Abstract

Recent studies have shown that glutamate may serve important roles in the pathobiology of primary brain tumors. Glutamate is produced and secreted from gliomas via specific glutamate transporters as a by-product of glutathione synthesis. Glutamate also plays a major role in the phenotype of malignant gliomas by several mechanisms. The consequential interaction of glutamate with peritumoral neuronal glutamate receptors leads to the development of seizures and excitotoxicity. The latter is thought to promote the expansion gliomas in the vacated surrounding tissue. Glutaminergic receptors such as α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) which lack the GluR2 subunit can activate the AKT and MAPK pathway, to promote the invasion of glioma cells into normal brain tissue. Stimulation of glutaminergic receptors also leads to the activation of focal adhesion kinase, which regulates the proliferation and motility of malignant glioma cells. Given the extensive involvement of glutamate in the development of gliomas, it is likely that pharmacological therapies targeting glutaminergic receptors and glutamate transport may be useful to inhibit glutamate-mediated glioma growth.

Keywords

AMPA • Excitotoxicity • Gliomas • Glutamate • Glutathione

1 Introduction

Over the last decade, numerous studies have identified several unique factors that can promote the growth of malignant gliomas. These include a high abundance of vasculature, nutrients, and growth factors that promote the proliferation of tumor cells and specific white matter tracts that pave the way for invading cells to transverse across the brain. Similar to other cancers, the growth of malignant gliomas is dependent on important signalling pathways by activated tyrosine kinases and absence of important tumor suppressor protein such as p53. However, several clinical trials using therapy targeting traditional growth factor pathways such as epidermal growth factor receptor (EGFR), platelet derived growth factor receptor (PDGFR), mTOR, and protein kinase C (PKC) have been unsuccessful (Ohgaki and Kleihues 2009). This suggests that gliomas may possess yet unidentified characteristics which are likely to be of greater therapeutic value.

The excitotoxic neurotransmitter, glutamate, is of major importance in the development of gliomas since (1) it is a very abundant growth factor and (2) it acts as an

important motogen in the CNS (Noch and Khalili 2009). Glutamate is released by glioblastomas via system x_c^- to promote their malignant behavior triggering apoptosis of surrounding tissue and enhancing the invasive nature of gliomas (Ye et al. 1999; Kim et al. 2001). Current experience indicates that 80 % of glioblastomas recurrences occur within 2–3 cm of the perimeter of the original resection cavity (Kim et al. 2009). Therefore, reducing glutamate levels may be empirical for inhibiting the growth of these tumors (Ye and Sontheimer 1999a). Successful treatment of glioma cells may require an increased understanding of glutamate dynamics in the brain to develop novel approaches aimed at improving current ineffective therapies (Savaskan et al. 2011; Simon and von Lehe 2011).

2 Glutaminergic System in the CNS

Two broad categories of excitatory amino acid receptors have been identified in the brain: ionotropic receptors which contain an integral ion channel and metabotropic receptors which are coupled to G proteins (Lalo et al. 2011). The NMDA receptor of which there are also subtypes is one of the three types of ionotropic receptors, the other two being α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and the kainate receptor (Ekici et al. 2012; Fuchs et al. 2012). Glutamate is the primary endogenous excitatory neurotransmitter in the CNS which will activate these receptors. All neurons in the CNS appear to be sensitive to NMDA-mediated toxicity (Savaskan et al. 2011; Simon and von Lehe 2011).

Of the ionotropic receptor channels, the NMDA receptor is unusual in that it is gated by both ligands and voltage (Singh and Kaur 2009). Glutamate is unable to activate the NMDA receptor at normal resting membrane potential (−70 mV) due to the blockage of the ion channel by Mg^{2+} ions. Mg^{2+} is only removed when the target cell is partially depolarized (e.g., by additional synaptic inputs) to around −30 mV to −20 mV, allowing agonist induced currents to occur. Once activated, the NMDA receptor is permeable to Ca^{2+}, Na^+, and K^+ ions. Ca^{2+} entry is thought to activate Ca^{2+}-dependent secondary messenger cascade which contributes to certain forms of long-lasting synaptic modification (Frandsen et al. 1989; Mattson et al. 1991). It is thought that sustained increases in intracellular free Ca^{2+} due to excessive NMDA receptor activation may be central to neuronal cell death in several neurodegenerative diseases of the brain.

Glutamate uptake is the major route of degradation of glutamate from the extracellular space, making it an important function for nonmalignant astrocytes. The uptake of glutamate into astrocytes occurs predominantly by two Na^+-dependent excitatory amino acid transporters EAAT1 or EAAT2, otherwise known as Glt-1 and Glast. These transporters are highly localized in the astrocytic membrane (Allritz et al. 2010; Unger et al. 2012). Upon uptake into astrocytes, glutamate is converted to the glutamine by the catalytic activity of glutami synthetase (GS). Glutamine is then released and retaken into neurons where it is hydrolyzed by glutaminases to regenerate glutamate which is stored in synaptic vesicles (Chretien et al. 2002).

3 Glutamate Release from Gliomas

In neuronal cells, glutamate is generally released from specific synaptic vesicles in a Ca^{2+}-dependent pathway. However, in astrocytes, glutamate is released via a number of different mechanisms including vesicular release (Montana et al. 2006; Ponzio et al. 2006), reverse operation of Na^{+}-dependent glutamate transporters (Courtney et al. 1990), swelling of activated anion channels (Kimelberg et al. 1990a, b, c; Kimelberg and Kettenmann 1990), and through specific hemichannels (Ye et al. 2003). Recent studies have failed to associate these pathways as the mechanism of glutamate release in gliomas. These studies suggest that glutamate release in malignant gliomas may occur predominantly via the Na^{+}-independent system x_c^- cysteine glutamate exchanger (Ye and Sontheimer 1999b) (Fig. 1). This important amino acid transporter fosters the release of glutamate from glioma cells concomitantly with the uptake of cysteine necessary for the production of the endogenous antioxidant, glutathione (GSH) (Sato et al. 1999). In primary cells, GSH, which contains the highly reactive –SH group, maintains the normal cellular redox status by binding with reactive oxygen species and nitrosylative radicals. In gliomas, GSH provides a mechanism of protection for the malignant cells by enhancing the cell's redox status and stimulating excitotoxicity in the peritumoral brain (Kandil et al. 2010). Several analogs of the transported amino acids have been shown to disrupt system x_c^- and impair glutamate release from glioma in vivo (Patel et al. 2004). Additionally, inhibition of system x_c^- using the inhibitor, L-alpha-aminoadipate, leads to more than 50 % reduction in intracellular GSH levels in C6 gliomas, suggesting that the majority of GSH formed in these cells is due to system x_c^--mediated uptake of glutamate. Reduced GSH levels due to blockade of system x_c^- can trigger apoptosis of glioma cells via activation of the JNK and p38 MAPK pathways (Kandil et al. 2010).

Apart from its role in the production of GSH in glioma cells, glutamate can also be converted to α-ketoglutaraldehyde via the catalytic activity of glutamate dehydrogenase (GDH), which is highly expressed in glioma cells (Yang et al. 2009). Glutamate also serves as an important intermediate for energy production in the tricarboxylic cycle (TCA) due to its metabolism of the essential substrate α-ketoglutaraldehyde (Yang et al. 2009). Therefore, inhibition of glutamate release from gliomas provides a novel target to reduce the survival of malignant glioma cells by depleting important sources of energy for these glycolysis-impaired cells and reducing their redox defense status.

As previously mentioned, EAAT1–5 have been implicated in glutamate release in both astrocytes and neurons. However, these transporters appear to be dysfunctional, or not expressed in most gliomas (de Groot et al. 2005). One study showed that EAAT2 is highly expressed in low-grade astroglial tumors, but at significantly lower levels in high-grade glioblastoma tumors. Interestingly, the expression of EAAT2 can regulate glioma cell viability. For instance, the presence of EAAT2 in high-grade glioblastoma tumors makes these cells highly vulnerable to cytotoxicity

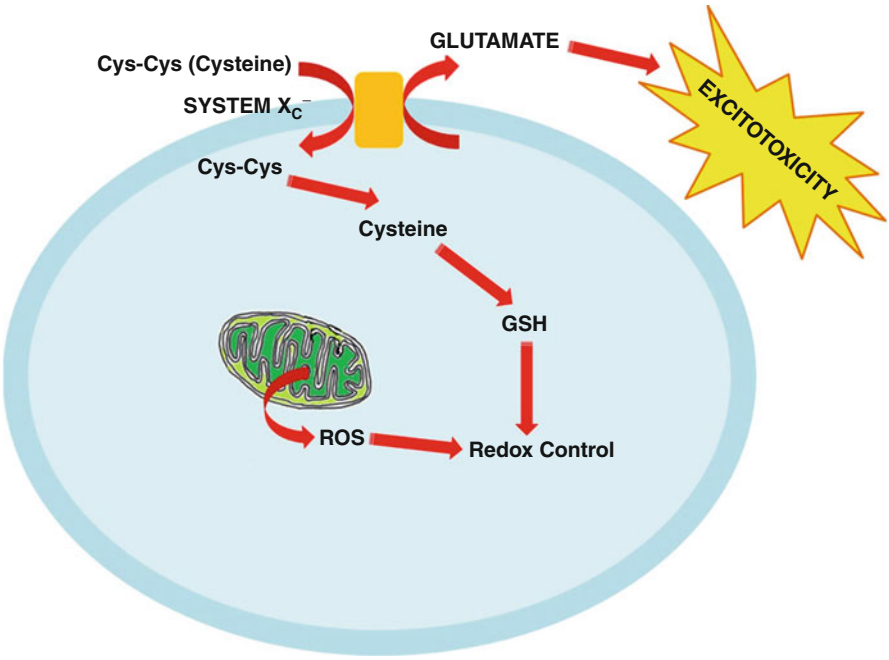

Fig. 1 Glutamate is released from glioma cells via system x_c^- involving the uptake of cysteine necessary for the production of the endogenous antioxidant glutathione (GSH)

via an apoptotic mechanism, and increased EAAT2 expression *ex vivo* can reduce tumorigenicity (de Groot et al. 2005).

Astrocyte elevated gene-1 (AEG-1) is an oncogene that is overexpressed in several tumor cells, including glioblastoma tumors, and is involved in glioma progression (Kang et al. 2005; Lee et al. 2011). AEG-1 has been shown to increase in astrocytes progressing into malignant gliomas, parallel to a decrease in EAAT2 expression (Hu et al. 2009; Baumann and Dorsey 2011; Noch et al. 2011). Recently, Lee et al (2011) showed that AEG-1 repressed EAAT2 expression at the transcriptional level, causing a reduction in glutamate uptake by glial cells, culminating in neuronal cell death (Lee et al. 2011). These findings have also been reiterated in samples of glioma cells obtained from glioma patients indicating a decline in NeuN expression correlating with increased AEG-1 expression (Lee et al. 2011).

4 Effect of Released Glutamate on Neighboring Brain Cells

In the brain, neurons, astrocytes, and microglial and vascular cells are located in close proximity to gliomas, all of which are equally responsive to the released glutamate by a number of different mechanisms.

4.1 Neuron

As earlier discussed, increased levels of glutamate in the extracellular spaces can lead to neurodegeneration by promoting glutamate excitotoxicity. This represents an alternative mechanism for the promotion and expansion of tumoral growth in the adjacent brain tissue. Excitotoxicity is a biochemical process that occurs in response to overactivation of neuronal NMDA receptors in the peritumoral brain, leading to hyperexcitability and seizures which occur frequently in conjunction with gliomas (Moots et al. 1995). Ye et al. (1999) showed that glioma cells release excitotoxic concentrations of glutamate which can induce widespread excitotoxicity in surrounding neurons as well as cellular edema (Ye and Sontheimer 1999a). The loss of these neuronal cells can be prevented by treating neurons with the NMDA receptor antagonist, MK-801/D(-)-2-amino-5-phosphonopentanoic acid, or inhibition of glutamate release from system x_c^- both in vitro and in tumor-bearing mice (Chung et al. 2005).

4.2 Astrocyte

Unlike neurons and oligodendrocytes, astrocytes are less vulnerable to millimolar concentrations of glutamate (Oka et al. 1993). Astrocytes typically respond to increased neuronal glutamate release by the rapid uptake of glutamate into the cytoplasm using the EAAT1 and EAAT2 transporters. It is likely that the function of these excitatory amino acid transporters may be impaired in astrocytes in the presence of gliomas, or they may lose their ability to catabolize glutamate to the nontoxic metabolite glutamine. Studies have shown that reactive gliosis, which is common during excitotoxicity, induces a loss in GS activity (Ortinski et al. 2010). Such loss may enhance the vulnerability of neurons to glutamate-mediated excitotoxicity and impair the normal homeostatic role of astrocytes in the brain. As well, reduced GS activity can lower GABAergic signalling by disrupting glutamate-glutamine cycling (Ortinski et al. 2010).

Astrocytes also express glutaminergic receptors. NMDA and AMPA ionotropic receptors are functionally expressed in astrocytes (Lee et al. 2010). Overactivation of the NMDA receptor can trigger glial cell death, whereas AMPA activation can alter astrocyte morphology, promote glutamate release from astrocytes, and induce deleterious changes in gene expression and normal cellular function (Weber et al. 2001). Metabotropic glutaminergic receptors may also be altered in response to changes in extracellular levels of glutamate and can modulate the expression of glutamate transporters (Aronica et al. 2003).

4.3 Glioma

Ionotropic NMDA, AMPA, and metabotropic glutaminergic receptors are all expressed in glioma cells in cell line cultures and patient-derived glioblastoma

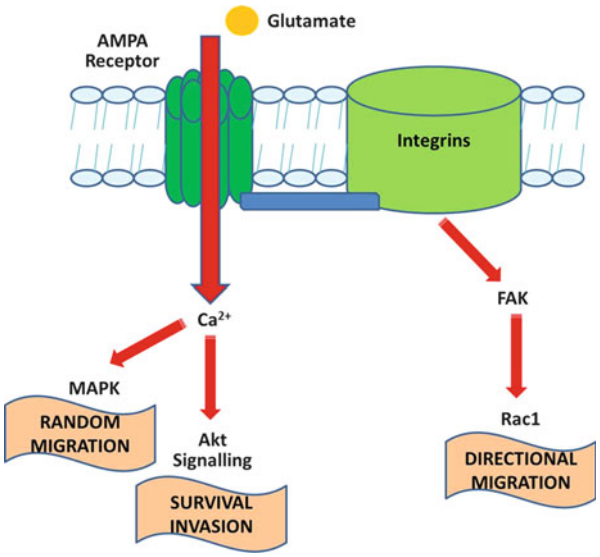

Fig. 2 Autocrine/paracrine-mediated activation of the AMPA receptor by glutamate promotes cell survival and cellular motility

specimens. The NMDA subunits NR2A, NR2B, and NR2C are expressed in several glioma cell lines (Stepulak et al. 2009). Additional studies have demonstrated antitumoral effects with NMDA receptor antagonists (Rzeski et al. 2001). Moreover, kainite receptors have also recently been discovered in several glioma cell lines cultures (Albasanz et al. 1997; Liu et al. 1997).

The AMPA receptor containing the subunits GluR1, GluR3, and GluR4 has been shown to be highly expressed in high-grade gliomas (Ishiuchi et al. 2007). The GluR2 subunit, which is lacking in most gliomas, modulates Ca^{2+} permeability. If an unedited form of the GluR2 subunit is present, Ca^{2+} permeable receptors are established. However, the presence of an edited form of the GluR2 subunit makes the AMPA receptor impermeable to Ca^{2+} and is the case at the synapses. Hence, the absence of the GluR2 subunit in gliomas induces the influx of Ca^{2+} through the AMPA receptor (Ishiuchi et al. 2007). Furthermore, one study showed that loss of GRIA2, the gene coding for GluR2 expression, leads to a poor prognosis in glioblastomas (Colman et al. 2010). Taken together, this suggests that the AMPA receptor is crucial for the development of glioblastomas. Increased Ca^{2+} appears to be an important mediator of glioma cell motility and tumor invasion.

