MPTP to

neural tissues other than the dopaminergic system, such as the subventricular zone (SVZ) and rostral migratory stream (RMS) in the adult brain, has been indicated. The cells undergoing apoptosis in the SVZ are A cells and MAO-B inhibitors completely protected against the neurotoxicity, suggesting that the MPTP neurotoxicity to A cells is mediated by the conversion of MPTP into MPP^+ by MAO-B. The neurotoxicity of MPTP to neuroblasts in the SVZ does not require DAT or other monoamine transporters. There is a strain difference in the susceptibility of the MPTP neurotoxicity between susceptible C57BL/6 and resistant BALB/c mice. However, MAO-B, DAT, neural NOS (nNOS), and inducible NOS (iNOS) expression levels do not influence the strain susceptibility to MPTP. MPTP and MPP^+ can pass through the placenta and embryonic or newborn BBB, and finally reach the brain. The number of MAO-B-positive glial cells in the brain increases in MPTP-treated embryonic and newborn mice, indicating the involvement of MAO-B in the acute neurotoxicity. MPTP or MPP^+ administration into embryonic and newborn mice causes a loss of TH-positive cells and fibers in the nigrostriatal system and increases the number of apoptotic cells in the SVZ. Delayed regeneration of dopaminergic neurons due to the loss of SVZ A cells may be one of possible causes of the pathological condition. With increased attention to dopaminergic neurogenesis in MPTP-induced animal models, such animals become useful as a tool for establishing the contact to PD on neurogenesis.

List of Abbreviations

6-OHDA	6-Hydroxydopamine
BBB	Blood–brain barrier
BrdU	Bromodeoxyuridine
CNS	Central nervous system
DA	Dopamine
DAT	Dopamine transporter
DCX	Doublecortin
DG	Dentate gyrus
icv	Intracerebroventricularly
iNOS	Inducible NOS
MAO-B	Monoamine oxidase B
MMPs	Metalloproteinases
$MPDP^+$	1-Methyl-4-phenyl-2,3-dihydropyridinium
MPP^+	1-Methyl-4-phenylpyridinium
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
nNOS	Neural NOS
NOS	Nitric oxide synthase
OB	Olfactory bulb
PCNA	Proliferating cell nuclear antigen
PD	Parkinson's disease
RMS	Rostral migratory stream
Ro 16-6491	*N*-(2-aminoethyl)-4-chlorobenzamide
SERT	Serotonin transporter

SGZ	Subgranular zone
SN	Substantia nigra
SNpc	Substantia nigra pars compacta
SVZ	Subventricular zone
TH	Tyrosine hydroxylase
TUNEL	Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling
VMAT2	Vesicular monoamine transporter 2

1 Introduction

Parkinson's disease (PD) is an age-related degenerative disorder of the central nervous system (CNS). It is often characterized by muscle rigidity, tremor, a slowing of physical movement (bradykinesia), and, in extreme cases, a loss of physical movement (akinesia). The symptoms of PD are attributed to the loss of pigmented dopamine-secreting (dopaminergic) neurons in the pars compacta region of the substantia nigra (SNpc) and a subsequent striatal deficiency of dopamine (DA). The idiopathic PD is also pathologically characterized by the presence of cytoplasmic neuronal inclusions, called Lewy bodies, in the affected region of the brain. The etiology of the disease has been poorly understood, and novel non-dopaminergic therapeutic strategies still remain challenging since the initial description was first described by James Parkinson in 1817 (Parkinson 1817). Although pharmacological dopamine replacement strategies provide a temporary symptomatic relief, there are at present no therapeutic methods for stopping the progressive neuronal cell loss (Borta and Hoglinger 2007).

Animal models are important tools in elucidating mechanisms involved in the pathological process and in investigating the new therapeutic strategies in PD. Currently, both genetic and toxic models of PD are available, but the use of neurotoxins such as 6-hydroxydopamine (6-OHDA), paraquat, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and rotenone are still the most popular means for modeling the destruction of the nigrostriatal dopaminergic neurons seen in PD (Przedborski and Ischiropoulos 2005). Among them, 6-OHDA and MPTP have been more extensively used by investigators to produce PD models despite their limitations. 6-OHDA is a structural analog of catecholamines, DA and noradrenaline, and exerts its toxic effects on catecholaminergic neurons (Simola et al. 2007). Since 6-OHDA does not penetrate the blood–brain barrier (BBB) in adult rats, it must be administrated stereotactically into the substantia nigra (SN) or striatum to damage the dopaminergic nigrostriatal system (Perese et al. 1989; Przedbroski et al. 1995). Recognition of MPTP as a neurotoxin occurred early in 1982, when several young drug addicts mysteriously developed a profound Parkinsonian syndrome after the intravenous use of street preparations of meperidine analogs that, unknown to anyone, were contaminated with MPTP (Przedborski and Vila 2003; Langston et al. 1983), an incidental by-product during the chemical synthesis of a meperidine analog (Fig. 1)

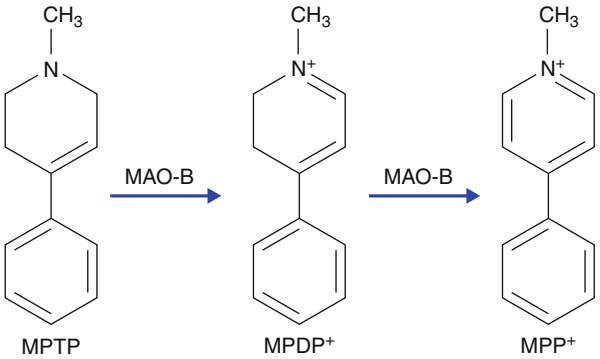

Fig. 1 MPTP is a by-product during the chemical synthesis of a meperidine analog. MPTP neurotoxicity develops only after metabolization to $MPDP^+$ by MAO-B in glial cells, and further to MPP^+, the active toxic compound (He and Nakayama 2009)

with potent heroin-like effects (Przedborski and Vila 2003). MPTP has been found to produce irreversible Parkinsonism in humans almost indistinguishable from PD (Langston et al. 1983; Blume 1983). It is also well known that MPTP depletes striatal dopamine and causes a damage to the SNpc dopaminergic neurons in nonhuman primates and several species of rodents (Burns et al. 1983; Langston et al. 1984; Heikkila et al. 1984; Chiueh et al. 1984).

Recently, a great deal of interest has been focused on the stem cell therapies for PD. In addition to the fetal nigral transplantation, the capability of self-repairing in central nervous system (CNS) in adult mammalian has also been considered as a new insight into the cell-based approach for the treatment of neurodegenerative disorders. In PD or its animal models, it has attracted much attention whether the depletion of dopaminergic neurons triggers an activation of neural stem cells and their subsequent migration into the damaged area, and finally results in repopulation of dopaminergic neurons in SN. We have recently reported several results (He et al. 2006, 2008a, b; He and Nakayama 2009; Popolo et al. 2004), which will provide evidences available for endogenous neurogenesis in response to neurotoxin damages, and provide perspective on the contact of neurotoxin-based animal models on PD. This chapter will mainly describe such MPTP-induced neural damages in the subventricular zone (SVZ) as well as SNpc and striatum, and subsequent neurogenesis in the brain of the mouse. In addition, the strain difference in the susceptibility to MPTP in the mouse, and the relations of MPTP neurotoxicity and aging are mentioned.

2 Neurotoxicity of MPTP to Dopamine Neurons

MPTP is a by-product of the chemical synthesis of a meperidine analog, with potent heroin-like effects (Przedborski and Vila 2003), that causes damage to dopaminergic neurons and depletes dopamine in a manner similar to that seen in PD. When administered to animals, MPTP passes through the BBB and is converted, mainly in glial cells, into its active form, 1-methyl-4-phenylpyridinium (MPP^+), by an enzyme, monoamine oxidase B (MAO-B) (Blum et al. 2001). For the last two decades, MPTP has been widely

used to generate animal models of PD in rodents and nonhuman primates. A few studies have confirmed that MPTP can induce apoptosis of dopaminergic neurons in vivo (Tatton and Kish 1997; Vila et al. 2001; Spooren et al. 1998). When injected intraperitoneally (ip) with a subacute regimen, which consists of one injection per day (30 mg/kg per day) for 5 consecutive days, MPTP induces dopaminergic cell loss by a mechanism mainly involving apoptosis (Przedborski and Vila 2001). The use of this subacute regimen has been the main approach to studying the apoptosis of dopaminergic cells in mice. The induction of apoptosis in mouse nigrostriatal glia has also been demonstrated with this regimen (Serra et al. 2002), indicating that neurotoxicity of MPTP is not specifically restricted to dopaminergic neurons in the mouse brain. Furthermore, results from studies in vitro show that MPTP or MPP^+ induces apoptosis in primary cultured cerebellar granular neurons (Dipasquale et al. 1991; Du et al. 1997), mesencephalic dopaminergic neurons (Mochizuki et al. 1994), and neuroblastoma cells (Itano and Nomura 1995; Sheehan et al. 1997) as well as PC12 cells (Hartley et al. 1994; Desole et al. 1997).

3 Neurotoxicity of MPTP to Neural Stem Cells

3.1 The Origin and Properties of Neural Stem Cells

Neurogenesis continues into adult life in the brain of rodents (Altman 1963; Privat and Leblond 1972), nonhuman primates (Gould et al. 1999a, b; Pencea et al. 2001), and humans (Bernier et al. 2000; Eriksson et al. 1998) (Fig. 2). Neurogenesis has been confined largely to two discrete areas, the subventricular zone (SVZ), and the subgranular zone (SGZ) of the dentate gyrus (DG) (Garcia-Verdugo et al. 1998).

The SVZ, located throughout the inner wall of the lateral ventricle, is the largest germinal region and harbors neural stem cells that retain the capacity to generate multiple cell types (Doetsch et al. 2002). The SVZ is composed of neural progenitor cells (migrating neuroblasts, A cells), neural stem cells (astrocytes, B cells), neural precursor cells (rapidly dividing transit-amplifying cells, C cells), and ependymal cells (Doetsch et al. 1997, 1999). Neural stem B cells divide to give rise to clusters of precursor C cells, which in turn generate neuroblast A cells (Doetsch et al. 1999). Newly generated A cells in the SVZ migrate through a network of tangential pathways in the lateral wall of the lateral ventricle and then converge onto the rostral migratory stream (RMS) to enter the olfactory bulb (OB) with a behavior of "chain migration" (Doetsch and Alvarez-Buylla 1996), where they differentiate into granule cells and interneurons (Doetsch and Alvarez-Buylla 1996; Lois and Alvarez-Buylla 1994). It has been suggested that prokineticin 2 serves as a chemoattractant for SVZ-derived neuroblast A cells, which appears to guide the migration of A cells from the SVZ through the RMS to their final layers in the OB (Ng et al. 2005). The multipotential A cells reside in the SVZ and RMS are eliminated through apoptosis to maintain a balance for proper development of the mammalian nervous system (Brunjes and Armstrong 1996; Levison et al. 2000;

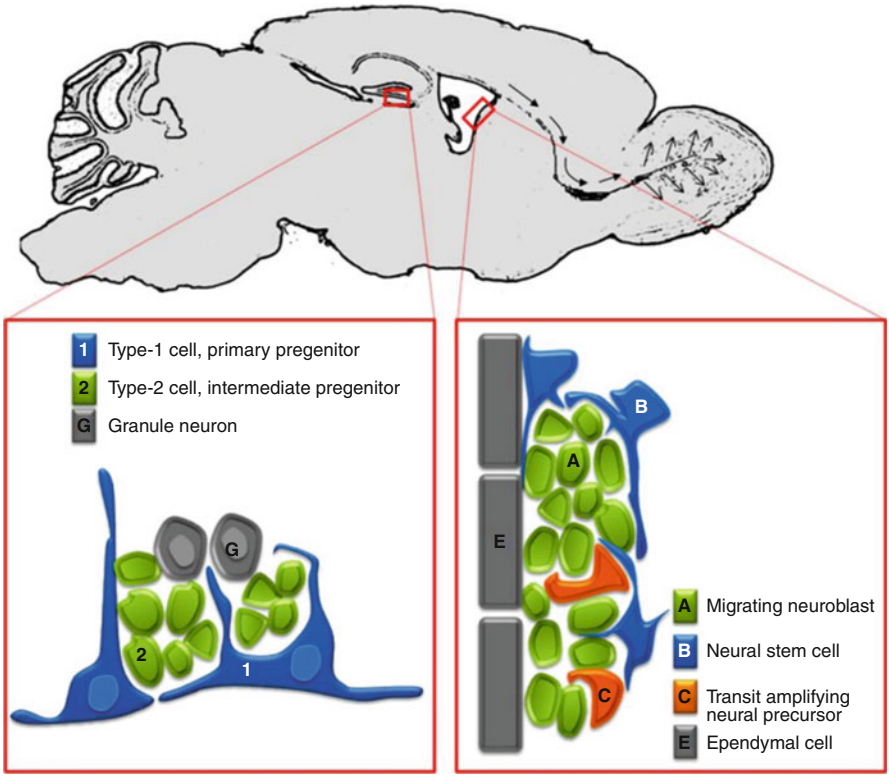

Fig. 2 Schematic representation showing the migratory pattern of newly generated A cells in the SVZ (*up*), and the cell population in the SGZ of DG (*bottom left*) and SVZ (*bottom right*) in adult rodent brain (He and Nakayama 2009)

Biebl et al. 2000). Metalloproteinases (MMPs) may also play a crucial role in the migration of individual A cells since the migration rates are reduced by the presence of inhibitors of MMPs (Bovetti et al. 2007). The architecture and function of the adult human SVZ differs significantly from that described in other mammals. There are four layers with varying thickness and cell densities throughout the lateral ventricular wall: a monolayer of ependymal cells (Layer I), a hypocellular gap (Layer II), a ribbon of cells (Layer III) composed of astrocytes, and a transitional zone (Layer IV) into the brain parenchyma (Quinones-Hinojosa et al. 2006).

The DG is a part of the hippocampal structure. Neuronal progenitors in the adult mammalian hippocampal DG reside in the SGZ, which is located in the hilus immediately beneath the granular layer of the DG (Kaplan and Hinds 1977; Cameron et al. 1993). Neurogenesis in the DG was first demonstrated 40 years ago by autoradiography in rodents (Altman and Das 1965), and thereafter was further demonstrated in all mammalian species including human (Eriksson et al. 1998) and nonhuman primates (Gould et al. 1998, 1999a, b). Two types of neural progenitors can be identified in the SGZ according to their specific morphologies

and expression of unique sets of molecular markers (Zhao et al. 2008). The primary progenitors (type-1 cells) have the appearance of radial glia, which also express glial fibrillary acidic protein (GFAP). They share the similar features with type B cells residing in the adult SVZ and then are suggested as the putative stem cell population (Seri et al. 2001). Type-2 cells (intermediate progenitors) are GFAP negative and highly proliferative (Kempermann et al. 2004), sharing similar features with neuroblast A cells residing in the adult SVZ. Type-2 cells may arise from type 1-cells, but direct evidence delineating this lineage relationship is still lacking (Zhao et al. 2008). The newborn type-2 cells disperse and migrate a short distance into the granule cell layer where they differentiate, extend axons, and express neuronal marker proteins (Cameron et al. 1993; Kuhn et al. 1996). The migration of newborn neurons in the DG may also be controlled by guidance cues, as these cells only migrate to the hilus or the molecular layer under pathological conditions, such as in animal models of temporal lobe epilepsy (Zhao et al. 2008).

3.2 Neurotoxicity of MPTP to SVZ Neural Stem Cells

MPTP neurotoxicity develops only after metabolization to 1-methyl-4-phenyl-2,3-dihydropyridinium ($MPDP^+$) and further to 1-methyl-4-phenylpyridinium (MPP^+), the active toxic compound, by MAO-B (Fig. 1) (Przedborski and Vila 2003). Since MPP^+ is selectively transported into presynaptic dopaminergic nerve terminals through the dopamine transporter (DAT) (Chiba et al. 1985; Javitch et al. 1985; Gainetdinov et al. 1997; Bezard et al. 1999; Pifl et al. 1993), and the absence of the DAT on dopaminergic neurons confers a complete protection against MPTP toxicity (Gainetdinov et al. 1997; Bezard et al. 1999), the neurotoxicity of MPTP is suggested to be selective to dopaminergic neurons in SN. MPTP is mainly used in nonhuman primates and in rodents (Gerlach and Riederer 1996; Przedborski et al. 2001). In rodents, the C57BL/6 mice are widely used to create the PD animal model for understanding the disease pathogenesis in a great deal of reports despite their limitations.

In recent years, the selective neurotoxicity of MPTP to neural tissues other than the dopaminergic system in the adult brain has been elucidated. Several studies (Serra et al. 2002; He et al. 2006, 2008a) have demonstrated that MPTP also destroys forebrain migrating neuroblasts and nigrostriatal glial cells (astrocytes) in the adult mouse brain. In our previous studies (He et al. 2006, 2008a), the number of apoptotic cells in the SVZ and RMS peaked at 24 h after MPTP-injections, and decreased thereafter, paralleling the change in the number of cleaved caspase-3-positive cells (Fig. 3). The cells undergoing apoptosis in the SVZ, RMS, and OB were identified as A cells using immunohistochemistry and ultra-structural analyses, while a few were astrocytes (B cells) and none were transit-amplifying precursors (C cells) (He et al. 2006, 2008a). The decrease in A cell numbers was most marked at day 2 and lasted to day 8 after the administration (He et al. 2006, 2008a). We also demonstrated that MAO-B inhibitors, such as deprenyl or *N*-(2-aminoethyl)-4-chlorobenzamide (Ro 16-6491), completely protected

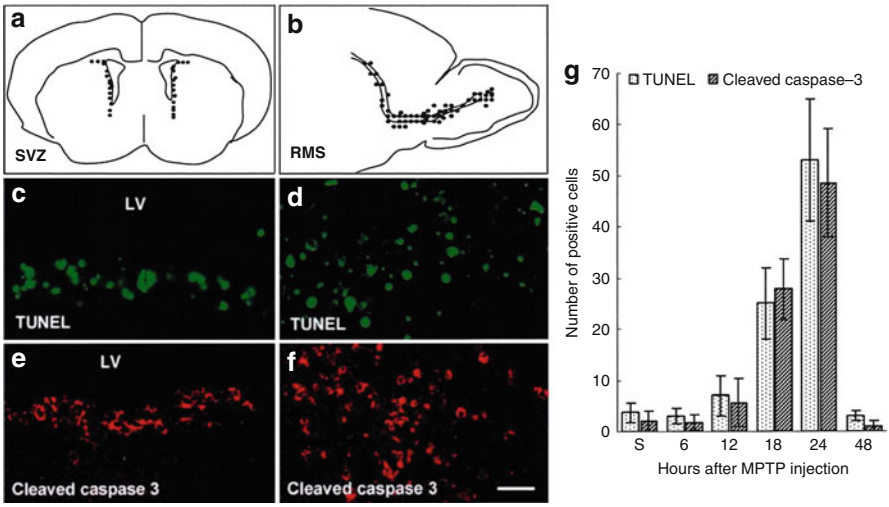

Fig. 3 Detection of apoptotic cells in the SVZ (coronal section) and RMS (sagittal section) with fluorescence TUNEL and immunofluorescence staining for cleaved caspase-3. (**a**, **b**) Schematic distribution of apoptotic cells in the SVZ and RMS with the positions of the cells undergoing apoptosis indicated by *dots*. (**c**, **d**) Apoptotic nucleus (*green*) in the SVZ and RMS revealed by the TUNEL technique, and (**e**, **f**) cleaved caspase-3 staining (*red*) in the same field. Scale bar = 50 μm. (**g**) The results of a quantitative analysis of TUNEL-positive or cleaved caspase-3-immunoreactive cells in the SVZ of MPTP-treated mice. The number of TUNEL-positive or cleave caspase-3-immunoreactive cells peaked at 24 h and had declined to very low levels by 48 h after MPTP injection. Neither TUNEL-positive nor cleaved caspase-3-immunoreactive cells were found in control animals at any time point. Abbreviation: *LV* lateral ventricle (He et al. 2006)

against MPTP neurotoxicity to A cells, suggesting that MPTP-neurotoxicity to A cells is also mediated by the conversion of MPTP into MPP^+ by MAO-B (He et al. 2008b).

3.3 Neurotoxicity of MPTP to Neural Stem Cells Is Not Regulated by Monoamine Transporters

In dopaminergic neurons, MPP^+ enters into the cytoplasm via the dopamine transporter (DAT) (Gainetdinov et al. 1997; Javitch et al. 1985), is concentrated by an active process within the mitochondria, and impairs mitochondrial respiration by inhibiting complex I of the electron transport chain (Vila and Przedborski 2003). DAT is thus thought to play a crucial role in the MPTP neurotoxic process.

On the other hand, other monoamine transporters, including vesicular monoamine transporter 2 (VMAT2), serotonin transporter (SERT), and norepinephrine transporter (NET) may also contribute to MPTP toxicity. It has been reported that the dopaminergic neurotoxicity of MPTP is enhanced by the injection of VMAT2 inhibitors (German et al. 2000; Reinhard et al. 1988; Staal and Sonsalla 2000) as well as in heterozygous VMAT2-knockout mice (Takahashi et al. 1997) due to the

involvement of VMAT2 in the clearance of MPP^+ from dopaminergic neurons and the resultant accumulation of MPP^+ inside the cell (Liu and Edwards 1997). Additionally, the inhibition of SERT or NET by the administration of their inhibitors selectively attenuates MPTP-induced depletion of serotonin and norepinephrine, respectively (Andrews and Murphy 1993). MPTP-induced neurotoxicity is also reduced in NET-knockout mice (Rommelfanger et al. 2004). However, the functions of SERT and NET in MPTP-induced neurotoxicity still remain unknown.

A study is performed to elucidate the role of DAT and other monoamine transporters including VMAT2, SERT, and NET on the SVZ neuroblast apoptosis induced by MPTP administration. The results of the study indicated that there are no DAT-positive neuroblasts in the SVZ (Fig. 4), whereas some neuroblasts were immunopositive for VMAT2 and SERT (Shibui et al. 2009). TUNEL-positive cells were semiquantitatively analyzed after the injection of GBR12909, a DAT inhibitor; tetrabenazine, a VMAT2 inhibitor; fluoxetine, a SERT inhibitor; or desipramine, a NET inhibitor, prior to MPTP injection. However, the injection of the transporter inhibitors had no influence on the MPTP-induced neuroblast apoptosis in the SVZ (Shibui et al. 2009). This finding suggests that the neurotoxicity of MPTP to neuroblasts in the SVZ does not require DAT or other monoamine transporters, and the MPTP-induced apoptosis may be executed through other unknown pathways.

4 Neurogenesis After MPTP-Induced Injury

Neurogenesis is a key event during both physiological and pathological processes, and is regulated by a variety of stimuli, such as hormones, intrinsic growth factors, neurotransmitters, exogenously applied agents, environmental enrichment, exercise, and age.

Dopamine has been shown to regulate cell cycles in the developing brain (Spencer et al. 1998). The activation of dopamine receptors influences cell proliferation in the lateral ganglionic eminence and the neuroepithelium of the frontal cortex in embryonic mice (Ohtani et al. 2003; Popolo et al. 2004). By using immunohistochemical and ultrastructural analyses, it was demonstrated that dopamine 2 like (D2L) receptors are expressed predominately on C cells in the SVZ, whereas A cells express both D1L and D2L receptors in the mouse brain (Hoglinger et al. 2004). The dopaminergic fiber is also confirmed to contact precursor cells in the SVZ of adult human and primates (Hoglinger et al. 2004; Freundlieb et al. 2006). Thus, dopamine seems to play a key role in the regulation of adult mammalian neurogenesis.

Zhao et al. (2003) first provided morphological evidences that the administration with MPTP leads to a twofold increase of bromodeoxyuridine (BrdU) incorporation in nigral dopaminergic neurons 3 weeks after the lesion in mice, which was not detectable in the granular cell layer of DG. The newly generated dopaminergic neurons are demonstrated to be derived from the cells lining the ventricular system, namely, SVZ cells. By using the nestin second intron enhancer-controlled LacZ reporter transgenic mouse model coupled with the MPTP lesion system, Shan et al.

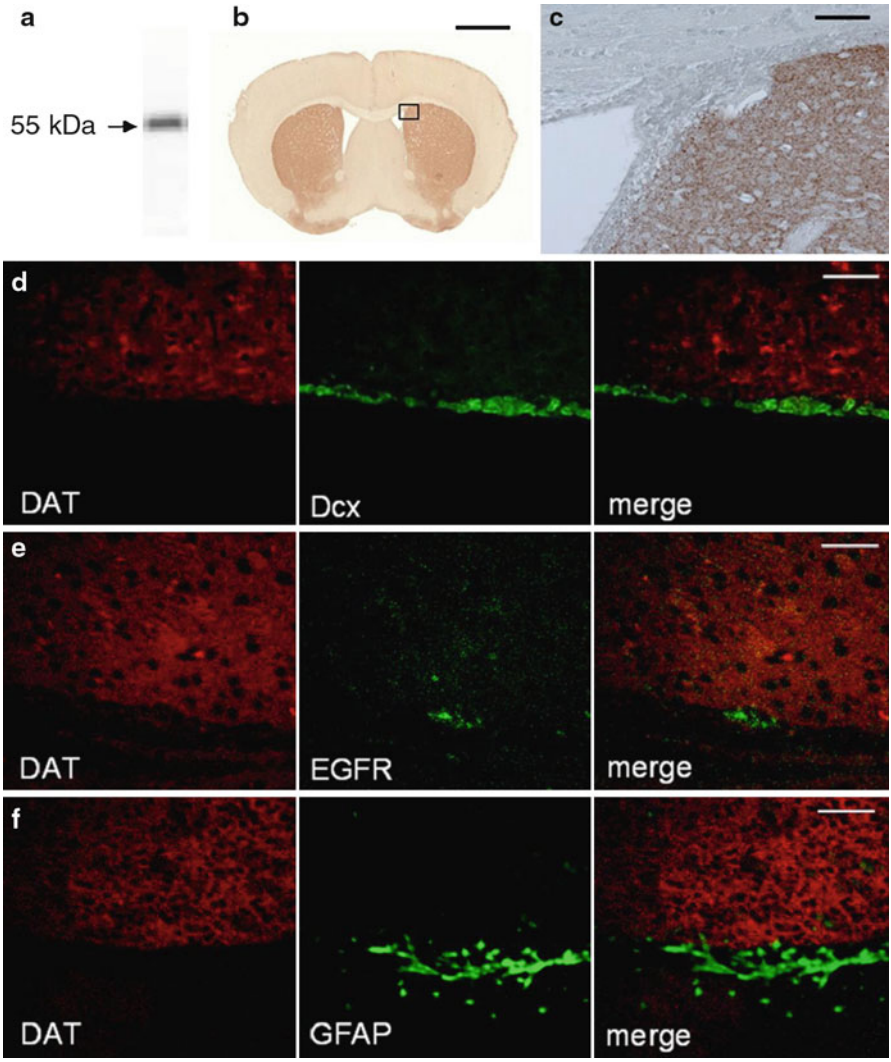

Fig. 4 (**a**) Western blot analysis demonstrates the expression of a 55 kDa DAT protein in the mouse cerebrum. (**b**) A representative coronal section through the striatum and SVZ were immunostained for DAT and showed the expression of DAT in the striatum, but not in the SVZ. (**c**) Higher magnification of the *boxed area* in (**b**). (**d–f**) The sections were also double labeled for DAT and either Dcx, EGFR, or GFAP. GFAP-positive neural stem cells, EGFR-positive neural precursor cells, or Dcx-positive neuroblasts (*green*) do not express DAT (*red*). Scale bars in (**b**) 1.5 mm, (**c**) 30 μm, and (**d–f**) 15 μm (Shibui et al. 2009)

also demonstrated that there are increased dopaminergic neurogenesis in the SN (Shan et al. 2006), supporting the findings by Zhao et al. Increased neurogenesis after the MPTP injury was also confirmed in a very recent article (Peng et al. 2008), in which MPTP lesions in the mouse brain increased the incorporation of BrdU as

well as the number of cells that co-expressed BrdU and the immature neuronal marker, doublecortin (DCX), in the DG, SVZ, and the striatum, but not in the SN, although no differentiation of newly generated cells into dopaminergic neurons was investigated. Thus, neurogenesis in the nigrostriatal system in response to MPTP damage, if it does occur, may be a later event in the self-repairing process of injured SVZ.

5 Strain Differences in the Susceptibility of MPTP

There are species differences in the susceptibility to MPTP injection; for example, human and monkeys are susceptible, whereas rats and hamsters are relatively resistant (Burns et al. 1983; Chiueh et al. 1984; Langston et al. 1984; Mitra et al. 1994). Mice are middle susceptible, but show marked strain differences (Sundstrom et al. 1987; Riachi and Harik 1988; Hamre et al. 1999); C57BL/6 mice are susceptible, while BALB/c mice are resistant, to MPTP neurotoxicity (Sedelis et al. 2000; Yasuda et al. 2008; Filipov et al. 2009). MPTP induces severe degeneration of dopaminergic neurons when administrated to C57BL/6 mice, but such lesions are not observed in BALB/c mice. However, the reason for such strain differences remains unclear.

To clarify which factor(s) cause such strain differences, MPTP or MPP^+ was intracerebroventricularly (icv) injected into adult C57BL/6 (highly susceptible) and BALB/c (resistant) mice (Ito et al. 2013a). Both C57BL/6 and BALB/c mice injected with MPP^+ showed a significant decrease in tyrosine hydroxylase (TH)-immunopositive areas in the striatum and TH-positive cells in the SNpc a few days after injection, compared to saline-injected control mice, and the decrease rates in the BALB/c mice were lower than that in C57BL/6 mice. MPTP-injected C57BL/6 mice, however, showed no lesions in the striatum and SNpc (Fig. 5). These findings indicate that factors other than MAO-B can influence the strain susceptibility between C57BL/6 and BALB/c mice after the conversion from MPTP to MPP^+.

Intact BALB/c mice showed higher DAT protein expression in the striatum than intact C57BL/6 mice (Ito et al. 2013b). MPTP-treated BALB/c mice showed a more significant increase of MAO-B expression than MPTP-treated C57BL/6 mice (Ito et al. 2013b). The increase of neural nitric oxide synthase (nNOS) and inducible NOS (iNOS) protein expressions in MPTP-treated BALB/c mice was more pronounced in the striatum and SNpc than in MPTP-treated C57BL/6 mice (Ito et al. 2013b).

These results indicate that MAO-B, DAT, nNOS, and iNOS expression levels do not influence the different strain susceptibility to MPTP.

6 Aging and MPTP Neurotoxicity

While there have been many researches on the neurotoxicity of MPTP in adult mice including our study (He et al. 2004), there have been only a few in fetal and

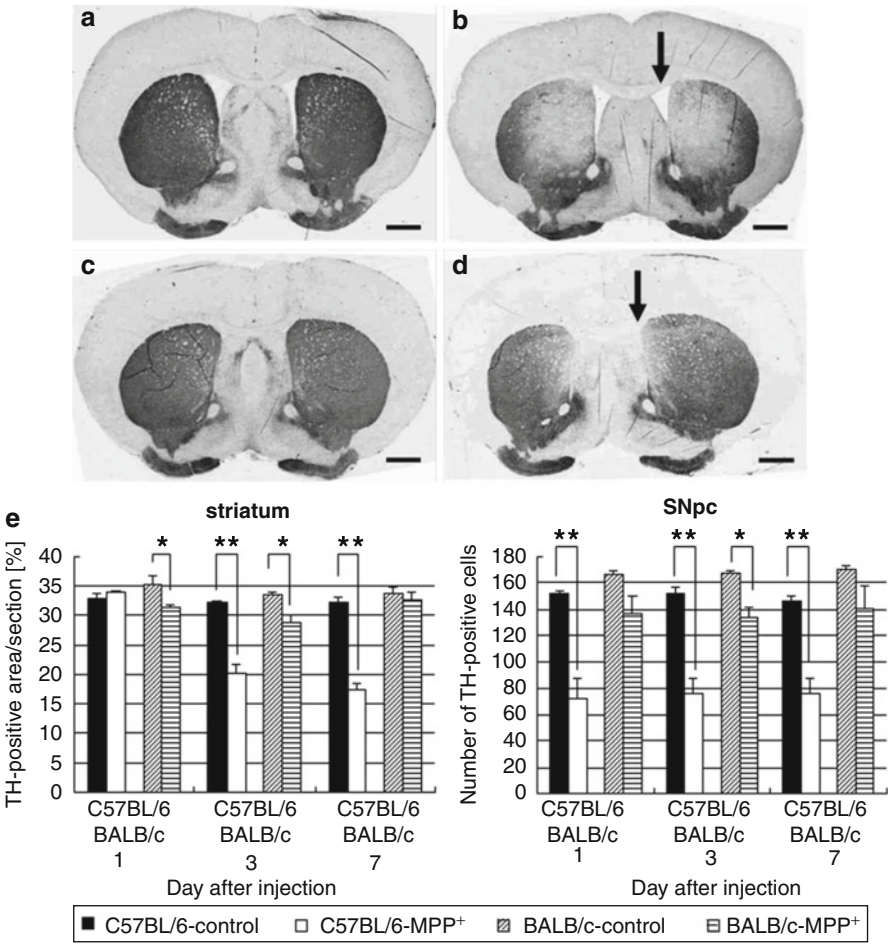

Fig. 5 TH immunoreactivity in the striatum at day 7 after injection. In mice injected icv with MPP^+, a reduction in TH-positive areas was observed at the injection (*arrows*) and contralateral sides of the striatum, especially adjacent to the lateral ventricles in C57BL/6 (**b**) and BALB/c (**d**) mice. However, no lesions were found in control C57BL/6 (**a**) and BALB/c (**c**) mice. Bar = 1 mm. (**e**) Strain difference in susceptibility to MPP^+ of C57BL/6 and BALB/c mice. Significant decreases in TH-positive areas in the striatum and TH-positive cells in the SNpc were documented in C57BL/6 mice at days 3 and 7, and at days 1, 3, and 7, respectively. In BALB/c mice, significant decreases in TH-positive areas and TH-positive cells were observed at days 1 and 3, and day 3 after injection, respectively. The decrease rates of BALB/c mice were smaller compared to those in C57BL/6 mice. Data are expressed as the mean ± standard error ($n = 3$–5). $^*p < 0.05$ and $^{**}p < 0.01$ (Ito et al. 2013a)

newborn mice. Chronic MPTP exposure during the organogenesis period (days 6–15 of gestation) reduced the fetal weight, motor activity, number of striatal TH-positive cells, and amounts of DA and homovanillic acid (Wolfgang and Beat 1991). Such toxicity was enhanced when MPTP was administered postnatally

(Muthian et al. 2010). By contrast, fetal mice treated once with MPTP at gestation day 17 showed unchanged DA concentrations in the brain 24 h after injection and 24 h after birth, and in the striatum 14 and 28 days after birth compared to control mice (Melamed et al. 1990). Recently, we have demonstrated that MPTP and MPP^+ cause a loss of TH-positive cells and fibers and an increase of apoptotic cells in the SVZ of embryonic mice when injected into dams, and of newborn mice when injected ip (Sai et al. 2012). The results indicate that MPTP and MPP^+ pass through the placenta and embryonic or newborn BBB, and finally reach the brain. Further, the results of immunohistochemistry and double-labeling immunofluorescent stainings demonstrated an increase of MAO-B-positive glial cells in the brain in MPTP-treated mice, indicating the involvement of MAO-B in the acute neurotoxicity of MPTP also in both embryonic and newborn mice. The expression of DAT was not observed in the nigrostriatal area of embryonic mice and in the area and SVZ of newborn mice.

7 Conclusion

The administration of MPTP to susceptible animals such as C57BL/6 mice induces SVZ neuroblastic A cell apoptosis as well as SNpc and striatal dopaminergic cell injury. The conversion from MPTP to its active form, MPP^+, is conducted mainly in MAO-B-positive ependymal cells and GFAP-positive cells in the SVZ. MPTP-induced neuroblast apoptosis in the SVZ is not prevented by the inhibition of monoamine transporters such as DAT, VMAT2, SERT, or NET, indicating that these transporters are not necessarily required to exert the neurotoxicity.

Recent results (Ito et al. 2012b) indicate that the nNOS or iNOS expression level is not involved in the different susceptibility to MPTP between susceptible C57BL/6 and resistant BALB/c, though there are a few reports (Chalimoniuk et al. 2006; Joniec et al. 2009) describing the significant increase of nNOS and iNOS expressions in the striatum and SNpc in C57BL/6 mice after MPTP administration. Factors influencing the strain difference in the susceptibility to MPTP toxicity are still unknown at present.

Both MPTP and MPP^+ can pass through the placenta and BBB and cause acute toxicity to the SN, striatum, and SVZ in the brain of embryonic and newborn mice as well as adult mice. The involvement of MAO-B in the acute neurotoxicity is confirmed regardless of the age of animals.

The replacement of lost neurons in a damaged brain area is the best way of therapeutic development for neurodegenerative diseases. Neurogenesis is, however, still a most controversial issue in studies of neurodegenerative diseases and their animal models. As mentioned, MPTP destroys neuroblastic A cells in the SVZ in the adult brain, followed by a transiently impaired neurogenesis. Though it still remains to be investigated whether and how multiple potential neural stem cells migrate into the nigrostriatal system and replace the lost dopaminergic neurons, delayed regeneration of dopaminergic neurons due to the loss of SVZ A cells may be one of possible causes of the pathological condition. With

increased attention to dopaminergic neurogenesis in MPTP-induced animal models for PD, it is expected that such animals become useful as a tool for establishing the contact to PD on neurogenesis.

N-Methyl-(R) Salsolinol and the Enzymes Catalyzing its Synthesis and Metabolism in Parkinson's Disease

Makoto Naoi and Wakako Maruyama

Contents

Abstract

Salsolinol (1-methyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline) is an endogenous catechol isoquinoline detected in the human brain. It is produced by the

nonenzymatic Pictet-Spengler reaction as the racemic mixture. However, a novel enzyme, (*R*)salsolinol synthase, was isolated from the human brain, which catalyzes the enantio-specific synthesis of (*R*)salsolinol from dopamine and acetaldehyde or keto acids. *R*-Salsolinol is *N*-methylated by (*R*)salsolinol *N*-methyltransferase (*N*-MT) into 2(*N*)-methyl-(*R*)salsolinol [*N*M-(*R*)Sal], which is oxidized by an oxidase sensitive to semicarbazide. *N*M-(*R*)Sal induces cell death in the dopaminergic cells of the rat substantia nigra after the systemic administration. The behavioral and pathological changes in rats were quite similar to those in other animal models of Parkinson's disease, using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or 6-hydroxydopamine. In cellular experiments, *N*M-(*R*)Sal binds to type A monoamine oxidase and induces apoptosis through activation of mitochondrial death signaling. Furthermore, *N*M-(*R*)Sal levels increase in the cerebrospinal fluid from parkinsonian patients, and the activity of its synthesizing neural (*R*)Sal *N*-MT is significantly higher in the lymphocytes prepared from parkinsonian patients than in control. The enantioselective neurotoxicity of *N*M-(*R*)Sal suggests that the enzymes related to the synthesis of this toxin might be associated with the etiology for PD. This chapter reviews the role of *N*-methylated isoquinolines and enzymes catalyzing *N*-methylation of small molecules in the pathogenesis of Parkinson's disease.

Keywords

Dopamine • Neurodegeneration • Parkinson's disease • Salsolinol

List of Abbreviations

CSF	The cerebrospinal fluid
DA	Dopamine
$DMDHIQ^+$	1,2-dimethyl-6,7-dihydroxyisoquinolinium ion
IQ	Isoquinoline
IVF	Intraventricular fluid
MAO-A and MAO-B	Type A and B monoamine oxidase
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
*N*M-(*R*)Sal	*N*-methyl-(*R*)salsolinol
N-MT	*N*-methyltransferase
Norsal	Norsalsolinol
PD	Parkinson's disease
ROS and RNS	Reactive oxygen and nitrogen species
Sal	Salsolinol
Sal-1-CA	Salsolinol-1-carboxylic acid
SAM	*S*-adenosyl-L-methionine
SN	Substantia nigra
TH	Tyrosine hydroxylase
TIQ	1,2,3,4-tetrahydroisoquinoline
β-CB	β-carboline

1 Introduction

The pathological hallmark of Parkinson's disease (PD) is the selective loss of dopamine (DA) neurons in the substantia nigra (SN) and the accumulation of inclusion body called Lewy body in the brain. Several genes have been identified to be responsive for the familial form of PD. However, the molecular mechanism to develop the disease remains enigmatic, and various epidemiologic conditions have been proposed as risk factors in PD. The selective cell loss of DA neurons suggests that DA itself may be associated with the pathogenesis of PD. DA is oxidized enzymatically by monoamine oxidase [MAO, EC 1.4.3.4] and produces hydrogen peroxide and also nonenzymatically oxidized into toxic semiquinone with superoxide anion. DA oxidation induces oxidative stress, dysfunction of mitochondria and ubiquitin-proteasome system, and inflammation and activates death signal pathway in DA neurons. In addition, the discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) suggested that endogenous DA-derived toxins might be involved in the neuronal loss in PD (Collins 2002).

DA-derived isoquinolines (IQs) have been proposed as endogenous neurotoxin candidates and intensively investigated in cellular and animal experiments. Salsolinol (1-methyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline, Sal) is one of DA-derived 1,2,3,4-tetrahydroisoquinolines (TIQs) and was identified in urine from PD patients treated with L-DOPA (Sandler et al. 1973) and the human brain. Sal derivatives, β-phenylethylamine-derived TIQs, and indoleamine-derived β-carbolines (β-CBs) were found in the urine, cerebrospinal fluid (CSF), and brain (Collins 1980; Sjöquist et al. 1981). Figure 1 summarizes the chemical structure of major IQs detected in the human brain.

Racemic forms of IQs are produced by nonenzymatic condensation of monoamines with aldehydes or keto acids in the Pictet-Spengler reaction. However, the

predominant occurrence of the (*R*)enantiomers was confirmed in mammalian tissues (Dostert et al. 1889, 1990), suggesting the enzymatic synthesis of Sal. From the human brain, we isolated three major enzymes in Sal metabolism: (*R*)salsolinol synthase catalyzing the enantioselective synthesis *R*-Sal, a (*R*)salsolinol *N*-methyltransferase (*N*-MT) methylating *R*-Sal at 2(*N*) position into N-methyl-(R)salsolinol [*N*M-(*R*)Sal], and *N*M-(*R*)Sal oxidase producing 1,2-dimethyl-6, 7-dihydroxy-1,2,3,4-tetrahydroisoquinoline ion ($DMDHIQ^{\pm}$).

This chapter summarizes the results on the enzymatic biosynthesis and metabolism of (*R*)Sal and *N*M-(*R*)Sal, the occurrence of Sal derivatives in the human brain, the preparation of in vivo model of PD in rat, and the molecular mechanism behind the programmed cell death induced by *N*M-(*R*)Sal. Finally the analyses of clinical samples from PD patients are presented to show the possible association of *N*M-(*R*)Sal with the pathogenesis of PD. The role of *N*M-(*R*)Sal and a neutral (*R*)Sal *N*-MT and other *N*-MTs in the selective degeneration of DA neurons in PD is discussed.

2 Biosynthesis of (*R*)salsolinol Derivatives in Human Brain

2.1 (*R*)Salsolinol Synthase Catalyzing the Enantio-Specific Synthesis of (*R*)salsolinol

In foods and beverages, Sal occurs as racemic mixture produced by the nonenzymatic condensation in the Pictet-Spengler reaction. However, Sal has an asymmetric center at 1 position, and (*R*)-enantiomer was dominant in urine from healthy volunteers, suggesting the stereoselective biosynthesis (Dostert et al. 1989). Dostert et al. (1990) proposed the biosynthesis pathway of (*R*)Sal in human, as shown in Fig. 2. The condensation of DA with pyruvic acid yields salsolinol-1-carboxylic acid (Sal-1-CA), which was detected in the human brain caudate nucleus, the CSF, and urine, but the enantiomeric structure was not determined (Ung-Chhun et al. 1985). The nonenzymatic decarboxylation of Sal-1-CA produces 1,2-dehydrosalsolinol, which was also identified in human urine (Dostert et al. 1990). The presence of an enzyme catalyzing the oxidative decarboxylation of Sal-1-CA into 1,2-dehydrosalinol was reported in rat kidney (Collins and Cheng 1988), but the enzyme has neither been characterized nor detected in the human brain. The enantioselective reduction of 1,2-dehydrosalsolinol or the direct decarboxylation of Sal-1-CA into (*R*)Sal has never been confirmed in animals or plants.

The enzyme participating in the enantio-specific biosynthesis of (*R*)Sal was isolated from the human brain. (*R*)Sal synthase was purified from the cytosolic fraction prepared from human gray matter as a monomer with molecular mass of 34.3 kDa. Table 1 summarizes the basic characteristics of this enzyme. (*R*)Sal synthase catalyzes the enantioselective synthesis of (*R*)Sal and (*R*)Sal-1-CA from DA with acetaldehyde or pyruvic acid (Naoi et al. 1996b). This enzyme synthesizes also norsalsolinol (6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline, Norsal) from DA and formaldehyde, but adrenalin and noradrenalin are not the substrate.

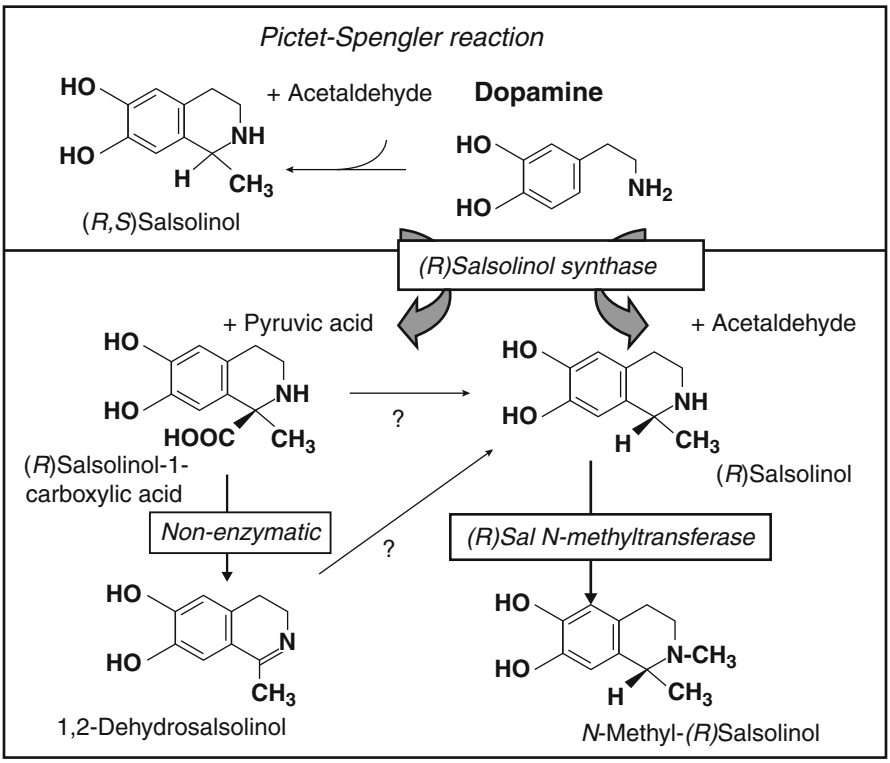

Fig. 2 Nonenzymatic and enzymatic synthesis of (*R*)-enantiomer of Sal derivatives in the human brain. Dopamine is condensed with acetaldehyde into (*R*/*S*)Sal by the Pictet-Spengler reaction. (*R*) Salsolinol synthase condenses DA with acetaldehyde or pyruvic acid to yield (*R*)Sal and (*R*)Sal-1-carboxylic acid, which is nonenzymatically converted into1,2-dehydrosalsolinol. The enantioselective synthesis of (*R*)Sal from (*R*)Sal-1-carboxylic acid or 1,2-dehydrosalsolinol has not been confirmed. SAM-dependent *N*-methyltransferase catalyzes the *N*-methylation of (*R*)Sal into *N*M-(*R*)Sal. *N*M-(*R*) Sal is further oxidized into $DMDHIQ^+$ enzymatically by *N*M-(*R*)Sal oxidase or nonenzymatically

The enzymatic activity to produce Norsal is the highest, followed by that to (*R*)Sal-1-CA and (*R*)Sal. However, this synthase does not produce *N*M-(*R*)Sal directly from *N*-methyldopamine (epinine) with acetaldehyde, suggesting that *N*M-(*R*)Sal is synthesized by two-step reactions with (*R*)Sal synthase and an *N*-MT.

2.2 (*R*)Salsolinol *N*-Methyltransferase

The conversion of N-methylation of (R)Sal into 132 NM-(R)Sal was con rmed in our studies using in vivo microdialysis in rat brain, and the highest activity was in the SN (Maruyama et al. 1992). In the sample from the human brain, (*R*)Sal *N*-MT activity was detected with two peaks at pH 6–7 and 8–9, and the activity of sample prepared from the striatum was higher at pH 7.0 than at the more alkaline pH

Table 1 Characteristics of enzymes related to the metabolism of *N*-methyl-(*R*)salsolinol

	(*R*)salsolinol synthase	Neutral (*R*)salsolinol *N*-Methyltransferase

(*R*)Sal synthase and (*R*)Sal *N*-methyltransferase were isolated from the cytoplasm fraction of human brain gray matter and the striatum, respectively

[a](*R*)Sal synthase was purified by stepwise column chromatograph with twice large DEAE, once small DEAE, and finally gel-filtration column, to a single protein with 1 700-fold purification from the cytoplasm fraction (Naoi et al. 1996a, b)

[b](*R*)Sal *N*-methyltransferase was purified by stepwise column chromatograph with a DEAE, and finally gel-filtration column, to a single protein with 130-fold purification from the cytoplasm fraction

(Fig. 3a, inserted). A neutral (*R*)Sal *N*-MT with the optimum pH at 7.0 was isolated from the cytoplasm fraction of the human brain as a single protein with the molecular mass of 35.6 kDa (Fig. 3a) (Naoi et al. 1997). *S*-Adenosyl-L-methionine (SAM) was a methyl donor. This neutral *N*-MT had the strict affinity to (*R*)Sal, and (*S*)Sal was not the substrate. Previously, a *N*-MT for 1,2,3,4-TIQ was isolated from the human brain, and the reaction was optimal at pH 8.25 (Naoi et al. 1989), which might correspond to alkaline (*R*)Sal *N*-MT. There was no correlation between the activities of the neutral and alkaline *N*-MT, and the age and sex did not affect the activities in any brain regions (Maruyama et al. 1997c).

Amine *N*-MT A from bovine liver was reported to *N*-methylate stereospecifically (*R*)-norsalsoline (7-hydroxy-6-methoxy-1-methyl-1,2,3,4-TIQ) and (*R*)salsolidine (6,7-dimethoxy-1-methyl-1,2,3,4-TIQ) (Bahnmaier et al. 1999). Recombinant human amine *N*-MT [tryptamine *N*-MT, EC 2.1.1.49] concerts benzylisoquinoline, tetrahydropapaveroline (THP), 6-O-methyl-THP and norreticuline into the *N*-methylated derivatives with a strict preference for (*R*)-configuration (Grobe et al. 2011). At present, it is not confirmed whether they can *N*-methylate Sals.

2.3 *N*-Methyl-(*R*)salsolinol Oxidase and Other Enzymes Related to the Metabolism

An enzyme catalyzing the oxidation of *N*M-(*R*)Sal into $DMDHIQ^{\pm}$ was identified in the human brain (Naoi et al. 1995). This oxidase is sensitive to semicarbazide,

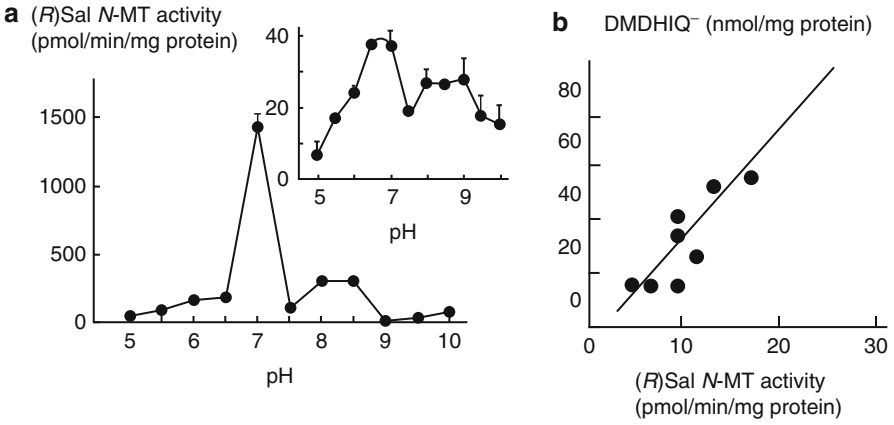

Fig. 3 The pH-dependent activity of (*R*)Sal *N*-MT and relation to Sal derivatives in the human brain. (**a**) The effect of pH on neutral (*R*)Sal *N*-MT activity purified from the human striatum. Inserted figure represents the effect of pH on the activity of (*R*)Sal *N*-MT in the cytoplasm fraction for the human striatum. (**b**) The relationship of $DHDMIQ^+$ levels in the SN with neutral (*R*)Sal *N*-MT activity in the caudate from the control human brains. Significant correlation was confirmed between the $DMDHIQ^+$ level in the substantia nigra and the activities of neutral *N*-methyltransferase in the caudate ($r = 0.905$, $p < 0.001$) and putamen ($r = 0.616$, $p < 0.05$)

but not inhibited by clorgyline and deprenyl, inhibitors of type A and B monoamine oxidase (MAO-A, MAO-B). It is localized in cytoplasm, but not in mitochondria as in the case with MAO. It catalyzes also the oxidation of *N*M-(*S*)Sal and 2(*N*)-methyl Norsal (*N*M-Norsal) with much less activity than to *N*M-(*R*)Sal. (*R*)- and (*S*)-Sal and Norsal were not the substrate of this enzyme. *N*M-(*R*)Sal is also nonenzymatically oxidized (Ung-Chhun et al. 1985; Maruyama et al. 1995).

3 The Occurrence of Salsolinol Derivatives in the Human Brain

3.1 Occurrence of (*R*)- and (*S*)-Enantiomers

The reported contents of Sal derivatives in the human brain basal nuclei were varied from 0.2 to 10 ng/g wet tissue weight, indicating the difficulty in the quantitative analyses of human materials. The occurrence of (*R*)- and (*S*)-Sal derivatives in the human brain was reported, but the results are contracting, as summarized in Table 2. We quantitatively determined (*R*)- and (*S*)-Sal derivatives in the human brain from control without the history of any neurological disorder (Maruyama et al. 1997a). (*R*)Sal was detected ubiquitously in the frontal lobe, caudate, putamen, and SN, but the (*S*)Sal was under detection limit. *N*M-(*R*)Sal content was significantly high in the SN and $DMDHIQ^+$ was detected only in the SN. Others reported similar results. Sal derivative contents were high

[a]Decreased, [b]increased, or [c]not changed in PD and aging

in the striatum followed by the SN and hypothalamus (Musshoff et al. 1999; DeCuypere et al. 2008a). However, Musshoff et al. (1999) reported the presence of minor amounts of (*S*)Sal in addition to (*R*)Sal with ration of about 1–2, and DeCuypere et al. (2008a) found the same amounts of (*R*)- and (*S*)-enantiomers of Sal and *N*M-Sal in the caudate and putamen, SN, and frontal lobe. At present, the reason of the discrepancy has not been well clarified. However, it is clear that (*R*)-enantiomers of Sal and *N*M-Sal are synthesized in the brain, and the enzymatic synthesis of (*R*)Sal derivatives is predominant in the brain regions with low DA contents, suggesting that nonenzymatic synthesis of racemic Sal might occur in the regions containing high levels of free DA. In addition, Sal derivatives may be transported into the brain through the blood–brain barrier (BBB) (Thümen et al. 2002), and racemic Sal derivatives derived from food and beverages might contribute to the presence of (*S*)Sal derivatives in the brain.

In the human brain, Norsal was also detected in the striatum, followed by the SN and hypothalamus (Musshoff et al. 1999). *N*M-Norsal was identified also in the same regions and immunochemically co-localized with a neuronal marker, neuron-specific enolase, and a catecholamine marker, tyrosine hydroxylase (TH) (DeCuypere et al. 2008b).

In neurons, Sal derivatives are localized in distinct intracellular compartments depending on their chemical structure. Sal derivatives are accumulated in the mitochondrial and membrane-nuclear fraction, 90–60 % of the total amounts, after 3-day incubation of (*R*)Sal and Norsal with PC12 cells (Maruyama et al. 1993). These results might be relevant with the recent result that *N*M-(*R*)Sal binds to MAO-A in the mitochondria (Yi et al. 2006). $DMDHIQ^+$ binds to melanin, which may cause its high contents in the SN (Naoi et al. 1994a). ^{3}H-Sal was reported to bind to a selective binding site in the striatum, cortex, median eminence, and hypothalamus of the rat brain, and the binding was displaced with DA, L-DOPA, carbidopa, and apomorphine, but not by DA receptor ligands, inhibitors of DA transport (Homicsko et al. 2002). The presence of this Sal-binding protein has not been confirmed in the human brain.

3.2 Factors Affecting the Salsolinol Levels

In human brain samples, (*R*)Sal levels decreased in the caudate, putamen, and SN according to the age, and a negative correlation was confirmed between *N*M-(*R*)Sal levels in the striatum and the age (Maruyama et al. 1997c). Alcohol intake markedly increased racemic Sal in blood and maybe also in the brain, but this issue has not been settled. The presence of alcohol did not affect the levels of (*R*)-enantiomer of Sal and *N*M-Sal in any brain regions (Naoi et al. 2004).

These results suggest that the concentration of the (*R*)-enantiomers may depend on the activity of the synthesizing enzymes. The relationship between the activities of Sal-related enzymes and Sal derivative levels was examined in human brain regions (Naoi et al. 1997). A good correlation was confirmed between the activity of neutral (*R*)Sal *N*-MT, but not that of alkaline *N*-MT, in the striatum (putamen and caudate) and the concentration of $DMDHIQ^+$ in the SN (Fig. 3b). *N*M-(*R*)Sal is synthesized in the striatum, oxidized into $DMDHIQ^+$, and transported and accumulated in the SN, as in the case with the rat PD model, where $DMDHIQ^+$ was detected in the SN after injection of *N*M-(*R*)Sal in the striatum (Naoi et al. 1996b). There was no other relationship that was confirmed between other enzyme activities and Sal derivative levels in frontal cortex and thalamus. In rat brain, the levels of racemic *N*M-Sal reached to the maximum within 2–6 h after the intraperitoneal injection, but *N*M-Sal was quickly eliminated from the brain (Lorenc-Koci et al. 2008). This rapid clearance of Sal may account for the discrepancy of the Sal contents with the activity of synthesizing enzymes in the human brain regions.

Sal derivatives are O-methylated by catechol-O-methyltransferase (COMT) (Hötzl and Thomas 1997) and oxidized by FAD-containing monooxygenase (Wu et al. 1992) and debrisoquine 4-monooxygenase (Iwahashi et al. 1993). However, it has not been studied whether the same enzymes are associated with the catabolism of Sal derivatives in the human brain.

4 Neurotoxicity of *N*-Methyl-(*R*)salsolinol: In Vivo and In Vitro Studies

4.1 An Animal Model of Parkinson's Disease

A PD model was established with *N*M-(*R*)Sal. After 1-week continuous injection in the rat striatum, *N*M-(*R*)Sal caused behavioral changes, such as akinesia, twitching, postural disturbance, and spontaneous rotation (Naoi et al. 1996b). The number of DA neurons stained with TH antibody and the contents of DA, noradrenaline, and their metabolites reduced markedly in the SN of the injected site. On the other hand, *N*M-(*S*)Sal, (*R*)Sal and (*S*)Sal, Norsal, and *N*M-Norsal did not induce significant biochemical-histopathological changes in rats. $DMDHIQ^+$ caused severe necrotic reaction at the injected site, but the behavioral and neurochemical changes were only transit.

The preparation of animal models of PD with Sal and other endogenous IQs has been also reported. Chronic administration of racemic Sal and TIQ caused a decrease in DA metabolism in the SN and striatum of rats, suggesting the loss of DA neurons (Antkiewicz-Michaluk et al. 2000). Systematic administration of racemic *N*M-Sal into rat perturbed CA metabolism but failed to cause the cell death in the SN (Lorenc-Koci et al. 2008). TIQ and *N*-methyl-6,7-dimethoxyisoquinolinium ion were infused in rat supra-nigral region and produced 42 % and 20 % SN cell loss, respectively, and reduced DA contents in the striatum, but behavioral change was not observed (McNaught et al. 1996). Intraperitoneal injection of TIQ reduced TH-immunoreactive neurons and DA levels in the striatum (Lorenc-Koci et al. 2000). Administration of indoleamine-derived 2(*N*)-methyl-β-CB into the rat SN induced the reduction of DA metabolites and the massive necrotic features (Neafsey et al. 1989). The presence of a methyl group at 9(*N*) position of β-CB increased the in vivo neurotoxicity markedly (Matsubara et al. 1998).

4.2 Induction of Apoptosis by *N*-Methyl-(*R*)salsolinol and Its Molecular Mechanism

In PD, apoptosis of dopamine neurons was confirmed in the SN by detection of activated caspase 3, increased Bax, and nuclear translocation of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Hartmann et al. 2000; Tatton 2000). In human dopaminergic neuroblastoma SH-SY5Y cells, *N*M-(*R*)Sal induces apoptosis (Akao et al. 1999, 2002; Maruyama et al. 1997b, 2001a, b). Among Sal derivatives, *N*M-(*R*)Sal is the most potent to induce DNA damage, whereas *N*M-(*S*)Sal, (*R*)- and (*S*)-Sal, and 1-carboxy-Sal are much less cytotoxic. Apoptosis is initiated with increased membrane permeability in mitochondria, as shown by the collapse in membrane potential, $\Delta\Psi m$, and swelling of mitochondria. Then, cytochrome c is released in the cytoplasm, caspase 3 is activated, GAPDH is translocated in nuclei, and finally nucleosomal DNA is fragmented and condensed. Only (*R*)-enantiomer of *N*M-Sal induced $\Delta\Psi m$ collapse in SH-SY5Y cells (Maruyama et al. 2001a, b) and also in isolated mitochondria (Akao et al. 2002), suggesting the presence of a binding protein of *N*M-(*R*)Sal. *N*M-(*R*)Sal binding to MAO-A located in mitochondria

outer membrane initiates apoptosis signaling (Yi et al. 2006). *N*M-(*R*)Sal binds to MAO-A at the substrate-binding site, which is suppressed by knockdown of MAO-A expression by short-interfering RNA (siRNA) and also by serotonin (5-hydroxytryptamine, 5-HT) and clorgyline, a MAO-A-specific substrate and inhibitor.

Sal derivatives cause also oxidative stress and mitochondrial dysfunction, proposed causal factors for dopaminergic neural loss in PD. *N*M-(*R*)Sal increases reactive oxygen and nitrogen species (ROS, RNS) in the dialysate of in vivo microdialysis at the rat striatum, but (*R*)Sal reduces the ROS levels at the distinct concentrations (Maruyama et al. 1995). (*R*)Sal, *N*M-(*R*)Sal, and $DHDMIQ^+$ inhibit the activities of complexes I (NADH-Q reductase) and complex II (succinate-Q reductase) in mitochondrial electron transfer pathway, and $DHDMIQ^+$ is the most potent inhibitor (Morikawa et al. 1998). *N*-Methylation of Sal and TIQ increases the inhibition of complex I and the cytotoxicity, as shown with *N*M-isoquinolinium ion ($NM\text{-}IQ^+$) and *N*M-TIQ (Suzuki et al. 1992), 1,2,3,4-tetrahydro-2-methyl-4,6,7-isoquinolinetriol (Willets et al. 1996), and *N*M-Norsal (Storch et al. 2002). Increased ROS production plays a major role in the cytotoxicity of racemic Sal, which particularly inhibits complex II (Storch et al. 2000). TIQ and IQ induced apoptosis in PC12 and SK-N-MC cells through the inhibition of complex I and increased ROS production (Seaton et al. 1997).

5 *N*-Methyl-(*R*)salsolinol and *N*-Methyltransferases in Parkinson's Disease

5.1 Salsolinol Derivatives in the Parkinsonian Brain

The changes in the amounts of Sal derivatives have been scarcely reported in the brain and CSF from PD patients. In the caudate nuclei of the brains from PD patients, the lower levels of (*R*)Sal, (*S*)Sal, *N*M-(*R*)Sal, and *N*M-(*S*)Sal were reported in comparison with the normal brain (DeCuypere et al. 2008a). On the other hand, in the CSF, *N*M-(*R*)Sal was increased in PD compared to control and patients with multiple system atrophy (MSA) (Maruyama et al. 1996a). The *N*M-(*R*)Sal contents in PD ($n = 16$) were 8.32 ± 2.89 nM (4.54–15.7), whereas in control ($n = 29$) and MSA ($n = 5$) 4.53 ± 2.08 (0.62–11.9) and 3.59 ± 1.52 (1.33–5.25). The relative concentration of *N*M-(*R*)Sal versus homovanillic acid (HVA), a DA metabolite, is significantly higher in PD than in control and MSA, suggesting the increased synthesis of *N*M-(*R*)Sal in PD. In the PD CSF, Sal was detected (Moser and Kämpf 1992) and Sal was increased in PD patients with dementia (Antkiewics-Michaluk et al. 1997). In the intraventricular fluid (IVF) from parkinsonian patients treated with L-DOPA, *N*M-(*R*)Sal and a trace amount of (*R*)Sal were detected in addition to $DMDHIQ^+$, but the (*S*)-enantiomers were not (Maruyama et al. 1996b). The amounts of *N*M-(*R*)Sal in the CSF and IVF had a tendency to increase at the early Hoehn and Yahr stage and decrease according to the advancing Hoehn and Yahr stage by disease duration (Maruyama et al. 1999) (Fig. 4a). In the CSF from the PD patients ($n = 9$), *N*M-*R*-Sal levels

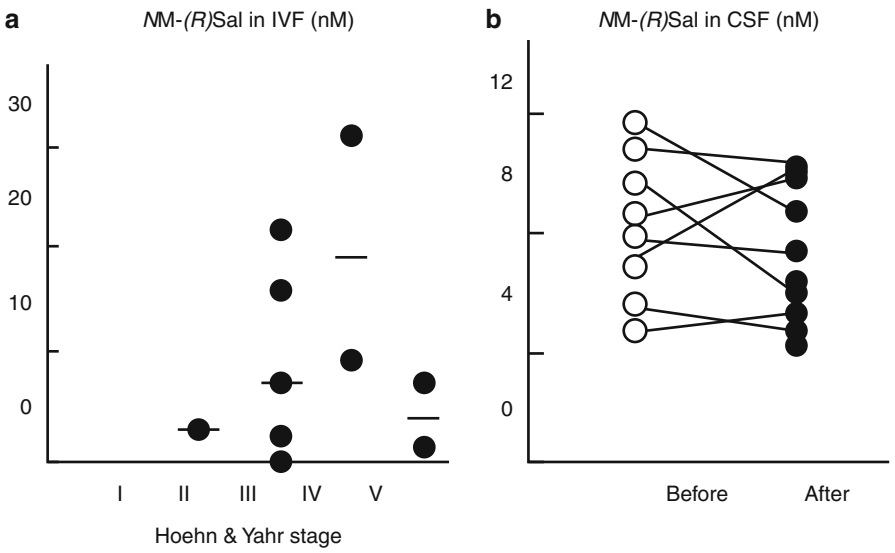

Fig. 4 The effects of Hoehn and Yahr stage and disease duration on *N*M-(*R*)Sal levels in the IVF and CSF. (**a**) The effects of the Hoehn and Yahr stage on the *N*M-(*R*)Sal levels in the IVF from parkinsonian patients. (**b**) Decline of *N*M-(*R*)Sal levels in the CSF of the same PD patients after 2 years of disease duration

decreased after 2 years of L-DOPA medication (Fig. 4b). The levels of Sal and *N*M-Norsal in the CSF were negatively correlated with the duration of PD (Moser et al. 1995; Müller et al. 1999). In plasma from de novo parkinsonian patients, (*R*)- and (*S*)-Sal levels were not increased, but (*R*)Sal levels were inversely related to the duration and intensity of PD, in contrast to (*S*)Sal and DA (Müller et al. 1998), whereas L-DOPA therapy increases Sal, Norsal, and *N*M-Norsal in urine (Scholz et al. 2004).

These results indicate that Sal derivative increase at the early phase of PD and reduce according to the disease progression. The loss of DA neurons caused by the disease progression and also aging reflects the Sal levels in the postmortem brain samples and in the CSF and IVF. Significant reduction of *N*M-(*R*)Sal in the SN for PD brains compared to control (DeCuypere et al. 2008a) may indicate the accelerated cell loss of DN neurons by this neurotoxin.

5.2 Neutral (*R*)salsolinol and Other *N*-Methyltransferases

The enzyme activities for Sal synthesis and metabolism were investigated in lymphocytes isolated from PD patients (n = 24) and control subjects without neurological disease (n = 56) (Naoi et al. 1998). The enzymatic activities of neural (*R*)Sal *N*-MT were found to increase significantly in PD lymphocytes, whereas the activities of alkaline (*R*)Sal *N*-MT and *N*M-*R*-Sal oxidase were not changed (Fig. 5a). The relationship between (*R*)Sal *N*-MT activity in the lymphocytes and

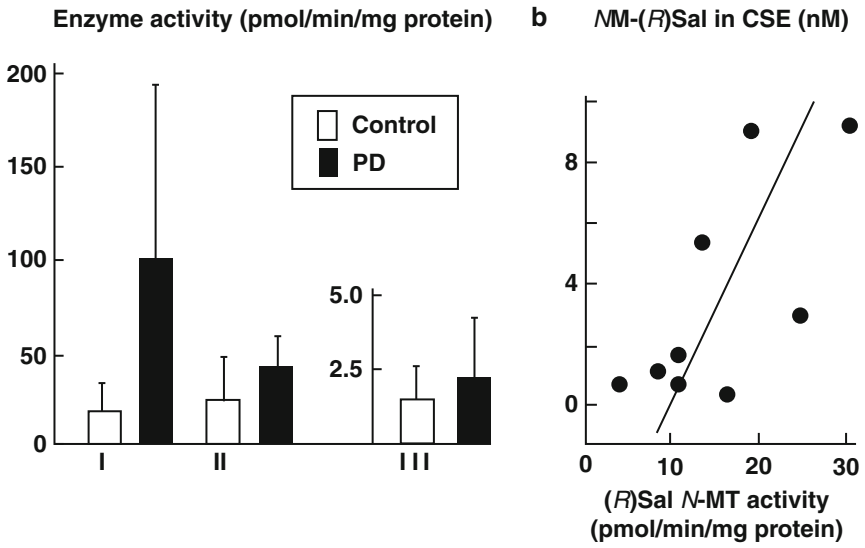

Fig. 5 The activities of (*R*)Sal *N*-MT and related enzymes in lymphocytes from PD patients and its relation to *N*M-(*R*)Sal levels in the CSF. (**a**) The enzymatic activity of neutral (I) and alkaline (*R*)Sal *N*-MT and *N*M-(*R*)Sal oxidase (III) in lymphocytes prepared from control (*white column*) and PD patients (*black column*). The column and bar represent the mean and SD. (**b**) The relationship of neutral (*R*)Sal *N*-MT activity in lymphocytes with *N*M-(*R*)Sal levels in the CSF from the same PD patients

*N*M-(*R*)Sal levels in the CSF was investigated (Fig. 5b). A weak correlation between them was observed ($y = -3.65 + 0.62$, $R = 0.71$, $p < 0.05$), but the limited number of the samples ($n = 9$) could not yield a conclusive result.

The increase in (*R*)Sal *N*-MT in PD lymphocytes was reexamined in other groups of control and PD patients (Fig. 6a, b). The activities of (*R*)Sal *N*-MT in PD lymphocytes ($n = 41$) were mainly distributed as being higher than 35 pmol/min/mg protein, whereas in control lymphocytes ($n = 205$) the activities were mostly lower than 30 pmol/min/mg protein. The activities did not show significant relationship to Hoehn-Yahr stage and the duration of illness, in contrast to the *N*M-(*R*)Sal contents in the CSF and IVF (Fig. 6c, d). The activities in lymphocytes were not affected by the gender, the age of PD onset, and the age of the patients when the samples were taken, and the dose of L-DOPA administered. These results suggest that (*R*)Sal *N*-MT activity may be genetically determined and the increased activity observed in PD may be neither secondary to the disease process nor to the treatment. (*R*)Sal *N*-MT was isolated and purified from the control brain, but we have no chance to investigate whether this enzyme changes its enzymatic properties in the PD brain.

N-Methylation of Sal, TIQs, and β-CB increases the cytotoxicity, as discussed above (Naoi et al. 1994b; Maruyama et al. 1997b; Matsubara et al. 2002; Williams and Ramasden 2005). Mammalian SAM-dependent *N*-MT [EC. 2.1.1] is a large family of enzymes catalyzing *N*-methylation of small molecules, and these *N*-MTs have similar molecular weights in the range of 25–35 kDa and share common enzymatic

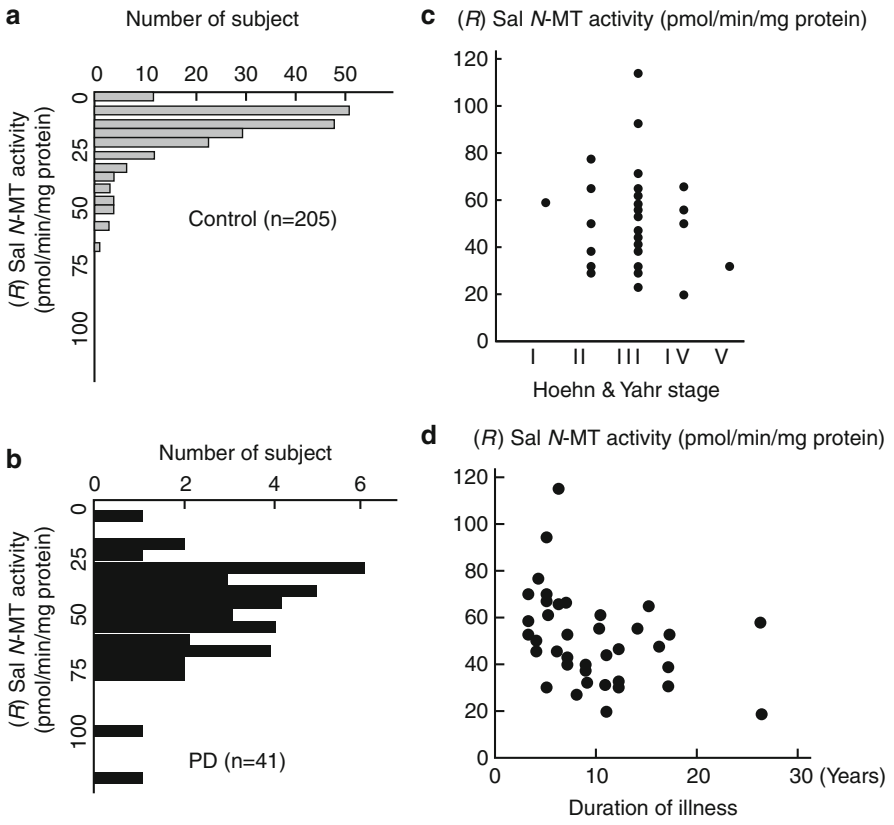

Fig. 6 Distribution of activity of neutral (*R*)Sal *N*-MT in lymphocytes and the effects of disease progress. (**a**) The activity in control subjects (n = 205). (**b**) In lymphocytes from PD patients (n = 41), the activity was distributed to higher than 35 pmol/min/mg protein. (**c**) The effects of the Hoehn and Yahr stage on the activity of neutral (*R*)Sal *N*-MT in lymphocyte from PD patients. (**d**) The effects of disease duration on the activities of neutral (*R*)Sal *N*-MT in lymphocytes from PD patients

characteristics. Nicotinamide *N*-MT [EC 2.1.1.1] is isolated from human liver, has a molecular weight of 29kDa as a monomer, and *N*-methylates nicotinamide and other pyridine (Aksoy et al. 1994). This *N*-MT converts 4-phenyl-1,2,3,6-tetrahydropyridine and 4-phenylpyridine into MPTP and MPP^+, suggesting the biosynthesis of MPTP derivatives from endogenous or environmental precursors (Ansher et al. 1986). The *N*-methylation of nicotinamide produces *N*-methylnicotinamide, which has MPP^+-like cytotoxicity (Fukushima et al. 2002). The protein levels of nicotinamide *N*-MT were higher in the CSF from PD patients (65 years old or younger) than control and decreased with aging (Aoyama et al. 2001). In the cerebella and caudate from PD patients, high expression of this *N*-MT protein and activity was confirmed, and the disease duration was negatively correlated with the expression (Parsons et al. 2002). The increased nicotinamide *N*-MT in PD may be relevant with the increased levels

of *N*-methylnicotinamide in parkinsonian brain (Williams et al. 1993) and high urinary excretions of nicotinamide metabolites in younger PFD patients, which declined with aging (Aoyama et al. 2000).

In PD brain, the activity of β-CB 9(*N*)-MT, which methylates nitrogen at 9 position in β-CB, but not at 2, increased in the frontal cortex in PD (Gearhart et al. 2000). Phenylethanolamine (PEA) *N*-MT (noradrenalin *N*-MT), which catalyzes the methylation of noradrenalin into adrenalin [EC 2.1.1.28], was reported to have β-CB 2(*N*)-MT, which methylates nitrogen at 2 position of β-CB (Gearhart et al. 2002). The thr15Ile polymorphism of a histamine *N*-MT [EC 2.1.1.8] was reported to be associated with PD (Palada et al. 2011) and the increase in histamine, which is related to DA neuron loss in PD (Anichtchik et al. 2000). However, recent papers did not confirm the association of this functional polymorphism with PD and essential tremor (Keeling et al. 2010) and AD (Marasovic-Susnjara et al. 2011).

6 Conclusion

These presented results from the basic research using cellular and animal models to the analyses of clinical samples from parkinsonian patients prove that *N*M-(*R*)Sal may be involved in the pathogenesis of PD as an endogenous dopaminergic toxin. However, these results cannot be free from criticism. The quite high concentrations of these IQs are used for very short time of experiment, which might not reasonably reflect the slowly processing neuronal loss in PD. The postmortem studies of IQ contents in the parkinsonian brain cannot draw the common consensus because of unavoidable variations in the quantitative data. These results seem to suggest that the neurotoxin hypothesis might pass away as the pathogenesis of PD, if we cannot establish new approach.

However, the results on (*R*)Sal *N*-MT, nicotinamide *N*-MT, and other *N*-MT suggest that we should investigate the enzymes in the metabolism of Sal derivatives in relation to the pathogenesis of PD. *N*-MT might be a good candidate for this study, since this enzyme can convert small molecules of endogenous and environmental protoxins into cytotoxic *N*-methylated toxins. The activity is regulated genetically and also by environmental factors, protoxin levels in diets, and cellular signals, such as interferon-γ (Yamada et al. 2010). These results suggest that the study on *N*-MT brings us further insights on the genetic and environmental factors as the pathogenesis of PD. If we can find the methods to suppress the synthesis of toxins with inhibitors, we can develop novel neuroprotective therapy to prevent the onset and progress of degeneration of DA neurons.

Acknowledgment This work is supported by The Research Funding for Longevity Sciences (23-2) from National Center for Geriatrics and Gerontology (NCGG), Japan.

Declaration of Approval from the Ethical Committee

The Ethical Committee of Iwate Medical University, Aichi Medical University, National Institute for Longevity Science, and Neurological Clinic (Dr. H. Narabayashi) approved the protocol for the examination of the CSF samples and lymphocytes and of the IVF. The patients were fully informed about the risk and the benefits of the examination.

Regulation of DA Homeostasis and Role of VMAT2 in DA-Induced Neurodegeneration

Eugene V. Mosharov

Contents

Abstract

Metabolic turnover of dopamine (DA) and other monoamines is tightly regulated by their synthesis, degradation, and compartmentalization. DA transmission plays important roles in learning and behavior, while abnormal DA tone is implicated in multiple neurological disorders, including Parkinson's disease (PD), schizophrenia, and psychoses. Free cytosolic DA can produce oxidative stress and protein damage and is suspected to contribute to the development of PD. Vesicular monoamine transporter 2 (VMAT2) sequesters DA into synaptic vesicles, thereby occupying a unique position where it facilitates DA synaptic transmission while preventing the deleterious effects of DA presence in the cytosol. This review summarizes recent findings on the regulation of DA cellular homeostasis and on the relationship between VMAT2 activity and DA-mediated neurotoxicity.

Keywords
Dopamine • Neurotoxicity • VMAT

List of Abbreviations

AADC	Aromatic L-amino acid decarboxylase
DA	Dopamine
DA_{cyt}	Cytosolic DA concentration
DAT	DA uptake transporter
DOPAC	3,4-dihydroxyphenylacetate
DOPAL	3,4-dihydroxyphenylacetaldehyde
LC	Locus coeruleus
L-DOPA	L-3,4-dihydroxyphenylalanine, levodopa
MAO	Monoamine oxidase
METH	Methamphetamine
MPP^+	1-methyl-4-phenylpyridinium
MSN	Medium spiny neurons
PD	Parkinson's disease
SNpc	Substantia nigra pars compacta
ROS	Reactive oxygen species
TH	Tyrosine hydroxylase
VGLUT2	Vesicular glutamate transporter 2
VTA	Ventral tegmental area
VMAT	Vesicular monoamine transporter

1 Introduction

Dopaminergic transmission in the brain plays important role in movement control, decision making, motivation, reward, learning, and other essential behavioral and cognitive functions. The three most thoroughly characterized dopaminergic projections are the nigrostriatal, mesolimbic, and mesocortical systems that each originate in the ventral midbrain and project to the striatum, limbic system, and cortex, respectively. These systems are targeted by drugs of abuse and psychostimulants, and abnormal DA neurotransmission in these pathways is linked to a number of diseases. Altered sensitivity to DA in mesolimbic and mesocortical pathways has been implicated in schizophrenia, narcolepsy, and effective disorders (van Rossum 1966; Gamo and Arnsten 2011), whereas degeneration of nigrostriatal neurons in PD represents the best-studied link between DA neurotransmission and neuropathology (Fahn 2008; Obeso et al. 2008).

PD is characterized by the preferential loss of DA neurons in the substantia nigra pars compacta (SNpc), although other neuronal populations, including locus coeruleus (LC), raphe nuclei, the dorsal motor nucleus of the vagus nerve, and the peripheral autonomic neurons, are also affected. Neurodegeneration in SNpc

with the concomitant depletion of striatal DA is responsible for the cardinal motor symptoms of PD: tremor, rigidity, bradykinesia, and postural instability (Fahn 2008; Obeso et al. 2008). Other features of PD include inflammation and the appearance of alpha-synuclein-positive "inclusions" known as Lewy bodies and Lewy neurites. Age is the greatest risk factor of PD; the likelihood that an individual will develop the disease is ~0.5 % at the age of 65 and increases by ~0.2 % each subsequent year (de Rijk et al. 1997; Baldereschi et al. 2000; Fahn and Sulzer 2004). The majority of PD cases are idiopathic, although at least 10 % of patients are now thought to have "familial" forms of the disease (reviewed in Martin et al. 2010); research to unveil new genetic causes of PD still continues.

SNpc and LC contain large quantities of neuromelanin, a dark pigment that gives names to these brain areas. Neuromelanin appears in SNpc neurons within 3 years of birth and increases linearly with age (Zecca et al. 2002). The pigment is derived from the oxidized metabolites of DA that form stable complex with iron, copper, and other metals (Sulzer et al. 2000; Zucca et al. 2006) and can be produced by DA neurons in vitro within several days of treatment with DA precursor L-3,4-dihydroxyphenylalanine (L-DOPA) (Sulzer and Zecca 2000). Because of the selective vulnerability of neuromelanin-containing neurons, dysregulation of DA homeostasis has been suggested to underlie neurodegeneration in PD (Edwards 1993; Gainetdinov et al. 1998a; Uhl 1998; Sulzer 2001; Lotharius and Brundin 2002).

2 DA Metabolism and Toxicity

Accumulation of cytosolic DA (DA_{cyt}) is toxic to cells in vitro (Mytilineou et al. 1993; Pardo et al. 1995; Sulzer et al. 2000; Fuentes et al. 2007; Mosharov et al. 2009) and several mechanisms for DA-mediated toxicity have been proposed. Spontaneous oxidation of DA in the presence of molecular oxygen produces hydrogen peroxide, hydroxyl radical, and superoxide (Graham 1978; Sulzer and Zecca 2000). Oxidation of the catechol moiety of DA yields DA-o-quinone and dopaminochrome (Sulzer and Zecca 2000); the latter can undergo a one-electron reduction to leukoaminochrome o-semiquinone radical that has been shown to produce other reactive species (Paris et al. 2009). Furthermore, DA-o-quinone reacts with free cysteine and exposed cysteine residues of proteins and glutathione, producing 5-S-cysteinyl-DA following cleavage by proteases. 5-S-cysteinyl-DA can undergo further oxidation and is toxic to cultured cells (Spencer et al. 2002) or when injected into the mouse brain (Zhang and Dryhurst 1994). 5-S-cysteinyl adducts of DA and its metabolites are readily detected in human SNpc confirming the physiological relevance of DA-induced protein damage (Fornstedt et al. 1989; Montine et al. 1995; Hastings and Berman 1999).

Other mechanisms of DA-mediated neurotoxicity include stabilization of toxic α-synuclein protofibrils (Rochet et al. 2004; Mosharov et al. 2006), inhibition of chaperone-mediated autophagy by DA-synuclein adducts (Martinez-Vicente et al. 2008), and reactions of DA with nitric oxide (Daveu et al. 1997), peroxynitrite

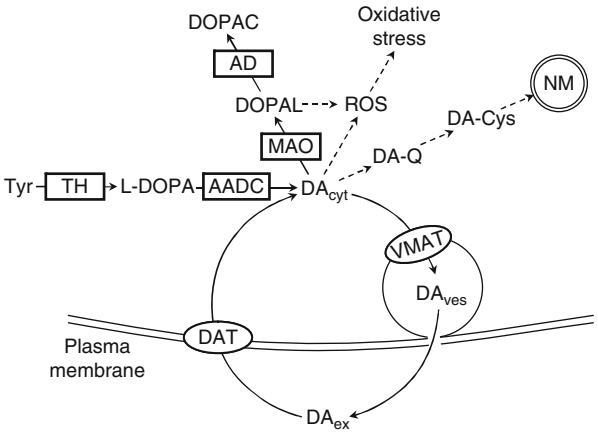

Fig. 1 DA homeostasis. Abbreviations: *AADC* aromatic L-amino acid decarboxylase, *AD* aldehyde dehydrogenase, *DA* dopamine (cytosolic, vesicular, and extracellular pools), *DAT* DA uptake transporter, *DA-Cys* 5-S-cysteinyl-DA, *DA-Q* DA-o-quinone, *DOPAC* 3,4-dihydroxyphenylacetate, *DOPAL* 3,4-dihydroxyphenylacetaldehyde, *L-DOPA* 3,4-dihydroxy-L-phenylalanine, *MAO* monoamine oxidase, *NM* neuromelanin inside autophagic vacuoles, *ROS* reactive oxygen species, *TH* tyrosine hydroxylase, *Tyr* tyrosine, *VMAT* vesicular monoamine transporter

(Daveu et al. 1997; Vauzour et al. 2008), and aldehydes (Collins and Bigdeli 1975; Deitrich and Erwin 1980; Naoi et al. 1993; Marchitti et al. 2007). Several recent reports confirm that a buildup of DA_{cyt} is indeed sufficient to induce progressive nigrostriatal neurodegeneration in rodents ((Caudle et al. 2007; Chen et al. 2008); also see below), although clinical studies of L-DOPA toxicity produced controversial results (Fahn et al. 2004; Holford et al. 2006; Chan et al. 2007).

Considering the toxic potential of DA, it is not surprising that multiple cellular mechanisms exist to ensure that DA concentration in the cytosol does not increase uncontrollably. It has been suggested that neuromelanin biosynthesis acts as one of the mechanisms for regulating toxic DA by-products by sequestering them into autophagic vacuoles (Sulzer and Zecca 2000). Other mechanisms include feedback inhibition of DA synthesis, catabolic DA cleavage, and synaptic vesicle sequestration.

2.1 Synthesis

Catecholamine neurotransmitters DA, norepinephrine, and epinephrine are defined by the presence of a catechol ring and an amine side-chain; together with indoleamine serotonin, these compounds are referred to as monoamines. DA and other catecholamines are synthesized from the nonessential amino acid tyrosine by a series of enzymatic reactions (Fig. 1).

In the first and typically rate-limiting step, tyrosine hydroxylase (TH) attaches a hydroxyl group to the aromatic ring of tyrosine using molecular oxygen,

tetrahydropterin, and ferrous iron (Fe^{2+}) as substrates and cofactors (Ramsey and Fitzpatrick 2000). TH activity is regulated on transcriptional, translational, and posttranslational levels (reviewed in (Goldstein and Lieberman 1992; Kumer and Vrana 1996; Fitzpatrick 2000; Daubner et al. 2011). The latter includes phosphorylation-dependent activation of TH by various kinases and its inhibition by DA, which competes for the binding site with tetrahydrobiopterin. This feedback mechanism limits DA production when its cytosolic concentration increases.

The second enzyme in DA biosynthesis, aromatic L-amino acid decarboxylase (AADC), uses pyridoxal phosphate as a cofactor and converts L-DOPA to DA. AADC activity can be regulated by second messenger systems; antagonists acting on extracellular DA receptors enhance AADC activity and agonists diminish it (reviewed in Hadjiconstantinou and Neff (2008)). Again, these mechanisms act to decrease DA production when its extracellular concentration increases. We recently found that AADC activity is increased by cytosolic Ca^{2+} (Mosharov et al. 2009). Although under normal conditions this mechanism may help to boost DA availability during high exocytotic activity, it may also increase the vulnerability of catecholaminergic cell populations that rely on Ca^{2+}- driven pacemaking, i.e., SNpc and LC neurons (Hetzenauer et al. 2006; Surmeier et al. 2010).

Importantly, AADC is not saturated under physiological conditions and increased L-DOPA concentration leads to its immediate conversion to DA. As L-DOPA is able to cross the blood–brain barrier, in the early 1960s it was introduced as an effective medication for PD (Hornykiewicz 2010). L-DOPA (levodopa), frequently in combination with the peripheral inhibitors of AADC carbidopa or benserazide, alleviates cardinal symptoms of PD and has remained the most commonly used drug for the treatment of the disease. L-DOPA treatment, however, does not halt the progression of PD, due to the ongoing loss of striatal terminals that store and release DA.

2.2 Cleavage

DA can be catabolized in the brain in a three step reaction that yields homovanillic acid (HVA) as a final product. First, monoamine oxidase (MAO) deaminates DA to produce 3,4-dihydroxyphenylacetaldehyde (DOPAL), which is further oxidized to 3,4-dihydroxyphenylacetate (DOPAC) by aldehyde dehydrogenase. In the next reaction catalyzed by catechol-O-methyltransferase (COMT), a methyl residue is attached to one of the hydroxyl groups of the catechol ring preventing its possible auto-oxidation to quinone. COMT however is located in postsynaptic neurons and glial cells thus playing limited role in the clearance of DA in catecholaminergic neurons (Kaakkola et al. 1987; Myohanen et al. 2010).

Of the first two reactions, MAO-mediated deamination of DA that takes place on the outer membrane of the mitochondria is the rate-limiting step. There are two isoforms of the enzyme: MAO-A is expressed in catecholaminergic cells and MAO-B is more abundant in glial cells and serotonergic and histaminergic neurons (Westlund et al. 1985). Even though MAO constitutes the first step of detoxification

of DA, it produces two highly reactive compounds, DOPAL and hydrogen peroxide (H_2O_2), which can react with each other producing hydroxyl radical. Although aldehyde dehydrogenase activity is very high and maintains the steady-state concentration of DOPAL at low levels, possible neurotoxicity of the aldehyde metabolites of amines was predicted 60 years ago due to their extremely reactive nature (Blaschko 1952). Indeed, the presence of DOPAL and its conjugation products in the brain and their toxicity has been experimentally demonstrated both in vitro and in vivo (reviewed in (Burke et al. 2004)). The proposed mechanism of toxicity involves formation of free radicals followed by the opening of the mitochondrial permeability transition pore and apoptosis.

DOPAC, the final product of intracellular DA cleavage, possesses a catechol ring and, similar to DA and L-DOPA, can auto-oxidize to a quinone that further reacts with cysteine residues of proteins and glutathione. Cysteine conjugated catechols, 5-S-cysteinyl-DOPAC, 5-S-cysteinyl-DA, and 5-S-cysteinyl-DOPA, are considered to be markers of excess cytosolic DA and oxidative stress in vivo (Hastings and Berman 1999; Caudle et al. 2007).

Overall, intracellular DA catabolism may not provide neuroprotection because of the reactive nature of the DA cleavage products. Interestingly, two MAO inhibitors that cross the blood–brain barrier, selegiline and rasagiline, have been successfully tested as neuroprotective therapy in PD either as monotherapy or in combination with L-DOPA. It has been suggested, however, that the neuroprotective effect of these drugs does not depend on inhibition of MAO but rather is ascribed to the stabilization of mitochondria and the induction of antiapoptotic Bcl-2 protein family and neurotrophic factors (reviewed in Naoi and Maruyama (2010); Weinreb et al. (2010)).

2.3 Synaptic Vesicle Sequestration

Monoamines are stored at high concentrations in secretory vesicles. These organelles provide protection against degradation by metabolic enzymes and enable regulated release via exocytosis. Moreover, acidic pH of the vesicles prevents auto-oxidation of DA allowing to accumulate high intravesicular neurotransmitter concentrations. Vesicular monoamine transporters (VMAT) responsible for DA uptake into synaptic vesicles are members of the mammalian major facilitator superfamily (MFS) which show structural and functional homology to bacterial toxin-extruding exporters (TEXAN) (Yelin and Schuldiner 1995; Fluman and Bibi 2009). In prokaryotes, multidrug resistance transporters are located on the plasma membrane and remove toxins from cytosol into the extracellular milieu, whereas in eukaryotes they are found on membranes of various cellular organelles and transport their substrates from cytosol into endocytic compartments.

In accordance with the toxin-extruding nature of VMAT, mammalian cDNA of the transporter was cloned by Robert Edward's laboratory on the basis of the protection that it provided against 1-methyl-4-phenylpyridinium (MPP^+).

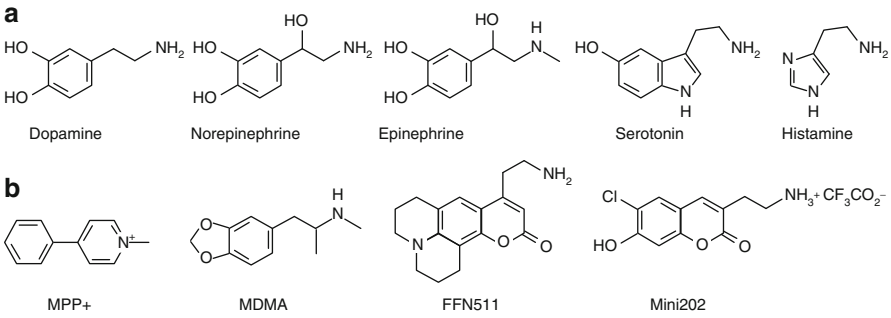

Fig. 2 Examples of (**a**) native and (**b**) synthetic substrates of VMAT. Abbreviations: *MPP*$^+$ 1-methyl-4-phenylpyridinium, *MDMA* 3,4-Methylenedioxymethamphetamine, ecstasy, *FFN511* false fluorescent transmitter 511, the first published optical probe designed to be a VMAT substrate, *Mini202* a fluorescent ratiometric VMAT substrate sensitive to changes in vesicular pH

This neurotoxin is an active metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a compound that induces parkinsonism in humans and is used in animal models of PD. VMAT-mediated resistance results from the removal of the neurotoxin from cytosol into vesicular organelles and is blocked by VMAT inhibitor reserpine (Liu et al. 1992a, b).

There are two isoforms of mammalian VMAT that are encoded by two separate genes that share 60 % homology (reviewed in (Guillot and Miller 2009; Wimalasena 2011)). The more abundantly expressed VMAT2 is found in central and sympathetic neurons, mast cells, and histamine-releasing cells in the gut, whereas VMAT1 expression is limited to the large dense core vesicles of peripheral endocrine cells, including adrenal chromaffin cells where it is co-expressed with VMAT2 (Weihe et al. 1994; Peter et al. 1995; Erickson et al. 1996).

Substrate specificity of VMATs is surprisingly poor, and in addition to native transmitters, it can transport a diverse range of synthetic substrates (Fig. 2; see (Wimalasena 2011) for review). It appears that two principle structural constrains that define whether a substance is a VMAT substrate are the presence of the aminoethyl group and of an aromatic ring. Such substrate promiscuity was recently exploited to develop a new set of fluorescent VMAT substrates, FFN511 (Gubernator et al. 2009) and Mini202 (Lee et al. 2010), that provide optical tools for studies of stimulation-dependent exocytosis in catecholaminergic cells (Fig. 2).

VMAT-mediated translocation of DA across secretory vesicles membrane depends on the electrochemical gradient (Johnson 1988):

$$\mathrm{Log}\left(\frac{\mathrm{DA_{ves}}}{\mathrm{DA_{cyt}}}\right) = \frac{\Delta\Psi \cdot F}{R \cdot T} + 2 \cdot \Delta\mathrm{pH},$$

where $\mathrm{DA_{ves}}$ and $\mathrm{DA_{cyt}}$ are catecholamine concentrations inside and outside the vesicle, $\Delta\Psi$ is electrical gradient, F is Faraday's constant, R is the universal gas

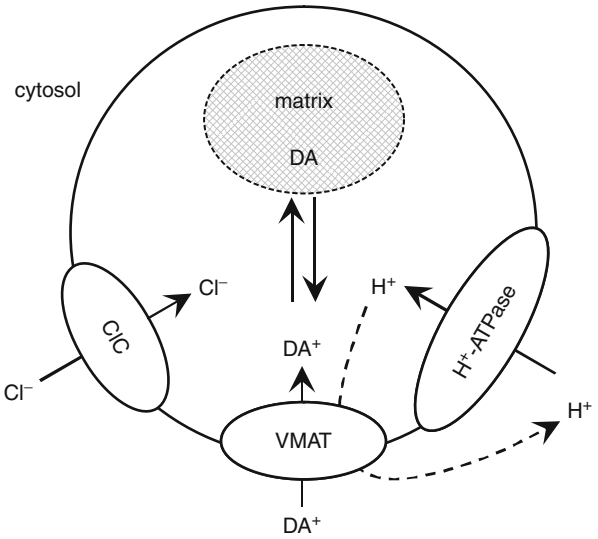

Fig. 3 VMAT-mediated uptake of DA into synaptic vesicles. VMAT exchanges two protons that move from vesicle to the cytosol for one positively charged DA molecule that moves from cytosol into the vesicle. Steep intravesicular proton gradient is generated by V-type H^+-ATPase that uses the energy of ATP hydrolysis to achieve vesicular pH of ~5.5. Chloride channels (*ClC*) help to dissipate positive charge resulting from the accumulation of protons and catecholamines inside the vesicles. Similarly, vesicular uptake of negatively charged glutamate in some midbrain DA neurons that co-express VMAT2 and VGLUT2 increases the amount of stored DA. As small synaptic vesicles have diameters of ~50 nm and release 1,000–3,000 molecules of DA during exocytosis (Pothos et al. 1998), vesicular concentration of neurotransmitter should reach 25–75 mM. Interestingly, in such a small organelle, pH 5.5 corresponds to 0.1 protons per vesicle

constant, T is absolute temperature, and ΔpH is the difference in pH between the cytosol and the vesicle.

Both the electrical and the chemical parts of the gradient are important for the transport (reviewed in (Edwards 2007; Guillot and Miller 2009)). The chemical gradient of protons is created by the vesicular proton pump, V-type H^+-ATPase (Fig. 3), and VMAT uses this energy by exchanging two protons for one DA molecule. As DA is positively charged, the electrical gradient also becomes important. The influx of Cl^- via the chloride channels neutralizes the buildup of positive charges due to the accumulation of DA and protons inside the vesicles therefore promoting neurotransmitter uptake. Work on isolated vesicles demonstrated that vesicle acidification is indeed much more efficient in the presence of chloride ions (Johnson 1988). Similarly, it has been shown that the knockout of the ClC-3 channel expressed on the vesicular membrane impairs vesicle acidification and induces degeneration of neuronal terminals in vivo (Stobrawa et al. 2001; Jentsch et al. 2005).

Recent data (Hnasko et al. 2010; Stuber et al. 2010) indicate that a subpopulation of midbrain neurons that project to the nucleus accumbens shell co-express VMAT2 and vesicular glutamate transporter 2 (VGLUT2). Vesicular uptake of negatively charged glutamate was found to promote accumulation of DA in the same vesicles, probably by dissipating $\Delta\Psi$ and increasing the pH gradient that drives VMAT2-mediated monoamine transport. This suggests yet another presynaptic mechanism that regulates dopaminergic transmission.

At a steady state, when $\Delta\Psi$ and pH in the cytosol are constant, a linear correlation is expected (i) between DA_{ves} and DA_{cyt} and (ii) between DA_{ves} and the square of the proton concentration in the vesicle:

$$DA_{ves} = A \cdot DA_{cyt} \cdot [H^+]^2_{ves}, \text{ where } A = 10^{\frac{\Delta\Psi \cdot F}{R \cdot T}} / [H^+]^2_{cyt}$$

Indeed, both relationships have been confirmed using optical measurements of vesicular pH and electrochemical detection of DA_{cyt} and the amount of the transmitter released during stimulation-dependent vesicle exocytosis (Pothos et al. 1998; Markov et al. 2008; Mosharov et al. 2009). It is important to note, however, that the total amount of stored DA can be much higher than the amount calculated from DA_{ves} because of the presence of the vesicular "matrix" (Fig. 3). In large dense core vesicles that store norepinephrine and epinephrine, negatively charged chromogranins and secretogranins bind catecholamines allowing up to 0.5 M concentrations of vesicular transmitter (Albillos et al. 1997), which would be impossible if the osmotic and the electrical gradient were not dissipated. It remains an open question whether similar polyelectrolyte proteins play a role in DA storage in small synaptic vesicles, although the high concentrations of vesicular transmitter seem to imply this (Fig. 3).

2.4 Reuptake

DA released by stimulation-dependent exocytosis acts on pre- and postsynaptic DA receptors, and its action is terminated by (1) passive diffusion, (2) COMT-mediated catabolism, and (3) reuptake by the dopamine uptake transporter (DAT).

DAT-mediated reuptake of DA has received considerable attention because this transporter is targeted by psychostimulants and drugs of abuse (reviewed in (Schmitt and Reith 1187; Zhu and Reith 2008; Sulzer 2011)). DAT activity and surface expression is regulated by phosphorylation/dephosphorylation in response to changes in extracellular DA concentration. Reuptake of DA and termination of its action on extracellular receptors also plays an important role in regulating intracellular DA pools, as illustrated in DAT-deficient mice (Gainetdinov et al. 1998b; Jones et al. 1998). In addition to expected significant elevation of extracellular DA levels, the tissue content of dopamine in DAT knockout striatum was less than 5 % of wild-type levels. It was suggested that recycled DA contributes

significantly to the maintenance of vesicular stores of DA in striatal projections of midbrain neurons. Alternatively, the observed reduction of DA intracellular stores may be due to hyperactivation of DA autoreceptors and the consequent inhibition of DA synthesis discussed above.

The importance of balanced maintenance of DA concentration in neuronal cytosol was demonstrated in a transgenic mouse that was engineered to express DAT on the plasma membrane of glutamatergic medium spiny neurons (MSNs) (Chen et al. 2008). MSNs constitute the majority of the neuronal population in the striatum and normally are exposed to DA only from the outside. In these transgenic animals however, MSNs can take up DA released by striatal projections of the midbrain dopaminergic neurons. Within several weeks following the induction of DAT expression, the mice develop motor dysfunctions, significant striatal and cortical atrophy, and progressive neurodegeneration of MSNs accompanied by oxidative stress, protein damage, and decreased glutathione levels. L-DOPA treatment worsened these symptoms, while reducing DA input to the striatum by lesioning the medial forebrain bundle had the opposite effect, demonstrating the dependence of the pathology on DA supply.

2.5 Spatial Considerations

The contribution of vesicular DA uptake differs significantly between the cell bodies and axonal terminals of neurons as the later have smaller cytosolic volume and higher concentration of vesicles. Because of this difference in stored-to-total DA ratio, DA_{cyt} in synaptic terminals will be more dependent on VMAT-mediated DA uptake, which can be illustrated by a simple calculus. If one synaptic vesicle releases all its content inside the neuronal soma, the change in DA_{cyt} will equal $DA_{ves}/N_A/V_{cell}$, where DA_{ves}, vesicular quantal size, is ~2,000 molecules (Pothos et al. 1998); N_A is Avogadro's Constant ($6.023*10^{23}$ molecules/mole); and V_{cell} is the cell soma volume (~1.77 pL for a cell with a diameter of 15 μm). It follows that emptying one vesicle would increase DA_{cyt} by ~2 nM. If, however, vesicular content is emptied inside a synaptic terminal with the diameter of ~1 μm, DA_{cyt} will be increased by >6 μM: a 3,000-fold difference.

We have recently investigated the contribution of DA metabolic pathways in the maintenance of cytosolic neurotransmitter concentration in cultured chromaffin cells (Mosharov et al. 2003) and neuronal cell bodies (Mosharov et al. 2009). Adrenal chromaffin cells, which lack neurites and are filled with secretory vesicles that each contain ~1,000,000 epinephrine or norepinephrine molecules (Wightman et al. 1991), are closer to synaptic terminals in their stored-to-total DA ratio. Cytosolic catecholamine concentration in these cells is 10–20 μM and can be increased severalfold by L-DOPA treatment. Consistent with strict control of the level of cytosolic catecholamine concentration, inhibition of either MAO or VMAT does not alter cytosolic transmitter levels, presumably because one pathway compensates for decreased activity of the other. When, however, both MAO and VMAT are blocked simultaneously, cytosolic catecholamine levels increase by more than sixfold.

In contrast to chromaffin cells, DA_{cyt} in neuronal cell bodies is below the limits of detection (<0.1 μM) unless augmented by L-DOPA pretreatment (Mosharov et al. 2009). Importantly, DA_{cyt} increases readily upon treatment with MAO inhibitors, but no contribution of somatic VMAT-mediated uptake can be detected either in the absence or in the presence of MAO blockade. Obviously, some DA secretory organelles reside in or close to neuronal cell bodies, as evident from somatodendritic DA release from midbrain neurons (Rice et al. 1997; Jaffe et al. 1998); however, the number of DA storage vesicles in the soma is probably insufficient to have significant effect on DA_{cyt} following VMAT blockade.

Amphetamine and its derivatives are often used to disrupt vesicular and DA_{cyt} pools. These psychostimulants have multiple intracellular sites of action, including inhibition of MAO, stimulation of catecholamine synthesis, redistribution of catecholamines from secretory vesicles to the cytosol, and induction of catecholamine reverse transport from the cytosol to the extracellular milieu via dopamine and norepinephrine uptake transporters (reviewed in (Sulzer 2011)). Chromaffin cells acutely treated with methamphetamine (METH) display decreased quantal size (Sulzer et al. 1995; Anderson et al. 1998; Mundorf et al. 1999) and increased cytosolic catecholamine levels, indicating that effects of METH on DA metabolism and the leakage of DA from vesicles are the dominant processes in these cells (Mosharov et al. 2003). In contrast, neurons exposed to METH showed decreased DA_{cyt} in the somas (Mosharov et al. 2009), demonstrating that DAT-mediated reverse transport governs the steady-state DA concentration, while redistribution of neurotransmitter from vesicles has negligible effect in neuronal cell bodies. While it is currently impossible to measure cytosolic DA in axonal terminals due to their small size, their similarity to chromaffin cells suggests a possibility that an equally large increase in DA_{cyt} occurs in METH-treated neuronal terminals. If so, this may explain a significant increase in striatal 5-S-cysteinyl-DA levels (LaVoie and Hastings 1999) and the pattern of METH-induced neurodegeneration in which neurites but not cell bodies are damaged in vitro (Cubells et al. 1994; Larsen et al. 2002), in animal models in vivo (Ricaurte et al. 1982), and in imaging studies of METH abusers after prolonged abstinence (Sang et al. 2007).

2.6 Duration of Exposure

The time during which a cell is exposed to the toxic effect of DA and its metabolites is another parameter that significantly affects neurotoxicity. In vitro, DA-mediated neurotoxicity depends linearly on the dose (concentration*time) of cell exposure to elevated DA_{cyt} levels, i.e., neurons can be quite resistant to short bursts of high DA_{cyt} but are compromised if small elevations in cytosolic transmitter persist for sufficiently long time (Mosharov et al. 2009). This consideration becomes very important when comparing data obtained from experiments in cellular and animal models with neuropathology in human as even the early onset type of PD develops over decades of life, which is orders of magnitude longer than the life span of rodents and cells in culture.

3 VMAT Expression and DA-Mediated Neurotoxicity

3.1 Less VMAT, More Toxicity

Considerable experimental evidence supports the idea that decreased vesicular uptake correlates with enhanced toxicity. Reserpine, an inhibitor of VMAT, induces parkinsonism by depleting releasable pool of DA from striatal terminals (Carlsson et al. 1957). The striatum of animals treated with reserpine shows marked rise in 5-S-cysteinyl-DA and oxidized glutathione levels, indicative of elevated cytosolic DA production and an ongoing oxidation stress (Fornstedt and Carlsson 1989; Spina and Cohen 1989; Bilska et al. 2007). Although no dopaminergic cell loss has been reported in reserpinized animals, a 7-day treatment with tetrabenazine, another VMAT inhibitor, induces irreversible histological changes in the neurons of SNpc (Satou et al. 2001). In the amphetamine-induced model of axonal degeneration in the striatum, reserpine exacerbated drug-induced toxicity, whereas pretreatment with TH inhibitor α-methyl-p-tyrosine provided protection (Wagner et al. 1983). Additionally, reserpine causes concentration-dependent death of RCSN-3 cells, a catecholaminergic cell line derived from adult rat SNpc (Fuentes et al. 2007).

Several genetic mouse models with various levels of VMAT2 expression have been created to study the role of the transporter in neurotoxicity (see (Guillot and Miller 2009; Taylor et al. 2011) for comprehensive reviews). Mice with a homozygous deletion of VMAT2 transporter ($VMAT2^{-/-}$) do not show any gross anatomical abnormalities, including normal number of neurons in SNpc, but die within a few days after birth, probably because they do not feed (Fon et al. 1997; Takahashi et al. 1997; Wang et al. 1997). The brains of $VMAT2^{-/-}$ animals manifest severely compromised DA storage (~1.5 % of wild-type levels). Midbrain neuronal cultures from these mice show normal morphology and TH fibers density but contain only 3 % of the intracellular DA levels of the $VMAT2^{+/+}$ cultures and are unable to accumulate DA within synaptic vesicles (Fon et al. 1997; Yamamoto et al. 2007). Importantly, $VMAT2^{-/-}$ neurons are significantly more sensitive to METH-induced neurodegeneration of primarily neurites and display intense labeling for ROS formation upon drug treatment (Larsen et al. 2002). These data indicate that although METH-induced oxidative stress does not require the presence of a vesicular pool of DA, vesicular sequestration of the neurotransmitter provides significant neuroprotection.

In contrast to animals with complete VMAT2 deletion, VMAT2 heterozygous mice ($VMAT2^{+/-}$) are viable to adulthood. $VMAT2^{+/-}$ mice display ~50 % reduced total DA, diminished levels of extracellular striatal DA, as well as decreased potassium- and amphetamine-evoked DA release in vivo and in postnatally cultured cells (Fon et al. 1997; Takahashi et al. 1997; Wang et al. 1997). Although the animals perform normally on motor tests, they show depressive-like phenotype and impairments in learned helplessness and conditioned place preference paradigms (Takahashi et al. 1997; Wang et al. 1997; Fukui et al. 2007). As expected, mice are more sensitive to neurodegeneration induced by

methamphetamine and MPTP (Gainetdinov et al. 1998a; Fumagalli et al. 1999), confirming the ability of VMAT2 to protect cells by removing toxins from the cytosol. Though no PD-like neuropathology was observed in VMAT2$^{+/-}$ mice up to 7-month of age, further studies are required to determine whether neurodegeneration of the nigrostriatal system may occur later in life. Interestingly, while no loss of the nigrostriatal biochemical markers was found in VMAT2$^{+/-}$ animals injected with L-DOPA for 28 days (Reveron et al. 2002), cultured DA neurons from these mice show increased vulnerability to the toxic effect of L-DOPA (Kariya et al. 2005).

Another line of mice that proved extremely helpful in PD research expresses only 5 % of the normal level of VMAT2. The first generation of mice that have a hypomorphic allele of the VMAT2 (VMAT2-deficient KA1 line (Mooslehner et al. 2001)) was later found to have a spontaneous deletion of the alpha-synuclein gene (Specht and Schoepfer 2001; Colebrooke et al. 2006). As this protein plays an important role in the pathology of PD (reviewed in (Vila and Przedborski 2004; Eriksen et al. 2005; Sulzer 2007; Dawson et al. 2010)), further breeding was done to remove all traces of alpha-synuclein deficiency.

The resulting VMAT2-LO mice show 95 % reduction of VMAT2 expression and 85 % reduction in DA levels in the striatum (Caudle et al. 2007). As the animals age, they show signs of PD-like progressive neurodegeneration, including L-DOPA-responsive motor deficits; oxidative stress and protein damage; decreased DA, DAT, and TH levels in the striatum; and pathological accumulations of alpha-synuclein and a reduced number of DA neurons in the SNpc (Caudle et al. 2007; Taylor et al. 2011). Importantly, animals do not manifest motor symptoms and some of the biochemical markers until they are 12–28-month-old (Taylor et al. 2011), highlighting the slow nature of progressive neurodegeneration in this animal model.

The onset of the motor symptoms in PD is accompanied and generally preceded by a variety of nonmotor disturbances, including but not limited to olfactory deficits, constipation, sleep disorders, and depression. It has been suggested that degeneration of other monoamine systems, such as norepinephrine neurons in LC and serotonin neurons in the dorsal raphe nucleus, may contribute to the development of the nonmotor symptoms (reviewed in (Dauer and Przedborski 2003; Fornai et al. 2007; Rommelfanger and Weinshenker 2007; Fahn 2008; Obeso et al. 2008; Delaville et al. 2011; Lang 2011)). Biochemical characterization of VMAT2-LO mice revealed progressive depletion of all monoamines (Caudle et al. 2007; Taylor et al. 2009) as well as age-dependent neurodegeneration in the LC that preceded the loss of neurons in the SNpc (Taylor et al. 2011), similar to the clinical data from PD patients. Moreover, VMAT2-LO mice demonstrate early deficits in olfactory discrimination, delayed gastric emptying, altered sleep latency, anxiety-like behavior, and age-dependent depressive behavior (Taylor et al. 2009), confirming the involvement of monoamine dysfunction in the manifestation of nonmotor symptoms of PD. Overall, the VMAT2-LO mouse model recapitulated the majority of motor and nonmotor symptoms of PD and demonstrates that

a reduced capacity of cells to sequester DA and other monoamines inside storage vesicles is sufficient to cause PD-like neurodegeneration of neurons and their axonal projections.

3.2 More VMAT, Less Toxicity

As VMAT2 should prevent DA-induced toxicity by sequestering neurotransmitter inside synaptic vesicles, enhancing VMAT-mediated transport is expected to be neuroprotective. Clinical data indirectly support this claim as neurons in the ventral tegmental area, a dopaminergic cell population that is spared in PD, express higher levels of VMAT2 and produce lower amounts of neuromelanin compared to neurons in SNpc (Hirsch et al. 1988; Zecca et al. 2001; Liang et al. 2004). Furthermore, higher expression level of VMAT2 compared to that of DAT has been suggested to predict lower vulnerability of neuronal populations in PD (Uhl 1998; Miller et al. 1999), while gain-of-function haplotypes in the human VMAT2 gene reduce the risk of developing PD in women (Glatt et al. 2006).

The link between neurotoxicity and the activity of VMAT2 has been directly studied in vitro using cultured cells. As described above, mouse midbrain neurons treated for several days with DA precursor L-DOPA produce neuromelanin due to accumulation of cytosolic DA and downstream oxidation products (Sulzer et al. 2000). Virus-mediated overexpression of VMAT2 in these cultures prevents neuromelanin synthesis, increases the number of DA molecules packaged per synaptic vesicle, decreases DA_{cyt}, and efficiently protects neurons from L-DOPA-induced cell death (Pothos et al. 2000; Sulzer and Zecca 2000; Mosharov et al. 2009). Similarly, overexpression of VMAT2 in primary rat mesencephalic cultures and PC12 cells, a pheochromocytoma-derived cell line, increases intracellular DA content, augments stimulation-dependent DA release, and attenuates cell death induced by METH; downregulation of VMAT2 using virally delivered shRNAs produces an opposite effect (Vergo et al. 2007). Additionally, increased expression of VMAT2 in vivo is able to mitigate the oxidative stress and gliosis caused by METH (Guillot et al. 2008). Together these data strongly support the inverse relationship between DA-induced neurotoxicity and the activity of VMAT2.

4 Conclusion

Overview of enzymes and transporters involved in DA homeostasis illustrates that all metabolic steps work to maximize the amount of DA available for exocytosis while at the same time limiting the accumulation of potentially toxic cytosolic transmitter. Importantly, all except one metabolic step in DA turnover affect neurotoxicity and neurotransmission in the same direction, i.e., by altering the levels of cytosolic and vesicular DA in synchrony. For example, increased activities of TH and AADC will enhance DA-mediated toxicity and the amount of DA stored

in vesicles, whereas increased catabolism will diminish them both. The sole exception is the activity of VMAT, which has opposing effects on cytosolic and vesicular DA levels. This unique position of VMAT in DA handling provides therapeutic advantages that can be explored in future drug development.

Acknowledgments I thank Drs. David Sulzer and Yvonne Schmitz for their help during the preparation of the manuscript. The project was supported by the Picower Foundation, the Parkinson's Disease Foundation, and grants number R01NS075222 and R03NS064373 from the National Institute of Neurological Disorders and Stroke.

Rotenone as Preclinical Model Compound in Parkinson Disease

Jason R. Cannon and J. Timothy Greenamyre

Contents

Abstract

The motor symptoms of Parkinson's disease (PD) are characterized by a combination of bradykinesia, resting tremor, rigidity, and postural instability, which are caused by striatal dopamine depletion resulting from loss of nigral dopamine neurons and dopaminergic projections. At the time of diagnosis,

there is already extensive loss of striatal dopamine and nigral dopamine neurons. Patients also commonly experience a host of cognitive, psychiatric, autonomic, sleep, and sensory disturbances that likely result from pathology to regions outside the substantia nigra. These nonmotor abnormalities may occur decades before diagnosis. "Preclinical" PD is the disease before motor symptom severity elicits a PD diagnosis. Currently, there is an emphasis on the creation and characterization of preclinical models to identify early-stage PD features and test early intervention strategies. The rat rotenone model tests the hypothesis that nigral dopamine neurons are selectively sensitive to systemic mitochondrial complex I inhibition. The model replicates selective loss of nigral dopamine neurons and was the first neurotoxicant model to reproduce intracellular α-synuclein accumulation, similar to Lewy bodies. Subsequent investigations have found the model to replicate many additional PD features. In this chapter, the utility of this model to examine preclinical PD endpoints is evaluated. The major emphasis is pathological and functional alterations that are known to occur in the earliest stages of PD or even be predictive of disease development. Finally, specific rotenone administration regimens to produce preclinical PD models are detailed. In summary, available data suggest that the rat rotenone model is an excellent system to examine preclinical PD.

Keywords
Parkinson's disease • Preclinical • Rotenone

List of Abbreviations

6-OHDA	6-hydroxydopamine
AD	Alzheimer's disease
DNA	Deoxyribonucleic acid
LBD	Lewy body dementia
MIBG	Metaiodobenzylguanidine
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
PD	Parkinson's disease
PET	Positron emission tomography
RBD	REM behavior disorder
REM	Rapid eye movement
SPECT	Single-photon emission computed tomography

1 Introduction

Parkinson's disease (PD) is characterized behaviorally by the presence of a combination of the cardinal motor features that include bradykinesia, resting tremor, rigidity, and postural instability. These key motor deficits are caused by striatal dopamine depletion that results from the loss of nigral dopamine neurons and their striatal dopaminergic projections (Bertler et al. 1958; Carlsson et al. 1958;

Moore et al. 1971). A major pathological hallmark is the presence of cytoplasmic inclusions known as Lewy bodies in surviving dopamine neurons (Forno 1996). Aggregated α-synuclein and ubiquitin are major components of Lewy bodies, and mutations in α-synuclein that promote aggregation or in proteins that affect proteasomal activity cause PD (Morris 2005; Spillantini et al. 1997). In addition to pathology in the nigrostriatal dopamine system, pathology is evident in other brain regions, particularly in brainstem nuclei, where α-synuclein accumulation occurs and is thought to temporally precede nigral aggregation (Braak et al. 2003; Braak et al. 2004). Systemic pathology also occurs, especially in the enteric nervous system (Braak et al. 2006; Wakabayashi et al. 1988). PD patients also commonly experience a host of cognitive, psychiatric, autonomic, sleep, and sensory disorders that likely result from pathology to neuronal regions outside the substantia nigra (Adler 2005; Emre 2004; McDonald et al. 2003; Papapetropoulos and Mash 2005).

Pharmacologic and surgical approaches can effectively treat many of the motor symptoms. However, current treatment options do not slow or prevent disease progression. PD is currently thought to affect at least 5 million individuals worldwide (Dorsey et al. 2007). The most significant risk factor for PD is ageing (Collier et al. 2011). Thus, given that the average life span is rising, in part due to medical advances related to cardiovascular diseases and cancers, PD incidence is expected to increase in an ageing population.

The causes of most cases of PD remain unknown. Genetic factors continue to be identified. However, monogenetic causes likely account for less than 10 % of total PD cases. Environmental exposures have long been linked to PD, with numerous structural and use classes of compounds linked to PD and other neurodegenerative diseases. While many reports have suggested links between environmental exposures and PD, identifying specific causative risk factors has been very difficult (Cannon and Greenamyre 2011). More recently specific toxicant exposures have been identified as risk factors using specialized epidemiological techniques. Notably, exposures to the herbicide paraquat and the pesticide rotenone have been identified as PD risk factors (Tanner et al. 2011). The identification of these toxicants as risk factors is supported by the fact that both of these toxicants have been utilized extensively to model PD in animals. Unfortunately, for most PD cases there is limited understanding of etiology. The majority of cases are thought to arise from a combination of genetic predisposition and environmental exposures. There is some evidence for a role of specific interactions in PD risk; however, our understanding of these interactions remains rudimentary (Cannon and Greenamyre 2012).

Thus, there are two key challenges that PD researchers and clinicians continue to have: (1) identifying causative factors (a reduction in exposure to causative factors could, in principle, reduce PD incidence over time) and (2) the development of disease-modifying therapies (such therapies would slow or halt progression in addition to treating the primary motor symptoms). While work to accomplish these goals typically involves human studies, animal models are extensively utilized during the earliest stages and throughout the process. Unfortunately, translating positive results from neurotoxicant-based animal studies to clinical trials has been largely unsuccessful. There are several possible explanations: (1) Neuroprotective

regimens are usually administered prior to toxicant insult. This type of regimen bears little relevance to a clinical setting, where a patient would be treated after diagnosis. Thus, positive studies from pretreatment regimens may have little relevance and translational impact in humans. (2) Relevance of the model. Most neurotoxicant models do an outstanding job of lesioning the nigrostriatal dopamine system. However, a model that does so in hours or a few days does not reproduce the chronic development of pathology in human PD. Further, regimens that simply prevent the primary mechanism of action of the insult in a neurotoxicant model are unlikely to be meaningful, for example, showing that an antioxidant is protective in an acute oxidative stress model (6-hydroxydopamine, 6-OHDA) or that a drug which alters 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) metabolism or metabolite accumulation in dopamine neurons is unlikely to provide substantially useful information on whether it is a viable neuroprotective agent (Cannon and Greenamyre 2010). (3) Failure to appreciate early-stage features of PD and PD models. The earlier a neuroprotective intervention is administered in the disease process, the more likely it will have a disease-modifying impact. The use of preclinical animal models can help to test potential therapeutics for an early-stage administration both directly and indirectly, by aiding in the development of early-stage diagnosis and testing whether therapeutic regimens prevent development of preclinical endpoints or are neuroprotective. Currently, preclinical animal models are limited – most models focus on reproducing the end-stage phenotype, primarily major striatal dopamine depletion and nigral dopamine cell loss. In this brief chapter, the development and use of the rotenone model to reproduce and identify preclinical features of PD is critically evaluated.

2 The Rotenone Model of Parkinson's Disease

Rotenone is a compound that occurs naturally in the roots of a variety of plant species. It is a highly selective inhibitor of mitochondrial complex I that has been historically used as an insecticide and to kill fish (Ravanel et al. 1984). Systemic complex I inhibition occurs in PD patients (Parker et al. 1989; Schapira et al. 1989). Thus, it has been hypothesized that toxicants that produce systemic complex I inhibition may have a role in PD. It should be noted that the classic dopaminergic neurotoxicant, MPTP, also selectively inhibits complex I. However, due to its affinity for the dopamine transporter, it selectively affects catecholaminergic neurons (Javitch et al. 1985; Nicklas et al. 1985). Conversely, rotenone is a highly lipophilic molecule able to enter all cells and produce complex I inhibition.

There have been many attempts to produce a rotenone model of PD, including high-dose systemic administration and intracerebral infusions that produce nonspecific lesions (Ferrante et al. 1997; Heikkila et al. 1985; Rojas et al. 2009). A major advancement came when systemic rotenone was chronically administered to rats at much lower doses, producing complex I inhibition similar to that observed in PD patients. This regimen produced highly selective nigral dopamine neuron degeneration (Betarbet et al. 2000). Here, for the first time in an animal model,

cytoplasmic, α-synuclein-positive inclusions that have striking similarities to Lewy bodies were observed in surviving dopamine neurons. Reproduction of this key pathological feature represented a major advantage over other available neurotoxicant models. While variability in the number of animals that exhibited a lesion and variability in the magnitude and morphology of the lesion were major obstacles for using the model in neuroprotection and potentiation studies, a more recent version is much more reproducible (Cannon et al. 2009). While the rat is the most common species that rotenone has been used to model PD, it has been used in other major biological models including *Drosophila*, *C. elegans*, and zebrafish (Cannon and Greenamyre 2010). Not only has the rotenone model replicated key PD features, it has been found to predict previously unknown features of human PD. Notably, rotenone treatment in the rat produces iron accumulation in the substantia nigra through a previously unknown mechanism involving transferrin and transferrin receptor 2 (Mastroberardino et al. 2009). This study also found the same alterations in the brains of PD patients. In addition to replicating these key pathological features, the rotenone model has been found to be useful in reproducing several key preclinical features of PD, which are discussed in this chapter.

3 Preclinical Parkinson's Disease and the Relevance of the Rotenone Model

What is preclinical PD? Simply stated, "preclinical" is the disease before characteristic motor symptoms become severe enough that the patient enters a clinic and is diagnosed with PD. Certainly, there is much patient-to-patient variability in the threshold of symptoms that are required to reach "clinical" PD. However, it is worth noting that by the time a patient is diagnosed with PD, ~70–80 % of striatal dopamine and ~50–60 % of nigral dopamine neurons are lost (Bernheimer et al. 1973). Thus, it is thought that damage and cell loss may occur over several decades before the pathology becomes severe enough to elicit noticeable symptoms.

3.1 Autonomic Dysfunction

Autonomic dysfunction may precede motor deficits by decades. For example, gastrointestinal dysfunction in the form of reduced bowel movements is a risk factor for future development of PD, an average of 12 years into follow-up (Abbott et al. 2001). A second study confirmed that constipation is a risk for PD (Savica et al. 2009). Both studies conclude that gastrointestinal dysfunction can precede the PD diagnosis by 10–20 years. Interestingly, Lewy bodies and Lewy neurites are also found in the myenteric and submucosal plexuses of the gut (Braak et al. 2006; Lebouvier et al. 2008; Wakabayashi et al. 1990). While these histological examinations were performed postmortem, the temporal development of symptoms would suggest that pathology in the gut is an early event in PD.

In rats treated with low-dose rotenone, which does not elicit overt nigrostriatal toxicity (2.0 mg/kg/day, 5x/week for 6 weeks), gastrointestinal dysfunction similar to that in PD patients is observed (Drolet et al. 2009). Insoluble α-synuclein-positive aggregates strikingly similar to that which occur in the gut of PD patients were found in the small intestine myenteric plexus 6 months after treatment. Neuronal loss in the gut and increased gastric transit time were also found in this study, also 6 months after rotenone treatment. Thus, chronic, low-dose systemic rotenone produces gastrointestinal dysfunction, in the absence of overt motor deficits or brain pathology. A second rat study also showed the development of delayed gastric emptying and enteric neuron dysfunction after rotenone treatment (Greene et al. 2009). Direct gastric administration of rotenone in mice is also able to produce α-synuclein aggregation (Pan-Montojo et al. 2010). The pathological findings in this study also showed that pathology in the gut preceded that in the substantia nigra. Thus, chronic rotenone treatment in rodents is able to reproduce this key preclinical event that occurs in many PD patients. Beyond simply validating the ability of this model to replicate key PD features, it is expected that gastrointestinal endpoints in future studies will provide much useful information on the pathophysiology of gut abnormalities in PD and a useful tool for examining treatments relevant to autonomic symptoms.

3.2 Olfactory Pathology and Deficits

The olfactory system is also affected in the earliest stages of PD. α-Synuclein accumulation in the anterior nucleus of the olfactory bulb precedes nigral pathology (Braak et al. 2003). Further, at onset, olfaction is typically severely impaired in the majority of PD patients, with normal function or mild impairment in other parkinsonian disorders (Hawkes 2003). Olfactory deficits may also be an important marker for Lewy body dementia (LBD), and although Alzheimer's disease (AD) patients may exhibit olfactory loss, it is typically less severe than in LBD (Olichney et al. 2005; Postuma et al. 2010). While numerous studies have found olfactory deficits to be predictive, the time where the predictive power is significant is typically 2–4 years prior to diagnosis (Postuma et al. 2010). Specificity may also be low; while those in the lowest quartile of olfactory function in the Honolulu-Asia Ageing Study had an odds ratio of 5.2 for developing PD, only 2 % of those in this quartile developed PD (Postuma et al. 2010; Ross et al. 2008).

In the rotenone model, examination of oxidative damage in the brain found that the most affected areas were the midbrain and olfactory bulb (Sherer et al. 2003). While this data was obtained from animals exhibiting severe parkinsonism, the data suggest that this brain region is a target and should be evaluated in earlier stages of the model or under low-dose regimens. Specifically, functional (olfactory thresholds and discrimination) and detailed neuroanatomical (examination of specific cell populations) studies are needed to determine how closely effects on the olfactory system resemble that which occur in human PD.

3.3 Pathology in Brainstem Nuclei

Pathology in the brainstem occurs in PD and is thought to precede damage to nigral dopamine neurons. In particular, α-synuclein accumulation in the dorsal motor nucleus of the vagus (acetylcholinergic) and locus coeruleus (noradrenergic) occurs in the earliest stages of PD (Braak et al. 2003, 2004). Pathophysiology in these nuclei may underlie some of the nondopaminergic PD symptoms.

To date one group has reported overt neuronal loss in the locus coeruleus after systemic subcutaneous rotenone administration (Lin et al. 2008). This finding was observed along with the typical nigrostriatal dopamine neuron degeneration. A recent in vitro study found that rotenone treatment promotes α-synuclein aggregation in primary neuronal cultures from the locus coeruleus (Chaves et al. 2010). A more thorough examination is needed to determine how early the locus coeruleus is affected in the rotenone model.

Mice receiving gastric rotenone administration exhibit inflammation in the dorsal motor nucleus of the vagus and α-synuclein-positive aggregate formation in acetylcholine positive neurons (Pan-Montojo et al. 2010). Notably, in this time-course study, brainstem pathology occurred prior to nigral pathology. Thus, chronic rotenone treatment is able to replicate the temporal development of key preclinical brainstem pathology.

3.4 Cardiac Function

Cardiac function is clearly altered in PD patients. In particular, postganglionic sympathetic innervation is affected in PD and DLB patients (Postuma et al. 2010). Although it requires cardiac metaiodobenzylguanidine (MIBG) scintigraphy to measure, which is costly, PD patients typically exhibit abnormal MIBG scintigraphy in the earliest disease stages (Spiegel et al. 2007).

Rotenone-treated rats that exhibit nigrostriatal dopamine lesions have decreased baroreflex sensitivity similar to that which occurs in PD patients (Yu et al. 2008). In this study, cardiac function was assessed at the end of rotenone administration. Given that in human PD patients, attenuated baroreflex function may precede motor symptoms, it is possible that rotenone treatment may recapitulate this preclinical PD symptom (Goldstein 2011; Goldstein et al. 2007). Evaluation of cardiac function in rotenone-treated rats, before nigrostriatal lesions develop or at subthreshold doses, will help to determine if this is a preclinical feature of the model.

3.5 Sleep Disorders

Sleep disorders are also common in PD patients and may precede motor deficits. Most notably is REM behavior disorder (RBD), where patients do not exhibit the normal atonia that occurs in REM sleep. The result is ultimately “acting out” of dreams, which may lead to crying out, kicking, or thrashing (Gagnon et al. 2006).

RBD occurs in roughly one third of PD patients, with about another one third exhibiting asymptomatic loss of atonia (Gagnon et al. 2002). RBD is also common in other neurodegenerative disorders. It is thought to stem from damage to pontine nuclei, which are affected in the early stages of PD. Further, those with RBD have a high risk for developing PD, with 40–60 % developing a neurodegenerative disorder (1/2 develop PD) 10 years after follow-up (Postuma et al. 2010). Thus, the long-lag period indicates that RBD/reduced REM atonia is a key preclinical feature of many PD cases. PD patients also exhibit insomnia and excessive daytime somnolence, also thought to arise in part due to degeneration of pontine nuclei (Braak et al. 2003; Chaudhuri et al. 2006; Postuma et al. 2010).

A few sleep-related studies have been conducted on rotenone-treated rats. The first report found that both vehicle (dimethyl sulfoxide and polyethylene glycol; 1:1) and rotenone-treated animals exhibited sleep disturbances, rendering interpretation of the direct effect of rotenone on sleep architecture difficult to discern (Garcia-Garcia et al. 2005). A later study in rotenone-treated rats found that slow-wave sleep was increased during the active time (dark) and decreased during the inactive period (light) (Yi et al. 2007). Further, REM sleep was enhanced during the dark period. Interestingly, this study found that alterations to sleep architecture were not mediated by dopamine. More detailed studies are needed to assess the temporal development of sleep disturbances in rotenone-treated rats. Muscle activity will also need to be assessed to determine if atonia occurs during REM, following rotenone treatment.

3.6 Oxidative Stress and Damage to Biomolecules

Oxidative stress has long been known to occur in human PD. Proving a direct causative role for oxidative stress in human PD is difficult because brain samples are obtained at autopsy. It should be noted that many of the prominent models of PD (6-OHDA, MPTP, and rotenone) utilize oxidative stress (through different mechanisms of action) to effectively lesion the nigrostriatal dopamine system and replicate the key pathogenic features of clinical PD (Betarbet et al. 2006; Przedborski and Vila 2001; Schwarting and Huston 1996). Such data would suggest that oxidative stress is important in the pathogenesis of the disease, not simply a by-product of end-stage pathology.

Diverse examples of oxidative damage in the human PD brain include increases in total iron content in the substantia nigra (thought to be a contributor to oxidative stress), superoxide dismutase (involved in cellular response to oxidative stress), lipid peroxidation (a marker for oxidative damage to lipids), protein oxidation, and DNA oxidation versus age-matched controls (Alam et al. 1997; Dexter et al. 1989; Floor and Wetzel 1998; Saggu et al. 1989; Sofic et al. 1988). However, brain oxidative stress and damage are difficult to utilize as preclinical features in humans due to sampling availability of relevant endpoints until after autopsy.

Oxidative stress and damage in PD is not limited to the brain, with evidence in serum and systemic tissues. For example, an overall index of serum oxidant status is

increased in PD patients and the antioxidant status is decreased (Forte et al. 2004). More specifically, plasma lipid peroxide levels are increased in PD patients (Kilinc et al. 1988), indicating a general systemic oxidative damage in PD. Serum levels of superoxide dismutase and glutathione peroxidase have been found in PD patients, indicating a systemic response to oxidative stress (Kalra et al. 1992). Oxidation of plasma nucleic acid is also increased in PD patients (Abe et al. 2003; Kikuchi et al. 2002). Additionally, several cell types undergo oxidative damage in PD, including platelets (Gotz et al. 2000; Krige et al. 1992; Yoshino et al. 1992), erythrocytes (Kilinc et al. 1988; Younes-Mhenni et al. 2007), lymphocytes (Migliore et al. 2001, 2002; Petrozzi et al. 2001), and neutrophils (Gatto et al. 1996; Vitte et al. 2004).

Rotenone has been found to selectively lesion nigral dopamine neurons through complex I inhibition, resulting in oxidative stress, to which these neurons are particularly susceptible (Sherer et al. 2003). Given the number of clinical PD parameters that the rotenone model replicates, it is highly likely that oxidative stress in the earliest disease stages is important in human PD pathogenesis. In vitro studies have shown that rotenone treatment leads to progressive oxidative stress in neuroblastoma cells (Sherer et al. 2002). Further, work in organotypic slice cultures showed the development of oxidative stress along with loss of nigral dopamine neurons. Both oxidative stress and neuronal loss were prevented with antioxidant treatment (Testa et al. 2005). Later work showed that DJ-1, an important oxidative stress protein, is itself oxidatively modified in nigral neurons from both lesioned and non-lesioned rotenone-treated rats (Betarbet et al. 2006). This finding suggests that oxidative stress and damage are early events occurring prior to overt neuronal loss. Specialized redox imaging performed as a time course in zebrafish larvae also shows that oxidative stress is an early event after rotenone treatment (Horowitz et al. 2011).

Systemic studies on the temporal development of oxidative stress are limited in the rotenone model. Studies in progress in the Greenamyre lab (unpublished) show that DNA damage in the blood is profound and occurs within hours of the first rotenone administration. Studies in the future on the temporal development of damage to specific cell types are expected to be highly informative.

4 Practical Considerations: Executing and Utilizing the Rat Rotenone Model to Assess Preclinical Endpoints

In the rat rotenone model, there are two basic regimens to assess preclinical endpoints:

1. Standard dose, with early sampling. While there are certainly lab-to-lab differences, dependent on age and strain, in our experience, administration of systemic rotenone at 3.0 mg/kg/day will typically produce debilitating motor deficits ~7–14 days after initial administration (Cannon et al. 2009). Sampling at 5 days or less, before motor deficits or nigrostriatal pathology arises, allows for the assessment of preclinical endpoints. A major advantage of this approach is that it is known that at this dose, animals will eventually develop the key motor and pathological features

of end-stage PD. However, sampling after an acute administration may result in the inability to detect preclinical endpoints that develop chronically.

2. Low-dose, long-term treatments. Animals treated at rotenone doses 2.0–2.5 mg/kg/day do not typically develop severe motor deficits or nigrostriatal pathology (Cannon et al. 2009; Drolet et al. 2009). A major advantage to this approach is that the development of long-term preclinical endpoints can be assessed. For example, after 2.0 mg/kg/day rotenone, 5 days/week for 6 weeks, rotenone treatment was discontinued and rats were found to develop gastrointestinal pathology and transit deficits 6 months later (Drolet et al. 2009). A dose of 2.5 mg/kg/day was found to elicit motor symptoms in few wild-type animals, but potentiation occurred in transgenic animals expressing disease-causing mutations in α-synuclein (Cannon et al. 2013). Thus, low-dose, long-term rotenone can be used to assess the development of preclinical endpoints and potentiation (especially, gene-environment interactions). Potential disadvantages are that animals likely will not eventually develop a phenotype characteristic end-stage PD and a lengthy dosing period may be required to elicit the desired preclinical features. Rats treated at 2.0–2.5 mg/kg/day, as long as 60 days, may not develop motor deficits (Cannon et al. 2009). Thus, it may be somewhat more difficult to determine the importance of potential preclinical features in a model that does not develop the key features of end-stage pathology. Further, evaluation at up to 6 months of age can be costly and time consuming. However, it should be noted that low-dose neurotoxicant exposures and chronic development are likely more relevant to human exposures and the temporal development of the disease.

5 Future Directions: The Need for Better Preclinical Models and Suggested Uses

Modeling preclinical features is of major importance to advancing PD research. First understanding the key preclinical features of the disease will aid in earlier diagnosis. This will be particularly important as neuroprotective agents become available in the future. The earlier a neuroprotective agent could be administered, the more likely it would be effective. Second, a better understanding of preclinical features will increase our understanding of the pathophysiology of PD and perhaps lead to new therapeutic targets.

5.1 How Can the Rotenone Model be Further Validated for Modeling Preclinical Use?

While it is now over a decade old, the rotenone model continues to evolve. In its most recent form, it is much more reproducible and amenable to neuroprotection and potentiation studies (Cannon et al. 2009, 2013; Tapias et al. 2010). Current data suggest that the rotenone model can replicate many of the key preclinical features. However, much more data is needed. In particular, alterations in olfactory function,

sleep architecture, and cardiac function need to be further assessed to determine when they may occur, relative to nigrostriatal dopamine system degeneration. Advanced olfactory tests able to measure discrimination are now available for use in rats and could be tested in the rotenone model (Tillerson et al. 2006). More detailed sleep studies need to be performed on rats. In particular, given the risk of developing PD in those with RBD, particular focus should be on REM and muscle activity to assess atonia during REM. Evaluation should be repeated in conjunction with other behavioral assays to determine when sleep disturbances arise relative to motor deficits.

5.2 What Are Some Potential Future Uses of Preclinical Rotenone Model?

The identification of preclinical features in the rotenone model provides further validation of model utility. The key question is as follows: how can modeling preclinical features of PD be used to advance our understanding of the disease? It is important to note that although it is now over a decade in use, the rotenone model is still several decades younger than other prominent neurotoxicant modes (6-OHDA, MPTP). Thus, we are still learning much about the model.

In humans, imaging can identify neurological dysfunction prior to diagnosis. Dopaminergic PET and SPECT have high sensitivity and specificity for parkinsonism, with studies estimating that measurable abnormalities may occur 4–7 years before clinical PD (Hilker et al. 2005; Morrish et al. 1998; Postuma et al. 2010; Ravina et al. 2005; Vingerhoets et al. 1994). As these imaging techniques become readily available for rodents with high enough resolution, it should be possible to noninvasively determine temporally, when dopaminergic dysfunction begins in live animals. This would be particularly useful in low-dose, long-term studies, where sampling for biomarkers and nondopaminergic effects can be obtained. Here, an emphasis on what occurs prior to or near the beginning of nigrostriatal dopamine system dysfunction will be important.

Most PD cases likely arise from multiple insults. Thus, when studying etiological factors, exposure to environmentally relevant mixtures at different times in development/life span and exploring the effects of gene-environment interactions are important. Practically, in a laboratory setting, this is expensive and difficult, because even studying a single insult in an animal model is costly and time consuming. Nonetheless, combination and multiple "hit" approaches are being explored in animal models and are becoming more common as a way to address exposures relevant to human health. Given its environmental relevance and now being implicated as a bona fide risk factor, rotenone exposure is particularly relevant to such studies. For example, low-dose rotenone (2.0–2.5 mg/kg/day) reproduces many preclinical features as described above, yet in the absence of overt nigrostriatal toxicity. This regimen is ideal for examining potentiation and synergistic effects from other insults. A recent study where striatal dopamine terminal loss and severe parkinsonian behavioral features were observed in rats

expressing disease-causing mutations in α-synuclein, but not in wild type, shows how the model can be used to assess potentiation (Cannon et al. 2013). It is expected that such forms of the rotenone model will continue to be used in transgenic animals or along with other toxicants of relevance to continue to identify etiological factors.

6 Conclusion

The rotenone model replicates the key behavioral, neurochemical, and pathological features of PD. Many models, both neurotoxicant and genetic based, have shown promise in replicating at least some of the key preclinical features of PD. Here, we have presented specific evidence that the rotenone model replicates many key preclinical features of human PD. It has the major advantages of environmental relevance, chronic development, and reproduction of important pathological hallmarks. Future studies are required, but it is expected that findings from the rotenone model will confirm its relevance to model preclinical PD. Finally, exploratory studies in the rotenone model may identify preclinical features that are not yet known to occur in human PD patients.

Part III

Glutamate Receptor Agonists and Antagonists

Concept of Excitotoxicity via Glutamate Receptors

Juan C. Piña-Crespo, Sara Sanz-Blasco, and Stuart A. Lipton

Contents

Abstract

Since its inception, the concept of glutamate excitotoxicity has provided a foundational framework for understanding the role played by excitatory amino acids in disease states of the brain. At the same time, it has served as a guiding principle in the development and evaluation of new anti-excitotoxic drugs, many of which show promise as neuroprotective therapies in a number of neurological conditions. The discovery that glutamate receptors on the cell surface can engage, through second messengers such as calcium (Ca^{2+}), nitric oxide (NO), and inositol

phospholipids, downstream intracellular signaling cascades involved in cell death helped uncover the complexity of the excitotoxic cascade. The identification of numerous intracellular effectors of excitotoxicity has provided a physiological and pharmacological basis for understanding the cellular and molecular mechanisms behind glutamate-mediated nerve cell injury and its role in neuropsychiatric diseases. More recently, knowledge of the molecular biology of glutamate receptors has allowed, for the first time, the identification of differences in the pattern of expression of glutamate receptors in human populations afflicted by neuropsychiatric diseases. This knowledge will be useful in uncovering genes that may confer individual susceptibility to excitotoxic damage and, as a result, predisposition to the development of certain mental and neurological diseases. In this chapter, the role of glutamate receptor overactivation in excitotoxic cell injury as well as potential neuroprotective therapies for limiting glutamate-mediated neurotoxicity in disease states of the central nervous system will be discussed.

List of Abbreviations

AMPA	2-amino-3-(3-hydroxy-5-methyl-isoxazol-4-yl)propanoic acid)
ATP	Adenosine-5′-triphosphate
BAD	Bcl-2-associated death promoter
BAX	Bcl-2-associated X protein
Bcl-2	B-cell lymphoma 2 protein
Bcl-X_L	B-cell lymphoma – extra large protein
Ca^{2+}	Calcium
DA	Domoic acid
DCD	Delayed calcium deregulation
DNA	Deoxyribonucleic acid
EAAs	Excitatory amino acids
ER	Endoplasmic reticulum
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
Glu	L-glutamate
GluRs	Glutamate receptors
KA	Kainic acid
MCU	Mitochondrial calcium uniporter
mNCX	Mitochondrial Na^+/Ca^{2+} transporter
mPTP	Mitochondrial permeability transition pore
NCX	Na^+/Ca^{2+} exchanger
NMDA	*N*-methyl-D-aspartic acid
NO	Nitric oxide
PMCA	Plasma membrane Ca^{2+} ATPase
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SIAH1	Seven in absentia homolog E3 ubiquitin-protein ligase
VDAC	Voltage-dependent anion-selective channel
$\Delta\psi m$	Inner mitochondrial membrane potential

1 Introduction

L-Glutamate is a major excitatory amino acid neurotransmitter in the brain (Nicholls et al. 2012; Watkins and Evans 1981; Watkins 2000). Under physiological conditions, glutamate plays fundamental roles in nerve cell function and brain plasticity (Bliss and Collingridge 1993; Cooke and Bliss 2006) through activation of glutamate receptors (GluRs) (Hollmann and Heinemann 1994; Traynelis et al. 2010). In contrast, excessive activation of GluRs during neurological conditions can lead to loss of nerve cell function and cell death through a process known as excitotoxicity (Olney 1978; Olney 2003). Glutamate-mediated excitotoxicity is initiated by buildup of excess glutamate in the extracellular space that leads to overactivation of GluRs, disruption in cell membrane permeability, and downstream activation of signaling cascades involved in loss of nerve cell function, cell damage, and death (Farooqui et al. 2008; Gillessen et al. 2002; Lau and Tymianski 2010). Significant experimental and clinical evidence implicates excitotoxicity in the loss of neuronal cell function and cell death associated with acute neurological conditions such as traumatic brain injury (Arundine and Tymianski 2004; Yi and Hazell 2006), stroke (Besancon et al. 2008; Brouns and De Deyn 2009; Doyle et al. 2008), hypoxia-ischemia (Jensen 2005), amnesic shellfish poisoning (Jeffery et al. 2004; Lefebvre and Robertson 2010; Perl et al. 1990; Teitelbaum et al. 1990), and epileptic seizures (Meldrum 1993), as well as during chronic neurodegenerative diseases (Lipton and Rosenberg 1994; Mattson 2003; Mehta et al. 2013) such as Alzheimer's disease (Hu et al. 2012; Mucke and Selkoe 2012), Parkinson's disease (Beal 1998; Surmeier et al. 2011), Huntington's disease (Raymond et al. 2011), AIDS encephalopathy and dementia complex (more recently termed HIV-associated neurocognitive disorders) (Kaul et al. 2001; Mattson et al. 2005), multiple sclerosis (Trapp and Stys 2009), and neuropathic pain syndromes (Latremoliere and Woolf 2009).

Neuronal function, as well as susceptibility to excitotoxic cell damage, depend on the expression of specific repertoires of receptors and ion channels. Since abnormal patterns of expression of genes encoding glutamate receptors have been described in a number of brain disorders, current research efforts may unveil how dysregulated expression of glutamate receptors affects neurotransmission and nerve cell susceptibility to excitotoxic cell death.

2 Historical Background

Although interest into the role of glutamate in the nervous system dates back to the early twentieth century (Weil-Malherbe 1950), it was not until the 1950s that evidence for a direct excitatory action of glutamate on the brain was first described (Hayashi 1952; Okamoto 1951) and insights into its mechanism of action were first inferred (Hayashi 1954). These findings were soon followed by reports of glutamate-induced neurotoxicity after observation of acute degenerative lesions in the inner retina of newborn mice (Lucas and Newhouse 1957) and depolarization of neurons in the spinal cord (Curtis et al. 1959).

During the 1960s, research into the structure-function relationship of a large number of neutral and acidic amino acids led to the concept an "amino-acid-receptor complex" present in the extracellular surface of neurons (Curtis et al. 1960). In an effort to elucidate the chemical basis of the activity and specificity of glutamate and aspartate on the "amino acid receptor," Watkins and colleagues synthesized *N*-methyl-D-aspartic acid (NMDA) (Watkins 1962), a non-metabolizable agonist with remarkable selectivity for the "amino-acid-receptor complex." Sensitivity to NMDA became a key criterion for the initial pharmacological classification of glutamate receptors into NMDA and non-NMDA receptors (Lodge 2009).

Further evidence supporting a neurotoxic role for glutamate appeared in 1969, when Olney and collaborators described neuropathological lesions in the brain of rodents and primates after systemic administration of glutamate and structurally related analogues (Olney 1969; Olney and Sharpe 1969). During the ensuing decade, Olney and colleagues proposed the concept of excitotoxicity to describe the acute neurotoxic effects of glutamate in the brain (Olney and Ho 1970; Olney 1978) and provided further experimental support for its potential role in brain pathology particularly in the newborn brain.

During the 1980s, preclinical studies reported evidence of significantly high levels of extracellular concentrations of brain glutamate in experimental models of hypoxia-ischemia in vivo (Benveniste et al. 1984; Hagberg et al. 1985), a finding later confirmed in humans (Bullock et al. 1995). At the same time, preclinical studies confirmed the neuroprotective action of glutamate receptor antagonists against hypoxic-ischemic neuronal cell death in vitro (Rothman 1984) and in vivo (Simon et al. 1984). However, successful translation of these early preclinical findings into clinically effective therapies has been an elusive target (O'Collins et al. 2006; Sutherland et al. 2012; Tymianski 2010), mainly because of lack of therapeutic strategies that can selectively target pathologically active GluRs without affecting normal glutamatergic neurotransmission (Lipton 2007).

A need for understanding the intracellular signaling cascades activated by neurotoxic glutamate led to the identification of calcium (Ca^{2+}) (Choi 1985; Choi 1987), inositol phospholipids (Sladeczek et al. 1985; Sugiyama et al. 1987), and nitric oxide (NO) (Garthwaite et al. 1988) as key intracellular effectors of glutamate signaling. This set of key insights provided the physiological and pharmacological frameworks for a greater understanding of the cellular and molecular mechanisms responsible for glutamate-mediated nerve cell injury (Choi 1988; Rothman and Olney 1986) and its potential role in neurological diseases (Greenamyre 1986). In 1987, a fatal incident due to consumption of shellfish contaminated with domoic acid (DA), a naturally occurring glutamate analogue, provided direct evidence for glutamate-mediated neurotoxicity in humans (Perl et al. 1990; Teitelbaum et al. 1990).

During the 1990s, glutamate research experienced one of its most important and significant periods with the cloning and functional expression of 26 different glutamate receptor genes (Table 1) (Alexander et al. 2011; Boulter et al. 1990; Hollmann et al. 1989; Hollmann and Heinemann 1994). This unveiled the molecular basis for the functional and pharmacological diversity of glutamate receptors in the central nervous system (Gereau and Swanson 2008; Traynelis et al. 2010).

Table 1 IUPHAR* classification of cloned glutamate receptors (GluRs)

	Receptor	Pharmacology	Gene		Previous nomenclature	
Ionotropic receptors			*Human*	*Mouse/rat*	*Rat*	*Mouse*

**IUPHAR Committee on Receptor Nomenclature and Drug Classification* (http://www.iuphar-db.org/index.jsp)

The molecular biology of glutamate receptors laid down the foundations for detailed cellular, molecular, and genetic studies into the role of glutamate dysfunction in diseases of the brain (Lipton and Rosenberg 1994; Nakanishi 1992).

3 Glutamate Receptors

Glutamate receptor-mediated signaling occurs through activation of two different types of receptors: ion channel-coupled (ionotropic) and G-protein-coupled (metabotropic) receptors. Ionotropic glutamate receptors (iGluRs) are coupled to ion channels and are responsible for fast changes in membrane permeability

(Traynelis et al. 2010; VanDongen 2009); metabotropic glutamate receptors (mGluRs) are coupled to intracellular effector systems via G-proteins (Nicoletti et al. 2011; Niswender and Conn 2010).