Continued release of glutamate can lead to activation of AMPA receptor in the glioma and surrounding cells. Autocrine and paracrine activation of the AMPA receptor has been demonstrated in vivo (Lyons et al. 2007) (Fig. 2). Overexpression of the GluR1 subunit in the AMPA receptor can activate FAK-dependent signalling pathway independent of the AMPA receptor activation (Piao et al. 2009). Although the mechanism associated with FAK activation remains unclear, it may be associated with FERM protein or integrin activity. Activation of the AMPA receptor due to glutamate enhances cellular detachment via Rac1 and stimulates transwell migration in vitro and promotes tumor invasion in vivo (Piao et al. 2009).

Metabotropic receptors, including mGluR3 and mGluR5, have been described in several low- and high-grade glioma cell lines (Caruso et al. 1997; Condorelli et al. 1997). However, characterization of these receptors in human glioma samples remains to be accomplished.

5 Targeting the Glutaminergic System as Antitumoral Agents

Given the importance of glutamate in the biology of glioma growth and invasion, current agents which modulate the glutaminergic system may represent potential therapeutic agents. If modulators of the glutaminergic system can limit tumor invasion into the peritumoral brain, these drugs may represent novel therapies which can inhibit glioma infiltration in humans. Several clinical trials have been performed and are summarized here.

5.1 Antagonism of the AMPA Receptor

It is well established that glutamate released from gliomas can activate glutaminergic receptors on the same or neighboring cell. However, these drugs are limited due to severe side effects when translated into the clinic (Lipton 2004). Talampanel is a noncompetitive antagonist of the AMPA receptor that can penetrate the brain and demonstrated a favorable outcome in preclinical studies (Calabrese et al. 2007). The drug has demonstrated an excellent safety profile in a single-arm Phase II study in 32 patients with recurrent glioblastomas or anaplastic gliomas as a monotherapy (Iwamoto et al. 2010). In another larger Phase II study, talampanel was given in newly diagnosed glioblastoma patients in combination with radiation therapy and temozolomide (Grossman et al. 2009). The data collected so far indicates a favorable survival rate with no added toxicity when used in combination. However, additional randomized placebo-controlled trials are necessary to adequately establish the efficacy of this new drug compared with radiation and standard treatment regimes.

5.2 Antagonism of Other Glutaminergic Receptors

Other glutamate receptor antagonists may also be of clinical benefit for the treatment of patients with gliomas. Memantine, a noncompetitive NMDA ion channel blocker, is currently approved for the treatment of mild to moderate Alzheimer's disease (AD). Interestingly, preclinical studies have reported reduced glioma proliferation following treatment with memantine (Rzeski et al. 2001). Apart from its antitumoral activity, memantine may also attenuate excitotoxicity in neuronal cells due to increased glutamate in the extracellular space. This may also be important in inhibiting metabolic pathways utilized by malignant glioma cells.

Additionally, metabotropic glutamate receptors may also represent a useful target to attenuate NMDA receptor-mediated excitotoxicity and reduce neurological dysfunction, seizures, and increased tumor invasion. LY341495, a selective Group II metabotropic glutamate receptor antagonist, has been shown to reduce glioma proliferation, and clinical trials are under way (Arcella et al. 2005).

5.3 Blockade of System x_c^- in Gliomas

As previously discussed, the system x_c^- represents the main mechanism of glutamate release from gliomas. This unique transporter can be inhibited using sulfasalazine and FDA-approved drug that can significantly slow down tumor growth in mice (Chung et al. 2005). A Phase I study of this agent in 9 heavily pretreated patients with poor performance was terminated by the investigator due to poor efficacy outcomes.

5.4 Inhibition of Glutamate Reuptake

Enhancing glutamate uptake in glial cells represents an alternative means to prevent glutamate accumulation in peritumoral tissue and reduce glioma invasion in surrounding brain tissue. This notion has been demonstrated in vitro and in preclinical studies where ectopic expression of EAAT2 in gliomas limits their growth both in vitro and in vivo. However, this concept is yet to be translated to the clinic (Robe et al. 2004).

Glutamate Neurotoxicity Related to Energy Failure

Arne Schousboe

Contents

Abstract

Glutamate is the major excitatory neurotransmitter mediating its effects via a plethora of receptors being either ionotropic or metabotropic. Each of these two mechanistically different receptor subtypes can be subdivided into distinctly different subclasses based on different pharmacological properties. Under physiological conditions the glutamatergic neurotransmission is instrumental for a large number of basic neurochemical functions such as learning and memory. Therefore, pharmacological manipulations of glutamatergic neurotransmission

are associated with severe side effects. One particular pathophysiological area in which pharmacological intervention in glutamatergic neurotransmission has been of considerable interest is related to energy failure such as that observed during stroke leading to an ischemic condition. This has been shown to be associated with a large overflow of glutamate into the extracellular space of the brain which leads to over activation of glutamate receptors resulting in massive neuronal degeneration normally referred to as excitotoxicity. The reason for this overflow of glutamate is the fact that efficient removal of glutamate from the extrasynaptic area is mediated by a number of highly efficient, high-affinity glutamate transporters, the majority of which is located on astrocytes ensheathing the synapses. As the transporters are functionally coupled to the Na^+/K^+-ATPase, energy failure leading to reduced levels of ATP renders the transporters functionally inadequate resulting in efflux of glutamate from the cytoplasmic pool of glutamate. The energy substrates in the brain are under normal conditions limited to glucose and lactate but also glycogen which is selectively located in the astrocytes can play an important role both under physiological and pathophysiological conditions. These aspects are discussed in detail and evidence is presented pointing towards a hitherto neglected role of glycogen in the maintenance of glutamatergic activity during physiological conditions.

List of Abbreviations

AAT	Aspartate aminotransferase
AMPA	(*RS*)-2-amino-3-(3-hydroxy-5-methyl-4-isoxazolyl)propionic acid
EAAT-1	Excitatory amino acid transporter-1
EAAT-2	Excitatory amino acid transporter-2
GABA	Gamma-amino butyric acid
GDH	Glutamate dehydrogenase
GLAST	Glutamate-aspartate transporter
GLT-1	Glutamate transporter-1
GS	Glutamine synthetase
KA	Kainic acid
LDH	Lactate dehydrogenase
NMDA	N-methyl-D-aspartic acid
PAG	Phosphate-activated glutaminase
PC	Pyruvate carboxylase
TCA	Tricarboxylic acid

1 Introduction

Energy failure in the brain may be the result of stroke or global ischemia, both of which will lead to a drastic reduction of the availability of glucose and oxygen (Dugan and Kim-Han 2006). This condition is normally referred to as

oxygen-glucose deprivation (OGD) when used in in vitro systems such as cultured cells (e.g., Bonde et al. 2003). This condition is associated with degeneration of neurons in the brain as well as in tissue culture systems. It was shown in the pioneering work of Lucas and Newhouse (1957) that exposure of the central nervous system to excess amounts of glutamate will lead to neurodegeneration. Subsequently it was demonstrated that ischemia results in overflow of glutamate to the extracellular space in the brain (Benveniste et al. 1984). Based on this, it was suggested that glutamate would be likely to play a central role in the mechanisms leading to neurodegeneration induced by ischemia. The term excitotoxicity was coined by Olney et al. (1971) based on the observation that glutamate is not only an excitatory neurotransmitter (Curtis et al. 1959) but also acts as a neurotoxin.

The present review will deal with a delineation of the role of glutamate receptors in the neurotoxic actions of glutamate as well as a discussion of mechanisms involving glutamate transporters responsible for the overflow of glutamate during energy failure. This will include a discussion of glutamate metabolism as well as the role of glycogen, glucose, and lactate as energy substrates in relation to glutamate neurotransmission. Additionally, it will be discussed to what extent inhibitory neurotransmission mediated by GABA could play a role as a regulatory mechanism.

2 Glutamate Receptors

2.1 Ionotropic Receptors

Based on pharmacological characterization and subsequent cloning, the ionotropic glutamate receptors are subdivided into three major classes, i.e., N-methyl-D-aspartic acid (NMDA), (*RS*)-2-amino-3-(3-hydroxy-5-methyl-4-isoxazolyl) propionic acid (AMPA), and kainic acid (KA) receptors (Braüner-Osborne et al. 2000). As each of these subgroups consists of a number of subunits that can be assembled in different combinations, the total number of possible receptors is much higher and these different receptors have pharmacologically and functionally distinct properties (Braüner-Osborne et al. 2000). This has turned out to be very important in attempts to design strategies to ameliorate glutamate-mediated neurodegeneration (Schousboe and Frandsen 1995; Ikonomidou and Turski 1995; Braüner-Osborne et al. 2000).

2.2 Metabotropic Glutamate Receptors

Subsequent to the demonstration that exposure of nervous tissue preparations to glutamate resulted in stimulation of inositol phospholipid metabolism (Sladeczek et al. 1985; Nicoletti et al. 1986a, b), cloning studies have identified eight subtypes of metabotropic glutamate receptors (see Braüner-Osborne et al. 2000). These are further subdivided into three subgroups consisting of group I acting on

phospholipase C leading to an increase in inositol phosphates and groups II and III that are coupled to adenylate cyclase which is inhibited leading to a decrease in the cellular content of cyclic AMP (see Braüner-Osborne et al. 2000). Due to the fact that this group of receptors plays a fundamental role in the regulation of a number of important brain functions, an enormous effort has been made to make glutamate analogs of restricted conformation acting as agonists and antagonists on the different subtypes and a comprehensive list of such compounds is provided by Bräuner-Osborne et al. (2000).

3 Glutamate Transporters

Subsequent to its release as neurotransmitter and interaction with the receptors, glutamate must be inactivated. This process is mediated via high-affinity transporters, the capacity of which is more pronounced in astrocytes compared to neurons (Schousboe 1981; Gegeslashvili and Schousboe 1997; Danbolt 2001; Schousboe et al. 2012). This notion is based on studies of the kinetics of glutamate uptake into cultured neurons and astrocytes as well as detailed immunocytochemical localization studies using specific antibodies prepared from peptide libraries generated from the cloned transporters (see Schousboe et al. 2012 and references therein). The following sections will provide a short description of the two major astroglial transporters GLAST (EAAT-1) and GLT-1 (EAAT-2).

3.1 GLAST and GLT-1

A glutamate transporter was co-purified with the enzyme UDP galactose: ceramide galactosyltransferase (Schulte and Stoffel 1995) and this procedure was used to clone the glutamate-aspartate transporter named GLAST (Storck et al. 1992). At the same time another glutamate transporter was purified using a synaptosomal membrane preparation from rat brain (Danbolt et al. 1990). This enabled the production of a specific antibody which was subsequently used to clone this glutamate transporter named GLT-1 as it turned out to be different from GLAST (Pines et al. 1992). In spite of the fact that synaptosomal membranes had served as the starting material in the purification procedure, it became clear from immunohistochemical studies at the light and electron microscopic level that GLT-1 is almost exclusively localized in astroglial cells (Danbolt et al. 1992; Levy et al. 1993; Rothstein et al. 1994; Chaudhry et al. 1995). While GLAST is also essentially only expressed in astrocytes (Chaudhry et al. 1995; Lehre et al. 1995; Schmitt et al. 1997), the regional expression pattern of the two transporters shows a differential distribution with higher expression of GLT-1 in cortical areas and higher levels of expression of GLAST in cerebellum compared to cortex (Lehre et al. 1995).

3.2 Energy Requirements of Glutamate Transport

Detailed studies by Levy et al. (1998) of the stoichiometry of the ionic dependence of glutamate transport mediated by GLT-1 have shown that this requires co-transport of three sodium ions and one proton and countertransport of one potassium ion. This movement of ions needs to be reversed by the concerted action of the Na^+/K^+-ATPase and the Na^+/H^+ exchanger. As the latter process is also dependent on the ATPase, a total of four sodium ions need to be transported which consumes 1.3 mol of ATP. Interestingly, it has been reported recently that a tight coupling appears to exist between the glutamate transporters and the sodium-potassium ATPase (Cholet et al. 2002; Rose et al. 2009; Genda et al. 2011; Bauer et al. 2012) which would make the processes highly efficient.

It should be considered that the neurotransmission process consists of not only inactivation of glutamate by the astrocytic transporters but also of the vesicular packaging of glutamate prior to its release as a transmitter. This process involves the vesicular H^+-ATPase (Maycox et al. 1988) which likely has the same ATP stoichiometry as the mitochondrial F-type ATPase coupled to ATP production. Hence, vesicular filling is associated with approximately one third mol of ATP per mol of glutamate transported into the vesicles.

4 Glutamate Metabolism

4.1 Astrocytes

Glutamate transported into the astrocytes subsequent to release from vesicles in the presynaptic nerve endings will be metabolized either by the astrocyte specific enzyme glutamine synthetase (GS) or by oxidation in mitochondria after conversion to α-ketoglutarate catalyzed by either glutamate dehydrogenase (GDH) or aspartate aminotransferase (AAT) as described in detail elsewhere (e.g., Sonnewald et al. 1997; Schousboe et al. 2012). There is evidence to suggest that the metabolic pathways involved in the oxidation of glutamate are dependent on the prevailing glutamate concentration in the astrocyte (Sonnewald et al. 1997). Thus, the GDH catalyzed conversion to α-ketoglutarate prevails over the transamination catalyzed by AAT at elevated glutamate concentrations. This impacts on the energy homeostasis of glutamate metabolism since the GDH reaction produces NADH which subsequently gives rise to ATP production by oxidative phosphorylation (see McKenna et al. 2012), whereas the transamination reaction does not provide energy in the form of ATP. Regardless of the reaction responsible for the conversion of glutamate to α-ketoglutarate, subsequent metabolism of this tricarboxylic acid (TCA) cycle intermediate to carbon dioxide via pyruvate recycling (see Waagepetersen et al. 2009) provides 24 mol of ATP. Hence, glutamate can be regarded as an excellent energy substrate in the brain and its metabolism can to some extent replace that of glucose in astrocytes (Hertz et al. 2000).

4.2 Neurons

In both glutamatergic and GABAergic neurons, glutamate is formed by deamination of glutamine catalyzed by phosphate-activated glutaminase (PAG). Glutamine must be provided by surrounding astrocytes as neurons are incapable of performing a net synthesis of glutamine from glucose as they do not express the enzymes pyruvate carboxylase (PC) and GS (see Schousboe et al. 2012), both of which are astrocyte specific (Norenberg and Martinez-Hernandez 1979; Yu et al. 1983). In glutamatergic neurons this newly formed glutamate can be taken up into vesicles for transmitter use or it may be used as an energy substrate as explained above (Sect. 4.1). In GABAergic neurons it is either converted to transmitter GABA by decarboxylation or used as energy substrate (see Schousboe et al. 2012).

5 Consequences of Energy Failure in Glutamatergic Neurotransmission

5.1 Glycogen, Glucose, and Lactate as Energy Substrates

The brain is the most energy-demanding organ accounting for about 20 % of the resting metabolic rate albeit amounting to only 2 % of the body weight (see McKenna et al. 2012). The majority of the energy consumption (75 %) is related to signaling processes, whereas the remaining energy consumption is associated with basic cellular activities (McKenna et al. 2012). In the adult brain glucose is the main obligatory energy substrate but alternative substrates such as ketone bodies and lactate can be utilized. The use of ketone bodies will be prominent during prolonged fasting (McKenna et al. 2012). Interestingly, during strenuous exercise leading to lactate production in the muscles and high lactate plasma levels, lactate can be taken up into the brain (Quistorff et al. 2008). Glucose is metabolized in the glycolytic metabolic pathway leading to production of pyruvate which can either be oxidatively metabolized in the mitochondria to CO_2 and water or it can be reduced to lactate catalyzed by lactate dehydrogenase (LDH) in which case lactate is the end product of glucose metabolism. It has been proposed that in astrocytes glucose is preferentially converted to lactate which is subsequently transferred to the neurons where it is converted to pyruvate via the LDH reaction and further oxidatively metabolized (Pellerin and Magistretti 1994). This process, referred to as the astrocyte-neuron lactate shuttle, has subsequently been extensively discussed and it seems clear that astrocytes have a significant oxidative metabolism which on a volume basis is comparable to that in neurons (Hertz et al. 2007). It is important to note that the combination of glycolysis and oxidative metabolism of pyruvate requires the presence of the malate-aspartate shuttle (or an equivalent mechanism) which can secure exchange between the cytosol and the mitochondria of the redox couple NAD^+/NADH as the mitochondrial membrane is impermeable to NAD^+ and NADH (McKenna et al. 2012). In this context it should be noted that astrocytes are equipped with all enzymes as well as mitochondria necessary to carry out the

metabolic processes involved in oxidative metabolism of glucose to CO_2 and water (Lovatt et al. 2007). It is also interesting to note that lactate is unable to fully replace glucose as an energy substrate for neurons during enhanced activity as that seen during exposure to depolarizing signals in the form of glutamate or elevated potassium (Bak et al. 2006; 2012).

During recent years brain glycogen has attracted attention although its concentration is quite low compared to that in other organs such as liver and muscle. However, its concentration exceeds that of free glucose, but during glucose deprivation this amount of glycogen would, if metabolized by the concerted action of glycogenolysis and glycolysis, only provide enough energy to maintain brain function for a few minutes (McKenna et al. 2012). The availability of specific pharmacological tools to inhibit the key enzyme in glycogenolysis, glycogen phosphorylase, has facilitated studies aimed at elucidating the functional role of glycogen (Obel et al. 2012). Such studies have provided evidence that glycogen turnover involving the glycogen shunt, i.e., the conversion of glucose-6-phosphate to glycogen and its reappearance as glucose-1-phosphate and thus glucose-6-phosphate (see Schousboe et al. 2010; Kreft et al. 2012), is of fundamental importance for the maintenance of a fully functional glutamatergic neurotransmission system (Schousboe et al. 2007, 2010; Obel et al. 2012; Parpura et al. 2012). Since the functional integrity of this system is a prerequisite to avoid excitotoxic neuronal death, glycogen metabolism is obviously also important in relation to neurotoxic damage (Obel et al. 2012).

5.2 Energy Failure and Glutamatergic Neurotransmission

As pointed out above (Sect.3.2), glutamate transport is energy dependent due to the requirement of an intact transmembrane sodium gradient. In addition to this, the process responsible for packaging of transmitter glutamate into synaptic vesicles is ATP dependent since it utilizes the proton gradient generated by the action of the H^+-ATPase. It is interesting that the ATP required in both of these processes may originate from the glycolytic metabolic pathway rather than the TCA-coupled oxidative phosphorylation pathway (Ikemoto et al. 2003; Schousboe et al. 2011). As pointed out above, glycogen metabolism and turnover seems to play an important functional role in this context.

Regardless of the metabolic processes required for ATP production, it is clear that failure of generation of ATP will result in a reduced glutamatergic transmission, i.e., vesicular release will be decreased (Schousboe and Waagepetersen 2005). Since the GABA-mediated inhibitory neurotransmission is based on the same principles as the glutamatergic system, GABA neurotransmission will be reduced as well. A possible functional interrelationship regarding glutamatergic and GABAergic neurotransmission will be provided below (see Sect. 6). As pointed out above the high-affinity glutamate transporters are energy dependent and as a consequence of this, energy failure will result in reversal of the transporters and an overflow of glutamate from the metabolic, cytosolic pool into the extracellular

space (see Schousboe and Waagepetersen 2005). This, in turn, will lead to an overstimulation of glutamate receptors resulting in excitotoxic neurodegeneration (see Sect. 5.3).

5.3 Energy Failure and Excitotoxicity

The demonstration almost 30 years ago by Benveniste et al. (1984) using the microdialysis technique that ischemia leads to an excessive overflow of glutamate and aspartate in rat hippocampus provided compelling evidence that ischemia-induced energy failure leading to pronounced neurodegeneration was very likely related to an excitotoxic mechanism as described by Olney and Ho (1970). Numerous studies using pharmacological tools to delineate the role of the different types of glutamate receptors (see Sect. 2) performed in cultured neurons as well as in the intact brain in vivo during the years subsequent to the study by Benveniste et al. (1984) have demonstrated that overstimulation of these receptors is responsible for the neurodegeneration associated with brain energy failure (see Choi and Rothman 1990; Schousboe and Frandsen 1995).

In accordance with the fact that glutamate transporters are energy dependent, energy failure has been shown to result in reversal of the glutamate transporters (Nicholls and Attwell 1990; Phillis et al. 2000; Bonde et al. 2003). This therefore is the most likely explanation why ischemia leads to overflow of glutamate and aspartate as mentioned above.

The molecular mechanisms associated with stimulation of glutamate receptors subsequently leading to neuronal degeneration are extremely complex involving disturbances of Ca^{2+} homeostasis, free radical formation, and NO generation, the concerted action of which results in activation of proteases, DNA degradation, and disruption of the cytoskeleton (see, e.g., Dugan and Kim-Han 2006). A detailed discussion of this is beyond the scope of the present review.

6 Possible Interaction Between Excitatory and Inhibitory Neurotransmission

There is evidence to suggest that the expression level of $GABA_A$ receptors may have an impact on glutamatergic, excitatory activity and excitotoxicity is exacerbated by reduced GABA receptor activity (Schwartz-Bloom and Sah 2001). Additionally, the metabotropic $GABA_B$ receptors are involved in the regulation of glutamate release and hence excitatory transmission (Nicoll 2004). In this context it is interesting that cerebral ischemia and oxygen-glucose deprivation, both of which will result in energy failure, result in a decrease in the cell surface expression of $GABA_A$ receptors (Alicke and Schwartz-Bloom 1995; Mielke and Wang 2005) which as stated above contributes to ischemic brain damage (Schwartz-Bloom and Sah 2001).

This interrelationship between glutamatergic and GABAergic neurotransmission is of importance not only for neurodegeneration induced by energy failure but also for generation of seizures and epileptic episodes. A recent review provides a detailed discussion of the significance of the machinery for synthesis, release, transport, and metabolism of glutamate and GABA as targets for development of drugs for seizure control (Rowley et al. 2012). This may be interesting in relation to neurodegeneration as well.

7 Conclusion

The present short review has provided a discussion of the correlation between energy metabolism and the homeostatic mechanisms regulating excitatory, glutamatergic activity. It is clear that energy failure will inevitably result in excessive glutamate overflow which, in turn, will produce neurodegeneration. Three decades of intensive pharmacological research has provided a wealth of information about strategies to ameliorate such neuronal damage but little has so far been achieved regarding development of clinically efficient drugs to prevent ischemia-induced neurodegeneration.

Abstract

Extracellular concentrations of the excitatory glutamate are maintained at relatively low levels to avoid an excessive activation of glutamate receptors (GluRs) that can trigger a cell death. This neuronal loss induced by hyperexcitation of GluRs has been associated with a wide range of acute and chronic neurological disorders such as Parkinson's disease (PD). In fact, altered glutamatergic neurotransmission and metabolical dysfunction seems to be crucial in the pathophysiology of PD. Moreover, degeneration of dopamine nigral neurons of the substantia nigra *pars compacta* (SNpc) provokes striatal dopaminergic denervation and a cascade of functional modifications in the activity of basal ganglia nuclei including excitatory glutamate transmission. Glutamate receptors are divided into two distinct groups, ionotropic and metabotropic receptors. The ionotropic receptors (iGluRs) are further subdivided into three groups: (i) α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), (ii) kainate, and (iii) *N*-methyl-D-aspartate (NMDA) receptor channels. The metabotropic receptors (mGluRs) are coupled to GTP-binding proteins (G proteins) and regulate the production of intracellular messengers. In this chapter, we review recent progress in the research of GluRs with special emphasis on the molecular diversity of the mGluR system and its implications in the physiopathology of PD. Finally, based on these evidences, we highlight possible therapeutic strategies that might be important to slow down the progression of PD as well as to modulate levodopa-induced dyskinesias.

Keywords

AMPA • GluRs • Glutamate • Neurotoxicity • NMDA • Parkinson's disease • Substantia Nigra

1 Introduction

Parkinson's disease (PD) is a neurodegenerative disorder characterized by motor symptoms including tremor and bradykinesia (Dauer and Przedborski 2003; Schapira 2009). The primary pathophysiology underlying PD is the degeneration of dopaminergic neurons in the substantia nigra *pars compacta* (SNpc) (Jellinger 2002). Loss of these neurons causes pathological changes in neurotransmission in the basal ganglia circuits (Carlsson et al. 1957). The ability of ionotropic and metabotropic glutamate receptors to modulate neurotransmission throughout the basal ganglia suggests that these receptors may be targets for reversing the effects of altered neurotransmission in PD (Blandini and Armentero 2012; Leaver et al. 2008). Studies in animal models suggest that modulating the activity of these receptors may alleviate the primary motor symptoms of PD as well as the side effects induced by dopamine replacement therapy (Gardoni et al. 2012; Konitsiotis et al. 2000). Moreover, glutamate receptor ligands may slow disease progression by delaying progressive dopamine neuron degeneration

(Fell et al. 2009; Johnson et al. 2009). Antagonists of N-methyl-D-aspartate (NMDA) receptors have shown promise in reversing motor symptoms, levodopa-induced dyskinesias, and neurodegeneration in preclinical PD models (Blandini and Armentero 2012; Johnson et al. 2009). The effects of drugs targeting α-amino-3-hydroxy-5-methyl-4-isoazolepropionic acid (AMPA) receptors are more complex; while antagonists of these receptors exhibit utility in the treatment of levodopa-induced dyskinesias, AMPA receptor potentiates show promise for neuroprotection (Johnson et al. 2009; Kobylecki et al. 2010). Pharmacological modulation of metabotropic glutamate receptors (mGluRs) may hold even more promise for PD treatment due to the ability of mGluRs to fine-tune neurotransmission. Antagonists of mGluR5, as well as activators of group II mGluRs and mGluR4, have shown promise in several animal models of PD (Johnson et al. 2009). As these drugs reverse motor deficits in addition to providing protection against neurodegeneration, glutamate receptors therefore represent exciting targets for the development of novel pharmacological therapies for PD. However, several approaches have been undertaken concluding in few results remarkable for humans. Nonselective blockade induces unacceptable psychiatric and cognitive adverse effects, while selective blockade is still under investigation with little benefit to date (Fantin et al. 2008; Hallett and Standaert 2004). The arduousness of finding an appropriate pharmacological therapy targeting NMDA receptors prompted much interest on metabotropic glutamate receptors (mGluRs) as novel targets for the management of PD.

2 Glutamate Receptor Subtypes

2.1 Ionotropic Glutamate Receptors

There are three major types of ionotropic glutamate receptors (iGluRs), which are named after the agonists that were originally identified to activate them selectively, and are, thus, called NMDA, AMPA, and 2-carboxy-3-carboxymethyl-4-isopropenylpyrrolidine (kainate) receptors (Fonnum 1984; Kostandy 2012). Native receptors of all of these families are likely heteromeric assemblies comprising more than one type of subunit (Kew and Kemp 2005). Although the average overall amino acid identity of ionotropic glutamate receptor subunits across the three families is only in the 20–30 % range, they share common structural features, which clearly place them into a single large superfamily. The transmembrane topology of the glutamate receptor family differs from the classic four transmembrane domain model of the nicotinic acetylcholine receptor, which has extracellular amino- and carboxy-termini and a large intracellular loop between transmembrane domains 3 and 4 (Traynelis et al. 2010). Ionotropic glutamate receptor subunits possess an extracellular amino-terminal domain, which exhibits homology to the metabotropic glutamate receptor (mGluR) bilobed agonist-binding domain, followed by a first transmembrane domain, and then a pore-forming membrane-residing domain that does not cross the membrane but forms a reentrant loop entering from and exiting to the cytoplasm (Fonnum 1984). The second and third

transmembrane domains are linked by a large extracellular loop, and the third transmembrane domain is followed by an intracellular carboxy-terminus (Dingledine et al. 1999; Mayer and Armstrong 2004). The crystal structure of the iGluR ligand-binding domains, which comprise polypeptides in both the amino-terminus (S1 domain) and the extracellular loop between transmembrane domains 3 and 4 (S2 domain), has confirmed this topology model for the ionotropic glutamate receptor family (Armstrong et al. 1998; Mayer and Armstrong 2004). Several studies have shown an implication of NMDA and AMPA receptors in PD alterations but not kainate receptors, so we haven't focused on them in this chapter.

2.1.1 NMDA Receptors

N-methyl-D-aspartate (NMDA) glutamate receptors are excitatory receptors widely involved in the basal ganglia circuitry and therefore constitute a promising target for the development of new drugs to prevent or treat PD (Hallett and Standaert 2004). NMDA receptors are ligand-gated ion channels composed of multiple subunits, which have distinct cellular and regional patterns of expression. NMDA receptors are widely found in all of the structures implicated in basal ganglia circuits, although there is a different composition of its units depending on the physiology of the circuit. For example, NMDA receptors present in the striatum, which mainly are located postsynaptically on striatal neurons, are crucial for dopamine-glutamate interactions since the abundance, structure, and function of these striatal receptors are modified by dopamine depletion and they could be further varied by pharmacological treatments used in PD (Hallett et al. 2005). In animal models, NMDA receptor antagonists are effective antiparkinsonian agents and can reduce the complications of chronic dopaminergic therapy (wearing off and dyskinesias) (Del Dotto et al. 2001). Use of these agents in humans has been limited because of the adverse effects associated with nonselective blockade of NMDA receptor function, but the development of more potent and selective pharmaceuticals holds the promise of important new therapeutic approach for PD.

2.1.2 AMPA Receptors

AMPA receptors are mainly implicated in most of the excitatory neurotransmission in the brains of mammals and also taking part in synaptic plasticity processes thought to form the base of memory and learning and the organization of neural networks during embryogenesis (O'Neill and Witkin 2007). It has been shown, using molecular cloning techniques, that the AMPA receptor family has a group of four different subunits named GluR1–4 being native AMPA receptors most likely tetramers produced by the assembly of one or more of these subunits generating homomeric or heteromeric receptors (Santos et al. 2009). Experimental data indicate that the modulation of AMPA receptors, correlated with an increased hippocampal activity, could have a crucial role in the therapeutic treatment of cognitive deficits (Chappell et al. 2007). Moreover, clinical studies have indicated that AMPA receptor modulators enhance cognitive function not only in elderly subjects but even in neurological and psychiatric patients (Lees 2000). The pathway in which AMPA receptors is implicated

is still known, but it has been postulated, using in vitro and in vivo studies, that AMPA receptors could induce the activation of a protein tyrosine kinase, Lyn, which would recruit the mitogen-activated protein kinase (MAPK) signaling pathway increasing the expression of BDNF (Hayashi et al. 1999; Zhang et al. 2010). In conclusion, several selective and systemically active AMPA receptor potentiators have been reported which main functions are to modulate glutamatergic transmission, to enhance synaptic transmission and long-term potentiation, and to increase neurotrophin expression (O'Neill et al. 2004). All these functions situate AMPA receptor potentiators as a new potential class of drugs effective for treating cognitive impairments and depression and stimulating neuroprotective effects in PD.