3.1 Ionotropic Glutamate Receptors

iGluRs are essential mediators of fast synaptic transmission due to their ability to generate a response within milliseconds of glutamate binding. Based on their agonist selectivity, iGluRs have been classified into three major subclasses: AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid), kainate, and NMDA receptors (Table 1). iGluRs are cation-selective glutamate-gated ion channels composed of four glycosylated transmembrane subunits assembled around a central aqueous pore that spans the cell membrane. Each receptor contains three major domains: an extracellular glutamate-binding domain related to amino acid-binding bacterial periplasmic proteins, a transmembrane pore-lining domain related to the pore-forming region or "P-loop" of K^+ channels, and an intracellular regulatory domain (Gereau and Swanson 2008; Kumar and Mayer 2012; Traynelis et al. 2010).

3.1.1 AMPA Receptors

Upon activation by L-glutamate or AMPA, AMPARs mediate responses that are characterized by rapid onset, offset, and desensitization kinetics, but when they are activated by the neurotoxin kainate or domoic acid (DA), they produce large non-desensitizing responses. Four AMPAR subunits have been cloned and termed: GluA1, GluA2, GluA3, and GluA4 (Alexander et al. 2011; Boulter et al. 1990; Keinanen et al. 1990); they can form homomeric receptors as well as heteromeric receptors when expressed with other subunits. Functionally, they show rapid kinetics and low Ca^{2+} permeability in the presence of the GluA2 subunit (although the RNA-unedited form of GluA2 is permeable to Ca^{2+}) (Gereau and Swanson 2008; Traynelis et al. 2010).

3.1.2 Kainate Receptors

So far, five different sequence-related genes encoding kainate receptors (KARs) have been identified and termed: GluK1, GluK2, GluK3, GluK4, and GluK5. KARs bind kainate with intermediate to high affinity with GluK1 and GluK2 being the only kainate receptors capable of forming functional receptors upon in vitro expression. The others kainate receptor subunits can form functional receptors only when co-expressed in combination with GluK1 or GluK2 receptors. In contrast with AMPARs, KARs strongly desensitize upon activation by the neurotoxin kainate.

3.1.3 NMDA Receptors

NMDA receptors are characterized by high Ca^{2+} permeability, voltage-dependent block by Mg^{2+}, high single-channel conductance, slow gating kinetics, and activation by the concerted action of glutamate and glycine (VanDongen 2009).

During glutamatergic synaptic transmission, NMDA receptors mediate the slow component of synaptic currents. NMDA receptors result from the assembly of three different subfamilies of subunits: NR1, NR2, and NR3 (Table 1).

3.2 Metabotropic Glutamate Receptors

Metabotropic glutamate receptors (mGluRs) play an important role in the transduction of glutamate-mediated signaling via coupling through G-proteins to intracellular second messenger cascades. They have been classified into groups 1, 2, and 3. Group 1 (mGluR1 and mGluR5) receptors are coupled to phospholipase C, mediating increases in intracellular calcium. Group 2 (mGluR2 and mGluR3) and group 3 (mGluR4, mGluR6, mGluR7, mGluR8) are negatively coupled to adenylate cyclase, producing a decrease in forskolin-induced cAMP (Nicoletti et al. 2011; Niswender and Conn 2010).

4 Mechanisms of Excitotoxicity

Glutamate neurotoxicity results from a buildup of either endogenous excitatory amino acids (EAAs), exogenous glutamate-like substances in the brain, or excessive glutamate receptor activity (often NMDA receptors) in the presence of normal agonists due to loss of normal Mg^{2+} block. This form of neurotoxicity is often due to malfunctioning of cellular processes responsible for regulating endogenous EAA levels in the brain or to exposure to toxic levels of exogenous EAA analogues known as excitotoxins. These events produce intense activation of glutamate receptors on the cell surface that generates abnormally high levels of intracellular Ca^{2+}, which activates catalytic enzymes, generates highly toxic free radicals, and disrupts cell energy production. Eventual depletion of ATP stores leads to the collapse of transmembrane electrochemical gradients, loss of nerve cell excitability, neurotransmission failure, and cell death by either necrosis or apoptosis (Choi 1988; Gillessen et al. 2002; Rothman and Olney 1986).

5 Intracellular Effectors of Glutamate Neurotoxicity

5.1 Calcium

Ca^{2+} ions are powerful activators of nerve cell excitability and metabolism. Intracellular Ca^{2+} concentrations are kept relatively low by high-energy-requiring processes of active Ca^{2+}extrusion and Ca^{2+} sequestration in intracellular stores. Active Ca^{2+} efflux is mostly carried out by the Na^{+}/Ca^{2+} exchanger (NCX) and plasma membrane Ca^{2+} ATPase (PMCA), while storage of intracellular Ca^{2+} localizes mainly to the endoplasmic reticulum (ER) and mitochondria. Extracellular Ca^{2+} concentrations (1–2 mM) are over one order of magnitude larger than inside nerve

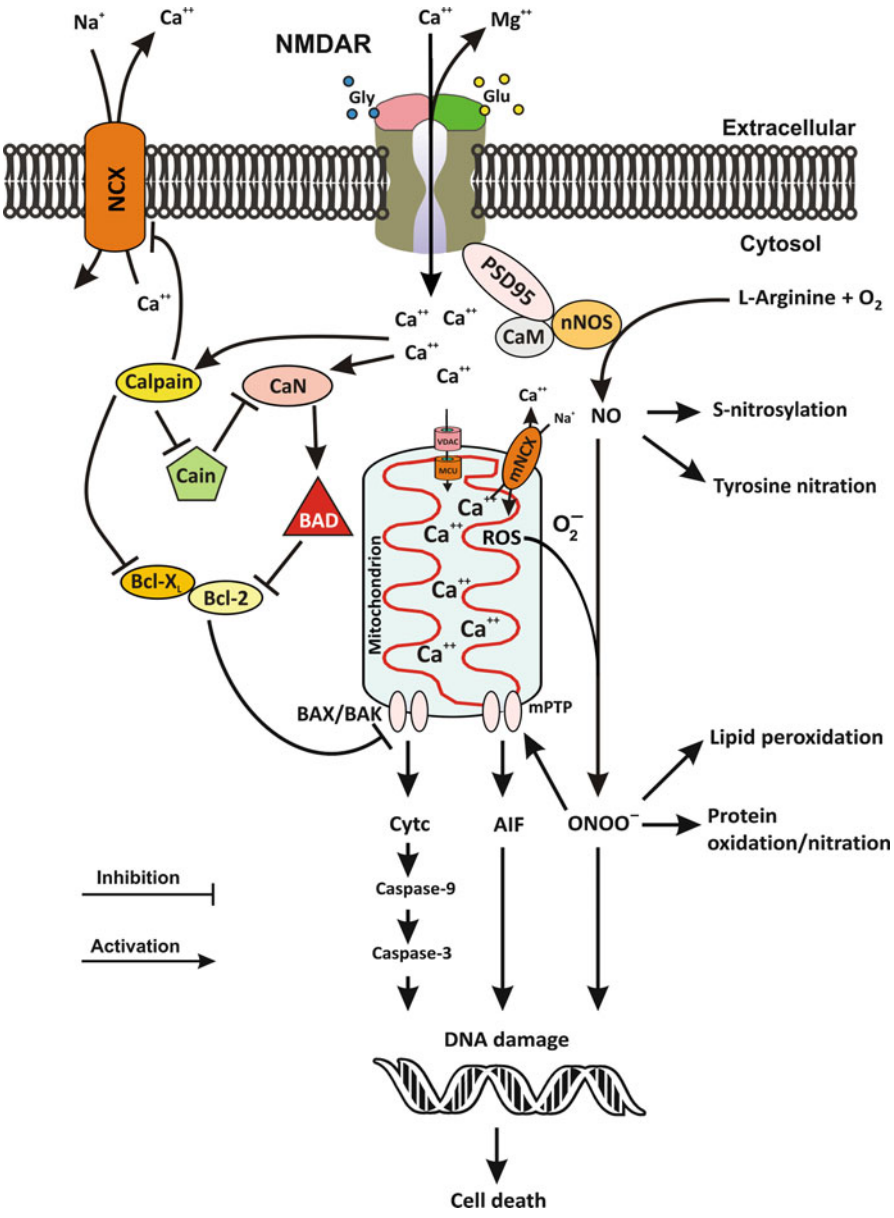

Fig. 1 Intracellular effectors of excitotoxicity. The events leading to excitotoxic cell death include overactivation of Ca^{2+}-permeable glutamate receptors (GluRs), excessive Ca^{2+} influx, and Ca^{2+}-dependent activation of intracellular effector enzymes such neuronal nitric oxide synthase (nNOS), calcineurin (CaN), and calpain together with Ca^{2+} uptake into mitochondria. Subsequent mitochondrial dysfunction due to excessive Ca^{2+} accumulation, and generation and release of toxic amounts of free radicals such as nitric oxide (NO) and reactive oxygen species (ROS) contribute to the production of peroxynitrite ($ONOO^{-}$) that together with depletion of

cells (50–200 nM). During overactivation of Ca^{2+}-permeable GluRs (Brorson et al. 1994; Choi 1985; Lu et al. 1996), this large electrochemical gradient drives the flow of extracellular Ca^{2+} into the cytoplasm where it generates an over tenfold increase in intracellular Ca^{2+}. In vitro, even a brief, few seconds long, exposure to neurotoxic levels of glutamate can trigger loss of intracellular Ca^{2+} homeostasis and cell death. Glutamate-induced intracellular loading of Ca^{2+} is characterized by an immediate but transient GluR-mediated Ca^{2+} influx that is followed by a transient return to baseline Ca^{2+} levels that can last hours until a secondary wave of sustained intracellular Ca^{2+} develops that is irreversibly followed by cell death (Randall and Thayer 1992). This dynamic demonstrates how GluR-mediated calcium influx activates specific effector pathways involved in cell death. Intense excitotoxic injury can result in necrosis (Syntichaki and Tavernarakis 2003), while less fulminant or chronic insults can cause synaptic damage followed by apoptosis (Ankarcrona et al. 1995; Bonfoco et al. 1995).

Although there is general consensus regarding the important role of intracellular Ca^{2+} in excitotoxic nerve cell death (Choi 1985; Choi 1988), many of the intracellular signaling events underlying glutamate-induced cell death are less well characterized. Reactive oxygen species (ROS), reactive nitrogen species (RNS), caspases, and lipases are among the most important Ca^{2+}-dependent effectors thought to be involved in glutamate-induced neurotoxicity. These processes are detailed below and summarized in Fig. 1.

5.2 Reactive Oxygen Species (ROS)

GluR-mediated excitotoxicity generates reactive oxygen species (ROS) such as superoxide (O_2^-), hydrogen peroxide (H_2O_2) and hydroxyl (OH^-) radicals (Dykens et al. 1987; Dykens 1994; Lafon-Cazal et al. 1993). ROS cause cell damage through lipid peroxidation and oxidative damage of proteins and DNA (Chinopoulos and Adam-Vizi 2006; Rigoulet et al. 2011; Van Houten et al. 2006). Numerous neuroprotective strategies, including trapping, scavenging, and inhibition of ROS synthesis, have been shown to be effective under in vitro conditions (Dykens et al. 1987; Majewska and Bell 1990; Puttfarcken et al. 1992); however, evidence of their

Fig. 1 (continued) mitochondrial ATP levels promotes opening of the BAX/BAK channel, mitochondrial permeability transition pore (mPTP), or breakdown of the mitochondrial membrane to release cytochrome c (Cyt c) and the apoptosis-inducing factor (AIF). While Cyt c mediates caspase-dependent apoptosis, AIF translocates into the nucleus where it produces DNA fragmentation, chromatin condensation, and apoptosis through a caspase-independent mechanism. Simultaneously, Ca^{2+}-dependent activation of calcineurin (CaN) and calpain promotes calpain-dependent inhibition of the anti-apoptotic Bcl-X_L/Bcl-2 complex and Cain, an inhibitor of calcineurin-mediated cell death. Once calcineurin (CaN) is freed from Cain-dependent inhibition, it can activate the Bcl-2-associated death promoter (BAD), which produces further inhibition of Bcl-X_L/Bcl-2 complex. This allows the formation of a BAX/BAK mitochondrial channel permeable to pro-apoptotic molecules such as Cyt c

neuroprotective activity in vivo is still lacking. Since mitochondria are both a source of ROS (Dugan et al. 1995; Reynolds and Hastings 1995) and a target for ROS-induced damage, protection and rescue of mitochondrial function is key to reducing glutamate-mediated neurotoxicity (Cho et al. 2010; Perez-Pinzon et al. 2012).

5.3 Reactive Nitrogen Species (RNS)

Nitric oxide (NO) can react with superoxide radicals (O_2^-) to generate peroxynitrite ($ONOO^-$), a highly toxic and strongly oxidizing and nitrating agent that causes lipid peroxidation, protein oxidation, and DNA damage (Brown 2010). Inhibition of NO synthesis or genetic deletion of its synthesizing enzyme, nitric oxide synthetase (nNOS), can protect neurons from glutamate neurotoxicity (Dawson et al. 1991; Dawson et al. 1996; Lipton et al. 1993). Because of its close physical association to intracellular scaffoldings such as postsynaptic densities (PSDs), which anchor GluRs to postsynaptic sites (Sattler et al. 1999), nNOS is one of the first Ca^{2+}-dependent intracellular effectors activated by Ca^{2+} influx through GluRs, namely, NMDARs. Through this pathway, neurotoxic glutamate levels generate large amounts of RNS, especially NO, which causes misfolding and malfunction of intracellular signaling proteins through abnormal S-nitrosylation and tyrosine nitration (Martinez-Ruiz et al. 2011; Nakamura and Lipton 2011). Among the most important deleterious effects of NO accumulation is inhibition of energy-generating intracellular systems that leads to the collapse of intracellular ATP levels and cell death through either necrosis or apoptosis. During this process, NO causes further release of glutamate through inhibition of mitochondrial function, reverse glutamate uptake, and glutamate exocytosis (Brown 2010). In addition, neuronal cell death can be triggered by NO-dependent nitrosylation of the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH), which promotes its association with the E3 ubiquitin-protein ligase SIAH1 and translocation into the nucleus (Hara et al. 2005). There is currently considerable need for effective cell-permeable inhibitors to protect nerve cells from the abnormally high levels of protein nitrosylation observed during pathological overactivation of brain GluRs (Nakamura and Lipton 2010).

5.4 Caspases

Caspases are intracellular aspartate-specific proteases that play a central role in apoptotic nerve cell death (Troy et al. 2011). They are strongly associated with glutamate-induced excitotoxic apoptosis (Tenneti et al. 1998; Tenneti and Lipton 2000), where their activation occurs via the mitochondrial or intrinsic apoptotic pathway (Budd et al. 2000). Overactive glutamate receptors produce excessive calcium influx and ROS, which causes mitochondrial calcium overload and energy depletion that triggers mitochondrial permeabilization and release of

cytochrome c (Cyt *c*) into the cytoplasm. Cyt *c* relieves calcium-induced inhibition of inositol trisphosphate receptors (IP_3R) and initiates the formation of the apoptosome which activates the apoptotic caspase cascade (Kroemer et al. 2007). The interplay between activated caspases and calpains is thought to underlie the neurotoxic effect of glutamate through excitotoxic apoptosis (Hara and Snyder 2007).

5.5 Calpains

Calpains are a group of intracellular Ca^{2+}-dependent cysteine proteases activated during excitotoxic apoptosis (Ankarcrona et al. 1995; D'Orsi et al. 2012; Vosler et al. 2008). Calcium overload due to GluR overactivation causes calpain activation and subsequently cell death through cleavage and inactivation of signaling and structural intracellular proteins (Brorson et al. 1995; Liu et al. 2008; Siman et al. 1989). Although the exact sequence of events is not clearly understood, the interplay between caspases and calpains (Wu et al. 2007) involves Ca^{2+}-dependent activation of calpain which causes cleavage and internalization of the membrane-bound Na^+/Ca^{2+} exchanger 3 (NCX3) and leads to an increase in intracellular calcium and cell death in a form of active necrosis (Bano et al. 2005). Activated calpains also target the protein Cain/Cabin-1, an intracellular inhibitor of calcineurin-mediated cell death (Kim et al. 2002; Lai et al. 1998). Calpain-mediated Cain/Cabin-1 inactivation removes a key restrictive control over calcineurin dephosphorylation of the pro-apoptotic protein Bcl-2-associated death promoter (BAD). Dephosphorylated BAD binds and inactivates the antiapoptotic proteins Bcl-2 and Bcl-X_L (Wang et al. 1999). In addition, activated calpains can directly cleave and inactivate Bcl-2 and Bcl-X_L (Vandenabeele et al. 2005), which are responsible for preventing activation of the pro-apoptotic mitochondrial membrane permeabilization complex formed by Bcl-2-associated X protein (BAX)/Bcl-2-antagonistic/killer (BAK) (Yang et al. 1997). Activation of the BAX/BAK complex forms a pore on the mitochondrial outer membrane that is responsible for the release of cytochrome c that initiates caspase-mediated apoptosis (Liu et al. 1996; Ow et al. 2008). An alternative pathway activated by calpains during excitotoxicity involves activation and release of the apoptosis-inducing factor (AIF) (Cao et al. 2007; Landshamer et al. 2008; Polster et al. 2005; Yu et al. 2002), a mitochondrial flavoprotein involved in caspase-independent apoptosis (Susin et al. 1996). The importance of calpain inhibitors as a potential neuroprotective agents is highlighted by their significant neuroprotective effect against excitotoxic brain damage induced by cerebral ischemia and traumatic brain injury (Koumura et al. 2008; Kupina et al. 2001; Lubisch et al. 2003; Nimmrich et al. 2010; Wang et al. 1996).

5.6 Lipases

NMDAR-mediated glutamate neurotoxicity activates Ca^{2+}-dependent phospholipase A2 (PLA2), which triggers release of arachidonic acid (AA) from membrane

phospholipids (Dumuis et al. 1988; Lazarewicz et al. 1988). Extracellular release of arachidonic acid can inhibit transporter-mediated glutamate (Volterra et al. 1992), while intracellular metabolism of AA by lipoxygenases (LOX), cytochrome P450 (CYP), and cyclooxygenases (COX) generates bioactive eicosanoids that trigger neuroinflammatory cell damage.

6 Role of Mitochondria in Glutamate Excitotoxicity

Calcium accumulation in mitochondria is a key event in glutamate excitotoxicity (Duchen 2012; Orrenius et al. 2003). It has been shown in many neurodegenerative diseases that overactivation of calcium-permeable GluRs causes an increase of intracellular calcium that induces overloading of calcium in the mitochondria, followed by an increase in free radicals and a decrease in ATP levels (Thayer and Wang 1995). In fact, the amount of calcium taken up by the mitochondria is decisive in cell death by glutamate excitotoxicity. Once the mitochondrial capacity for Ca^{2+} sequestration is exceeded due to depletion of mitochondrial energy resources, mitochondrial failure occurs (Rizzuto et al. 2012) (Fig. 2).

Physiologically, Ca^{2+} transport to the mitochondria through a complex formed between the voltage-dependent anion-selective channel (VDAC) and the mitochondrial calcium uniporter (MCU) contributes to the maintenance of low levels of Ca^{2+} in the cytosol (Rizzuto et al. 2012). The main route of Ca^{2+} entry into the mitochondria is through the Ca^{2+} uniporter (MCU), which is activated by Ca^{2+} in an allosteric manner (Kirichok et al. 2004). During pathological increases in cytosolic Ca^{2+} concentration, mitochondria accumulate Ca^{2+} ions and sometimes Ca^{2+}-phosphate complexes form as reversible calcium deposits (David et al. 2003; Pivovarova et al. 1999). In excitable cells, the primary method of calcium extrusion out of the mitochondria is the Na^{+}/Ca^{2+} transporter (mNCX), responsible of the low basal $[Ca^{2+}]_{mit}$. Because of its low carrier capacity, the Na^{+}/Ca^{2+} transporter (mNCX) can be easily overtaken by Ca^{2+} influx through the Ca^{2+} uniporter (MCU), generating a net accumulation of Ca^{2+} in mitochondria. An alternative pathway for Ca^{2+} extrusion is the H^{+}/Ca^{2+} exchanger, but it is slow and saturates at a lower $[Ca^{2+}]_{Cit}$ than the Na^{+}/Ca^{2+} transporter; so its contribution to fast calcium exchange is limited (Bernardi 1999; Gunter et al. 1991).

Still another route for Ca^{2+} extrusion is via the transitory opening of the mitochondrial permeability transition pore (mPTP) complex, which controls excessive influx of toxic levels of Ca^{2+} (Bernardi and von Stockum 2012; Ichas et al. 1997; Zoratti and Szabo 1995). It is known that factors such as increased oxidative stress (ROS), mitochondrial Ca^{2+} overload, and metabolic stress promote mPTP opening (Duchen 2000a; Duchen 2000b). mPTP opening determines whether a cell dies or survives. Although its opening mechanism is not very well understood, it is known that mitochondrial Ca^{2+} overload is enough to promote its opening. It has been proposed that partial mitochondrial depolarization can prevent Ca^{2+} overload in mitochondria (Budd and Nicholls 1996; Sanz-Blasco et al. 2008). Simultaneous measurements of $[Ca^{2+}]$ and inner mitochondrial

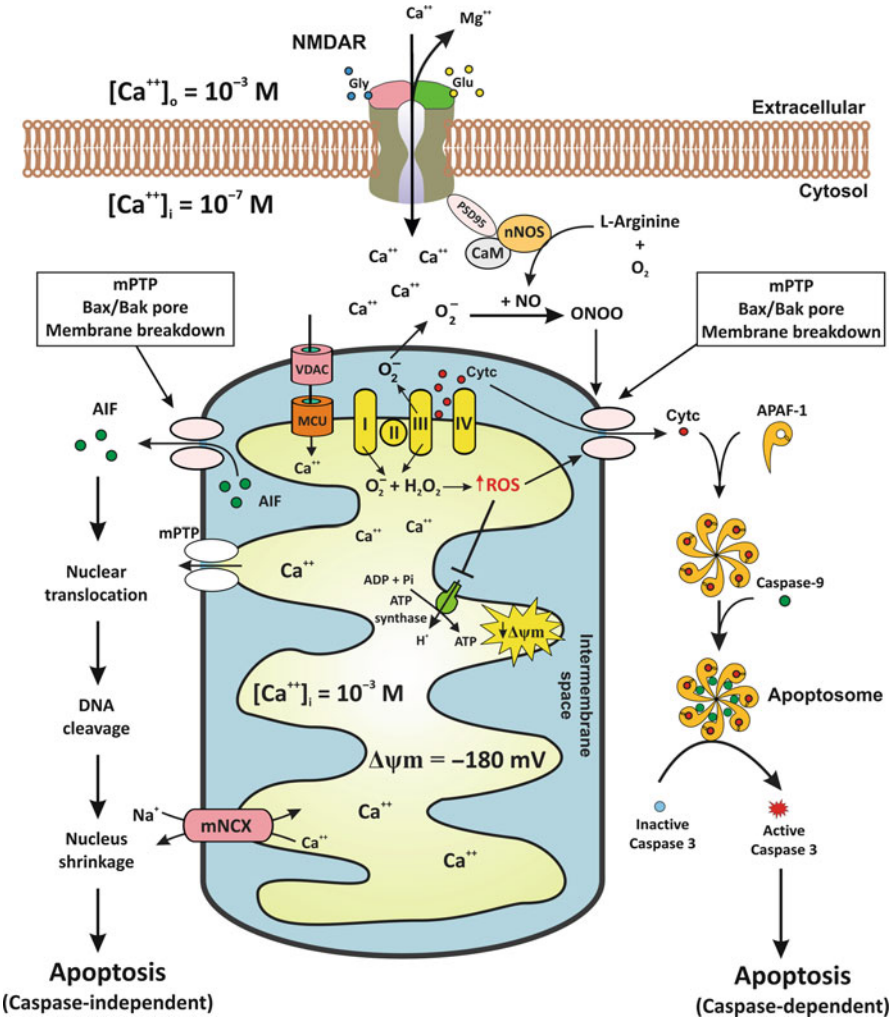

Fig. 2 Mitochondrial contribution to excitotoxicity. During GluR-mediated excitotoxicity, excess Ca^{2+} is transported into mitochondria by a complex formed between the voltage-sensitive anion channel (VDAC) and the mitochondrial Ca^{2+} uniporter (MCU). Although Ca^{2+} concentrations are higher inside the mitochondria compared with the cytosol, Ca^{2+} is normally transported inside mitochondria due to a large electrical gradient across the mitochondrial membrane, known as the inner mitochondrial membrane potential ($\Delta\psi m = -180$ mV). As excess Ca^{2+} accumulates, it produces a persistent depolarization of the inner mitochondrial membrane potential that triggers the synthesis of ATP via the ATP synthase and increases the activity of the electron transport chain with the subsequent production of reactive oxygen species (ROS). Persistent accumulation of ROS in mitochondria may inhibit ATP synthesis and the activity of the respiratory chain, leading to energy failure and loss of mitochondrial homeostasis. As the integrity of the mitochondria deteriorates, key internal components of the mitochondria such as cytochrome c (Cyt c) and apoptosis-inducing factor (AIF) are released into the cytosol where they act as powerful triggers of apoptosis. Cyt c interacts with apoptotic protease-activating factor 1 (APAF-1) and

membrane potential ($\Delta\psi m$) in hippocampal neurons during exposure to toxic glutamate levels show that $[Ca^{2+}]c$ increases transiently followed by a variable degree of recovery. This is then followed by a failure of the cell to maintain a low cytoplasmic free Ca^{2+} concentration, called delayed calcium deregulation (DCD). During this process, $\Delta\psi m$ changes only slightly during the initial phase, showing a progressive and complete depolarization later on (Abramov and Duchen 2008) that causes ATP depletion and cell death. GluR-dependent transient mitochondrial calcium loading can also initiate oxidative damage and/or inhibit mitochondrial respiration (Ward et al. 2000) observed as a reduction in oxygen consumption due to inhibition of mitochondrial complexes I, II/III, and IV (Rego et al. 2000).

7 Clinical Relevance of GluR-Mediated Excitotoxicity

Although the original concept behind the mechanism of excitotoxicity originated in strong preclinical evidence suggesting that acute and chronic neurotoxicity can use the excitatory amino acid glutamate to produce nerve cell injury and cell death (Olney 1969; Olney 1978), it was not until 20 years later that a direct link between glutamate excitotoxicity and clinical disease in humans could be identified (Perl et al. 1990; Teitelbaum et al. 1990). Although equally strong preclinical (Benveniste et al. 1984; Cook et al. 2012a; Cook et al. 2012b; Hagberg et al. 1985) and clinical (Bullock et al. 1995) evidence supports a significant role for GluR-mediated excitotoxicity in hypoxia-ischemia and stroke, the initial pace of discovery of anti-excitotoxic drugs based in GluR antagonists has been slower than expected (O'Collins et al. 2006; Savitz and Fisher 2007). One of the reasons for the slow progress of discovery of anti-excitotoxic therapies based in GluR antagonists has been the fact that most inhibitors of GluRs cannot discriminate between GluRs engaged in physiologically relevant glutamatergic neurotransmission and pathologically active GluRs associated with disease states (Lipton 2004; Lipton 2007). The search for clinically tolerated GluR antagonists that block excitotoxicity by preferentially targeting pathologically active GluRs led to the identification of memantine, an uncompetitive NMDA receptor antagonist (Chen et al. 1992; Chen and Lipton 2006) that preferentially blocks pathologically active GluRs and protects neurons against excitotoxic injury (Fig. 3) (Lipton 2007). Memantine's neuroprotective activity has made it a drug of choice in the treatment of chronic neurological diseases such as Parkinson's (Olney et al. 1987; Rabey et al. 1992), dementia with Lewy bodies (Sabbagh et al. 2005), and Alzheimer's disease, for which it is approved by the FDA for clinical use (Fleischhacker et al. 1986; McShane et al. 2006; Reisberg et al. 2003).

Fig. 2 (continued) caspase 9 to form the apoptosome, which activates caspase 3, a key powerful mediator of apoptotic cell death. Loss of mitochondrial integrity also allows the release of the apoptosis-inducing factor (AIF) into the cytosol where it enters the nucleus and causes DNA fragmentation, chromatin condensation, and nucleus shrinkage through a caspase-independent mechanism of apoptosis

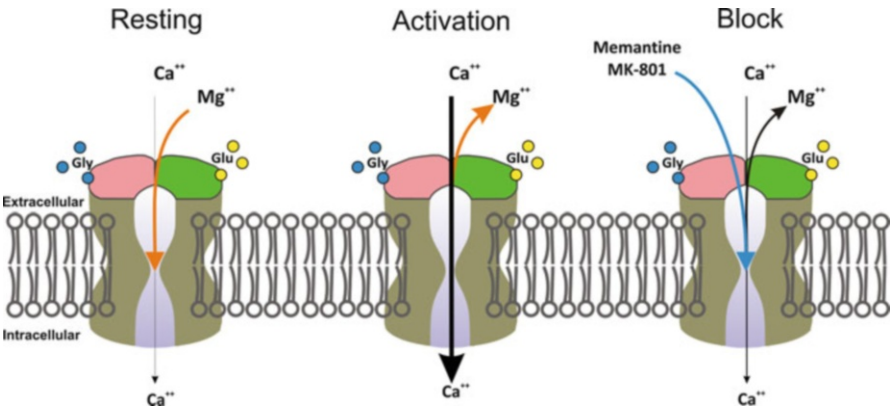

Fig. 3 Preferential block of pathologically active GluRs. Ca^{2+}-permeable NMDARs are an important mediator of GluR excitotoxicity. Under resting conditions, a steep electrochemical gradient favors Ca^{2+} influx through NMDARs while a voltage-dependent block by extracellular Mg^{2+} interferes with Ca^{2+} influx. During NMDAR activation, transient depolarization is required to force Mg^{2+} out of the channel and allow Ca^{2+} influx into the cell. Once the cell returns to its normal resting potential, Mg^{2+} block of Ca^{2+} influx is restored while excess Ca^{2+} is pumped out of the cell. Selective NMDAR antagonists, such as memantine, act as activity-dependent open-channel blockers that, similar to Mg^{2+}, can gain access to the inside the ion channel pore and block the influx of Ca^{2+} through NMDARs during excessive pathological activation. Because its blocking effect requires prior activation of the receptor by glutamate, which exposes binding sites that are otherwise hidden during the resting state, the efficacy of the drug increases as the activity of the receptor increases and vice versa. In addition to this property, preferential block of pathologically active GluRs requires drugs to be highly selective for their specific target, to avoid interference with other neurotransmitter systems and unwanted side effects, and to have low affinity for its binding site (in the case of memantine, produced by a relatively rapid off-rate from the channel) in order to minimize inhibition of the receptor during normal physiological function. In contrast, MK-801 has a very slow off-rate from the channel, blocking physiological activity and producing multiple side effects

Recently, ketamine, an NMDAR open-channel blocker and dissociative anesthetic with anti-excitotoxic properties (Choi et al. 1989; Choi 1990), has been shown to possess strong antidepressant activity in both preclinical and clinical studies of depression (Skolnick et al. 2009).

An alternative anti-excitotoxic strategy that has produced positive clinical results makes use of drugs that boost the function of glutamate transport systems to reduce extracellular levels of glutamate (Fumagalli et al. 2008; Rothstein 1996). An example of such drugs is riluzole (Fumagalli et al. 2008), which is currently approved by the FDA for the treatment of amyotrophic lateral sclerosis (Bensimon et al. 1994; Lacomblez et al. 1996; Miller et al. 2012).

A growing body of evidence suggests GluR-mediated neurotoxicity facilitates growth of gliomas, one of the most aggressive and malignant forms of brain cancers (Takano et al. 2001; Watkins and Sontheimer 2012; Ye and Sontheimer 1999). Glioma cells can cause excitotoxic cell death in the surrounding brain tissue by releasing toxic amounts of glutamate through the cystine-glutamate antiporter

(SXC, SLC7A11) (Buckingham et al. 2011; Watkins and Sontheimer 2012). Clinical trials are currently under way to test the neuroprotective efficacy of the NMDAR antagonist memantine and the SXC inhibitor sulfasalazine in patients suffering from glioma (*ClinicalTrials.gov*: NCT01260467; NCT01430351, NCT01577966).

8 Conclusion

Although the full implications of excitotoxicity are not yet fully understood, a large body of evidence points towards a role for excitotoxic processes in brain disease. Either as a cause or consequence of other pathological process, the role of excitotoxicity in brain disease has become increasingly undeniable and as a result, difficult to ignore when trying to understand a series of neurodegenerative and neuropsychiatric disorders.

Abstract

Disorders of the central nervous system (CNS) are amongst the most complex disease states and lead to some of the most devastating conditions found in medicine today. It is well established that both genetic and epigenetic factors influence the pathogenesis of neurodegenerative disorders. More recently a growing body of evidence suggests that changes in neurotransmitter systems may underlie the pathogenic mechanisms of neurodegenerative disorders, such as Alzheimer's disease and Parkinson's disease. Excitatory amino acids (EAA) are known to play key roles in neurotransmission, neuromodulation, and neurotoxicity. EAA receptors are classified into two major subdivisions, ionotropic glutamate receptors (iGluRs) and metabotropic glutamate receptors (mGluRs). L-Glu-gated ion channels, more commonly known as (iGluRs), are the primary mediators of fast excitatory synaptic transmission between neurons in the mammalian CNS. Evidence suggests that the iGluR receptor systems are involved in a number of pathophysiology conditions. This chapter will detail the current state of knowledge regarding the involvement of iGluRs in neurodegenerative and other disorders.

Keywords

Alzheimer's disease • Excitotoxicity • Ionotropic glutamate receptor • Neurodegeneration • Parkinson's disease

List of Abbreviations

AD	Alzheimer's disease
AMPA	Alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionate
AMPAR	AMPA receptor
CNS	Central nervous system
EAA	Excitatory amino acid
iGluR	Ionotropic glutamate receptor
Kainate	(2S,3S,4S)-3-(carboxymethyl)-4-prop-1-en-2-ylpyrrolidine-2-carboxylic acid
L-Glu	L-glutamate
NMDA	(2R)-2-(methylamino)-butanedioic acid
NMDAR	NMDA receptor

1 History of Central Nervous System Disorders

Disorders of the central nervous system (CNS) have been a part of recorded history since ancient times. The Greek Athenian philosopher Socrates (469–399 BC) is

believed to have experienced neuropsychological disturbances in the form of "demonic orders" or what are now medically referred to as auditory command hallucinations. Similarly, the Greek historian Aristotle (384–322 BC) who was said to have suffered from epilepsy was the first to propose that all mental illness was caused by physical problems of the body (see Traicté de l'Epilepsie by Jean Taxol, 1602). Texts also allude to various other notable historical figures being afflicted with neurological disorders including Julius Caesar (epilepsy), Mozart (manic depression), and Joan of Arc (schizophrenia). Neurological disorders have not only been part of the human condition since the beginning of civilization but also played pivotal roles in human history.

2 Multifactorial Etiology of CNS Disorders

Disorders of the CNS are complex disease states with more than 600 disorders currently recognized. Of all CNS disorders, neurodegenerative diseases are the most prevalent. Etymologically, neurodegeneration is made up from prefix "neuro-," which refers to cells of neuronal origin, and "degeneration," which in the context of an organ or tissue system refers to the process of losing function or structure. Clinically, neurodegenerative diseases comprise a diverse assemblage of disorders that present with heterogeneous pathological and clinical expression patterns. These diseases are typically characterized by nervous system dysfunction resulting from the progressive loss of neuron structure or function often with accompanying neuronal cell death. Cell death primarily affects subsets of neurons in specific functional systems and may involve either the entire neuron (neuronopathy) or be restricted to the axon (axonopathy). While the etiology of neurodegenerative diseases is often unknown, a variety of factors have been identified that determine an individual's susceptibility to disease, including an individual's age, race, gender, and genetic makeup. Environmental factors such as exposure to chemicals and infectious agents have also been shown to increase the risk of neurodegenerative diseases. The most prevalent neurodegenerative diseases include Alzheimer's disease and other dementias, Huntington's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease).

3 Prevalence of Neurodegenerative Disorders

Dementia is the term typically used when referring to a decline in intellectual functioning, including problems with episodic memory, critical reasoning, and objective thinking. Within the general population, the most common disorders that cause neurological impairments include Alzheimer's disease, dementia with Lewy bodies, frontotemporal dementia, and microvascular brain injury. The primary risk factor for dementia is age, with incidence rates doubling for every 5 years after the age of 65. Gender has also been found to affect the incidence of dementia, with woman having a higher risk of developing the condition. Cohort longitudinal

studies estimate that the prevalence rate for all dementias is between 10 and 15 per 1,000 person-years. According to estimates from the World Health Organization, 0.441 % of people worldwide will have dementia by 2015 and that the prevalence will increase to 0.556 % by 2030 (World Health Organization 2012). As of 2010, there were an estimated 35.6 million people worldwide affected by dementia. According to the World Alzheimer Report, released by Alzheimer's Disease International, the prevalence of dementia will double every 20 years to 65.7 million in 2030 and to 115.4 million in 2050 (ASD International 2012). Currently, 58 % of people afflicted with dementia live in developing countries. It is estimated that by 2050 this will rise to 71 %. Alzheimer's disease is the most common form of dementia, accounting for between 50 % and 70 % of all dementia cases.

4 Societal Cost of Neurodegenerative Disorders

With a general trend for increasing life expectancies worldwide, neurodegenerative disorders are becoming one of the most costly diseases for societies. In 2009, it was estimated that the approximate cost of dementia worldwide was approximately US$422 billion yearly. The costs associated with neurodegenerative disorders can be categorized into direct medical costs and indirect costs. Direct medical costs include those associated with long-term care by health-care professionals in addition to the cost of nursing home care. It is estimated that over two-thirds of nursing home residents suffer from some sort of dementia. It is often the case that the primary caregiver for a person suffering from a neurodegenerative disorder is a relative or close friend. This can result in significant indirect costs that include caregiving time and the loss of economic productivity for both the patient and caregiver. It has been estimated that the total costs for an Alzheimer's patient are between $18,000 and $77,500 per year in the United States. Dementia caregivers themselves often suffer psychosocial and physical problem which can be directly related to the duties of the caregiver toward the sufferer. It has been estimated that a caregiver may give up to 47 h per week nonwork-related time to the care of a sufferer. It therefore remains that neurodegenerative disorders will continue to represent a major challenge for any society.

5 A Brief History of L-Glutamate

In 1866, the German chemist K. Heinrich Ritthausen discovered and identified L-glutamate. However, the role of L-Glu as a nervous system excitant was not fully elucidated until the mid-twentieth century. In 1954, Hayashi observed that direct injection of glutamate into the brain resulted in seizure activities. Similarly, Curtis et al. (Curtis and Eccles 1959; Curtis et al. 1959) showed glutamic acid to be effective for evoking repetitive discharges from interneurons located in the spinal cord of the cat. Subsequent studies by Curtis revealed that application of glutamic acid could induce neuron depolarization with concomitant increases in the firing of

action potentials (Curtis et al. 1959). Concomitant with the presence of high concentrations of glutamate in nervous tissue leads to speculation that L-Glu had an important neurophysiological role. In 1963, a seminal paper by McLennan was published that outlined the criteria required to establish substances as neurotransmitters. In the same year, iontophoretic studies of the effects of L-Glu on neurons in the mammalian cerebral cortex proposed that L-Glu was a putative excitatory neurotransmitter in the CNS (Krnjevic and Phillis 1963). The discovery by Takeuchi and Takeuchi of L-Glu-induced depolarization in muscle at locations corresponding to sites of synaptic innervation added further evidence for the role of L-Glu as a neurotransmitter (Takeuchi and Takeuchi 1963). Since then, numerous experiments have unequivocally determined that L-Glu is the major excitatory neurotransmitter in the vertebrate CNS.

6 Glutamate Receptors

The receptors mediating L-Glu neurotransmission can be classified into two major groups, ionotropic and metabotropic (Fig. 1a). L-Glu-gated ion channels, more commonly known as ionotropic glutamate receptors (iGluRs), are the primary mediators of fast excitatory synaptic transmission between neurons in the mammalian CNS. iGluRs have been typically classified by the synthetic agonists that mimic the effects of L-Glu: (2R)-2-(methylamino)butanedioic acid (*N*-methyl-D-aspartate; NMDA), 2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl)propanoic acid (AMPA), and (2S,3S,4S)-3-(carboxymethyl)-4-prop-1-en-2-ylpyrrolidine-2-carboxylic acid (kainic acid; kainate) (Fig. 1b). The first cloning of an L-Glu receptor was by Gunderson (1984) who observed that messenger RNA (mRNA) from human brain injected into *Xenopus* oocytes was able to produce both L-Glu- and kainate-sensitive channels in addition to voltage-operated channels. In 1989, Hollmann screened a rat brain cDNA library for kainate-gated ion channels that were subsequently expressed in *Xenopus* oocytes (Hollmann et al. 1989). The resulting cDNA clone was found to encode a single protein of 99,800 relative molecular mass that formed a functional ion channel that possessed both pharmacological and electrophysiological properties of the kainate subtype of L-Glu receptor. Based on its sensitivity to kainate, the receptor was named GluR-K1. However subsequent binding studies of this channel revealed that the receptor was in fact an AMPA receptor protein based on its non-desensitizing responses to kainate. The GluR-K1 receptor was subsequently renamed to GluR1 to reflect this (Sommer et al. 1990).

Over the next few years, additional AMPA receptor family members were cloned including GluR1 (Keinanen et al. 1990), GluR2 (Nakanishi et al. 1990), GluR3 (Bettler et al. 1990; Boulter et al. 1990), and GluR4 (Gallo et al. 1992). In 1990, Bettler et al. cloned a low-affinity kainate-binding subunit they termed GluR5 (Bettler et al. 1990). This receptor subunit displayed only 40–41 % amino acid identity with the other AMPA/kainate receptor subunits known to exist (GluRs1–4). Expression of this clone in Xenopus oocytes resulted in homomeric channels that were only weakly responsive to L-Glu. Investigations determined that

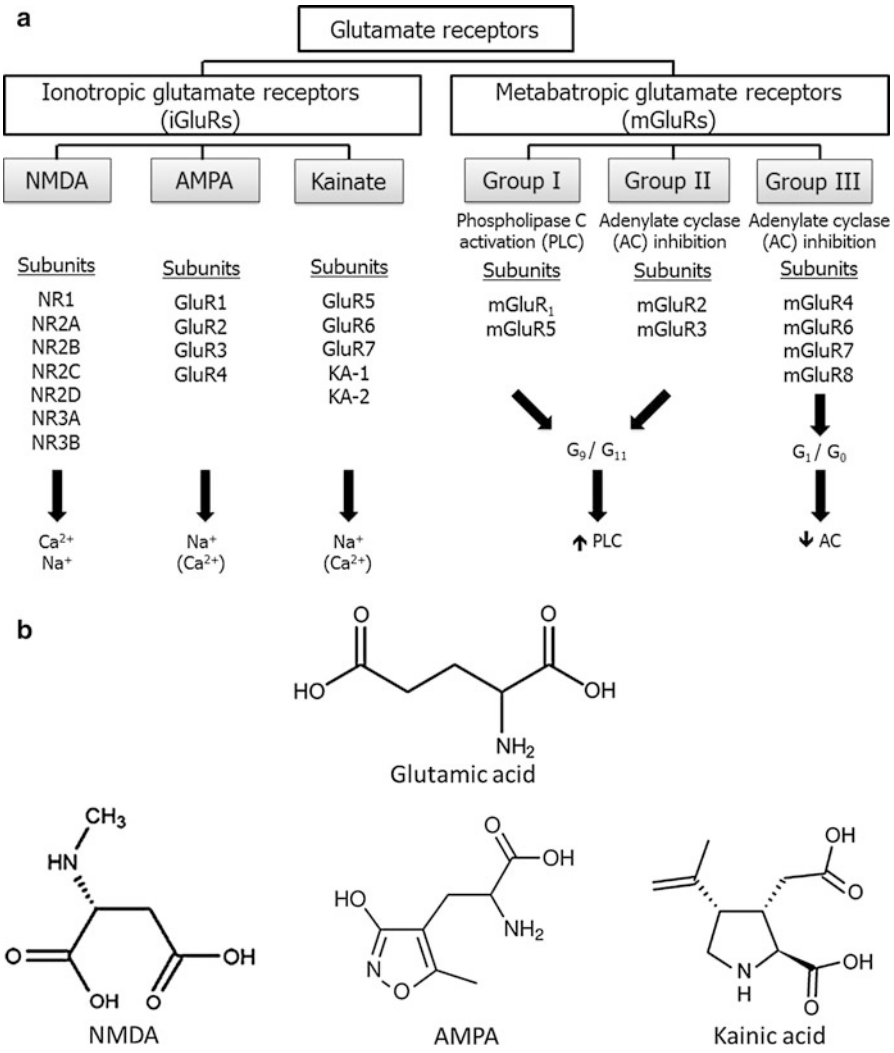

Fig. 1 (**a**) Family of glutamate receptors. (**b**) Structures of L-Glu, NMDA, AMPA and Kainate

the sequence similarity of GluR5 was significantly below the 70 % inter-subunit identity that was characteristic of the other AMPA/kainate receptors identified suggesting that GluR5 was in fact a different subtype of L-Glu receptor. This was confirmed in 1992 by Sommer (Sommer et al. 1992) who reported the desensitization of this subunit to kainate. Other kainate-selective receptors were cloned in the early 1990s including GluR6 (Egebjerg et al. 1991), GluR7 (Bettler et al. 1992; Lomeli et al. 1992), KA1 (Werner et al. 1991), and KA2 (Herb et al. 1992; Kamboj et al. 1992). It should be noted that when KA1 and KA2 subunits are expressed either alone or with each other, it does not result in the formation of functional

channels. However, co-expression of KA1 and KA2 with either Glu5 or Glu6 is able to form functional channels albeit with modified properties (Fisher and Mott 2011). The NMDA receptor subunits were first cloned by Moriyoshi et al. (1991), Yamazaki et al. (1992), and Karp et al. (1993) and were termed NR1 (also referred to as NMDAR1). In 1993, Ishii et al. (1993) cloned an additional four subunits, which they termed NR2A-D. Two NR3 subunits have also been cloned termed NR3A and NR3B (Sucher et al. 1995; Das et al. 1998).

Each functional iGluR subtype is formed by the heteromeric assembly of four subunits from a single class, e.g., NMDA subunits can only assemble with other members of the NMDA subfamily. Of the 16 iGluR subunits identified in human, 7 belong to the NMDA class (NR1, NR2A-D, NR3A-B), with the remaining 9 being members of the non-NMDA class, 4 to the AMPA class (GluR1–4) and 5 to the kainate class (GluR5–7 and KA1–2) (Fig. 1a). Two other subunits, known as δ1 and δ2, are termed orphan receptors because while they share high sequence similarity to other iGluR subunits, there is currently no evidence to indicate that they form functional iGluRs (Schmid et al. 2008). Recently, a new nomenclature for ligand-gated ion channels has been proposed by Collingridge et al. (2009) and is currently being reviewed by the nomenclature committee of International Union of Basic and Clinical Pharmacology (IUPHAR) IUPHAR (NC-IUPHAR).

7 NMDA Receptors

The NMDA subtype of iGluRs is involved in activity-dependent forms of synaptic plasticity, synapse consolidation, and excitatory amino acid (EAA)-mediated neuronal toxicity (Hynd et al. 2004a). NMDA receptors (NMDARs) are found on most CNS neurons (Petralia et al. 1994a, b, c) and mediate Ca^{2+} influx in response to the coincident binding of L-Glu and glycine (Constantine-Paton 1990; Bliss and Collingridge 1993; Seeburg 1993).

Functional NMDARs exist as tetrameric or pentameric complexes comprising proteins from three families of homologous subunits, designated NR1, NR2A-D, and NR3A-B (Monyer et al. 1992; Ishii et al. 1993; Dingledine et al. 1999). The presence of the NR3 subunits serves to have an inhibitory effect on NMDAR activity. The NR1 subunit functions to bind glycine, whereas the NR2 subunits bind L-Glu. For both the NR1 and NR2 mRNA transcripts and subunit proteins, distinct spatial and temporal expression patterns have been found (Bockers et al. 1994). While the NR1 subunit is expressed ubiquitously in the brain, the NR2 subunits show marked regional and developmental variations (Watanabe et al. 1992; Akazawa et al. 1994; Monyer et al. 1994). The function and modulation of NMDAR channels is both spatially and temporally regulated (Bockers et al. 1994; Rigby et al. 1996). The NR1 mRNA undergoes alternate splicing of three exons (4, 20, and 21) to give eight functionally distinct subunit variants (Sugihara et al. 1992; Durand et al. 1993; Hollmann et al. 1993). Exon 4 encodes a 21-amino acid amino-terminal cassette (designated "N1"), while exons 20 and 21 encode two consecutive carboxy-terminal 37- ("C1") and 38-amino acid ("C2") cassettes

(Zimmer et al. 1995). Both the gene sequence and the intron/exon organization of the human NR1 gene show a high degree of homology to the rat gene, with exception of the deletion of rat exon #3 (Hollmann et al. 1993). In vivo, NMDARs are regulated by a variety of agents including glycine, Mg^{2+}, Zn^{2+} and H^{+} ions, and polyamines. Alternative splicing of the N1 cassette has been shown to modulate both the ligand affinity and channel characteristics of NMDARs. Insertion of the N1 cassette results in the formation of receptors with decreased sensitivity to proton inhibition, increased current amplitudes, and altered responses to protein kinase C activation (Durand et al. 1993; Traynelis et al. 1995). Deletion of the cassette potentiates responses to the polyamines spermine, spermidine, and Zn^{2+} (Zhang et al. 1994; Traynelis et al. 1995). In contrast deletion of the N1 cassette has been shown to potentiate the response to polyamines in the presence of saturating concentrations of glycine (Durand et al. 1993) in addition to low-micromolar Zn^{2+} concentrations (Hollmann et al. 1993). In contrast, both N-terminal variants are inhibited by high-micromolar concentrations of Zn^{2+} and at low glycine concentrations. Potentiation of NMDARs occurs dose dependently and involves an increase in both peak channel open probability and peak channel current duration (Araneda et al. 1993).

8 AMPA Receptors

The AMPA type of iGluRs (AMPARs) are believed to be the most common type of neurotransmitter receptor in the CNS. AMPARs are multimeric ligand-gated ion channels that like NMDARs play crucial roles in synaptic transmission and plasticity (Ozawa et al. 1998). AMPARs are heteromeric and are composed from four different subunit types, designated as GluR1, GluR2, GluR3, and GluR4 (previously referred to as GluRA-D, respectively) (Collingridge et al. 2009). Each of the subunits is encoded for by a separate gene. Native AMPARs typically occur in a symmetric "dimer of dimers" configuration, consisting of GluR2 and either GluR1, GluR3, or GluR4. Dimerization of the subunits is initiated in the endoplasmic reticulum and occurs via interaction of a conserved N-terminal domain consisting of the amino acids leucine, isoleucine, and valine-binding protein motif. The association of different GluR subunits gives rise to receptors with different channel properties and ionic conductances (Derkach et al. 2007). Each GluR subunit consists of approximately 900 amino acids with each exhibiting 65–75 % sequence homology when compared to the other subunits (Hollmann and Heinemann 1994).

Similar to other iGluRs, the GluR subunits possess a structure consisting of an extracellular N-terminal domain, an intracellular C-terminal domain, and three membrane-spanning hydrophobic domains termed M1, M3, and M4. In addition, one membrane reentrant loop (M2) is also present (Bennett and Dingledine 1995). Within each subunit, the ligand-binding domain is made up from an N-terminal region designated as S1 and S2. However, AMPAR subunits show the greatest difference in their C-terminal sequence, which determines how each subunit interacts with cellular scaffolding proteins. Each AMPAR has four agonist-binding

sites, each of which is formed by the N-terminal region and the extracellular loops located between TM's III and IV. The binding of an agonist (such as L-Glu) results in a structural rearrangement of these two loops, such that each is moved toward each other, resulting in opening of the channel pore. Ion flow through AMPARs only occurs upon coincident binding of two agonists with increases in current flow occurring following binding of two more agonists at the unoccupied sites. Due to the rapid nature for both AMPAR desensitization and resensitization kinetics, it has been suggested that they are the primary mediators for fast excitatory neurotransmission in the CNS. Long-term potentiation (LTP) via AMPARs occurs by both an increase in the number of AMPARs at the postsynaptic surface and increases in the single channel conductance of the receptor channel (Lee and Kirkwood 2011).

Native AMPAR subunits exist as two splice variants, known as the "flip" and "flop" types. Alternative splicing is based on the insertion/deletion of a 38-amino acid sequence located at the C-terminal end of an extracellular loop located between transmembrane segments III and IV (Seeburg et al. 1998). The resulting AMPARs show altered desensitization kinetics including the speed of receptor desensitization, the speed at which the receptor is subsequently resensitized in addition to the rate at which the AMPAR channel closes (Frandsen and Schousboe 2003). The flip variant has been shown to occur in the prenatal CNS, while the flop variant is the form found in the adult CNS.

AMPARs are permeable to the monovalent cations, Na^+ and K^+. However, in contrast to NMDARs, AMPARs are typically impermeable to the divalent cation, calcium. Ca^{2+} permeability of AMPARs is controlled by the GluR2 subunit. Posttranscriptional editing of the GluR2 mRNA results in a single amino acid change from the uncharged amino acid glutamine (Q) to the positively charged arginine (R). This substitution occurs in transmembrane region II, known as the Q/R editing site. AMPARs containing glutamine, GluR2(Q), are permeable to Ca^{2+}, while receptors containing arginine, GluR2(R), are not due to the unfavorable energetics required for calcium to enter past the positive-charged amino acid. In the adult CNS, the majority of GluR2 subunits exist as the GluR2(R) form, resulting in Ca^{2+}-impermeable AMPARs. This impermeability is believed to protect against neuronal excitotoxicity. The GluR2 subunit has also been shown to modulation of the receptor by polyamines (Stromgaard and Mellor 2004). AMPARs lacking a GluR2 subunit are capable of being blocked in a voltage-dependent manner, preventing the passage of positive ions (K^+, Na^+) through the channel pore.

The phosphorylation of AMPAR subunits has been shown to alter both synaptic transmission and plasticity in the CNS. Phosphorylation of AMPARs at the intracellular carboxy-terminus has been well established. Serine/threonine phosphorylation sites have been identified on all four AMPA subunits and serve to regulate channel localization, open probability, and ionic conductance (Santos et al. 2009). The GluR1 subunit has four phosphorylation sites which are located at serine 818 (S818), S831, and S845 and threonine 840 (T840) (Lee et al. 2007). Phosphorylation of S818 by protein kinase C (PKC) has been shown to play a crucial role in

long-term potentiation (LTP) (Boehm et al. 2006). Similarly, during LTP, S831 is phosphorylated resulting in the trafficking of GluA1-containing AMPARs to the synapse (Lee et al. 2000). The phosphorylation of S845 by protein kinase A has been shown to regulate channel open probability (Castellani et al. 2005). In contrast, the T840 site has been implicated in long-term depression (LTD) (Lee et al. 2007).

9 Kainate Receptors

The kainate types of iGluRs are formed from five distinct subunit types – GluR5 (GluK1), GluR6 (GluK2), GluR7 (GluK3), KA1 (GluK4), and KA2 (GluK5). Similar to both the NMDA and AMPA receptors, kainate receptor subunits can associate in multiple ways to form tetrameric receptors (Contractor et al. 2011). In vivo, the GluR5–7 (GluK1–3) subunits associate to form both homomeric receptors (i.e., receptors that are composed only of one type of GluR subunit) and heteromeric receptors (i.e., receptors whose subunit composition consists of different GluR subunits). In contrast, both the KA1 and KA2 (GluK4 and GluK5) subunits can only form functional receptors when combined with one of the GluR5–7 (GluK1–3) subunits.

Similar to other iGluRs, kainate receptors share a high degree of structural similarity to other subunits of the iGluR family. Receptors consist of an extracellular N-terminal domain that is involved in receptor assembly that, together with a loop between TMIII and TMIV, forms the ligand-binding domain (S1) and a reentrant loop (TMII) that forms the lining of the pore region of the ion channel. Entry of the TMII segment occurs only partially into the plasma membrane before dipping back to the cytoplasm. This segment has been termed the "p loop" and determines the calcium permeability of the receptor. GluRs 5–7 (GluK1–3) have been shown to occur in numerous splice variants and to undergo both RNA editing, giving rise to a variety of receptor types with differing pharmacological and functional properties (Jaskolski et al. 2004). The ion channels formed by kainate receptors are permeable to K^+ and Na^+, but typically impermeable to Ca^{2+}. Similar to AMPARs, the ionic conductance of kainate receptors is approximately 20pS; however, their channel kinetics are significantly shorter in duration when compared to AMPARs. Association of receptors with the protein Neto1 has been shown to slow the activation and deactivation kinetics of synaptic responses (Lerma 2011). By modulating the likelihood of depolarization of the postsynaptic neuron, kainate receptors can directly affect the amount of neurotransmitter that is released into the synaptic cleft (Huettner 2003).

Similar to both NMDA and AMPA receptors, kainate receptors are widely distributed throughout the brain. Based on this distribution it has been suggested that rather than being direct mediators of synaptic transmission, the receptors may instead play a role in modulating synaptic plasticity. The spatial distribution for the GluR5–7 subunits is found in somewhat higher levels in the CA3 region of the hippocampus, the striatum, and inner layers of the cerebral cortex. In contrast, both

the KA1 and KA2 subunits are more spatially restricted, with KA1 present only in the hippocampus (Darstein et al. 2003) while KA2 subunits found in the striatum and the inner/outer layers of the cortex (Gallyas et al. 2003). Kainate receptors are the least studied amongst those in the iGluR family, which is largely due to the lack of selective agonists and antagonists for this subtype. Kainate receptors have been implicated in several disease states from clinical data, autopsy brain studies, and animal models including knockout mice (Swanson 2009; Matute 2011). However, due to the crossover activity of many antagonists with AMPARs, it has been difficult to specifically determine the contribution of kainate receptor block to specific neurodegenerative disorders. NBQX, which has shown improvement of akinesia in rat models of Parkinson's disease, is an antagonist at both AMPA and kainate receptors, but is more potent at AMPA receptors. Thus, for the purpose of this chapter, mainly the effects of NMDA and AMPA receptors will be discussed.

10 L-Glu-Mediated Neuronal Excitotoxicity

The first report of the neurotoxic effects of L-Glu was published by Hayashi in 1954 following the observation that direct application of L-Glu was sufficient to induce seizure activity. Subsequent studies by Lucas and Newhouse (1957) showed that subcutaneous injection of L-Glu into postnatal mice resulted in degeneration of neurons in the retina. In 1969 Olney coined the term "excitotoxicity" when he showed that L-Glu-mediated cell death was not limited to the retina but could also occur in the CNS. Application of L-Glu could result in the selective death of postsynaptic neurons and that glutamate agonists could act as potent neurotoxins. Based on the ability of L-Glu to activate iGluRs and that L-Glu antagonists were able to mediate the resulting neurotoxicity, only the term "excitotoxicity" was coined, a portmanteau of excitatory and neurotoxicity. Excitotoxicity is thus defined as the pathological processes by which neurons are either damaged or killed as a result of excessive stimulation by excitatory amino acids (EAAs).

Neuronal excitotoxicity occurs when iGluRs are repetitively activated by endogenous EEAs. As the primary mediator of excitatory neurotransmission in the CNS, L-Glu is considered to be the major endogenous excitotoxin in the brain. Within the brain, L-Glu is synthesized from L-glutamine and Krebs cycle intermediates. When viewed as a complete organ, the concentration of *intracellular* L-Glu is between 5 and 15 mmol/kg wet weight, which far exceeds the *extracellular* L-Glu concentration, which is normally in the range of 0.2–5 mmol/L (Erecinska and Silver 1990). Within presynaptic neurons, L-Glu is stored in vesicles whose contents are subsequently released into the synaptic cleft via a Ca^{2+}-dependent mechanism. Once in the synaptic cleft, L-Glu binds to – and activates – postsynaptic iGluRs. Under normal physiological conditions, L-Glu is present in the synaptic cleft at a concentration of 0.6 μM (Bouvier et al. 1992). During synaptic transmission, the concentration of L-Glu in the synaptic cleft is increased up to 1 mM, which is then rapidly returned to normal over a millisecond time course

(Clements et al. 1992). The excitatory action of L-Glu is terminated by its removal from the synaptic cleft. To date, two primary mechanisms for synaptic L-Glu removal have been identified. The first involves the reuptake of L-Glu into the presynaptic neuron, while the second occurs via a glial cell-based high-affinity reuptake system (Castagna et al. 1997; Kanai et al. 1994). As a result of these sodium-dependent transport systems, a 5,000–10,000-fold concentration gradient of L-Glu exists between the intracellular and extracellular neuronal environments (Ferrarese et al. 1993).

The overactivation of iGluRs by L-Glu results in excessive amounts of Ca^{2+} entering the postsynaptic neuron. This influx of calcium can result in the sequential activation of a number of degradative enzymatic, nucleolytic, and proteolytic pathways (Zundorf and Reiser 2011). As a result, cellular DNA, RNA, and proteins begin to be degraded along with dismantling of the cytoskeleton and cell membrane. With continued L-Glu stimulation and concomitant calcium ion influx, the neuron undergoes cellular degeneration. Excitotoxic theories suggest that the cellular mechanisms normally involved in excitatory neurotransmission can be transformed into mechanisms of neuronal cell destruction (Olney et al. 1986; Whetsell and Shapira 1993). EAA neurotoxicity in animal models has been found to be cellularly selective, with distinctive degenerative patterns produced by different EAAs (Coyle et al. 1981).

11 Excitotoxicity and Neurodegenerative Disorders

Excitotoxicity is thought to be a major contributing factor to a variety of degenerative disorders, including spinal cord injury and hearing loss (ototoxicity), and in neurodegenerative diseases of the central nervous system (CNS). Excessive activation of iGluRs has been implicated in a variety of neurodegenerative diseases including traumatic brain injury (Luo et al. 2011), amyotrophic lateral sclerosis (ALS) (Grosskreutz et al. 2010), multiple sclerosis (Frigo et al. 2012), epilepsy (Czuczwar 2000), hypoxia-ischemia, and chronic neurodegenerative disorders such as Alzheimer's (Woods and Padmanabhan 2012), Parkinson's (Surmeier et al. 2010), and Huntington's diseases (Raymond et al. 2011).

12 Involvement of iGluRs in Alzheimer's Disease

Alzheimer's disease (AD) is the most frequent cause of cognitive deficit in the aged population with the prevalence of probable AD is 3 % in subjects aged 65–74, 19 % in those aged 75–84, and 47 % in those over 85. AD represents the fourth most common cause of death in Western countries (Forsyth and Ritzline 1998). With the continuing increase in the world's aged population, projections indicate that by 2050 over 115 million people will suffer from AD (World Health Organization 2012). While normal cognitive losses do occur as part of the normal aging process, the cognitive impairments observed in dementia patients are both qualitatively and

quantitatively more severe (Roses 1998a, b). Following postmortem histopathological examination, ~75 % of patients that presented with a clinical diagnosis of dementia are confirmed to have AD (Evans 1989).

The impairments in memory and cognition observed in AD can be correlated to the neuropathological features of the disease, including neuronal loss and plaque and tangle formation in both the cortex and hippocampus (Hyman et al. 1986; Albin and Greenamyre 1992; Bobinski et al. 1998). While neuronal loss is generally restricted to the pyramidal cells in layers III and IV, damage to L-Glu-innervated neurons is also observed. In AD, neuronal cell death is generally restricted to neuronal cell bodies and dendrites, with axons, terminal boutons, and glial, endothelial, and ependymal cells relatively spared. There is mounting evidence that the region-selective pattern of neuronal cell destruction may occur as a consequence of EAA dysfunction, resulting in the cognitive symptomatology observed. The neurodegeneration observed in AD may therefore arise from both the regional and cellular distribution of an EAA defect, with the observed pathology resulting from the heterogeneous distribution of EAA receptor subtype(s), including NMDA, AMPA, and the kainate receptor types (Hynd et al. 2004a).

12.1 AMPA Receptors in AD

Data from both experimental and clinical trials have suggested that modulation of AMPA receptors may be therapeutically effective in the treatment of neurodegenerative diseases. Reduced levels of the AMPA receptor subunits GluR1, GluR2, and GluR2/3 have been found in the pathologically susceptible areas of the AD brain, including the CA1 region of the hippocampus (Armstrong et al. 1994; Aronica et al. 1998; Garcia-Ladona et al. 1994; Ikonomovic et al. 1997; Wakabayashi et al. 1994). In AD patients, reductions in AMPAR expression can be correlated to disease progression and disease severity (Carter et al. 2004). Within the subiculum, a reduction in GluR2 and GluR2/3 protein levels was found to correlate with Braak stages I–II and stages III–IV, respectively. While in Braak stages V–VI, both GluR2 and GluR2/3 protein levels were similar to those of Braak stages I–II. In contrast, despite reduced subiculum GluR1 protein levels in patients with severe AD, a direct correlation between Braak staging and protein loss throughout all stages of the disease has not been demonstrated (Armstrong et al. 1994; Schaeffer and Gattaz 2008; Yasuda et al. 1995). Within the pathologically spared regions, hippocampal regions, CA2 and CA3, and the dentate gyrus, AMPAR subunits show relatively little change across all Braak stages.

AD is typically characterized by the presence of amyloid plaques and intracellular neurofibrillary tangles. Amyloid is the general term given for peptides produced by the cleavage of amyloid precursor protein (APP). The amyloid beta (Aβ) peptide is the primary component of amyloid plaques, which are thought to be triggered by the self-aggregation of Aβ into oligomers. It is the near ubiquitous presence of both amyloid plaques and neurofibrillary tangles that is thought to contribute to the degeneration of neurons and subsequently to the progressive

decline in cognitive function observed in AD (Shankar and Walsh 2009). Loss of GluR2/3 immunoreactivity has been shown to precede the formation of neurofibrillary tangles in both the hippocampus and entorhinal cortex in the brains of AD sufferers (Ikonomovic et al. 1997). A reduction in the binding of AMPA to receptors has also been observed in AD cases when analyzed by quantitative autoradiography (Dewar et al. 1991). The trafficking of AMPARs has also been shown to be disrupted by soluble Aβ peptides (Shankar et al. 2007).

Ca^{2+}/calmodulin-dependent protein kinases II (CaMKII) are serine/threonine-specific protein kinases involved in signaling cascades that are important in mediating long-term potentiation (LTP). Aβ has been found to impair AMPAR receptor trafficking and function by reducing CaMKII synaptic distribution (Gu et al. 2009). By competition with the proteolytic maturation of brain-derived neurotrophic factor (BDNF), Aβ can also interfere with synaptic potentiation by reducing AMPAR trafficking (Zheng et al. 2010). Similarly, overexpression of APP in cultured hippocampal neurons has been shown to result in reductions in the recycling of presynaptic vesicles. PSD-95 is a neuronal protein that associates with receptors and cytoskeletal elements at synapses. In PSD-95 knockout mice, reduced AMPAR receptor activity is observed. The loss of PSD-95 may contribute to AMPAR-dependent LTP deficits observed in AD. Significantly decreased levels of PSD-95 have been found in the AD brain (Sultana et al. 2010). Altered AMPA receptor currents that correlate with the reduced GluR2/3 immunoreactivity precede NFT deposition and synapse loss (Ikonomovic et al. 1997).

12.2 NMDA Receptors in AD

Many neurodegenerative disorders, including AD, involve abnormalities in synaptic structure and function. NMDARs show altered expression in a variety of neurodegenerative diseases, including AD and Parkinson's disease (PD). Immunohistochemical analysis of the distribution of NMDAR subunits in AD has to date yielded conflicting results. In a study of the AD patients with mild/modest pathology, staining for the NMDAR in the hippocampus was found to be indistinguishable from that of controls. However, in cases with severe AD changes, a more complex staining pattern was observed (Ikonomovic et al. 1999). Furthermore, quantitative autoradiography has revealed substantially higher binding to NMDARs in the striatum and nucleus accumbens in AD patients (Ulas et al. 1994). A follow-up study however showed significantly lower NR1 mRNA levels in layer III of the entorhinal cortex in AD brains using in situ hybridization. Similar reductions were also observed in layers II and IV–VI of the entorhinal cortex and in granule cells of the dentate gyrus. However, no differences in mRNA expression were observed in the CA1 region of the hippocampus or the subiculum (Ulas and Cotman, 1997). Locally lower NMDAR levels have been reported in the AD hippocampus, although no reductions were noted in either the occipital cortex or caudate (Sze et al. 2001). The basis of these discrepancies may be a result of alternative splicing of the NMDA NR1 mRNA that yields distinct protein subunit variants.

In the AD brain, regional variations in the expression of NMDA NR1 splice variants have been shown to occur between areas that are pathologically susceptible and those that remain relatively spared (Hynd et al. 2004b, 2001). The N1 (exon 4) cassette of the NR1 mRNA is particularly important in the modulation of the mature receptor. Exon 4 encodes a 21-amino acid segment in the N-terminal domain (Durand et al. 1993). Insertion/deletion of the N1 cassette yields NMDAR splice variants (designated the $NR1_{1XX}$ and $NR1_{0XX}$ variants, respectively) that are subject to distinct modulation by endogenous molecules, including the polyamines spermidine, spermine, and putrescine. Polyamines are a group of organic polycations that are protonated at physiological pH. Polyamines are present in all nucleated cells and occur in the mammalian brain in micromolar concentrations (Sarhan and Seiler 1989). They modulate various cellular functions, including cellular growth and differentiation (Tabor and Tabor 1984), regulation of gene expression (Celano et al. 1989), protein synthesis and phosphorylation (Lenzen et al. 1986), and programmed cell death (Ha et al. 1997). The action of polyamines on the NMDAR complex consists of both stimulatory and inhibitory components (Reynolds and Miller 1989; Williams et al. 1989; Rock and Macdonald 1995). While polyamines do not directly activate the NMDAR, they act to potentiate or inhibit L-Glu-mediated responses in the presence of glycine. Both $NR1_{0XX}$ and $NR1_{1XX}$ variants are inhibited by high-micromolar Zn^{2+} concentrations and potentiated by polyamines at low glycine concentrations (Zhang et al. 1994). However, only $NR1_{0XX}$ variants are potentiated by polyamines at saturating glycine concentrations (Durand et al. 1993). The concentration of polyamines in the brain shows marked changes in response to pathological state (Paschen 1992). In particular, levels of brain polyamines are altered in AD (Morrison et al. 1995; Morrison and Kish 1995). In AD cases, mean levels of spermidine, the immediate biosynthetic precursor to spermine, are markedly increased compared to controls in the temporal cortex of patients. Conversely, putrescine levels are decreased in the same region in AD cases. In one study, the ratio of NR1 1XX:0XX was found to be significantly reduced in regions of the AD brain most susceptible to pathological damage (Hynd et al. 2001), while levels of the $NR1_{1XX}$ mRNA were found to be lower in cingulate gyrus, the hippocampal formation, and superior temporal gyrus in AD cases. Conversely, $NR1_{1XX}$ levels were unchanged in both the motor and occipital cortices in AD cases and controls. These results suggest that, at least in the pathologically susceptible temporal cortex of AD patients, stimulation of the NMDAR (as a consequence of elevated spermidine levels) may be increased and its antagonism (through lowered putrescine levels) would be decreased. The selective vulnerability of neurons in AD may be attributed, in part to local variations in the composition and hence function of the NMDA NR1 receptor.

The co-expression of NR1 variants with an NR2(A–D) subunit results in heteromeric channels with distinct electrophysiological and pharmacological profiles. Significantly lower levels of both the NR2A and NR2B mRNAs were found in susceptible brain regions, including the hippocampus, temporal, and cingulate cortices (Hynd et al. 2004b).

13 Involvement of iGluRs in Parkinson's Disease

Parkinson's disease (PD) is the second most common neurodegenerative disorder in the world after Alzheimer's disease, affecting about 1 % of adults over 60 years of age. PD is a disease which is more common in the elderly and prevalence rises from 1 % in those over 60 years of age to 4 % of the population over 80 (de Lau and Breteler 2006). Although the mean age of onset is around 60 years, 5–10 % of cases are diagnosed as young onset PD between the ages of 20 and 50 (Samii et al. 2004).

The hallmark of PD pathology is loss of dopaminergic neurons in the substantia nigra pars compacta of the midbrain, which manifests itself with symptoms such as bradykinesia, muscle rigidity, and tremor. Bradykinesia involves delayed voluntary movements, difficulty in undertaking rapid motor tasks and multitasking, and also decreased facial movements. Rigidity affects the patient's posture because of an increase in tone throughout all movements. The tremor or shaking primarily affects the hands, arms, legs, jaw, and face. As these symptoms become more pronounced, patients may have difficulty walking, talking, or completing other simple tasks. The first symptoms appear after a large proportion of the dopaminergic neurons are lost. The severity of how PD affects different people varies greatly and there is no way to predict the symptoms. Although some people become severely disabled, others experience only minor motor dysfunctions.

Current established therapies focus primarily on alleviating the motor symptoms using dopamine replacement therapy with levodopa (L-DOPA) (Calabresi et al. 2010; Wu and Frucht 2005), which is a dopamine precursor. However, long-term complications after continuous use of levodopa involve disabling fluctuations and dyskinesias (Calabresi et al. 2010).

However, the chronic and progressive neurodegeneration in PD also affects non-dopaminergic pathways, which causes nonmotor symptoms, such as autonomic dysfunction, cognitive and psychiatric changes, sensory symptoms, and sleep disturbances (Samii et al. 2004). The striatum is the principal input structure of the basal ganglia, where excitatory glutamatergic input and dopaminergic input convey and interact. The depletion of nigrostriatal dopaminergic neurons leads to overactivity of the glutamatergic pathways within the striatum and output nuclei. The involvement of the glutamatergic system in the pathogenesis and symptomatology of PD is well established (Blandini et al. 1996; Chase and Oh 2000; Lange et al. 1997; Starr 1995), and the iGluRs are of interest as potential targets for anti-PD treatment therapies.

13.1 NMDA Receptors in PD

NMDARs are widely expressed in the CNS, including all of the structures of the basal ganglia, but with different subunit compositions. The abundance of NMDA receptors in the postsynaptic density of glutamatergic synapses suggests an important role in rapid response to neurotransmitter release and modulation of glutamate excitation in both physiological and pathological conditions, including PD.

Due to the presumed involvement of NMDARs in PD, NMDA receptor antagonists have therefore been of major interest for the treatment of PD in recent years, but results from both experimental studies and human trials have given mixed results. In one study by Calon (Calon et al. 2003), tissue obtained at autopsy showed increased binding of 3H-Ro 25–6981 (an NR1/NR2B-selective antagonist) in the lateral putamen when compared to controls, while binding of 3H-CGP39653 (an NR1/NR2A-selective antagonist) was unchanged in PD patients with levodopa-induced motor complications. Another study reported a decrease in the abundance of NR1/NR2B subunits in the striatum of a parkinsonian model of the rat. In contrast, no changes in the NR2A subunit were found (Dunah et al. 2000). An in vivo study used positron emission tomography to compare NMDA receptor activation in PD patients with and without levodopa-induced dyskinesias showed an increased activity in patients with dyskinesias compared to those without dyskinesias (Ahmed et al. 2011).

The noncompetitive low-affinity NMDA receptor antagonist amantadine in combination with levodopa or as monotherapy has showed limited antiparkinsonian effects and reduction in dyskinesia in PD patients (Crosby et al. 2003). Remacemide, another low-affinity NMDA receptor antagonist, showed promising antiparkinsonian effects in rodent and primate models of PD (Greenamyre et al. 1994), but when tested in 279 PD patients with motor symptoms and treated with levodopa, it showed only modest improvements although not significant (Shoulson et al. 2001). Therapeutic levels of MK-801, a noncompetitive NMDA receptor antagonist, suppress dyskinesia but also worsen parkinsonism such as sensorimotor deficits in the 6-hydroxydopamine (6-OHDA) rat model (Paquette et al. 2010). Memantine, an NMDA receptor antagonist, showed promise in treating PD patients with motor symptoms taking levodopa (Rabey et al. 1992), but in a larger study with PD patients with dementia, there was no effect on motor symptoms (Aarsland et al. 2009). However, there was an overall improvement in cognitive functions. More recent studies have focused on subtype-selective NMDA receptor antagonists, primarily those selective for the NR2B subunit, with expectation to achieve antiparkinsonian effects without the adverse effects seen from nonspecific antagonists. However the effects of NR2B-selective NMDA receptor antagonists as PD therapeutics have been mixed. The NR1/NR2B-specific NMDA receptor antagonist CP-101,606 showed limited effect on parkinsonian symptoms when administered as monotherapy but showed only a modest potentiation of antiparkinsonian actions of levodopa treatment in PD patients (Nutt et al. 2008) and in a marmoset model of PD (Nash et al. 2004). Another NR2B subtype-selective antagonist, CI-1041, successfully prevented levodopa induced dyskinesias when coadministered, in parkinsonian monkeys (Hadj Tahar et al. 2004). Ro 25–6981 is subtype-specific for active NR2B-containing NMDA receptors and has showed antiparkinsonian effect in both rat and marmoset models of PD, in addition to potentiating levodopa treatment and potentiating dopamine receptor agonists apomorphine, A68930, and quinpirole in rats (Loschmann et al. 2004). Single-dose monotherapy of MK-0657 did not improve motor functions in PD patients, and although the drug was well tolerated, it had adverse effects such as an increase in

blood pressure (Addy et al. 2009). NR2B subtype-selective NMDA receptor antagonists may have potential as therapeutic agents to treat PD, but maybe the mode of action needs to be further investigated so that a drug with fine-tuned properties for best antiparkinsonian effects can be developed.

13.2 AMPA Receptors in PD

AMPARs mediate the vast majority of fast excitatory neurotransmission in the brain and are therefore of interest in regards to the glutamatergic involvement in PD. Increased binding of AMPA in the lateral putamen in PD patients experiencing motor complications, suggests an involvement of AMPA receptors in levodopa-induced motor complications (Calon et al. 2003). Several AMPA receptor antagonists have been tested for their antiparkinsonian effect and for their ability to relieve levodopa-induced dyskinesia in rodents (Bibbiani et al. 2005; Megyeri et al. 2007; Stauch Slusher et al. 1995) and monkey models of PD (Bibbiani et al. 2005; Konitsiotis et al. 2000). However, the results are not totally conclusive. The AMPA antagonist GYKI-47261 given in combination with levodopa produced an improvement in dyskinesias; however, significance was not reached (Bibbiani et al. 2005). In contrast, another study showed that the AMPA antagonist LY300164, in combination with various concentrations of levodopa, increased motor activity by up to 86 % and decreased levodopa-induced dyskinesia by up to 40 % (Konitsiotis et al. 2000). GYKI-52466 and GYKI-53405, two noncompetitive AMPA receptor antagonists, exerted only limited effect on dopamine turnover in striatum tissue of rats with experimental Parkinson's when administered alone, but potentiated the effect of levodopa when given in combination (Megyeri et al. 2007). Significant improvements for akinesia were shown in parkinsonian rats after administration of the AMPAR antagonists NBQX, GYKI-52466, and YM90K (Stauch Slusher et al. 1995). Perampanel, another noncompetitive AMPAR antagonist, has been in clinical trials for treatment of PD after showing encouraging results in relieving motor symptoms in animal models. Perampanel was found to be effective in the treatment of refractory partial-onset seizures in three pivotal (Phase 3) clinical trials, although no evidence for improved cognitive functions was found (French et al. 2012).

Although excitotoxicity of the glutamatergic pathways is suggested to play role in PD, stimulatory modulation of AMPA receptors may also have therapeutic potential for the disease. Potentiators of the AMPA receptors, which stimulate synaptic transmission, synaptic plasticity, and cognition, also increase the production of BDNF (Hyman et al. 1991; Lauterborn et al. 2000). BDNF is associated with reduced neurotoxicity and improved neurological signs in cultured dopaminergic neurons (Hyman et al. 1991) and in animal models of Parkinson's disease as shown after LY503430 treatment (Murray et al. 2003). In contrast, the positive AMPA receptor modulator CX516 was reported to cause dyskinesia in a primate model of PD when administered alone or in combination with levodopa (Konitsiotis et al. 2000). The variable results of AMPA potentiators as therapeutics for PD may

therefore depend on which class of potentiators they belong to, since they have been suggested to show distinct mode of actions, potencies, and selectivities at different AMPA receptors (O'Neill and Witkin 2007). Further investigations will be required in order to fully determine the extent of AMPAR modulation in PD.

14 Traumatic Brain Injury

Traumatic brain injury (TBI), also known as intracranial injury, is a form of acquired primary brain injury that occurs when an external force causes damage to the brain. TBIs can be classified based on the mechanism (i.e., closed or penetrating head injury) and severity of the injury, in addition to the physical location of the injury (e.g., localized or global) (Bruns and Hauser 2003). In addition to the initial primary injury, TBI is often associated with secondary injuries that occur in the hours and days following the primary injury. These injuries result in a cascade of events that serve to alter cerebral blood flow and further contribute to the damage resulting from the primary traumatic insult (Chang et al. 2009). Trauma to the brain can result in vascular damage that results in reduced blood perfusion and may lead to transient ischemia. Ischemia is defined as a restriction in blood supply, with concomitant damage or dysfunction to both cells and tissue. The resulting cerebral hypoxia in which blood flow is reduced to inadequate levels leads to the death of brain tissue or cerebral infarction/ischemic stroke (Bjornsson et al. 2006). TBI typically causes impairment in both cognitive performance and fine motor functions that often persist for months after the initial injury occurs.

14.1 NMDA Receptors in TBI

TBI has been shown to cause a marked elevation in the concentrations of extracellular glutamate and aspartate proximal to the trauma site. This results in the excessive activation of NMDARs and neuronal cell death (Bullock 1995; Hovda et al. 1995). Microdialysis studies in humans reveal that there is sustained increases in the concentration of L-Glu lasting between 6 h and several days following TBI (Faden et al. 1989; Choi et al. 1990). Along with this increase, the density of activated NMDARs increases in the hippocampus but decreases in the cortex at the impact site in mice. Interestingly, a study by Kumar (Kumar et al. 2002) using RT-PCR analysis did not show any significant change in the mRNA levels of NR1, NR2A, and NR2B following injury in comparison with controls, suggesting nontranscriptional changes (i.e., protein) occur in the levels of these subunits. Interestingly, protein levels of NR1, NR2A, and NR2B were found to transiently decrease from the time of TBI up until 12 h post-injury before returning to pre-injury levels at 24 h. In contrast, a study by Schumann showed that the expression of the NR1, NR2A, and NR2B subunits were increased in the hippocampus, but decreased in the cortex at the site of the TBI (Schumann et al. 2008). This study revealed that the increase in NMDAR subunit expression in the

hippocampus was associated with an increase in NR2B tyrosine phosphorylation. Furthermore, that inhibition of NR2B phosphorylation PP2, a tyrosine kinase inhibitor, was able to restore NMDAR subunit expression to pre-TBI levels. Importantly, inhibition of NR2B phosphorylation was also found to result in significant improvements in long-term recovery of motor functions following TBI.

Administration of NMDA receptor antagonists has been shown to reduce injury severity after TBI (Faden et al. 1989). Pretreatment with either the noncompetitive NMDA antagonist dextrorphan or the competitive NMDA antagonist CGS 19755 was found to limit the release of extracellular L-glutamate following TBI (Panter and Faden 1992). In mice subject to mild TBI, it was observed that cellular viability was reduced in the hippocampus of the mice subjected to trauma while animals preconditioned with 75 mg/kg NMDA no reductions in cellular viability were observed. Similarly, in rats subjected to percussion trauma of the cortex, pretreatment with the NMDAR antagonist 3-((+/−)-2-carboxypiperazin-4-yl)-propyl-1-phosphonate (CPP) was successful in mitigating cortical damage (Bernert and Turski 1996). Based on their role in activity-dependent forms of synaptic plasticity (Constantine-Paton 1990; Constantine-Paton et al. 1990) and long-term potentiation (Bliss and Collingridge 1993), NMDARs are believed to play a role in memory and learning following TBI. Mice preconditioned with NMDA and subject to object recognition tasks following TBI were found to be protected against impairments in both long- and short-term memory. In contrast, in mice treated with NMDA, long-term impairments in memory were found when assessed in the step-down inhibitory avoidance test at 7 days following the initial training session (Moojen et al. 2012). Long-term behavioral deficits are often observed in patients following TBI. A study by Hayes (Hayes et al. 1988) showed that pretreatment with phencyclidine, an NMDA antagonist, was able to attenuate the long-term behavioral deficits in the rat produced by TBI. Preconditioning of mice with low-dose concentrations of NMDA has also been used to protect against locomotor deficits observed after TBI. Mice preconditioned with NMDA (75 mg/kg) 24 h prior to TBI induction were found to be protected against all motor deficits revealed by footprint tests. However, this protective effect was not seen when mice were tested in rotarod tasks (Costa et al. 2010). These data suggest that excitotoxicity is mediated by NMDARs with the degree of activation contributing to the pathophysiology of brain injury and ultimately the severity of locomotor dysfunction.

Cerebral hypoperfusion following TBI often occurs as a result of loss of responsiveness to cerebrovascular dilator stimuli via NMDAR-mediated impairment of cerebral hemodynamics. Tissue plasminogen activator is a known activator of NMDARs and is upregulated following TBI. Treatment of mice with a catalytically inactive variant of tissue plasminogen activator was able to prevent impairment of cerebral hemodynamics and decrease excitotoxic neuronal death post-TBI (Armstead et al. 2012). Similarly, the polyamine-site NMDAR antagonist ifenprodil was able to protect against both brain edema and breakdown of the blood–brain barrier after TBI (Dempsey et al. 2000). MK-801, a noncompetitive blocker of the NMDAR, has also been used to treat the neuropathological insults following fluid-percussion brain injury in the rat. In a study by McIntosh, MK-801

treatment significantly attenuated the development of focal brain edema at the site of injury 48 h after TBI (McIntosh et al. 1990). At the molecular level, influx of Ca^{2+} may not be the only factor contributing to neuronal cell death following elevated concentrations of L-Glu. Recent studies have shown that activation of extrasynaptic NMDARs triggered by L-Glu or hypoxic/ischemic following TBI activates a CREB (cAMP response element-binding protein) pathway. This pathway results in the loss of mitochondrial membrane potential and neuronal apoptosis. These results suggest that pharmacological inhibition of EAA neurotransmission including the use of NMDA antagonists may be used to improve neurological outcome after TBI.

14.2 AMPA Receptors in TBI

AMPARs are critical for synaptic plasticity, and a number of recent studies have focused on the role of AMPARs in the physiological and pathophysiological processes following TBI. In vivo, AMPARs are subject to alterations based on subunit composition and receptor trafficking to and from the plasma membrane. A number of recent reports have shown that both the composition and function of synaptic AMPARs change after mechanical injury (Arundine and Tymianski 2003). As a result of these changes, the normally Ca^{2+}-impermeable AMPARs can become Ca^{2+} permeable, thereby affecting calcium signaling and the pathophysiology following TBI. In 2010, Beattie (Beattie et al. 2010) showed that the pro-inflammatory cytokine tumor necrosis factor (TNF)α, a potent regulator of AMPAR trafficking, can rapidly increase the surface expression of Ca^{2+}-permeable AMPARs following TBI. This increase in combination with increased levels of extracellular L-Glu after TBI may play an important role in enhancing excitotoxic cell death after CNS injury. Using an in vitro model of TBI, Spaethling (Spaethling et al. 2008) showed that Ca^{2+}-permeable AMPARs appear 4 h following injury to cortical neurons. Interestingly, mechanical injury has been shown to modulate AMPAR kinetics via an NMDA receptor-dependent pathway (Goforth et al. 2004). Activation of the NMDAR can lead to CaMKII activation to produce a sustained reduction of AMPA receptor desensitization. Expression of the GluR1 subunit of the AMPAR has also been shown to be significantly decreased in the rat hippocampus following TBI (Kharlamov et al. 2011).

15 Involvement of iGluRs in Epilepsy

Epilepsy is a common name for a variety of chronic neurological disorders characterized by seizures resulting from excessive neuronal activity in the brain. The highest incidence occurs in young children and the elderly. These seizures can involve specific systems of the brain (partial seizures) or develop in a restricted area of the brain but then spread to involve multiple cortical and subcortical circuits. In the early 1940s, it was suggested that epileptic seizures occur when the "quantity of the

glutamic acid in human brain surpasses the critical level" after observing that injection of glutamate into the grey matter of the motor cortex of dogs and humans caused epileptic seizures. As the major excitotoxic neurotransmitter in the brain, L-Glu plays a major role in the initiation and spread of seizure activity by acting on iGluRs.

16 AMPA Receptors in Epilepsy

Due to their role in excitatory neurotransmission in the brain, AMPARs have recently become the subject of interest in the pathogenesis of epilepsy. AMPAR antagonists have proven therapeutic potential as antiepileptic drugs in clinical trials. Both talampanel and perampanel, two noncompetitive AMPA receptor antagonists, have proven to reduce seizure frequency in patients with refractory partial seizures (Chappell et al. 2002; Stephen and Brodie 2011). Adverse effects such as dizziness and ataxia were the most common.

17 NMDA Receptors in Epilepsy

At present, the NMDAR is probably the iGluR which has been studied the most as a therapeutic target for treatment of epilepsy. However, despite a large number of studies demonstrating up- or downregulation of particular NMDA receptor subunits' mRNA expression in various animal models of epilepsy, and several NMDA receptor antagonists showing anticonvulsant effect in in vivo animal studies, there is debated evidence for NMDA receptor antagonists as useful treatment for epilepsy in humans (Ghasemi and Schachter 2011). Felbamate, a promiscuous NMDA receptor inhibitor, was approved by the FDA in 1993 but is only used for patients with intractable partial seizures, infantile spasms, or Lennox-Gastaut syndrome, because the potential benefit outweighs the side effects. Remacemide, a low-affinity NMDA receptor blocker, showed improvement as adjunctive therapy in several clinical trials in patients with drug-resistant seizures (Ghasemi and Schachter 2011). Ketamine, an open-channel blocker, has shown both positive and adverse effects in clinical trials. Amantadine, an NMDA receptor blocker, has shown improvements in patients with refractory absence seizures as both mono- and add-on treatment. The results from memantine, an open-channel NMDA receptor blocker, in patients with seizures have been inconclusive despite promising animal studies. In summary, lower doses of NMDA receptor antagonists, such as memantine and remacemide, have shown antiepileptic effects with less severe side effects as adjunct therapy compared with monotherapy (Ghasemi and Schachter 2011).

18 Kainate Receptors in Epilepsy

Kainate receptors may play a more modulatory role in fine-tuning excitatory and inhibitory neurotransmission to prevent over excitation, which may lead to epilepsy.

Systemic or intracerebral injection of kainate, an analog of L-Glu, is well known to cause epileptic seizures, originating from the CA3 region of the hippocampus (Vincent and Mulle 2009). Thus, modulating the kainate receptors may have clinical implications in the treatment of epilepsy. Using knockout mice, two independent studies have shown the involvement of the kainate receptor subunit GluK2 in kainate-induced seizures, which are a model for temporal lobe epilepsy (Fisahn et al. 2004; Mulle et al. 1998). Therefore, interfering with GluK2 activity may have potential as antiepileptic drugs. In addition, GluK1 has shown increased expression in the hippocampus of patients suffering from temporal lobe epilepsy (Li et al. 2010), which supports that GluK1 antagonists LY37770 and LY382884 can block seizures in vivo and epileptiform activity in hippocampal slices induced by pilocarpine or electrical stimulation (Barton et al. 2003; Smolders et al. 2002). Topiramate, a GluK1 antagonist, was approved by the Food and Drug Administration (FDA) in 1996 for the treatment of epilepsy both as a mono- and adjunctive therapy.

19 Conclusion

Since its discovery in the 1950s, our understanding of the role that L-Glu plays in both normal synaptic transmission and neurodegenerative disorders has increased dramatically. Numerous experiments have revealed how the molecular mechanism of the human brain can be transformed into implements of neuronal cell destruction. With the advent of gene cloning and transgenic animal models, our understanding of iGluRs and the role they play in neurodegenerative disorders is increasing at an exponential rate. Despite the relative lack of new therapeutics for the treatment of neurodegenerative disorders, the next decade will undoubtedly be one of significant advances for the diagnosis of neurodegenerative diseases and in the development of new and improved treatment regimens for sufferers.

Abstract

Glutamate was identified as the main excitatory neurotransmitter in the mammalian central nervous system (CNS) following the observation in the early 1950s that glutamate can induce seizure activity and excite neurons in the mammalian brain. Over the last two decades, selective ligands, including competitive agonists and antagonists and allosteric modulators, have been developed to further investigate the functional role of glutaminergic receptors. Glutamate released from synapses can activate ligand-gated cation channels at postsynaptic cells to mediate fast postsynaptic potentials. These ion channel-forming ionotropic glutamate receptors (iGluRs) are divided into *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxyl-5-methyl-isoxazole-4-prorionate (AMPA), and kainate (KA) receptors. While only 20–30 % of the amino acid sequence is shared among these receptor subtypes, they share similar structural features and their activity is based on specific pharmacological preference. In this chapter, we will describe the structure and composition of iGluRs and infer their pharmacology, with a particular focus on their role in the CNS and their relevance to the pathogenesis of neurodegenerative diseases.

1 Introduction

Human neurodegenerative diseases are characterized by extensive loss of neurons, resulting in a number of neurological deficits (Hague, Klaffe et al. 2005). Excitatory amino acids serve as major neurotransmitters in the cerebral cortex and hippocampus. Under normal physiological conditions, excitatory amino acids are essential for the maintenance of normal psychological functions including learning and memory. Dysregulation of the excitatory amino acid system in various CNS diseases is associated with the development of several cognitive pathologies including schizophrenia, delirium, and dementia (Javitt and Zukin 1990). Overactivation of the excitatory amino acid system can also lead to cell death, giving rise to the concept of excitotoxicity (Olney 1978). Excitotoxicity refers to the process of neuronal cell death arising from prolonged exposure to excitatory amino acids with different permeabilities, leading to elevated Ca^{2+} influx (Wong, Cai et al. 2002; Berliocchi, Bano et al. 2005). The subsequent Ca^{2+} overload can stimulate the activation of a number of different enzymes which can degrade proteins, lipids, and nucleic acid (Berliocchi, Bano et al. 2005) (Fig. 1). Apart from glutamate, which is the principal excitatory neurotransmitter in the mammalian CNS, other constitutive amino acids,

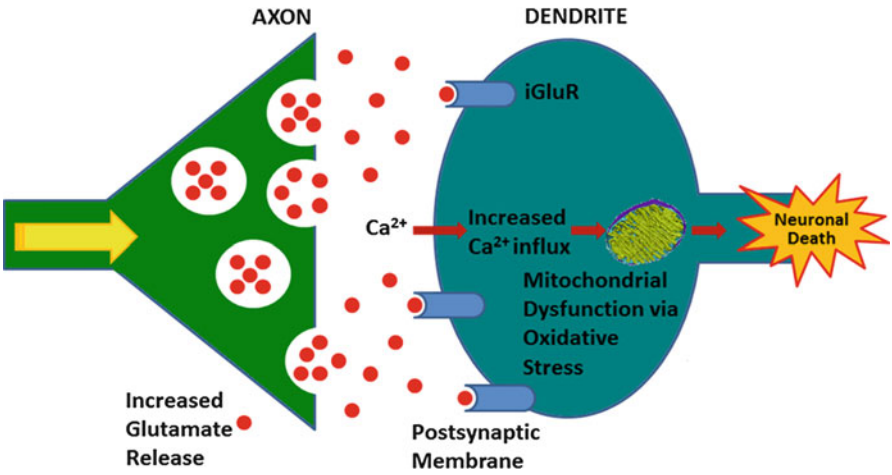

Fig. 1 Schematic representation of glutamate-induced excitotoxicity in neurons. Excitotoxicity due to increased glutamate release from hyperactive neuronal circuits in the brain can activate ionotropic glutamate receptors. Overactivation of these receptors leads to high intracellular calcium influx, disrupts mitochondrial function, and culminates in cell death

such as aspartic acid, and exogenous compounds, such as quinolinic acid and kainate, or of synthetic origin such as NMDA, can induce excitotoxicity (Foster, Collins et al. 1983; Hertz, Dringen et al. 1999).

Neurodegenerative disorders have distinct clinical symptoms and genetic etiologies. While some neurodegenerative conditions are considered "sporadic," due to lack of well-defined genetic associations common to all patients, others do have specific genetic mutations. For instance, the majority of cases of Alzheimer's disease (AD) are sporadic, only around 5 % of these cases are familial forms of autosomal-dominant (not sex-linked) inheritance, that usually occurs before the age of 65 (Blennow, de Leon et al. 2006). While these genetic mutations can affect a variety of proteins, sufficient evidence suggests that excitotoxicity represents a convergence point in neuronal degeneration (Dodd 2002; Kawamata and Shimohama 2002). Overactivation of ionotropic glutamate receptors iGluR (Fig. 2) can participate in fast glutaminergic synaptic transmission, leading to impaired calcium homeostasis and increased free radical generation, culminating in programmed cell death (Rae, Moussa et al. 2006).

2 Structural Features of Ionotropic Glutamate Receptors

The first transmembrane domain of the iGluR family (Fig. 3) contains a pore-forming membrane-residing domain that forms a re-entrant loop entering from and exiting to the cytoplasm (Dingledine and McBain 1994; Dingledine, Borges et al. 1999). A large extracellular loop provides a link between the second and third transmembrane domains, followed by an extracellular carboxy-terminus.

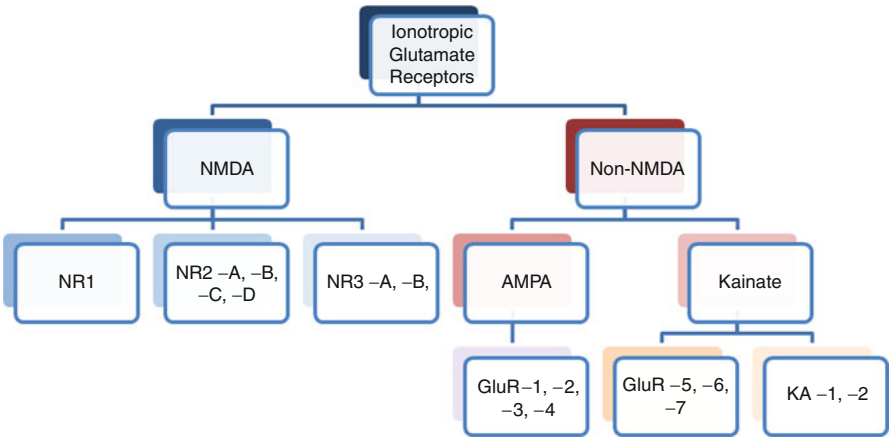

Fig. 2 Family of ionotropic glutamate receptors based on structure and function

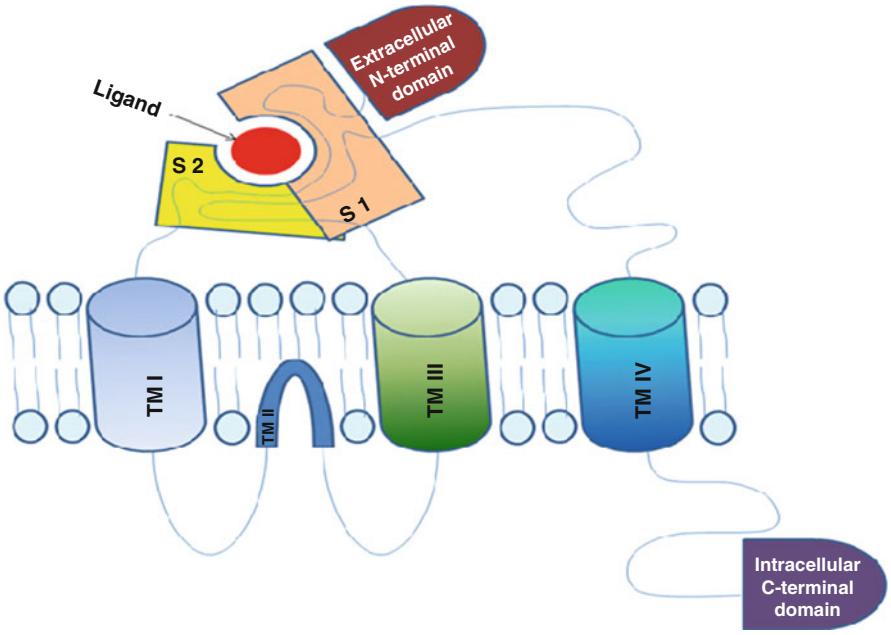

Fig. 3 Schematic diagram of iGluR subunit topology. The extracellular amino-terminal domain is followed by the first transmembrane domain (TM I). The membrane-residing domain (TM II) forms a re-entrant loop. The third and fourth transmembrane domains (TM III and TM IV) are linked by an extracellular loop. The agonist-binding domain is located in a pocket between polypeptide segments S1 and S2

The crystal structure of iGluR ligand binding domains consists of unique polypeptides attached to both the extracellular amino terminus and the extracellular loop between transmembrane domain 3 and 4 (Armstrong, Sun et al. 1998; Mayer and Armstrong 2004).

2.1 NMDA Receptors

NMDA receptors are ligand-gated ion channels that exist as heterotetrameric complexes at the membrane surface. Molecular cloning has identified seven subunits (NR1, NR2A-D, and NR3A and B), each of which represent products of different genes. These amino acid sequences are 18 % (NR1 and NR2), 55 % (NR2A and NR2C), 70 % (NR2A and NR2B), and 25 % (NR3 and NR1, or NR3 and NR2) identical (McBain and Mayer 1994).

Electrophysiological studies have shown that activation of the NMDA receptor requires occupation of two independent glutamate and glycine sites (Clements and Westbrook 1991). Therefore, functional NMDA receptors are composed of the constitutive NR1 subunit and at least one NR2 subunit, or NR1 and both NR2 and NR3 subunits (Mayer and Armstrong 2004). While the exact role of NR3 remains unknown, site-directed mutagenesis has shown that the NR2 subunit contains the glutamate-binding site while the binding site for the co-agonist glycine is carried on the NR1 subunit (Seeburg, Burnashev et al. 1995; Nishi, Hinds et al. 2001; Chatterton, Awobuluyi et al. 2002; Loftis and Janowsky 2003; Matsuda, Fletcher et al. 2003). This glycine-binding domain resembles the clamshell-like architecture reminiscent of the AMPA and kainite subunit-binding pockets (Kew, Koester et al. 2000; Kew and Kemp 2005).

The NR2 and NR3 subunits are differentially expressed in a distinct spatiotemporal pattern (Monyer, Sprengel et al. 1992). In the rodent and human brain, the NR2A and NR2B subunits are predominantly expressed in the forebrain, while the NR2C is expressed in cerebellar granule cells and several nuclei (Monyer, Sprengel et al. 1992; Monyer, Burnashev et al. 1994). However, the expression of the NR2D subunits is confined to the diencephalon and midbrain where it is upregulated significantly during development (Monyer, Sprengel et al. 1992). The NR3 subunit also shares similar spatiotemporal distribution, with the NR3A receptor also highly expressed during development, although expression of the NR3A receptor persists in some neuronal populations during adulthood (Nishi, Hinds et al. 2001). Unlike the NR3A subunit, NR3B is localized in somatic motor neurons in the brainstem and spinal cord. When expressed with NR1 and NR2, the NR3 subunit suppresses NMDA channel unitary conductance and Ca^{2+} permeability relative to NR1/NR2-containing receptors (Nishi, Hinds et al. 2001; Chatterton, Awobuluyi et al. 2002; Loftis and Janowsky 2003; Matsuda, Fletcher et al. 2003). Moreover, NR3A knockout mice exhibit increased NMDA-mediated currents and increased spine density in cortical neurons (Das, Sasaki et al. 1998). Lee et al. (2011) recently showed that adult and fetal human primary astrocytes express all known NMDA receptor subunits (Lee, Ting et al. 2011). This is in accordance to previous

immunohistochemical studies showing that NR1 and NR2A/NR2B are present in rodent astrocytes (Conti, DeBiasi et al. 1996; Conti, Barbaresi et al. 1999). Native NMDA receptors are therefore composed of NR1 in combination with one or more NR2 subunits (e.g., NR1/NR2A, NR1/NR2B, or NR1/NR2A/NR2B), or alternatively, NR1 may exist in combination with both NR2 and NR3 subunits (e.g., NR1/NR2B/NR3A) (Kew and Kemp 2005).

2.2 AMPA Receptors

Cloning studies have shown that AMPA receptors are composed of four closely related subunits (GluR1, GluR2, GluR3, and GluR4) (Borges and Dingledine 1998). These four subunits appear to be products of separate genes. The polypeptide sequence of each subunit is about 900 amino acids in length and sharing 70 % (GluR1 and 2) and 73 % (GluR2 and 3) homology (Rosenmund, Stern-Bach et al. 1998). Like NMDA receptors, native AMPA receptors are heteromeric in composition and expressed differentially in the brain. GluR2 plays a predictive role in determining the permeability of AMPA receptors to Ca^{2+} (Bowie and Mayer 1995). AMPA receptors lacking the GluR2 subunit are Ca^{2+} permeable and exhibit evidence of inward channel rectification due to voltage-dependent block of the ion channel by intracellular polyamines (Bowie and Mayer 1995). The molecular property determining the Ca^{2+} impermeability of the GluR2 subunit can be attributed to the presence of an arginine (R) positioned at a critical site in the pore loop, M2 domain which is replaced by glutamine (Q) in other AMPA subunits (Seeburg and Hartner 2003).

The diversity of AMPA receptor subunits is due to two genetic processes: RNA editing and alternative splicing. Editing is a posttranscriptional change in at least one base in the pre-mRNA where the codon encoded by the gene differs to the mRNA. In AMPA receptors, editing is restricted to the GluR2 subunit. In the primary transcript of GluR2, glutamine at position 586 in the M2 putative membrane is replaced with an arginine (Dingledine, Borges et al. 1999). The arginine codon is absent in the GluR2 gene and is introduced in the mRNA by dsRNA adenosine deaminase which converts adenosine to inosine which is subsequently read as guanosine. Editing is regulated during development, such that 99 % of the GluR2 subunit is in the arginine form in the postnatal stage (Dingledine, Borges et al. 1999).

Alternative splicing affects the 38 amino acid sequence in the extracellular S2 domain preceding the C-terminal transmembrane domain M4 of each of the four subunits (Dingledine, Borges et al. 1999). The small segment exists in two alternatively spliced forms referred to as Flip and Flop which are encoded by adjacent exons of the receptor genes. The Flip form is expressed prenatally while the Flop variants are expressed postnatally. These variants can influence the rate and effect of desensitization of heteromeric AMPA receptors and also their sensitivity to specific allosteric modulators (Dingledine, Borges et al. 1999).

AMPA receptors lacking edited GluR2 receptors are expressed in the hippocampus and amygdala. These receptors demonstrate high Ca^{2+} permeability and

predominate in inhibitory interneurons, while non-edited, Ca^{2+} impermeable GluR2 receptors are found in pyramidal cells (Geiger, Melcher et al. 1995). Extensive evidence in cerebellar stellate cells has shown that activity-induced Ca^{2+} influx through GluR2-lacking AMPA receptors regulates the targeting of GluR2-containing AMPA receptors, suggesting the existence of a self-regulatory mechanism influencing Ca^{2+} permeability at the synapses (Liu and Cull-Candy 2002).

2.3 Kainate Receptors

Five subunits of the kainate family of receptors have been cloned: GluR5, GluR6, GluR7, KA1, and KA2 (Bleakman, Gates et al. 2002). These receptors have been subdivided into two families based not only on sequence homology but also agonist-binding properties. GluR5-7 are approximately 70 % identical with each other and 40 % homologous with AMPA receptors (Bleakman, Gates et al. 2002). KA1 and KA2 also share 70 % amino acid sequence homology with each other but only 40 % with GluR5-7. GluR5-7 have a lower affinity kainate-binding site (K_D of 50–100nM), whereas KA1 and KA2 c have a higher affinity kainate-binding site (K_D of 5–15nM) (Bleakman, Gates et al. 2002).

Kainate receptors are tetrameric with GluR5-7 forming homomeric and heteromeric combinations. However, KA1 and KA2 cannot form functional homomeric receptors, but combine to form heteromeric assemblies with GluR5-7 (Alt, Weiss et al. 2004). Interestingly, KA2 is not expressed on the cellular surface in the absence of GluR5-7, but is translocated to the endoplasmic reticulum, suggesting the existence of an endoplasmic reticulum signal that is shielded in the presence of other kainate receptors (Gallyas, Ball et al. 2003).

Similar to AMPA receptors, GluR5-7 are susceptible to RNA editing and alternative splicing to introduce further heterogeneity. GluR5-6 but not GluR7 mRNA can be edited at the Q/R site on the M2 segment (Dingledine, Borges et al. 1999). Analogous to AMPA receptors, the addition of arginine can foster lower permeability to Ca^{2+}. However, unlike GluR2, RNA editing appears to be incomplete during aging and a large number of both edited and non-edited GluR5-6 receptors are distributed in the adult brain (Dingledine, Borges et al. 1999).

Kainate receptors are distributed throughout the CNS (Bowie and Mayer 1995; Bleakman, Gates et al. 2002). The KA1 and KA2 subunits are both localized in hippocampal CA3 and dentate granule neurons; however, KA2 is more dominant. GluR6 appears to be the major subunit in both presynaptic and postsynaptic receptors at mossy fiber synapses in the hippocampal CA3 region (Kerchner, Wilding et al. 2002). The GluR5 subunit appears to be predominant in the dorsal root ganglion cells (Contractor, Swanson et al. 2000; Kerchner, Wilding et al. 2002). GluR5 is expressed predominantly in hippocampal interneurons where it plays a critical role in regulating the effects of glutamate released by astrocytes (Liu, Xu et al. 2004). GluR5 is also strongly expressed in the temporal lobe. Functional studies have shown that GluR5-containing receptors are involved in synaptic excitation in the amygdala (Rogawski, Gryder et al. 2003).

3 Pharmacology of Ionotropic Glutamate Receptors

Several iGluR agonists and antagonists have been identified. Information regarding the structure and function of these ligands has helped to increase our body of understanding regarding the pharmacology of these receptors and markedly increased our knowledge of receptor physiology and pathophysiology in the CNS.

3.1 NMDA Receptors

NMDA is the most common agonist at the glutamate-binding site (located on the NR2 subunit) of the NMDA receptor (Fig. 4). While it demonstrates lower potency than glutamate, it is not quite a full agonist and shows little selectivity between the NMDA receptor subtypes (Addae, Evans et al. 2000). Another selective full agonist at NMDA receptors is quinolinic acid (QUIN) (De Carvalho, Bochet et al. 1996). QUIN is an endogenous metabolite of the kynurenine pathway (KP). In the CNS, the KP represents the principal route of L-tryptophan metabolism, leading to the formation of the essential pyridine nucleotide nicotinamide adenine dinucleotide (NAD^+) (Stone 2001). During neuroinflammation, increased activity of the primary KP enzyme indoleamine 2,3-dioxygenase (IDO-1) directs the KP to stimulate

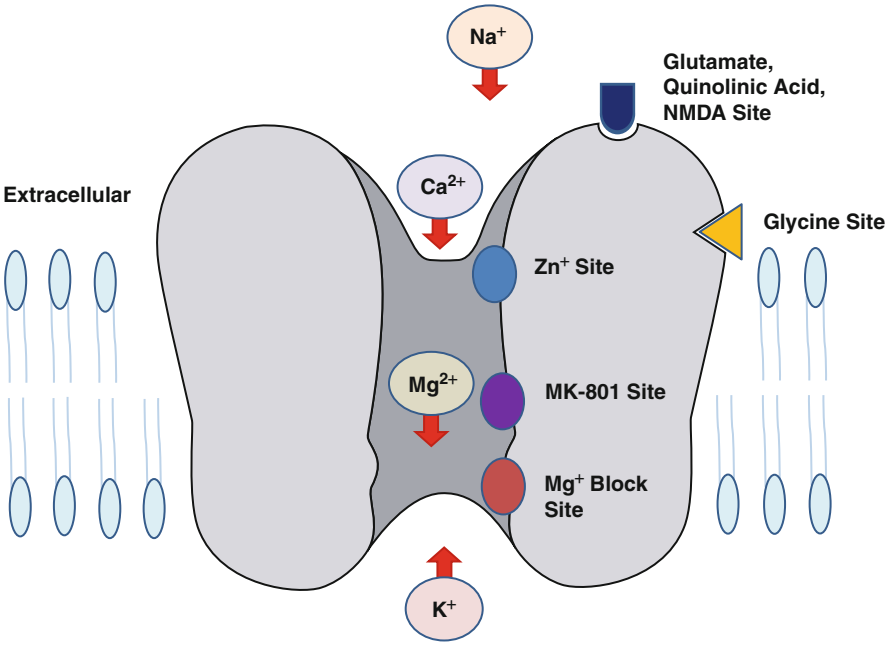

Fig. 4 The NMDA receptor showing binding sites for both glutamate and glycine. The ligand-gated ion channel facilitates movement of calcium, sodium, and potassium across the postsynaptic membrane

QUIN production by activated microglia and invading macrophages, leading to neuronal and glial cell death (Guillemin 2003; Guillemin, Smythe et al. 2004).

Other NMDA receptor agonists include L-aspartate, homocysteate, and homoquinolinate, while *cis*-2,3-piperidinedicarboxylic acid is a low efficacy agonist (Jane, Olverman et al. 1994; Christie, Jane et al. 2000). Additional compounds demonstrate agonist or partial agonist activity at the glycine co-agonist site on the NR1 subunit. Vinyl substituted glycine derivatives such as *S*-hydroxyvinyl glycine can also act as agonists at the glycine site (Kemp, Foster et al. 1988; Priestley, Horne et al. 1990; Priestley, Ochu et al. 1994; Priestley, Laughton et al. 1995). While D-serine is an agonist at low concentrations, it can act as a competitive antagonist at the glutamate site at high concentrations. Other glycine-site partial agonists include L-alanine and D-cycloserine (Kemp and Leeson 1993).

Continuous activation of the NMDA receptor can lead to increased intracellular Ca^{2+} permeability and conductance which can trigger a cascade of events leading to either apoptosis or necrosis. The downstream effectors include free radical production, mitochondrial membrane depolarization, and caspase activation (Chen, Harris et al. 1995; Colwell, Altemus et al. 1996; Catts, Ward et al. 1997; Araque, Sanzgiri et al. 1998; Budd, Tenneti et al. 2000; Comoletti, Muzio et al. 2001). Given the importance of NMDA receptors in normal physiological function and in the etiology of neurodegenerative diseases, several NMDA receptor antagonists have been developed to target the glutamate and glycine recognition sites and the NMDA ion channel pore. An example of a high-affinity competitive antagonist of the glutamate site is (*R*)-2-amino-5-phosphonopentanoate (D-AP5) (Jane, Olverman et al. 1994). While this compound shows high in vivo affinity due to the appropriately placed ω-phosphonic acid group, it cannot penetrate the blood-brain barrier (BBB) due to its highly charged nature (Kew and Kemp 2005). Recently, adenosine triphosphate (ATP) has been shown to be a dual modulator of the NMDA receptor. While ATP can antagonize the NMDA receptor at the glutamate site at low glutamate concentrations, it can act simultaneously to enhance NMDA function at high glutamate concentrations (Kloda, Clements et al. 2004).

Similarly, numerous inhibitors have been identified at the glycine recognition site (Bergeron, Meyer et al. 1998). Kynurenic acid (KA), a metabolite of the KP, was the first glycine site antagonist described and displayed weak inhibition of the NMDA receptor against QUIN toxicity. In one study, the required concentration of KA to display neuroprotection was tenfold greater than the agonist, QUIN (Jhamandas, Boegman et al. 2000). Many synthetic antagonists of the glycine site were later developed using KA as the pharmacophore (Hartley, Monyer et al. 1990; Foster, Kemp et al. 1992; Kemp and Leeson 1993; Dannhardt and Kohl 1998; Honer, Benke et al. 1998). These compounds include synthetic high-affinity derivatives such as quinolines, quinolones, and indoles. However, compounds of this class can bind tightly to plasma protein which compromises their ability to cross the BBB and produce potent in vivo activity (Bristow, Hutson et al. 1996).

The most potent NMDA antagonists used to treat neurodegenerative diseases are the NMDA ion channel pore blockers. Following the identification of ketamine and phencyclidine as selective NMDA receptor antagonists, the highly potent in vivo

active antagonist dizocilpine (MK-801) was developed (Foster, Gill et al. 1987, 1988; Farlow 2004). However, long-term NMDA receptor inhibition by MK-801 has previously been shown to be toxic to cultures of rat cortical neurons (Hwang, Kim et al. 1999). Subsequently, lower affinity compounds such as 1,3-dimethyl-5-aminoadamantane (Memantine) have been developed and approved for clinical use (Farlow 2004). These compounds act as open channel blockers and are irreversibly trapped within the closed pore. Memantine has quicker reversibility, making it efficacious and better tolerated than MK-801 (Kew and Kemp 2005).

A more recent development in NMDA receptor antagonists has been the identification of allosteric modulators that can inhibit the receptor by an interaction with the extracellular N-terminal domain of the NR2 subunit (Kew and Kemp 2005). Compounds such as Ifenprodil and Benzimidazole have high NR2 affinity compared with other NMDA subtypes but produce additional off-target effects by modulating adrenergic receptors and human ether-a-go-go (hERG) ion channels (Finlayson, Witchel et al. 2004). Recently, a phase III clinical trial for Troxoprodil used for the treatment of traumatic brain disease, failed due to poor efficacy (Kew and Kemp 2005).

3.2 AMPA Receptors

AMPA receptors have also been implicated in excitotoxicity due to their ability to increase intracellular Ca^{2+} overload (Borges and Dingledine 1998). Apart from AMPA itself, several agonists have been developed including ibotenic acid, quisqualic acid, and willardine (Stensbol, Madsen et al. 2002). While the distal acidic group varies between agonists, the amino acid moiety is highly conserved. Unlike glutamate and AMPA which are full agonists and induce rapidly desensitizing responses, kainate is a partial agonist with demonstrated low desensitization. The degree of desensitization has been linked to the extent of dimerization between pairs of subunits within the AMPA receptor (Stensbol, Madsen et al. 2002).

The first competitive AMPA receptor antagonists were 6-cyano-7-nitroquinoxaline-2,3-dione (CQNX) and 6,7-dinitro-quinoxaline-2,3-dione (DNQX). However, these compound showed low selectivity and could also antagonize the glycine-binding site of the NMDA receptor. More selective AMPA receptor antagonists include 2,3-dihydroxy-6-nitro-7sulfamoyl-benzo(F)quinoxaline (NBQX) (Birch, Grossman et al. 1988; Turski, Huth et al. 1998). However, these compounds show poor water solubility and represent failed clinical trials due to adverse side effects including nephrotoxicity. Several noncompetitive AMPA receptor antagonists have been developed. These include several 2,3-benzodiazepine compounds and quinazoline derivatives. These compounds are selective for AMPA over NMDA and kainate receptors and have recently entered clinical trials (Lazzaro, Paternain et al. 2002; Solyom and Tarnawa 2002).

Additionally, several AMPA-receptor-positive allosteric modulators have been developed. These new class of compounds can modulate receptor

desensitization/deactivation without activating the receptor when supplied alone (Danysz 2002). These compounds include cognitive enhancing "nootropic agents" such as 1-(4-methoxybenzoyl)-2-pyrrolidinone (aniracetam), benzamides, and benzothiadiazides. These compounds demonstrate distinct mechanistic profiles and are selective for individual AMPA receptor subunits (Danysz 2002).

3.3 Kainate Receptors

Kainate receptors have also been associated with increased Ca^{2+} influx, leading to excitotoxic neuronal cell death. Apart from kainate, several kainate-receptor agonists have been identified. These include 5-tert-butyl-4-isoxazolepropionic acid (ATPA), a substituted analogue of AMPA, and (*S*)-5-iodowillardine (Lerma, Paternain et al. 2001; Bleakman, Gates et al. 2002). These compounds show lower affinity to AMPA receptors. The quinoxalinedione compounds such as CNQX and NBQX are competitive antagonists at kainate receptors but show little discrimination between kainate and AMPA receptors (Lerma, Paternain et al. 2001; Bleakman, Gates et al. 2002). Derivatives of willardine also exhibit antagonist effects at both AMPA and kainate receptors. Kainate receptors also demonstrate rapid desensitization following agonist binding (Bleakman, Gates et al. 2002; Alt, Weiss et al. 2004). The lectin concanavalin A can rapidly inhibit receptor desensitization by interacting with *N*-glycosylated residues and increase receptor agonist affinity. It also exhibits activity at NMDA and AMPA receptors (Lerma, Paternain et al. 2001; Bleakman, Gates et al. 2002).

4 Molecular Mechanisms in Neurodegenerative Diseases

There is an attractive body of evidence incriminating glutaminergic dysfunction in the process of slow excitotoxicity associated with neuronal loss in Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and Amyotrophic Lateral Sclerosis (ALS).

4.1 Alzheimer's Disease

Alzheimer's disease (AD) is a progressive neurodegenerative disorder associated with the progressive loss of cholinergic neurons parallel to impairments in cognition and memory (Mattson 2004). The pathological hallmarks of AD include extracellular deposition of the β-amyloid peptide (Aβ) in senile plaques and formation of intracellular neurofibrillary tangles (NFTs) (Hartmann 1999). Accordingly, the Aβ hypothesis suggests that AD occurs as a response to increased production and extracellular deposition of Aβ and intracellular deposition of NFTs. These abnormal pathologies can trigger numerous neurotoxic deleterious processes including excitotoxicity, oxidative stress and energy depletion,

neuroinflammation, and cell death (Bamberger and Landreth 2001). Interestingly, the glutaminergic system is severely compromised by Aβ-mediated regulation of glutamate receptors in various brain regions, correlating with significant cognitive impairment (Parameshwaran, Dhanasekaran et al. 2008).

The neuronal degeneration in AD has been linked to overactivation of the NMDA receptor (Butterfield 1997). Recent studies have shown that Aβ can stimulate free radical formation through a mechanism involving NMDA receptors. QUIN can increase mRNA and protein expression of the inducible (iNOS) and neuronal (nNOS) forms of nitric oxide following overactivation of the NMDA receptor, leading to subsequent induction of nitric oxide synthase in human primary fetal astrocytes and neurons, triggering cell death (Braidy, Grant et al. 2009). Dysregulation of NMDA receptor activation and free radical formation may serve as dual deleterious roles in AD.

We have previously shown that QUIN is significantly increased in postmortem AD brain (Guillemin, Brew et al. 2007). Recently, our group has shown that the KP is activated in the AD brain with QUIN immunoreactivity reported in cortical microglia, astrocytes, and neurons, and in the perimeter of Aβ plaques and NFTs. We recently reported an accumulation of QUIN in dystrophic neurons in cortical sections from AD patients (Guillemin, Brew et al. 2005). Additionally, QUIN can increase tau phosphorylation and stimulates dysregulation of microtubule formation in vitro. We also found that QUIN can induce at least ten important neuronal genes strongly associated with AD pathology (Rahman, Ting et al. 2009). Therefore, excitotoxicity due to increased activation of NMDA receptors can enhance the vulnerability of local neurons consistent with AD pathology.

Restoration of homeostasis in the glutamatergic system using NMDA receptor antagonists has been shown to ameliorate the neurotoxic effects by NMDA activation both in vitro and in vivo. Memantine, a noncompetitive NMDA receptor channel blocker, has received marketing approval from the EMEA (European Medicines Agency), FDA (Food and Drug Administration), and TGA (Therapeutic Goods Administration) for the treatment of mild-to-severe AD in Europe, USA, and Australia (Doggrell 2003). It has strong voltage-dependency and fast kinetics to help provide neuroprotection and reverse deficits in memory and learning (Ferris 2003; Gallarda and Loo 2004; Kato 2004; Gardoni and Di Luca 2006).

4.2 Parkinson's Disease

Parkinson's disease (PD) is a neurological disease caused by degeneration of dopaminergic neurons in the substantia nigra, leading to a significant reduction in dopamine levels in the striatum (Mosley, Benner et al. 2006). Although the exact etiology of PD remains unknown, excessive glutaminergic drive has been proposed as a major source of excitotoxicity in the nigra (Barnum and Tansey 2010). Studies have shown that parkin (hereditary Parkinson disease PARK2 gene product) can modulate the stability and function of excitatory glutaminergic synapses (Yu, Sun et al. 2011). Postsynaptic expression of parkin can inhibit excitatory synaptic

transmission. Knockdown of parkin or PD-linked parkin mutants can promote synaptic function and facilitate the proliferation of glutamatergic synapses. Activation of the NMDA receptor can lead to increased Ca^{2+} influx which has been linked to cell death in PD (Yu, Sun et al. 2011). This is further supported by the observation that dopaminergic neurons expressing the calcium-binding protein calmodulin are selectively preserved in the PD brain (Pierson, Norris et al. 2004).

Several studies have shown that excitotoxicity plays a key role in toxicity induced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) toward dopaminergic neurons (Araki, Kumagai et al. 2000). MPTP is converted to the 1-methyl-4-phenylpyridinium ion (MPP^+) in glial cells by monoamine oxidase-B. The active metabolite is taken up by the dopamine transporter into dopaminergic neurons where it has been shown to inhibit mitochondrial complex I (Beal 2003). This not only compromises neuronal energy production, but also induces a slow excitotoxicity, leading to the loss of nigral cells. Inhibition of the glutamatergic corticostriatal tract has been shown to reduce the size of MPP^+-mediated lesions in the rat striatum. Furthermore, the glutamate-release inhibitor riluzole has been shown to inhibit glutamate release in the corticostriatal tract to attenuate intrastriatal administration of MPP^+ on dopaminergic neurons (Araki, Kumagai et al. 2000). MK-801 (dizocilipine), a noncompetitive NMDA receptor antagonist, has been shown to protect against the toxicity of MPTP in a rat model for PD (Hsieh, Gu et al. 2012). NBQX, an AMPA/kainate-receptor antagonist, has been shown to prevent the symptoms of PD, but not the neurodegeneration in MPTP-treated monkeys (Luqquin, Obeso et al. 1993). The finding that MK-801 cannot protect against MPP^+ toxicity in primary cultures of dissociated mesencephalic neurons suggests that alternative mechanisms of action for MPTP may exist in vivo.

4.3 Huntington's Disease

Huntington's disease (HD) is an inherited neurodegenerative disorder characterized by cognitive and psychiatric impairment, and dyskinesia (Beal, Kowall et al. 1986). One of the major hypotheses developed to explain the vulnerability of medium-size spiny neurons (MSNs) in the neostriatum is the excitotoxicity hypothesis. Studies performed as early as the 1970s in rats, mice and other rodents demonstrated that striatal kainate injections can destroy MSNs while sparing neighboring axons and the effect is similar to HD pathology observed in humans (Ferrante, Kowall et al. 1993; Figueredo-Cardenas, Anderson et al. 1994; Estrada Sanchez, Mejia-Toiber et al. 2008). Similarly, striatal injections of QUIN in rats are able to reproduce the lesions reported in HD (Ellison, Beal et al. 1987; Bruyn and Stoof 1990; Ceresoli-Borroni, Guidetti et al. 1999). QUIN-induced lesions in experimental rodent models can be attenuated using NMDA receptor antagonists (Ellison, Beal et al. 1987; Bruyn and Stoof 1990; Ceresoli-Borroni, Guidetti et al. 1999). The QUIN model has been extended to primates where similar pathological hallmarks have been observed together with clinical symptoms of chorea (Bruyn and Stoof 1990).

Intrastriatal infusion of kainate has also been shown to induce excitotoxic lesions in the striatum and induces neuronal apoptosis via activation of NF-κB and induction of p53 and other pro-apoptotic proteins (Nakai, Qin et al. 2000). However, AMPA/kainate-receptor antagonists have been shown to be inactive in these models (Levine, Klapstein et al. 1999).

The HD gene and its protein product huntingtin (htt) have been proposed to play a key role in neuronal cell death. It has been demonstrated that mutant expression of htt can stimulate NMDA receptor activity to disrupt intracellular calcium homeostasis (Zhang, Li et al. 2008). Recent studies have shown that the postsynaptic density protein PSD-95 represents a link between htt and NMDA receptor function. One study has shown that PSD-95 can bind to the C-terminal of the NR2 subunit to stabilize the NMDA receptor (Roche, Standley et al. 2001). Co-immunoprecipitation studies have also revealed interactions between PSD-95 and NMDA receptor subunits NR1, NR2A, and NR2B, thus providing further evidence for the association of NMDA receptors with PSD-95 (Sun, Savanenin et al. 2001).

4.4 Amyotrophic Lateral Sclerosis

Amyotrophic Lateral Sclerosis (ALS) is characterized by progressive muscle weakness, leading to paralysis and death, generally due to respiratory failure. Histologically, ALS is characterized by the selective loss of both upper (corticospinal) and lower (spinomuscular) motor neurons (Boillee, Vande Velde et al. 2006; Boillee, Yamanaka et al. 2006). There are several lines of evidence to support the role of excitotoxicity in the loss of motor neurons. Intrathecal injections of kainate have been shown to induce neuronal damage in the spinal cord (Hugon, Ludolph et al. 1988; Hugon and Vallet 1990). These lesions are characterized by axonal swelling and impaired cytoskeletal architecture similar to those seen in ALS (Hugon and Vallet 1990). In chicken motor neurons, glutamate-initiated neurotoxicity is predominantly due to AMPA/kainate receptors. However, in rats, excitotoxicity is mediated by both NMDA and AMPA/kainate receptors (Estevez, Stutzmann et al. 1995; Carriedo, Yin et al. 1996). The observed toxicity in these cell types can be attenuated using AMPA/kainate-receptor antagonists but not NMDA receptor antagonists (Rothstein 1995). However, in humans, we have shown that QUIN can induce apoptosis of fetal motor neurons in a dose-dependent manner and the effect is ameliorated by blocking the NMDA receptor (Chen, Brew et al. 2011).

If excitotoxicity is indeed a major pathogenic mechanism in ALS, it is necessary to explain why only certain motor neurons are affected. A major factor determining the vulnerability of certain motor neurons to excitotoxicity is associated with the subunit composition of the iGluR that they may express. In situ hybridization studies have shown that the NR2B NMDA receptor subunit is absent in rat motor neurons while the GluR2 AMPA/kainate receptor is not present in human spinal motor neurons (Tolle, Berthele et al. 1993). In the absence of the GluR2 subunit,

AMPA/kainate receptors are more permeable to Ca^{2+} and this may explain the excitotoxicity observed in rats (Williams, Day et al. 1997). Nonetheless, direct electrophysiological studies investigating intracellular calcium influx into motor neurons resulting from AMPA/kainate-receptor-mediated excitotoxicity have not been investigated and no comparison has been made between iGluR in rats and humans.

Although no effective cures have been developed, anti-excitotoxic drugs have provided the first treatment for this debilitating disorder. Early trials conducted using the noncompetitive NMDA receptor antagonist dextromethorphan have shown negative results (Hollander, Pradas et al. 1992). Given that dextromethorphan is a weak NMDA receptor antagonist at the doses used (<150 mg/day), it may be ineffective in achieving complete receptor blockade (Beaton, Stemsrud et al. 1992). Moreover, pharmacokinetic studies have shown that side effects of the drug occur at doses five times higher than those used in the efficacy studies (Hollander, Pradas et al. 1994). Plasma levels of dextromethorphan necessary for significant NMDA receptor blockade were unlikely to be reached in the clinical trials.

Promising results have been obtained with the glutamate-release inhibitor and sodium channel blocker, riluzole. A modest increase in survival was observed following 1 year of treatment which was associated with a significant reduction in the rate of deterioration in motor function (Zoccolella, Beghi et al. 2007). Another trial confirmed the beneficial effects of riluzole on survival but not on motor function (Gurney, Fleck et al. 1998). Accordingly, riluzole has been approved and marketed for the treatment of ALS in various countries (Miller, Mitchell et al. 2007). While this is encouraging to those who argue that blockade of excitotoxicity is an important therapeutic strategy to treat neurodegenerative diseases, it remains to be demonstrated whether riluzole is neuroprotective in ALS.

5 Conclusion

The concept of excitotoxicity is implicated in the pathogenesis of a variety of neurodegenerative diseases. Neurodegenerative diseases may develop as a result of abnormally high concentrations of excitotoxic amino acids, or by a more insidious process whereby energetically weakened neurons become vulnerable to ambient concentrations of glutamate or an exogenous congener. Currently available anti-excitotoxic drugs have played vital roles in examining the factors which facilitate neuronal death in several experimental paradigms. Where suitable animal models are available, such as for AD and PD, iGluR inhibitors have paved the way for defining the etiology and treatment of neurodegenerative diseases in the clinic. The next decade will lead to the development of newer and more specific compounds to block excitatory neurotransmission, and may include NMDA and AMPA/kainate-receptor antagonists. The current century may witness a revolution in the treatment of neurological diseases using anti-excitotoxic drugs.

Glutamate Neurotoxicity, Transport and Alternate Splicing of Transporters

Aven Lee, Shannon Beasley, and David V. Pow

Contents

Abstract

Glutamate is the major excitatory neurotransmitter in the central nervous system and its levels in the synaptic cleft are tightly controlled by high affinity glutamate transporters (also known as *E*xcitatory *A*mino *A*cid *T*ransporters or EAATs). The EAAT family is comprised of five members (EAAT1-5), and these transporters are subject to alternative splicing. Alternative splicing of the EAAT genes is a fundamental mechanism that can give rise to multiple distinct

mRNA transcripts, producing protein isoforms with potentially altered functions. Numerous splice variants of EAATs have been identified in humans, rodents, and other mammalian species. All splice variants of EAATs cloned to date are either exon-skipping and/or intron-retaining types. These modifications may impact upon protein structure, posttranslational modification, function, cellular localization, and trafficking. Message and protein for these splice variants are detectable in the normal brain and, in many instances, have been shown to be induced by pathophysiological insults such as hypoxia. In addition, aberrant expression of EAAT splice variants has been reported in neurodegenerative conditions such as amyotrophic lateral sclerosis, Alzheimer's disease, ischemic stroke, and age-related macular degeneration. These EAAT variants may represent therapeutic targets and thus require an improved understanding of their regulation. This chapter describes recent developments in investigating the molecular heterogeneity, localization, function, structure, and regulation of the EAATs and their splice variants.

Keywords

EAAT • GLAST • GLT1 • EAAC1 • Excitotoxicity • Splicing • Stroke • Schizophrenia • Motor neurone • ALS • Glaucoma

List of Abbreviations

AD	Alzheimer's disease
ALS	Amyotrophic lateral sclerosis
AMD	Age-related macular degeneration
CNS	Central nervous system
EAAC1	Excitatory amino acid carrier 1
EAAT	Excitatory amino acid transporter
GABA	Gamma-aminobutyric acid
GLAST	Glutamate aspartate transporter
GLT-1	Glutamate transporter-1
GTRAP	Glutamate transporter associated protein
hnRNP	heterogeneous nuclear ribonucleoproteins
HSP70	70 kDa heat shock proteins
MAP2	Microtubule-associated protein 2
MLO-Y4	Murine long bone osteocyte Y4
mRNA	messenger ribonucleic acid
PDZ	Postsynaptic density (PSD), *Drosophila* disc large tumor suppressor (Dlg1), and zonula occludens-1 protein (ZO-1)
SLC	Solute carrier
SOD	Superoxide dismutase
SR protein	Serine/arginine-rich protein
SRPK	Serine/arginine-rich protein kinase
UTR	Untranslated region

1 Introduction

1.1 Neurotransmission: A Regulated Process of Neurotransmitter Release and Removal

The brain is a highly regulated environment, protected by a blood-brain barrier and other homeostatic mechanisms, to ensure that events such as neurotransmission are able to occur without impediment. Neurotransmission is typically mediated by the evoked fusion of one or more synaptic vesicles containing around 10,000 molecules of neurotransmitter, each of which can potentially activate a receptor molecule. Thus, the timeframe for the neurotransmission signaling event is heavily dependent upon the kinetics of clearance of the neurotransmitter. Accordingly, an understanding of the biological events that influence the kinetics of neurotransmitter removal from the extracellular space is central to our understanding of brain function.

Many neurotransmitters are removed from the extracellular space using high affinity neurotransmitter transporters, and these are frequently pharmacological targets. Thus, the serotonin transporter is a target for selective serotonin reuptake inhibitors (SSRIs) used to treat disorders such as depression. This whole area of pharmacology depends upon the drug interacting with a defined transporter that is expressed in a predictable manner with predictable properties. However, alternately spliced forms of many high affinity neurotransmitter transporters have been identified, including the serotonin transporter (Sakai et al. 2003), dopamine transporter (Talkowski et al. 2010), noradrenalin transporter (Sogawa et al. 2007), betaine-GABA transporter (Takenaka et al. 1995), and glycine transporters (Ponce et al. 1998; Hanley et al. 2000). In the case of the serotonin transporter, there is evidence for differential transport capacity of serotonin by the variant forms, while alternately spliced dopamine transporter may influence relative expression of the functional form of the transporter and thus perturb extracellular levels of dopamine. These types of finding lead to the conclusion that alternate splicing might be a mechanism that differentially regulates clearance of many neurotransmitters under differing physiological and pathophysiological states.

This chapter focuses upon the most abundant excitatory neurotransmitter in the central nervous system (CNS), namely, glutamate because glutamate is a molecule that may be dysregulated in a wide variety of CNS disease states, ranging from Alzheimer's disease, schizophrenia, motor neuron disease, and glaucoma to depression (Cowburn et al. 1988; McCarthy et al. 2012; Moghaddam and Javitt 2011). Therefore, an understanding of the transporters that mediate glutamate removal and the potential ways in which the transporters might be modified by events, such as alternate splicing, are central to our understanding of brain pathophysiology and ultimately to the development of therapeutic paradigms that optimize brain glutamate homeostasis. Extracellular and intracellular levels of

glutamate are regulated principally a family of high affinity sodium-dependent Excitatory Amino Acid Transporters (EAATs), which are members of the Solute Carrier Family-1 (SLC1) (Danbolt 2001). In the mammalian CNS, five major subtypes of EAATs have been identified; they share considerable homology (50–60 %) at the amino acid level, but each member exhibits distinct and differential localizations at the subcellular, cellular, and regional levels. EAAT1 (SLC1A3), the human homologue of the rodent glutamate/aspartate transporter (GLAST), is present in glia throughout the CNS but is particularly abundant in the radial (Bergmann) glia of the cerebellum and the radial (Müller) glia of the retina; EAAT2 (SLC1A2), the human homologue of glutamate transporter 1 (GLT-1), is present mainly in glia, particularly astrocytes, and is widespread throughout the CNS; EAAT3 (SLC1A1), the human homologue of Excitatory Amino Acid Carrier 1 (EAAC1), is localized to subsets of neurons throughout the CNS; EAAT4 (SLC1A6) is primarily localized to cerebellar Purkinje cells but with some expression in astrocytes (Hu et al. 2003) and EAAT5 (SLC1A7) is abundant in the retina, particularly in photoreceptors and populations of bipolar cells (Reviewed by Beart and O'Shea 2007).

One mechanism that is likely to influence EAAT function or dysfunction is alternative splicing. Alternative splicing of RNA is a common mechanism that allows a single gene to produce multiple different protein products (Lopez 1998). This versatile mechanism can also regulate parameters such as the amount of mRNA expressed and the stability of such mRNA. Changes in encoded protein sequence can affect nearly all aspects of protein function, including protein stability, binding properties, posttranslational modifications, cellular localization, and trafficking (Stamm et al. 2005). In recent years, many splice variants of EAATs have been described in humans, rodents, and other mammalian species. Message and protein for these splice variants are detectable in the normal brain and in some instances, their expression can be induced by pathophysiological insults. This chapter reviews recent progress in investigating the molecular heterogeneity, localization, function, structure, and regulation of the EAATs and their splice variants.

2 Splicing of Glutamate Transporters

2.1 Mechanism of Splicing

Alternative splicing of EAATs arises from differential removal of exons from the pre-mRNA that was transcribed from the DNA, or in some instances the retention of introns from the pre-mRNA, to yield many distinct mRNA and protein isoforms. Exon skipping is a common mode of splicing in mammalian brain, generating, for instance, the four known forms of GLAST (EAAT1). By contrast, GLT-1 (EAAT2) is spliced in a combinatorial manner (exon skipping and/or intron retention) to produce many distinct protein isoforms (for review, see Lee and Pow 2010).

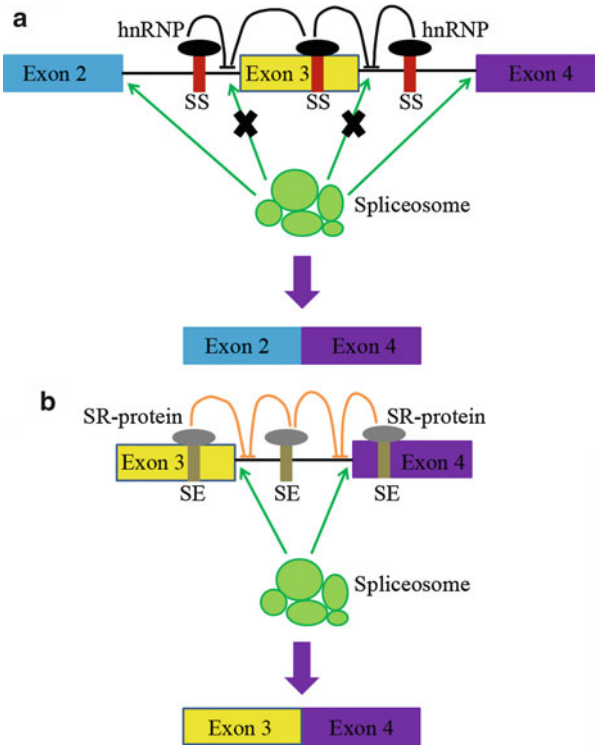

Fig. 1 (**a**) Model of splicing repression: hnRNPs bind to splicing silencers (*SS*) located in exons and introns of the pre-mRNA; this inhibits component of the spliceosome from binding to consensus splice site sequences at the ends of introns, resulting in skipping of the exon (*yellow*). (**b**) Model of splicing activation: SR proteins bind to splicing enhancers (*SE*) located in exons and introns; this facilitates binding of spliceosome components to consensus splice site sequences in the pre-mRNA that ultimately lead to excision of the targeted intron and ligation of flanking exons (Adapted from Wang and Burge 2008; Black 2003)

It is notable that alternate splice variants for EAAT3 and EAAT4 have not so far been described in the mammalian brain, though single nucleotide polymorphisms are undoubtedly present. However, given the limited attention that has been paid to these transporters to date, it is plausible that splice variants may exist but have not yet been detected, and this remains to be resolved. A similar situation has recently been resolved for EAAT5, which had until recently been described in mammals as a single form of the protein. Lee et al. (2012a) have recently demonstrated that it also exists as multiple splice variants, and that all splice variants cloned to date are either exon-skipping or intron-retaining types.

The regulation of EAAT splicing involves consensus splice site sequences in the pre-mRNA and cellular factors such as the "spliceosomes" which are dynamic complexes of proteins and RNA that act as ribozymes, to typically excise introns and ligate the flanking exons. In addition to the consensus splice site sequence on the pre-mRNA, auxiliary elements such as splicing enhancers and splicing silencers can strongly influence alternative splicing; such elements are variable in sequence and contain binding sites for serine/arginine-rich (SR)-proteins or heterogeneous nuclear ribonucleoproteins (hnRNPs), the binding of which can activate or repress the adjacent splice sites, respectively (Fig. 1). Therefore, the binding of

SR proteins and hnRNPs to such elements strongly influences the choice of splicing sites and regulate the formation of active spliceosomes in the pre-mRNA. Whether an exon is included in the mature transcript is determined by the concentration or activity of each type of regulators (SR proteins and hnRNPs). Concentration of SR proteins and hnRNPs can vary significantly between different cell types, and it is thought that such differential expression of SR proteins and hnRNPs affects the splicing of many pre-mRNAs (for reviews, see Chen and Manley 2009; Matlin et al. 2005).

The activity of SR proteins is strongly influenced by the phosphorylation state of these proteins. At least four different protein kinase families have been shown to phosphorylate SR proteins. The most specific of these is the SRPK family (e.g., SRPK1 and SRPK2), which are typically localized to the cytoplasm of cells, indicating that regulation of SR proteins is a cytoplasmic event. SR protein kinases are also regulated; SRPK1 binds to co-chaperones including heat shock proteins such as HSP40, in turn influencing interactions with HSP70 and HSP90. Accordingly, stress responses in cells such as astrocytes and neurons, including production of heat shock proteins, may modify pre-mRNA splicing for transporters such as GLT-1 (EAAT2). The activity of hnRNP proteins can also be modified by phosphorylation. For example, hnRNP A1 is directly phosphorylated by PKA, PKC, and Casein Kinase II (reviewed in Lynch 2007). Serine/threonine phosphorylation under hypoxia and stress conditions (van der Houven van Oordt et al. 2000; Daoud et al. 2002; Allemand et al. 2005) was previously shown to cause hyperphosphorylation and accumulation of hnRNPs in the cytosol. This could serve the purpose of removing such regulatory factors from pre-mRNA processing events. Indeed, a number of in vivo studies have clearly shown that splice site selection is altered following hypoxia and application of osmotic shock (van der Houven van Oordt et al. 2000; Daoud et al. 2002). Accordingly, stressors such as hypoxia are likely to affect the nuclear ratio of specific splicing regulators (SR proteins and hnRNPs) in cells such as astrocytes, thereby varying the regulation of alternative splicing of particular EAATs.

2.2 Splicing of 5′-Untranslated Region

Alternative splicing is a mechanism used for generating 5′-heterogeneity of transporters such as GLT-1 (EAAT2). Multiple alternative 5′-untranslated regions (UTR) exist for GLT-1 in human, rat, and mouse, with studies showing that mRNA levels for such variants change following pathological insults. Tian et al. (2007) showed that GLT-1 variants with longer 5′-UTRs (>310 nucleotides) were highly regulated at the translational level by factors such as corticosterone and retinol. In addition, some disease-associated insults, such as elevated glutamate levels and oxidative stress, were shown to affect the translational efficiency of such transcripts in primary astrocyte cultures. These observations suggest that expressions of such GLT-1 variants at the mRNA level are highly regulated under normal and disease state conditions and will thus influence GLT-1 protein expression.

2.3 Splicing of 3′-Untranslated Region

Splicing of the GLT-1 gene can produce transcripts with long 3′-UTR's; both human EAAT2 and mouse GLT-1a are known to contain unusually long 3′-UTRs (>9 Kb), suggesting that they contain potential elements that control mRNA localization, translational efficiency, or stability of mRNA (Kim et al. 2003; Kirschner et al. 1994). The 3′-UTR of human EAAT2 is reported to contain 23AU-rich elements (AUUUA) and 8 putative polyadenylation signals that could potentially be used to generate shorter EAAT2 transcripts (Kim et al. 2003); thus, Munch et al. (2000) have reported human EAAT2 transcripts of varying sizes (1.8, 2.4, 7, and 12 Kb) in human brain. Furthermore, sequences at the extreme end of the EAAT2/GLT-1a 3′-UTR is highly conserved between human, rat, mouse, and macaque, suggesting that this region has a regulatory function in posttranscriptional control (Kim et al. 2003). Computational analyses of the 3′-UTR of GLT-1a have also revealed the presence of putative K boxes, which are binding sites for microRNAs such as miR-218 (Lewis et al. 2005). Interestingly, this binding site is absent in the 3′-UTR of another alternately spliced form of GLT-1 called GLT-1b, suggesting that miR-218 may be a specific regulator of GLT-1a (for a detailed review, see Lauriat and McInnes 2007). Alignment analysis of 3′-UTRs between GLT-1a and GLT-1b revealed that there are sequences unique to each variant. These unique regions may contain potential regulatory elements that control the differential expression of the two GLT-1 variants. The complete sequence of the 3′-UTR of a third form called GLT-1c is unknown, and thus, it is not known if this variant contains any unique 3′-UTR sequences. However, it is interesting to note that expression levels of both GLT-1b and GLT-1c are much lower than that of GLT-1a in brain tissue homogenates, raising the possibility that in brain at least, their expression may be more tightly controlled by trans-acting factors (such as RNA-binding proteins) (Lauriat and McInnes 2007). Conversely, the highly abundant expression of GLT-1b and GLT-1c in the retina albeit in distinct populations of neurons, relative to GLT-1a (Pow et al. 2000; Rauen et al. 2004), suggests both a cell-specific enhancement of GLT-1b and GLT-1c expression and a co-associated suppression of expression of GLT-1a in this tissue.

2.4 Alternative Splicing and Generation of PDZ-Binding Motifs

Three distinct C-terminal regions of GLT-1 are generated from alternative splicing, and these variants are referred to as GLT-1a, GLT-1b, and GLT-1c. GLT-1a is the wild-type form of GLT-1 cloned by Pines et al. (1992) and contains 11 exons. GLT-1b lacks exon 11 and the coding region terminates in the intron after exon 10, generating a novel 11 amino acid sequence at the C-terminus (Chen et al. 2002; Schmitt et al. 2002). Similarly, GLT-1c includes exons 1 to 10 and terminates with a small exon spliced in from partial sequences of intron 10, again generating a novel 11 amino acid sequence at the C-terminus (Rauen et al. 2004).

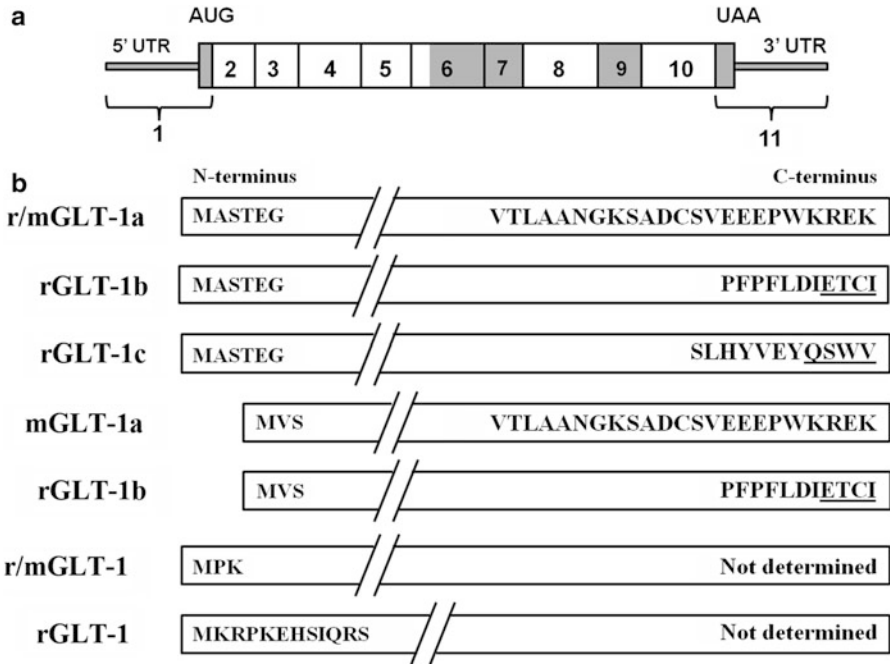

Fig. 2 (**a**) Exon structure of GLT-1 mRNA with exons subject to alternate splicing depicted in gray. Exons are depicted by *rectangles*; *UTR* untranslated region, *AUG* start codon, *UAA* stop codon. (**b**) Schematic illustration depicting "normally" spliced GLT-1 (referred to as GLT-1a), and known alternate N-terminal and C-terminal amino acid sequences, with PDZ motifs underlined. "m" prefix denotes sequences identified in mouse; "r" indicates sequences from rat

The last four amino acids in the C-termini of both GLT-1b (ETCI) and GLT-1c (QSWV) conform to the consensus sequence of a class I PDZ-binding motif (X-S/T-X-Φ_{COOH}), where X is any residue and Φ is a hydrophobic residue (Ivarsson 2012) (Fig. 2). These motifs are similar to the C-terminal PDZ motif (ETKM) present on GLAST that bind to the NHERF1 PDZ protein, which in turn interacts with ERM proteins and the astrocyte cytoskeletal protein GFAP (Lee et al. 2007; Sullivan et al. 2007b). Disruptions of these interactions were shown to perturb glutamate transport (Sullivan et al. 2007b). The PDZ proteins are particularly interesting, because they play key roles in anchoring transmembrane proteins to the cytoskeleton and hold together signaling complexes (Reviewed by Romero et al. 2011). Accordingly, the GLAST-NHERF1 interactions may limit the targeting of this transporter to central "core" zone of astrocytes where GFAP predominates (Sullivan et al. 2007b).

GLT-1b does not interact with NHERF1 (Lee et al. 2007) and potential PDZ-binding partners that associate with this transporter variant in astrocytes are still unclear. Bassan et al. (2008) have shown that GLT-1b can interact with the PDZ protein PICK1; however, very little PICK1 is expressed by astrocytes.

Similarly, Gonzalez-Gonzalez et al. (2008) demonstrated GLT-1b interactions with PSD95; however, this PDZ protein is mainly expressed in neurons, and anatomical co-localization of GLT-1b and PSD95 has not been demonstrated to indicate a functional relationship between the two proteins in brain.

No PDZ-binding partner has been identified for GLT-1c, which is abundantly expressed in photoreceptors of the retina. GLT-1c is also expressed in the brain at low levels, being primarily restricted to end-feet of astrocytes (Rauen et al. 2004). The differential expression of GLT-1c relative to GLT-1b may be indicative of interactions with different PDZ proteins and participation in different signaling pathways.

PDZ-binding motifs are also present on other EAATs, including EAAT3, EAAT4, and EAAT5. Neuronal EAAT4 was previously shown to interact with GTRAP48 (glutamate transporter-4 associated protein), a PDZ-domain-containing protein expressed predominantly in the cerebellum (Jackson et al. 2001). GTRAP48 specifically interacts with the C-terminal PDZ motif (ESAM) of EAAT4 and positively modulates its glutamate transport activity by enhancing the cell surface expression of EAAT4 (Jackson et al. 2001). Similarly, the cell surface density of EAAT3 is regulated via interaction of its C-terminal PDZ motif (TSQF) with the PDZK1 adaptor protein (D'Amico et al. 2010). The retinal EAAT5 has also been reported to contain a PDZ-binding motif (ETNV) at its C-terminus, based on findings from yeast two-hybrid screening, making it likely that the EAAT5 C-terminus may be involved in EAAT5-PDZ interactions (Arriza et al. 1997). The inclusion of PDZ-binding motifs in many of the EAATs suggests that interactions with PDZ-domain-containing proteins are common and probably important for creating differential targeting with consequential functional diversity. It is therefore plausible that splice variants differing in their C-terminal PDZ motif sequences may play distinct roles in regulation of neurotransmission or development.