2.2 Metabotropic Receptors

Glutamate receptors are a group of G protein-coupled receptors (GPCRs), which are differentially localized throughout the basal ganglia and could be a good therapeutic target for PD treatment (Waxman et al. 2007). Glutamate receptors regulate excitatory and inhibitory synaptic transmission acting on synaptic mechanisms (Waxman and Lynch 2005). Structurally, we can difference eight subtypes of mGluRs, divided into three groups according to their sequence homology and G protein-coupling specificity (Conn et al. 2005; Conn and Pin 1997; Pin and Acher 2002; Pin and Duvoisin 1995). Group I mGluRs include mGluR1 and mGlu5, both of them activate phospholipase and protein kinase C and raise intracellular calcium levels. Group II mGluRs consist of two mGluR subtypes (GluR2 and GluR3) which mainly inhibit adenylyl cyclase. Group III mGluRs include mGluR4, mGluR6, mGluR7, and mGluR8, which structurally are located presynaptically, and functionally act causing a reduction in neurotransmitter release (Waxman et al. 2007). mGluRs are the most relevant glutamate receptors implicated in therapeutic strategies for PD treatment at present and will be widely reviewed in this work.

3 Distribution of Glutamatergic Receptors and Excitotoxicity

In spite of its ubiquitous role as an excitatory neurotransmitter in the intermediary metabolism in the brain, glutamate can be highly toxic to neurons, a phenomenon known as "excitotoxicity." This neuronal death is a result of an excessive stimulation of the NMDA receptor and the subsequent massive influx of extracellular Ca^{+2}. This increase in cytoplasmic Ca^{+2} activates a number of Ca^{+2}-dependent enzymes implicated in the catabolism of phospholipids, proteins, nucleic acids, and the nitric oxide synthase activity. All this events lead to a global breakdown of cellular homeostasis including membrane rupture, cytoskeletal alterations, and nitric and oxide free-radical production (Koutsilieri and Riederer 2007) (Fig. 1). During the last decade numerous reviews have addressed the role of glutamate receptors and related synaptic mechanisms in preclinical research on neurodegenerative diseases

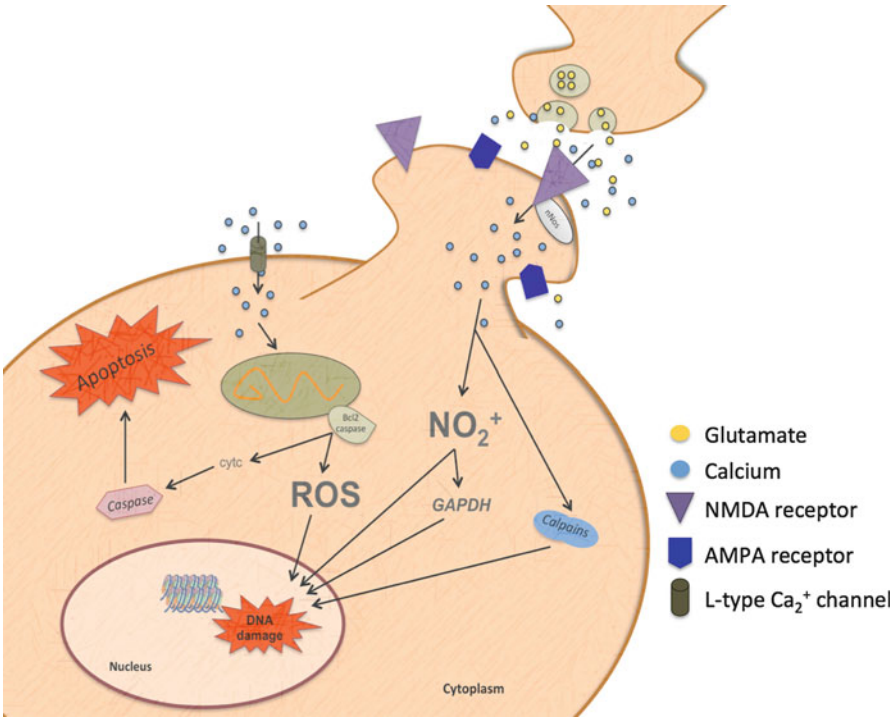

Fig. 1 Excitotoxicity of glutamate release and its implication in synaptic plasticity. One of the major functions of glutamate receptors, both metabotropic and ionotropic receptors, appears to be the modulation of synaptic plasticity. Overstimulation of NMDA receptor increases Ca^{2+} influx into the cell (neuron) which leads to the breakdown of cellular homeostasis, the lost of mitochondria function, and the release of nitric oxide and other free radicals

(Johnson et al. 2009; Lau and Tymianski 2010; Luscher and Huber 2010; Ondrejcak et al. 2010; Palop and Mucke 2010a, b; Randall et al. 2010).

3.1 Ionotropic Receptors

3.1.1 NMDA Receptors

Studies designed to determine NMDA receptor distribution have shown that these receptors are found throughout the brain but predominantly within the forebrain (Bean et al. 2006; Beckerman et al. 2012; Collingridge et al. 2013; Monaghan et al. 1998) (Fig. 2). Furthermore, quantitative comparisons of the distribution of NMDA receptors determined by the binding sites of the different ligands have suggested the presence of multiple pharmacologically distinct types of NMDA receptors (Monaghan and Jane 2009). Following the molecular cloning of NMDA receptor subunits, the distribution of each subunit was examined using in situ hybridization, histochemistry, and biochemical analysis using subunit-specific antibodies

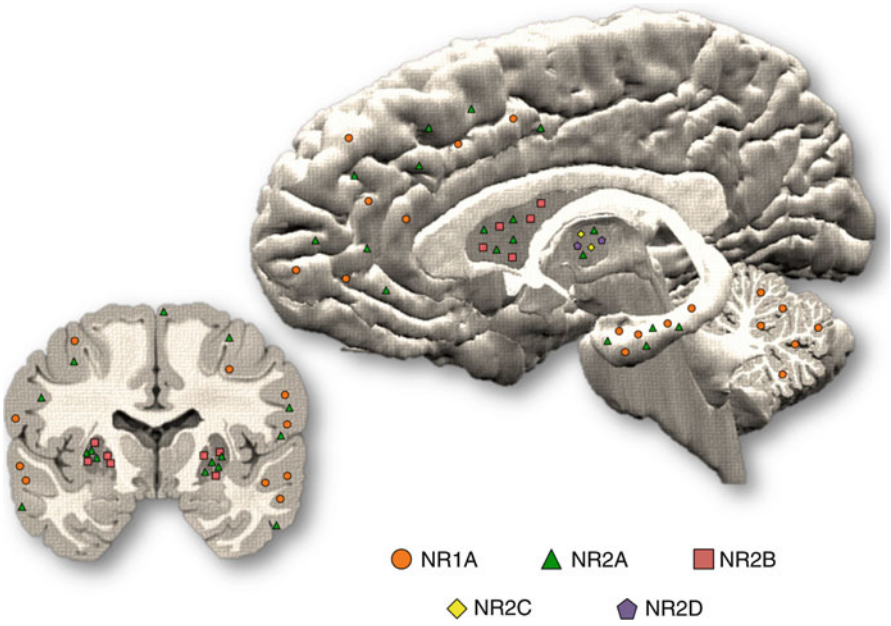

Fig. 2 Distribution of ionotropic glutamate receptors in the human brain. Using the binding sites of different ligands, the ubiquitous distribution of ionotropic glutamate receptors in the nervous system especially in the forebrain has been determined

(Dunah et al. 1999; Yamada and Nabeshima 1998). The NR1A mRNA is distributed widely in the brain but more so in the cerebral cortex, hippocampus, and cerebellum (Ehlers et al. 1995; Hara and Pickel 2008). The NR2A transcript is selectively present in the forebrain with a high-level expression in the cerebral cortex, hippocampus, septum, caudate-putamen, and olfactory bulb (Ling et al. 2012). The NR2B mRNA is expressed predominantly in the granule cell layer of the cerebellum, with weak expression in the olfactory bulb and thalamus (Jarzylo and Man 2012; Kaufmann et al. 2012). In sum, while NR2A and NR2B transcripts are found in a subset of hippocampal neurons, most likely interneurons (Kuppenbender et al. 2000), low levels of the NR2D transcript are detected in the thalamus, brain stem, and olfactory bulb, being predominant in the supraoptic nucleus (Doherty and Sladek 2011).

The location of NMDARs is also related with its signaling: (i) intrasynaptic NMDAR location is involved in neuronal survival, and (ii) extrasynaptic NMDARs have a crucial role in cell-death pathways (Papadia et al. 2005). Among other neurological alterations, NMDA receptor dysfunction may be a primary factor in the aetiology of schizophrenia, where NMDA receptor antagonists induce cortico-limbic degeneration and induct psychotic states, thus hastening a neurotoxicity and neuronal degeneration, which can be hampered using dopaminergic antagonists (Dawson et al. 2012).

3.1.2 AMPA Receptors

It has been shown that AMPA receptors in glutamatergic synapses mediate the transmission of low frequency and are involved in the expression of long-term potentiation (LTP) and long-term depression (LTD) processes, considered the cellular correlates of memory formation (Bliss and Collingridge 1993). At early time points of human embryogenesis, most of excitatory synapses are thought to be postsynaptically "silent," since their functional receptors are NMDA receptors but not AMPA ones (Daw et al. 2007; Isaac et al. 1995; Li and Zhuo 1998; Liao et al. 1995; Scott et al. 2007). Such selective pattern of synaptic activation has been termed "silent synapses" because the NMDA pore is largely hampered at resting membrane potentials (Isaac et al. 1995; Nowak et al. 1984; Scott et al. 2007). Following protocols that generate LTP, however, these functionally inhibited synapses rapidly become AMPA receptor responsive (Isaac et al. 1995; Liao et al. 1995). One possible mechanism to explain this observation is a synaptic transfer of a pool of preassembled AMPA receptors from an intracellular compartment to the postsynaptic membrane. Then, this intimate relation between AMPA and NMDA receptor is the basis of the search of alternative pathways to prevent the activation derived from an excessive NMDA excitotoxicity: NMDA antagonists, as AMPA-type receptors, have been tested and have demonstrated beneficial effects on the damage to the white substance covering the axons of neurons (Park et al. 2003). Its efficacy in preclinical models of stroke is greater than some NMDA receptors' antagonists, but some of these compounds exhibit problems of solubility or adverse effects, primarily by inhibiting the fast excitatory synaptic transmission (Clarkson et al. 2011). Excitotoxicity mediated by the alterations of AMPA receptor has been implicated in the selective vulnerability of motor neurons in amyotrophic lateral sclerosis (ALS) (Corona and Tapia 2007), in the induction of neurological deficits including schizophrenia (Tsai and Coyle 2002), and it could also underlie the cognitive deficits related with neurodegenerative diseases such as Alzheimer's disease (Kamenetz et al. 2003).

3.2 Metabotropic Receptors

Metabotropic receptors (mGluRs) are expressed throughout the CNS (Fig. 3). However, specific subtypes are expressed in restricted areas, such as the hippocampus where preferential expression of the receptor subtypes $mGluR1_b$, mGluR2/3, $mGluR4_a$, and mGluR5 has been demonstrated (Blumcke et al. 1996). mGluR3 is expressed widely in the CNS (Makoff et al. 1996a, b). mGluR4 expresses different subtypes in the thalamus, hypothalamus, and caudate nucleus, and mGluR6 is expressed in the retina (Vardi et al. 2000) (Fig. 2).

3.2.1 Group I mGluRs

Both mGlu1 and mGlu5 are most often located postsynaptically, where they are related to neuronal depolarization and excitability (Lujan et al. 1997). Nevertheless, in the midbrain, mGluR1 induces hyperpolarization of dopamine neurons

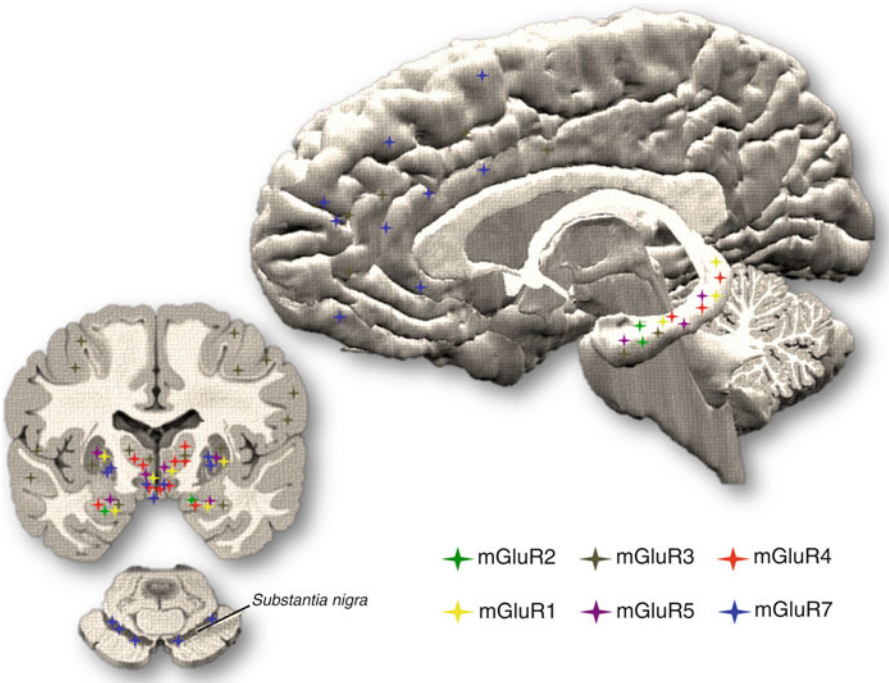

Fig. 3 Distribution of metabotropic glutamate receptors in the human brain. Metabotropic receptors are ubiquitously localized throughout the CNS, although its different subtypes are specifically expressed in the hippocampus, thalamus, and striatum

(Katayama et al. 2003). Both receptors are primarily coupled to Gq/G11 proteins (Masu et al. 1991) and have been implicated in some human disorders such as inherited ataxia and cerebellar disorders, associated with an altered expression of mGlu1 receptors in Purkinje cells (Catania et al. 2001; Conti et al. 2006; Sachs et al. 2007). However, although these data suggest that the mGluR1 could be implicated in inherited cerebellar disorders, no inductive alterations on this receptor have been determined in infant idiopathic early-onset ataxia patients (Rossi et al. 2010). Moreover, it has also been shown that mGlu1 receptor antagonists can protect hippocampal neurons against "postischemic" degeneration induced by oxygen-glucose deprivation (Pellegrini-Giampietro 2003). Recent studies have also proposed the blockade of mGlu1 receptors as a novel treatment for schizophrenia, but it has to be corroborated in the next years (Nicoletti et al. 2011).

On the other hand it has been postulated that mGlu5 has a synergic role with NMDA receptors, both acting in the control of the neuronal activity of prefrontal cortex and also being implicated in cognitive dysfunction associated with schizophrenia, being a potential treatment for schizophrenic syndromes (Conn et al. 2009).

3.2.2 Group II mGluRs

Group II mGluRs, mGlu2/3 receptors, are principally present in astrocytes surrounding the neuronal soma and synapses. They also have a presynaptic distribution inhibiting neurotransmitter release and leading to neuronal resting (Liu et al. 1998). These receptors are presynaptically localized on subthalamic nucleus terminals, and their activation inhibits excitatory transmission at subthalamic synapses resulting in a reduced excitatory drive through the indirect pathway (Murray et al. 2002).