2.5 Alternative Splicing and Generation of Exon-Skipping EAAT Variants

Several exon-skipping GLAST (EAAT1) variants are generated from alternative splicing. Huggett et al (2000) identified a splice variant of GLAST, lacking exon 3 (GLAST-1a), which is expressed in brain and bone. MLO-Y4 cells transfected with GFP-tagged GLAST and GLAST-1a appear to target the proteins to different cellular compartments; GLAST was targeted to the plasma membrane whereas GLAST-1a appeared to be expressed within internal vesicles (Huggett et al. 2002). When an antibody was later developed against GLAST-1a, expression of this protein was readily demonstrable in populations of astrocytes throughout the brain and retina (Macnab et al. 2006). There are notable differences between the distribution of GLAST-1a and wild-type GLAST in retina; GLAST-1a is preferentially localized to the outer end-feet of Muller cells, whereas GLAST is distributed throughout the cells, suggesting targeting and compartmentalization to different

parts of the cells. GLAST-1b is an exon 9–skipping form of GLAST and based on preliminary studies in transfected HEK293 cells was suggested to be a nonfunctional glutamate transporter which exerts a dominant negative effect on wild-type GLAST function (Vallejo-Illarramendi et al. 2005). Expression of GLAST-1b is highly upregulated at the protein level (albeit mainly in neurons), following insults such as hypoxia (Sullivan et al. 2007a). GLAST-1c is a splice variant of GLAST, lacking both exon 5 and exon 6 that was cloned from neonatal hypoxic pig brain (Lee et al. 2012b). GLAST-1c protein was shown to be abundantly expressed in astrocytes and oligodendrocytes in rat brain, pig brain, and human brain, including gray and white matter. Similarly, expression of GLAST-1c was observed in primary astrocyte cultures and in cultured oligodendrocytes. In astrocytes, GLAST-1c rapidly redistributed to the cell surface upon stimulation of protein kinase with phorbol esters, suggesting that phosphorylation plays a key role in the targeting of this protein.

Numerous exon-skipping variants of GLT-1 have been identified in human and rodent brains. These include a GLT-1 splice variant, missing exon 7, and a form, missing both exon 7 and exon 9 (Scott et al. 2011). Meyer et al. (1998, 1999) have discovered a form of GLT-1 missing exon 9 as well as more complex splice variants such as a form missing parts of exon 6 and exon 7 and a form that skips between part of exon 7 and part of exon 11. Little information is available on the expression of these proteins. Macnab and Pow (2007a) have generated antibodies against the splice site of the exon 9–skipping form of GLT-1 and demonstrated its expression in populations of white matter astrocytes. More recently, Lee et al. (2011) cloned an exon 4–skipping form of GLT-1 from the rodent brain, and an antibody that selectively recognized this variant revealed strong signals in gray matter astrocytes. Interestingly, the 5′-UTR of the exon 4–skipping GLT-1 is 306-nucleotides longer than that of regular GLT-1 (Pines et al. 1992). This is of interest because Tian et al. (2007) have shown that some GLT-1 transcripts bearing longer 5′-UTR are translationally regulated by factors such as corticosteroids and retinol as well as by several disease-associated insults in primary astrocyte cultures and in mice. Therefore, the possibility exists that translational regulation may play an important role in expression of exon 4–skipping GLT-1 under normal and disease conditions.

EAAT5 also exists as alternatively spliced forms in the retina. By PCR cloning and sequencing, Lee et al. (2012a) recently demonstrated the presence of five novel splice variant forms of EAAT5 which skip either partial or complete exons in the rat retina: Three of the splice variants skipped full exons, resulting in forms of EAAT5 that skipped exon 3, exon 9, or exon 10; another variant skipped a large portion of exon 7, while a fifth variant skipped part of exon 8 and all of exon 9 (Fig. 3). Each of the EAAT5 variants was shown to be expressed at the protein level by Western blotting using splice site–specific antibodies (Lee et al. 2012a). EAAT5 is particularly interesting since this protein exhibits a relatively large chloride conductance, associated with modest transport activity, suggesting a function more closely related to ligand-gated chloride channels than classic transporters. This has led to the finding that wild-type EAAT5 functions as an “inhibitory” presynaptic glutamate receptor in retinal bipolar cells (Wersinger et al. 2006).

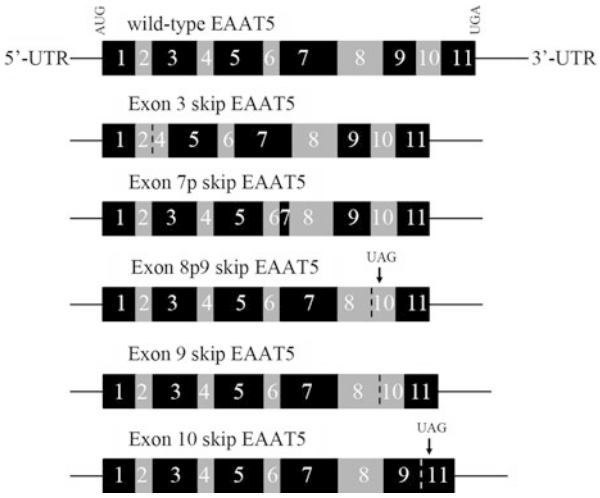

Fig. 3 Exon structure of wild-type EAAT5 mRNA and alternatively spliced forms of EAAT5. Exons are depicted by *rectangles*; *UTR* untranslated region, *AUG* START codon, *UGA* STOP codon, *arrow* indicates premature STOP codon (*UAG*) in the Exon8p9skip and Exon10skip variants of EAAT5

Currently, it is unknown whether the EAAT5 splice variants could function as transporters or receptors. These variants appear to be missing key structural features that may be important for chloride conductance or glutamate binding/transport. Thus, the functional characterization of such variants may require analysis beyond the determination of whether they conduct chloride or translocate glutamate.

2.6 Splicing of N- and C-Termini

At least, three 5′-variants of GLT-1 have been identified in brain which contain varying lengths of upstream open-reading frames encoding GLT-1 proteins with distinct N-terminal sequences: MASTEGANN, MPK, or MKRPKEHSIQRS (Rozyczka and Engele 2005; Münch et al. 2002; Peacey et al. 2009). A different 5′-variant of GLT-1 has also been identified in liver which contain the N-terminal sequence MVS (Utsunomiya-Tate et al. 1997); differences in the 5′-ends of the GLT-1 transcripts in brain and liver suggest the presence of tissue-specific promoters. In addition, at the 3′ end of the GLT-1 gene, there is extensive differential exon usage that can result in the generation of at least three distinct C-termini sequences (see Fig. 2b). Thus, at least 12 variant forms of GLT-1 protein potentially exist, depending on the splicing at the 5′ and 3′-ends of the GLT-1-coding sequence. Uptake studies in cultured cells and *Xenopus* oocytes have shown that functional and pharmacological properties of GLT-1 variants are not changed by alterations in their N- and C-termini sequences (Utsunomiya-Tate et al. 1997; Peacey et al. 2009). Therefore, N- and C-terminal splicing may be more important for differential expression or targeting of the transporters to particular cell types than in regulating the properties of glutamate uptake.

3 Are the EAAT Variants Generated by Alternative Splicing Functional?

While N- and C-terminal splicing can produce functional EAAT variants such as GLT-1b and GLT-1c, very little information is available on the functional properties of exon-skipping variants such as GLAST-1a, GLAST-1b, and GLAST-1c. The exon 9–skipping GLAST-1b has received little attention because when overexpressed in HEK293 cells, it was localized to the endoplasmic reticulum (ER) and thus is unable to act as a plasmalemmal glutamate transporter. When co-expressed with wild-type GLAST, it exerted a dominant negative effect over GLAST function and reduced GLAST insertion into the plasma membrane, suggesting that GLAST-1b could potentially act as an interfering subunit of the GLAST homo-oligomeric structure (Vallejo-Illarramendi et al. 2005). However, when a specific antibody was later developed to GLAST-1b (Macnab and Pow 2007b), it was shown that rather than being restricted to the ER, GLAST-1b was readily demonstrable in the plasma membranes of a very small subset of neurons. Not only was GLAST-1b targeted to the plasma membrane, which would be essential for its role as a transporter but it was also shown that the expression levels rise dramatically in neurons after a hypoxic insult, indicating that expression is physiologically regulated (Sullivan et al. 2007a). Similar issues have arisen for GLAST-1a, which is an exon 3–skipping variant of GLAST. Interestingly, some algorithms have predicted that the loss of exon 3 would produce a reversal of the membrane topology of GLAST-1a (Huggett et al. 2000), where the orientation of the glutamate-binding/-translocating region and the direction of glutamate transport may also be reversed (Fig. 4). This does not however imply a loss of function but rather may indicate a different function for GLAST-1a, such as acting as a glutamate "efflux" protein. Patch clamping experiments in brain slices have clearly demonstrated that glutamate transporters can operate in reverse, transporting glutamate from inside to outside of the cell under conditions such as anoxia (Billups and Attwell 1996; Rossi et al. 2000). Furthermore, alternative splicing of the bile acid transporter (ASBT) gene is known to generate an exon 2–skipping variant that functions as a bile acid efflux protein and localized to basolateral domains of cholangiocytes. This is in contrast to wild-type ASBT which functions to take up bile acids across the apical membranes of cholangiocytes (Lazaridis et al. 2000). Thus, alternative splicing can alter the cellular targeting and/or functional properties of transporters.

In the case of GLAST-1c, which skips exons 5 and 6, this variant has significant key features in common with the prototypical bacterial aspartate transporter GLTph (Yernool et al. 2004), which appears to be an ancestral form of glutamate transporter; these include the absence of glycosylation sites, and much of the same extracellular loop that is missing in GLAST-1c is also absent in GLTph. Such similarities between GLAST-1c and a functional prototypic transporter may support the view that GLAST-1c is plausibly a functional glutamate transporter and possibly represents a primitive form of GLAST. Accordingly, the possibility that GLAST-1a, GLAST-1b, and GLAST-1c are involved in either directly transporting glutamate or in regulating the trafficking of wild-type GLAST must remain a possibility at this stage.

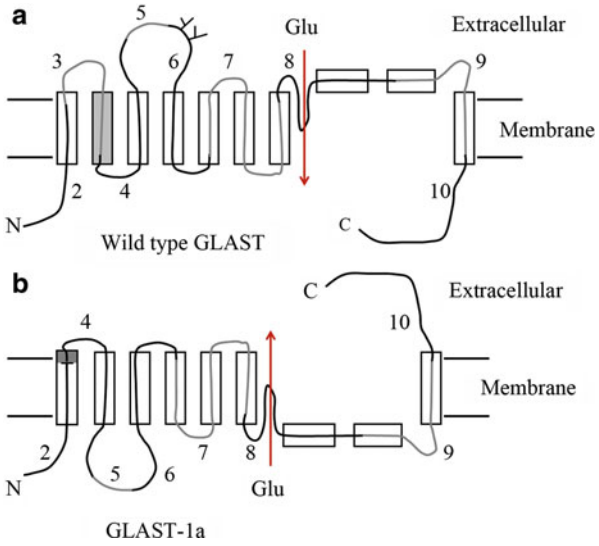

Fig. 4 Predicted transmembrane (*TM*) topologies of wild-type GLAST and GLAST-1a; the extracellular surface and the plasma membrane are indicated. Exon boundaries are overlaid onto the predicted topologies to demonstrate the predicted changes in topology that result from the skipping of exon 3. Deletion of exon 3 in GLAST-1a converts the first two TM domains into one and is predicted to reverse the membrane topology, resulting in an extracellular C-terminal region that may be associated with the reversal of glutamate transport (Adapted from Huggett et al. 2000)

4 Disease Association of EAAT Splice Variants

Much evidence exists for the differential regulation of EAAT2 and EAAT2b in amyotrophic lateral sclerosis (ALS) Meyer et al., 1999. Dramatic reduction in EAAT2 protein has been observed in motor cortex of ALS patients without alterations in EAAT2 (GLT-1) mRNA levels, suggesting posttranscriptional regulation may be involved (Bristol and Rothstein1996; Rothstein et al. 1995; Fray et al. 1998). This is in contrast to expression of EAAT2b (GLT-1b) protein, which is increased in motor cortex of ALS patients (Maragakis et al. 2004). A number of animal models have been used to study the potential role(s) of EAAT expression in ALS. Studies in mice where the animals are fed with cycads reveal behavior and histological features resembling ALS-PDS. In these animals, there is a significant downregulation of GLT-1a protein in spinal cord and primary somatosensory cortex; GLT-1b protein levels were significantly decreased in the spinal cord, in the motor, somatosensory, and piriform cortices, and in the striatum. Notably, GLT-1b expression was decreased in areas where GLT-1a expression was unaltered, suggesting differential regulation of the two transporter subtypes (Wilson et al. 2003). Similarly, Munch et al. (2002) have also shown that the N-terminal splicing of GLT-1a was altered in the spinal cord of SOD transgenic mice, suggesting a link between altered splicing of the 5′-end sequences of GLT-1

gene and ALS. Whether changes in expression or splicing of GLT-1 are aspects of early causation, or a consequence of ALS, remains open to interpretation. However, Guo et al. (2003) produced a double transgenic SOD mutant mice overexpressing GLT-1a which showed significant delays in grip-strength decline and a delay in the loss of motor neurons (Guo et al. 2003). However, these transgenic animals did not show decline in the onset of paralysis nor did they live longer. These results suggest that loss of GLT-1/EAAT2 may contribute to, but do not initially cause, motor neuron degeneration in ALS (Guo et al. 2003).

Aberrant expression of EAAT splice variants has been observed in Alzheimer's disease (AD). Scott et al. (2011) showed increased mRNA expression of an exon 9–skipping form of EAAT2 and protein for this variant has been observed in neurons of AD brain (Pow and Cook 2009). Similarly, protein for the exon 3–skipping form of EAAT1 has been observed in neurons of the AD cortex (Pow and Cook 2009). It is plausible that changes to the splicing of GLT-1 (EAAT2) and GLAST (EAAT1) may explain why there has been a paradoxical observation of an apparently decreased GLAST and GLT-1 expression but increased glutamate reuptake activity in cortex of AβPP23 mice (Schallier et al. 2011), suggesting possibly that modified forms of the transporters were present and functional but not detected with the tools used. Aberrant neuronal expression of EAAT splice variants has also been observed in other pathophysiological states. Thus, Sullivan et al. (2007a) have shown expression of an exon 9–skipping form of GLAST (GLAST-1b) in populations of neurons after a hypoxic insult. GLT-1b, which has an alternatively spliced C-terminal region, was also shown to be aberrantly expressed in neurons after hypoxic insult (Pow et al. 2004). In both scenarios, it has been proposed that an elevation of extracellular glutamate concentration may be driving the expression of the EAAT subtypes. Similar observations have been seen in disease states such as glaucoma and age-related macular degeneration (AMD) as well as in stroke where glutamate excitotoxicity has been implicated. For example, induced expression of a C-terminal splice variant of GLT-1 (GLT-1c) has been demonstrated in retinal ganglion cells in response to elevated intraocular pressure in rats or in human eyes afflicted by glaucoma (Sullivan et al. 2006), and this has been interpreted as being adaptive, to protect the ganglion cells that are vulnerable to glutamate excitotoxicity. Conversely, a complete loss of GLT-1c from photoreceptors in peri-macular regions was observed in AMD patients (Pow et al. 2005) and may explain why these cells lose their content of glutamate that acts both as a neurotransmitter and as an essential metabolic fuel for these cells, which subsequently die. In stroke, induced expression of the exon 3–skipping form of GLAST (GLAST-1a) has been observed in cerebral cortex of ischemic rats induced by middle cerebral artery occlusion (MCAo) (Fig. 5; Pow et al. Unpublished data). Thus, anomalies in local excitation (as a result of ischemic stroke) can induce expression of glial glutamate transporter splice variants such as GLAST-1a in affected neurons, possibly as a protective mechanism. This is in contrast to expression of GLT-1a mRNA and protein, which was reported to be decreased in cerebral cortex of ischemic rats induced by MCAo (Rao et al. 2001a). Interestingly, decreasing GLT-1a expression by antisense knockdown was shown to

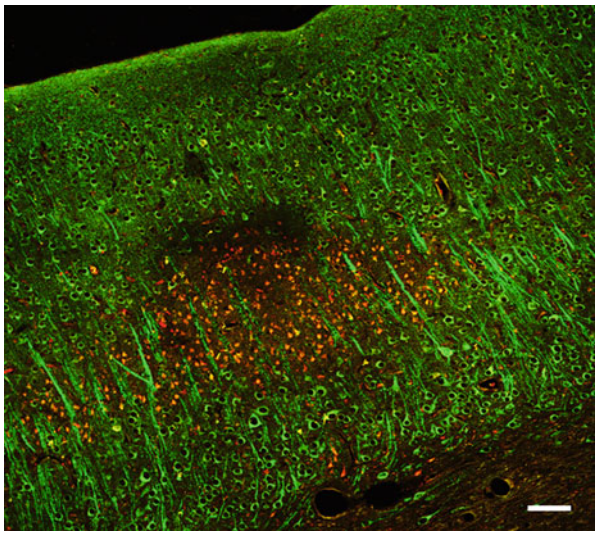

Fig. 5 Image of rat cortex after a stroke induced by transient middle cerebral artery occlusion, immunolabeled for MAP2 (*green*) which labels cell bodies and dendrites of healthy neurons. The large central area where the neurons have lost MAP2 labeling represents the incipient lesion area; GLAST-1a labeling (*red*) is upregulated in this area. Scale bar, 50 μm

exacerbate neuronal damage induced by MCAo (Rao et al. 2001b) while targeted overexpression of GLT-1a reduced ischemic brain injury caused by MCAo (Harvey et al. 2011), suggesting that increasing the capacity to remove extracellular glutamate may provide beneficial outcomes against ischemia-induced glutamate excitotoxicity.

In Schizophrenia, an ambiguous literature exists concerning the expression level of EAATs with increases and decreases being reported. Thus, Smith et al. (2001) examined postmortem tissues from Schizophrenia subjects by in situ hybridization and showed elevated expression of EAAT2 mRNA in thalamus. Similar studies by Ohnuma et al. (1998, 2000) have reported reduced expression of EAAT2 mRNA in prefrontal cortex and parahippocampal regions of Schizophrenia subjects. Conversely, Bauer et al. (2008) did not detect changes in transcript or protein expression of EAAT2 in postmortem prefrontal cortex tissues of Schizophrenia patients using in situ hybridization and Western blotting. One possible limitation of these studies is the putative effects of psychotropic medications on EAAT expression. Several studies have addressed this issue by examining expression of EAAT2 (GLT-1) in animals treated with such drugs. Melone et al. (2001) have shown that short-term (3 weeks) administration of oral clozapine (25–35 mg/kg per day) to rats reduced expression of GLT-1a in cerebral cortex, resulting in decreased glutamate transport and increased extracellular glutamate concentration. Suppression of GLT-1a expression was also observed in rat brain after long-term (6 months) chronic antipsychotic treatment with clozapine (45 mg/kg per day) (Schmitt et al. 2003). The current literature, therefore, suggests that GLT-1a expression is regulated by exposure to antipsychotic drugs. There is no data at present as to whether changes in GLT-1a expression are due to changes in splicing or to changes in overall transcription or translation of the mRNA.

5 Conclusion

Alternative splicing of EAATs is a common mechanism that allows for diversification of a single gene into different protein products. For EAAT2, many of the splice variants produced by N- and C-terminal splicing have been shown to be functional, however, with changes in tissue distribution. For other EAAT members such as EAAT1 and EAAT5, "exon skipping" is the most common mode of splicing whereby certain exons have been removed, therefore resulting in shorter protein products. This highly versatile mechanism can regulate the amount of mRNA and changes in protein sequence that is likely to affect many aspects of protein function such as substrate-binding properties, posttranslational modifications, cellular localization, and trafficking. Interestingly, some of the "exon skipping" EAAT variants cloned to date lack significant portions of the C-terminal regions, suggesting that critical interactions such as binding to the cytoskeleton of the cell would be differentially affected in such variants. Conversely, others lack portions of the N-terminal region and thus may exhibit deficiencies in parameters such as chloride conductances. Where key structural elements of a transporter are missing, it is often dismissed as "junk protein," but biological systems are extremely conservative and unlikely to waste energy making junk in physiological situations. Instead we suggest, by homology to more recent ideas on "junk DNA," that it is plausible that many of these novel proteins may instead have primary functions that are distinct from their initially described roles as glutamate transporters or receptors. In some cases, the splice variants have been shown to possess a dominant negative effect on the co-transporter function, suggesting an important role in the functional regulation of the wild-type transporter. Validating the function of such EAAT variants will require further experimental analysis. From a clinical perspective, however, these EAAT variants are of particular interest, given that their expression and/or regulatory pathways are associated with neurological disorders such as Alzheimer's disease, glaucoma, and macular degeneration as well as hypoxia. Determining whether EAAT changes in any of these disease states are causal or consequential and whether modulation of the activity for a specific EAAT variant might evolve as a therapeutic option are just two examples for the many questions waiting to be answered. Further studies of alternative splicing regulation of EAATs will no doubt reveal new opportunities.

Abstract

Infection with human immunodeficiency virus (HIV)-1 not only targets and compromises cells of the immune system and eventually causes AIDS but also triggers a variety of neurological problems that can culminate in frank dementia. Several lines of evidence suggest that HIV-1 strikes at the brain in at least two ways: (i) by causing toxicity leading to neuronal injury and death and (ii) by impairing neurogenesis without killing neural precursors. Both of the pathogenic mechanisms share the involvement of neuroinflammatory mediators, and both processes seem to be influenced by host and viral factors, including the interferon response, age and viral subtypes, as well as treatment and comorbidity factors, such as drug abuse. Development of both HIV-associated neurocognitive disorders (HAND) and AIDS goes hand-in-hand, and despite

viral control and life-prolonging effects of combination antiretroviral treatments (cART), neuroinflammation and concomitant activation of macrophages and microglia accompany the continued development of HAND in HIV patients. Besides intact HIV-1, six of its proteins have been linked to neuronal injury. Experimental evidence supports two different, but not exclusive, hypotheses of how HIV-1 causes neuronal damage in the brain. The "direct injury" hypothesis proposes that viral proteins directly compromise neurons, whereas the "indirect" or "bystander effect" hypothesis states virus infection and viral components trigger in macrophages and microglia and astrocytes the production of neurotoxins that injure neurons. HIV-1 and its six neurotoxic protein components can trigger a plethora of cellular responses and signaling mechanisms. However, it appears that the HIV-1 and its viral components cause neurotoxicity via converging mechanisms even if the virus and each component may start out their pathogenic mechanism by interacting with different host cell factors. Converging mechanisms in HIV neurotoxicity include neuroinflammation, MAPK signaling, altered gene expression, oxidative stress, interference with the cell cycle machinery and autophagy, excitotoxicity, synaptic injury, and, ultimately, neuronal apoptosis.

Keywords

HIV-1 • Infection • Inflammation • Brain • Cognition • Dementia • Neurotoxicity • Excitotoxicity • Neurogenesis • Neurons • Astrocytes • Macrophages • Microglia • Host-pathogen Interaction • Immune Response • Co-morbidity • Drug Abuse

List of Abbreviations

AIDS	Acquired immunodeficiency syndrome
ANI	Asymptomatic neurocognitive impairment
ANT	Adenine nucleotide translocator
ApoE3	Apolipoprotein E3
BBB	Blood–brain barrier
cART	Combination antiretroviral therapy
CEBP	CCAAT-enhancer-binding protein
CNS	Central nervous system
COUP-TF	Chicken ovalbumin upstream promoter transcription factor
CSF	Cerebrospinal fluid
Dox	Doxycycline
EAAs	Excitatory amino acids
Env	Envelope protein
ER	Endoplasmic reticulum
ERK-1/ERK-2	Extracellularly regulated kinase-1 and kinase-2
GABA	γ-aminobutyric acid

GSK	Glucagon synthase kinase
HAART	Highly active antiretroviral therapy
HAD	HIV-associated dementia
HAND	HIV-associated neurocognitive disorders
HIV-1	Human immunodeficiency virus-1
HIVE	HIV encephalitis
HNE	Hydroxynonenal
IFN	Interferon
IL	Interleukin
iNOS	Inducible nitric oxide synthase
IRIS	Immune reconstitution inflammatory syndrome
LPS	Lipopolysaccharide
LRP	Low-density lipoprotein receptor-related protein
LTP	Long-term potentiation
MAPK	Mitogen-activated protein kinase
MCMD	Minor cognitive motor disorder
MCP	Monocyte chemoattractant protein
mGluRs	Metabotropic glutamate receptors
miR	MicroRNAs
MLK	Mixed lineage kinase
MMPs	Metalloproteinases
MND	Mild neurocognitive disorder
Nef	Negative factor
NMDAR	*N*-methyl-*D*-aspartate-type glutamate receptor
Pol	Polymerase
PTPC	Permeability transition pore complex
Rb	Retinoblastoma protein
Rev	Regulatory for expression of viral proteins
RyR	Ryanodine receptors
SCID	Severe combined immunodeficiency
SIV	Simian immunodeficiency virus
Tat	Transactivator of transcription
tg	Transgenic
TLR	Toll-like receptors
TNF	Tumor necrosis factor
TNFR	TNFα receptor
TRAIL	TNF-related apoptosis-inducing ligand
TUNEL	Terminal-deoxynucleotidyl-transferase-mediated dUTP nick-end labeling
UPR	Unfolded protein response
Vif	Viral infectivity factor
Vpr	Viral protein r
Vpu	Viral protein u

1 Introduction

Human immunodeficiency virus-1 (HIV-1) is a retrovirus belonging to the subgroup of lentiviruses (Barre-Sinoussi et al. 1983; Alizon et al. 1984; Hahn et al. 1984; Wain-Hobson et al. 1985). HIV was discovered in 1983 using lymphoid tissue from one of a quickly increasing number of patients presenting with lymphadenopathy followed by an acquired immunodeficiency syndrome (AIDS) (Barre-Sinoussi et al. 1983; Hahn et al. 1984; Barre-Sinoussi 2003). In 2011, an estimated 34.2 million people were living with HIV infection or AIDS, and despite improvements in therapy and access to treatments, the epidemic caused 2.5 million deaths (UNAIDS; www.unaids.org).

Although HIV-1 primarily targets and compromises cells of the immune system and eventually causes AIDS (Stevenson 2003), it was observed early on in the epidemic that the virus can also cause a variety of neurological problems that can culminate in frank dementia (Loewenstein and Sharfstein 1983; Jordan et al. 1985; Petito et al. 1985). While AIDS-related opportunistic infections obviously affected the central nervous system (CNS), in particular in the absence of treatment, HIV-1 infection itself seemed also able to initiate a number of neurological syndromes (Jordan et al. 1985; Petito et al. 1985). Today it is widely accepted that HIV-1 can directly trigger neurological conditions, including peripheral neuropathies, vacuolar myelopathy, and a clinical syndrome of cognitive and motor dysfunction that has early on been designated AIDS dementia and later on HIV-associated dementia (HAD) (Navia et al. 1986a, b; Petito et al. 1986). A milder and, in the presence of antiviral treatment, more common form of HAD is termed minor cognitive motor disorder (MCMD) (Ellis et al. 1997; Kaul et al. 2001; Gendelman et al. 2005; Power et al. 2009). In recognition of a changing clinical presentation, neurocognitive complications of HIV-1 infection have more recently been categorized as HIV-associated neurocognitive disorders (HAND) (Antinori et al. 2007). HAND defines three categories of disorders with increasing severity according to standardized measures of dysfunction: (i) asymptomatic neurocognitive impairment (ANI), (ii) mild neurocognitive disorder (MND), and (iii) HAD.

The mechanisms contributing to the development of the various forms of HAND remain incompletely understood, although it is known that anemia early in HIV-1 infection appears to presage later neuropsychological impairment (McArthur et al. 1993). In order to learn how HIV infection can lead to dementia or the milder forms of HAND, scientists have employed a variety of strategies. Besides neurological and neuropsychological assessments, which are essential to identify the clinical domains of HAND, the current knowledge is based on multiple methodological approaches, including analyses of cerebrospinal fluid (CSF), neuroimaging, histopathological studies on *postmortem* brain specimens, animal models ranging from monkeys to rodents, and in vitro models using neuronal, glial, and immune cells from humans, monkeys, and rodents (Maung et al. 2012). New and sometimes surprising insights into the ways HIV-1 compromises the CNS came from the

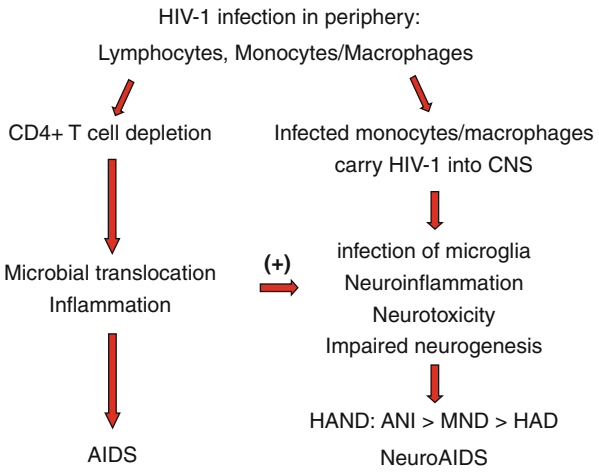

Fig. 1 *Schematic outline of key pathological processes and events associated with HIV-1 infection and the development of HAND, neuroAIDS, and AIDS*. HIV-1 infection occurs in the periphery, but soon afterwards the virus arrives in the brain, presumably carried by infected infiltrating macrophages and possibly lymphocytes. In the brain, the virus can infect microglia. Infected macrophages and microglia release viral proteins and host factors that can stimulate uninfected cells contributing to the development of neuroinflammation, neurotoxicity, and impaired neurogenesis. The latter two processes are presumed to underlie the development of HAND. In the periphery, HIV infection most often leads to the loss and eventual depletion of $CD4^+$ T cells, including those in the intestinal tract. The weakened immune surveillance seems to enable microbial translocation, which further contributes to inflammation. Depletion of $CD4^+$ T cells will eventually result in the development of AIDS. Peripheral inflammation also seems to promote neuroinflammation and the development of HAND and neuroAIDS

discovery of HIV-1 coreceptors, the chemokine receptors CCR5 and CXCR4, in the brain as well as from progress in understanding neuroinflammation and neural stem cell biology (Lavi et al. 1998; Miller and Meucci 1999; Kaul et al. 2001; Kramer-Hammerle et al. 2005; Minghetti 2005; Kaul et al. 2005; Gonzalez-Scarano and Martin-Garcia 2005; Jones and Power 2006). Currently, there is strong evidence suggesting that HIV-1 may strike at the brain in at least two ways: (i) by causing toxicity leading to neuronal injury and death and (ii) by impairing neurogenesis without killing neural precursors (Fig. 1) (Kaul 2008). Both of the two mechanisms appear to share the involvement of inflammatory processes, and both seem to be influenced by host and viral factors, including aging and viral subtypes, as well as treatment and comorbidity factors, such as drug abuse (Kaul 2008; Kaul 2009; Gannon et al. 2011). While we cannot yet reliably determine how much impairment of neurogenesis contributes to HAND, based on currently available information, this chapter will discuss what may be the most destructive mechanism for the CNS during HIV-1 infection: neurotoxicity.

2 HIV-1 Infection, AIDS, and HIV-Associated Neurocognitive Disorders

HAD as the most severe manifestation of HAND occurred at the beginning of the AIDS epidemic primarily in patients with advanced HIV disease and $CD4^+$ T cell counts below 200 μl^{-1} (McArthur et al. 1993). The introduction in the mid-1990 of combination antiretroviral therapy (cART), which was also called "highly active antiretroviral therapy" (HAART), was a major advance in the treatment of HIV infection that in most cases significantly delayed the progression to AIDS. Thus, cART increased the life span of people infected with HIV-1 and resulted in a temporary decrease in the incidence of HAD from 20 % to 30 % to as low as 10.5 % (McArthur et al. 2003). Control of peripheral viral replication and the treatment of opportunistic infections continue to extend survival times, and HIV infection has become a chronic rather than acute disease. Unfortunately, however, cART fails so far to prevent the eventual development of MND or HAD or to reverse HAND (Cunningham et al. 2000; Cysique et al. 2006; Giancola et al. 2006; Nath and Sacktor 2006; Ellis et al. 1997; Antinori et al. 2007; Liner et al. 2008; Boisse et al. 2008; Brew et al. 2008; Heaton et al. 2010, 2011; Gannon et al. 2011). In the era of cART, MND may be more prevalent than overt dementia, but as an AIDS-defining illness, the incidence of dementia has increased in recent years and HAD still constitutes a significant independent risk factor for death due to AIDS (Ellis et al. 1997; Liner et al. 2008). In a group of 669 HIV patients who died between 1996 and 2001, more than 90 % had been diagnosed with HAD as an AIDS-defining condition within the last 12 months of life (Welch and Morse 2002). In addition, the proportion of new cases of HAD displaying a $CD4^+$ T cell count greater than 200 μl^{-1} has been growing (McArthur et al. 2003). Of note, recent therapeutic guidelines for AIDS suggest to start cART only once the number of $CD4^+$ T cells begins to decline. Since this might occur up to years after initial peripheral infection, cART most likely has no chance to forestall the entry of HIV-1 into the CNS (Kramer-Hammerle et al. 2005). Furthermore, distinct patterns of viral drug resistance in plasma and CSF compartments have been ascribed to limited penetration of certain antiretroviral drugs, such as HIV protease inhibitors and several of the nucleoside analogues, into the CNS (Cunningham et al. 2000; Kaul et al. 2005; Kramer-Hammerle et al. 2005). On the other hand, several studies have found clear evidence that cART can benefit the brain and neurocognitive performance, in particular if the therapeutic compounds reach the CNS in concentrations sufficient to suppress virus (Smurzynski et al. 2011; Letendre et al. 2004; Patel et al. 2009; Winston et al. 2010; Gannon et al. 2011). At the same time, some studies suggest that long-term exposure to cART poses a potential toxicological problem, which may contribute to neurocognitive deterioration on its own (Liner et al. 2008, 2010; Letendre et al. 2008; Cardenas et al. 2009; Marra et al. 2009; Schweinsburg et al. 2005).

Early studies during the AIDS epidemic indicated that HIV penetrates into the CNS soon after infection in the periphery and then resides primarily in perivascular macrophages and microglia (Ho et al. 1985; Gartner 2000; Gonzalez-Scarano and Martin-Garcia 2005). Therefore it is not very surprising that despite cART the

prevalence of dementia may be rising as people live longer and age with HIV-1 infection (Lipton 1997; Jones and Power 2006; Cunningham et al. 2000; McArthur et al. 2003; Kaul et al. 2005, 2001; Kramer-Hammerle et al. 2005; Brew et al. 2009; Lindl et al. 2010; Gannon et al. 2011).

The blood–brain barrier (BBB) seems to play an important role in the acute and chronic HIV infection of the CNS as it potentially controls the infiltration of virus-infected and uninfected peripheral immune cells, such as monocytes and macrophages (Gartner 2000; Nottet et al. 1996; Gras and Kaul 2010). Astrocytes and microglia produce chemokines – cell migration-/chemotaxis-inducing cytokines – such as monocyte chemoattractant protein (MCP)-1, which appear to attract peripheral blood mononuclear cells across the BBB into the brain parenchyma (Asensio and Campbell 1999). In fact, an increased risk of HAD has recently been connected to a mutant MCP-1 allele that causes increased infiltration of monocytes and macrophages into tissues which may enhance the transfer of HIV-1 into the brain and promote neuroinflammation (Gonzalez et al. 2002; Gras and Kaul 2010). Alternatively, it has been suggested that the proinflammatory cytokine TNFα promotes a paracellular route for free virus across the BBB (Fiala et al. 1997).

Importantly, infectious events in the periphery and the associated immune response and inflammatory processes influence all cell types in the CNS (Turrin and Rivest 2004; Chakravarty and Herkenham 2005). Potentially important for the understanding of all aspects of HIV disease are recent findings strongly suggesting that the pathogenic or nonpathogenic course of HIV/simian immunodeficiency virus (SIV) infection may be determined by the reaction of plasmacytoid dendritic cells to the virus, in particular the time and amount of interferon (IFN)-α production (Mandl et al. 2008). Signaling via Toll-like receptors (TLR)-7 and −9 and the extent of downstream activation of interferon regulatory factor (IRF)-7 appears to control how much IFNα is being produced. While IFNs are important for an antiviral immune response, the lasting production of IFNα in HIV/SIV infection is suspected to result in erroneous and exhaustive immune activation which in turn may lead to immune suppression and progression to SIV/AIDS (Mandl et al. 2008). Besides immune suppression, the extensive production of IFNα can be of direct detrimental consequence to the brain, as IFNα production in the HIV-infected CNS directly correlates with neurocognitive impairment (Sas et al. 2007). In contrast, IFNβ induces a dominant-negative form of the transcription factor CCAAT-enhancer-binding protein (CEBP)-β and suppresses SIV in macaque macrophages (Dudaronek et al. 2007). Moreover, IFNβ triggers in macrophages and microglia the expression of the antiviral and neuroprotective β-chemokines CCL3/MIP-1α, CCL4/MIP-1β, and CCL5/RANTES (Kitai et al. 2000; Garzino-Demo et al. 1998; Kaul and Lipton 1999; Kaul et al. 2007).

HIV-1/SIV infection also affects the intestinal tract and can cause leakage of bacteria or bacterial products into the bloodstream (Brenchley et al. 2006). Such microbial translocation is reflected by elevated plasma levels of lipopolysaccharide (LPS), which is associated with increased monocyte activation and dementia in HIV-infected patients (Ancuta et al. 2008). Thus, immune activation and inflammation are prime suspects regarding a contribution to neurotoxicity, impairment of

neurogenesis, and the development of HAND, but the biological effects of IFNβ suggest that innate immunity can also protect.

3 Neuropathology of HIV-1 Infection Before and After Introduction of cART

Development of HAND and in particular HAD in patients during their lifetime has been correlated to a *postmortem* neuropathological diagnosis that has often been referred to as HIV encephalitis (HIVE) (Petito et al. 1986; Masliah et al. 1992). The salient pathological features include microglial nodules; activated resident microglia; HIV-infected multinucleated giant cells; infiltration predominantly by monocytoid cells, including blood-derived macrophages; widespread reactive astrocytosis; myelin pallor; and decreased synaptic and dendritic density, combined with selective neuronal loss (Petito et al. 1986; Masliah et al. 1997). The designation and hallmarks of HIVE indicate that signs of neuroinflammation have commonly been found in HIV patients since the beginning of the AIDS epidemic. Surprisingly, however, *antemortem* measures of cognitive dysfunction did not correlate well with numbers of HIV-infected cells, multinucleated giant cells, or viral antigens in CNS tissue (Glass et al. 1995; Achim et al. 1994; Wiley et al. 1994; Masliah et al. 1997). Instead, the pathological characteristics showing the best correlation with clinical signs of HAD were increased numbers of microglia (Glass et al. 1995), decreased synaptic and dendritic density, selective neuronal loss (Masliah et al. 1997; Achim et al. 1994; Wiley et al. 1994), elevated tumor necrosis factor (TNF)-α mRNA in microglia and astrocytes (Wesselingh et al. 1997), and evidence of excitatory neurotoxins in CSF and serum (Heyes et al. 1991). Thus, several lines of evidence pointed toward an important role of inflammatory factors, macrophages/microglia, and neurotoxins in the development of HAD. In addition, two recent studies also suggested a crucial role of mononuclear phagocytes because the findings showed that the amount of proviral HIV DNA in circulating monocytes and macrophages correlated well with HAD, whereas viral load was a less reliable indicator (Shiramizu et al. 2005, 2006).

Neuronal damage and loss has been observed *postmortem* in distinct brain regions of HIV and AIDS patients, including frontal cortex (Ketzler et al. 1990; Everall et al. 1991), substantia nigra (Reyes et al. 1991), cerebellum (Graus et al. 1990), and putamen (Everall et al. 1993). Focal neuronal necrosis appeared to occur in HAD brains early in the AIDS epidemic (Ho et al. 1989), whereas neuronal apoptosis has more recently been linked to HAD (Petito and Roberts 1995; Adle-Biassette et al. 1999). The localization of apoptotic neurons was correlated with signs of structural atrophy and microglial activation, in particular within subcortical deep gray structures (Adle-Biassette et al. 1999). Surprisingly, however, neuronal death was not clearly associated with viral burden or a history of dementia. On the other hand, a separate study found that cellular DNA fragmentation detected by terminal-deoxynucleotidyl-transferase-mediated dUTP nick-end labeling (TUNEL) in basal ganglia correlated well with HAD (Rostasy et al. 2000).

To be sure, the neuropathology of HIV infection and AIDS has shifted following the introduction of cART (Anthony and Bell 2008; Boisse et al. 2008; Brew et al. 2008). Although the number of opportunistic infections declined, two *postmortem* studies found evidence of increased infiltration and activation of macrophages and microglia in hippocampus and basal ganglia of cART-experienced patients in comparison to cases from the time before cART and a higher prevalence of HIV-associated encephalitis at the time of autopsy (Anthony et al. 2005; Bell 2004; Langford et al. 2003). Even more encephalitis and severe leukoencephalopathy was observed in *postmortem* specimens from AIDS patients who had failed cART (Anthony et al. 2005). In line with these findings, more recent neuropathological descriptions also reported various forms with severe HIVE and white matter injury, extensive perivascular lymphocytic infiltration, "burnt-out" forms of HIVE, and aging-associated β-amyloid accumulation with Alzheimer's-like neuropathology (Everall et al. 2005; Green et al. 2005; Achim et al. 2009).

Signs of neuroinflammation were commonly found in HIV patients since the beginning of the AIDS epidemic (HIVE) (Masliah et al. 1992), and neuroinflammation usually developed with the progression of HIV patients from the latent, asymptomatic stage of the disease to AIDS and HAD. Therefore, inflammation itself was generally seen as a pathological mechanism, and improved therapy was expected to ameliorate neuroinflammation. Surprisingly, autopsy cases of HIV-related death collected since the advent of cART rather suggested the opposite (Bell 2004; Everall et al. 2005; Anthony et al. 2005). However, the predominant localization of neuroinflammation had changed. Specimen from pre-cART patients showed strong involvement of basal ganglia, whereas post-cART cases displayed extensive signs of inflammation in hippocampus and adjacent regions of entorhinal and temporal cortex (Anthony and Bell 2008). Interestingly, cART seemed to have limited or prevented lymphocyte infiltration, with the exception of occasional, distinct instances, termed "immune reconstitution inflammatory syndrome" (IRIS), where massive lymphocytosis was associated with pronounced demyelination and white matter damage (Anthony and Bell 2008; Boisse et al. 2008). Thus, despite viral control and life-prolonging effects of cART, neuroinflammation and concomitant activation of macrophages and microglia accompany the continued development of HAND in HIV patients.

4 Chemokine Receptors and HIV-1 Infection of the Brain

Chemokine receptors are members of the large family of G-protein-coupled seven transmembrane-spanning domain receptors. Their ligands are primarily small proteins, the chemokines, which trigger leukocyte trafficking and participate intimately in the inflammatory and anti-infection responses of the immune system (Locati and Murphy 1999; Dragic et al. 1996; Oberlin et al. 1996; Tran and Miller 2003). Beyond the immune defense, chemokines and their receptors contribute to organogenesis, including hematopoiesis, angiogenesis, and development of heart and

brain (Tachibana et al. 1998; Zou et al. 1998; Ma et al. 1998; Locati and Murphy 1999), and are essential for maintenance, maturation, and migration of hematopoietic and neural stem cells (Lapidot and Petit 2002; Tran and Miller 2003). However, some pathogens are able to hijack certain chemokine receptors for their purposes, such as the mediation of HIV-1 infection (Dragic et al. 1996; Oberlin et al. 1996; Locati and Murphy 1999; Sodhi et al. 2004).

HIV-1 infects macrophages and lymphocytes in the periphery and microglia in the brain after binding of the viral envelope protein gp120 to CD4 in conjunction with one of several possible chemokine receptors. CD4 and HIV-1/gp120 coreceptors are likely the first sites of host-virus interaction. Different HIV-1 strains may use CCR5 (CD195) – and CCR3 on microglia – or CXCR4 (CD184) or a combination of these chemokine receptors to enter target cells, depending on specific properties of their gp120 (Dragic et al. 1996; Oberlin et al. 1996; He et al. 1997a). Generally, "T-tropic" viruses predominantly infect T lymphocytes via the α-chemokine receptor CXCR4 and/or the β-chemokine receptor CCR5. In contrast, "M-tropic" HIV-1 primarily enter macrophages and microglia via CCR5 and CCR3, although CXCR4 may also be involved (He et al. 1997a; Michael and Moore 1999; Ohagen et al. 1999; Chen et al. 2002). Of note, usage of CCR5 is neither necessary nor sufficient for macrophage tropism, and CXCR4-preferring viruses can infect macrophages (Gorry et al. 2005; Li et al. 1999; Yi et al. 1998, 2003). In any case, chemokine receptors play crucial roles on several levels in HIV-1 disease (Verani and Lusso 2002). Usually, CCR5-preferring HIV-1 strains (R5-tropic) are transmitted between humans, and individuals lacking CCR5 are highly resistant to primary HIV infection (Liu et al. 1996). CXCR4-using viruses (X4-tropic) occur in about 50 % of infected individuals later in the course of HIV-1 disease and generally indicate progression to AIDS (Michael and Moore 1999). These X4-tropic viruses can easily be transmitted via blood transfusion or shared needles in intravenous drug users. However, in many HIV/AIDS patients, R5-tropic viruses evolve over time into more cytopathic variants possessing higher CCR5 affinity combined with diminished CD4 dependence, and a switch in coreceptor usage does not occur (Gorry et al. 2005).

In the brain, neurons and astrocytes express among other chemokine receptors also CCR5 and CXCR4 (Asensio and Campbell 1999; Miller and Meucci 1999), although these cell types, in contrast to microglia, are not thought to harbor productive HIV-1 infection under in vivo conditions. However, HIV infection of astrocytes seems to occur and require the help of a mannose receptor (Liu et al. 2004). Contrasting earlier reports indicating nonproductive infection, recent studies suggest that under certain conditions of immune activation, astrocytes may be able to produce virus (Li et al. 2011). In any case, several in vitro studies strongly suggest that CXCR4 is prominently involved in HIV-associated neuronal damage, whereas CCR5 may play a dual role by mediating either a toxic or protective effect depending on the kind and concentration of its available ligands (Hesselgesser et al. 1998; Meucci et al. 1998, 2000; Kaul and Lipton 1999; Kaul et al. 2007).

5 HIV-1-Induced Neurotoxicity

While progress is being made in unraveling the pathological processes, it remains a controversial issue how exactly HIV-1 infection provokes neuronal injury and death as well as neurocognitive and motor impairment (Kaul et al. 2005; Mattson et al. 2005; Gonzalez-Scarano and Martin-Garcia 2005; Kramer-Hammerle et al. 2005). There is general agreement that HIV does not infect postmitotic, mature neurons, but the mechanism of neuronal damage is in question.

Recent evidence suggests that viral clade may influence the occurrence of HIV-associated neuronal injury and development of HAND (reviewed in Gannon et al. (2011)). However, the HIV-1 genome of all clades encodes nine gene products which serve three major biological functions: (i) structure (Gag, polymerase (Pol), envelope protein (Env, gp120 and gp41)), (ii) regulation (transactivator of transcription (Tat), regulatory for expression of viral proteins (Rev)), or iii) accessory functions (viral protein u (Vpu), viral protein r (Vpr), viral infectivity factor (Vif), negative factor (Nef); recently reviewed in Ellis et al. (2007)). Most of these viral factors have been linked to distinct functions during infection and in the viral life cycle. Thus, whereas various HIV proteins affect the course of viral infection and disease, the envelope gp120 seems to play a major role in the induction of apoptosis in infected and uninfected bystander lymphocytes (Perfettini et al. 2005a, b). On the other hand, six HIV proteins have been reported to directly or indirectly affect neurons and glia (Ellis et al. 2007), and there exists ample evidence for neuronal injury by the five viral proteins Tat, Nef, Vpr, and the Env proteins gp120 and gp41 (Brenneman et al. 1988; New et al. 1997; Adamson et al. 1996; Piller et al. 1998; Koedel et al. 1999; Kaul et al. 2001, 2005; Mattson et al. 2005).

Human macrophages (and lymphocytes) provide suitable models to investigate HIV infection and potential neurotoxic effects in vitro and also in vivo, when injected into immunocompromised mice. However, using the intact virus and infection does not permit to study the contribution of a particular virus component to CNS injury. In order to study the injurious potential of HIV components in the brain in vivo, a number of transgenic mouse models have been generated (Toggas and Mucke 1996; Maung et al. 2012; Power et al. 2012; Gorantla et al. 2012). Transgenic mice expressing HIV/gp120 or Tat in their brains manifested several neuropathological features observed in AIDS brains, such as decreased synaptic and dendritic density, increased numbers of activated microglia, and pronounced astrocytosis (Toggas et al. 1994; Kim et al. 2003; Fitting et al. 2010). HIV/gp120 transgenic mice also developed significant physiological and behavioral changes, such as reduced escape latency, swimming velocity, and spatial retention at 12 months of age (Mucke et al. 1995; Krucker et al. 1998; Asensio et al. 2001; D'hooge et al. 1999). Following induction of Tat expression with doxycycline (Dox), inducible HIV-/Tat-transgenic (iTat-tg) mice displayed failure to thrive, impaired movement, and compromised spatial learning and memory (Kim et al. 2003; Carey et al. 2012; Fitting et al. 2012). HIV/Vpr-transgenic mice showed injury and loss of neurons and astrocytes but surprisingly lacked overt signs of neuroinflammation (Jones et al. 2007;

Power et al. 2012). Nevertheless, Vpr-tg mice developed learning and memory impairment. The relevance of the transgenic models was supported by findings obtained in two mouse models using HIV-infected human immune cells. In the first model, HIV-infected human macrophages were intracerebrally administered into mice with severe combined immunodeficiency (SCID) (Tyor et al. 1993; Persidsky et al. 1996), and the second model employed mice with a humanized hematopoietic system (Gorantla et al. 2010; Dash et al. 2011). The chimeric mice in the second model were infected with HIV-1 and followed for 15 weeks. The neuropathology in these latter two models using intact HIV-1 also resembled numerous pathological features of human AIDS brains and was in particular comparable to the brain injury observed in both HIV/gp120tg and HIV/iTat-tg mice.

Over time investigations using in vitro and in vivo models have generated evidence for at least two different hypotheses on how HIV-1 initiates neuronal damage in the brain. The hypotheses can be described as the "direct injury" hypothesis and the "indirect" or "bystander effect" hypothesis. These two hypotheses are by no means mutually exclusive, and while the available data support a role for both, an indirect form of neurotoxicity may predominate in a setting where monocytic, glial, and neuronal cells are present (Fig. 2) (Gartner 2000; Kaul et al. 2001, 2005; Mattson et al. 2005; Gonzalez-Scarano and Martin-Garcia 2005).

5.1 Direct Neuronal Toxicity

The hypothesis that HIV proteins can directly injure neurons without any contribution of nonneuronal cells (microglia and/or astrocytes) is supported by experiments showing that several viral proteins, including envelope protein gp120, are toxic in serum-free primary neuronal cultures (Meucci et al. 1998, 2000) and in neuroblastoma cell lines (Hesselgesser et al. 1998). The impact of neurotoxic factors secreted by non-neuronal cells is minimized in these experimental paradigms because serum-free neuronal cultures contain few if any nonneuronal cells and neuroblastoma or other neuron-type cell lines do not contain cells of other phenotypes.

In case of HIV envelope protein gp120, which interacts with several members of the chemokine receptor family (see above), the direct form of HIV-induced neuronal injury may be mediated by chemokine receptor signaling in the absence of CD4 (Hesselgesser et al. 1998). Indeed, experiments employing an inhibitor of CXCR4 can in some cases prevent HIV/gp120-induced neuronal apoptosis (Meucci et al. 1998; Kaul and Lipton 1999; Zheng et al. 1999; Meucci et al. 2000). In a different study, gp120 was found to interact at nanomolar concentrations with the glycine binding site of the *N*-methyl-*D*-aspartate-type glutamate receptor (NMDAR) (Fontana et al. 1997), suggesting an alternative mechanism by which HIV/gp120 may directly interfere with neuronal function and viability.

Interestingly, gp120 of the CXCR4-preferring HIV-1 strain IIIB can be endocytosed by neuronal axons and subsequently disturb axonal transport

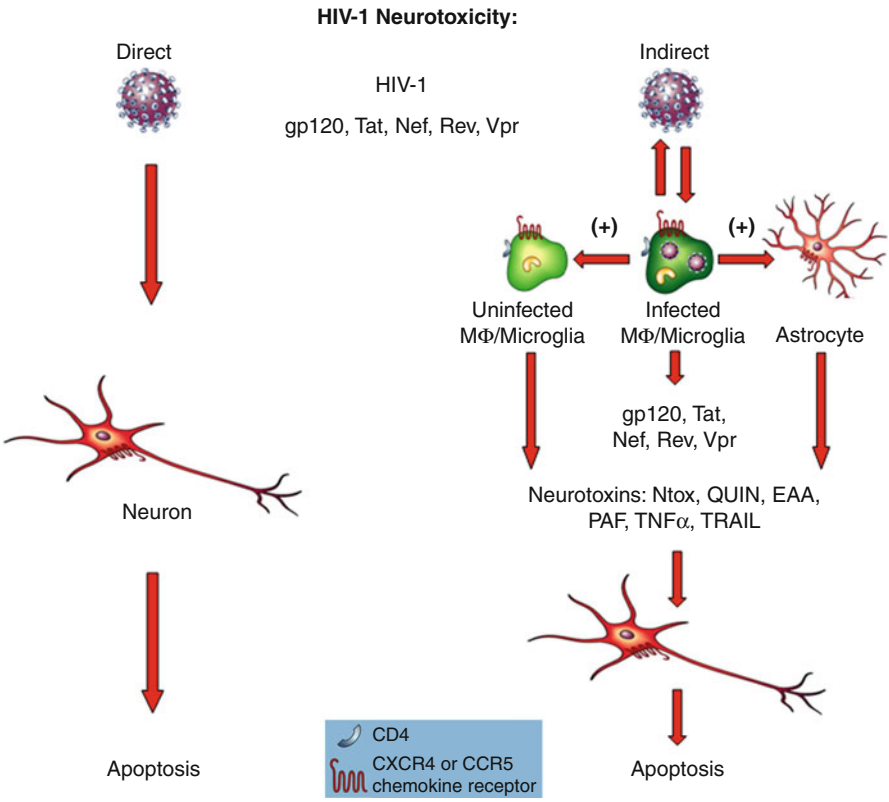

Fig. 2 *Schematic representation of direct and indirect HIV-1-induced neurotoxicity*. Studies using in vitro and in vivo models have generated evidence for at least two different hypotheses on how HIV-1 initiates neuronal damage in the brain: the "direct injury" hypothesis and the "indirect" or "bystander effect" hypothesis. These two hypotheses are by no means mutually exclusive. The "direct injury" hypothesis proposes that HIV and its proteins can directly damage and kill neurons without any contribution of nonneuronal cells, in particular microglia and/or astrocytes. The "indirect" or "bystander effect" hypothesis suggests that activation of macrophages and microglia by HIV infection or viral components and subsequent release of neurotoxins, such as excitotoxins and/or proinflammatory cytokines and mediators, provide the predominant trigger for neuronal injury and death. Macrophages (MΦ) and microglia are the major productively HIV-infected cell type in the brain and as such produce and release the virus and its components as well as cytokines and other factors that can stimulate uninfected MΦ/microglia and astrocytes. It is important to note that toxic viral proteins among factors released from microglia and excitatory glutamate and cytokines set free by astrocytes may all act in concert to provoke neurodegeneration and HAND, even in the absence of extensive viral invasion of the brain. Final neuronal loss seems to occur through apoptosis

(Mocchetti et al. 2012). Since neurotrophic support is critically dependent on this mode of transport, gp120 may not only compromise the endocytotic compartment but also neurotrophin function, and thus promote neuronal injury and demise. A follow-up study by the same group provided evidence that gp120 in addition

alters the neuronal processing of brain-derived neurotrophic factor (BDNF) in a fashion that facilitates neuronal deterioration (Bachis et al. 2012).

The viral regulatory protein Tat can freely diffuse through membranes and therefore interact with cellular binding partners on the surface as well as inside a cell (Fawell et al. 1994). Moreover, Tat can in principle interact with all cells although the consequences may vary between the individual cell types and depending on what Tat-interacting cellular factors are present. Tat can be taken up into neuron-like PC12 cells by a receptor-mediated mechanism (Liu et al. 2000) and may also have a direct effect on primary neurons by potentiating the response to excitotoxic stimuli (reviewed in (Mattson et al. 2005)). The various cell surface receptors that can interact with Tat include chemokine receptors, such as the CCR2, CCR3, and the HIV coreceptor CXCR4 (CD184), the low-density lipoprotein receptor-related protein (LRP), group I metabotropic glutamate receptors (mGluRs), and NMDA-type ionotropic glutamate receptors (Albini et al. 1998; Ghezzi et al. 2000; Xiao et al. 2000; Eugenin et al. 2007; Neri et al. 2007; Li et al. 2008). Inside a cell, Tat can affect glucagon synthase kinase (GSK) 3β and various transcription factors, such as nuclear receptor chicken ovalbumin upstream promoter transcription factor (COUP-TF) and AFF4 (Maggirwar et al. 1999; Rohr et al. 2000; He et al. 2010). A more recent study linked for the first time Tat to dysregulation of neuronal microRNAs (miR), including miR-128. The upregulation of miR-128 inhibited expression of the presynaptic protein SNAP25 (Eletto et al. 2008) and indicated a new way of how Tat may compromise synaptic function. Another report described a Tat-induced pathway to neurite retraction that required p73 and p53 and also led to accumulation of the pro-apoptotic Bcl-2 family protein Bax (Mukerjee et al. 2008). Finally, another direct pathway to neuronal injury initiated by Tat seems to involve activation of neuronal ryanodine receptors (RyR) by Tat, which causes a rapid loss of calcium (Ca^{2+}) from the endoplasmic reticulum (ER) and induces the unfolded protein response (UPR) and mitochondrial hyperpolarization (Norman et al. 2008). The latter is associated with a compromised capability to buffer intracellular Ca^{2+} and thus may affect neuronal excitability and synaptic activity.

Experiments using cultured hippocampal neurons suggested that the HIV protein Vpr may cause direct neurotoxicity through formation of a cation-permeable channel (Piller et al. 1998; Huang et al. 2000). Other studies found that HIV-1 Vpr induced apoptosis via a direct interaction with the mitochondrial adenine nucleotide translocator (ANT) and an effect on the permeability transition pore complex (PTPC) (Jacotot et al. 2000). However, the compromise of mitochondrial membrane potential and nuclear apoptosis triggered by Vpr were blocked in the presence of Bcl-2 (Jacotot et al. 2001). In human NT2 cell-derived neurons, Vpr was found to activate caspase-8 and trigger apoptosis (Pomerantz 2004). In a separate study, Vpr caused neuronal apoptosis accompanied by cytochrome c release, p53 induction, activation of caspase-9, and a diminishing effect on whole-cell currents. The same study found in Vpr-transgenic (tg) animals that the viral protein affected γ-aminobutyric acid (GABA)-ergic and cholinergic neurons in the basal ganglia besides a decreased immunoreactivity for subcortical synaptophysin and an

increase in activated caspase-3 (Jones et al. 2007). Of note, the in vivo neuropathology caused by Vpr in the tg mouse model may have resulted from direct and indirect effects (Power et al. 2012). Vpr was also reported to affect neuronal development by inducing mitochondrial dysfunction, reduced intracellular ATP concentration, compromised axonal transport of mitochondria, and consequent inhibition of axonal outgrowth (Kitayama et al. 2008).

HIV/Nef was also found to compromise neuronal survival, but the mechanism of the reported direct effect remained unknown (Trillo-Pazos et al. 2000). Of note, other studies found that Nef was present in astrocytes of HAD patients and induced apoptosis in astrocytes and neurons (He et al. 1997b). However, Nef triggered neuronal death indirectly because neurotoxicity required the presence of astrocytes and depended on their release of the CXCR3 ligand CXCL10/IP10 (van Marle et al. 2004).

A study investigating the potential neurotoxicity of HIV/Rev in vivo observed a lethal effect in mice that was linked to possible disturbance of cell membranes (Mabrouk et al. 1991). However, an in vitro study using nonneuronal cells found that Rev disturbed the structure of nucleoli and slowed the cell cycle during mitosis (Miyazaki et al. 1995). Thus, one may wonder whether Rev can affect besides HIV-infected, activated lymphocytes producing virus, also proliferating neural precursor cells.

While the absence of nonneuronal cells permits the investigation of potential direct effects of viral proteins on neurons, one ought to bear in mind that because of the absence of nonneuronal cells, a predominantly indirect effect cannot be detected. Notably, in the pathophysiological setting of the brain, neurons always encounter the potential toxins in the presence of glial and sometimes immune cells. Therefore, direct interaction of viral proteins with neurons, such as gp120 with neuronal chemokine receptors (Hesselgesser et al. 1997, 1998), may contribute to neuronal injury, but numerous additional studies suggest that activation of macrophage HIV coreceptors and subsequent release of neurotoxins, such as excitotoxins, chemokines, and/or proinflammatory cytokines, provide the predominant trigger for neuronal injury and death (Giulian et al. 1993; Kaul and Lipton 1999; Porcheray et al. 2006; O'Donnell et al. 2006; Cheung et al. 2008; Eggert et al. 2010; Medders et al. 2010).

5.2 Indirect Neuronal Toxicity

Intact HIV-1, as well as picomolar concentrations of isolated viral envelope gp120, can induce neuronal death via CXCR4 and CCR5 receptors in cerebrocortical and hippocampal neurons and neuronal cell lines from humans and rodents (Hesselgesser et al. 1998; Iskander et al. 2004; Walsh et al. 2004; Meucci et al. 1998; Ohagen et al. 1999; Kaul and Lipton 1999; Chen et al. 2002; Garden et al. 2004; Kaul et al. 2007). In mixed neuronal/glial cerebrocortical or hippocampal cell cultures which model the cellular composition of brain regions affected by HIV, virus and gp120-induced apoptotic death appears to be mediated predominantly via the release of toxins from microglia and macrophages rather than by direct neuronal

damage (Brenneman et al. 1988; Iskander et al. 2004; Walsh et al. 2004; Giulian et al. 1990; Kaul and Lipton 1999; Chen et al. 2002; Garden et al. 2004; Medders et al. 2010). In fact, both the absence or inactivation of macrophages and microglia basically abrogates the neurotoxicity of HIV-1 and gp120 in mixed neuronal/glial cultures (Giulian et al. 1990; Giulian et al. 1993; Kaul and Lipton 1999; Chen et al. 2002; Garden et al. 2004; O'Donnell et al. 2006; Medders et al. 2010). Since at least in vitro inhibition of microglial activation suffices to prevent neuronal death after gp120 exposure, it seems likely that stimulation of CXCR4 or CCR5 in macrophages and microglia is a prerequisite for the neurotoxicity of HIV-1 and gp120 (Ohagen et al. 1999; Kaul and Lipton 1999). This hypothesis is further supported by our observation that introduction of HIV coreceptor-expressing macrophages sufficed to restore neurotoxicity of gp120 in cerebrocortical cultures genetically deficient in both CXCR4 and CCR5 (Medders et al. 2010).

Chemokine receptors, including HIV coreceptors, are highly conserved between species (Maung et al. 2012). Therefore, our group recently studied the role of chemokine receptors in the neurotoxicity of gp120 using mixed neuronal/glial cerebrocortical cell cultures from rat and mouse. We observed that gp120 from CXCR4 (X4)-preferring as well as CCR5 (R5)-preferring and dual tropic HIV-1 strains all were able to trigger neuronal death, thus suggesting that both HIV coreceptors can mediate neurotoxicity, each alone and in combination (Kaul et al. 2007).

Experiments with cerebrocortical cell cultures from chemokine receptor knockout and wild-type mice addressed the role of each HIV coreceptor separately. Neurotoxicity of X4-preferring gp120 was strongly reduced or absent in CXCR4-deficient cerebrocortical cultures, while gp120 from a R5-preferring HIV-1 strain showed no longer neurotoxicity in the absence of CCR5. Surprisingly, however, gp120 of the dual tropic HIV-1_{SF2} exerted even greater neurotoxicity in CCR5 knockout cultures compared to wild-type or CXCR4-deficient cerebrocortical cells. Nevertheless, gp120 of HIV-1_{SF2}, like all other tested gp120s, was no longer toxic to double KO cerebrocortical cultures lacking both chemokine receptors (Kaul et al. 2007). The finding that the CCR5 or CXCR4 knockout significantly decreased neurotoxicity by CCR5- or CXCR4-preferring gp120s, respectively, resembles the specificity of HIV coreceptors in human cells and thus confirmed the rodent system as a suitable model.

In addition, we observed earlier that the CCR5 ligands CCL4/MIP-1β and CCL5/RANTES protected neurons against gp120-induced toxicity (Kaul and Lipton 1999). Interestingly, this protective effect was strictly dependent on CCR5 but occurred no matter if gp120 preferred CXCR4 or CCR5 or both coreceptors. While the β-chemokines may have prevented CCR5-preferring gp120 from interacting with its receptor by competitive displacement, the blockade of CXCR4-mediated toxicity apparently involved heterologous cross-desensitization of this receptor via stimulation of CCR5 (Kaul et al. 2007). These findings were consistent with a primarily neurotoxic activation of CXCR4 by gp120. In contrast, CCR5 may at least in part have stimulated cytoprotective signals depending on the HIV-1 strain from which a given envelope protein originated and depending on

whether or not antiviral and cytoprotective β-chemokines were present (Cocchi et al. 1995; Kaul et al. 2007).

Interestingly, in macrophages, HIV-1 infection and exposure to just the envelope protein gp120 seem to trigger a similar neurotoxic phenotype (Giulian et al. 1990, 1993). Tat and Nef each alone also causes activation of mononuclear phagocytes and release of cytokines as it can occur upon viral infection (Federico et al. 2001; Olivetta et al. 2003; Sui et al. 2006). In contrast, Vpr seems to promote a rather anti- than proinflammatory phenotype despite evidence that this viral protein plays an important role in HIV production in macrophages (Herbein et al. 2010; Power et al. 2012).

In any case, uninfected macrophages and microglia can be stimulated by factors released from infected cells. These factors include cytokines, such as IL-1β, IL-6, and TNFα, but also TNF-related apoptosis-inducing ligand (TRAIL), matrix metalloproteinases (MMPs), arachidonic acid metabolites, and platelet-activating factor (PAF), and shed viral proteins, such as gp120, Tat, Vpr, and Nef (Wahl et al. 1989; Achim et al. 1993; Gelbard et al. 1994; Miura et al. 2003a, b; Ryan et al. 2004; Conant et al. 1998; Johnston et al. 2000; Herbein et al. 2010). Variations of the HIV-1 gp120, in particular in its V1, V2, and V3 loop sequences, have been implicated in modulating the neurotoxicity of macrophages and microglia (Power et al. 1994, 1998). Activated microglia affect all cell types in the CNS, resulting in further upregulation of cytokines, chemokines, and endothelial adhesion molecules within the brain (Gartner 2000; Kaul et al. 2001, 2005; Gonzalez-Scarano and Martin-Garcia 2005; Kramer-Hammerle et al. 2005).

Some of the secreted factors from activated microglia or macrophages and astrocytes may directly or indirectly contribute to neuronal damage and apoptosis as discussed above for viral proteins. Directly neurotoxic host factors released from HIV-infected or activated microglia and macrophages include excitatory amino acids (EAAs) and related substances, such as quinolinate, a not completely characterized amine compound named "Ntox" but potentially also TRAIL (Giulian et al. 1990; Kramer-Hammerle et al. 2005; Lipton et al. 1991; Heyes et al. 1991; Kaul et al. 2001, 2005; Gonzalez-Scarano and Martin-Garcia 2005; Yeh et al. 2000; Miura et al. 2003a, b; Ryan et al. 2004). EAAs and quinolinic acid can trigger neuronal apoptosis through a process known as excitotoxicity. This detrimental process involves excessive Ca^{2+} influx and free radical (nitric oxide and superoxide anion) formation by overstimulation of glutamate receptors (Lipton et al. 1991), activation of stress-associated protein kinases and caspases, and production of proinflammatory lipids (Kaul et al. 2001; Mattson et al. 2005; Gonzalez-Scarano and Martin-Garcia 2005; Kramer-Hammerle et al. 2005; Jones and Power 2006; Nicotera et al. 1997).

It is important to note that toxic viral proteins among factors released from microglia and glutamate and cytokines set free by astrocytes may all act in concert to provoke neurodegeneration and HAND, even in the absence of extensive viral invasion of the brain. Furthermore, HAND and HAD might share the critical involvement of neuroinflammation and microglial activation with several other neurodegenerative diseases, such as Alzheimer's disease,

multiple sclerosis, Parkinson's disease, and even frontotemporal lobe dementia (Block and Hong 2005).

5.3 Downstream Cellular and Molecular Mechanisms in HIV-1 Neurotoxicity

Beyond infection by intact HIV-1, six of the viral protein components directly or indirectly affect immune cells, neurons, and glia (Ellis et al. 2007), and ample evidence exists for neuronal injury by the five viral proteins Tat, Nef, Vpr, and the Env proteins gp120 and gp41 (Brenneman et al. 1988; New et al. 1997; Adamson et al. 1996; Piller et al. 1998; Koedel et al. 1999; Kaul et al. 2001, 2005; Mattson et al. 2005). Therefore, it is not surprising that the available information suggests that HIV can trigger a plethora of cellular responses and signaling mechanisms. However, it appears that the various viral components that exert cyto- or neurotoxicity do so, at least in part, by converging mechanisms even if each component may start out its contribution to pathogenesis by interacting with different host cell factors. Currently recognized converging mechanisms include neuroinflammation, oxidative stress, interference with the cell cycle machinery, excitotoxicity, and apoptosis.

Recently, we and others found that p38 mitogen-activated protein kinase (MAPK) plays an essential role in the induction of neuronal injury and apoptotic death by HIV-1 gp120, Tat, and the intact virus (Kaul and Lipton 1999; Kaul et al. 2007; Choi et al. 2007; Medders et al. 2010; Singh et al. 2005; Sui et al. 2006; Eggert et al. 2010). Activation of microglia and macrophages by HIVgp120 via CD4, chemokine coreceptors, and downstream p38 MAPK is crucial to neurotoxin production (Kaul and Lipton 1999; Medders et al. 2010). Similarly, others reported that HIV-1 infection as well as Tat and gp120 all activate p38 MAPK and upstream, the mixed lineage kinase (MLK) 3 in infected or stimulated, neurotoxic monocytes and macrophages (Sui et al. 2006; Eggert et al. 2010). Moreover, we have observed that p38 MAPK signaling is essential upon exposure to HIV gp120 for both the neurotoxic phenotype of macrophages and microglia and the subsequent induction of neuronal apoptosis by macrophage toxins (Medders et al. 2010). The requirement of p38 MAPK activity in both macrophages and neurons for the occurrence of HIV gp120 neurotoxicity therefore parallels the indispensability previously reported for the transcription factor p53 (Garden et al. 2004).

Increased activity of p38 MAPK has been linked to inflammation of the brain, such as that seen in HIVE patients and Alzheimer's disease (AD) (Kaminska et al. 2009). Furthermore, neurons showed increased activity of p38 MAPK when they were cocultured with LPS-stimulated microglia, and this kinase signaling was essential to induction of neuronal death (Xie et al. 2004). Amyloid-β-induced activation of p38 MAPK resulted in upregulation of proinflammatory cytokines TNFα, immunologic, inducible nitric oxide synthase (iNOS), and interleukin (IL)-1β and subsequent neuronal death (Delgado et al. 2008). Our and other groups showed that inhibition of p38 MAPK activity in vitro with pharmacological

inhibitor SB203580 or dominant-negative p38αAF (TGY substituted with AGF) prevented neuronal death induced by HIV-1 gp120 or glutamate (Kaul and Lipton 1999; Singh et al. 2005; Kaul et al. 2007; Choi et al. 2007; Chaparro-Huerta et al. 2008). HIV-1 Tat and gp120 both were found to activate MLK 3, which controls p38 MAPK and JNK pathways, in neurons (Sui et al. 2006; Gallo and Johnson 2002). Inhibition or MLK 3 protected neurons from toxicity of gp120, Tat, and HIV-1-infected macrophages (Sui et al. 2006; Eggert et al. 2010). Of note, while pharmacological inhibition of p38 MAPK or JNK can both independently ameliorate the toxicity of Tat in cerebellar granular neurons, only blockade of p38 MAPK, but not JNK, could prevent Tat-induced death in striatal neurons (Singh et al. 2005; Sui et al. 2006).

In neurons, p38α MAPK activity is regulated by the intracellular Ca^{2+} concentration and the small GTPase Rho. The concentration of intracellular Ca^{2+} in turn is linked to the activity of the NMDAR-regulated ion channel and excitotoxicity (Semenova et al. 2007). A number of studies have suggested that excitotoxicity itself constitutes one important mechanism of HIV-1-induced neurotoxicity (Dreyer et al. 1990; O'Donnell et al. 2006; Kaul et al. 2001; Lindl et al. 2010). The link between glutamate receptors, influx of Ca^{2+}, Rho, and activation of p38α certainly suggests that in neurons synaptic activity may be a major regulator of the kinase's baseline activity. Our studies indicate that inhibition of p38 MAPK prevents neuronal death in the context of HIV/gp120-induced, macrophage-mediated neurotoxicity, but surprisingly, neurons surviving in the absence of kinase inhibition display a higher level of active p38 MAPK compared to control cells not exposed to neurotoxins (Medders et al. 2010).

Macrophages and microglia infected with HIV-1 or stimulated by viral gp120, Tat, or Nef release neurotoxins, some of which stimulate the NMDAR, an ionotropic glutamate and neurotransmitter receptor (Dreyer et al. 1990; Chen et al. 2002; Smith et al. 2001; Sui et al. 2007). NMDAR antagonists can ameliorate neuronal cell death in vitro due to HIV-infected macrophages or purified recombinant gp120 (Dreyer et al. 1990; Chen et al. 2002) and in vivo in gp120 transgenic mice (Toggas et al. 1996). Under physiological conditions, activation of ionotropic glutamate receptors in neurons initiates a transient depolarization and excitation. However, extended or excessive NMDAR activation results in excitotoxicity because the prolonged channel opening leads to a sustained elevation of the intracellular Ca^{2+} concentration and thus compromises mitochondrial function and cellular energy metabolism, which in turn causes the generation of free radicals (Lipton and Rosenberg 1994; Doble 1999; Olney 1969). In case the initial excitotoxic insult is fulminant, for example, in the ischemic core of a stroke, the neurons die early from loss of ionic homeostasis, resulting in acute swelling and cell lysis (necrosis). If the insult is milder, as seen in several neurodegenerative disorders, including HAND/HAD, neurons may enter a delayed death pathway known as programmed cell death or apoptosis (Nicotera et al. 1997; Petito and Roberts 1995). Neuronal apoptosis following exposure to gp120-induced macrophage toxins or after a direct excitotoxic insult involves Ca^{2+} overload, activation of p38 MAPK and p53, release of cytochrome c and other molecules such as apoptosis-inducing

factor (AIF) from mitochondria, activation of caspases, free radical formation, lipid peroxidation, and chromatin condensation (Tenneti et al. 1998; Kaul and Lipton 1999; Asensio and Campbell 1999; Garden et al. 2002, 2004; Kaul et al. 2007). The increase of intracellular Ca^{2+} has also been linked to the detrimental activation of the Ca^{2+}-dependent protease Calpain and the activating, proteolytic cleavage of the cell cycle-dependent kinase (Cdk)-5 (Wang et al. 2007). Excessive activation of Ca^{2+}-dependent proteolysis has also been implicated in synaptic injury where the scaffolding inside of pre- and postsynaptic endings may be compromised and thus disturb timely trafficking and localization of vesicles as well as receptor signaling (Lindl et al. 2010). In line with Ca^{2+}-dependent oxidative stress is a different study reporting that in human neurons, CXCR4 mediates the toxic effect of gp120 via a process involving the synthesis of ceramide and NADPH-dependent production of superoxide radicals (Jana and Pahan 2004).

Oxidative stress is a well-recognized cellular response triggered by infections, inflammation, as well as excitotoxicity and occurs in the context for HIV infection or exposure to viral proteins (Roederer et al. 1992; Walmsley et al. 1997; Shi et al. 1998; Corasaniti et al. 2000; Mollace et al. 2001; Boven et al. 1999; Haughey et al. 2004; Louboutin et al. 2007; Agrawal et al. 2009). Oxidative damage occurs in proteins, lipids, and nuclear DNA and can therefore contribute in several ways to neuronal deterioration (Louboutin et al. 2010; Haughey et al. 2004; Bonfoco et al. 1995; Zhang et al. 2012). Interestingly, gp41 in infected cells was found to correlate with the expression of iNOS in AIDS brains and cause neurotoxicity in vitro in an NO-dependent fashion (Adamson et al. 1996). Oxidative stress alters proteins by causing carbonylation and affects lipid metabolism. The latter leads to generation of distinct patterns of ceramide, sphingomyelin, and hydroxynonenal (HNE) detectable in brain tissue and CSF of HAND patients (Turchan et al. 2003; Haughey et al. 2004; Mattson et al. 2005). In line with oxidative stress is the upregulation of the transcription factor ATF-6ß and of the ER chaperone BiP indicating ER stress in neurons and astrocytes of brains from neurocognitively impaired HIV patients (Lindl et al. 2007). In a more recent follow-up study, the same group linked ATF-6ß and BiP to an "integrated stress response," which brains of HAND/HAD patients may share with other neurodegenerative diseases (Akay et al. 2012).