Although both receptors, mGlu2 and mGluR3, are mostly expressed in the CNS, they have differences in their location, so while mGluR2 is uniquely in the preterminal region of the axons, far from the active zone of the neurotransmitter release (Lujan et al. 1997; Ohishi et al. 1993a; Tamaru et al. 2001), mGlu3 receptor is expressed not only in presynaptic and postsynaptic sites but also in glial cells (Ohishi et al. 1993b; Tamaru et al. 2001). Functionally, both receptors are implicated in the same human disorders. Both dysfunctions in the mGlu2/3 receptors are correlated with the following: (i) anxiety, both receptors regulate the synaptic transmission and plasticity in the amygdala (Lin et al. 2005; Wang and Gean 1999); (ii) schizophrenia, the hyperglutamatergic theory of schizophrenia has been corroborated using glutamate agonist in experimental animal models, and mGluR2/3 receptor agonists have been developed as antipsychotic drugs (Aghajanian and Marek 1999); and (iii) depression, the systemic treatment with a selective mGlu2/3 receptor antagonist has beneficial effects on this mental disorder (Feyissa et al. 2010). Apart from these effects described, mGluR2/3 receptors have a special significance in neurodegenerative diseases, as the inhibition of mGlu2 receptors decreases excitotoxic death, and mGlu3 receptors are also implicated in neuroprotective pathways (Corti et al. 2007).

3.2.3 Group III mGluRs

Group III mGluRs are identified in microglia and astrocytes as well as in presynaptic membrane like mGluR7 receptor (Geurts et al. 2005; Niswender and Conn 2010). This specific subcellular distribution is not still but modified during the development of the CNS and may play a key role for its proper progressive organization: (i) mGluR7 and mGluR8 are presynaptically located in the striatum, the globus pallidus, and in the substantia nigra pars reticulata (SNpr), where their activation inhibits GABA as well as glutamate transmission (Kosinski et al. 1999), and (ii) mGluR4 appears to be more selectively located in striatopallidal synapses and inhibits synaptic activity at this level (Valenti et al. 2003). In relation with this variety on location, glutamate also presents a changeable affinity for these receptors since it shows a high affinity to mGluR4 and mGluR8 but a very low one to mGluR7 (Schoepp et al. 1999). Apart from their implication in Parkinson's disease which would be further intensely described, these receptors have shown a significant relevance in human disorders such as (i) anxiety: it has demonstrated the negative modulation of both mGlu8 and mGlu4 receptors in the induced anxiety in rodents (Nicoletti et al. 2011), but mGlu7 has an uncertain role in this disease (Lavreysen and Dautzenberg 2008); and (ii) neuroinflammation and immune misbalanced: mGlu4 receptor has been recently implicated in the crosstalk between

the nervous and immune system, where the activation of this receptor induces the differentiation of antigen specific T cells into T regulatory ones (Fallarino et al. 2010). With regard to mGlu6 expression is not as much ubiquitous in the CNS as the other group III receptors, and physiologically it is almost exclusively implicated in the visual region since it is localized in the dendrites of bipolar cells of the retina acting on the visual physiology in darkness and being part of human visual pathologies (Nawy 2000; Xu et al. 2012).

4 Implication of Glutamate Receptors in Parkinson's Disease

4.1 NMDA Receptors as a Therapy for Parkinson's Disease

Under physiological conditions there is a neurotransmitter balance in striatum between the activation of striatal neurons through NMDA receptors and inhibition by the D2 receptors (Di Chiara et al. 1994). In PD, the depletion of nigrostriatal dopamine results in disinhibition of the striatal neurons and therefore in a relative glutamatergic overactivity (Greenamyre 1993). Moreover, the dopaminergic deficit results in enhanced activity of the STN which projects to the output nuclei of the basal ganglia rendering them overactive (Rodriguez et al. 1998). These known regulations classify PD as "a secondary glutamate overactivity syndrome" (Riederer et al. 2001) (Fig. 4). Changes in abundance of NMDA subunits in striatum have been described in dopamine-denervated rats as well as in MPTP-treated parkinsonian monkeys (Betarbet et al. 2004; Hallett et al. 2005). In the 6-OHDA-lesioned rat model, dopamine depletion results in alterations in abundance of NR1 and NR2B subunits in striatal synaptosomal membrane fractions, while NR2A is unchanged (Hallett and Standaert 2004). This was shown to be due to a selective reduction of complexes composed of NR1/NR2B without any change in receptors composed of NR1/NR2A. Chronic levodopa treatment of 6-OHDA-lesioned rats restores the abundance of NR1, NR2A, and NR2B subunits in homogenate and synaptosomal membrane fractions (Hallett and Standaert 2004). Similar redistribution occurs in the MPTP-lesioned macaque where the dopamine depletion induced by MPTP intoxications resulted in a marked decrease in striatal NR2B subunits, while the upregulation of NR2A expression in synaptosomal membranes may play a pivotal role in levodopa-induced dyskinesias (Hallett et al. 2005).

A large number of studies have examined the efficacy of nonselective NMDA antagonists in animal models of PD showing that NMDA receptor blockade attenuates parkinsonian findings and increases dopaminergic therapy (Lange et al. 1997; Marin et al. 2000). For humans, amantadine has been the mostly studied drug in clinical trials, showing antidyskinetic properties in PD patients with motor complications as well as an increased lifespan (Hubsher et al. 2012). A related compound, memantine, which is approved for treatment of dementia, did not seem to share the efficacy of amantadine in PD (Merello et al. 1999; Varanese et al. 2010). Finally, dextromethorphan, an antitussive, reduces dyskinesias in PD patients, but patients show somnolence (Chen 2011; Jimenez et al. 1999).

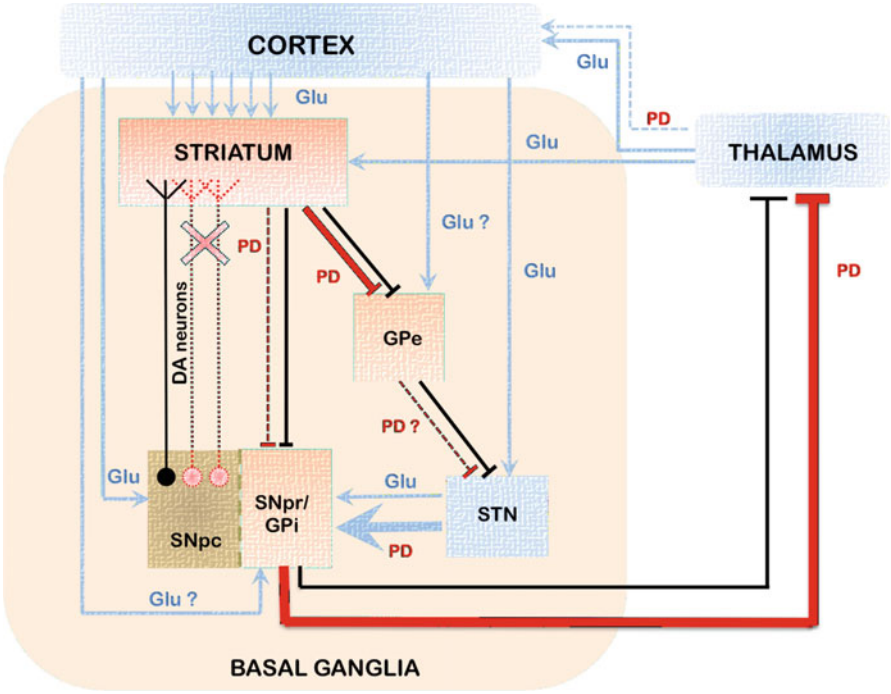

Fig. 4 Glutamatergic pathways involved in Parkinson's disease. In Parkinson's disease the striatal dopaminergic deficit results in an enhanced activity of the subthalamic nucleus which projects to the output nuclei of the basal ganglia rendering them overactive

Nowadays, based on the experimental evidence on the significance of the NMDA receptor subtypes and the limitations in the beneficial effects of the current therapy, future studies should be focused on selective NMDA antagonists in order to achieve powerful antiparkinsonian effects without adverse effects in cognition. This would facilitate cell preservation during excitotoxic processes while not causing complete inhibition of the receptor and therefore allowing physiological neurotransmission.

4.2 AMPA Receptors as a Therapy for Parkinson's Disease

It is difficult to define an antiparkinsonian treatment that targets AMPA receptors since they have dual effects, while AMPAR antagonists provide symptomatic benefits, AMPAR potentiators induces neuroprotection (Johnson et al. 2009). The role of AMPA receptors in dyskinesias has been well described: using animal models such as MPTP-lesioned nonhuman primates and 6-OHDA-lesioned rats, it has been demonstrated that pharmacological blockade of AMPARs decreases levodopa-induced dyskinesias (LIDs) and possibly enhances the antiparkinsonian

effect of levodopa (Bibbiani et al. 2005; Kobylecki et al. 2010; Konitsiotis et al. 2000). On the other hand, AMPAR agonists administered either alone or in combination with levodopa can induce dyskinesias (Konitsiotis et al. 2000). Moreover, using animal models it has been shown that the blockade of AMPA receptors could improve LIDs (Kobylecki et al. 2011; Silverdale et al. 2005). The antidyskinetic effect induced by AMPA receptor blockade derives of its action at the cellular level, as it has been demonstrated that AMPAR antagonists reduce the striatal upregulation of met-enkephalin gene expression induced by DA depletion and lately exacerbated by chronic levodopa administration (Perier et al. 2002). All these data suggest that the pathophysiological adaptations of medium spiny neurons caused by DA depletion and chronic levodopa treatment are mediated by the stimulation of AMPA receptors (Sgambato-Faure and Cenci 2012).

4.3 mGluRs as a Therapy for Parkinson's Disease

Several studies have shown that the pharmacological modulation of mGluRs can ameliorate motor abnormalities in experimental models of PD. There is also evidence of a neuroprotective effect against glutamatergic toxicity, to date in a lesser degree as with iGluRs. To avoid an excessive extension of the text and facilitate its comprehension, we will exclude the full-extension names of the molecules used in the different studies.

4.3.1 Group I mGluRs Studies

Inhibition of group I mGluRs (mGluR1 and mGluR5) seems to be promising in PD therapy (Fig. 5). The role of group I mGluRs leading to excitotoxicity and their antagonist protective properties have been proved in non-PD models of neurodegeneration (Rao et al. 2000). There is high experimental evidence of the contribution of group I mGluRs to posttraumatic or postischemic neuronal excitotoxicity. Selective mGluR5 antagonists such as MPEP or the more selective MTEP are known neuroprotective agents. Whether this effect is mediated by mGluR5 or by off-target inhibition of postsynaptic NMDAR is controversial (Lea et al. 2005). In a striatal model of excitotoxicity, MPEP did show a neuroprotective effect, but the direct blockade of NMDA receptors appeared not to be involved (Popoli et al. 2004). The role of mGluR1 ligands in excitotoxicity is not still clear. Whereas the antagonists have shown neuroprotective activity (Faden et al. 2001), the agonists may facilitate either neurotoxicity or neuroprotection (Allen et al. 2000; Nicoletti et al. 1999). EMQMCM, a novel, highly selective uncompetitive antagonist of mGlu1 receptors, has demonstrated significant effects against kainate-induced excitotoxicity in both in vitro (in the cortical and hippocampal neuron) and in vivo animal models (Smialowska et al. 2012). In the particular case of basal ganglia, prevalent distribution of mGluR5 in the striatum and in the limbic system is well documented: both subtypes of group I mGluR are postsynaptically expressed by medium spiny neurons (Tallaksen-Greene et al. 1998) as well as by all interneurons, including cholinergic cells. As mGluRs do not cause any effect on the

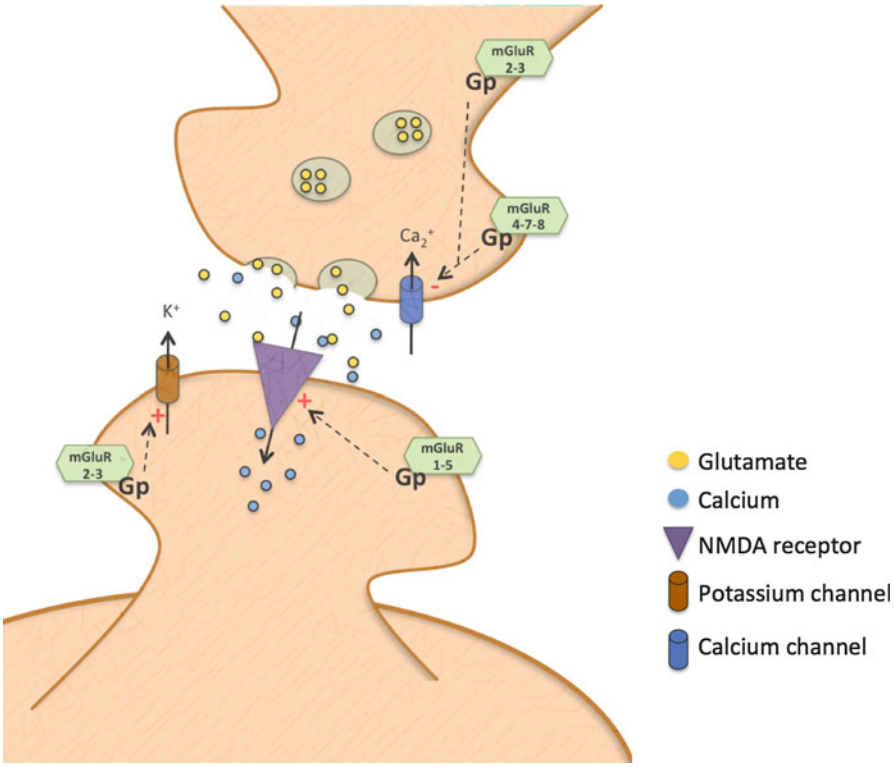

Fig. 5 Pre- and postsynaptic location of different metabotropic glutamate receptors. Among the glutamate receptors, metabotropic glutamate receptors are mostly implicated in Parkinson's disease. mGluR2 and mGluR3 are both pre- and postsynaptically located; however, mGluR4, mGluR7, and mGluR8 are located at the presynaptic level and mGluR1–mGluR5 in the postsynaptic neuron

membrane properties of the spiny neurons, its action should be indirect. Instead, they enhance the cationic currents gated by NMDA receptors (Pisani et al. 2001). Postsynaptic location of $mGluR1_a$ and mGluR5 in the subthalamic nucleus has been demonstrated showing an excitatory effect (Awad et al. 2000). PET scan of the striatum of MPTP parkinsonian monkeys showed an increased binding of mGluR5, and this upregulation of mGluR5 might play a role in disease progression in PD (Sanchez-Pernaute et al. 2008). More specifically, the blockade of mGluR5 was shown to alleviate akinesia in both 6-OHDA- and haloperidol-treated animals (Breysse et al. 2002; Ossowska et al. 2001). In addition, a study showed that mGluR5 knockout mice are less sensitive to MPTP toxicity, and mGluR5 antagonists are effective in reducing the MPTP-induced nigrostriatal damage in wild-type mice (Battaglia et al. 2003). Additionally, chronic and systemic treatment with MPEP, a selective mGluR5 antagonist, has not only anxiolytic-like effects but also neuroprotection as diminished dopaminergic cell loss in the SNpc in 6-OHDA-treated mice and rats (Chen et al. 2011).

4.3.2 Group II mGluRs Studies

Group II and III mGluRs modulate the corticostriatal input which is the major excitatory drive to the basal ganglia (Fig. 5). Activation of presynaptic group II and III mGluRs inhibits glutamatergic transmission in the striatum (Rouse et al. 2000). Moreover, all three groups of mGluRs have shown to depress transmission at glutamatergic synapses in the SNpc modulating the dopaminergic pathway from the SNpc to the striatum (Wigmore and Lacey 1998). Activation of presynaptic mGluRs in the nigrostriatal synapse increases dopamine release in the direct pathway (Rouse et al. 2000). In fact, intranigral or intraventricular injection of the group II mGluRs agonist DCG-IV reduces akinesia in the reserpine-treated rat model of PD. The selective group II mGluRs agonist LY379268 was assessed to provide both functional relief and neuroprotection in the same rodent model of PD (Dawson et al. 2000). In MPTP-lesioned mice, prior treatment with LY379268 reduced the extent of nigrostriatal degeneration. Since now on, electrophysiological studies suggest that group II mGluRs are presynaptically located on STN terminals in the SNpr and the activation of these receptors selectively reduces transmission at excitatory STN synapses. Therefore, LY354740, a highly selective agonist of group II mGluRs, inhibits synaptic excitation of the SNpr (Bradley et al. 2000). However, these results were dependent on the dose and regimen of MPTP administration: (i) they were only observed under conditions in which MPTP produced a massive degeneration of nigral dopaminergic neurons, and there was no effect with lower doses of MPTP; (ii) while systemic administration of LY379268 failed to reverse akinesia or to produce typical antiparkinsonian rotational behavior, intraventricular administration provided a dose-dependent increase in locomotor activity in these rats. Moreover, the group II mGluRs antagonist, LY341495, blocked the protective effect of the LY379268 and amplified the damage produced by MPTP, even with low exposure (Battaglia et al. 2003).

4.3.3 Group III mGluRs Studies

The largest evidence of clinical and pathological antiparkinsonian properties belongs to group III mGluRs. Research with general group III mGluR agonists has been developed. In this instance, intracerebral treatment with the L-SOP and L-AP4 (group III mGluR agonists) significantly reduced the akinesia induced by reserpine in rats (MacInnes et al. 2004). Injections were performed in the SNpr, GP, and intraventricularly. But the main studies have focused on specific group III mGluR subtypes.

Group III mGluRs, mGlu4R, and mGlu7R are expressed in synaptic terminals of the striatum, while there is no evidence about the presence of mGluR8. The two group III mGluR agonists ACPT-I and L-AP4 have shown similar potencies on mGluR4 and mGluR8 and lower affinity for mGluR7. No consistent effects on other mGluRs have been demonstrated. Pallidal injections of each glutamate receptor agonist have antiparkinsonian actions in haloperidol- and 6-OHDA-treated rats (Lopez et al. 2007), but the infusion of the same molecules into the SNpr had opposite effects in controls and 6-OHDA-treated rats, inducing catalepsy. Nevertheless, this akinetic effect is probably mediated by mGluR8 activation and not by

mGluR4. More recently, a new group III orthosteric agonist has been identified: LSP1-3081 activates selectively and dose dependently all group III receptors transiently expressed in HEK293 cells (its potency is equivalent to that of L-AP4). LSP1-3081 was found to display the highest potency on mGlu4 receptor, followed by mGlu8, and very low on mGlu7. It is also devoid of nonspecific agonist or antagonist activity on group I or II mGluRs, and on targets other than mGluRs, it has less nonspecific effect than L-AP4 (Cuomo et al. 2009). The same authors proved that LSP1-3081 and L-AP4 depressed corticostriatal glutamatergic transmission by modulating presynaptic group III mGluRs. Both compounds also inhibited GABA input to striatal MSNs. Presumably, a reduction of glutamatergic activity on subthalamo-pallidal synapses and GABA transmission in the striatopallidal pathway are also implicated in antiparkinsonian and anti-excitotoxicity properties of group III mGluRs activation. In this sense, presynaptic activation of group III mGluRs has been shown to inhibit GABA release in the GP (Matsui and Kita 2003; Valenti et al. 2003), SNpc (Valenti et al. 2005), and SNpr (Wittmann et al. 2001). The effect of L-AP4 on striatopallidal GABAergic transmission was absent in mGluR4 KO mice (Valenti et al. 2003). These data indicate that activation of mGluR4 could decrease (or modulate) the increased inhibition of the GP that has been suggested in PD models. In the same study, direct ventricular injections of L-AP4 produced robust antiparkinsonian effect in both acute (haloperidol-induced catalepsy and reserpine-induced akinesia) and chronic 6-OHDA PD models. Taking into account the low affinity for mGluR7 of the above-described group III mGluR agonists and the fact that mGluR8 has a low distribution in the striatum, mGluR4 is probably the principal vehicle to start the response to group III mGluRs agonists. To confirm the previous hypothesis, the selective mGluR8 agonist (S)-DCPG was tested to inhibit glutamatergic signaling (Cuomo et al. 2009). However, no effects were found. The same tests were performed with L-AP4 and LSP1-3081 in mGluR4 KO mice. There was no modification of postsynaptic currents in the slices of these mice. Meanwhile, in the wild type, LSP1-3081 significantly inhibited the amplitude of postsynaptic currents. Finally, the same researchers demonstrated that intrastriatal L-AP4 injection improves akinesia in 6-OHDA-lesioned rats. The former studies emphasize the importance of subtype-selective group III mGluR agonists as antiparkinsonian drugs. However, the high conservation of the glutamate-binding site makes it difficult to develop highly selective orthosteric ligands for individual mGluR subtypes. To improve specificity, ligands that interact at sites other than the orthosteric one have been developed. These are called positive allosteric modulators (PAMs). In mice histological studies, previous systemic injection of the selective PAM of mGluR4, PHCCC, protects nigrostriatal neurons against MPTP toxicity. In knockout mice for mGlu4R, there was no benefit from PHCCC. Direct GP infusion showed the same results as systemic treatment (Battaglia et al. 2006). Unfortunately, PHCCC has low potency and poor aqueous solubility, and it is also an mGluR1 antagonist with similar potency as mGluR4 (Annoura et al. 1999). Thus, it is not useful for PD.

Using high-throughput screening (HTS), multiple novel PAMs of mGluR4 were identified. The lead from this cluster of structurally related compounds was

VU0155041. Among its particularities, it exhibits submicromolar potency; it is highly selective for mGluR4 relative to other mGluRs and other targets including NMDAR and has an improved aqueous solubility. The same researches demonstrated efficacy of VU0155041 in two rodent models of PD: haloperidol-induced catalepsy and reserpine-induced akinesia (Niswender et al. 2008). A few additional novel chemical mGluR4 PAMs have been introduced later on and have shown some antiparkinsonian activity in both haloperidol-induced catalepsy and reserpine-induced akinesia models (Hopkins et al. 2009). One of them, VU0364770, has exhibited efficacy in reversing haloperidol-induced catalepsy, forelimb asymmetry, and attention deficits in 6-OHDA-lesioned rats. When coadministered with an adenosine 2A receptor antagonist or with levodopa, it also showed potentiation of their efficacy (Jones et al. 2012). The latest could mean a levodopa-sparing role of the compound. In conclusion, mGluR4 positive allosteric modulation is a promising area of research to bring about symptomatic as well as potentially disease-modifying treatment.

Another potential specific target for the management of PD is mGluR7s. While mGluR4 is highly expressed in the striatum and the GP, it is little or not expressed in SN where mGluR7 is predominant (Corti et al. 2002). mGluR7s have also high expression in the striatum and very low pallidal expression. In the striatum, mGluR7s are localized presynaptically on the corticostriatal glutamatergic synapses, where they are found to decrease the glutamatergic tone and attenuate transmission in cholinergic interneurons. AMN082 is an mGluR7 selective PAM (Mitsukawa et al. 2005). Intrastriatal injection of this compound reverses haloperidol- and 6-OHDA-induced parkinsonism in rats and haloperidol-induced Parkinsonism in mice. This effect was absent in mGluR7 knockout mice, demonstrating that it is mediated by mGluR7 (Greco et al. 2010). The anti-cataleptic property of the compound was evident only in narrow doses, causing motor impairment at higher doses. AMN082, at high doses, decreases locomotor activity of mGluR7 knockout and wild-type mice, demonstrating that this negative effect is not mGluR7 related (Palucha et al. 2007; Salling et al. 2008).

Apart from the striatum and GP, the SN is another key location for group III mGluRs. Injection of L-SOP or L-AP4 into the SNpr reversed akinesia in the reserpine-treated rat model, while infusion of L-AP4 in the SNpc prevented the akinesia and the nigrostriatal degeneration in the 6-OHDA-lesioned rat. These responses were each inhibited by pretreatment with the group III mGluRs antagonist CPPG, confirming they were mediated by activation of group III mGluRs (Austin et al. 2010). This effect seems to be mediated by presynaptic inhibition of glutamatergic input from the STN. A similar study explored selective targeting of mGluR4, mGluR7, and mGluR8 in the SNpr. Activation of mGluR4 (with PHCCC in combination with a subthreshold concentration of L-AP4) or mGluR7 (with AMN082 also in combination with a subthreshold concentration of L-AP4) reduced the release of the glutamate analogue, [^{3}H]-D-aspartate, from SNpr tissue prisms in vitro. In contrast, the mGluR8 selective agonist, (S)-3,4-DCPG, failed to provoke the same inhibition. Provided that glutamatergic afferents from the STN comprise the major excitatory input into the SNpr, mGluR4, and mGluR7,

activation may be effective for restricting glutamate release in this location (Broadstock et al. 2012). Reversal of reserpine-induced akinesia was produced following direct injection of PHCCC or AMN082 into the SNpr. Both of them acted in the absence of a subthreshold dose of L-AP4. The effects of both PHCCC and AMN082 were inhibited by CPPG, the selective group III mGluRs antagonist, confirming that these responses are mediated through group III mGluRs. Contrary to what it should be expected, injection of (S)-3,4-DCPG into the SNpr produced a dose-dependent reversal of akinesia. However, pretreatment with CPPG did not inhibit this effect, suggesting it was driven through other mechanisms independent of group III mGluRs.

Group III mGluRs have also a neuroprotective effect by preventing excitotoxicity induced by iGluRs. In this instance, excess of extracellular glutamate activates presynaptic group III mGluRs, this inhibits glutamate release, and then the activation of postsynaptic NMDARs is diminished (Vera and Tapia 2012).

5 Conclusion

In spite of the innumerable preclinical studies conducted in experimental animal models of PD associated with LIDs, such as rodents and nonhuman primates, some of which generated impressive results, the possibility to consistently attenuate or mitigate the development of LIDs in the clinical setting is still an unmet need. This is mostly due to the incomplete understanding of the neural and molecular substrates of this phenomenon, although numerous studies suggest a decisive role of glutamate receptors on this phenomenon. In fact, non-dopaminergic neurotransmitter receptors expressed by striatal neurons, such as specific subtypes of ionotropic (NMDA) and metabotropic (mGluR5) glutamate receptors, play a crucial role in the modulation of corticostriatal inputs, as well as in the modulation of the striatal output to downstream nuclei of the basal ganglia circuit. As consequence, in addition to the changes directly caused by PD, the involvement of these receptors triggers further modifications in basal ganglia functional organization, which set the ground for the functional alterations that underlie LIDs. Based on these concepts, drugs acting not only directly on glutamate receptors as NMDA and mGluR5 but even indirectly on adenosine A2A receptors have been proposed as antidyskinetic agents, showing auspicious effects. Considering that mGluR5 receptors contribute to these receptor mosaics, it is likely that new anti-LID pharmacological strategies will have to rely on compounds capable of acting, simultaneously, on all the components of these receptor mosaics, thereby combining the effects of adenosine and metabotropic receptor antagonists. However, the ubiquitous location of the different subtypes of glutamatergic receptors leaves open new ways of research in the field of PD.

Acknowledgments The authors thank the support by grants from the Spanish Ministry of Science (FIS 2010–02827), Fundación Séneca (FS/15329/PI/10), and CIBERNED (Centro de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas). Finally, the authors declare that there is no conflict of interests in the present work.

Lead and Excitotoxicity

Abdur Rahman

Contents

Abstract

Lead (Pb^{2+}) is a known neurotoxicant, but the mechanism of its neurotoxicity is not clearly understood. Several biochemical alterations have been shown to be caused by Pb^{2+} exposure in mammalian brain, but none of these changes alone can explain the mechanism of Pb^{2+}-induced impairment of learning and memory. The most mechanistically relevant biochemical abnormalities that are directly involved in learning and memory are the excitotoxic effects caused by modulation of the *N*-methyl-D-aspartate-type glutamate receptors (NMDAR) in glutamatergic synapses. Pb^{2+} is known to affect not only the expression of the different subunits of the NMDARs but also the ontogenic developmental switch

of the various NMDAR subunits that is essential for learning and memory. Overactivation of serine/threonine protein phosphatases (PPs) appears to be involved in these synaptic changes. PPs may not only affect the functions of the various subunits of the NMDAR directly by modulating the phosphorylation state of these subunits but may also affect their downstream function by modulation of the phosphorylation state of the downstream effectors like the cyclic AMP response element binding protein (CREB) and other proteins involved in this process. There is a great need to put these isolated pieces of information together and workout the exact pathway(s) that are disturbed by Pb^{2+}.

1 Introduction

Lead (Pb^{2+}) is a toxic heavy metal with no known physiological functions in the body. Because of its excessive use in industry, humans have been, and are constantly being, exposed to Pb^{2+}. Although Pb^{2+} poisoning in both its acute and chronic forms has gradually declined with a reduction in the use of leaded gasoline over the last few decades and with increasing surveillance of industrial and domestic exposure, it has not disappeared (Dorea 2004; Bellingr and Bellinger 2006). Pb^{2+} gets into the body through food and water, environmental pollution, agricultural technology, and food processing. Absorption and retention in the body depends on age, chemical environment of the gastrointestinal tract, and nutritional status of the individual. Generally conditions that favor calcium absorption also favor Pb^{2+} absorption and retention. The total body amount does not affect absorption, as there is no feedback mechanism for its absorption (DeMichele 1984).

Pb^{2+} toxicity affects several organ systems including the nervous, hemopoietic, renal, reproductive, endocrine, and skeletal systems (Goyer 1995; Borja-Aburto et al. 1999). The severity of these toxic effects depends on the duration of exposure, dose, and the developmental stage of the subjects. Children are particularly at increased risk of toxicity because of their frequent exposure and increased absorption and retention capacity. The hemopoietic, renal, and reproductive systems are affected at relatively high doses, whereas the central nervous system (CNS) is affected by low doses (Borja-Aburto et al. 1999).

Pb^{2+} has long been known as a neurotoxic metal but the underlying biochemical mechanism of the neurotoxic effects of Pb^{2+} is not well understood at present despite the large body of research done on this subject. Three very exhaustive reviews on the health effects of Pb toxicity and in particular on the neurotoxic effects of Pb^{2+} have been written in the past decade (Toscano and Guilarte 2005; White et al. 2007; Neal and Guilarte 2010). Of the many biochemical changes

studied, the most relevant and best studied area is the excitatory effect of Pb^{2+} at the glutamatergic synapses. This chapter is aimed to focus on the excitotoxic effects of Pb^{2+} and to augment these reviews by adding recent findings reported in the literature in the area of Pb^{2+} neurotoxicity.

2 Neurotoxicity of Lead

Pb^{2+} neurotoxicity is known since the late nineteenth century (reviewed by Toscano and Guilarte 2005). While high blood Pb^{2+} levels (>70 μg/dL) are known to cause overt encephalopathy (Chisolm 2001), low levels (as low as 7 μg/dL) in children are associated with neurobehavioral and endocrine alterations such as an increase in hyperactivity and distractibility, delayed puberty, and cognitive deficits in the form of IQ changes (Needleman et al. 1979; Bellinger 1995; Nevin 2000; Selevan et al. 2003). Studies have demonstrated a cognitive deficit of 0–5 points on the IQ scale for every 10 μg/dL increase in blood Pb level (Bellinger 1995). It has been estimated by the USEPA that a reduction of a single IQ point results in an added financial burden of US$ 8,346 per intoxicated child (Reviewed by Toscano and Guilarte 2005).