Autophagy allows cells to remove exhausted or damaged organelles or to replenish their resources under starvation conditions and appears to be an essential mechanism to maintain cellular homeostasis. Recent studies strongly suggest that autophagy is disturbed in HIV infection and neurodegenerative diseases, including HIVE and HAND (Espert et al. 2006; Alirezaei et al. 2008; Zhou et al. 2011; Hui et al. 2012). Another mechanistic link to HIV neurotoxicity is suggested by the observation that both TNFα and excitotoxic glutamate concentrations seem to compromise neuronal autophagy and in this way also promote cell death (Alirezaei et al. 2008).

HIV-infected or gp120-activated microglia also release inflammatory cytokines, such as TNFα (Achim et al. 1993; Wesselingh et al. 1997; Persidsky et al. 1997). TNFα directly affects glutamate neurotransmission in a p38 MAPK-dependent

manner by increasing the synaptic expression of certain glutamate receptors (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; AMPAR) and inhibiting long-term potentiation (LTP) (Butler et al. 2004; Pickering et al. 2005). Interestingly, a significant change in the expression at the RNA level of a number of ion channels was reported for brains of HIV patients with various degrees of HAND in comparison to uninfected controls (Gelman et al. 2004). Those disturbances of the ion channel repertoire were likely to affect excitability of neuronal membranes, neurotransmission, as well as the propagation of action potentials in neurons. Therefore, it was proposed that a channelopathy could be underlying the development of HAND and its most severe form, HAD. In any case, TNFα can inhibit astroglial glutamate transporters and thus promote neurotoxicity by facilitating glutamate excitotoxicity (Pickering et al. 2005) or even provoke neurotransmitter release from glial cells (Benveniste and Benos 1995; Bezzi et al. 2001). Interestingly, TNFα can synergize with HIV/Tat to initiate neuronal death, but antioxidants block the process (Ohagen et al. 1999). Finally, it remains possible that TNFα activates caspases in neurons via TNFα receptor-1 (TNFR1). TNFR1 is expressed on at least some neurons, and it can initiate caspase-8 activation, which in turn may activate caspase-3, leading to apoptosis. We found that neutralization of TNFα with antibody or pharmacological inhibition of caspase-8 prevented the neurotoxicity of HIV/gp120 in cultured cerebrocortical neurons (Garden et al. 2002).

Supporting a prominent role of neuronal apoptosis in the development of HAND and HAD, activated caspase-3 and p53 were prominently detected in neurons of brains from neurocognitively impaired HIV patients (Garden et al. 2002). Furthermore, in vitro, neuronal caspase-3, caspase-8, and caspase-9 were found to be necessary for HIV-1/gp120 to cause neurotoxicity, and p53 was essential not only in neurons but also in microglia (Garden et al. 2002, 2004; Tun et al. 2007). Separate studies suggested that CXCR4 and p53 are connected through signaling pathways that mediate toxic or protective mechanisms depending on whether gp120 or SDF-1, the receptor's natural binding partner, serves as the ligand (Khan et al. 2005). Contrary to gp120 of $HIV1_{IIIB}$, CXCL12/SDF-1 was neuroprotective in this experimental paradigm. The α-chemokine activated Akt and MAPKs (Khan et al. 2004) and regulated the expression and localization of cell cycle proteins (Khan et al. 2003, 2005). CXCL12/SDF-1 increased acetylation of p53 and p21 as well as the expression of retinoblastoma protein (Rb) while reducing the amount of phosphorylated Rb in the nucleus. Together with a reduction of the activity of the transcription factor E2F1, an overall anti-apoptotic effect was observed. In contrast, envelope protein of $HIV\text{-}1_{IIIB}$ triggered activation of Apaf-1 and promoted cell death. Besides these in vitro findings, a role for a disturbed cell cycle machinery in the development of HAND was supported by abnormal changes in the expression pattern of the same cell cycle proteins in *postmortem* brains of nonhuman primates with SIV encephalitis and humans with HIVE (Jordan-Sciutto et al. 2002). Interestingly, these changes in cell cycle proteins also correlated with the presence of activated microglia and macrophages. Moreover, cell cycle inhibition has been shown to protect neurons in excitotoxic circumstances from induction of apoptosis (Park et al. 2000).

6 Effects of HIV-1 on Neurogenesis

Compared to the discovery of HIV-induced neurotoxicity, the appreciation of the virus' effect on neurogenesis is a relatively recent development. Notably, HIV primarily seems to compromise the proliferation of neural progenitors but not kill the cells (Krathwohl and Kaiser 2004a, b; Okamoto et al. 2007; Peng et al. 2008). Therefore, HIV does not exert a lethal cytotoxic effect on neural precursors, but rather exacerbates the effects of the above-discussed toxicity in postmitotic and terminally differentiated neurons by impairing neurogenesis and brain homeostasis.

It is widely accepted that HIV-1 fails to productively infect neurons, but it has been reported that neural progenitor cells are permissive to the virus (Lawrence et al. 2004; Mattson et al. 2005; Schwartz and Major 2006). However, infection seems dispensable as HIV-1 gp120 and chemokines suffice to disturb human or rodent neural progenitor cells (Krathwohl and Kaiser 2004a, b; Okamoto et al. 2007). One study showed that chemokines promoted the quiescence and survival of human neural progenitor cells via stimulation of CXCR4 and CCR3 and a mechanism that involved downregulation of extracellularly regulated kinase-1 and kinase-2 (ERK-1/ERK-2) with simultaneous upregulation of the neuronal glycoprotein reelin (Krathwohl and Kaiser 2004a). Exposure to intact HIV-1 also caused quiescence of neural progenitors through engagement of CXCR4 and CCR3. In contrast to the chemokines, the viral envelope protein gp120 downregulated ERK-1/ERK-2 but had no effect on reelin (Krathwohl and Kaiser 2004b). Interestingly, the effects of both the chemokines and HIV-1/gp120 were reversible and could be inhibited with recombinant apolipoprotein E3 (ApoE3), but not ApoE4. Finally, fewer adult neural progenitor cells were detected in the dentate gyrus of the hippocampus in *postmortem* brain specimen from HAD patients than from non-demented and uninfected controls (Krathwohl and Kaiser 2004b).

Cultures of primary rodent and human neural progenitor cells obtained from fetal or adult tissue express CXCR4 and CCR5 besides the neural progenitor marker nestin and readily undergo cell division. After several rounds of proliferation, the progenitors exit the cell cycle and begin to express neuronal markers such as βIII-tubulin (TuJ1). We found that exposure to HIV-1/gp120 in vitro reduced the proliferation of adult progenitors without producing cell death. Others observed a virtually identical effect brought about by HIV Tat (Mishra et al. 2010). Similar to what others observed in brain specimen from HAD patients, we found a reduction of proliferating neural progenitors in the hippocampal dentate gyrus of transgenic mice that express HIV/gp120 in the brain in comparison to non-transgenic controls (Okamoto et al. 2007). Accounting for these effects, we found that gp120 inhibited proliferation of neural progenitor cells through activation of a pathway that involved p38MAPK, MAPK-activated protein kinase-2, a cell cycle checkpoint kinase, and Cdc25B/C which in turn caused a delay of the cell cycle in the G1 phase. The decrease in neural progenitor proliferation caused by gp120 constituted an impairment in neurogenesis because there were fewer progenitor cells available to differentiate into neurons (Okamoto et al. 2007). Neurogenesis in the dentate gyrus of the hippocampus has been implicated in learning and memory formation,

neurocognitive functions which are compromised in HAND. The apparent ability of HIV-1 or its component gp120 and Tat to interfere with the normal function of neural progenitor cells suggested the possibility that HAND might develop as a consequence not only of injury and death of existing neurons but also due to virus-induced disturbance of brain homeostasis and renewal mechanisms.

7 Comorbidity Factors of HAND and HIV-1 Neurotoxicity

HIV infection, HAND, and AIDS are frequently associated with the use of recreational drugs, such as methamphetamine, cocaine, and opiates (Rippeth et al. 2004; Urbina and Jones 2004; Kapadia et al. 2005; Mitchell et al. 2006; Nath 2010; Beyrer et al. 2010; Gannon et al. 2011). Intravenous drug use not only is a risk factor for contracting HIV through needle sharing but also promotes coinfection with hepatitis C virus (HCV) (Gatignol et al. 2007; Clifford et al. 2009; Cherner et al. 2005). The scientific literature provides ample evidence that both abused drugs and infectious agents, such as HIV and HCV, compromise the immune and nervous system, but this still-expanding topic is beyond the scope of this chapter. However, there exist excellent reviews addressing the apparent intersection of HAND and HIV-induced neurotoxicity and impaired neurogenesis with drug abuse (Hauser et al. 2006; Ferris et al. 2008; Nath 2010).

HIV infection has become a chronic rather than acute disease due to efficient control of peripheral viral replication by cART and the treatment of opportunistic infections. With the improved survival times, the population of HIV patients has begun to age. While aging is a normal physiological process, evidence is accumulating that HIV infection may lead to earlier occurrence of aging symptoms physically, immunologically, and mentally (Deeks 2009; Brew et al. 2009). Thus, aging is becoming a comorbidity factor associated with long survival of HIV infection. In reverse, the virus can also be seen as a comorbidity factor of aging that accelerates an otherwise normal but later ensuing increase of frailty.

8 Conclusion

HIV-1 infection continues to trigger neurological problems that can culminate in frank dementia, despite efficient virological control by cART. Currently, strong evidence suggests that HIV-1 can strike at the brain in at least two ways: (i) by causing toxicity leading to neuronal injury and death and (ii) by impairing neurogenesis without killing neural precursors. Both of the pathogenic mechanisms share the involvement of neuroinflammatory mediators, and both processes seem to be influenced by host and viral factors, including the interferon response, age, and viral subtypes, as well as treatment and comorbidity factors, such as drug abuse. Microbial translocation may enhance systemic and central inflammation during HIV-1 infection and thus promote the development of HAND. Thus, despite viral control and life-prolonging effects of cART, neuroinflammation and concomitant

activation of macrophages and microglia accompany the continued development of HAND in HIV patients. Besides intact HIV-1, six viral proteins have been reported to directly or indirectly affect neurons and glia and cause neurotoxicity: Tat, Nef, Vpr, Rev, and the Env proteins gp120 and gp41. Experimental evidence generated at least two different hypotheses on how HIV-1 initiates neuronal damage in the brain: (i) the "direct injury" hypothesis and (ii) the "indirect" or "bystander effect" hypothesis. These two hypotheses are by no means mutually exclusive. However, macrophages and microglia constitute the primary productively infected cell type in the brain, suggesting that an indirect form of neurotoxicity may predominate in a setting where monocytic, glial, and neuronal cells are present. Considering that beyond infection by intact HIV-1, six of the viral proteins trigger neuronal injury, it is not surprising that the available information suggests a plethora of cellular responses and signaling mechanisms. However, it appears that the various viral components that exert cyto- or neurotoxicity do so, at least in part, by converging mechanisms even if each component may start out its contribution to pathogenesis by interacting with different host cell factors. Currently recognized converging mechanisms in HIV neurotoxicity include neuroinflammation, MAPK signaling, altered gene expression, oxidative stress, interference with the cell cycle machinery, excitotoxicity, synaptic injury, and neuronal apoptosis.

Cancer-Mediated Neurotoxicity

Andrzej Stepulak, Radosław Rola, and Krzysztof Polberg

Contents

Abstract

The central nervous system is particularly susceptible to cancer, and its treatment side effects result in significant neurologic morbidity and mortality. Conversely, recent improvements in treatment protocols have extended average life expectancies in various subgroups of cancer patients. As a result of the extended survival, quality of survival is becoming much more important, and attention is increasingly being paid to the disease-free period between treatment and death. The majority of the research, however, focuses on potential side effects of various therapeutic modalities. The following contribution is devoted to

exploration of a relatively new concept of tumor-related neurotoxicity with special emphasis on the role of glutamate and glutamate-dependent pathways in tumor development and progression as well as in glutamate-dependent excitotoxicity and its consequences.

Keywords
Cancer • Glutamate • Neurotoxicity • Receptors

List of Abbreviations

AMPA	α-amino-3-hydroxy-5-methyl-4 isoxazolepropionate
EAAT	Excitatory amino acid transporter
ECM	Extracellular matrix
FAK	Focal adhesion kinase
GDH	Glutamate dehydrogenase
Glu	Glutamate
HAA	Hydroxyanthranilic acid
HDI	Histone deacetylase inhibitor
IDO	Indoleamine 2,3-dioxygenase
iGluR	Inotropic glutamate receptor
KA	Kainate
KYNA	Kynurenic acid
LTD	Long-term depression
LTP	Long-term potentiation
MAGUK	Membrane-associated guanylate kinase
mGluR	Metabotropic glutamate receptor
NMDA	*N*-methyl-D-aspartate
NOS	Nitric oxide synthase
PIC	Picolinic acid
QA	Quinolinic acid
TMZ	Temozolomide
TSC	Tumor stem cell

1 Introduction

According to GLOBOCAN database of the International Agency for Research on Cancer, almost 12.7 million new cases of cancer were reported worldwide in 2008, resulting in more than 7.6 million deaths (Ferlay et al. 2010). A significant percentage of those patients are expected to develop complications in sites distant to the original tumor location. The nervous system is particularly susceptible to such complications that result in significant neurologic morbidity and mortality. These effects may be direct, with direct cancer involvement of the brain, spine, or peripheral nervous system (PNS) or indirect as in paraneoplastic neurologic syndromes (Giglio and Gilbert 2010) with symptoms ranging from delirium, amnesia,

aphasia, psychotic disturbance, sensory disturbance, ataxia, and autonomic dysfunction to eye movement disorders (Bataller and Dalmau 2004). Still, the impairments of cognitive functions such as language, memory, visuospatial perception, time–space orientation, and attention or executive functions are the most prevalent (Reid-Arndt et al. 2010). From this perspective a distinct subpopulation of cancer patients is patients with brain tumors, both primary and metastatic ones who, in fact, show signs of cognitive decline in almost all of the cases (Hottinger et al. 2009). As a matter of fact, a cognitive dysfunction often is present at diagnosis in many of those patients, more frequently in rapid-growing tumors such as glioblastoma than in slow-growing ones such as low-grade gliomas (Correa 2010). On the other hand, improvements in treatments have extended average life expectancies in various subgroups of patients with brain tumors, although in most instances the patient cannot be cured and will eventually die from the disease (DeAngelis 2001). As a result of the extended survival, quality of survival is becoming much more important, and attention is increasingly being paid to the disease-free period between treatment and death (Weitzner and Meyers 1997).

The exact pathophysiology of cognitive deficits in patients with brain tumors is not entirely understood. Studies have shown that tumor itself, its progression, tumor-related neurological complications, and epilepsy can cause them (Klein et al. 2002; Aoyama et al. 2007). Diaschisis, in which there is dysfunction of brain areas connected to the original lesion, owing to altered metabolism and blood flow, might also contribute (Taphoorn and Klein 2004). On top of that, disturbances in connectivity between functional networks in the brain have also been reported (Bartolomei et al. 2006). The question remains, however: what is the underlying mechanism responsible for these disturbances?

A recent discovery of glutamate as a neurotrophic factor for gliomas, acting in autocrine or paracrine fashion, not only revealed a potential signaling pathway important for glioma invasion and established a new tool for cancer treatment but also opened a new avenue of research into the mechanisms responsible for neuronal network impairments found in brain tumor patients. Glial tumors, especially malignant gliomas, release significant amounts of Glu into extracellular space, which acts as a growth factor for malignant cells. In the last decade evidence has emerged implicating a role for glutamate as a signal mediator that stimulates cancer cell proliferation and motility via activation of glutamate receptors (GluRs) (de Groot and Sontheimer 2011). Moreover, excess of glutamate causes neurodegeneration of the peritumoral tissue, enabling tumor progression (de Groot and Sontheimer 2011). On the other side, elevated glutamate concentrations in the brain exert neurotoxicity, resulting in neuronal excitotoxicity and cell death, enabling brain tumors to expand, and cause seizures in the tumor-bearing patients (Sontheimer 2008; Buckingham et al. 2011). Importantly, glutamate is considered as one of the major excitatory mediators in the central nervous system (CNS). It affects several physiological processes such us learning, memory, or behavior (Peng et al. 2011). Excessive activation of glutametergic system (high levels of Glu and activation of respective receptors) results in neural cells death called excitotoxicity that is involved in

pathophysiology of various neurodegenerative diseases and other CNS pathologies (epilepsy, hypoxia, stroke) (Lau and Tymianski 2010). Thereby, glioma-derived glutamate seems to be important endogenous neurotoxin.

Glutamate activates two principal classes of receptors: ionotropic (iGluRs) and metabotropic (mGluRs) glutamate receptors. The mGluR receptor family comprises of eight subtypes (mGluR1-8) that are subdivided into three groups based on the sequence similarities and G-protein coupling to specific signal transduction mechanisms. mGluR1 and mGluR5, which are coupled to the phospholipase C, belong to group I. Group II consists of mGluR2 and mGluR3, whereas group III contains mGluR4, mGluR6, mGluR7, and mGluR8, which are all negatively coupled to adenylate cyclase. mGluRs function as dimers, with two glutamate molecules being required for full receptor activation (Shin et al. 2008; Kew and Kemp 2005). In neurons mGluR receptors modulate synaptic transmission and are involved in activity-dependent modification of synaptic transmission such as long-term potentiation and long-term depression, whereas in glial cells they exert a variety of effects that are crucial for glial function and glial–neuronal interaction under physiologic and pathologic conditions (D'Antoni et al. 2008). iGluRs, on the other hand, are subdivided into three groups according to structural similarities and synthetic agonists that activate them: N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), and 2-carboxy-3-carboxymethyl-4-isopropenylpyrrolidine (kainate, KA) receptors.

N-methyl-D-aspartate (NMDA) tetrameric receptors consist of two obligatory NR1 subunits and two of four types of regulatory subunits: NR2A, B, C, and D. The NR1 subunit is necessary for calcium conductivity of the channel, while the NR2 and NR3 subunits determine electrophysiological and pharmacological properties of the receptor. Activation of NMDA receptor requires binding of two agonists: glutamate and glycine. Concurrent membrane depolarization abrogates the magnesium block, which allows calcium and sodium cations to enter the cell. NR3 subunits may assemble with NR1 subunits in order to create a functional glycine receptor that is not affected by glutamate. NMDA receptors are implicated in synaptic transmission and neuronal plasticity phenomena such as long-term potentiation (LTP) and long-term depression (LTD) (Kew and Kemp 2005; Traynelis et al. 2010).

AMPA receptors are homo- or heterotetramers composed of subunits known as GluR1–GluR4. They mediate fast excitatory synaptic signaling in the brain and are involved in activity-dependent modulation of synaptic plasticity. AMPA receptors gate Na+/Ca^{2+} in response to ligand binding. Conductance and kinetic properties of the channel depend upon subunit composition. Influx of ions causes a fast excitatory postsynaptic response in neurons, and Ca^{2+} can also activate second messenger pathways. The GluR2 subunit plays a critical role in the determination of the permeability of AMPARs. The genomic DNA of the GluR2 subunit contains a glutamine (Q) residue at amino acid 607, but during the process of nuclear RNA editing, glutamine is replaced by arginine (R) in the vast majority of neuronal cells, which results in a very low calcium permeability for receptors containing the

GluR2 subunit (Madden 2002; Kew and Kemp 2005). The kinetics and amplitude of the excitatory synaptic response are determined by the biophysical properties of the receptor subunit combination (Traynelis et al. 2010).

KA receptors are composed of tetrameric assemblies of GluR5–7 and KA1/2 subunits. GluR5–7 subunits can form homomeric functional receptors as well as combine with KA1 and KA2 to form heteromeric receptors with distinct pharmacological properties. KA1 and KA2 subunits do not form homomeric functional receptors. Similar to GluR2, GluR5 and GluR6 undergo glutamine/arginine editing (Contractor et al. 2011).

The glutamate cellular system includes also a number of proteins transporting glutamate, namely, high-affinity sodium and potassium-coupled excitatory amino acid transporters (EAAT1/GLAST, EAAT2/GLT-1, EAAT3/EAAC1, EAAT4, EAAT5). The major function of these transporters is to maintain the extracellular glutamate concentration at a low, nontoxic level in order to prevent overstimulation of glutamate receptors. Glu uptake occurs primarily through EAAT1 and EAAT2 transporters present on membranes of nonmalignant astrocytes (de Groot and Sontheimer 2011).

2 Developments in the Field

Neurotoxic effects of glutamate and its relevance for the CNS as a potential neurotransmitter were recognized for the first time over 60 years ago. In 1952, severe convulsions were observed following glutamate administration into the central nervous system (CNS) of dogs and monkeys (Hayashi 1952), and in 1957 the neurotoxic effects of sodium-L-glutamate on the inner layers of the retina were described (Lucas and Newhouse 1957). In 1959, direct evidence that Glu depolarized individual neurons of the spinal cord was provided (Curtis et al. 1959). With the identification of natural or synthetic substances (NMDA, AMPA, KA) capable to discriminate and activate different glutamate receptors, followed by receptor antagonist/agonist development and mapping of the various iGluR subtypes to distinct CNS regions by radioligand binding techniques, and finally with molecular receptor characterization based on structure-function analysis, significant progress was made in elucidating the role of GluRs in physiology and CNS disorders (Bowie 2008).

Various studies have proven glutamate to be the major excitatory neurotransmitter in the brain that plays a key role in learning and memory, thanks to its role in the induction and maintenance of long-term potentiation (LTP) and long-term depression (LTD). For that, its signaling pathways have been extensively studied in the CNS. Accordingly, aside from the physiological functions of Glu, much effort has been made in order to resolve its mechanism of action causing neurotoxicity, termed excitotoxicity (Lau and Tymianski 2010).

Excessive glutamate levels cause neuronal dysfunction and degeneration by the complex excitotoxic mechanism, which involves hyperactivation of glutamate receptors, massive influx of Ca^{2+} cations resulting in “overactivation” of selected

signaling pathways. Different levels of magnitude and heterogeneity of neurodegeneration were observed following glutamate application in cultured neurons, however. Depending on the intensity of glutamatergic insult, apoptotic or necrotic types of cell death can occur. Intense glutamatergic stimulation causes necrosis, mediated by acute mitochondrial dysfunction, whereas milder glutamate influence results in the activation of several intracellular pathways, associated with other cell death types (Lau and Tymianski 2010).

The crucial player in glutamate-mediated excitotoxicity is a calcium influx into the cells, mainly through NMDA receptor channels (Lau and Tymianski 2010). NMDA receptors (dependent on subunit-specific differences) are approximately 3–4 times more permeable to Ca^{2+} than unedited Ca^{2+}-permeable AMPA, and Ca^{2+}-permeable AMPA receptors still show a slightly greater Ca^{2+} permeability than KA receptors (Traynelis et al. 2010). After three-phase time-dependent rise of calcium that includes initial 5–10-min-lasting acute phase, subsequent 2-h latent phase with normal Ca^{2+} concentration followed by calcium sequestration in mitochondria in third sustained phase, a metabolic acidosis and free radical generation develop that result in mitochondrial damage. Glutamate-mediated calcium-dependent neurodegeneration has also been linked to the generation of nitric oxide (NO for a nitric oxide synthase (NOS) knockout mice demonstrated attenuated NMDA-mediated excitotoxicity). More detailed studies revealed a structural scaffold – a postsynaptic density protein of molecular weight 95 kDa (PSD-95) connecting NR2B subunit of NMDA receptor and NOS. It is of particular importance for NO is directly neurotoxic, nitrosylating GADPH (glyceraldehyde 3-phosphate dehydrogenase, an ubiquitous glycolysis enzyme), which together with ubiquitin ligase (Siah1) enhances p300/CBP-associated acetylation of nuclear proteins (Lau and Tymianski 2010), including histones, thereby potentially influencing gene expression. Produced NO, together with free superoxide radicals, also causes protein modifications, lipid peroxidation, and DNA damage, resulting in subsequent cell death. Caspases, classical apoptotic cysteine proteases, activated downstream of calcium influx, and mitochondrial dysfunction play a significant role in this process as well. Other cellular cysteine proteases, calpains, might also be involved in glutamatergic excitoxicity by the cleavage and release of apoptosis-inducing factor (AIF) from the mitochondria, which after nuclear translocation causes cell death, preceded by chromatin condensation and DNA fragmentation. Moreover, AIF release is linked to the activation of PARP-1 (poly(ADP)-ribose polymerase), enzyme involved in DNA repair in an alternative excitotoxic mechanism (Lau and Tymianski 2010).

The normal nontoxic Glu concentration between 1 and 3 μM in the brain is maintained by excitatory amino acid transporters, mainly EAAT1 and EAAT2, predominantly expressed in nonmalignant astrocytes. However, as demonstrated in vitro, Glu concentration exceeding 500 μM is present in cultured glioma cells. Likewise Glu concentrations in the range of 100 μM were reported at the tumor margin of the glioblastoma-bearing patients (de Groot and Sontheimer 2011).

In contrast to neurons and glial cells, glioma cells release Glu mainly by employing x_c^- cysteine–Glu exchanger system, which requires extracellular

cysteine to be incorporated to the cell and intracellular Glu to be released outside the cell. It has been suggested that Glu may be generated from glutamine via a glutaminase reaction and/or by glutamate dehydrogenase (GDH). These notions are supported by the observation that high levels of liver type glutaminase and GDH have been demonstrated in gliomas. Their expression might be promoted by the oncogene *c-myc*, which stimulates glutamine metabolism and is overexpressed in treatment-resistant glioma stem cells. Additionally, EAAT1/2 transporters are often dysfunctional in glioma cells, and their expression (especially EAAT2) seems to be inversely correlated with the degree of malignancy with almost no expression in GBM cells (de Groot and Sontheimer 2011). In consequence glioma cells release high amounts of glutamate while having impaired glutamate uptake system, which results in excessive amounts of Glu in peritumoral area.

On the other hand, iGluRs and mGluRs are ubiquitously present on neurons and glial cells (Bowie 2008). Glu released from gliomas may then exert peritumoral excitotoxicity directed to neurons and oligodendrocytes. Astrocytes are usually resistant, even to high glutamate concentration (millimolar range). Still, peritumoral astrocytes probably lose their glutamate uptake potential and/or ability to synthesize glutamine from Glu. Thereby, high-grade gliomas probably also kill astrocytes, which is supported by observations that the space surrounding expansive tumors is devoid of normal brain cells (de Groot and Sontheimer 2011).

Another NMDA receptor agonist quinolinic acid (QA) might be considered as an additional endogenous neurotoxin involved in cancer-mediated neurotoxicity. QA is produced in kynurenine pathway, metabolizing an essential amino acid tryptophan (TRP). To achieve the final product, nicotinamide adenosine dinucleotide (NAD), yet another potential neurotoxin, 3-hydroxyanthranilic acid (HAA), and two endogenous neuroactive intermediates – the NMDA antagonist, kynurenic acid (KYNA), and the neuroprotectant, picolinic acid (PIC) – are generated along the pathway. The kynurenine pathway has been shown to be present in neurons, astrocytes, and microglial cells, as well as in brain tumor cells (Chen and Guillemin 2009). The differential pattern of kynurenine pathway expression was also demonstrated in neuroblastoma cells when compared to neurons. Neuroprotective PIC was produced primarily by immature and mature neurons, but not by the tumor cells. In contrast, neuroblastoma cells were able to produce the excitotoxin QA (Guillemin et al. 2007). QA is a heterocyclic amino acid that selectively activates the neuronal NMDA receptors and has been demonstrated to have immunomodulatory and neurotoxic properties, causing neuronal cell death after direct intracerebral administration (Chen and Guillemin 2009). It has been shown that QA can directly increase the proliferation rate of brain tumor cells in vitro (Guillemin et al. 2007) while being directly toxic to the surrounding neurons and thus mirroring the effects mediated by high amounts of glutamate. Interestingly, this effect can be abrogated by endogenous neuroprotectants, synthesized in the same pathway. KYNA and PIC may effectively block QA-induced neurotoxicity without affecting its excitatory effect. Kynurenic acid acts on the glycine modulatory site at low concentrations while at higher ones on the glutamate site of the NMDA receptors. KYNA was also shown to antagonize AMPA receptors and the alpha 7 nicotinic acetylcholine receptors.

Accordingly, KYNA was reported to exert sedative and anticonvulsant effects; it was also proved to be protective against brain ischemia. PIC is less potent and appears to act via a different mechanism attenuating calcium-dependent glutamate release and/or chelating endogenous zinc (Chen and Guillemin 2009). Interestingly, neurons seem to synthesize it, while neuroblastoma cells do not (Guillemin et al. 2007).

Furthermore, quinolinic acid and 3-hydroxyanthranilic acid can effectively suppress T cell proliferation (Chen and Guillemin 2009) thus potentially attenuating the immune defense system. This could be mediated by overexpressed indoleamine 2,3-dioxygenase (IDO) enzyme, a component of the kynurenic pathway, involved in the conversion of tryptophan to *N*-formylkynurenine. IDO is being expressed by a plethora of cells, including glial tumor cells, dendritic cells, and monocytes in the tumor's vicinity, which in turn has implicated this molecule as one of the key mediators of the tumor immune escape. Beyond the tryptophan depletion, accumulation of IDO metabolites, 3-hydroxyanthranilic acid, KYNA, and QA, within the tumor environment and in the blood seems to increase the suppression of antitumor immune responses being quite detrimental in particular for the T cell, inducing both their anergy and death, as well as to impair NK cellular cytotoxicity by particularly targeting the expression of key NK receptors involved in target recognition (Zamanakou et al. 2007).

A commonly voiced concern about the possible role of QA in neuronal damage is that its concentrations in the blood and cerebrospinal fluid (CSF) are usually lower than these required to induce neuronal damage. However, the QA levels may be many times greater in the extracellular space around activated glial cells (Stone et al. 2012), or brain tumors, and there may be subsets of neurons which are particularly sensitive to quinolinic acid toxicity like neurons within the dentate gyrus of the hippocampus.

Notably, an enhanced degradation of TRP is observed in patients with various types of cancer. On the other hand patients with decreased TRP serum/plasma levels and increased concentrations of tryptophan catabolites have been reported to be involved in the development of mood disorders, especially depression. IDO activation, described above, leads to the accumulation of neurotoxic metabolites, which are supposed to induce depressive-like behavior. Resulting imbalance between neuroprotective (KYNA) and neurotoxic (QA) metabolites has been proposed to be critical for the development of depressive symptoms in patients with CNS tumors. On the other hand, decreased tryptophan availability might also affect neurosignaling by impaired synthesis of neurotransmitters serotonin and NAD, resulting in the development of depression (Kurz et al. 2011).

Taken all together, aberrant activation of the kynurenine pathway may contribute to the persistence and development of brain tumors and might be, at least in part, responsible for neurotoxicity associated with them.

3 Important Scientific Research

Direct evidence for neurotoxic function of glutamate released by glioma cells was provided for the first time in 1999. It was demonstrated then that established glioma

cell lines and primary cultures grown from the patient tissues harvested during biopsy release large amounts of glutamate, resulting in elevations of Glu that exceed 100 μM within hours sufficient to activate glutamate receptors on hippocampal neurons in coculture experiments and to induce delayed Ca^{2+}-dependent cell death (Ye and Sontheimer 1999).

Crucial data, which confirmed that glutamate excitotoxicity contributes to tumor expansion in vivo, were obtained by implanting different clones of rat glioma C6 cells in striata of adult rats. Clones that actively released glutamate developed aggressive tumors that expanded faster than tumors composed of wt C6 cells or derived from clones that were deficient in glutamate. Tumor size correlated with glutamate secretion by these clones and was not affected by proliferation rate and mitotic activity; as expected it also correlated with survival time of tumor-bearing animals. Consistent with the coculture experiments, tumors from clones releasing high amounts of Glu generated high degree of degenerated neurons, accompanied by the inflammatory response in surrounding brain areas (Takano et al. 2001). Based on this data it was concluded that glutamate acts as an important autocrine/paracrine signal that promotes glioma cell invasion and the formation of tumor metastasis (Lyons et al. 2007).

Subsequent studies proved that GluR antagonists negatively affect proliferation of different types of cancer cells in vitro (Rzeski et al. 2001) and growth of implanted tumors in vivo (Stepulak et al. 2005; Takano et al. 2001). Accordingly, the involvement of glutamate receptors in the proliferation and migration of cancer cells was also suggested. Follow-up study by Ishiuchi et al. provided evidence that gliomas express functional AMPA receptors (Ishiuchi et al. 2002). NMDA and kainate receptor subunits were also demonstrated in brain tumor-derived cell lines (Stepulak et al. 2009). Still, their functional significance was not unequivocally proved. AMPA receptors seem to be crucial for promoting tumor cell proliferation and invasion. The presence of GluR2 subunit of the AMPAR is critical to the receptor function. In its edited form GluR2 makes AMPAR impermeable for calcium entry into the cell, resulting in attenuated ability of glioma cells to invade in vitro and in vivo, as demonstrated by overexpression of GluR2 subunit (Ishiuchi et al. 2002). Ca^{2+} imaging experiments showed also that the released glutamate activates AMPAR and induced intracellular Ca^{2+} oscillations that are essential for cell migration (Lyons et al. 2007). Interestingly, brain-derived tumor cells expressed also unedited form of GluR2 subunit (Stepulak et al. 2009), thus enabling Ca^{2+} influx through AMPAR functioning ion channel. A similar situation might take place in brain tumors in vivo; direct proof requires further studies, though.

The significance of AMPAR expression in brain tumors was also demonstrated in the clinic. Lack of GluR2 expression has been shown to be an independent prognostic factor for a poor prognosis in patients with high-grade glioma (Colman et al. 2010). GluR2 was absent in fast-growing GBM-derived tumor stem cells and high-grade glioma specimens but was expressed in slow-growing stem cells and low-grade glioma specimens (Beretta et al. 2009). Increased GluR1 expression was observed in glioblastoma samples when compared to anaplastic astrocytomas and low-grade gliomas. AMPA-mediated signaling in glioma cell lines was attributed to

MAP kinase (ERK1/2) activation, and gene silencing of the GluR1 AMPA receptor subunit results in abrogation of AMPA-mediated signaling and tumor growth (de Groot et al. 2008). It has been also shown that GluR1 overexpression in glioma cells with subsequent activation of focal adhesion kinase (FAK) is responsible for increased cell adhesion to the extracellular matrix (ECM) in vitro (de Groot and Sontheimer 2011).

GluR2 overexpression in glioma cells inhibits proliferation and induces apoptosis by inactivating extracellular signal-regulated kinase (ERK)1⁄2 via Src kinase (Beretta et al. 2009). MAP kinase seems to be an intracellular mediator connecting mGluR3 receptor with bone morphogenetic proteins (BMP)-Smads transcription factors signaling. Activation of mGluR3 results in sustained undifferentiated state of glioma-initiating cells, whereas pharmacological blockade of mGluR3 stimulates differentiation of these cells and limits the growth of implanted tumors (Ciceroni et al. 2008). Akt kinase pathway, crucial for proliferation of various cancer cells types, seems to be another important downstream effector of AMPAR-mediated signaling in glioma cells. A dominant-negative form of Akt inhibits cell proliferation and migration accelerated by overexpression of Ca^{2+}-permeable AMPA receptor. In contrast, introduction of a constitutively active form of Akt rescues tumor cells from apoptosis induced by the conversion of Ca^{2+}-permeable AMPA receptor to Ca^{2+}-impermeable receptors by the delivery of GluR2 cDNA (Ishiuchi et al. 2007) proving the importance of this type of signaling for tumor cell homeostasis. Since glutamate receptors appear to be vital for glioma invasion and metastasis, inhibition of these receptors and/or GluR-dependent signaling pathways opens a new field for therapeutic intervention that should result in an inhibition of tumor invasion, along with reduction of neurotoxic side effects mediated by the tumor.

Expansion of the tumor may explain a frequent occurrence of seizures initiated by the tumor and the surrounding brain. Over 80 % of glioma patients suffer seizures during the course of their diseases (de Groot and Sontheimer 2011). However, the mechanism responsible for these seizures has not been unequivocally proved and may be related to the expression and activation of GluRs in different types of brain tumors and glial cells. Subunits from each receptor class, including ionotropic NR1, NR2A/B (NMDA) GluR1, GluR2 (AMPA), and GluR5-7 (kainate) and metabotropic mGluR1, mGluR2/3, mGluR5, and mGluR7a subtypes, were demonstrated in glioneuronal tumors from patients with intractable epilepsy. Group I mGluRs (mGluR1 and mGluR5) were highly represented, whereas low expression of mGluR2/3 (group II) and mGluR7 (group III) was observed in the neuronal component of the tumors, supporting the central role of glutamatergic transmission in the mechanisms underlying the intrinsic and high epileptogenicity of these lesions. Increased expression of mGluR2/3, mGluR5, and GluR5-7 proteins in peritumoral reactive astrocytes suggests its possible contribution to the generation and propagation of seizure activity (Aronica et al. 2001). In astrocytes iGluRs, especially AMPARs, are able to form functional ion channels, and their activation can alter astrocytes morphology and function, whereas mGluRs appear to regulate the expression of Glu transporters (de Groot and Sontheimer 2011).

Astrocytes predominantly express mGluR3 and mGluR5, and their activation enhances glutamate uptake, thus protecting neurons from glutamate-mediated toxicity. These mechanisms are often disrupted under pathologic conditions. The mGluR5-mediated upregulation of glutamate transport is lost in chemically activated astrocytes in rat ALS model, and an enhanced release of glutamate induced by the activation of glial mGluR5 receptors contributing to glutamate-mediated neuronal death was observed after status epilepticus (D'Antoni et al. 2008). Thus, tumor-released glutamate may potentiate excitotoxicity mediated by astrocytes by activating mGluR5 receptors. In microglia, activation of mGluR2 induces mitochondrial depolarization and apoptosis or, alternatively, induces an activated phenotype, which underlies microglia-mediated neurotoxicity, mediated probably by the secretion of TNFa and Fas ligand from activated microglia (D'Antoni et al. 2008).

Recently, the involvement of KARs activated by the endogenous agonist glutamate in the generation and propagation of epileptiform seizures was discussed (Vincent and Mulle 2009). Nonsynaptic source of glutamate derived from the activity of astrocytes increases the activation of KARs in neighboring interneurons. On the other hand, apoptotic and necrotic death of neurons is associated with dose-dependent kainate (KA)-induced excitotoxicity in vivo (Vincent and Mulle 2009; Wu et al. 2005) and involvement of KA receptors in epileptiform seizure induction was demonstrated by injection of KA in rodents (Vincent and Mulle 2009). Thereby, it is possible that activation of KAR by glioma-released glutamate could contribute to the development of the seizures observed in glioblastoma patients. This hypothesis is supported by the observation that NMDA receptor antagonists given before or after the induction of KA-mediated seizures prevent most of the excitotoxic damage, suggesting pivotal role of NMDA receptors in KA-induced excitotoxicity (Vincent and Mulle 2009). Seizures might be also activated by quinolinic acid (QA) acting on NMDA receptors and producing neuronal damage (Stone et al. 2012), which have been shown to be produced by neuroblastoma cells (Guillemin et al. 2007).

4 Recent Findings

Despite recent improvements in treatment strategies, the results of therapy in patients with glioblastoma are unsatisfactory. Effective treatment is limited due to biological properties of the tumor and the clinical advancement of the disease upon diagnosis. Because of the low efficacy of the traditional chemotherapy, new therapeutic tools acting selectively on specific metabolic pathways pathologically deregulated in glioma cells are still needed. On the other hand, development of new tools attenuating tumor- and glutamate-induced neurotoxicity is of great importance.

Since, new types of the targeted therapy, including blockade of growth factors, like EGFR, GFs-mediated downstream signaling (Ras–ERK1/2, Akt–mTOR, PKC), proteasome, and microtubule inhibitors, proved to be of limited value in the clinic (Adamson et al. 2009), glutamatergic signaling system has attracted great

attention. As described above, glutamate receptor signaling has been implicated in tumor biology, and receptor antagonists have been shown to be sufficient to suppress cancer growth in experimental studies (Arcella et al. 2005). Unfortunately, the majority of tested compounds, although promising in animal experiments, failed in clinical trials (Lau and Tymianski 2010). It is of interest, however, that in contrast to other NMDA receptor antagonists, memantine has been approved for the treatment of Alzheimer disease and has shown some antitumor effects in vitro (Rzeski et al. 2001; Takano et al. 2001). It is worth mentioning that doses, which inhibit tumor cells proliferation, are much higher than those applicable for Alzheimer disease. The other iGluR antagonists show similar properties, even though it has been shown that some of them exert their activities at relatively low, clinically relevant doses both in vitro (Rzeski et al. 2001) and in vivo (Stepulak et al. 2005). Unfortunately, potential side effects, psychotic in particular, are limiting factors of iGluR antagonists' therapy (Lau and Tymianski 2010).

On the other hand, very promising results of treatment of newly diagnosed glioblastoma patients with talampanel combined with temozolomide (TMZ) and radiation therapy (RT) were reported. Talampanel, an oral, noncompetitive AMPAR antagonist with excellent brain penetration, combined with RT and TMZ, significantly prolonged median survival time, without any additional toxicity, as compared to RT–TMZ-treated patients (Grossman et al. 2009). This provides a solid base for future studies with similar, newly synthesized inhibitors.

Recently, another group of potential therapeutic agents that inhibit glutamate release has draw attention. Glioma cells in the presence of deficient glutamate uptake systems upregulate the glutamate exchanger X_c- cysteine–glutamate antiporter that leads to progressive Glu accumulation in peritumoral tissue (de Groot and Sontheimer 2011). A disruption of this system using shRNA attenuated Glu release in vivo, prolonged survival of tumor-bearing animals, and diminished glioma-induced neurodegeneration and brain edema (Savaskan et al. 2008). It has been shown that an inhibition of the X_c- transporter by sulfasalazine results in tumor volume reduction by 60–80 % in animal model (Sontheimer 2008). Despite several limitations such us poor systemic bioavailability because of its rapid cleavage by colonic bacteria and a half-life of ~80 min in circulation, clinical trials with sulfasalazine in the treatment of newly diagnosed low-grade gliomas are ongoing (de Groot and Sontheimer 2011).

Another drug aimed on inhibition of glutamate release and attenuation of its neurotoxicity is riluzole (2-amino-6-trifluoromethoxybenzothiazole). Riluzole is an anticonvulsant and neuroprotective agent approved by FDA for different indications (treatment of amyotrophic lateral sclerosis – ALS). Its main mechanisms of action involve inhibition of Na^+-gated channels, postsynaptic blockade of ionotropic GluRs without direct receptor interaction, and potentiation of glutamate uptake by activation of glutamate transporters (Bellingham 2011).

Riluzole has been shown to inhibit proliferation and glutamate release in melanoma, both in vitro and in vivo (Namkoong et al. 2007); however, it has not been tested in glioma treatment, yet. Nevertheless, inhibition of cellular systems of glutamate release seems to be an interesting target for future therapies of brain tumors aimed on reduction of tumor-mediated neurotoxicity.

On top of tumor-mediated neurotoxicity, one should remember that present therapeutic strategies result in significant toxicity directed to brain cells (Rinne et al. 2012). Thus, the development of new neuroprotective agents has become a necessity. One of the most promising approaches involves application of a novel class of drugs aimed at disruption of protein complexes between GluRs and scaffolding proteins. It is of particular value that these specific peptides disrupt interactions between NMDAR and PSD95 or KAR and PSD95 without influencing synaptic activity or calcium influx, which in turn inhibits downstream neurotoxic signaling without interfering with neurotransmission (Vincent and Mulle 2009). Another group of peptides, named membrane-associated guanylate kinase (MAGUK) inhibitors, dissociates spatial relationship between NMDAR and NOS in a competitive manner, inhibiting NOS-mediated neurotoxicity. One of these peptides – NA1 – is currently in a phase II clinical trial (Lau and Tymianski 2010).

For years, agents such as psychostimulants and acetylcholinesterase inhibitors have been used to treat cognitive dysfunction in patients with brain tumors. Recently, however an improvement in cognitive functions in high-grade glioma patients treated with methylphenidate and modafinil, known for their neuroprotective capabilities (van Vliet et al. 2008; Ludolph et al. 2006), was reported. Donepezil, another compound with proven neuroprotective activity against glutamate-induced excitotoxicity (Shen et al. 2010), has also been shown to improve cognitive performance in patients with brain tumors.

Currently clinical trials are being conducted in order to determine the potential neuroprotective effects of memantine and lithium in patients with brain metastases (Correa 2010). Finally, there is some evidence that GluR5-containing KARs represent a novel target for AED (antiepileptic drug) development, since GluR5 antagonists prevent and interrupt limbic seizures without overt side effects in the experimental models (Vincent and Mulle 2009), thereby are of potential interest also for glioma-mediated seizures.

5 Conclusion

Brain tumors, especially glioblastoma, are still a therapeutic conundrum in the context of short survival times and low quality of life of the patients that arise from the neurotoxicity mediated by both tumor and side effects of applied therapies. An improvement of anticancer therapy on one side and attenuation of neurotoxicity on the other define future challenges on the field. Thereby, additional therapeutic approaches are needed to supplement existing strategies (Candolfi et al. 2009). A deregulated glutamatergic system in glioma is definitely one of the plausible therapeutic targets. Still, a number of questions regarding the role of ionotropic glutamate receptors in carcinogenesis remain unanswered. Even though initial reports confirmed the role of glutamate and its receptors in oncogenesis and their antagonists proved to exhibit a therapeutic potential, a practical implementation of those compounds remains elusive. The main obstacle relates to their serious side effects, in particular related to the CNS. Moreover, relevant information on the role

of the aforementioned receptors in peripheral tissues is also missing. The receptors themselves exist in various configurations of subunits that affect their pharmacological proprieties; on top of that receptor subunits undergo posttranslational and epigenetic modifications, which additionally increase their variability. iGluR antagonists are usually receptor or even subunit specific; accordingly a prospective therapy will probably require prior analysis of receptors in a given tumor. Nonetheless, existing data, in particular the results of clinical trials with talampanel in gliomas, are encouraging and support the search for novel antagonists of ionotropic glutamate receptors with superior pharmacologic proprieties to be implemented into antitumor and neuroprotective therapeutic protocols. On the other hand, strategies aimed on the inhibition of glutamate release with subsequent disruption of autocrine glutamate signaling loop, or strategies involving intracellular targets, where different signaling pathways converge, including those implementing histone deacetylase inhibitors (HDI) together with other standard or targeted types of therapy, are also of interest.

Another important advance that has recently changed our way of thinking about glial tumors biology relates to the concept of the so-called tumor stem or tumor-initiating cells (TSCs). It has been recently proven that within a total population of glioblastoma cells, there appears to be a small subpopulation of cells that are highly tumorigenic, with capacity for self-renewal (Singh et al. 2004). Because they share many properties with neural stem cells, it has been suggested that they originate from neuronal stem cells (Alcantara Llaguno et al. 2009). These cells are functionally defined with self-renewal and cell differentiation in vitro and their capability for tumor propagation in vivo (Li et al. 2009). The most important aspect of their presence within glial tumors is that this population appears to be particularly resistant to conventional radiation (Bao et al. 2006) and chemotherapy (Liu et al. 2006). What is of particular interest, however, is the fact that only recently this specific cellular subpopulation has been proven to express high concentrations of functional calcium-permeable AMPA receptors when compared to the differentiated tumor cultures consisting of non-stem cells. This raise the possibility that glutamate secretion in the glioblastoma microenvironment may stimulate brain tumor-derived cancer stem cells (Oh et al. 2012). This finding suggests that therapeutic strategies aimed at glutamate-dependent excitotoxic pathway disruption might also influence TSCs, possibly initiating their differentiation thus rendering them more susceptible to conventional therapeutic modalities. This hypothesis requires further substantiation, though.

A possible strategy to overcome these obstacles involves more personalized diagnosis and treatment, including analysis of genetic abnormalities of particular tumor cell populations, as well as assessment of potential treatment efficacies of arrays of drugs tested on primary cell cultures, derived from samples of tumors harvested during surgery.

In the context of neurotoxicity approaches that render physiological glutamatergic transmission intact and simultaneously disrupt excitotoxic pathways are of particular interest. Another potential therapeutic strategy for neuroprotection involves mimicry of the glutamate blocking activity of endogenous neuroprotective agents, such as kynurenic acid or melatonin. Nevertheless, a lack of significant

success with therapeutic protocols that interfere with NMDA–AMPA-dependent mechanisms of excitotoxicity implies that some other potential therapeutic targets have to be explored.

Abstract

At present, no effective cure is available to slow down or prevent progressive neuronal loss in the pathogenesis of Alzheimer's disease (AD). All currently approved therapeutic agents provide symptomatic relief only. However, current agents under development exhibit potential protective effects on disease course. In this chapter, we consider currently marketed drugs for AD, including acetylcholinesterase inhibitors (AChEI) and antagonists of *N*-methyl-D-aspartate (NMDA) receptors. This work also discusses potential cognitive enhancers under clinical trial. We also review new therapies that are likely to slow down disease progression by mechanisms unrelated to amyloid or tau.

Keywords

ACE inhibitors • Alzheimer's disease • Amyloid • Antioxidants • Tau

1 Introduction

Alzheimer's disease (AD) is an irreversible, progressive neurodegenerative disorder characterized by impaired learning and memory loss. One of the major pathological hallmarks of AD is the presence of a high density of extracellular senile plaques containing amyloid beta (Aβ) in the hippocampus and cerebral cortex (Shen et al. 2008). Irregular processing and accumulation of Aβ can impact negatively on important metabolic pathways within neurons and glial cells leading to neuronal and synaptic dysfunction and neurodegeneration. Aβ generation is regulated by the sequential proteolytic activity of β-secretase (BACE) and γ-secretase proteases (De Strooper et al. 2010; Hashimoto et al. 2010; Marks and Berg 2010; Neugroschl and Sano 2010; Tabaton et al. 2010). When the α-secretase pathway is used for the processing of amyloid precursor protein, no Aβ is generated (Nord et al. 2010). Presenilins 1 and 2 are the core components for the catalytic activity of γ-secretases, which are necessary for Aβ formation and progression of AD (Rocher-Ros et al. 2010).

Intracellular neurofibrillary tangles (NFTs) containing hyperphosphorylated tau protein are the second hallmark for AD (Attems et al. 2012; Wei et al. 2012). In the healthy neuronal population, tau protein helps to stabilize microtubules in the cytoskeleton (Kon et al. 2012). Although the mechanism for tau hyperphosphorylation in AD remains unclear, this hyperphosphorylation also occurs in numerous dementias and in the pathogenesis of other neurodegenerative disorders including Parkinson's disease (PD) (Lasagna-Reeves et al. 2012).

Prodromal mild cognitive impairment precedes AD, with more than half of these individuals progressing to AD within 4 years of symptomatic onset. Most individuals with mild cognitive impairment show early signs of AD pathology in their brain, including enhanced Aβ deposition and NFTs (Petersen et al. 1999). Owing to the postmitotic nature of neuronal cells, therapeutic agents that can slow down and/or reverse the pathogenic AD cascade prior to irreversible neuronal damage may alter the disease course in AD (Olazaran et al. 2010).

AD is the most common cause of dementia among elderly people over 65 years of age. For every 5-year age group beyond 65, the percentage of people with AD doubles. Scientists estimate that around 4.5 million people worldwide suffer from AD (Olazaran et al. 2010). Despite the alarming increase in the prevalence of AD, there are no disease-modifying drugs available. Currently approved treatments include the acetylcholinesterase inhibitors (AChEI) donepezil, galantamine, and rivastigmine and memantine, an antagonist of *N*-methyl-D-aspartate (NMDA) receptors. Other proposed therapies include β- and γ-secretase inhibitors, glucagon-like peptide-1 (GLP-1), bapineuzumab, solanezumab, statins, nonsteroidal anti-inflammatory drugs (NSAIDs), Cerebrolysin, psychotropic agents, and dietary supplements, vitamins, and nutraceuticals.

2 Acetylcholinesterase Inhibitors

The progressive degeneration of cholinergic neurons in the basal forebrain and reduced cholinergic neurotransmission in the cerebral cortex and other areas contribute significantly to impaired learning and memory observed in patients with AD. This neurochemical abnormality has provided the rationale for the development of first-line drugs for the treatment of AD which induce the cholinergic system in which the neurotransmitter acetylcholine is lacking (Pepeu and Giovannini 2009). Acetylcholinesterase inhibitors (AChEIs) are the first class of agents approved by the US Food and Drug Administration (FDA) for the treatment of AD. Tacrine (Cognex) was first approved in 1993 but is now rarely used due to elevations in hepatic enzymes and will not be discussed here. In 1996, donepezil was approved under the trade names Aricept, Adonep, Yasnal, and others. It was followed by rivastigmine (Exelon, Prometax, Ristidic, Vastigmex, or Evertas) in 2000 and galantamine (Reminyl, Razadyne, or Nivalin) (Pohanka 2011).

Inhibitors of acetylcholinesterase (AChE) share similar mechanisms of action while exhibiting additional pharmacological properties. The response to treatment with AChEIs is similar, and no individual AChEI has been shown to display superiority to others in efficacy studies. AChEIs bind to the synaptic cleft, thus stimulating the release of acetylcholine from the presynaptic cholinergic terminal and increasing the potential for interaction with the postsynaptic cholinergic receptor, therefore promoting the function of the cholinergic receptor (Pohanka 2011). Donepezil is a selective reversible AChEI with an affinity to AChE which is 1,000-fold higher than towards butyrylcholinesterase (BCHE) (Perdomo et al. 2003).

Table 1 Pharmacodynamics of AChEIs

	AChEIs		
Characteristics	Donepezil	Rivastigmine	Galantamine
Indications	Mild to moderate and severe AD	Mild to moderate AD; Parkinson's disease dementia	Mild to moderate AD
Half-life (hrs)	70	1.5	7
Administration regime	q.d.	b.i.d. for capsule; q.d. for the patch	b.i.d. for the non-ER form; q.d. for the ER form
Metabolism by hepatic CYP enzymes	2D6, 3A4	No	2D6, 3A4
Protein binding (%)	96	40	18
Bioavailability	100	40	90
Absorption delayed by food (hrs)	No	No	Yes (1–2.5)
Time to reach peak serum concentration (hrs)	3–4	1	1 (2.5 with food); 4.5 with ER form
Titration schedule	Initial dose of 5 mg then advance to 10 mg after 1 month	Oral form: 1.5 mg b.i.d. for 4 weeks then 3 mg for 4 weeks then to 6 mg b.i.d. if tolerated	Non-ER form: 4 mg b.i.d. then 8 mg b.i.d. after 1 month to 12 mg b.i.d. after another month
		Patch form: initial patch of 5 cm^2 for 1 month then the 10 cm^2 patch	ER form: 8 mg q.d. after 1 month then to 16 mg for 1 month then 24 mg q.d. after another month
Adverse effects	Gastrointestinal, nausea, vomiting	Gastrointestinal, nausea, vomiting	Gastrointestinal, nausea, vomiting
	Reduced heart rate, sleep disturbances, muscle cramps	Reduced heart rate	Reduced heart rate

Abbreviations: q.d. every day; b.i.d. twice a day; ER extended release

Rivastigmine is a nonselective mixed inhibitor of both AChE and BCHE (Naik et al. 2009). Galantamine is an allosteric modulator of AChE with limited affinity towards BCHE. Apart from interaction with AChE, galantamine neuroprotective effects can be further attributed to its allosteric modulation of nicotinic acetylcholine receptor (nAChR) (Feng et al. 2010). The basic pharmacology and pharmacodynamics of these drugs are summarized in Table 1.

It remains unclear as to whether AChEIs have any disease-modifying properties in AD. It has been suggested that enhanced cholinergic transmission can slow down Aβ production (Kimura et al. 2005). Several imaging studies have shown a marked reduction in brain atrophy in patients treated with AChEIs (Krishnan et al. 2003). One study

has shown reduced decline in cognitive function in patients treated with AChEIs or in combination with memantine compared to placebo (Lopez et al. 2009). However, no disease-modifying effects have been reported in another study (Jack et al. 2008).

Huperzine, a metabolite in the Chinese lycopod *Huperzia serrata* (Huperziaceae), is another drug that has been shown to have a neuroprotective effect suitable for the treatment of AD. It exists in two forms: A and B. However, the A variant is most likely pharmacologically relevant. It is a noncompetitive inhibitor of AChE, with no effect on BCHE. As well, it is a potent antagonist of the NMDA receptor (Gao et al. 2009). It can also attenuate oxidative stress and upregulate endogenous antioxidant activity in the CNS (Coleman et al. 2008). Huperzine has become target for extensive pharmacological research and is available for the treatment of neurodegenerative diseases in China. However, it is yet to be approved in the USA, Europe, and Australia. Favorable outcomes from a current clinical trial will allow the drug to be approved for therapy purposes in those countries (Ma et al. 2007).

3 Memantine

Memantine antagonizes the NMDA receptor by replacing the potassium in the NMDA ion channel to reduce the efflux of intracellular calcium into neurons and prevent excitotoxicity and subsequent apoptosis. Prior to its approval for the treatment of AD, memantine was used for the treatment of Parkinson's disease in Germany (Winblad et al. 1999). In 2004, memantine (Namenda, Ebixa, or Axura) was approved for the treatment of moderate to severe AD by the FDA in the USA (Ferris et al. 2003; Moebius et al. 2003a, b; Reisberg et al. 2003) (Table 2).

Whether the neuroprotective effects of memantine on neuronal cells observed in vitro are responsible for the symptomatic relief observed in clinical trials remains to be examined. Reduced Aβ deposition and tau hyperphosphorylation have been reported in in vitro studies after treatment with memantine (Martinez-Coria et al. 2010). Memantine has also been shown to provide beneficial effects on long-term potentiation (LTP), which correlates with memory function (Frankiewicz and Parsons 1999). This observation provides a plausible explanation for the symptomatic relief reported in patients undergoing therapy with memantine.

Memantine may be administered alone or in combination with an AChEI. No adverse effects have been reported with patients receiving both drugs. Pharmacotherapy with an AChEI and memantine continues until the patient either succumbs to AD or the quality of life of the patient is significantly compromised that the combination therapy is vain. Some long-term open-labeled studies have shown that combination therapy with an AChEI and memantine may attenuate the progression of AD, although other studies show conflicting results (Lopez et al. 2009; Schneider et al. 2009; Schneider and Sano 2009).

Table 2 Pharmacodynamics of memantine

Indications	Moderate to severe AD
Half-life (hrs)	60–80
Metabolism by hepatic CYP enzymes	No
Protein binding (%)	50
Absorption delayed by food	No
Time to reach peak serum concentration (hrs)	3–7
Titration schedule	Initially 5 mg q.d. for 1 week, 5 mg b.i.d. for the next week, 10 mg in the morning and 5 mg in the evening for 1 week, and 10 mg hereafter

Abbreviations: q.d. every day; b.i.d. twice a day

4 β-Secretase Inhibitors

β-Secretase cleaves APP into two peptide fragments, Aβ40 and Aβ42 (Zhou et al. 2012). Therefore, inhibition of β-secretase may reduce plaque formation and slow down the progression of AD. Preliminary studies using β-secretase knockout models showed only minor phenotypic changes, suggesting that β-secretase inhibitors may be an effective therapeutic strategy (Tang and Ghosh 2011). Novel β-secretase inhibitors have been developed as potential preventative and/or intervention therapy for AD.

Treatment with the β-secretase inhibitor (GRL-8234) has been shown to attenuate age-mediated decline in cognitive function in a transgenic mice model expressing APP after long-term inhibitor treatment (Chang et al. 2011). Moreover, the same study showed that GRL-8234 reduced brain Aβ plaque load in these mice, suggesting a potential treatment for patients with late-stage AD (Chang et al. 2011).

TAK-070, a non-peptidic compound, has also been demonstrated to be a potent β-secretase inhibitor (Fukumoto et al. 2010; Takahashi et al. 2010). This compound can reduce the levels of soluble Aβ, promote neurotrophic levels of APP, and inhibit the extracellular deposition of insoluble Aβ. A clinical trial using TAK-070 is currently under consideration. Additional efficacy studies in rodents are underway (Fukumoto et al. 2010; Takahashi et al. 2010).

5 γ-Secretase Inhibitors

Inhibition of γ-secretase may also represent an important process to prevent the proteolytic processing of APP and regulate Aβ formation (De Strooper and Annaert 2010). However, these inhibitors have been shown to cause adverse effects in preclinical animal models and human clinical trials. In one study, inhibition of γ-secretase induced embryonic toxicity, likely due to impaired activation of the notch, which is vital for cellular development and differentiation (Donoviel et al. 1999).

In a Phase II clinical trial, the γ-secretase inhibitor LY450139 leads to unwanted side effects including drug-related rashes and lightening of hair color with none

reported in the placebo group (Fleisher et al. 2008). Similarly, a Phase III trial for the γ-secretase inhibitor semagacestat was halted after the cognitive symptoms worsened in patients receiving the drug compared those who were given the placebo. Moreover, the incidence of skin cancers was increased in patients receiving semagacestat (Samson 2010). Therefore, the key question is whether undesirable side effects may result from the inhibition of cleavage of additional substrates for APP processing and whether a therapeutic window is necessary for the administration of these inhibitors to reduce Aβ deposition.

Several agents, including NSAIDs and other organic compounds, have been recently shown to regulate γ-secretase activity, without interfering with notch signalling (Imbimbo and Giardina 2011; Imbimbo et al. 2011). These γ-secretase modulators may be efficacious for the treatment of AD without the serious adverse effects.

6 Bapineuzumab

Active immunization with synthetic full-length Aβ peptide (AN1792) has been discontinued due to significant cognitive and neurological impairment occurring as a result of meningoencephalitis occurring in 6 % of patients (Orgogozo et al. 2003). The antibody-mediated response to AN1792 has been associated with the N-terminal residues (Lee et al. 2005). Subsequent studies using antibodies which target the N-terminus of Aβ which do not contain T-cell activating epitopes can be protective against neurotoxicity and inhibit fibrillogenesis (McLaurin et al. 2002).

Bapineuzumab (AAB-001) is a humanized monoclonal antibody directed against the N-terminal region of Aβ. Magnetic resonance imaging (MRI) abnormalities have been noted in a Phase I trial which generally resolve. There are also reports of vasogenic edema, likely due to an interaction of bapineuzumab with Aβ occurring in the blood vasculature. These cases are largely associated with microhemorrhage which is asymptomatic (Black et al. 2010).

Additionally, bapineuzumab can improve cognitive performance assessed using the mini-mental state examination at lower doses compared to the placebo, while no change is observed in higher doses (>5 mg/kg). In a Phase II study, CSF t-tau and p-tau levels were significantly reduced at the end of the study compared with baseline in bapineuzumab-treated patients, while no change was detected in the placebo group. Interestingly, no difference was observed in Aβ levels in either group (Blennow et al. 2012; Winblad et al. 2012). These studies highlight the downstream effects of bapineuzumab on the neurodegenerative process in AD, which may prove useful as a disease-modifying therapy in the early stages of AD.

7 Solanezumab

Solanezumab (LY2062430) is a humanized monoclonal antibody that targets the central region of Aβ (Lachno et al. 2011; Reichert 2011; Samadi and Sultzer 2011).

Preclinical studies have shown that acute and subchronic treatment with solanezumab can ameliorate or reverse memory deficits in transgenic mice (Siemers et al. 2010; Panza et al. 2012; Uenaka et al. 2012). Unlike other disease-modifying immunotherapies, no effects on incidence or severity of cerebral amyloid angiopathy-associated microhemorrhages, a serious adverse effect associated with bapineuzumab, have been reported. Solanezumab displayed a good safety profile in a Phase II clinical study for AD and can significantly reduce cerebrospinal and plasma levels of Aβ and tau (Carlson et al. 2011; Farlow et al. 2012; Imbimbo et al. 2012).

In a Phase III trial, primary endpoints, both cognitive and functional, were not met in patients with mild to moderate AD. However, a statistically significant slowing of cognitive decline was shown in a prespecified secondary analysis of pooled data in patients with mild AD. Although solanezumab may be the first passive vaccine for the prevention of AD, immense scepticism still exists regarding the ability of this drug to slow down the progressive degeneration in patients with AD (Prodouz 2012). The next steps for solanezumab will be determined after discussions with pharmaceutical regulators.

8 Statins

Conflicting reports are available regarding the role of statins in improving brain function in AD. Epidemiological studies have shown a reduction in the risk of developing AD in patients using statins compared to those that have not been treated with cholesterol-lowering drugs. However, there are also numerous reports indicating significant cognitive decline following treatment with statins (Haag et al. 2009). Therefore, the usefulness of these drugs for the treatment of AD remains uncertain.

The neuroprotective effects of statins may be due to several mechanisms. Statins have demonstrated beneficial effects in the AD brain by enhancing degradation of extracellular Aβ by inducing the release of insulin-degrading enzymes from the resident microglial cells. Increase levels of soluble Aβ have been reported in microglia-depleted mice (Tamboli et al. 2010). However, since increased cholesterol levels is a risk factor for AD, it is difficult to determine whether the beneficial effects of statins in AD are related to the action of the statin or the improved lipid profile.

Numerous studies have been performed to determine the role of lipid-lowering agents for the treatment of AD. The Lipitor's Effect in Alzheimer's Dementia study found no significant difference in cognition or global function in patients with mild to moderate AD receiving Atorvastatin 80 mg/day for 72 weeks (Feldman et al. 2010). The Cholesterol Lowering Agent to Slow Progression of AD is a Phase III study currently underway to examine the safety and effectiveness of simvastatin to slow the progression of AD (McGuinness et al. 2010). Additional studies are needed to clarify the risks and benefits of statin therapy for the treatment of AD.

9 NSAIDs

A retrospective human epidemiological study showed that long-term use of NSAIDs, particularly ibuprofen, can protect against AD (Vlad et al. 2008). Similarly, experiments using rodent models for AD have predicted the effects of NSAIDs in humans, although little is known regarding the effect of NSAIDs on AD risk and pathogenesis. Prophylactic treatment of young 3xTg-AD mice with ibuprofen reduced intraneuronal Aβ oligomers and hyperphosphorylated tau and enhanced cognitive function (McKee et al. 2008). Ibuprofen has also been shown to reduce reactive oxygen species production by inhibiting the activity of nicotinamide adenine dinucleotide phosphate oxidase (Wilkinson et al. 2012). NSAIDs represent a promising therapeutic target also due to their modulatory effect on γ-secretase activity, without inhibiting important γ-secretase-dependent signalling pathways (Pettersson et al. 2011).

10 Glucagon-Like Peptide

Type 2 diabetes is a major risk factor for AD. Impaired insulin signalling appears to be a converging biochemical phenomena present in both diseases (Gotz et al. 2009; Ke et al. 2009). Apart from the pathological hallmarks in the AD brain, insulin receptors are reported to be desensitized in the AD brain, and this is referred to as type 3 diabetes (Steen et al. 2005). Therefore, effective treatment regime against type 2 diabetes may be of value in AD.

Activation of the glucagon-like peptide-1 (GLP-1) receptor has been recently shown to reduce Aβ deposition and downstream toxicity in both cellular and rodent models for AD (Li et al. 2010). Moreover, GLP-1 has been shown to reduce neuronal APP levels in vitro (Perry et al. 2003). Taken together, these studies provide further support for the association between diabetes and AD.

11 Cerebrolysin

Cerebrolysin is a parenterally administered digested peptide preparation present in the pig brain and mimics the action of endogenous neurotrophic factors. This compound has demonstrated neuroprotective effects. Positive effects of Cerebrolysin on Aβ- and tau-related pathologies, neuroinflammation, neurotrophic factors, oxidative stress, excitotoxicity, neurotransmission, brain metabolism, neuroplasticity, neuronal apoptosis and degeneration, neurogenesis, and cognition were demonstrated in experimental conditions (Allegri and Guekht 2012; Heiss et al. 2012; Masliah and Diez-Tejedor 2012; Menon et al. 2012; Sharma et al. 2012a, b; Thome and Doppler 2012; Vazquez-Roque et al. 2012; Xiao et al. 2012). As well, numerous studies have demonstrated symptomatic benefits in AD (Okamura et al. 2008). As a result, this drug is widely used in several countries,

although more definitive trials are needed to ensure the effectiveness of Cerebrolysin as a monotherapy or in conjunction with other treatment regimens.

12 Psychotropic Agents

Behavioral disturbances are common in AD and include depression, agitation, irritability, abnormal motor behaviors, and psychosis (Cummings 2003; Porter et al. 2003). At present, no drug is currently available to treat these behavioral disturbances. The use of conventional and atypical antipsychotics can increase the risk of mortality from ~ 2.6 % to ~ 4.5 % in patients with AD (Kales et al. 2007).

Several 1–12-week-long clinical trials have shown that risperidone is efficacious in reducing psychosis in nursing home patients with AD at low doses (Ballard and Howard 2006; Ballard and Waite 2006; Fossey et al. 2006). Similarly, there is no evidence for the use of antidepressants in AD (Rosenberg et al. 2010; Weintraub et al. 2010). Several studies have shown that valproate has no benefit for the treatment of agitation compared to placebo and induces severe toxicity (Herrmann and Lanctot 2007; Herrmann et al. 2007). Anxiolytics should be avoided in patients with AD as they induce confusion. Short-term benzodiazepines such as lorazepam or clonazepam may be useful in patients with frequent episodes of agitation (Tariot et al. 1998). Given the current evidence for benefit and harm for the indication of antipsychotics in AD, these drugs should only be prescribed with caution to patients where non-pharmacological therapeutics have failed and their behavioral change is extreme, administering the treatment only when needed and informing the patient and responsible carer of the associated risks.

13 Dietary Supplements, Vitamins, and Nutraceuticals

Dietary supplements and vitamins have been used in clinical trials for AD. Nutraceuticals describe nontraditional compounds that display pharmaceutical effects but cannot be advertised for a health disease claim. Formulations of these substances vary, and no regulatory standards are available to verify the potency of these compounds except that these products contain the active substance advertised.

13.1 Docosahexaenoic Acid

Docosahexaenoic acid (DHA) is the main constituent of the cellular membrane in the CNS. The levels of DHA are reduced with age but can be replenished to normal levels following dietary supplementation. DHA has also been shown to reduce Aβ deposition in mice and improve cognitive performance when administered as a dietary supplement (Geleijnse et al. 2012; Morris 2012; Rosales-Corral et al. 2012; Stough et al. 2012). One trial reported improvements in episodic

memory after post hoc analyses in older individuals who have cognitive test scores below the normal threshold for young adults (Okamura et al. 2008). However, DHA supplementation did not alter cognitive function in another study (Quinn et al. 2010).

13.2 B Vitamins

Increased level of homocysteine in the blood is a major risk factor for cardiovascular disease, AD, and other dementia-related disorders and can potentiate the neurotoxic effect of Aβ peptides in vitro. Homocysteine levels can be reduced by at least 30 % using regimens of B vitamins (B12 1 mg/day, B6 25 mg/day, and folic acid 5 mg/day). One trial showed a substantial reduction in homocysteine levels with these vitamins but did not reduce the rate of cognitive deterioration in AD patients compared to the placebo (Aisen et al. 2008).

13.3 Vitamin E

The antioxidant effects of vitamin E might be useful for the treatment of AD. In one study, vitamin E (1,000 IU b.i.d.) combined with selegiline (5 mg b.i.d.) delayed the time until patients with moderate AD require nursing home placement or succumb to the disorder, although no effect on cognition was reported (Sano et al. 1997). Another study reported no significant delay in conversion to AD or dementia when vitamin E was administered alone or with donepezil in patients with mild cognitive impairment (Petersen et al. 2005).

13.4 Homotaurine

Homotaurine (Vivimind) is an inhibitor of Aβ aggregation that is naturally found in certain seaweeds. It is marketed in Canada as a nutraceutical with no specific health claims. Although a Phase II safety trial reported reduced CSF Aβ levels, two follow-up 18-month Phase III trials did not show any efficacy (Aisen et al. 2006, 2011).

13.5 *Ginkgo biloba*

Ginkgo biloba leaves and extracts are currently used as over-the-counter preparations for the treatment of numerous medical conditions. The rationale for the use of *Ginkgo biloba* for the treatment of AD stems from its free radical scavenging activity or the inhibition of pro-inflammatory pathways or the potentiation of the cell stress response (Uluoglu and Guney 2010; Walesiuk and Braszko 2010; Serby et al. 2011). However, clinical studies are yet to validate the beneficial effects of *Ginkgo biloba* in improving cognitive function in AD patients.

13.6 Resveratrol

Resveratrol is a naturally occurring phytochemical that is found in highest levels in red wine and the skin of red grapes. A recent epidemiological study showed that monthly and weekly consumption of red wine is associated with a lower risk of dementia (Daffner 2010). Several studies have shown that caloric restriction enhance healthy living by activating a new class of histone deacetylase enzymes known as sirtuins (Ramesh et al. 2010; Smith et al. 2010; Wang et al. 2010). Resveratrol is a substance found in some plants which may activate sirtuins either directly or by its action on upstream signalling pathways to stimulate caloric restriction and slow down brain atrophy (Albani et al. 2010; Braidy et al. 2012; Massudi et al. 2012). Despite its poor penetration into the brain, some studies have shown that resveratrol can reduce brain Aβ aggregation (Chandrashekaran et al. 2010; Ladiwala et al. 2010; Sun et al. 2010). An NIA-funded clinical trial examining the importance of resveratrol for the treatment of AD is currently underway.

14 Conclusion

AChEIs and the NMDA receptor antagonist memantine are currently approved for the treatment of AD. Despite this, numerous agents have been identified that exert a plethora of neuroprotective effects that may be useful for the treatment of AD. The clinical impact of current agents that may slow down the progression of AD will be significant if these drugs are administered early during disease onset.

Epilepsy

Stjepana Kovac and Matthew C. Walker

Contents

Abstract

Epilepsy is a chronic disorder defined by recurrent and unprovoked seizures and is one of the commonest disorders of the brain. Despite the burgeoning of new antiepileptic drugs, the burden of medically intractable epilepsy has not reduced significantly. One-third of patients with epilepsy continue to have unprovoked seizures despite advances in treatment. Cell death in seizures has been observed in in vitro and in vivo models of epilepsy and is the hallmark of hippocampal sclerosis, the commonest pathology associated with drug-resistant epilepsy.

Neuroprotection in epilepsy has a long tradition and with the discovery of new pathways involved in seizure induced cell death, strategies have been refined accordingly. In this chapter we will provide a comprehensive overview on the proposed mechanisms underlying cell death in epilepsy and how these can be targeted by exogenous and endogenous neuroprotectants. We will focus on the NMDA receptor and its downstream signalling cascades and their role in seizure induced cell death and potential drug targets arising from this central position within the cascade of cell death. We will summarize evidence

supporting the involvement of AMPA receptors in seizure induced cell death. In the last part the focus will be on mitochondria and ROS as pivotal players in seizure induced cell death and how these are linked to NMDA receptor dysfunction. We will outline strategies targeting these downstream signalling cascades.

1 Introduction

Epilepsy is a chronic disorder defined by recurrent and unprovoked seizures and is one of the commonest disorders of the brain. Despite the burgeoning of new antiepileptic drugs in the twentieth and twenty-first century, the burden of medically intractable epilepsy has not reduced significantly. One-third of patients with epilepsy continue to have unprovoked seizures despite advances in treatment (Duncan et al. 2006). Cell death in seizures has been observed in in vitro and in vivo models of epilepsy and is the hallmark of hippocampal sclerosis, the commonest pathology associated with drug-resistant epilepsy (Swanson 1995; Deshpande et al. 2008). This neuronal death is critically dependent upon excessive neuronal activity and the duration of such activity (Pitkänen et al. 2002). Seizures are usually self-limiting; generalized tonic-clonic seizures typically last less than 90 s (Theodore et al. 1994). However, seizures can be prolonged, and status epilepticus (defined as continuous seizure activity lasting longer than 30 min), the maximal expression of epilepsy, can occur in people with or without a prior history of epilepsy (often as the result of acute brain pathology, e.g., stroke, infection or head injury). This condition is a medical emergency, as it can lead to substantial neuronal cell death, resulting in cognitive and neurological deficits. Even single prolonged seizures in humans can lead to permanent damage in the hippocampus (Pinto et al. 2011). Animal studies support this. The first studies, showing that electrographic seizure discharges alone rather than secondary systemic complications during generalized seizures can lead to cell death, were published by Meldrum and colleagues (1973).

Neuroprotection in epilepsy has a long tradition and was mainly aimed at preventing seizure-induced cell death. However, there is growing evidence that prolonged seizures result in not only neuronal cell death but also neuronal and network dysfunction, which also contribute to the associated morbidities. Therefore, a definition of neuroprotection in epilepsy should include preventing not just neuronal cell death but also network dysfunction (Sutula et al. 2003; Walker 2007). This is difficult to capture in an experimental setting, especially in experimental animal work. In contrast, robust assays are available to measure neuronal cell death in animals. Much research into neuroprotection in epilepsy has therefore focussed on seizure-induced cell death.

This chapter will provide a comprehensive overview on the proposed mechanisms underlying cell death in epilepsy and how these can be targeted by exogenous and endogenous neuroprotectants. The first part will focus on the NMDA receptor and its downstream signalling cascades and their role in seizure-induced cell death and potential drug targets arising from this central position within the cascade of cell death. Evidence supporting the involvement of AMPA

receptors in seizure-induced cell death will be summarized. The final part will focus on mitochondria and ROS as pivotal players in seizure-induced cell death and how these are linked to NMDA receptor dysfunction. Strategies targeting these downstream signalling cascades will be outlined.