The current limit of concern for childhood Pb^{2+} intoxication set by the Center for Disease Control and Prevention (CDC) is 10 μg/dL. However, recent data suggest that CNS toxicity may be exerted by blood Pb levels of <10 μg/dL (Lanphear et al. 2000; Canfield et al. 2003), as the nervous system is especially sensitive to the effects of Pb. In a prospective study, a lifetime blood Pb^{2+} levels <10 μg/dL was shown to be associated with cognitive deficits in children at 3 and 5 years of age (Canfield et al. 2003). In experimental animal models, Pb^{2+}-exposure causes deficits in spatial learning and long-term potentiation (LTP) (Altmann et al. 1991; Kuhlmann et al. 1997; Gilbert and Mack 1998; Nihei et al. 2000). It has been suggested that there is a "developmental window" that spans from gestation through lactation, in which exposure to low levels of Pb^{2+} is able to cause long-lasting cognitive function deficits (Kuhlmann et al. 1997). This concept of developmental window has been demonstrated by the reports that children that were previously, but not currently, exposed to Pb^{2+} exhibited lasting neurobehavioral and cognitive deficits (Needleman et al. 1979).

The hippocampus plays a pivotal role in learning and memory processes, and it has been suggested that this structure is particularly affected by Pb^{2+} (Bielarczyk et al. 1996; Sharifi et al. 2002). The most troubling aspect of Pb^{2+} toxicity in children is that neurotoxicity caused by Pb^{2+} exposure is irreversible. Chelation therapy, which is the primary means of treating children with blood Pb^{2+} levels of >45 μg/dL, can reduce the body burden of Pb^{2+} but does not reverse the cognitive or behavioral deficits associated with Pb^{2+} exposure (US, CDC 2002; Rogan et al. 2001; Dietrich et al. 2004). This highlights the possibility that Pb^{2+} exposure induces long-lasting (or permanent) changes in the brain during a critical period of development in childhood (Neal and Guilarte 2010).

Many biochemical changes have been reported in the brain that may explain the mechanism of Pb^{2+} neurotoxicity. Some of the reported biochemical alterations

caused by Pb^{2+} exposure in the brain include: altered adenylyl cyclase activity and reduction in the heme-containing enzymes and lower energy metabolism in the developing brain (Clarkson 1987), interference with cell adhesion molecules (Silbergeld 1992), reduced activity of alkaline phosphatase (Antonio and Lert 2000), decreased expression (Nihei et al. 2001) and activity (Xu et al. 2005) of protein kinase C, decreased production of transthyretin and low availability of thyroid hormone to the developing CNS (Zhang et al. 1996), decreased levels of nitric oxide in the hippocampus (Sun et al. 2005), altered neurotransmitter activity in the hippocampus (Reddy et al. 2007; Wang et al. 2007), and altered protein phosphorylation and impairment of the glutamatergic synapse transmission (Neal and Guilarte 2010). None of these biochemical changes alone explains the learning and memory deficits caused by the low-dose Pb^{2+} exposure. There is a need to put these pieces together and workout the pathway(s) involved in learning and memory that are affected by Pb^{2+} exposure. The understanding of such pathway(s) is essential to devising any therapeutic/intervention strategies to combat Pb^{2+}-induced neurotoxicity.

3 Hippocampal Plasticity, NMDA Receptor, and Learning

Hippocampus is the main brain region involved in the acquisition and consolidation of higher brain function, particularly spatial learning and memory. The disruption of hippocampal function by a variety of methods produces deficits in such brain functions (Izquierdo 1993; McNamara and Skelton 1993). The major cellular mechanism within the hippocampus believed to be responsible for acquisition of new memories is LTP, which is a long-lasting increase in synaptic efficacy following brief periods of stimulation of specific synapses (Malenka and Nicoll 1999; Hashemzadeh-Gargari and Guilarte 1999; Nihei et al. 2000, 2001; Shimizu et al. 2000).

Some forms of LTP in the hippocampus, specifically those induced in Schaffer collateral-CA1 and perforant path-dentate gyrus synapses, are dependent upon *N*-methyl-D-aspartate-type glutamate receptor (NMDAR) activation (Madison et al. 1991; Malenka and Nicoll 1993, 1999; Teyler and DiScenna 1987; Zalutsky and Nicoll 1990). LTP requires presynaptic glutamate release and subsequent activation of the postsynaptic NMDAR (Collingridge and Bliss 1987; Massicotte and Baudry 1991; McNaughton 1993). Disruption of NMDAR function pharmacologically or by deletion of specific NMDAR subunits using gene knockout techniques are associated with disruption of hippocampal LTP and learning and memory (Gilbert and Mack 1990; Robinson and Reed 1992; Morris et al. 1986; Neal and Guilarte 2010).

4 NMDA Receptors and Their Structure

Glutamate receptors are classified into metabotropic and ionotropic subtypes according to whether they exist as G-protein-coupled receptor or as an ion channel.

Both these receptor types mediate the actions of glutamate. Metabotropic glutamate receptors (mGluRs) have been extensively studied in hippocampal physiology. mGluRs are composed of eight isoforms (mGluR1–8), which are classified into groups I–III. Of these mGluR5, which belongs to group I, is primarily postsynaptic and is coupled preferentially to Gq/11 and its downstream effectors. Recent studies have demonstrated that mGluR5 is involved in learning and memory. mGluR5 has been shown to be critically important for both hippocampal synaptic plasticity and hippocampus-based learning and memory (reviewed by Xu et al. 2009a, b). Inhibition of mGluR5 with specific antagonist MPEF impaired the acquisition and consolidation of hippocampus-dependent memory, whereas its activation by specific agonist showed the opposite results (Gasparini et al. 1999).

Ionotropic receptors are further classified based on their selective agonists as NMDA, AMPA, and Kainate receptors (Hassel and Dingledine 2006). These receptors bind with glutamate with different affinities. Of these, NMDAR are the most tightly regulated and the most extensively studied. Activation of the NMDAR plays a central role in brain development, learning, and memory as well as in neurodegenerative diseases (Collingridge and Lester 1989; Ozawa et al. 1998; Scheetz and Constantine-Paton 1994). These receptors are located primarily in the hippocampus but also in the cerebral cortex (Monaghan et al. 1983; Monyer et al. 1994; Moriyoshi et al. 1991) and play an essential role in hippocampus-mediated learning and memory (Morris et al. 1982, 1986).

NMDAR is a tetrameric complex assembled from the ubiquitous NR1 subunit which is an essential component of all NMDAR complexes along with various combinations of NR2 or NR3 subunits. NR1 subunit is a constitutional component of NMDA receptors and is widely expressed throughout the CNS at all ages, whereas NR2A and NR2B are functional components whose expression varies with the developmental stage of the animal and the different regions of the brain (Xu and Rajanna 2006). A single gene encodes NR1, but at least eight splice variants of NR1 subunits (NR1A to NR1H) have been found (Laurie and Seeburg 1994; Zukin and Bennett 1995). These splice variants of NR1 impart different pharmacological characteristics to the NMDAR (Durand et al. 1992). Alternatively spliced exon 5 at the N terminus (N-cassette) encodes for a 21 amino acid sequence. Splicing of exon 5 results in transcripts designated as lacking (NR1-a) or containing (NR1-b) the N-cassette (Zukin and Bennett 1995). Exons 21 and 22 encode for two C-terminus cassettes, C1 and C2, which code for 37 and 38 amino acid sequences, respectively. The individual splicing of the C1 or C2 cassette results in transcripts designated as NR1–2 andNR1–3. The presence or absence of both C-terminus cassettes results in NR1–1 and NR1–4 variants. Deletion of the C2 cassette alters the reading frame and results in the creation of an additional coding region of 22 amino acids, the C2' cassette (Toscano and Guilarte 2005).

Compared to NR1, NR2 and NR3 are more complex and mostly determine the function of NMDAR channel. NR2 subunits are encoded by four distinct genes (NR2A–NR2D), while NR3 subunits are encoded by two distinct genes (NR3A and NR3B). NR2 subunits play positive roles in gating the NMDAR channel, while NR3 subunits play negative roles by forming an unconventional channel

(Perez-Otano and Ehlers 2004). The molecular biology of these subunits, their deferential developmental and regional expression and their distinct intracellular protein associations and functions are thoroughly reviewed by Neal and Guilarte 2010. Together, the associations between NR1 splice variants with other subunits exhibit an exquisite degree of heterogeneity and specialization and play essential roles in synaptic activity (Neal et al. 2011).

NMDAR subunits play critical roles in hippocampal synaptic plasticity. Blockades of NMDAR containing either NR2A or NR2B subunits lead to a selective defect in either LTP or long-term depression (LTD), respectively (Liu et al. 2004). The differential expression of various NMDR subunits across the developmental time span of peak LTP and hippocampus-mediated learning, together with the impairment of learning due to targeted knockout of NMDAR subunits strongly support the essential role of NMDAR in synaptic plasticity and learning and memory (Neal and Guilarte 2010).

5 Activity-Dependent Expression of NMDA Receptor Subunit

The expression of synaptic NMDAR subunit is controlled not only by a genetically programmed development of excitatory circuitry but also by the level of activity present at the synapse. Both in vivo and vitro studies from neuronal cultures have provided evidence for the activity-dependent modifications in NMDAR subunit expression (Toscano and Guilarte 2005). The expression of NR2A subunit, but not NR2B, has been shown to be dependent upon calcium influx mediated by NMDAR and L-type calcium channels since pharmacological blockade of NMDAR and L-type calcium channels decreased NR2A subunit expression but had no effect on NR2B expression. This resulted in the expression of NMDAR complexes with higher proportion of NR2B subunits with the corresponding functional implications (Hoffmann et al. 2000). A reduction in presynaptic exocytosis produced similar results (Lindlbauer et al. 1998). In addition, activity-dependent changes of NMDAR subunits also occur at the postsynaptic density (PSD). Pharmacologically blocking of the sodium channels resulted in decreased PSD levels of NR2A but increased levels of NR1 and NR2B subunits, whereas, activating these channels had the opposite effects (Ehlers 2003).

6 Lead and Synaptic Transmission

It has been suggested that a number of neurotoxic effects of Pb^{2+} may be due to its interference with neurotransmitter systems, particularly those which involve cellular calcium homeostasis, and calcium-dependent enzymes (Guilarte 1997; Finkelstein et al. 1998; Savolainen et al. 1998a, b; Bressler et al. 1999; Goyer and Clarkson 2001; Nihei and Guilarte 2001; Gilbert and Lasley 2002). Establishment of neuronal circuitries in the developing central nervous system depends on the

pattern of electrical activity going through the synapses. At early stages of brain development, most neurons fire spontaneously, and this spontaneous electrical activity is believed to be required for axonal outgrowth, pruning of synaptic connections, and maturation of neuronal signaling properties (Moody 1998). Therefore, it can be inferred that Pb^{2+}-induced impairment of learning and memory in children is a result of altered synaptic activity in the brain, particularly in hippocampus which is involved in cognitive processing (Swanson et al. 1997).

The mechanism by which Pb^{2+} alters synaptic activity remains unknown. It has been proposed that Pb^{2+} affect synaptic activity by mimicking the activity of calcium (Ca^{2+}). The ability of Pb^{2+} to substitute for Ca^{2+} is one of the primary mechanisms proposed for Pb^{2+} toxicity in the brain. This Ca^{2+}-mimetic ability of Pb^{2+} has been reported to enhance not only spontaneous neurotransmitter release but also inhibit evoked neurotransmitter release due to impeding Ca^{2+} influx through voltage-sensitive Ca^{2+} channels (Minnema et al. 1988; Kober and Cooper 1976; Atchison and Narahashi 1984; Braga et al. 1999a; Peng et al. 2002; Xiao et al. 2006). Pb^{2+} is also known to bind with intracellular Ca^{2+}-binding proteins and may prevent the detection of Ca^{2+} signaling essential to neurotransmission (Bouton et al. 2001; Marchetti 2003). Ca^{2+}-regulated proteins that are known to be targeted by Pb^{2+} include protein kinases, protein phosphatases, voltage-gated Ca^{2+} channels (VGCC), and Ca^{2+}-binding proteins that regulate mobilization and docking of synaptic vesicles (Atchison 2003; Suszkiw 2004; Braga et al. 1999a, b).

Pb^{2+} is also known to affect the neurotransmission of glutamate, which is the most abundant excitatory neurotransmitter in the brain. Glutamate and its receptors have an important role in LTP and synaptic plasticity, which are fundamental processes involved in learning and memory (Malenka and Nicoll 1999). Chronic developmental Pb^{2+} exposure of rats as well as in vitro acute Pb^{2+} exposure of hippocampal cultures and slices have been reported to decrease the release of glutamate and γ-aminobutyric acid (GABA) (Lasley and Gilbert 2002; Braga et al. 1999a; Xiao et al. 2006).

7 Lead and LTP

The effects of Pb^{2+} on hippocampal LTP has been demonstrated since the early 1990s. Developmental Pb^{2+} exposure increases the threshold for hippocampal LTP induction, reduces the magnitude of potentiation, and accelerates its decay (Reviewed by Toscano and Guilarte 2005; Altmann et al. 1994; Gilbert and Mack 1998; Gilbert et al. 1999a, b). Animals exposed to Pb^{2+} from early life showed deficient excitatory postsynaptic potential (EPSP) as well as cellular (population spike) components of this field response, and these effects persisted to adulthood despite termination of Pb^{2+} exposure at weaning (Gilbert et al. 1996, 1999a). Similar effects of Pb^{2+} exposure on LTP were also reported in hippocampal slices from exposed animals (Altmann et al. 1993; Sui et al. 2000). These data indicate that Pb^{2+} exposure reduced LTP magnitude and thus impaired the efficacy of the cellular mechanisms that support learning in the hippocampus (White et al. 2007).

This Pb^{2+}-induced deficits in hippocampal LTP has been suggested to be associated with a reduction in Ca^{2+}-dependent glutamate release (Lasley and Gilbert 1996; Lasley et al. 2001). However, the induction of LTP in mossy fiber-CA3, which is dependent upon an increase in glutamate release, is not affected by Pb^{2+} exposure (Kawamura et al. 2004), while the induction of LTP at excitatory synapses that are not dependent on increased glutamate release but are NMDAR dependent (i.e., Schaffer collateral-CA1 LTP or perforant path-dentate gyrus LTP) is impaired in the Pb^{2+}-exposed brain. These results clearly indicate that Pb^{2+}-induced deficits in LTP are NMDAR-specific (Toscano and Guilarte 2005).

8 Lead, Calcium, and Glutamate Release

Pb^{2+} mimics Ca^{2+} and disrupts cellular calcium homeostasis as well as the role of Ca^{2+} as an important intracellular second messenger (Simons 1993). Voltage-sensitive calcium channels (VSCCs), which regulate Ca^{2+} influx, are essential for many neuronal processes such as neurotransmitter release (Kobayashi and Mori 1998). Pb^{2+} may affect neuronal functions in two ways; first by inhibiting the entry of Ca^{2+} into the cell, as Pb^{2+} is a very potent inhibitor of VSCCs (Audesirk 1993; Busselberg et al. 1993; Evans et al. 1991; Minnema et al. 1988). Second, Pb^{2+} itself may enter cells through Ca^{2+} channels and by mimicking Ca^{2+} may affect its functions (Reviewed by Loikkanen et al. 2003).