2 Neuronal Cell Death in Epilepsy

For over 100 years, it has been recognized that status epilepticus can result in damage and injury to the hippocampus (Pfleger 1880). Prolonged convulsive seizures can lead to hypotension, ventilatory dysfunction, and metabolic acidosis due to excessive muscle activity that can lead to neuronal damage (Walton 1993). It was thought that this physiological compromise was the main mechanism underlying neuronal death, which would therefore be restricted to convulsive status epilepticus. Pioneering experiments by Meldrum and colleagues in baboons in the 1970s challenged the prevailing orthodoxy; they showed that brain seizure activity can cause neuronal damage even in the absence of a systemic convulsion; seizure-induced brain damage is therefore not just a secondary phenomenon (Meldrum et al. 1973). That seizure activity itself can cause neuronal injury is now widely accepted and it is appreciated that even non-convulsive status epilepticus, a condition encountered in certain clinical settings, such as in comatose patients in the intensive care unit, can result in neuronal damage (Schmutzhard and Pfausler 2011). A more vexed question is whether even single, brief seizures can cause neuronal damage. Longitudinal neuroimaging studies in humans and histopathological studies in animals indicate that repeated seizures over time can result in damage, in particular to the hippocampus (Kälviäinen and Salmenperä 2002; Kotloski et al. 2002).

3 NMDA Receptors and Seizure-Induced Cell Death

The NMDA receptor has been linked to epilepsy and is an important neuroprotective target in epilepsy. NMDA receptor dysfunction as in NMDA receptor encephalitis, where autoantibodies are directed against the NMDA receptor, can cause seizures (Dalmau et al. 2008). Anti-NMDA receptor antibody mediate reversible decreases in NMDAR surface density and synaptic localization (Hughes et al. 2010), which could explain the associated cognitive deficits seen with this condition but does not easily explain the common occurrence of seizures. NMDAR involvement is seen not only in rare cases of autoantibody-mediated epilepsy but also in more common epilepsies. Epileptogenic lesions such as focal cortical dysplasia have an altered pattern of NMDA receptor expression with an abundance of the NR2B subunit (Ying et al. 2004; Möddel et al. 2005). NMDA receptor activation during prolonged seizures may also regulate the expression and function of other channels. The current first-line treatments for status epilepticus target the benzodiazepine site of the GABA(A) receptor. However, prolonged seizure activity leads to NMDA receptor activation and internalization of GABA(A)

receptors (Muir et al. 2010) and therefore after ~30 min of seizure activity benzodiazepines lose their efficacy (Naylor et al. 2005). The reverse holds true for the NMDA receptor. NMDA receptor subunits are mobilized to the synaptic membrane after continuous seizure activity (Chen and Wasterlain 2006).

NMDA receptors have also been identified as the crucial mediator of glutamate-induced neurotoxicity, and it was later discovered that this is mainly mediated by Ca^{2+} influx (Lucas and Newhouse 1957; Curtis et al. 1959). NMDA receptor antagonists given early after status epilepticus in animal models have been shown to be neuroprotective (Schauwecker 2010; Loss et al. 2012). There is evidence that NMDA receptor excitotoxicity depends on the type of subunit expressed and on the location relative to the synapse with many proposing that the predominantly extrasynaptic NR2B subunit mediates detrimental effects on neurons (Monyer et al. 1994; Tovar and Westbrook 1999; Hardingham et al. 2002; Liu et al. 2007). In keeping with this, ifenprodil, which predominantly targets the NR2B-containing NMDA receptors, has been shown to be neuroprotective if given after status epilepticus (Frasca et al. 2011). However, the NMDA receptor not only has negative effects on neurons, as it is pivotal for long-term potentiation, a fundamental mechanism underlying memory consolidation. Moreover, the NMDA receptor has protective effects (Hardingham and Bading 2010). Such protective effects are mediated by CREB (cyclic-AMP response element-binding protein), a transcription factor which is activated by nuclear Ca^{2+}. CREB activation enhances pro-survival gene expression and therefore provides neuroprotection against insults (Chrivia et al. 1993; Hardingham et al. 2001; Papadia et al. 2005). CREB is regulated by the ERK 1/2 pathway and CaM kinase (Wu et al. 2001). Other important pathways that have been implicated in NMDA receptor-mediated neuroprotection include suppression of FOXO and boosting of antioxidant defense genes (Papadia et al. 2008). Interestingly, these pathways are affected by synaptic and extrasynaptic NMDAR activation in opposing fashions, emphasizing the dichotomy between protective synaptic and neurotoxic extrasynaptic NMDAR activation (Hardingham and Bading 2010; Fig. 1). More recently it has been discovered that synaptic NMDARs are gated by different endogenous co-agonists from those that gate non-synaptic NMDARs with the former being gated by *d*-serine and the latter by glycine (Papouin et al. 2012). This differential gating provides novel more specific targets for either the synaptic or extrasynaptic NMDARs. Interestingly, the same group found that NMDA-induced neurotoxicity relies solely on synaptic NMDAR activation, thereby challenging previous reports, which identified the extrasynaptic NMDAR as the major culprit for NMDAR-induced neurotoxicity.

One endogenous substance that acts at the glycine site of the NMDA receptor is kynurenic acid. The kynurenine pathway is the main route of amino acid tryptophan metabolism from dietary intake that is not used for protein metabolism. The two main members along this pathway are quinolinic acid and kynurenic acid. Both are linked to NMDA receptor function. Quinolinic acid acts as an agonist, whereas kynurenic acid acts as an antagonist at NMDA receptors (Stone and Perkins 1981; Vamos et al. 2009). Kynurenic acid acts at both the glutamate and at the allosteric glycine site of the NMDA receptor and at higher concentrations inhibits AMPA receptors

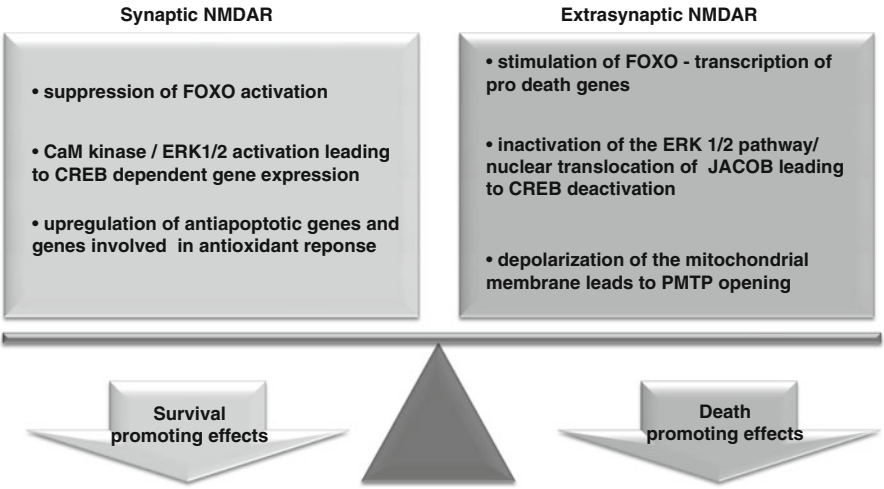

Fig. 1 Opposing effects of synaptic versus extrasynaptic NMDA receptors. *FOXO* forkhead box O class of transcription factors, *CREB* cyclic-AMP response element-binding protein, *CaM* nuclear Ca^{2+}/calmodulin-dependent protein. A more detailed summary of the opposing effects of synaptic versus extrasynaptic NMDA receptors is available in Hardingham and Bading (2010)

(Ganong and Cotman 1986; Watkins et al. 1990). Both receptors have been linked to epilepsy and epileptogenesis; kynurenic acid (KYNA) could therefore be an ideal neuroprotectant in epilepsy. There is evidence that the kynurenine pathway is involved in epilepsy and epileptogenesis. Depletion of KYNA within the hippocampus has been shown in pentylenetetrazole-induced seizures (Maciejak et al. 2009), and endogenously produced KYNA showed strong inhibitory effect on epileptiform activity vitro epilepsy model (Scharfman et al. 1999).

4 AMPA Receptors and Seizure-Induced Cell Death

The AMPA receptor is a tetrameric ionotropic transmembrane receptor for glutamate with fast synaptic transmission properties. It is the most abundant ionotropic glutamate receptor in the central nervous system. AMPA receptors are upregulated in neocortical tissue from patients suffering from pharmacoresistant epilepsy (Zilles et al. 1999; Palomero-Gallagher et al. 2012). Ion permeability of the receptor is determined by its subunit composition; GluR2-lacking receptors are permeable to Ca^{2+}, Na^{+}, and K^{+} and are inwardly rectifying, while channels containing the GluR2 subunit are selective for Na^{+} and K^{+} only (Isaac et al. 2007). Such differences in permeability are important, since in refractory status epilepticus, GluR2-subunits are internalized and the GluR2-lacking AMPARs are preferentially expressed on the surface of the cell. Furthermore, Rajasekaran and colleagues have shown that these receptor changes in the hippocampi of rats subjected to status epilepticus translate into changes in the functional properties of AMPAR-mediated currents, which show

increased inward rectification and the activation of which results in intracellular accumulation of Ca^{2+} (Rajasekaran et al. 2012). Drugs that target AMPA receptors have consequently also been shown to be neuroprotective in status epilepticus (Fritsch et al. 2010). AMPA receptor changes have not only been found in acquired epilepsy models but also in genetic models of epilepsy. The stargazer mice (lacking stargazing) have a trafficking defect in synaptic AMPARs in reticular thalamic nucleus cells and enhanced synaptic NMDARs activity leading to increases in thalamic excitability (Lacey et al. 2012). Targeting AMPA receptor trafficking therefore may reduce seizure-induced cell death.

5 Seizure-Induced Cell Death, Epilepsy, and Mitochondria

The common feature of both NMDA and GluR2-lacking AMPAR activation is an intracellular increase in Ca^{2+}. Ca^{2+} homeostasis is closely linked to the mitochondria and mitochondrial dysfunction leads to epilepsy in humans. It is well established that mutations in the mitochondrial genome or mutations in the nuclear genes coding for mitochondrial proteins lead to epileptic phenotypes (DiMauro 2004; Schapira 2006). Furthermore, a tight link between mitochondrial ATP production and seizures can be postulated, since seizures are a prominent feature in Leigh syndrome patients showing mutations in ATPase 6 gene (Canafoglia et al. 2001). Classical examples of mutations in the mitochondrial genome leading to seizures are MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) and MERRF (myoclonic epilepsy with ragged red fibres) syndrome (Rahman 2012). As implied in the names of mitochondrial disorders, multiple systems are affected; cerebral involvement represents only one facet of these multiorgan conditions. Epilepsies due to mutations in mitochondrial genes or nuclear genes coding for mitochondrial function are rare, when compared to the vast majority of epilepsies in general neurological practice. However, there is growing evidence that mitochondria and mitochondrial dysfunction may play an important role in many other epilepsies (Kann and Kovács 2007; Kann et al. 2011). Ongoing seizure activity induces ionic shifts and thereby increasing the demand for energy substrates to maintain transmembrane ion homeostasis (Lux et al. 1986). Therefore, it seems reasonable to link seizure activity to mitochondria, which are the main organelles responsible for the maintenance of transmembrane ion homeostasis. That mitochondria may play a prominent role in seizure generation is supported by the observation that mitochondrial membrane potential and Ca^{2+} concentrations change dramatically during epileptiform activity in vitro (Kovacs et al. 2005; Kovac et al. 2012). Mitochondrial complex I deficiency has been found in tissue resected from patient undergoing epilepsy surgery thus linking mitochondrial respiration to chronic seizure activity (Kunz et al. 2000). Another link comes from the effective treatment of refractory seizures with the ketogenic diet, a high-fat, low-carbohydrate diet (Bough et al. 2006; Bough 2008). Further analysis of the changes in gene expression secondary to the ketogenic diet showed mainly

upregulation of genes involved in oxidative phosphorylation and TCA cycle function (Bough et al. 2006). Finally, the pathology underlying one of the most common forms of epilepsy is hippocampal sclerosis which is characterized by apoptosis and necrosis, features that are tightly linked to mitochondria (Sloviter 1996).

But how do mitochondria contribute to seizure-induced cell death? There are two recognized forms of cell death: apoptosis and necrosis, and the mitochondria are important players in both. Apoptosis is defined as programmed cell death. A cascade of events leads to characteristic morphological cell changes with shrinkage of the cell with an intact cell membrane, fragmentation of DNA, and finally phagocytosis leading to cell death. In contrast necrotic cell death is described as a premature uncontrolled neuronal death that involves activation of hydrolytic enzymes and a rupture of the cell membrane followed by an inflammatory response.

Apoptosis involves intrinsic (activation within the cell or mitochondrion) and extrinsic (activation through plasma membrane receptors) pathways that converge to activate the executioner caspases, caspase 3 and caspase 7 (Tait and Green 2010). Inhibition of caspase 3 has been shown to be neuroprotective even if treatment is delayed for after the status epilepticus (Narkilahti et al. 2003b). Both pathways rely on mitochondrial outer membrane permeabilization (MOMP), which indicates a key point of no return. MOMP leads to release of cytochrome C. Cytochrome C is involved in electron transport during oxidative phosphorylation. However, it also leads to caspase activation after permeabilization of the outer mitochondrial membrane. Cells lacking cytochrome C fail to activate caspases and exhibit resistance to intrinsic apoptosis (Li et al. 2000).

Mitochondria act as a gatekeeper tuning Ca^{2+} concentrations in the cell and in cytoplasmic domains by buffering the Ca^{2+} during Ca^{2+} signalling. However, this buffering can be a starting point for apoptotic and necrotic cell death, if the matrix Ca^{2+} exceeds mitochondrial Ca^{2+} buffering capacity. This process leads to permeability transition, which is a phenomenon induced by high levels of matrix Ca^{2+}. It is characterized by the opening of the permeability transition pore (MPTP). The characteristic feature of MPTP opening is a permeability increase of the inner mitochondrial membrane to substances with small molecular masses (up to 1,500 Da) (Bernardi 1999; Crompton et al. 1999; Bernardi et al. 2006). Factors that have been indentified to contribute to mitochondrial permeability transition are Ca^{2+} accumulation and mitochondrial membrane potential depolarization, whereas a low pH, Mg^{2+}, and ADP prevent MPTP opening. The exact structure of the MPTP still needs to be characterized; however, it is most likely a multimeric complex, which may be assembled following activation (Zorov et al. 2009). Cyclophilin D (CypD) is a component of the MPTP, which is used pharmacologically, as the CypD inhibitors, such as cyclosporin A, are potent inhibitors of MPTP opening (Elrod et al. 2010). Strong evidence that MPTP could be a target for drug development comes from recent studies in ischemic heart disease. Inhibition of MPTP opening has been hypothesized to underlie the protective effect of ischemic preconditioning and post conditioning of myocytes (Hausenloy et al. 2009).

These strategies have been translated to the brain and MPTP opening has become a target in stroke and traumatic brain injury (Sullivan et al. 2005; Osman et al. 2011). Cyclosporin A prevents seizure-induced mitochondrial membrane depolarization, an event that leads to seizure-induced cell death (Kovac et al. 2012). Persistent MPTP opening leads to a depolarization of the mitochondrial membrane potential with a subsequent decrease in ATP production and matrix swelling induces breaks in the outer mitochondrial membrane. Release of cytochrome C which contributes to the formation of the apoptosome finally activates the executor caspases. Besides permanent opening, the MPTP can undergo transient "flickering" states which may prevent permanent opening through decreasing intra-matrix Ca^{2+} concentrations (Petronilli et al. 1999). Whether the cell will undergo apoptotic or necrotic cell death depends on the proportion of mitochondria undergoing MPTP opening. Mitochondria undergoing MPTP opening are not capable of ATP generation due to a dissipation of the mitochondrial membrane potential. However, ATP is required to aggregate the apoptosome which is necessary to induce programmed cell death via caspases. If not enough ATP is available for apoptosome formation, the rise in cytosolic Ca^{2+} will activate hydrolytic enzymes leading to necrosis (Gramaglia et al. 2004). It is important to note that increases in reactive oxygen species (ROS) contribute to MPTP opening by increasing Ca^{2+} load via stimulation of IP_3/ryanodine receptors and via inhibition of SERCA pumps and plasma membrane Ca^{2+} channels (PMCA) (Camello-Almaraz et al. 2006).

Inhibition of cell death pathways would seem a rational approach to prevent seizure-induced cell death. However, studies using this strategy have varying and inconsistent results. Inhibiting caspase 3 activation, for example, has been shown to be neuroprotective after status epilepticus in one animal model, whereas another study showed that this pathway is not involved in seizure-induced neuronal necrosis (Fujikawa et al. 2002; Narkilahti et al. 2003a, b; Walker 2007). Possible explanations for this variation are differences in the epilepsy models used in these studies and the time point at which the intervention takes place. Indeed, there may be more than one downstream pathway involved in mediating neuronal death in epilepsy and the relative importance of these pathways may depend upon a host of factors, highlighting the significant challenges facing the search for neuroprotective targets in epilepsy.

Given that energy failure and starvation play a pivotal role in seizure-induced cell death, anaplerosis seems to be an appealing strategy to reduce seizure-induced cell death. Anaplerosis is the replenishment of energetic substrates and is a strategy that has been used to prevent seizure-induced cell death and seizures themselves (for a comprehensive review see (Kovac et al. 2012)). Anaplerotic substrates, such as pyruvate or alpha-ketoglutarate, for example, reduce seizure-induced cell death both in vitro and in vivo (Yamamoto 1990; Yamamoto and Mohanan 2003; Kim et al. 2007; Carvalho et al. 2011; Kovac et al. 2012).

Factors that limit the use of anaplerotic substrates for the treatment of seizures and seizure-induced cell death are pharmacokinetic properties of these compounds and their bioavailability. Some of the compounds of the tricarboxylic acid cycle are not

membrane permeable (e.g., succinyl-CoA) or lack adequate transporters in the neuron, (e.g., citrate), preventing their use as an anaplerotic substrate (Gnoni et al. 2009).

Pyruvate seems to be the most promising anaplerotic substrate given its pharmacokinetic properties and evidence from in vivo and in vitro animal and human data. In addition pyruvate exhibits antioxidant properties as it acts as a free radical scavenger (Andrae et al. 1985; Bassenge et al. 2000; Varma and Hegde 2007).

6 Seizure-Induced Cell Death and Reactive Oxygen Species (ROS)

ROS can contribute to neuronal damage and therefore to seizure-induced cell death through a myriad of pathways. ROS, especially of mitochondrial origin, contribute to MPTP opening by increasing Ca^{2+} load via stimulating IP_3/ryanodine receptors and inhibiting SERCA pumps and plasma membrane Ca^{2+} channels (PMCA) (Camello-Almaraz et al. 2006). More recently ROS generated as a direct consequence of NMDA receptor activation have been described (Brennan et al. 2009).

Due to their reactive nature, ROS can contribute to cell death in a more direct manner. These are lipid peroxidation, protein denaturation inducing inactivation of enzymes, and nucleic acid damage. It needs to be highlighted that all these events are consequences of a very high intracellular ROS burden, exceeding the cell's capacity for antioxidant defense.

With regard to the brain, lipid peroxidation is probably the most important detrimental ROS effect, due to the abundance of lipids within the brain. Lipid peroxidation leads to the production of conjugated dienic hydroperoxides that decompose into aldehydes, dienals, or alkanes. These are toxic to the neuron and can lead to apoptosis (McCracken et al. 2000). Nuclear damage to DNA can lead to activation of repair enzymes such as poly (ADP-ribose) polymerase (PARP). This enzyme is known to lead to rapid ATP depletion which can stimulate cascades leading to cell death (Szabó 1998; Heeres and Hergenrother 2007). On the other hand, ROS induce release of cytochrome C from the mitochondria which activates the apoptosome inducing the caspase cascade, which leads to caspase 3-induced cleavage of nuclear DNA repair enzyme (Kim et al. 2000).

Oxidative stress has been implicated in the pathology associated with acute seizures, status epilepticus, and epilepsy. Acute increases in reactive oxygen species leading to damage of proteins, lipids, and ultimately cell death were shown after repeated seizures (Bruce and Baudry 1995; Liang et al. 2000; Tejada et al. 2007). It has been shown that antioxidant compounds such as vitamin C prevent seizure-induced neuronal death (Santos et al. 2008, 2009). Moreover, the lack of cellular antioxidants, as in superoxide dismutase mutant mice, leads to seizures in vivo (Lynn et al. 2005). In humans, magnetic resonance spectroscopy has shown decreased brain levels of glutathione, indicative of oxidative stress, in the brain of patients with epilepsy when compared to age-matched healthy controls (Mueller et al. 2001). Reactive oxygen species can damage lipids in cell membranes.

ROS degrade polyunsaturated lipids, forming malondialdehyde (MDA), which therefore is a marker of oxidative damage within a cell. MDA has been shown to increase following chronic epilepsy implying that seizure-induced ROS production leads to oxidative damage of lipids and cell membranes (Bruce and Baudry 1995; Frantseva et al. 2000; Tejada et al. 2007). Animal studies have shown decreased levels of glutathione in rats after prolonged seizures (Sleven et al. 2006), and the ketogenic diet, an effective treatment for pharmacoresistant seizures, increased glutathione levels in rat hippocampi (Jarrett et al. 2008).

Two mechanistically different therapeutic approaches can reduce the oxidative burden within the cell. One is blocking the source of free radical generation, whereas the other aims at scavenging the free radicals that have already been produced within the cell. The first approach requires identifying the source of free radical generation within the cell.

Several enzymes generate ROS within the cell. The candidate enzymes for ROS generation during seizures are the mitochondria, NADPH oxidase, and xanthine oxidase. Mitochondria, through reactions in the electron transport chain at complex I and III, are the main producers of ROS within the cell. That the NADPH oxidase may play an important role in seizure-induced ROS generation is suggested by the finding that NMDA receptors play a pivotal role in seizure-induced neuronal damage (Schauwecker 2010) and that recent evidence indicates that direct pharmacological activation of NMDA receptors can activate NADPH oxidase, increasing free radical production and consequently neuronal death (Abramov et al. 2007; Brennan et al. 2009; Girouard et al. 2009). Moreover, xanthine oxidase (XO) is also a major potential source of ROS during periods of increased metabolism such as occur during seizure activity.

Excessive NMDA receptor activation is a crucial event in acute neurological disease with detrimental downstream effects on neurons which include free radical generation (Lipton 1999) and there is a strong link between epilepsy and NMDA receptor dysfunction (Ying et al. 1999; Schauwecker 2010). Recent data suggest that NADPH oxidase is the primary source of superoxide induced by NMDA receptor activation (Brennan et al. 2009), and NADPH oxidase has been identified as a pivotal source of ROS generation in acute neurological disease such as stroke (Abramov et al. 2007).

In keeping with these findings, increases in NADPH oxidase activity have been linked to epilepsy models such as the pilocarpine and kainite model of epilepsy (Patel et al. 2005; Di Maio et al. 2011), and inhibition of NADPH oxidase was effective in reducing cell death in the in vivo pilocarpine model of temporal lobe epilepsy (Pestana et al. 2010).

ATP depletion results in adenine formation and consequently an increase in hypoxanthine and xanthine, substrates for xanthine oxidase (Xia and Zweier 1995; Kinugasa et al. 2003). Previous reports have suggested that there may be a beneficial effect of xanthine oxidase inhibition on seizures (Kramer et al. 1990; Tada et al. 1991; Zagnoni et al. 1994), although such an effect is not universally observed.

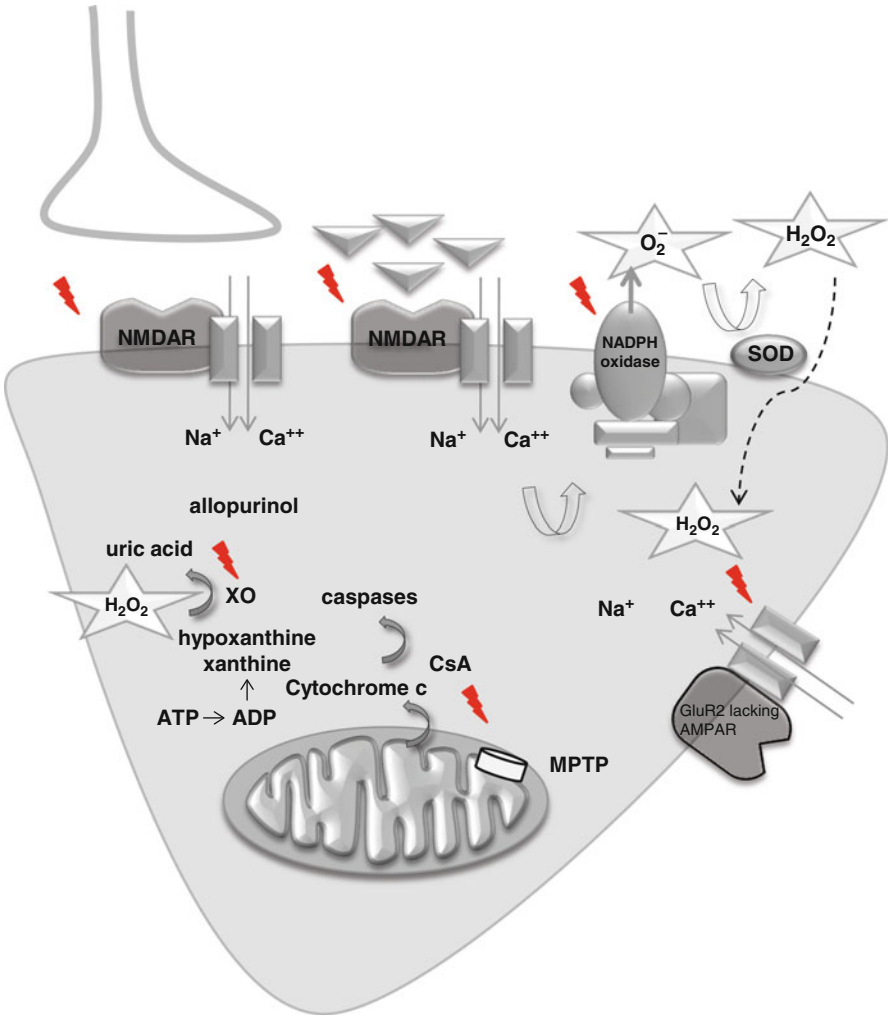

Fig. 2 Possible targets for neuroprotection in epilepsy. The figure illustrates potential targets of neuroprotection in epilepsy which include the ionotropic NMDA and AMPA glutamate receptor, the mitochondria and downstream mechanisms of ROS generation as the NADPH or xanthine oxidase. Abbreviations: *NADPH OX* NADPH oxidase, *MPTP* mitochondrial permeability transition pore, *CsA* cyclosporin A, *NMDAR* NMDA receptor, *AMPAR* AMPA receptor, *XO* xanthine oxidase, *SOD* superoxide dismutase

This chapter has outlined several mechanisms involved in seizure-induced cell death. The evidence for targeting NMDA and AMPA receptor, mitochondrial function, and ROS including several downstream targets of those receptors has been discussed. Neuroprotective targets in epilepsy are summarized in Fig. 2.

7 Conclusion

There are several interacting yet distinct mechanisms that can contribute to neuronal death in epilepsy, making common neuroprotective strategies challenging. The relative roles of each of the above mechanisms also show time dependency in status epilepticus with critical early steps likely to be the activation of ionotropic receptors and calcium influx, while later steps involve the activation of signalling and metabolic pathways. Directing treatments at the early steps has the advantage that there may be fewer targets but this strategy may be temporally less practical. Treating the later stages has a temporal advantage but the large number of pathways possibly involved presents a different challenge.

The observation that repeated brief seizures over time can lead to neuronal damage suggests that long-term neuroprotective strategies could offer the possibility of modifying comorbid declines in memory and other associated conditions such as depression.

Excitotoxicity and Amyotrophic Lateral Sclerosis

Kim A. Staats and Ludo Van Den Bosch

Contents

Abstract

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disorder characterized by the progressive and selective death of motor neurons in the motor cortex, brainstem, and spinal cord. The only therapy with proven efficacy for ALS patients is a treatment with riluzole that offers patients a moderate

increase in survival. Riluzole interferes with excitotoxicity, which is neuronal death caused by overstimulation of glutamate transporters. The high sensitivity of motor neurons to excitotoxicity is further illustrated by the observation that a number of exogenous toxic substances (excitotoxins) that stimulate glutamate receptors result in selective motor neuron death. This selective vulnerability of motor neurons to excitotoxic insults is due to their poor calcium buffering capacity in combination with the expression of calcium-permeable AMPA type of glutamate receptors. The AMPA receptor subunit responsible for calcium impermeability, GluR2, is expressed at lower levels, and RNA editing of GluR2 required for calcium impermeability is diminished in motor neurons of ALS patients. Not only calcium permeability of AMPA receptors but also glutamate transport into neighboring astrocytes plays an important role in ALS. Decreased levels of glutamate transporters are present in ALS patients and ALS animal models, implying an increased vulnerability to glutamate. This chapter aims to provide an overview of the known players and their interactions in the field of excitotoxic motor neuron death and in the context of ALS.

Keywords
ALS • Excitotoxicity • Motor neuron loss • Motor neuron disease • Glutamate

1 Introduction of ALS

1.1 Basics

Amyotrophic lateral sclerosis (ALS) is a devastating fatal neurodegenerative disease, with progressive loss of motor neurons of the motor cortex, brainstem, and spinal cord and denervation of muscle fibers, resulting in increasing muscle weakness and paralysis. The disease has an incidence of 2.7 cases per 100,000 people in Europe (Logroscino et al. 2010) and is more prevalent in the later years of life. In lack of a medical cure, average life expectancy is between 2 and 5 years. Patients usually die due to respiratory insufficiency or may opt for euthanasia where legislature permits (Maessen et al. 2010). Although ALS is characterized by degeneration of central nervous system tissue, mental functions remain largely unaffected resulting in a locked-in state (Kotchoubey et al. 2003). Only one drug is currently available to treat the disease, riluzole, and slows disease progression moderately (Miller et al. 2007).

1.2 ALS Genetics

There are both familial and sporadic cases of the disease, and a common disease mechanism is expected due to the indistinguishable clinical phenotypes of these patients. Approximately 90 % of ALS cases are sporadic in which a gene-environment

interaction is hypothesized. The remaining 10 % of ALS cases are inherited by mutations in a number of genes including superoxide dismutase 1 (SOD1), vesicle-associated membrane protein-associated protein B (VAPB), TAR DNA binding protein (TDP43), fused in sarcoma/translocated in liposarcoma (FUS/TLS), optineurin (OPTN), valosin-containing protein (VCP), ubiquilin2 (UBQLN2), and p62 (SQSTM1) which have been identified as causes of familial ALS (Van Deerlin et al. 2008; Rutherford et al. 2008; Del Bo et al. 2009; Kwiatkowski et al. 2009; Vance et al. 2009; Maruyama et al. 2010; Fecto et al. 2011; Deng et al. 2011; Johnson et al. 2010). In addition, hexanucleotide repeat expansions in the noncoding part of the "chromosome 9 open reading frame 72" (C9ORF72) gene were discovered as a new cause of ALS (Dejesus-Hernandez et al. 2011; Renton et al. 2011).

1.3 ALS Models

Overexpression of mutant forms of human SOD1 causes the ALS phenotype of transgenic SOD1 mice, which have made a large contribution to ALS research (Gurney et al. 1994). Many hallmarks of the disease are shared by patients and this rodent model, including specific motor neuron loss, aggregate formation, astrogliosis, microgliosis, and progressive paralysis. SOD1 detoxifies potentially cell-damaging free radicals, but the genetic ablation of SOD1 does not produce an ALS-like phenotype in mice (Reaume et al. 1996; Shefner et al. 1999), implying that mutant SOD1 causes the disease by a toxic gain of function. This gain of function may exert itself by protein misfolding, aggregation, impaired proteasome functioning, impaired retrograde transport, excitotoxic cell death, and others (reviewed in Bruijn et al. (2004)). Unfortunately, the discovery of the other ALS genes described above has not yet progressed into useful ALS model organisms, forcing most work described below to have been conducted on mutant SOD1 cells, on rodents, or on patients.

1.4 Non-cell Autonomous

ALS is a non-cell autonomous disease (Boillee et al. 2006a), meaning that multiple cell types affect disease pathology. By addition or deletion of mutant SOD1 in specific cell types, a number of cell types have been identified that influence the disease, including astrocytes (Yamanaka et al. 2008), microglia (Boillee et al. 2006b), Schwann cells (Lobsiger et al. 2009), and motor neurons (Jaarsma et al. 2008). Despite the influence of multiple cell types, mutant SOD1 expressed solely in neurons is sufficient to initiate the disease, with a slowed disease progression (Jaarsma et al. 2008). The vulnerability of motor neurons is also portrayed by the selective loss of motor neurons in the motor cortex, brainstem, and spinal cord in patients. There are a number of hypotheses that explain this cell type selectivity, including the long axons of these cells and the poor buffering of intracellular calcium.

1.5 Excitotoxicity in ALS

Glutamate is the neurotransmitter used to excite motor neurons that is the initiator of excitotoxicity in ALS. This neurotransmitter is the most abundant excitatory neurotransmitter in the brain and binds to *N*-methyl-D-aspartate (NMDA) or α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate (ionotropic) receptors and metabotropic glutamate receptors (mGluR). The levels of glutamate are increased in ALS patients (Fiszman et al. 2010; Spreux-Varoquaux et al. 2002), implying glutamate's role in the disease. The importance of excitotoxicity in ALS has been demonstrated mainly by the beneficial effects obtained by treating patients with riluzole. Although the precise mechanisms of this drug are not yet known, it has been shown to block NMDA receptors, it enhances reuptake of glutamate from the synaptic cleft, and it inhibits glutamate release by blocking voltage-gated sodium channels (Siniscalchi et al. 1999), thus preventing motor neuron cell death. Riluzole treatment increases predicted life span by 12 % in ALS mice (Lacomblez et al. 1996; Bensimon et al. 1994) and increases the probability of 1-year survival in patients by 9 % (Miller et al. 2007).

1.6 Non-glutamate Excitotoxins

A small number of substances are excitotoxic and can cause motor neuropathies and/or neurodegeneration. Domoic acid causes a motor neuropathy in some patients after food poisoning due to consumption of mussels containing high levels of this compound (Debonnel et al. 1989). Domoic acid is also associated with epileptic seizures in humans (Teitelbaum et al. 1990), sea lions (Scholin et al. 2000), and rats (Muha and Ramsdell 2011) and lowers the threshold for seizures in adult rats when exposed to it at neonatal stages (Gill et al. 2010). Also β-*N*-oxalyl-amino-L-alanine (BOAA), also known as β-oxalyl-L-α,β-diaminopropionic acid (ODAP), causes excitotoxicity. BOAA is highly present in the chickling pea (*Lathyrus sativus*) of which consumption leads to lathyrism (Streifler and Cohn 1981; Spencer et al. 1986). This substance is an AMPA receptor agonist (Willis et al. 1994; Kunig et al. 1994) that causes motor neuron degeneration (Chase et al. 1985; Weiss et al. 1989) and alternative effects on the central nervous system (Willis et al. 1994; Kunig et al. 1994). Another excitotoxin is one discovered by a high prevalence of ALS on the island of Guam, also known as the Western Pacific amyotrophic lateral sclerosis-Parkinsonism-dementia or the amyotrophic lateral sclerosis-Parkinsonism-dementia complex (ALS/PDC). Consumption of cycad seed products (*Cycas circinalis*) is responsible for the neurodegeneration in ALS/PDC of which β-methylamino-alanine (BMAA) is identified as a damaging substance (Steele and Guzman 1987; Hudson 1991; Wilson et al. 2002). BMAA is also a glutamate receptor agonist that causes motor neuron syndrome (Murch et al. 2004; Chang et al. 1993; Purdie et al. 2009) and damages motor neurons (Rao et al. 2006), cholinergic neurons in vitro (Liu et al. 2010; Brownson et al. 2002), and hippocampal neurons in vivo (Buenz and Howe 2007).

1.7 Poor Calcium Buffering

An additional explanation for the selective motor neuron vulnerability to excitotoxicity is poor capability of this cell type to buffer intracellular calcium; ALS-vulnerable spinal cord and brainstem motor neurons in mice display low endogenous calcium buffering capacities (Palecek et al. 1999; Lips and Keller 1998). In addition, ALS-resistant oculomotor neurons contain a far larger calcium buffering capacity than ALS-vulnerable motor neurons (von Lewinski and Keller 2005). This difference in calcium buffering capacity is directly due to the differential expression levels of the calcium-binding proteins calbindin-D28k and parvalbumin (Obal et al. 2006). The beneficial effect of calcium buffering by calcium-binding proteins is confirmed in experiments of acute neurodegeneration in a transgenic mouse by overexpressing the calcium-binding protein parvalbumin. According to expectations, parvalbumin overexpressing cells are protected against neurodegeneration induced by axotomy in vivo (Paizs et al. 2010) and excitotoxic cell death in vitro (Van Den Bosch et al. 2002a). In addition, parvalbumin overexpression delays disease onset and extends survival in ALS mice (Beers et al. 2001).

2 AMPA Receptors in Excitotoxicity in ALS

2.1 Basic Excitotoxicity

After release from the presynaptic neuron into the synaptic cleft, glutamate binds to NMDA, AMPA, or metabotropic receptors. The AMPA receptor plays an important role in motor neuron death in ALS. The AMPA receptor is a tetramer combining four different subunits (glutamate receptor units 1–4 (GluR1–4)) (Shi et al. 1999). All subunits bind glutamate, and the channels open after occupation of at least 2 binding sites (Mayer 2005). The importance of this receptor in ALS is demonstrated by the ablation of glutamate-induced apoptosis in cortical neurons in vitro (Cid et al. 2003) and in vivo when administering an AMPA receptor antagonist (Van Damme et al. 2003). The detrimental role of glutamate in the disease is demonstrated by the pronounced cell death that occurs to primary cultured neurons in vitro when exposed to low levels of glutamate, even as low as physiologically detected in cerebrospinal fluid (CSF) (Cid et al. 2003). To further illustrate the detrimental role of glutamate in ALS, administration of compounds that block the formation of glutamate increases cell survival, both in vivo and in vitro (Cid et al. 2003). In addition, decreasing vesicular glutamate transporter 2 (VGLUT2) extends survival of motor neurons in ALS mice but does not extend life span of ALS mice (Wootz et al. 2010).

2.2 AMPA Receptor-Mediated Cell Death

As discussed previously, motor neurons are excited by glutamate by, among others, the AMPA receptors. Interestingly, the AMPA receptors on motor neurons are

mainly calcium permeable in vitro (Van Den Bosch et al. 2000; Carriedo et al. 1996; Van Den Bosch et al. 2002b), which may explain the selective vulnerability of motor neurons to excitotoxic cell death. In addition, extracellular calcium entry via these calcium-permeable AMPA receptors is responsible for selective motor neuron death, as motor neuron death is inhibited by selective blockers of calcium-permeable AMPA receptors (Van Den Bosch et al. 2000). AMPA receptors of motor neurons have a lower rectification index and a higher relative calcium permeability ratio than other neurons (Van Damme et al. 2002). Not only in vitro but also in vivo motor neurons express calcium-permeable AMPA receptors (Greig et al. 2000). Interestingly, infusing the spinal cord of rats with AMPA receptor agonists induces neurodegeneration of specifically motor neurons and paralysis, which was blocked by coadministration of a selective blocker of calcium-permeable AMPA receptors (Corona and Tapia 2007; Sun et al. 2006). This demonstrates a specific vulnerability of motor neurons to AMPA receptor-mediated cell death.

2.3 GluR2 Subunit of the AMPA Receptor

The AMPA receptor plays an imperative role in excitotoxicity by its calcium permeability that is determined by the incorporation of the GluR2 subunit in the receptor complex. In most conditions, the AMPA receptor complex contains at least one GluR2 subunit and this prevents the influx of extracellular calcium into the neuron (Seeburg et al. 2001). In contrast, receptors lacking the GluR2 subunit are highly calcium permeable (Seeburg et al. 2001). Murine motor neurons contain lower levels of GluR2 mRNA compared to other neurons (Van Damme et al. 2002). In addition, laser capture microscopy and quantitative PCR demonstrated that the expression level of the GluR2 subunit is lower in (human) spinal motor neurons compared to other neurons (Heath et al. 2002; Kawahara et al. 2003), implying the intrinsic vulnerability of motor neurons to excitotoxicity. A general decrease of GluR2 is found in ALS model mice, portraying an increased vulnerability of these mice to excitotoxic insults (Zhao et al. 2008; Tortarolo et al. 2006). The role of GluR2 in ALS is investigated by genetically ablating GluR2 in ALS mice, which decreases survival in vivo and decreases cell survival in vitro (Van Damme et al. 2005). Upregulation of GluR2 expression in motor neurons of ALS mice increases survival (Tateno et al. 2004). In addition, pharmacological inhibition of the AMPA receptor prolongs survival in ALS mice (Van Damme et al. 2003; Tortarolo et al. 2006; Canton et al. 2001). Interestingly, the surrounding astrocytes influence the expression level of the GluR2 subunit in motor neurons, as soluble factors released from astrocytes affect GluR2 gene expression and neuronal vulnerability to excitotoxic insults, both in vitro and in vivo (Van Damme et al. 2007). Intriguingly, the presence of mutant SOD1 interferes with the production and/or secretion of these factors (Van Damme et al. 2007). Although not all these influencing factors are known, vascular endothelial growth factor (VEGF), brain-derived neurotrophic factor (BDNF), and glial cell-derived neurotrophic factor (GDNF) are able to upregulate GluR2 expression (Bogaert et al. 2010; Brene et al. 2000). Although the

role of AMPA receptors is established, there is no genetic evidence that polymorphisms in the GluR2 gene increase susceptibility for ALS (Bogaert et al. 2012).

2.4 GluR2 Editing

The GluR2 subunit's special characteristic of preventing calcium influx through the AMPA receptor is due to RNA editing at the Q/R site, and this process is also associated to ALS. This editing in the GluR2 pre-mRNA introduces a positively charged arginine at the Q/R site of the GluR2 peptide instead of the genetically encoded neutral glutamine (Burnashev et al. 1992). Under normal conditions, GluR2 pre-mRNA editing is virtually complete, but under pathological conditions it could become less efficient resulting in more calcium-permeable AMPA receptors. Indeed, it is reported that editing of pre-mRNA of GluR2 is defective in the spinal motor neurons of sALS patients (Kawahara et al. 2004). In addition, GluR2 gene expression and GluR2 RNA editing are reduced in the spinal cord of ALS patients (Takuma et al. 1999). Furthermore, the enzyme responsible for the RNA editing, adenosine deaminase acting on RNA 2 (ADAR2), is only present in 50 % of the motor neurons from sporadic ALS patients (Aizawa et al. 2010). Reduced editing at the Q/R site of GluR2 in mice results in a lethal phenotype accompanied with seizures and neurodegeneration (Brusa et al. 1995; Higuchi et al. 2000). Transgenic mice carrying a minigene with the GluR2 gene encoding an asparagine (GluR2-N) at the Q/R site, which makes editing impossible, are viable and fertile (Kuner et al. 2005) and are a useful tool to investigate the effect of calcium-permeable AMPA receptors, as AMPA receptors incorporating GluR2-N are permeable to calcium (Burnashev et al. 1992). The combined expression of the GluR2-N transgene and endogenous GluR2 alleles results in a twofold increase in permeability for calcium (Feldmeyer et al. 1999). Interestingly, these transgenic mice develop motor neuron degeneration late in life (Feldmeyer et al. 1999), and GluR2-N overexpression induces a progressive decline in function, as well as a degeneration of spinal motor neurons (Kuner et al. 2005). In accordance, GluR2-N expression in ALS mice exacerbates disease progression and reduces survival confirming the role for edited GluR2 in ALS (Kuner et al. 2005). In addition, conditional knockdown of ADAR2 in murine motor neurons causes a late-onset neurodegenerative condition (Hideyama et al. 2010).

3 Glutamate Transporters in ALS

3.1 Glutamate Transporter Levels in ALS

After release from the presynaptic neuron, glutamate is recycled by the glial and endothelial cells, including astrocytes. Astrocytic glutamate reuptake occurs by the glutamate transporters excitatory amino acid transporter 1 (EAAT1) and excitatory amino acid transporter 2 (EAAT2; also known as glutamate aspartate transporter

(GLAST1) and glutamate transporter 1 (GLT-1), respectively). These transporters internalize glutamate, for conversion to glutamine that is returned to the presynaptic neuron (Laake et al. 1995). Reduced glutamate uptake and EAAT2 protein expression are common in both ALS patients and ALS model systems (Staats and Van Den Bosch 2009). In vitro transfection of astrocytes with either mutant SOD1 or wild-type human SOD1 downregulates EAAT2 posttranscriptionally (Tortarolo et al. 2004), though it is unknown whether the downregulation of EAAT2 affects neuronal survival. Mutant SOD1 transfection also decreases glutamate transport in cell lines (Sala et al. 2005). Interestingly, this downregulation is present in ALS model rats at presymptomatic stages through to end stage (Howland et al. 2002), at end stage only (Warita et al. 2002), in ALS model mice at end stage (Bendotti et al. 2001), and in *post mortem* patient spinal cords by staining for EAAT2 (Sasaki et al. 2001). Interestingly, a decrease of EAAT2 protein is present in mutant SOD1 mice and in an environmental model of ALS/PDC (mice are fed with washed cycad flour containing BMAA, which causes an ALS-like phenotype (Wilson et al. 2002)) (Wilson et al. 2003). Although the loss of EAAT2 in ALS is apparent, it remains unclear whether this loss of EAAT2 proceeds or follows the loss of motor neurons.

3.2 Reducing Glutamate Transporters in ALS

To assess whether the loss of glutamate transport or the loss of EAAT2 specifically results in motor neuron loss, pharmacological and genetic tools have been employed. To begin, research conducted by pharmacologically inhibiting glutamate transport in the rat spinal cord failed to show any motor neuron loss despite the increased levels of glutamate (Tovar et al. 2009). This experiment has not (yet) been performed in ALS mice, leaving it to be elucidated whether decreased glutamate transport pharmacologically is detrimental for motor neuron survival in ALS. In contrast, a similar experiment has been performed to address whether EAAT2 loss specifically would induce motor neuron loss. EAAT2 null mice have been generated that live for approximately 6 weeks before they succumb to epileptic seizures and show increased vulnerability to acute brain injury (Tanaka et al. 1997). The heterozygous mice (containing 1 allele of EAAT2) were used to assess the effect of approximately 40 % knockdown of EAAT2 in the spinal cord in ALS mice (Pardo et al. 2006). This described knockdown resulted in a nonsignificant decrease of symptom onset and in significant, but moderate, decrease of life span in ALS mice (Pardo et al. 2006).

3.3 Increasing Glutamate Transporters in ALS

To assess the expected beneficial role of EAAT2 in ALS, transgenic mice overexpressing human EAAT2 in astrocytes only were crossbred with mutant SOD1 mice. Although glutamate uptake is increased in the mice and is protective on primary cortical neurons in culture, these effects were unable to affect

symptom onset or life span (Guo et al. 2003). Possibly, the expression levels were too low to induce an effect, or human EAAT2 is not as efficient as murine EAAT2 in mouse, as administration of ceftriaxone (a β-lactam antibiotic) or GPI-1046 (a synthetic, non-immunosuppressive derivative of FK506) increases EAAT2 protein levels and extends life span of ALS mice (Ganel et al. 2006; Rothstein et al. 2005). In addition, EAAT2 is also expressed by other cell types than astrocytes alone (Anderson and Swanson 2000), which were not targeted with this genetic experimental design. The beneficial effect of EAAT2 is often used as an explanation of beneficial effects found by cell transfers in ALS model rodents. For instance, the systemic transplantation of c-kit-positive cells from bone marrow in mutant SOD1 mice increases survival, which is, at least in part, attributed to increased EAAT2 expression induced by the transferred cells (Corti et al. 2010). The same holds true for the prolonged survival of ALS rats when treated with focal transplantation-based astrocyte replacement with wild-type glial-restricted precursors (GRPs) (Lepore et al. 2008). This study, interestingly, also focussed on the precise role of EAAT2 by also transplanting EAAT2 overexpressing GRPs and EAAT2 null GRPs. ALS mice treated with EAAT2 overexpressing GRPs show no additional increase of life span compared to wild-type GRP-treated ALS mice (which is already increased compared to controls). Intriguingly, this positive effect of transplantation of the wild-type GRPs is diminished in the mice transplanted with the EAAT2 null GRPs (Lepore et al. 2008). In addition, cocultures of human adipose-derived stem cells with astrocytes induce higher levels of EAAT2 in the astrocytes (Gu et al. 2010), though this treatment has not (yet) been shown to effect motor neuron survival in vitro or in vivo.

4 Conclusion

Excitotoxicity plays a major role in the pathophysiology of ALS. Excitotoxins can cause neurodegeneration and ALS/PDC. In addition, the only drug that prolongs survival in patients targets excitotoxicity. The specific vulnerability of motor neurons to excitotoxic insults may be explained by their poor calcium buffering capacity and their expression of calcium-permeable receptors. Cell death in ALS can be postponed by blocking the AMPA receptor, and applying AMPA receptor agonists induces neuronal death. The AMPA receptor subunit responsible for calcium impermeability, GluR2, is less expressed by motor neurons in comparison to other neuronal subtypes, and knockdown of this subunit prolongs survival in ALS mice. Moreover, the pre-RNA editing to obtain normal GluR2 is diminished in motor neurons and in ALS patients. In accordance, increasing unedited GluR2 in mice induces neurodegeneration. Not only AMPA receptor calcium permeability but also glutamate transport is affected in ALS. Decreased levels of EAAT2 are present in ALS patients and ALS rodents, implying an increased vulnerability to glutamate. In addition, increased levels of EAAT2 prolong survival, and decreased levels reduce survival in ALS mice. Future research may focus further to develop therapeutic strategies targeting excitotoxicity in ALS.

Excitotoxicity and Axon Degeneration

Anna E. King and James C. Vickers

Contents

Abstract

Excitotoxicity has been implicated as a key pathogenic pathway in a number of neurodegenerative diseases and conditions including Alzheimer's disease, amyotrophic lateral sclerosis, multiple sclerosis, brain trauma, and stroke. While acute excitotoxicity can result in the initiation of cell death pathways, chronic or low levels of excitotoxin exposure may result in a more slowly progressing pathological cascade. In this respect, there is emerging evidence that excitotoxicity can result in axonal degeneration and pathology, a key pathological feature of many of these neurodegenerative conditions. Recent evidence supports the notion that axon degeneration can be a separate and independent

process from cell death, and thus mechanisms involved need to be understood in order to provide axonal protection in neurological disease. While axon degeneration following transection (Wallerian degeneration) has been well documented, less is known about axon degeneration following other insults such as excitotoxicity and the mechanistic relationships they bear to Wallerian degeneration. In particular, how a primarily somatodendritic insult, such as excitotoxicity, results in a pathological cascade within the axon is unclear. This chapter reviews our current understanding of the pathological changes and mechanisms of excitotoxin-induced axon degeneration with particular reference to our understanding of other forms of axonal degeneration and potential mechanisms involved. An increased understanding of the mechanisms of axon degeneration in neurological disease is essential to the development of therapeutic agents targeting axon protection.

List of Abbreviations

Aß	Beta amyloid
ALS	Amyotrophic lateral sclerosis
AMPA	Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
CaMKII	Ca^{2+}/calmodulin-dependent protein kinase II
Cdk5	Cyclin-dependent kinase 5
CNP	2′3′-Cyclic nucleotide 3′-phosphodiesterase
CNS	Central nervous system
CRMP2	Collapsin response mediator protein 2
MAG	Myelin-associated glycoprotein
MPP	1-Methyl-4-phenylpyridine
NAD	Nicotinamide adenine dinucleotide
NFH	Neurofilament heavy chain
NFL	Neurofilament light chain
NFM	Neurofilament medium chain
NMDA	*N*-methyl-D-aspartate
Plp	Proteolipid protein
PNS	Peripheral nervous system
TTX	Tetrodotoxin
Wlds	Wallerian degeneration slow

1 Introduction

The toxicity of excitatory amino acids such as glutamate to neurons ("excitotoxicity") has been known since the 1950s (Lucas and Newhouse. 1957) and has since been implicated in the pathogenesis of a number of neurodegenerative conditions (Faden et al. 1989; Aarts et al. 2002; Hynd et al. 2004; Bogaert et al. 2010). Excitotoxicity was demonstrated by Olney (1969) to occur through overactivation of excitatory amino acid receptors and, in a variety of disease states, may also occur through the

impaired ability of cells to deal with sub-toxic levels of glutamate. In this regard, a characteristic of most neurodegenerative diseases is the slowly progressing cellular pathology and degeneration that occurs prior to overt cell death. Although excitotoxicity is generally considered a somatodendritic insult, there is also emerging evidence that excitotoxicity can play a role in axon degeneration, the latter a key feature of a number of neurodegenerative diseases including Alzheimer's disease, multiple sclerosis, and amyotrophic lateral sclerosis (ALS). The evidence for excitotoxic "axonopathy" and proposed mechanisms are discussed in this chapter.

2 Axon Degeneration in Neurodegenerative Disease

Axon degeneration is a prominent feature of neurodegenerative disease (Vickers et al. 2009) pathologically characterized by axonal swelling, axonal dystrophy, and distal axon dieback. It potentially represents one of the earliest findings in many diseases, and it has been proposed that it may be the cause of cellular dysfunction and degeneration through a dying back process. *ALS* is characterized by substantial early axonal degeneration in both the upper and lower motor neurons pathologically presenting as degeneration of the corticospinal tract and disconnection of the neuromuscular junctions and large axonal swelling referred to as "spheroids" in the proximal axons of lower motor neurons (Wood et al. 2003; Fischer et al. 2004). Causes of axonal degeneration have not been fully determined but are thought to involve axonal transport disruption. Axon transport disruption has also been implicated in axonal pathology in Alzheimer's disease, the latter which consists primarily of dystrophic neurites linked with Aß plaque formation (Vickers et al. 2009). Axon pathology linked with dystrophic neurite formation is accompanied by substantial demyelination (Mitew et al. 2010). Interestingly, putative demyelinating conditions, such as multiple sclerosis, are also associated with axonopathy and neuronal cytoskeletal changes indicative of axon transport disruption (Petzold et al. 2008). The precise cause of axonal degeneration in all of these conditions has not been determined and may be multifactorial in nature. However, there is substantial evidence for a role of excitotoxicity in the pathogenesis of these diseases, leaving the possibility that axonal degeneration results from excitotoxic processes.

3 Mechanisms of Axon Degeneration

Axon degeneration following axonal transection has been very well defined and involves a process termed "Wallerian degeneration". A number of reviews describe the time course of Wallerian degeneration including the distinct phases of retraction of cut ends, formation of swollen end bulbs, latency period, axonal beading, sudden axonal fragmentation, and clearing of axonal segments by glial cells (e.g., Coleman 2005; Luo and O'Leary 2005; Wang et al. 2012,). Mechanistically, Wallerian degeneration has been shown to involve calcium influx (Knoferle et al. 2010), activation and loss of calpains (Glass et al. 2002; AraujoCouto et al. 2004),

activation of autophagy (Knoferle et al. 2010) and microtubule disruption (Zhai et al. 2003). Caspase activity and other apoptotic mechanism are not generally associated with Wallerian degeneration (Finn et al. 2000). Much of our understanding of the nature of axonal degeneration comes from a mutant mouse model, the slow Wallerian degeneration (Wlds) mouse, in which Wallerian degeneration is substantially delayed, suggesting that axon degeneration is an active process. Analysis of the genetic mutation that is responsible for this delayed degeneration revealed a splicing of two mRNAs to form a fusion protein consisting of Nmnat1 (an NAD+ salvage enzyme) and the N terminal protein of Ube4b (an E4 ubiquitin ligase) (Mack et al. 2001). Current research supports the notion that Nmnat1 activity is important for axonal protection in Wlds mice, and Ube4b may be responsible for directing it to the axon instead of the nucleus (Conforti et al. 2009). However, the protective role of Nmnat1 remains unclear (Sasaki et al. 2009, reviewed in Coleman and Freeman 2010). Despite the increasing knowledge on mechanisms of Wallerian degeneration, it remains unclear if other mechanisms of axonal degeneration exist. One type of axon degeneration that has been described that does not appear to involve Wallerian degeneration is developmental axon retraction, which occurs when a small shortening of the axon is required, for example, during neurite outgrowth and synapse formation. Axon retraction involves preservation of the axonal cytoplasm through gradual retrograde transport of materials to more proximal axon segments (reviewed in Luo and O'Leary 2005).

Axon degeneration that occurs in neurodegenerative disease, however, is not usually associated with direct severing of the axon, although it frequently shares many similarities with Wallerian degeneration, such as axon thinning, beading, and fragmentation (for review, see Saxena and Caroni 2007). In contrast, in a number of diseases and conditions, axon degeneration may occur by a dying back axonopathy, beginning at the distal axon (Cavanagh 1964), or may involve formation of large axonal swellings or spheroids (Trapp et al. 1998; King et al. 2011). Furthermore, the protective effect of the Wlds gene in some but not all (for review, see Coleman 2005) mouse models of disease suggests that different mechanisms may be involved. Pertinent to the current topic is whether axon degeneration induced by excitotoxicity occurs via a Wallerian-type degeneration or by a different mechanism.

4 Morphological Characteristics of Excitotoxin-Induced Axon Degeneration

Despite its clear relevance to neurological diseases, few studies have examined the consequence of excitotoxicity to the axonal compartment. In vitro studies suggest that axonal changes may occur rapidly, prior to the hallmarks of neuronal cell death, and within 2–6 h of exposure to glutamate receptor agonists (King et al. 2007; Hou et al. 2009). Axonal degeneration also occurs following exposure to application of both NMDA (Chung et al. 2005; King et al. 2007) and non- NMDA (King et al. 2007) agonists. However, the type of degeneration occurring following such insults may be specific to both the particular pattern of receptor activation and the cell

type (King et al. 2007). In cultured rodent cortical neurons, glutamate, NMDA, and kainic acid exposure result in axonal retraction, beading, thinning, and subsequent fragmentation of the axon (Chung et al. 2005; King et al. 2007; Hou et al. 2009; Hosie et al. 2012) that resembles the morphological changes to axons undergoing Wallerian degeneration. However, cultured motor neurons may respond in an entirely different manner, particularly following kainic acid exposure, with a proportion of motor neuron axons displaying distinct axonopathic features characterized by large swollen structures in distal axon segments (King et al. 2007) that may show more resemblance to distal axon dieback described in a number of neurological diseases. These types of distal motor axon swellings have been described in mouse models of spinal muscular atrophy (Cifuentes-Diaz et al. 2002) although they may not be characteristic of all types of distal axon dieback, which in some cases may be more associated with distal axon atrophy and thinning (Schaefer et al. 2005). Distal axon degeneration was also more prominent than proximal degeneration in an in vivo rat model of somatodendritic NMDA exposure to retinal ganglion cells in a glaucoma model (Saggu et al. 2008, 2010).

5 The Role of the Cytoskeleton in Excitotoxin-Induced Axon Degeneration

Axonal degeneration involves a breakdown of the components of the neuronal cytoskeleton. The neuronal cytoskeleton is composed of three distinct types of filaments, namely, microtubules, intermediate filaments (including neurofilaments), and microfilaments, all of which can undergo posttranslational modifications that affect their stability and function. Although distinct, the components of the cytoskeleton are dynamically connected with each other, and there are a vast number of associated proteins for linking and regulation and to enable intracellular transport. Neurofilaments, consisting of light (NFL, 61 KDa), medium (NFM 90 KDa), and heavy (NFH 115 KDa) chains (Lariviere and Julien 2004), are fibrous subunits that are only present in some eukaryotic organisms including vertebrates, nematodes, and mollusks and are likely to have broader functions than just serve as a structural scaffold (reviewed in PerroneCapano et al. 2001).

Cytoskeletal breakdown has been previously characterized for classic forms of Wallerian degeneration. In the initial stages, there is a depolymerization of the *microtubules*, which occurs within 4 h in in vitro models (Zhai et al. 2003). Depolymerization of microtubules is not accompanied by tubulin degradation, but is followed at 8–12 h by loss of neurofilament subunits (Zhai et al. 2003). Both microtubule depolymerization and loss of neurofilaments are dependent on degradation by the ubiquitin-proteasome system (Zhai et al. 2003). Our studies have examined the cytoskeletal changes in cultured cortical neurons following excitotoxic stimulation following a range of glutamate concentrations. A chronic low-dose treatment resulted in specific loss of NFH, with a relative sparing of the NFM and NFL subunits at 24 h posttreatment (Fig. 1. Chung et al. 2005). While beading of NFM and NFL were apparent at this time point with higher glutamate

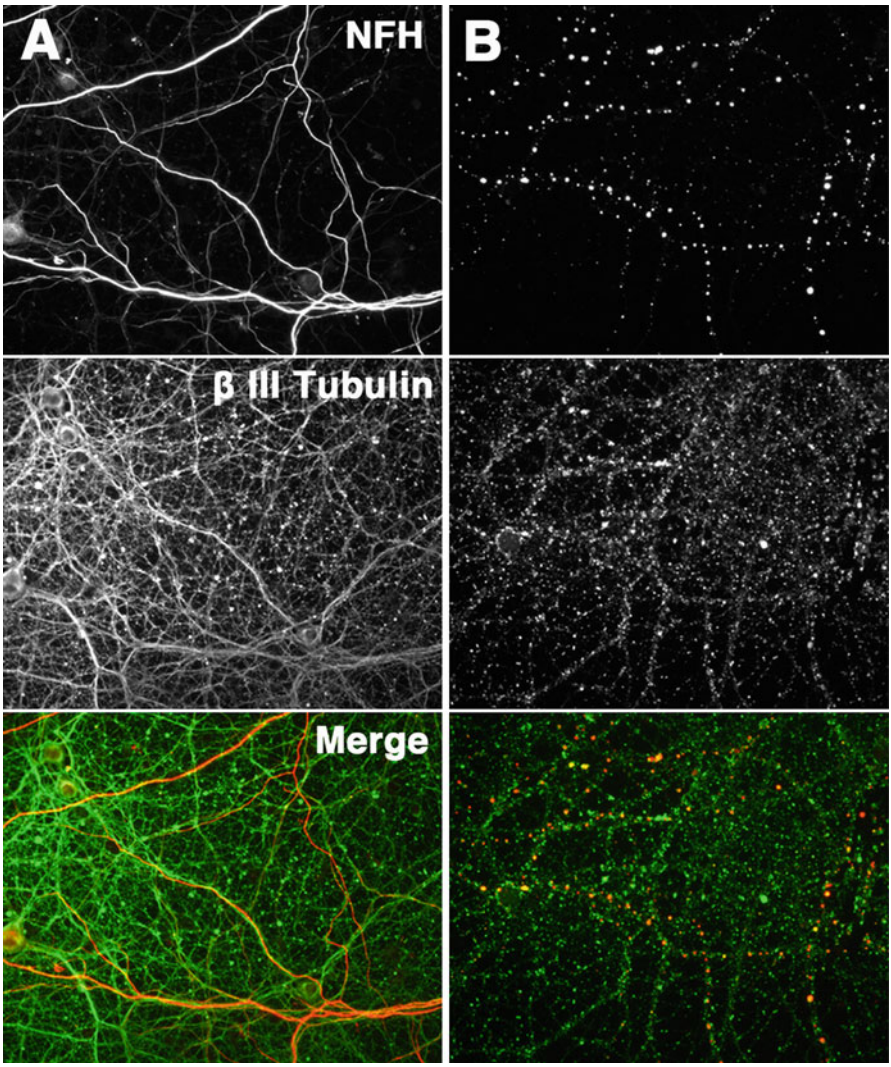

Fig. 1 Cytoskeletal architecture in primary cultured rat cortical neurons at 21 DIV. (**a**) In untreated cultures NF-H immunoreactivity was found primarily in thick axonal processes, and co-localized with βIII-tubulin. (**b**) Following treatment with 10 μM glutamate fragmentation of microtubule proteins was present accompanied by beading and loss of neurofilament proteins, particularly the NFH subunit (Modified with permission from Chung et al. 2005)

treatments (100 μm), their degradation was delayed relative to the NFH subunit. The differential vulnerability of neurofilament subunits may reflect their temporal expression during development, with the NFH subunit being the last to be expressed. In a similar fashion to Wallerian degeneration, tubulin immunoreactivity remained intact until later stages indicating that tubulin subunits were not degraded.

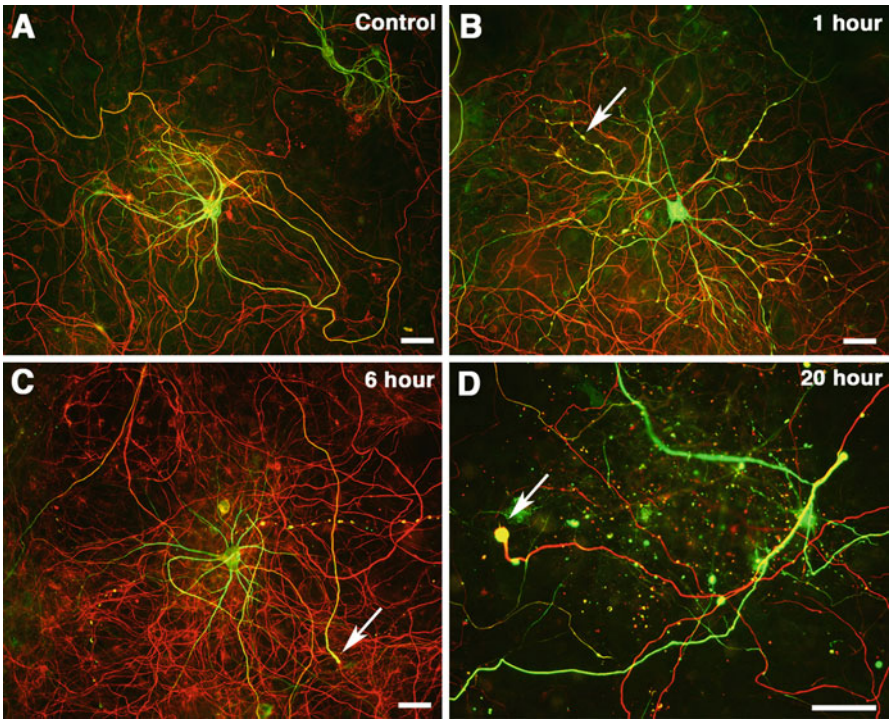

Fig. 2 Time-course of pathological changes following 100 μM kainic acid exposure in cultured motor neurons at 21 DIV. (**a**) Untreated motor neuron immunolabelled for dephosphorylated neurofilament protein (*green*) and phosphorylation-independent NFM (*red*). (**b**) Following 1 h of kainic acid exposure, beading was present in dendrites (*arrow*). (**c**) Axon swellings (e.g., *arrow*) developed following 6 h of kainic acid exposure and were frequently associated with expression of de-phosphorylated neurofilament protein (*green*) in the axonal network. (**d**) Following 20 h kainic acid exposure the distal portions of axonal segments frequently expanded to form large bulbous structures (*arrows*). Scale Bars: 50 μm (Modified with permission from King et al. 2007)

Distal axon degeneration induced by low-dose kainic acid in cultured spinal motor neurons, on the other hand, was characterized by a distinct set of cytoskeletal changes (King et al. 2007). In these neurons, dephosphorylated neurofilament protein (SMI32 immunoreactivity) is normally localized to the somatodendritic compartment and the proximal axon (King et al. 2007). However, following kainic acid treatment, there was a mislocalization of non-phosphorylated neurofilament to the more distal axon compartment, which was accompanied by accumulation of neurofilament proteins and mitochondria in axonal swellings (Fig. 2). Swollen, neurofilament-rich distal axon segments may be caused by a disruption of retrograde axonal transport mechanisms and have been shown to occur in a mouse model of Kennedy's disease due to decreased expression of the retrograde transport motor protein dynactin 1 (Katsuno et al. 2006). The presence of multiple cytoskeletal components and organelles in these swellings suggests a nonspecific disruption

of retrograde transport. Alterations in neurofilament phosphorylation have been reported in other models of kainic acid toxicity, with decreased phosphorylated and increased non-phosphorylated epitopes of NFH in a rat model of kainic acid exposure to the hippocampus (Wang et al. 1992) and in cultured spinal neurons exposed to sublethal kainic acid (Vartiainen et al. 1999). In contrast, blockade of non-NMDA receptors in cultured spinal neurons (Vartiainen et al. 1999) or glutamate exposure of dorsal root ganglion neurons (Kesavapany et al. 2007) caused increased neurofilament phosphorylation, which was localized to the soma. The significance of the changes in localization of these neurofilament epitopes remains unclear; however, dephosphorylation has been implicated in slowing of axonal transport through irregular and fused crossbridges (Gotow 2000). Conversely, in cultured cortical neurons, glutamate toxicity has been linked to slowing of anterograde transport through increased neurofilament phosphorylation and resultant dissociation of neurofilament from kinesin anterograde motors (Yabe et al. 2001). Thus, it is possible that both phosphorylation and dephosphorylation of neurofilament proteins can affect transport within the axon.

6 Molecular Mechanisms of Cytoskeletal Disruption in Excitotoxin-Induced Axon Degeneration (Calpains Versus Caspases)

The role of specific proteases in cytoskeletal breakdown following excitotoxic insult remains unclear. Calpains, calcium-activated cysteine proteases, have been implicated in cytoskeletal breakdown following traumatic brain injury and axon transection (Kampfl et al. 1996) and in focal axonal beading (Kilinc et al. 2009). Furthermore, a study by Higuchi et al. (2005) demonstrated the protective effect of calpain, but not caspase, inhibition on the degeneration of neuronal processes and downstream subacute cell death, following kainic acid exposure in vivo, although acute cell death was not affected. In this model, calpain activation was associated with increased tau phosphorylation through cleavage of the CDK5 activator p35 to p25 (Nath et al. 2000; Kilinc et al. 2009). Calpain activation was higher in the somatodendritic compartment leading to the hypothesis that tau phosphorylation occurs in the soma, resulting in depletion of axonal tau, with microtubule disruption-induced axonal degeneration occurring later than somatodendritic changes. Detailed analysis of the axonal processes in this model was not performed, and the role of calpain in axonal beading, a common feature of both excitotoxic and Wallerian axon degeneration, was not determined. However, in a cell culture model of glutamate excitotoxicity in cortical neurons, calpain inhibition was protective against axonal beading and thinning that occurred from 2 h post-glutamate exposure (Hou et al. 2009). The authors showed that, in addition to calpain, CaMKII is activated, and the two proteins affect the microtubule-associated protein (Fukata et al. 2002) collapsin response mediator protein 2 (CRMP2). CaMKII causes phosphorylation of CRMP2, which is protective against calpain-mediated proteolysis, although

CaMKII inhibition is also protective against axonal beading, suggesting a central modulatory role of CRMP2 in axon integrity (Hou et al. 2009). Furthermore, overexpression of CRMP2 protects against axonal beading and subsequent degeneration. It is interesting to note that phosphorylation of neurofilaments has also been shown to protect these proteins from calpain-mediated proteolysis (Goldstein et al. 1987). Thus, dephosphorylation of neurofilaments, as occurs in motor neuron axons following kainic acid exposure (King et al. 2007), may make these proteins more vulnerable to proteolysis. Neurofilament proteolysis is involved in removing excess neurofilaments under physiological conditions (reviewed in Liu et al. 2004), and thus, it is unclear whether dephosphorylation of neurofilament is a protective mechanism to remove excess neurofilament from the axon terminal following transport disruption or a consequence of the pathological cascade (King et al. 2007).

Caspase activation, which can occur by a number of different mechanisms including both intrinsic pathways such as mitochondrial release of cytochrome c and extrinsic pathways such as activation of death receptors, is thought not to be involved in axon degeneration following transection (Wallerian degeneration) despite its activation in the soma (Finn et al. 2000). Similarly, in models of neurodegenerative disease such as ALS, caspase inhibition fails to protect against axon degeneration despite protection from neuronal cell death (Gould et al. 2006). Conversely, caspase activation has been implicated in axon degeneration following a number of insults including psychosine toxicity (a sphingolipid involved in Krabbe's disease, Smith et al. 2011), amyloid toxicity (Nikolaev et al. 2009), and MPP toxicity (Morfini et al. 2007). Reports of the role of caspase activation following growth factor deprivation are controversial, with some authors finding that it is involved (Schoenmann et al. 2010) and others finding no involvement (Finn et al. 2000). Our studies using cortical neurons in compartmented chambers to allow application of toxins and inhibitors to either the axon or somatodendritic compartment of the cell indicated that caspase inactivation with the pan-caspase inhibitor Z-FAD-FMK to either the somatodendritic compartment or the axon provides some protection against axon degeneration induced by somatodendritic excitotoxicity, with an overall decrease in axon degeneration of 42 % and 33 %, respectively (Hosie et al. 2012). This suggests that axon degeneration following excitotoxicity involves degenerative processes occurring in both the axon and the soma. Elucidating the role of calpains and caspases in excitotoxic axon degeneration in specific cell types is an area of future investigation.

7 How Is Degeneration Initiated in the Axon Following Excitotoxic Insult?

Following excitotoxic insult, degeneration is initiated in the axon, and the type of degeneration is cell type specific. However, it remains unclear how the insult is transferred from glutamate receptors, the mediators of the insult, to the axonal

compartment. Glutamate receptors involved in synaptic signaling are predominantly located on the postsynaptic densities of glutamatergic synapses and at extrasynaptic sites on the somatodendritic compartment of neurons. Increase in calcium influx in this region is unlikely to spread to the axon terminals. It is possible that axon degeneration results only from cell death; however, as discussed, protection from cell death does not protect the axon, and axon degeneration is apparent prior to cell death (Chung et al. 2005; Higuchi et al. 2005; King et al. 2007; Hou et al. 2009). Axon degeneration may be initiated through a number of different mechanisms that will be examined in more detail: (1) non-apoptotic somatic changes resulting in axon transport disruption and subsequent axon starvation, (2) soma-axon signaling, and (3) glutamate receptor expression on the axonal compartment (Fig. 3).

7.1 Axon Starvation

A potential mechanism of initiation of axon degeneration through excitotoxic insult is through transport disruption, which results in reduced delivery of mitochondria or cytoplasmic components to the axon. Slowing of the transport of neurofilament proteins has been demonstrated following glutamate exposure to primary cortical neurons in culture (Ackerley et al. 2000). Transport disruption was accompanied by an increased phosphorylation of the neurofilament subunits (Ackerley et al. 2000), which has previously been associated with decreased transport rates (Lewis and Nixon 1988). Accumulation of phosphorylated neurofilament subunits in the soma of dorsal root ganglia following exposure to glutamate has also been reported (Kesavapany et al. 2007). As described earlier, aberrant phosphorylation of microtubule-associated proteins such as tau may prevent their transport into the axon leading to microtubule disassembly. The differential role of phosphorylation of cytoskeletal proteins in the soma in axon degeneration in different neuronal populations has not been investigated. More recently experiments in cultured hippocampal neurons have demonstrated disruption of motor proteins themselves following excitotoxic stimulation. A C-terminally truncated form of the retrograde dynein/dynactin motor complex p150Glued was formed after glutamate exposure and was also present in tissue from Alzheimer's disease cases (Fujiwara and Morimoto 2012). Overexpression of the wild-type protein was protective against neuritic beading and knockout of the protein exacerbated beading (Fujiwara and Morimoto 2012). Collectively, these data suggest a role for transport failure in excitotoxin-induced degeneration; however, the mechanisms by which axon transport failure results in axon degeneration remain unclear. Recent data indicates that axon transport disruption alone may not be sufficient to induce axon degeneration, at least on a rapid scale (Marinkovic et al. 2012). Furthermore, the links between failure of axon transport in the soma and axonal blebbing or distal axonal neurofilament accumulations, which occur rapidly following excitotoxin exposure in cell culture models, remain to be elucidated.

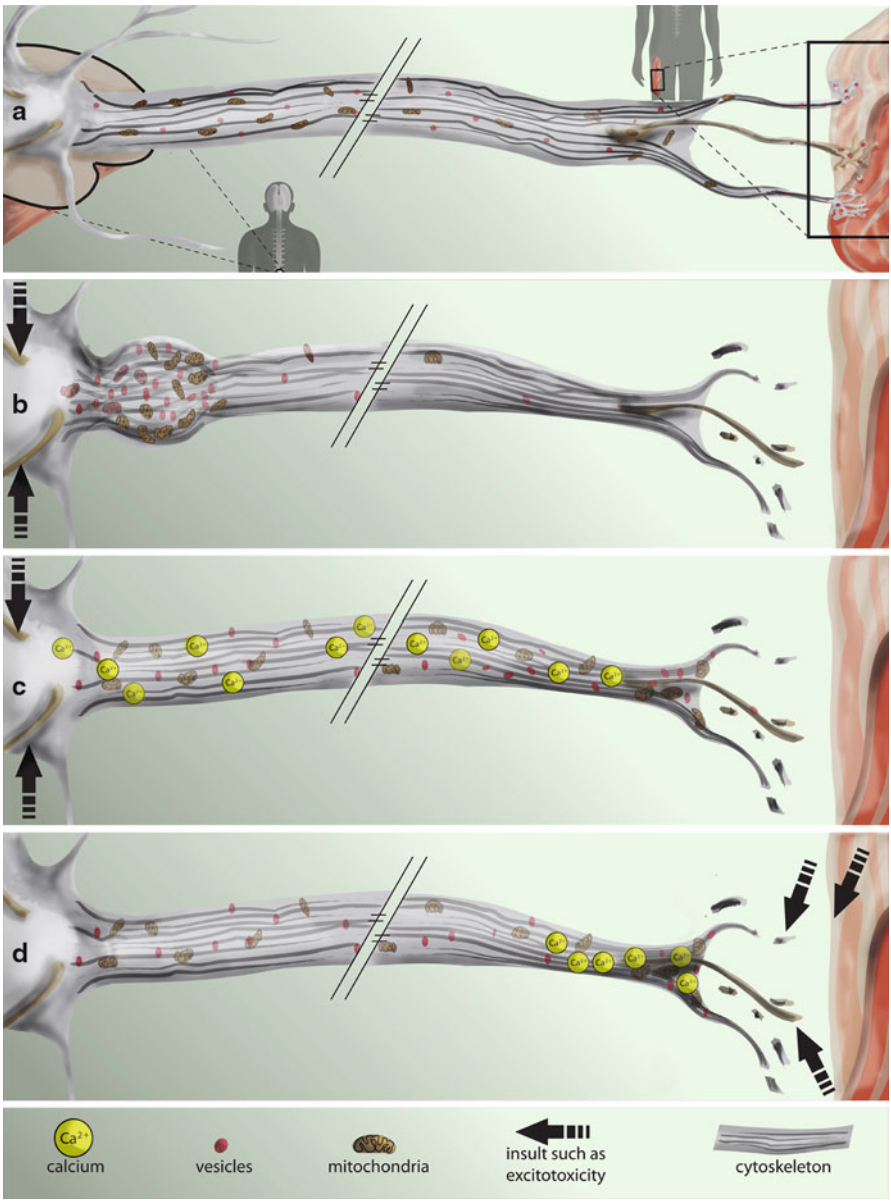

Fig. 3 Potential mechanisms of axon degeneration induced by excitotoxicity. (**a**) Motor axons are spatially separated from the somatodendritic compartment. (**b**) Excitotoxicity to the somatodendritic compartment may result in transport blockage and withering of the distal axon. (**c**) Somatodendritic exposure may result in a signal (such as calcium, or newly translated protein) being transferred to the distal axon regions. (**d**). Distal axon exposure to excitotoxicity may directly result in degeneration (Figure courtesy of Graeme McCormack)

7.2 Axon-Soma Signaling

An alternative mechanism of initiation of axon degeneration following somatodendritic glutamate receptor stimulation is production of an axon destruction signal and/or loss of an axon maintenance signal. There is little information on this type of initiation of axon destruction instigated specifically by excitotoxicity. However, excitotoxic mechanisms of degeneration are calcium dependent; therefore, studies examining changes in calcium influx following nontoxic glutamate exposure may give an indication of changes that could occur following excitotoxicity. A study by Yamada and colleagues (2008), in developing granule neuron cultures, demonstrated that growth cone modulation by glutamate in immature neurons occurs through perikaryal AMPA receptor-mediated glutamate exposure, suggesting soma to distal axon signaling. Despite the absence of action potentials in these immature neurons, signaling was the result of a sweep of calcium along the axon. Both perikaryal and distal axon glutamate exposure resulted in a fast calcium transient throughout the whole cell, but only perikaryal exposure resulted in a subsequent calcium sweep from proximal to distal axon. The calcium sweep could also be initiated by depolarization and perikaryal calcium increase and involved release of calcium from intracellular stores. A study by Christie and Jahr (2008) examined the contribution of NMDA receptor stimulation to axonal calcium increase in stellate cells. They demonstrated that bath application of NMDA to cerebellar slice cultures, in the presence of TTX to block action potentials, caused increases in intracellular calcium concentrations in both axons and dendrites. Axonal calcium increases particularly occurred at axonal boutons, thought to be the sites of en passant presynaptic terminals. However, calcium increase was higher in boutons closer to the soma and lower in distal axon segments, suggesting that the increase in calcium arose from somatic NMDA receptor activation, with a passive propagation of depolarization to axonal voltage-gated calcium channels. Local activation of dendritic NMDA receptors confirmed this somatodendritic transfer (Christie and Jahr 2008). In addition to passive transfer of calcium currents, action potentials caused large increases in axonal calcium concentrations in boutons (Christie and Jahr 2008). It is currently unclear if these calcium increases are sufficient to cause activation of axonal degeneration mechanisms or if axonal beading corresponds to positions of boutons in axons. However, together these data suggest that somatodendritic glutamate exposure can result in axonal calcium influx even without action potential. In the event that axon potentials are initiated in hyperexcitable neurons, it has been shown that calcium entry can occur through the reverse operation of the sodium calcium exchanger that can be the result of persistent sodium influx (Stys et al. 1992).

Aside from calcium influx, studies investigating other intracellular signaling mechanisms in excitotoxin-induced axon degeneration are lacking. In terms of axon degeneration, inhibition of protein synthesis in the soma results in axon degeneration without cell loss and proteasome inhibition following axon

transection is protective against axon degeneration, supporting the hypothesis that a protein/proteins synthesized in the soma are required for axon maintenance (Gilley and Coleman 2010). These authors have identified the NAD+ synthesizing enzyme Nmnat2 (an isoform of the Wlds protein Nmnat1) as a likely candidate for an axonal survival signal. Involvement of these processes in excitotoxin-induced axon degeneration and distal axon dieback has not yet been investigated.

7.3 Axonal Expression of Glutamate Receptor Proteins

Although the prime site of glutamate receptor expression is on the postsynaptic density of the somatodendritic compartment, where they are involved in synaptic transmission, recent advances have demonstrated other roles for glutamate receptors (Araque and Perea 2004), and their expression has been demonstrated at a number of non-synaptic locations. Their presence at extrasynaptic sites on the somatodendritic compartment has been well documented (Passafaro et al. 2001; Tovar and Westbrook 2002; Kane-Jackson and Smith 2003) where they are thought to play a modulatory role (Diamond and Jahr 2000; Jourdain et al. 2007) in addition to acting as a reserve supply for synaptic receptors (for recent review, see Newpher and Ehlers 2008). The axonal expression of glutamate receptors has been less well documented, although they have been reported to be present in immature neurons (Yamada et al. 2008) on growth cones (Zheng, et al. 1996; King et al. 2006) and are present in presynaptic terminals (recently reviewed in Pinheiro and Mulle 2008). Recently AMPA/kainate receptors have been demonstrated to be present on myelinated axons (Ouardouz et al. 2009a, b). The functional activity of axonal receptors is currently disputed (e.g., Berretta and Jones 1996; Huang and Bordey 2004; Christie and Jahr 2008). In many excitotoxic models, particularly in cell culture, excitotoxins are bath applied, leaving the possibility that excitotoxin-induced axon degeneration occurs directly through stimulation of axonal glutamate receptors. To directly test the hypothesis that axonal glutamate exposure can result in axon degeneration, we have recently utilized compartmented microfluidic chambers (Taylor et al. 2005) to allow specific exposure of the axonal compartment to glutamate. Our findings demonstrate that axon degeneration characterized by beading and fragmentation resulted from prolonged (24 h), but not acute (Underhill and Goldberg 2007), exposure of the axons to glutamate without subsequent apoptosis of the soma, even after 72 h (Fig. 4, Hosie et al. 2012). Western blot analysis confirmed the presence of AMPA/kainate receptors in the axons, although NMDA receptors could not be detected by this method. In this study, caspase inhibition was protective against axonal excitotoxin-induced axon degeneration. Interestingly protection was higher when caspase activation in the soma was prevented, suggesting that axon-soma-axon signaling is involved in degeneration rather than direct degeneration resulting from calcium influx in the axon (Hosie et al. 2012).

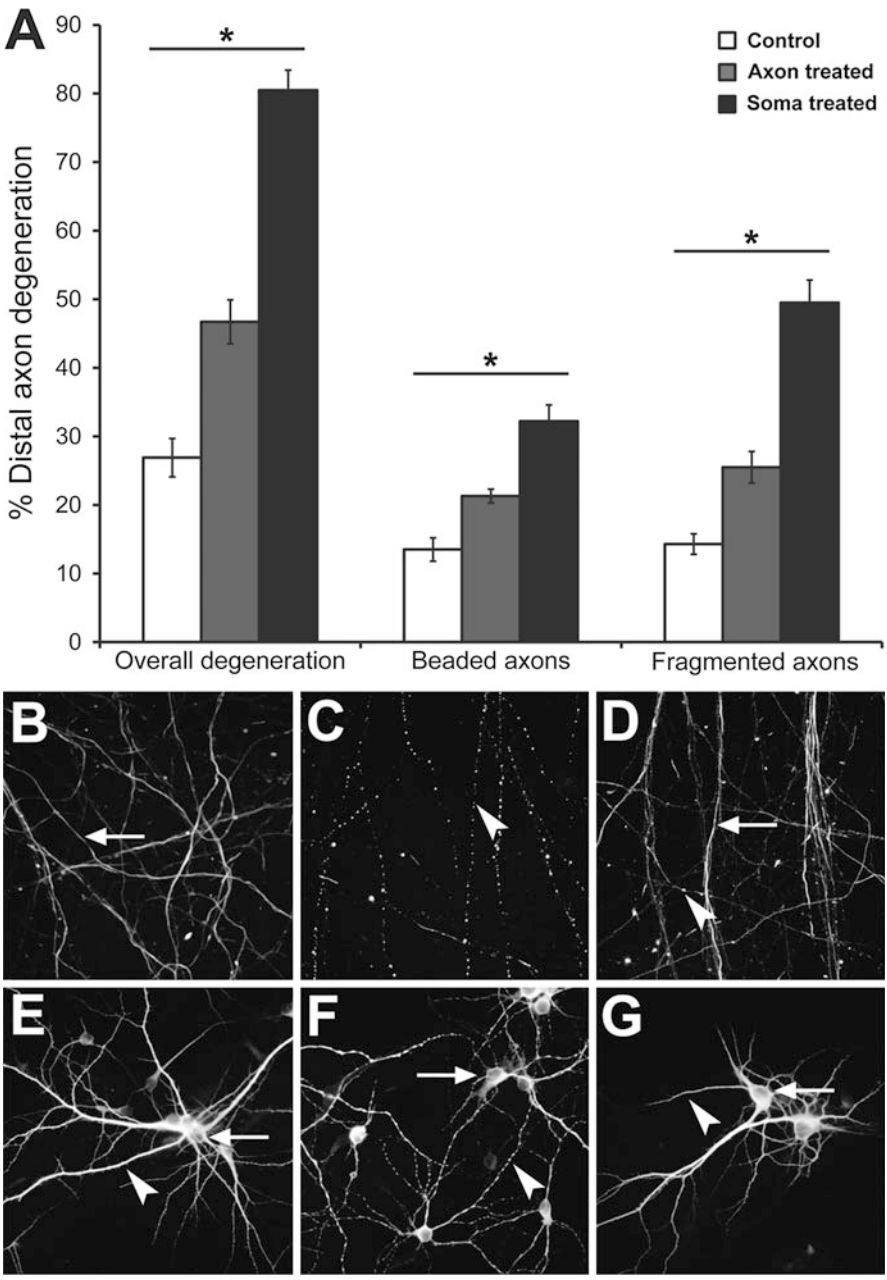

Fig. 4 Axon degeneration in cortical neurons grown in compartmentalized microfluidic chambers (Taylor et al. 2005) and exposed to 100 μM glutamate to either the somatodendritic compartment or the isolated axon compartment. (**a**) Quantitation of axonal beading and fragmentation following glutamate exposure indicated a significant threefold increase in axon degeneration (beading plus fragmentation) following somatodendritic exposure, and a significant 1.5-fold increase following

8 White Matter Excitotoxicity

In addition to excitotoxicity directly acting on the neuron to induce axon degeneration, there is increasing evidence that axon degeneration can be initiated in white matter indirectly through disturbed neuron-glia interactions. White matter tracts are vulnerable to damage following brain trauma (Kraus et al. 2007; Sharp and Ham 2011) and hypoxia/ischemia (Pantoni et al. 1996; Yam et al. 1998), and white matter excitotoxicity has been particularly implicated in multiple sclerosis (Pitt et al. 2000; Smith et al. 2000). Direct application of excitotoxins to white matter tracts of the optic nerve (Matute 1998) or internal capsule (Fowler et al. 2003) confirmed the role of excitotoxicity in the degeneration of the white matter tracts as a distinct process from somatodendritic exposure. Damage is characterized by injury to both the axonal process and surrounding glial cells. Axonal damage included swollen and bulbous profiles, cytoskeletal disruption such as loss of neurofilament (Fowler et al. 2003; Cuthill et al. 2006), and disruption to axonal electrical activity (Stys et al. 1992). Nonneuronal damage included damage to the myelin sheath (Li and Stys 2000) and focal swelling and cytoskeletal breakdown of oligodendrocytes and astrocytes (Pantoni et al. 1996; Li and Stys 2000). Although damage to axons following hypoxia can occur through non-excitotoxic pathways (Underhill and Goldberg 2007), non-NMDA (Agrawal and Fehlings 1997; Li and Stys 2000; Tekkok and Goldberg 2001) receptor antagonists are protective against white matter degeneration both in vitro and in vivo, suggesting a role for excitotoxicity in this damage, specifically mediated through non-NMDA receptors. The role of NMDA receptors remains less clear (Yam et al. 2000; Li and Stys 2000), although recent reports similarly suggest a role for NMDA receptor stimulation (Bakiri et al. 2008). In acute spinal cord slices, white matter degeneration occurs via a calcium-dependent mechanism (Li and Stys 2000).

White matter excitotoxicity is thought to occur predominantly through *oligodendrocytes*, which possess both AMPA and NMDA receptors, localized to the soma and the myelin sheath (Li and Stys 2000; Brand-Schieber and Werner 2003; Karadottir et al. 2005; Salter and Fern 2005; Micu et al. 2006) and have been shown to be vulnerable to excitotoxicity both in vitro (Yoshioka et al. 1996; Sanchez-Gomez and Matute 1999) and in vivo (Matute 1998). Toxicity can occur both through direct stimulation of the receptors and indirect mechanisms involving transporters (Oka et al. 1993), and the mechanisms involved are dependent on the type and duration of insult. For a recent review on white matter excitotoxicity and

Fig. 4 (continued) exposure to the isolated axon compartment. Representative immunocytochemical images of axons (NFM, **b**–**d**) and somatodendritic compartment (MAP2, **e**–**g**) in control (**b**, **e**), soma treated (**c**, **f**) and axon treated (**d**, **g**) cultures. Axons demonstrated increased beading and fragmentation following treatments. *Arrows* indicate whole axons, arrowheads indicate fragmented and beaded axons. MAP2 immunoreactive dendrites demonstrated increased beading following somatodendric exposure (**f**) but not following axonal exposure (**g**). *Arrows* indicate soma, arrowheads indicate dendrites. Scale bar: 50 μm (Reproduced with permission, from Hosie et al. 2012)

its role in disease, see reviews by Matute et al. 2007; Matute and Ransom 2012. The question remains to as to how oligodendrocyte damage following glutamate exposure results in axonopathy.

Recent advances have detailed interactions between oligodendrocytes and axons that extend far beyond the role of passive insulation. Signaling between the myelin sheath and the axon is essential in maintaining fine-tuning of myelination, which is important in regulation of precise neuronal activity within a network (Wake et al. 2011). A type of axo-myelinic synapse has been proposed with glutamate receptors on both the axon and innermost compact myelin sheath surrounding the axon (Stys 2011). It is hypothesized that this type of myelin-axon signaling could be responsible for activity-dependent signaling that allows optimization of axonal sheath thickness. In terms of axon support, it has been proposed that oligodendrocytes and other glia (Magistretti 2006) may provide neurotrophic support to the axon in times of energy shortage from the soma (reviewed in Nave 2010). Specific myelin/oligodendrocyte proteins additionally may promote axonal integrity and survival. Mouse models with knockout of the oligodendrocyte proteins plp and CNP have frequent axonopathy characterized by axonal swelling and cytoskeletal disruption (Lappe-Siefke et al. 2003; Edgar et al. 2004). These axon disruptions occur in the absence of gross myelin loss highlighting the importance of specific proteins in myelin-axon signaling to axonal maintenance and function. Myelin has been shown to have a protective effect on axons in injury paradigms and is protective against mild stretch injury (Staal and Vickers 2011). This protection may be through myelin-associated glycoprotein (MAG) signaling to the axon, as knockout of MAG in mice results in increased axon degeneration in both the CNS and PNS and increased axonal vulnerability to insults such as acrylamide toxicity (Nguyen et al. 2009). Protective effects of MAG may be through cytoskeletal stabilization as it has been shown to affect the phosphorylation of neurofilament heavy and medium chains (NFH and NFM), which in turn affects the caliber of the axon (Hsieh et al. 1994; Dashiell et al. 2002; Garcia et al. 2003). Myelination and specific myelin protein may also affect axon transport mechanisms. Plp has been shown to play a role in axonal transport (Edgar et al. 2004).

The importance of demyelination and loss of glial support of the axon is highlighted in multiple sclerosis, in which immune attack of the myelin sheath results in axonopathy (reviewed in Dutta and Trapp 2011). However, the role of excitotoxic mechanisms in white matter injury remains an area for future research. Axon degeneration may result directly from loss of interaction with myelin, specific oligodendrocyte proteins, loss of neurotrophic support, or alternatively direct excitotoxicity on the axon shaft (Hosie et al. 2012).

9 Conclusion

A number of diseases are characterized by axon degeneration, and excitotoxicity has been implicated as a pathogenic mechanism in these diseases. Axon degeneration may occur through a number of different excitotoxic mechanisms including somatodendritic glutamate exposure, direct axonal glutamate exposure, and glial

glutamate toxicity. A better knowledge of the mechanisms involved in specific diseases may aid in directing therapeutic interventions. For example, excitotoxicity is implicated in both multiple sclerosis and ALS, and both have evidence of increased glutamate within the cerebrospinal fluid (Shaw et al. 1995; Barkhatova et al. 1998) and involve axon degeneration. However, the mechanisms of axon degeneration are likely to be different, with ALS potentially involving somatodendritic exposure to the spinal motor neurons and subsequent axonal degeneration and multiple sclerosis involving degeneration through loss of myelin proteins. Therapeutics may need to target specific complements of glutamate receptors, or downstream signaling pathways, that are expressed on the axon, on glial cells, or at synaptic or non-synaptic sites on neurons.

An alternative mechanism of therapeutic intervention would be to target the pathways of axonal degeneration, which may show common features between various disorders. Cytoskeletal degeneration, in particular, is an attractive target, and trials of drugs that stabilize the microtubule network, such as taxol and epothilone, are having positive outcomes in a number of mouse models involving axonopathy including tau transgenic mouse models of AD pathology (Brunden et al. 2010; Barten et al. 2012; Zhang et al. 2012) and spinal cord injury (Hellal et al. 2011). In either scenario, drug targets that are well defined to specific components of the pathological cascade leading to axonal and neuronal degeneration are more likely to lead to successful treatment strategies. Thus, increasing our knowledge of mechanisms of axon degeneration in specific neurodegenerative conditions is fundamental to developing appropriate therapeutic agents.

Excitotoxicity in HIV Associated Neurocognitive Disorders

Belinda Cruse and Bruce J. Brew

Contents

Abstract

HAND (HIV associated neurocognitive disorders) represents a group of disorders, encompassing HIV associated asymptomatic neurocognitive impairment (ANI), HIV-associated mild neurocognitive disorders (MND), and HIV associated dementia (HAD). Even in the era of highly-active antiretroviral therapy, the prevalence of HAND is thought to be around 40 %, with milder forms making up a greater proportion of cases. HAND are clinically manifest as subcortical dementing

processes; correlating with the preferential involvement of the basal ganglia, subcortical white matter, frontal lobe and hippocampus in neuropathological studies.

A central mechanism leading to synaptic dysfunction and loss, neuronal dysfunction and apoptosis in HAND is excitotoxicity mediated through the excessive activation of neuronal (and probably astrocytic) NMDA receptors (NMDAR). There is direct and indirect evidence that in HAND, increased neuronal NMDAR activation occurs due to elevated extracellular glutamate; a result of both increased presynaptic release and impaired clearance from the synaptic space. In addition, high levels of quinolinic acid (QUIN) (an NMDAR agonist) released by activated macrophages (and to a lesser extent microglia) lead to excessive NMDAR activation and excitotoxicity. Furthermore, HIV related proteins (particularly gp120 and Tat) can both activate the NMDAR, and augment receptor activation by glutamate and other agonists.

In vitro evidence supports the role of NMDAR antagonists in the prevention of neuronal loss induced by HIV related proteins. Clinical studies have demonstrated that the NMDAR antagonist memantine is safe and tolerable in HAND patients; so far clinical trials have failed to demonstrate a clinically beneficial effect of this therapy on neurocognitive function in HAND patients, however trials are ongoing.

Dementia • Excitotoxicity • Glutamate • HIV • Neurocognitive disorders • NMDAR

1 Introduction

This chapter focuses the reader on the role of excitotoxicity in the pathogenesis of HIV-associated neurocognitive disorders (HAND) after first considering the epidemiology of this group of conditions and briefly outlining the pathological and clinical features of HAND. An overview of the multiple neuropathogenic pathways that contribute to HAND is presented, with a particular emphasis on changes in clinical, pathological, and possibly pathophysiological aspects of HAND that are taking place in the era of highly active antiretroviral therapy (HAART). Evidence for, and mechanisms of, NMDA receptor (NMDAR)-mediated excitotoxicity in HAND is then described in detail, followed by a discussion of current evidence regarding the use of adjunctive therapies (and more specifically NMDAR antagonists) in the treatment of HAND.

2 Epidemiology of HAND

HAND represents a group of disorders, encompassing HIV-associated asymptomatic neurocognitive impairment (ANI), HIV-associated mild neurocognitive disorders (MND), and HIV-associated dementia (HAD) (Antinori et al. 2007).

Despite the considerable prognostic improvement achieved in the HIV-infected population with the introduction of highly active antiretroviral therapy (HAART), it so far has failed to fully protect treated individuals from HAND, even in those patients in whom virologic suppression is achieved in the plasma and CSF (Simioni et al. 2010; Robertson et al. 2007; Cysique and Brew 2011; Cysique et al. 2006). Epidemiological studies in the post-HAART era indicate the prevalence of these disorders at around 40 % (similar to that in the pre-HAART era), despite a decrease in the prevalence of HAD after HAART introduction (Cysique et al. 2004; Heaton et al. 2010; Dore et al. 1999). Therefore, while milder forms of HAND (ANI and MND) make up a greater proportion of cases, these disorders impact significantly on affected individuals' quality of life and independence (Antinori et al. 2007) and mortality (Ellis et al. 1997) and clearly impact socioeconomically. HAND also appears to impact HIV-infected individuals at higher CD4 T-cell counts in the post-HAART era (Sacktor et al. 2001; Brew 2004).

3 Pathological Features

HIV probably enters the central nervous system (CNS) via infected monocytes from the periphery. These cells cross the blood–brain barrier (BBB) both as part of the usual process of perivascular macrophage turnover and because the permeability of the BBB is pathologically increased in the context of HIV infection (by the effects of systemic inflammation and the direct effects of gp120 and tat proteins (reviewed by Ivey et al. 2009; Langford and Masliah 2001; Toborek et al. 2003; Annunziata 2003)). While both of these processes are shown to contribute to the entry of HIV into the CNS, it is currently unclear which factor is of greater importance in the early pathogenesis of HAND or in fact which occurs first. Furthermore, transmigration across the BBB by infected and uninfected monocytes and macrophages is accelerated by inflammatory cytokines (produced in the periphery and centrally, as a result of neuroinflammation) (Persidsky et al. 2000), with resultant amplification of monocyte/macrophage chemotaxis and HIV delivery to the CNS. Within the CNS HIV productively infects monocytes and microglial cells and infects a smaller proportion of astrocytes in a restricted, non-cytolytic state (Churchill et al. 2009; Wang et al. 2004; Thompson et al. 2004).

Pathological changes, neuronal dysfunction and apoptosis, and corresponding volume loss on neuroimaging preferentially affect subcortical deep grey structures, the hippocampus, and the frontal cortex (Lindl et al. 2010; Bell 2004; Boissé et al. 2008; Moore et al. 2006).

Microscopically, HIV infection is associated with inflammatory infiltrates of mononuclear cells, with microglial and astrocyte activation. The neuroinflammatory changes in HIV infection are termed encephalitis (HIVE). Infiltration of blood-derived macrophages, together with microglial cells and, virtually pathognomonic of HIVE, multinucleated giant cells, are seen. Microglial nodules, multinucleated giant cells, and HIV antigens are frequently located in the basal ganglia and in a subset of patients in the subcortical white matter (termed HIV

leukoencephalitis) (Petito 2003). There is also a widespread reactive astrocytosis and a variable degree of myelin damage (Bell 2004) and a sparse lymphocytic infiltrate in leptomeninges and perivascular spaces (Petito 2003). Neurons are not infected by HIV; however, they are clearly affected, with diffuse or focal neuronal cell death in the grey matter in severe cases (Petito 2003). Furthermore diffuse synaptic and dendritic loss, together with neuronal loss, is reported in HIV-infected individuals (Everall et al. 1999; Bell 2004).

The clinical features that predominate in HAND are those of a subcortical dementing process, with effects on cognitive slowing and impairment, behavioral and emotional change (usually apathy, especially in the HAD stage), together with prominent gross and fine motor slowing and gait disturbance (McArthur et al. 2005; Staekenborg et al. 2008). While currently the exact clinicopathological correlate is not fully understood in HAND (Gray and Keohane 2003), neuronal degeneration (i.e., neuronal degradation and death) underlies the neuropsychological impairment in HIV infection (Moore et al. 2006). Massive neuronal death, however, is not commonly seen and is not the main pathological counterpart of HAND (Adle-Biassette et al. 1999). In fact milder forms of HAND appear to correlate more closely with reduced synaptic and dendritic density rather than overt neuronal loss (Everall et al. 1999). Importantly, some of these changes are thought to be reversible (Gray and Keohane 2003), offering potential therapeutic targets.

4 Neuropathogenesis of HAND

Neuronal and astrocyte loss in HAND have historically been found in close anatomical proximity to the aforementioned inflammatory infiltrates and activated microglia (Brew et al. 1995; Adle-Biassette et al. 1999; Kaul et al. 2005). These neuropathological findings imply that neurotoxicity in HAND occurs through indirect mechanisms, specifically through toxins produced by activated mononuclear cells and microglia, rather than as a direct effect of HIV. Further supporting this widely held view is the fact that cognitive changes observed clinically in HAND are more closely associated with neuronal loss, decreased synaptic and dendritic density, intensity of local inflammation (such as the number of microglial cells and markers of tumor necrosis factor-α (TNF-α) expression by microglia and astrocytes), and evidence of excitotoxins, as opposed to the number of HIV-infected cells or concentration of HIV proteins (reviewed in Kaul et al. 2001; Adle-Biassette et al. 1999).

Monocytes and microglial cells are activated by HIV infection; exposure to extracellular HIV proteins, cytokines, and chemokines liberated from other similarly activated microglial cells (reviewed by Bol et al. 2011); and other factors including quinolinic acid (QUIN), glutamate and L-cysteine, arachidonic acid, platelet-activating factor (PAF), NTox, superoxide anions, and TNF-α. Monocytes and microglial cells are considered central to the pathogenesis of HAND, both by virtue of their role as the principle cells infected by HIV and as a major source of neurotoxins (Valle et al. 2004). Importantly, however, abnormalities of astrocyte

function due to neurotoxic actions of some of the above cytokines and chemokines, astrocyte activation and astrocytosis, and astrocyte loss have also been implicated (Kaul et al. 2001) and will be further discussed. Indeed, while there is evidence of a direct role of some HIV proteins in the neuropathogenesis, the observed dissociation between the HIV viral burden in the brain and clinical deficits points to relatively more important roles of toxins produced by activated monocytes and microglial cells, most of which are uninfected with HIV (Brew et al. 1995).

A central mechanism leading to synaptic dysfunction and loss, neuronal dysfunction, and apoptosis in HAND is excitotoxicity mediated through the excessive activation of neuronal (and probably astrocytic) NMDAR and the subsequent, stereotyped cascade of intracellular events driven by intracellular Ca^{2+} overload and shared by many neuroinflammatory and neurodegenerative disorders. The other two classes of ionotropic glutamate receptors (AMPA and kainate) appear less relevant in HAND and will not be discussed in further detail in this review. NMDAR are heterotetrameric structures that are subtyped depending upon the subunit structure of the receptor. There are three NMDAR subunit groups: NMDAR subunit 1 (NR1), NR2, and the more recently described NR3, which appears to have roles in NMDAR regulation. In most receptors one NR1 subunit (of which there are eight splice variants, NR1a–h) is combined with one NR2 subunit (of which there are four (NR2A–D) differing by the gene or origin), forming NR1/NR2 heterodimers, two of which make up a functional NMDAR (Köhr 2006; Guillemin 2005a; Dingledine et al. 1999; Chatterton et al. 2002). Neurons expressing a high proportion of NMDARs which contain the NR2A and NR2B subunits (i.e., hippocampal, forebrain, and basal ganglia neurons) appear particularly sensitive to NMDAR-mediated excitotoxicity and indeed are particularly vulnerable in HIV infection (O'Donnell et al. 2006).

NMDAR activation in HAND is a result of several mechanisms, some of which are unique to HIV infection when compared with other neuroinflammatory and neurodegenerative disorders. Firstly, neuronal NMDAR activation follows elevated extracellular glutamate as a result of both increased presynaptic release and impaired clearance from the synaptic space. Secondly, high levels of QUIN (an NMDAR agonist) released by activated macrophages (and to a lesser extent microglia) lead to NMDAR activation and excitotoxicity. Thirdly, there are the direct effects of some HIV-related proteins which can both activate the NMDAR and augment receptor activation by glutamate and other agonists. Furthermore, astrocytes play an important homeostatic role in protecting cells from excitotoxic cell death by efficient uptake of glutamate and other neurotransmitters from the extracellular environment in healthy and diseased brains (reviewed by Sofroniew and Vinters 2010), a process which is disturbed in HAND and contributes to excitotoxicity.

Importantly, oxidative stress and lipid peroxidation also contribute to HAND and may occur purely because of downstream effects of NMDAR-mediated excitotoxicity, although there are direct effects of cytokines/chemokines or HIV proteins (particularly gp120 and tat) (reviewed by Mattson et al. 2005). The relative significance of these multiple pathways to cell death and dysfunction in HAND is difficult to establish with certainty, particularly as oxidative stress, inflammation,

and excitotoxicity share common final pathways to cell death by caspase activation and apoptosis. Furthermore, some of these pathways are sequential (rather than convergent) and therefore pathophysiologically inseparable. Additionally, caspases, p53 and other enzymes, and transduction systems that mediate apoptosis seem also to play a role in neuronal dysfunction, injury, and dendritic degeneration in the absence of cell death (Garden et al. 2002, 2004).

Alternative pathological mechanisms have been recently advanced and may act simultaneously with excitotoxicity to produce HAND. Of note in particular, HIV has been shown to additionally infect neural progenitor cells and adversely impact on adult neurogenesis (ANG) (the process of neuron generation from neural progenitor cells possibly occurring in adults), likely by perturbing neurotrophic support from astrocytes and altered metabolic processes in particular insulin homeostasis in the CNS (reviewed by Lindl et al. 2010; Mattson et al. 2005). Neuronal autophagy (a protective process by which terminally differentiated neurons process and degrade aged proteins within the cytosol ultimately leading to cell death) is also inhibited by HIV-infected microglial cells (Alirezaei et al. 2008a, b). Inhibition of autophagy is associated with the development of neurodegenerative disorders. HIV-induced inflammation also leads to increased levels of ubiquitinated proteins as a result of disruption of the immunoproteasome function, and thus disturbance in neuronal and synaptic function, hypothesized to contribute to neurocognitive impairment (Nguyen et al. 2010).

5 Neuropathogenesis of HAND in the Era of HAART

Importantly, there have been relatively few histopathological studies examining HAND-affected individuals, particularly in the pre-AIDS stage of illness (Bell 2004) and in the era of HAART. After the introduction of antiretroviral therapy (but before widespread use of HAART), HIVE remained at high levels, for example, 26 % in one autopsy study (Masliah et al. 2000). Despite its efficacy in the prevention of opportunistic infections, HAART does not fully protect from HIVE, and "burnt-out" forms of HIVE have been observed in autopsy studies in those treated with HAART, displaying neuronal loss and leukoencephalopathy, which correlate with worsening cognitive function prior to death (Gray et al. 2003). An important issue that follows from these observations is whether the clinical disorder of HAND in the current era is pathologically indeed the same disorder as that observed before the widespread use of HAART as several clinical and pathological changes have been observed. While an association between the presence and severity of HAD and HIV proviral load in the brain (Bell et al. 1998) and CSF, or markers of inflammation (such as beta-2 microglobulin), has been historically described, it is not consistently demonstrated in HAART-treated patients (Brew et al. 2007). Use of antiretroviral agents with high CSF penetrance and activity against resting monocyte-lineage cells in the CNS has not been demonstrated in human trials to consistently yield beneficial effects on neuropsychological function,

though this may be related to trial design issues (Cysique et al. 2011; Brew et al. 2007). While further evaluation of this therapeutic approach is required, this implicates processes that are independent of HIV itself as responsible for ongoing HAND neuropathogenesis. In addition, cognitive changes are now not as closely correlated with basal ganglia abnormalities, with changes in the mesial temporal lobe possibly more relevant (reviewed by Brew 2004). Furthermore, HAART itself leads to upregulation of lymphocytes with immune reconstitution (Hirsch et al. 2004), which may alter the neuropathology in HIV-infected individuals on treatment (Bell 2004). Additionally, as the HAART-treated population ages, superimposed or synergistic effects of other comorbidities may also impact on the clinical expression of HAND, particularly vascular dementia, Alzheimer's dementia (Brew 2004), and other medical disorders, or toxicity arising from HAART itself. Therefore, while excitotoxicity in HAND has definitely been demonstrated, clearly ongoing research is required to establish its relative importance currently and with further therapeutic advances.

6 Mechanisms of Excitotoxicity in HAND

6.1 Disturbed Glutamate Homeostasis

Excessive extracellular glutamate concentrations occur in HAND patients, reflected by increased concentrations of glutamate in the CSF (Ferrarese et al. 2001) and reduced total parietal glutamate (due to reduced intracellular (neuronal) glutamate levels) in HAND-affected individuals (Ernst et al. 2010). Increased extracellular glutamate could occur as a result of impaired clearance of glutamate from the synaptic space and/or increased glutamate release presynaptically.

The process of glutamate transport (and thus clearance) from the synaptic space occurs primarily through the actions of excitatory amino acid transporter 2 (EAAT2) located on pre- and postsynaptic neuronal membranes and astrocytes sheathing synapses in the CNS (Sheldon and Robinson 2007). Reduced astrocyte clearance of glutamate from the extracellular space has been demonstrated in HIV infection, firstly due to impaired transporter function, following dysregulated release of glutamate by astrocytes, and as a consequence of overt astrocyte loss.

Gp120 activates astrocytic Na+/H+ antiporters in rat and human astrocytes in vitro, leading to depletion of intracellular H+, indirect induction of outward K+ movement due to intracellular alkalinization, and a reduction in the Na+ gradient across the astrocytic membrane. These changes are thought to be responsible for reduced astrocyte uptake (and therefore excessive extracellular levels) of glutamate (Patton et al. 2000). Furthermore, gp120 induces transcriptional downmodulation of the EAAT2 transporter gene in both infected and uninfected human astrocytes and attenuates glutamate transport by the cells in vitro (Wang et al. 2004). HIV-infected astrocytes also demonstrate higher levels of astrocyte-elevated gene-1 (AEG-1) expression, known to decrease EAAT2 promoter activity

(and thus EAAT2 expression) (Sheldon and Robinson 2007 and references therein). In addition to adversely impacting on astrocyte uptake of glutamate, gp120 can stimulate the release of glutamate from astrocytes into the extracellular space (Benos et al. 1994).

QUIN (further detailed below) also impairs the function of EAAT2 on astrocytes and adversely impacts the glutamate-glutamine cycle within human fetal astrocytes (by inhibition of glutamine synthase (GS) enzyme) and therefore likely further contributes to the accumulation of glutamate in the extracellular environment (Ting et al. 2009). There is also evidence from rat models that QUIN impairs the uptake of glutamate (but not inhibitory neurotransmitters) by synaptic vesicles, representing another avenue leading to excessive extracellular glutamate (Tavares et al. 2000).

Loss of astrocytes in HIV infection clearly also can contribute to increased extracellular glutamate and therefore excitotoxicity and more broadly to the loss of trophic support, synaptic homeostasis, CNS metabolism, and maintenance of the blood–brain barrier (reviewed by Sofroniew and Vinters 2010). QUIN induces apoptosis of human astrocytes in vitro at concentrations comparable found in patients with HAND, in a dose-dependent manner (Guillemin et al. 2005b).

Astrocytes also display functional NMDAR that can be activated by QUIN (Braidy et al. 2009; Lee et al. 2010). Furthermore, astrocytes can support restricted HIV infection and sustain production of tat and nef, both of which can independently adversely impact on neuronal function and lead to neuronal death, as detailed below.

6.2 Role of the Kynurenine Pathway and Quinolinic Acid in Excitotoxicity

QUIN is an intermediate in the kynurenine pathway (KP), the major route of L-tryptophan catabolism (ending in the production of nicotinamide adenine dinucleotide (NAD)), and is implicated in the pathogenesis of many neuroinflammatory disorders, including HAND. QUIN is predominantly produced in the CNS by macrophages/microglia, after induction of the KP by proinflammatory cytokines, some interferons (particularly IFN-γ), and possibly by direct induction by HIV proteins tat and nef (Smith et al. 2001) produced within the CNS. Furthermore, BBB endothelial cells and pericytes can be activated across an intact BBB by inflammatory signals (IFN-γ in particular) from the periphery to produce QUIN precursors. These intermediaries can be further metabolized to QUIN by perivascular macrophages and microglia even in the absence of CNS HIV infection (Owe-Young et al. 2008).

QUIN causes dendritic injury at low concentrations (consistent however with levels found in HAND-affected individuals) and neuronal death at higher concentrations (Smith et al. 2001; Kerr et al. 1998) through activation of NMDAR. Neurons of the hippocampus, striatum, and neocortex are particularly sensitive to QUIN (reviewed in Guillemin et al. 2005a). QUIN is an endogenous competitive

partial agonist of NMDAR containing NR1 and NR2A or NR2B subunits (Priestley et al. 1995), the very neurons that are particularly vulnerable to HIV-induced neurotoxicity (O'Donnell et al. 2006).

Indeed, several lines of evidence support a significant contribution of QUIN to the NMDAR-mediated excitotoxicity that occurs in HAND (reviewed by Kandanearatchi and Brew 2012 and by Guillemin et al. 2005a). CSF QUIN levels are elevated in HAND-affected patients and correlate with the severity of HIV-associated cognitive impairment in some studies (Heyes et al. 1991) but not all (Valle et al. 2004). Furthermore, atrophy of brain regions that are particularly vulnerable to excitotoxic injury (but not regions established to be resistant to excitotoxic injury) correlates with elevations in CSF QUIN concentrations in HIV-infected patients (Heyes et al. 2001).

Animal models have also demonstrated neuronal loss in cell cultures following exposure to QUIN (Whetsell and Schwarcz 1989) and regional susceptibility to effects of QUIN in the brain that parallel those regions preferentially affected in HAND (reviewed in Guillemin et al. 2005a). Furthermore, pharmacological blockade of NMDAR activation and the KP upstream of QUIN production (Kerr et al. 1997) have been shown to attenuate the neuronal damage and loss by macrophage supernatants.

HAART appears to reduce CSF levels of QUIN in treated individuals, and mathematical modelling indicates that QUIN decay patterns parallel CSF HIV decrement and improvement in neurological performance (Valle et al. 2004). QUIN also directly activates astrocytes, thus amplifying the inflammatory response and astrogliosis in neuroinflammatory disorders including HAND (Ting et al. 2009 and reviewed in Guillemin et al. 2005a).

6.3 HIV Proteins as Excitotoxins

HIV proteins can adversely impact all resident cells in the CNS (including neurons) and blood-derived cells without requiring direct infection. Defective virions and viral particles, viral particles released by cell death, together with viral coat proteins shed by HIV upon cellular infection, are present in the extracellular environment. HIV-infected cells also express some HIV proteins in their surface and through cell-cell interactions impact on uninfected adjacent cells (Nath 2002). Furthermore, gp120, Tat, and Vpr have all been shown to be present in the serum of HIV-infected patients, and Tat (Schwarze et al. 1999) and gp120 (Annunziata 2003) can cross the (often defective) blood–brain barrier, representing another pathway by which CNS neurons and other cells may be exposed to HIV proteins in the absence of direct infection.

There is evidence that gp120 (and Tat to a lesser extent) acts directly as excitotoxins through NMDAR activation in HAND, further detailed below. Other HIV proteins have also been studied in isolation; however, currently there is a lack of convincing evidence to support a significant contribution to excitotoxicity. Of note, gp41 has been demonstrated to induce the release of glutamate from

astrocytes in vitro (Nath 2002 and references therein). Nef is toxic to human neurons and microglial cells in vitro (Trillo-Pazos et al. 2000) (possibly through adverse impacts on neuronal potassium currents across the neuronal membrane (Werner et al. 1991)). In vivo nef exposure also leads to monocyte/macrophage recruitment, increased production of TNF-α and astrogliosis, and behavioral change in rats (Mordelet et al. 2004). Vpr has not been established as a contributor to excitotoxicity; however, it has been shown experimentally to induce neuronal apoptosis possibly through activation of caspase-8 (Patel et al. 2000) and neuronal lysis through disturbance of membrane permeability with subsequent depolarization (Piller et al. 1998, 1999). Rev, Vpu, and other HIV proteins have been studied much less than the above proteins, and at this stage there is insufficient evidence describing a direct role of these proteins in the pathogenesis of HAND.

6.3.1 Gp120

As part of the HIV life cycle, gp120 forms virion spikes and interacts with receptors on target cells (Reitz and Gallo 2009). In addition, gp120 induces neuronal cell death of midbrain dopaminergic, hippocampal, cortical, and cerebellar granule neurons in vitro and within rodent brains in vivo (Bachis et al. 2003 and references therein). While experimental evidence suggests that gp120 has the capacity to induce neuronal apoptosis through cytokine receptor activation directly (reviewed in Gonzalez-Scarano and Martin-Garcia 2005) and involvement of the caspase system of enzymes (Garden et al. 2002), the relative importance of this effect pathophysiologically is not certain.

The bulk of evidence suggests that gp120 contributes to neuronal apoptosis ultimately through NMDA receptor-mediated excitotoxicity; however, again the relative importance of this protein overall in the excitotoxicity in HAND is not established. It has been demonstrated experimentally that HIV requires the presence of non-neuronal cells (microglia and macrocytes) to induce excitotoxicity (Meucci and Miller 1996; Kaul et al. 2001, 2005 and references therein), and gp120 has been implicated in the activation of these cells. Indeed, in vivo studies using transgenic gp120 positive mice have demonstrated that gp120 in the absence of HIV itself is sufficient to induce excitotoxic neuronal injury, reduced dendritic density, neuronal death, and behavioral changes consistent with HAND, effects that are at least partly ameliorated by the NMDAR antagonist treatment (Kaul et al. 2005 and references therein). The requirement of non-neuronal cells, however, for neurotoxicity in HIV implies a microglial cell-derived intermediate at play (QUIN, e.g., has been proposed as at least one of these intermediaries as detailed above as well as arachidonic acid (AA)). AA is released by astrocytes and macrophages in the presence of gp120. AA is known to reduce the reuptake of glutamate and other excitatory amino acids by astrocytes and nerve endings via EAA transporters in vitro. AA can also potentiate neuronal NMDAR activation by glutamate, increasing channel open time and mean open probability after activation (Miller et al. 1992; Lipton et al. 1994). There is also some evidence, however, that gp120 itself directly interacts with the NMDAR at its glycine binding site, potentiating its activation by endogenous agonists (Li et al. 2005; Kaul et al. 2001).

6.3.2 Tat

Tat is actively released extracellularly by HIV-1-infected lymphoid and glial cells and astrocytes and can be taken up by most cell types (including neurons) or interact with cell surfaces, thereby exerting toxicity to both infected and uninfected cells. Tat also appears to evade proteolysis by neurons and enter axonal transport systems and therefore can cause neuronal damage and microglial activation at sites distant from cells infected with HIV (reviewed by Li et al. 2009). Cells particularly sensitive to the neurotoxic effects of Tat are those in the striatum, dentate gyrus, and CA3 region of the hippocampus (Rumbaugh and Nath 2006).

Experimental evidence supports a role of Tat in NMDAR-mediated excitotoxicity by potentiating its activation by endogenous agonists (Haughey et al. 2001; Li et al. 2005; Mattson et al. 2005). The pathway of receptor potentiation involves phosphorylation of NMDAR subunits NR2A and NR2B and modulation of Zn-binding sites on the NMDAR (Haughey et al. 2001). This potentiation may explain the observed synergy between Tat and gp120 (Nath et al. 2000; Ferris et al. 2008), as well as with glutamate itself (Li et al. 2009 and references therein), in inducing excitotoxic neuronal cell death. Furthermore, Tat uniquely activates the NMDAR, at a site distinct from glutamate. In vitro rat hippocampal neurons are activated by Tat binding to a distinct modulatory site on the NR1 subunit of NMDARs at concentrations compatible to those in the brains of HIV-infected individuals (Song et al. 2003). The relative importance of this interaction with the NMDAR is uncertain, however, in the pathogenesis of HAND.

Like gp120, there is extensive evidence of Tat involvement in the widespread glial cell activation characteristic of HIVE (particularly monocytes and macrophages), with subsequent induction of a wide range of cytokines (Nath 2002; Mattson et al. 2005; Rumbaugh and Nath 2006). Indeed, Tat increases NO production by microglial cells through inducible NOS gene transactivation, an effect that is amplified in the presence of IFN-γ (Polazzi et al. 1999). Similar to gp120, Tat has also been demonstrated to bind and activate some chemokine receptors directly (Albini et al. 1998). Furthermore, Tat interferes with multiple molecular mechanisms in microglial cells experimentally, potentially further contributing to neuropathology (reviewed by Minghetti et al. 2004). Importantly, however, the relative importance of these multiple pathways to neuronal death induced by Tat experimentally is uncertain. Interestingly, astrocytes transfected with Tat are protected from oxidative stress and cellular injury experimentally, despite the extracellular release of Tat inducing neurite trimming and neuron death (Chauhan et al. 2003).

7 Adjunctive Therapeutic Approaches: The Role of NMDAR Antagonists

Current HAART fails to protect HIV-infected individuals from HAND even when viral suppression is achieved and immune system function optimized. Therefore, therapies that augment the partially protective effects of HAART are actively being sought. Multiple avenues for alternative therapies have been explored.

The following discussion will focus on agents that reduce excitotoxicity at the level of NMDAR activation; however, the associated rise in intracellular calcium with activation of NOS and apoptotic pathways and/or the impacts of locally and peripherally produced cytokines are also acknowledged as potential targets (Wallace 2006). For example, both lithium and valproate modulate apoptotic protein function; lithium also stabilizes Na+/K+ channels and reduces inflammation.

Notably, studies have shown preliminary efficacy of valproate in preventing neuronal dysfunction in animal models of HIVE (Dou et al. 2003, 2005) and in the treatment of HAND-affected individuals (Schifitto et al. 2009; Letendre et al. 2006).

The recognition that NMDAR activation plays a central role in neuronal degeneration and death in HAND has been facilitated by the use of NMDAR antagonists experimentally. Therapeutic trials of such antagonists have naturally progressed from these findings, however as yet their effectiveness in improving cognitive function or slowing the progression of HAND has not been established. Additionally, while changes to glutamate receptor functioning in astrocytes and microglial cells have been implicated in excitotoxic cell death cascades, the consequences of therapeutic manipulation of glutamate transporters in models of other neurodegenerative disorders have yielded conflicting results (Sheldon and Robinson 2007) and as yet have not been evaluated in the setting of HAND.

Memantine is a noncompetitive, low-affinity, open-channel blocker of the NMDAR (pharmacology reviewed by Lipton 2004), with preferential action on extrasynaptic NMDAR (those containing NR2B subunits) (Shin et al. 2011). It has an acceptable side effect profile due to its ability to prevent NMDAR activation at pathophysiological levels without compromising normal neuronal function; indeed, many experimental agents have failed in this regard with resultant excessive toxicity (Lipton 2004). It is used widely in the treatment of Alzheimer's dementia; however, as yet therapeutic trials examining its use in HAND have not led to recommendations for its use in this setting thus far. In addition, memantine is likely only to be effective when used preventatively or to slow dementia progression in affected patients, as it would have no impact on neuronal impairment once established (Wallace 2006).

Specifically, in vitro studies have demonstrated that neurons are protected from injury and death induced by gp120 (Lipton 1992) and gp120 and tat cotreatment (Nath et al. 2000) in the presence of memantine. Gp120-induced reductions in dendritic and presynaptic terminal density are also diminished in gp120+ transgenic mouse models when treated with memantine (Toggas et al. 1996). Furthermore, memantine has been demonstrated experimentally to prevent Tat-induced death of rat hippocampal neurons in culture. Interestingly, while failing to protect from Tat-induced synapse loss in this study, when administered after significant synapse loss had occurred, memantine induced a recovery of synapse number. The authors hypothesize that NMDA receptor subtypes differentially contribute to synaptic death and recovery and that synaptic NMDA receptor subtypes undergo pharmacological change during the neurotoxic process (Shin et al. 2011).

Memantine treatment in the setting of mild to severe forms of HAND has so far been demonstrated to be safe and tolerable in a double-blind 16-week trial

(followed by 20-week washout period), with proton magnetic resonance spectroscopy (MRS) data (measuring metabolites associated with glia and neuronal function in vivo) across the treatment period consistent with a neuroprotective effect in treated individuals (Schifitto et al. 2007). However, the open-label phase of this same study extended to 60 weeks of therapy yielded no statistically significant improvement in neuropsychological performance in those receiving memantine (Zhao et al. 2010). Importantly, however, study limitations necessitate further evaluation to more accurately assess the efficacy of memantine in those affected by HAND (Zhao et al. 2010).

8 Conclusion

So far current therapy for HIV infection has failed to protect treated patients from the development of HAND despite apparent efficacy in virologic control, as least as measured outside of the brain. While current evidence supports the contribution of multiple pathophysiological pathways in the development of HAND, a central role of NMDAR-mediated excitotoxicity is supported by both direct and indirect evidence. Indeed, HIV impacts on this pathway in some ways that are unique among other neuroinflammatory and neurodegenerative disorders, as outlined. Clearly further research is required in the area of HAND pathogenesis to establish the relative importance of NMDAR-mediated excitotoxicity in the development of these disorders (especially in the era of HAART). This would assist in the development of adjunctive therapies in the prevention and treatment of HAND.

Excitotoxicity in the Pathogenesis of Autism

M. M. Essa, Nady Braidy, S. Subash, R. K. Vijayan, and Gilles J. Guillemin

Contents

Abstract

Autism is a neurodevelopmental disorder characterized by stereotyped interests and behaviors and abnormalities in verbal and nonverbal communication. Autism is reported as a multifactorial disorder resulting from interactions between genetic, environmental, and immunological factors. Excitotoxicity and oxidative stress are potential mechanisms, which are likely to serve as a converging point to these risk factors. Numerous studies suggest that excitotoxicity is a likely cause of neuronal dysfunction in autistic patients. Glutamate is the main excitatory neurotransmitter generated in the CNS, and

overactivation of glutamate receptors triggers excitotoxicity. Hyperactivation of glutamatergic receptors, NMDA and AMPA, leads to activation of enzymes, which damage cellular structure, membrane permeability, and electrochemical gradients. The role of excitotoxicity in autistic subjects is summarized in this chapter.

Keywords
Autism • Excitotoxicity • Free radicals • Glutamatergic receptors • Ion channel • Membrane potential • Neurotransmitter

1 Introduction

Autism is a neurodevelopmental disorder associated with several cognitive manifestations including repetitive behaviors, social withdrawal, and abnormalities in verbal and nonverbal communications (Gillberg and Coleman 2000). Baron-Cohen et al. (2009) showed that autism affects 1–2 in 100 children, according to recent data on the broad array of autism spectrum disorders (ASD) (Baron-Cohen et al. 2009).

Excitotoxicity is an important pathological event mediated by neuronal excitation through overstimulation of neurons by excitatory amino acids receptors of glutamate and aspartate (Olney 1969). The pathological hallmarks of excitotoxicity include neuronal swelling, vacuolization, and neuronal dystrophy (Farooqui and Horrocks 1994). Under physiological conditions, excitatory receptors induce the influx of sodium, calcium, and potassium, which results in neuronal excitation (Lan et al. 2001). Excess levels of glutamate and other excitatory molecules result in overexcitation of the ionotropic glutamatergic receptors *N*-methyl-D-aspartate (NMDA) and 2-amino-3-(3-hydroxy-5-methylisoxazol-4-yl) propionate (AMPA) and the release of other excitotoxins followed by excessive calcium levels in cytosol. The influx of intracellular calcium triggers the induction of inducible nitric oxide (iNOS) and phosphorylation of protein kinase C. Increased iNOS enhances nitric oxide (NO•) production in excess, whereas protein kinase C activates phospholipase A2 which in turn results in the generation of pro-inflammatory molecules (Babu et al. 1994; Banion 1999). The subsequent generation of free radicals can inhibit oxidative phosphorylation and damage mitochondrial enzymes involved in the electron transport chain, which mitigate energy production (Eliasson et al. 1999).

Seizures represent important pathological event associated with excitotoxicity in autistic children. Experimental studies substantiated the relationship between seizure formation and excitotoxicity (Rogawski 1995). Elevation of glutamate levels in brain is the primary cause of seizure formation (Johnston 1995; Blaylock 2003).

2 Evidence for Excitotoxicity in Autistic Patients

Biochemical analysis has shown elevated serum level of glutamate in autistic patients compared to controls (Shinohe et al. 2006). Abnormalities in immune

system regulation have also been reported in autistic patients (Cohly and Panja 2005). Higher levels of tumor necrosis factor-α (TNF-α) receptor II have been observed in the sera of children with autism spectrum disorders (Chez et al. 2007). Microglial activation can further enhance the release of TNF-α, which increases reactive oxygen and nitrogen species and inhibits the reuptake of glutamate (Hu et al. 2001).

Increased glutamate may also occur as a result of interaction between pathogens with bacterial components, viruses, and lipopolysaccharides (Fontana et al. 1996). Impaired immunity promotes viral persistence in host tissues for a greater period of time and stimulates the release of glutamate and other excitotoxins, leading to increased production of reactive oxygen species, and energy depletion in neurons (Espey et al. 1998). Peroxynitrates and other peroxidation products reduce the function of mitochondrial enzymes by impairing oxidative phosphorylation and inhibiting complex II of the electron transport chain (Fosslier 2001; Novelli et al. 1988). Moreover, lipid peroxidation products can interact with synaptic protein and impair transport of glucose and glutamate to reduce energy production and increase vulnerability to excitotoxicity (Henneberry 1989).

The formation of seizures is associated with excitotoxicity and the accumulation of glutamate (Rogawski 1995). The infant brain is more vulnerable to excitotoxic effects since the developing brain contains more synaptic glutamate receptors than at birth, and that number slowly declines during the ageing process (Johnston 1995). There is substantial evidence that excitotoxicity is responsible for the mirror focus reported in temporal lobe seizures and cognitive decline associated with epilepsy (Ekonomou and Angelatou 1999; Olney et al. 1986). Pathological changes have been observed in the hippocampus after prolonged seizures in several cases of autism. These changes include the progressive loss of hippocampal neurons in the CA1 and CA3, as well as dendritic swelling in the hilus of the fascia dentate (Ekonomou and Angelatou 1999; Olney et al. 1986).

Excitotoxic processes in the brain can also be observed using magnetic resonance imaging (MRI), usually with cortical and subcortical atrophy and progressive ventricular dilation (Baxter et al. 1996; Gospe and Hecht 1998). A magnetic resonance spectroscopy study by Page et al. (2006) demonstrated that individuals with ASD have significantly higher concentrations of glutamate in the amygdale-hippocampal region than healthy age-matched controls (Page et al. 2006). Another study demonstrated increased NMDA receptor content in several cases of temporal lobe epilepsy, suggestive of dentate granule cell hyperexcitability (Mathern et al. 1999). Postmortem studies have suggested that dysfunction in the glutamatergic system in the cerebellum may also be involved in the pathophysiology of autism. Interestingly, a recent study found that the anatomic substrate of the limbic system is considerably smaller in autistic children compared to controls (Saitoh et al. 2001).

Additionally, Zilbovicius et al. (2000) used positron emission tomography to visualize neuronal damage in 75 % of autistic children. These changes were localized to the auditory association area and temporal cortex, similar to the areas of hypoperfusion reported in a majority of cases with infantile spasms

(Zilbovicius et al. 2000). As well, experimental lesions in the temporal lobe of nonhuman primates closely resemble temporal lesions observed in autistic children (Bachevalier 1994).

3 Conclusion

Autism is a multifactorial neurodevelopmental disorder characterized by deficits in neurobehavioral and neurological dysfunction. Excitotoxicity is triggered by potential mutation in ion channels and signalling pathways, viral and bacterial pathogens, toxic metals, and free radical generation. Overexpression of glutamate receptors and increased glutamate levels lead to increased calcium influx and oxidative stress and progressive cellular degeneration and cell death. Genetic defect, such as mutation in voltage gated or ligand channels that regulate neuronal excitability, leads to defect in synaptic transmission and excitotoxic condition in autism.

Glutamate and Neurodegeneration in the Retina

Thomas E. Salt

Contents

Abstract

L-Glutamate is a neurotransmitter throughout the various levels of retinal neurons (photoreceptors, bipolar cells, ganglion cells) and acts at a range of ionotropic (iGlu) and metabotropic glutamate (mGlu) receptors to exert its physiological roles. A function unique to the retina can be ascribed to mGlu6 receptors, which are expressed only by ON bipolar cells at the sign-inverting synapse formed by photoreceptors. More conventional excitatory sign-conserving synapses utilizing iGlu receptors are formed at other locations in the retina. Over-activation of iGlu receptors (and especially NMDA receptors) is known to lead to excitotoxicity in the retina, as in other areas of the nervous system, and this may be associated with excessive neuronal Ca^{2+} influx. This excitotoxicity can be prevented or countered by iGlu receptor antagonists, both in vitro and in vivo. Furthermore, in some experimental models of retinal neurodegeneration, e.g., for glaucoma or ischemia, a number of different types of iGluR antagonists have been shown to be effective in a variety of species. In particular, the uncompetitive NMDA antagonist memantine has shown promise

in experimental studies, but clinical trials to treat glaucoma with this drug have not had a successful outcome, possibly due to the unavailability of suitable markers of disease progression and heterogeneity of the disease in humans. It is thus important that further work is carried out so as to translate preclinical findings on neurodegeneration into successful clinical treatments.

Keywords
AMPA receptor • Glaucoma • mGlu receptor • NMDA receptor • Retina

List of Abbreviations

AMPA	(S)-α-amino-3-hydroxy-5-methyl-4-iso-xazolepropionic acid
EAAT	Excitatory amino acid transporter
L-AP4	(APB) L-2-amino-4-phosphonobutyric acid
mGlu	Metabotropic glutamate
NMDA	*N*-methyl-D-aspartate
RGC	Retinal ganglion cell

1 Introduction

The excitatory amino acid L-glutamate (henceforth referred to as "glutamate") has been known to have toxic effects in the eye and the retina for over five decades, since the early work of Lucas and Newhouse (Lucas and Newhouse 1957) and Kobayashi (Kobayashi 1967), working in mice and rabbits. Since then the role of glutamate as an excitatory neurotransmitter in the central nervous system and retina has been well established, based on the pioneering work of Curtis and Watkins (Curtis and Watkins 1963) and the subsequent development of a pharmacological receptor scheme for the excitatory amino acids (Watkins and Evans 1981; Lodge 2009; Traynelis et al. 2010).

As with several other neurotransmitter receptor systems, the glutamate receptors can be divided into two families: the ionotropic receptors (Traynelis et al. 2010) and the metabotropic receptors (Niswender and Conn 2010). The ionotropic glutamate receptors, commonly referred to as NMDA receptors (NR1, NR2A-D, NR3A, NR3B), AMPA receptors (GluR1-4), and kainate receptors (GluR5, GluR6, KA1, KA2), are tetra-heteromeric ligand-gated cation channels (Lodge 2009; Traynelis et al. 2010) that can have a wide variety of characteristics depending on their subunit composition. In addition, *delta* receptors have been described that appear to form homomeric receptors that are not activated by any known agonist (Traynelis et al. 2010). A standard IUPHAR-approved naming convention has been developed that supersedes the common nomenclature (Table 1) (Traynelis et al. 2010). Eight metabotropic glutamate (mGlu) receptor subtypes (mGlu1-mGlu8) have been characterized to date, all of which can be found in the retina, with mGlu6 having a particularly unique role in the visual ON pathway (Morgans et al. 2010) (see below). The mGlu receptors can be placed into three Groups (I, II, III) on the basis

Table 1 Ionotropic glutamate receptor subunits

			Example antagonists	
Receptor	Common subunit names	IUPHAR subunit names	Competitive	Uncompetitive
AMPA	GluR1, GluRA	GluA1	CNQX	
	GluR2, GluRB	GluA2	DNQX	GYKI-52466
	GluR3, GluRC	GluA3	NBQX	GYKI-53655
	GluR4, GluRD	GluA4	LY293558	
Kainate	GluR5	GluK1	CNQX	GYKI-53655
	GluR6	GluK2	DNQX	
			NBQX	
	GluR7	GluK3	LY382884	
	KA1	GluK4		
	KA2	GluK5		
NMDA	NMDAR1, NR1	GluN1		Mg^{2+}
	NMDAR2A, NR2A	GluN2A	D-AP5	MK-801
	NMDAR2B, NR2B	GluN2B	R-CPP	Phencyclidine
	NMDAR2C, NR2C	GluN2C		Ketamine
	NMDAR2D, NR2D	GluN2D		Memantine
	NR3A	GluN3A		
	NR3B	GluN3B		
delta	δ1, GluR delta-1	GluD1		
	δ2, GluR delta-2	GluD2		

Abbreviations: *AMPA* α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, *CNQX* 6-cyano-7-nitroquinoxaline-2,3-dione, *D-AP5* D-(−)-2-amino-5-phosphonopentanoic acid, *DNQX* 6,7-dinitroquinoxaline-2,3-dione, *NBQX* 2,3-dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f] quinoxaline-7-sulfonamide, *NMDA* *N*-methyl-D-aspartic acid, *R-CPP* 3-((R)-2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid

of their sequence homology, their pharmacological characteristics, and the types of intracellular transduction cascade to which they may couple in in vitro expression systems (Niswender and Conn 2010). Group I (mGlu1, mGlu5) receptors typically couple to postsynaptic inositol phosphate metabolism, while Group II (mGlu2, mGlu3) and Group III (mGlu4, mGlu6-8) receptors may couple to an inhibitory cyclic-AMP cascade (Table 2). However, it is becoming evident that these receptors may also couple to alternative signalling pathways in a context-dependent manner and this potentially adds complexity to the possible outcomes of mGlu receptor activation (Niswender and Conn 2010).

2 Glutamate Receptors in the Retinal Circuitry

Glutamate is found throughout the stages of retinal circuitry, from the photoreceptors which release glutamate tonically in the dark to the retinal ganglion cells (RGCs) that use glutamate as their major transmitter in the retinal output to the brain (Wassle 2004; Lukasiewicz 2009; Slaughter 2010). Photoreceptors release glutamate onto

Table 2 Metabotropic glutamate receptor groups and subtypes

			Orthosteric agonists		Orthosteric antagonists		Allosteric modulators	
Group	Receptor	Transduction mechanism	Subtype selective	Group selective	Subtype selective	Group selective	Positive	Negative

Abbreviations: *APDC* 2R,4R-4- aminopyrrolidine-2,4-dicarboxylate, *BINA* 3′-[[(2-cyclopentyl-2,3-dihydro-6,7-dimethyl-1-oxo-1H-inden-5-yl)oxy]methyl]-[1,1′-biphenyl]-4-carboxylic acid, *CDDPB* 3-cyano-N-(1,3-diphenyl-1H-pyrazol-5-yl)benzamide, *CHPG* 2-chloro-5-hydroxyphenylglycine, *CPCOOEt* 7-(hydroxyimino)cyclopropa[b]chromen-1a-carboxylate, *4CPG* (S)-4-carboxyphenylglycine, *CPPG alpha*-cyclopropyl-4-phosphonophenylglycine, *DCPG* (S)-3,4-dicarboxyphenylglycine, *DHPG* 3,5-dihydroxyphenylglycine, L-*AP4* L-2-amino-4-phosphonobutyric acid, *L-SOP* L-serine-*O*-phosphate, *MAP4* (S)-2-amino-2-methyl-4-phosphonobutanoic acid, *MMPIP* 6-(4-methoxyphenyl)-5-methyl-3-(4-pyridinyl)-isoxazolo[4,5-c]pyridin-4(5H)-one, *MPEP* 2-methyl-6-(phenylethynyl)-pyridine, *MPPG* (RS)-α-methyl-4-phosphonophenylglycine, *MTEP* 3-((2-methyl-1,3-thiazol-4-yl)ethynyl)pyridine.

either ON or OFF bipolar cells, and it is at this point in the retinal circuitry that opposite polarity light responses are first generated from the "OFF" response of the photoreceptors which reduce their glutamate release upon light stimulation. The ON bipolar cells express mGlu6 receptors in a highly specific manner (indeed this is almost the only location in the nervous system where this receptor is expressed to any significant extent (Nakajima et al. 1993)), and it has been shown that mGlu6 is an essential component of the retinal ON pathway (Nakajima et al. 1993; Morgans et al. 2010). In the dark, constant release of glutamate from photoreceptors activates mGlu6 receptors, and conversely light stimulation leads to a reduction of mGlu6 receptor activation due to a drop in glutamate release onto bipolar cells. This light-induced deactivation of the mGlu6 signal transduction pathway results in the opening of a nonselective cation channel that is now known to be TRPM1 (Morgans et al. 2010), and this generates the ON response of the ON bipolar cells, representing a sign inversion of the synaptic input from the photoreceptors. mGlu6 receptors can be activated by the synthetic glutamate analogue L-2-amino-4-phosphonobutyric acid (L-AP4, formerly known as APB), and application of this agonist to the retina functionally blocks the ON pathway as it achieves constant activation of mGlu6 receptors, mimicking the constant release of glutamate in darkness (Slaughter 2010). By contrast, OFF bipolar cells express AMPA and kainate receptors rather than mGlu6 receptors and this results in a synaptic OFF response that follows the polarity of the photoreceptor response (Lukasiewicz 2009; Slaughter 2010).

Retinal bipolar cells are predominantly glutamatergic, although glycinergic bipolar cells have also been described (Wassle 2004). NMDA receptors appear in the retinal circuitry postsynaptic to ON bipolar cells and OFF bipolar cells on RGCs and amacrine cells where they participate in both ON and OFF signalling pathways together with AMPA and kainate receptors (Lukasiewicz 2009; Slaughter 2010). There is spatial segregation of ON bipolar cell synapses and OFF bipolar cell synapses onto ON and OFF RGCs, respectively, and NMDA receptors appear to be localized primarily peri-synaptically at ON synapses, whereas they have a more subsynaptic location at ON synapses. Furthermore, it appears that different NMDA receptor subunit types are found at these locations, with NR2B-containing receptors more prevalent at ON synapses and NR2A-containing receptors more prevalent at OFF synapses of RGCs (Fletcher et al. 2000; Zhang and Diamond 2009). In addition to these complexities, the amino acids glycine and D-serine act as co-agonists at NMDA receptors, particularly those containing the NR2B subunit (Traynelis et al. 2010), and it is possible that these co-agonists have a specific role in ON pathway signalling (Gustafson et al. 2007; Kalbaugh et al. 2009).

In addition to the highly specific role of mGlu6 receptors in the ON pathway (see above), the other mGlu receptors are also found in the retina, but specific functional roles have not been so readily ascribed (Koulen et al. 1996, 1997; Dyka et al. 2004; Quraishi et al. 2007). However, a role for mGlu8 as a presynaptic receptor located on photoreceptors and bipolar cells is beginning to emerge, and it appears that at both of these locations, it may function as an autoreceptor to regulate the release of glutamate from photoreceptors and from bipolar cells (Koulen and Brandstatter 2002; Quraishi et al. 2010).

3 Glutamate Receptors in Neurodegenerative Mechanisms

Since the initial observations on retinotoxic effects of glutamate by Lucas and Newhouse (1957), there have been a vast number of studies in many species that have investigated the neurotoxic effects of glutamate and glutamate receptor agonists and neuroprotective effects of antagonists and modulators throughout the nervous system, and these have been extensively reviewed (Choi 1988; Danysz and Parsons 1998; Doble 1999; Waxman and Lynch 2005; Casson 2006; Luo et al. 2011). There has been a substantial focus on NMDA receptors, partly due to the early pharmacological characterization of NMDA receptors (Watkins and Evans 1981) but also due to the observation that neurotoxicity was caused by large amount of Ca^{2+} influx induced by over-activation of NMDA receptors, a mechanism that was termed *excitotoxicity* (Choi 1988; Luo et al. 2011). More recently, it has become evident that the subunit composition of NMDA receptors is also critical in how they may take part in excitotoxic processes, and in particular, incorporation of NR3 subunits may have a neuroprotective effect (Nakanishi et al. 2009; Low and Wee 2010; Luo et al. 2011).

It should also be noted that activation of kainate or AMPA receptors can also lead to excitotoxicity (Choi 1992). In particular, the presence of GluR2 in AMPA receptors results in low Ca^{2+} permeability in most situations, due to RNA editing of the GluR2 subunit at the so-called Q/R site. Thus, GluR2 content and Q/R editing is critical in controlling the Ca^{2+} permeability of the AMPA receptor, and it has been suggested that increased proportion of unedited GluR2 and reduction in the total amount of overall GluR2 in AMPA receptors makes neurons more susceptible to AMPA-receptor-mediated excitotoxicity (Kim et al. 2001; Lebrun-Julien et al. 2009).

4 Glutamate Transporters in Neurodegenerative Mechanisms

It has become evident that, in addition to glutamate receptors, the uptake of glutamate by neurons and glia via specific transporters (Excitatory Amino Acid Transporters, or EAATs) is a key component of synaptic transmission and excitotoxic processes, maintaining a physiological extracellular glutamate level and thus regulating the balance between signalling and pathology (Shigeri et al. 2004; Beart and O'Shea 2007; Bringmann et al. 2009; Furuya et al. 2012). In addition, it has also been suggested that EAATs provide glutathione precursors such as glutamate and cysteine to cells and that this is crucial to prevent oxidative stress and cell death in neurons (Harada et al. 2007; Had-Aissouni 2012). There are five major subtypes of EAAT that have been termed EAAT1-5 in humans with homologues in other mammals and vertebrates (Beart and O'Shea 2007). Within the retina, EAAT1 (also known as GLAST) is localized in Müller cells (the major retinal glial cells) and astrocytes (Rauen et al. 1997). EAAT2 (also known as GLT-1) is mainly localized in cone photoreceptors, cone bipolar cells, RGCs, and Müller

cells (Rauen et al. 1997; Furuya et al. 2012). EAAT3 (also known as EAAC1) is found on Müller cells and neurons including RGCs (Kugler and Beyer 2003; Furuya et al. 2012). EAAT4 has been found in photoreceptors and astrocytes albeit at lower levels than in the brain (Ward et al. 2004; Pignataro et al. 2005). EAAT5 is present in rod photoreceptors and bipolar cells of the retina (Fyk-Kolodziej et al. 2004; Lee et al. 2012), where it may serve to regulate glutamate levels and also modulate a chloride conductance in bipolar cells (Wersinger et al. 2006).

5 Glutamate Excitotoxicity in Retinal Diseases?

The death of RGCs and other retinal neurons upon injection of glutamate agonists has been reported in numerous studies conducted in many vertebrate species (Baltmr et al. 2010; Almasieh et al. 2012). Indeed use of NMDA to lesion RGCs is often used as a model of retinal diseases such as glaucoma (Baltmr et al. 2010; Almasieh et al. 2012). The question thus arises as to whether these excitotoxic mechanisms can be related to retinal disease processes that may occur in, for example, glaucoma or retinal ischemia. There are several strands of evidence to suggest that this may be the case. The most compelling of these is that in in vivo experimental models of glaucoma or ischemia produced by a variety of different means in different species from rodent to nonhuman primate, a range of NMDA receptor antagonists (administered locally or systemically), including MK-801 (Chaudhary et al. 1998; Schuettauf et al. 2000; Guo et al. 2006), memantine (Kim et al. 2002; WoldeMussie et al. 2002; Hare et al. 2004), ifenprodil (Guo et al. 2006), and eliprodil (Kapin et al. 1999), have proven to be effective. Similarly AMPA/kainate antagonists have also been shown to be effective (Schuettauf et al. 2000). Furthermore, genetic deletion of EAATs in mice produces an RGC pathology that bears similarities to glaucoma (Harada et al. 2007).

It has also been reported that glutamate levels are elevated in the vitreous of the eye in glaucoma (Dreyer et al. 1996; Brooks et al. 1997), although these findings have been called into question (Dalton 2001), and contradictory results have been published (Carter-Dawson et al. 2002; Kwon et al. 2005). Although superficially it might be attractive to think that glutamate could be elevated in the vitreous in glaucoma, it would seem that this would be unlikely given the prevalence of uptake and compartmentalization of glutamate in neural tissue (Meldrum 2000; Salt and Cordeiro 2006; Almasieh et al. 2012). Thus, a lack of detectable glutamate increase in the vitreous of the eye should not be taken to indicate that glutamate is not taking part in neurodegenerative processes (Salt and Cordeiro 2006; Osborne 2009).

Memantine is an uncompetitive (open channel blocker) NMDA antagonist with fast kinetics that is in clinical use for neurodegenerative conditions such as Alzheimer's disease (AD) in some countries (Lipton 1993; Parsons et al. 1999; Lipton 2004). This tolerability and apparent efficacy has made it an attractive candidate for retinal neuroprotection in glaucoma (Greenfield et al. 2005; Casson 2006). However, although preclinical data in experimental glaucoma provided positive data for memantine (Kim et al. 2002; WoldeMussie et al. 2002;

Hare et al. 2004; Yucel et al. 2006), positive data from clinical trials have not been forthcoming (Allergan Inc 2008; Osborne 2009). Although disappointing, this result could be due to a number of factors. For example, in addition to NMDA receptors, other factors are likely to contribute to glaucoma (Weinreb and Khaw 2004; Osborne 2009; Almasieh et al. 2012), and blockade of NMDA receptors may not be appropriate or sufficient in every case. Furthermore, it is possible, if not likely, that the end points and methods for monitoring disease progression and benefit of therapy were not appropriate (Osborne 2009). In this respect, recent advances in imaging of different phases of retinal neurodegeneration may be of benefit in any future clinical trials (Cordeiro et al. 2010).

6 Neuroprotection via Activation of Receptors

All of the known mGlu receptors have been found in the retina (Hartveit et al. 1995; Koulen et al. 1996, 1997; Dyka et al. 2004; Quraishi et al. 2007). It is known that activation of the Group II or the Group III mGlu receptors can be neuroprotective in some experimental situations (Copani et al. 1995; Bruno et al. 2001). In particular, systemic application of Group II-selective agonists is neuroprotective in whole-brain ischemia models (Bond et al. 1998); in the retina, the Group II agonist LY354740 has been shown to be neuroprotective against RGC apoptosis in a rat glaucoma model (Guo et al. 2006) and against anoxic damage in the goldfish (Beraudi et al. 2007). The mechanism of action remains to be elucidated, but it is known from work in cortical cells that activation of mGlu3 receptors on astrocytes rather than mGlu2 receptors on neurons is needed for protection against NMDA-induced excitotoxicity (Corti et al. 2007), and it may be that this stimulates production of certain growth factors (e.g., GDNF, TGF-*beta*) (Battaglia et al. 2009; Caraci et al. 2009) which may be important in preventing apoptotic cell death (Almasieh et al. 2012). Although activation of Group III receptors has been suggested to be neuroprotective in the brain (Copani et al. 1995; Bruno et al. 2001; Ngomba et al. 2011), it is unclear whether this would be appropriate in the retina given the importance of the closely related mGlu6 (and mGlu8) receptor in visual processing (see above). In this respect it is noteworthy that mutations of the mGlu6 receptor encoding gene, GRM6, cause visual deficits including night blindness that are attributable to dysfunction of the ON pathway (Dryja et al. 2005; Zeitz et al. 2005, 2007). Thus, Group III mGlu receptors may not be suitable targets for retinal neuroprotection.

7 Conclusion

Glutamate receptors play a pivotal role in the normal signalling functions of the retina, as they do elsewhere in the nervous system, with a notable specialization in the function of mGlu6 in the ON pathway. Over-activation of the ionotropic receptors causes excitotoxic neuronal death, and this may be of relevance in the

pathophysiology of retinal diseases such as glaucoma. Neuroprotective strategies aimed at blocking these processes may be useful, but further work is required to translate experimental results to clinical usage. It may be the case that different mechanisms or combinations of mechanisms are applicable in different diseases/patients, or even at different stages of the same disease. Thus, neuroprotective strategies might need to be tailored to individual patients with appropriate monitoring of disease progression, and this should be attainable in the future (Cordeiro et al. 2010).