A dose-dependent reduction in glutamate release in animals developmentally exposed to Pb^{2+} has been reported (Gilbert and Lasley 2007). Chronic Pb^{2+} exposure beginning in utero or in the early postweaning period and continuing throughout life alters presynaptic release of glutamate in the rat hippocampus. However, this Pb^{2+}-induced glutamate release appears to be dose-dependent. At lower Pb levels synaptic release of glutamate was diminished and this effect was reversed at higher level of Pb^{2+} exposure (Lasley and Gilbert 2002). This biphasic dose response indicates the presence of more than one mechanisms of Pb^{2+} action. The diminished glutamate release at lower Pb^{2+} levels appears to be due to the blocking of VSCC by Pb^{2+}. The increased glutamate release at higher level of Pb^{2+} exposure suggests the diminution of the K^+-stimulated transmitter response (White et al. 2007). Similar findings were reported from acute exposure of cultured hippocampal neurons to Pb^{2+} (Braga et al. 1999a, b). Recent studies have revealed that the loss of proteins involved in vesicular release, namely, synaptophysin and synaptobrevin, is also involved in Pb^{2+}-induced modulation of transmitter release (Neal et al. 2010).

In addition, nicotinic modulation of synaptic transmission has also been implicated in Pb^{2+}-induced transmitter release (Nihei et al. 2000). Hippocampal neurons exposed to various concentrations of Pb^{2+} inhibited somatodendritic $\alpha_4\beta_2$ nAChRs and α_7 nAChRs and caused substantial inhibition of transmitter release. This effect was found to be due the direct interaction of Pb^{2+} with these receptors (Ishihara et al. 1995; Mike et al. 2000). It has also been hypothesized that Pb-induced inhibition of nicotinic cholinergic modulation of action potential-dependent

transmitter release is mediated by a PKC-dependent mechanism (Braga et al. 2004). It has been suggested that Pb^{2+} activates PKC which in turn phosphorylates nAChRs, proteins associated with the receptors, and/or proteins linking the receptors to the action potential-dependent transmitter release process. Direct phosphorylation of nAChRs by PKC has been shown to reduce receptor activity in sympathetic neurons (Downing and Role 1987). However, this hypothesis has been disputed by other investigators (Seguela et al. 1993; Moss et al. 1996; Fenster et al. 1999).

9 Lead and NMDA Receptor

Glutamate receptors, particularly, the NMDAR are one of the most important targets of Pb^{2+} (reviewed by Xu and Rajanna 2006). The observation that Pb^{2+} exposure during development affects NMDAR-dependent LTP (LTP dependent on increased glutamate release) but not NMDAR-independent LTP in hippocampus provided the first experimental evidence that Pb^{2+} targets NMDARs (Gutowski et al. 1998; Kawamura et al. 2004). Since then, several studies demonstrated that Pb^{2+} is a selective and potent noncompetitive inhibitor of the NMDAR (Toscano and Guilarte 2005; White et al. 2007; Neal and Guilarte 2010; Neal et al. 2011). Pb^{2+} in micromolar concentration causes a reversible inhibition of the current activated by glutamate through the NMDAR channel in cultured and acutely dissociated neurons and reduces access to the NMDA receptor channel in brain tissue homogenates (Marchetti 2003; Lasley and Gilbert 1999). Decreased NMDA-specific glutamate receptor binding has also been reported in the brain of Pb^{2+}-exposed rats (Rajanna et al. 1997). A possible mechanism for this Pb^{2+}-induced inhibition of the NMDAR is the binding of Pb^{2+} at the zinc (Zn^{2+}) regulatory (inhibitory) site of the NMDAR in a voltage-independent manner (Lasley and Gilbert 1999).

The effect of Pb^{2+} on NMDA-activated current is dependent on developmental stages and NR subunit types (Ishihara et al. 1995; Omelchenko et al. 1997; Ujihara and Albuquerque 1992). In addition to acting as an NMDAR antagonist, Pb^{2+} exposure also disrupts normal NMDAR ontogeny. Pb^{2+}-induced changes in NMDAR subunits during development may form the basis for Pb^{2+} effects on synaptic plasticity and cognitive function (Reviewed by Lau et al. 2002). Developmental Pb^{2+} exposure has been shown to cause alterations in NR1 splice variant expression, NR2 subunit ontogeny, and NMDAR-dependent signaling (Neal et al. 2011). Adult rats exposed to Pb^{2+} during development and postweaning into adolescence suffered marked reductions in gene expression of the NR1 subunit of the NMDAR in the hippocampus (Monyer et al. 1992). Chronic developmental Pb^{2+} exposure in animals is known to alter expression of NR1 splice variants (Guilarte and McGlothan 2003; Xy et al. 2002; Guilarte et al. 2000). The mechanism of these Pb^{2+}-induced deficits in NR1 is proposed to be the altered targeting and cell surface expression of NMDAR subunits to the synapse due to changes in NR1 splice variant expression. The lower levels of NR1 subunit mRNA expressed

in the Pb^{2+}-exposed hippocampus are principally due to decreased levels of the NR1-4 and NR1-2 splice variants. A unique characteristic of these splice variants is that they lack the C1 cassette and impart the highest cell surface expression, PKC potentiation, and calcium kinetics to NMDAR complexes (Neal et al. 2011).

NR2A and NR2B are abundantly expressed in the hippocampus and may be involved in mediating Pb^{2+}-toxicity (Guilarte and McGlothan 2003; Lau et al. 2002; Marchetti 2003; Nihei and Guilarte 1999, 2001; Nihei et al. 2000; Perez-Otano and Ehlers 2004; Toscano et al. 2002; Waters and Machaalani 2004). Chronic Pb^{2+} exposure alters the composition of the NR2 subunits of the NMDR in the rat brain (Nihei and Guilarte 1999). Specifically, developmental Pb^{2+} exposure in animals decreased expression of the NR2A subunit with no change or a small increase in NR2B subunit expression (Nihei et al. 2000; Nihei and Guilarte 1999; Zhang et al. 2002; Guilarte and McGlothan 1998; Toscano et al. 2002; Neal et al. 2011). Chronic Pb^{2+} exposure not only reduces NMDAR level but also prevents or delays the developmental switch of NR1/NR2B complex to NR1/NR2A complex with reduction of activity-dependent synaptic plasticity in the mature brain. During early development, NR2B-containing NMDARs predominate until a developmental switch occurs, resulting in the incorporation of the NR2A subunit (Monyer et al. 1994). It is suggested that this developmental switch from predominately NR2B-containing NMDARs to NR2A-containing NMDARs is delayed or impaired during Pb^{2+} exposure (Toscano et al. 2002; Toscano and Guilarte 2005).

These NR2 subunit-specific effects of lead could be explained by the differential sensitivities of different subunits to Pb^{2+}. Gavazzo et al. (2008) have shown that Pb^{2+} interacts at the Zn^{2+} regulatory site of NMDAR complexes containing the NR2A but not the NR2B subunit. The NR2 subunits have different Zn^{2+} binding sites. NR2A-NMDAR binds Zn^{2+} at a high affinity (nM affinity), while the NR2B-NMDAR binds Zn^{2+} with lower affinity (μM range) (Paoletti et al. 2000; Rachline et al. 2005). These findings have been corroborated by the observations that recombinant NR1/NR2A complexes are more sensitive to Pb^{2+} inhibition than NR1/NR2B complexes (Omelchenko et al. 1996). Since Pb^{2+} and Zn^{2+} have similar potencies in inhibiting the NMDAR (Guilarte et al. 1994, 1995), it is likely that changes observed with NR2A-NMDARs but not NR2B-NMDARs may be a result of preferential inhibition of Pb^{2+} for NR2A-NMDARs (Guilarte et al. 1995; Gavazzo et al. 2008).

Furthermore, different concentrations of Pb^{2+} have differential influence on NMDAR subunits, and different subunits of NMDAR display different sensitivities to Pb^{2+}. A dose-dependent reduction by Pb in NMDAR-NR1, NR2A, and NR2B protein levels has been reported (Lau et al. 2002). The rank order of sensitivity of different subunits to Pb inhibition has been reported as follows: NR1A-NR2B > NR1A-NR2A > NR1A-NR2C (Gavazzo et al. 2001) and NR1B-NR2A > NR1B-NR2C > NR1B-NR2D > NR1B-NR2AC (Omelchenko et al. 1997).

Region-specific effects of Pb^{2+} on the expression of NR1 and NR2B subunits have also been reported. In cortical neurons, expression of NR1 was unchanged but that of NR2B was significantly increased by Pb^{2+}. In contrast, expression of

both NR1 and NR2B was significantly decreased in hippocampal neurons. Thus, it is likely that the toxic effects of Pb^{2+} may cause differential damage to different types of memory that are mediated by cortical and hippocampal neurons, respectively (Lau et al. 2002). Furthermore, both regional and developmental differences in the hippocampal neurons have been reported in Pb^{2+}-exposed rats. For example, the expression of NR1-2a mRNA in Pb^{2+}-exposed rats was significantly increased in areas CA1, CA4, and dentate gyrus (DG) at postnatal days (PND) 14–15 but in areas CA4 and DG at PND20–21 (Zhang et al. 2002; Guilarte and McGlothan 1998; Guilarte et al. 2000). On the other hand, Pb^{2+}-induced decreased expression of NR2A was observed in areas CA1, CA2, CA3, and DG at PND15 and areas CA1, CA3, and DG at PND20. Similarly, NR3A mRNA levels were also significantly decreased in CA1, CA4, and DG subfields at PND15 and CA1 and DG subfields at PND20 in Pb^{2+}-exposed rats (Zhang et al. 2002). These regional and developmental regulations of NMDAR mRNA splicing may lead to abnormality of natural NMDAR stoichiometry, control sensitivities to phosphorylation, and therefore kinetic properties of the NMDA channels and their involvement in LTP and synaptic plasticity (Zhang et al. 2002). Thus, this disruption of the ontogenetically defined pattern of NMDAR subunit expression and NMDAR-mediated calcium signaling in glutamatergic synapses appears to be the mechanism of Pb^{2+}-induced neurotoxicity and deficits in learning and memory. These changes are associated with deficits in long-term potentiation in the hippocampus and impairment of spatial learning (Nihei and Guilarte 2001; Toscano and Guilarte 2005; Zhang et al. 2002; Gilbert et al. 1996; Neal and Guilarte 2010).

10 Lead and NMDA Signaling

It has been reported that synaptic NMDARs mediate cyclic AMP response element binding protein (CREB) and extracellular signal-regulated kinases (ERK) activation, synaptic plasticity, and survival pathways. On the other hand, extra-synaptic receptors are associated with a CREB-shutoff pathway, ERK inactivation, and induction of cellular death pathways (Hardingham et al. 2002; Vanhoutte and Bading 2003; Ivanov et al. 2006). Changes in NMDAR subunit composition can result in altered NMDAR-dependent signaling. Many signaling pathways are dependent on NMDAR subunit composition and/or localization. Pb^{2+}-induced alterations in NMDAR subunit composition could interfere with the downstream signaling pathways including MAPK signaling (Cordova et al. 2004), calcium/calmodulin kinase II (CaMKII) activity (Toscano et al. 2005), protein kinase C (PKC) activity (Bressler et al. 1999), and CREB phosphorylation status and binding affinity (Toscano et al. 2002; 2003). CREB is a transcription factor for many NMDAR activity-dependent immediate early genes (IEGs), which play an essential role in memory consolidation (Athos et al. 2002; Bourtchuladze et al. 1994). Thus, CREB plays an important role in signal propagation from synapses to the nucleus by linking NMDAR activation and calcium-dependent signaling to the

expression of genes necessary for synaptic plasticity (Bredt et al. 1992). Altered IEG expression in animals exposed to Pb^{2+} has been observed (Kim et al. 2002), indicating that altered CREB activity due to Pb^{2+}-mediated disruption of NMDAR signaling may result in impaired learning and memory processes.

CREB phosphorylation is an important element of LTP. Induction of LTP (and learning) increases CREB phosphorylation (Mizuno et al. 2002; Schultz et al. 1999; Viola et al. 2000), whereas pharmacological inhibition of NMDAR-mediated signaling decreases CREB phosphorylation (Athos et al. 2002). CREB phosphorylation at serine-133 facilitates the recruitment of CREB-binding proteins and the assembly of transcriptionally active complex at the start site of CRE containing genes (Chirivia et al. 1993). Pb^{2+} exposure decreases CREB phosphorylation without affecting the total CREB levels and alters the ability of CREB family proteins to bind with CRE (Toscano et al. 2003), suggesting that the mechanisms that regulate the phosphorylation of CREB at serine-133 and the binding ability of CREB family proteins may be altered by Pb^{2+} exposure. This may affect the transcription of genes associated with learning, memory, and synaptic plasticity.

11 Lead and BDNF Signaling

Another potential signaling pathway that may be involved in Pb^{2+}-induced neurotoxicity is impaired NMDAR-dependent retrograde signaling of neurotrophic factors, particularly of brain-derived neurotrophic factor (BDNF). Pb^{2+}-exposed hippocampal neurons exhibit reduced proBDNF expression and BDNF release. Furthermore, complete recovery of Pb^{2+}-induced changes in presynaptic protein levels and vesicular neurotransmitter release has been reported in hippocampal neurons incubated with exogenous BDNF (Neal et al. 2010). Retrograde BDNF signal from the postsynaptic side has been implicated in axon morphology, synaptic connectivity, and synaptic ultrastructure (Neal and Guilarte 2010; Neal et al. 2010). NMDAR activation results in the generation and release of BDNF (Hartmann et al. 2001; Jiang et al. 2005; Walz et al. 2006), which may be essential to the generation or unmasking of presynaptic neurotransmitter release sites (Walz et al. 2006). BDNF signaling is known to modulate the expression of several pre- and postsynaptic proteins (Pozzo-Miller et al. 1999; Tartaglia et al. 2001). Of particular interest is the enhancement of NR2A expression but not the expression of NR2B in hippocampal slices exposed to exogenous BDNF (Small et al. 1998; Caldeira et al. 2007). These results are further supported by the reduced expression of NR2A but not the NR2B subunit and reduced vesicular release in BDNF knockout mice (Margottil and Domenici 2003). These observations suggest that NR2A-NMDARs may be preferentially linked to BDNF signaling. The altered expression of NR2A subunit by both Pb^{2+} exposure and impaired BDNF signaling strongly supports the hypothesis that the disruption of NMDAR activity-dependent BDNF signaling in involved in Pb^{2+}-induced toxicity in synapses (Neal et al. 2010).

12 Lead and Other Brain Cells

Most of the work on Pb^{2+}-induced neurotoxicity has focused on neuronal cells. Other support cells, which are severalfold greater in number than neurons and regulate/modulate the function of neurons, may also be affected by Pb^{2+} and thus may be involved in Pb-induced neurotoxicity. Of the support cells, astroglia are capable of uptaking 14-fold more Pb^{2+} than neurons. The uptake of Pb^{2+} by astroglia is suggested to be through voltage-dependent Ca^{2+} channels (Simons and Pocock 1987). This Ca^{2+}-dependent uptake of Pb^{2+} by astroglia may be induced by their interaction with neurons (Tiffany-Castiglioni 1993; Lindhal et al. 1999) and may involve glutamate-dependent increase in intracellular calcium (Cornell-Bell et al. 1990). The accumulation and storage of Pb^{2+} in astroglia may be a mechanism of protection for neurons which are more sensitive than astroglia to the toxic effects of Pb^{2+} (Holtzman et al. 1987; Tiffany-Castiglioni et al. 1986; Tiffany-Castiglioni 1993). On the other hand, such storage of Pb^{2+} in astroglia may provide a reservoir for its continuous release and thereby may contribute to the toxicity of adjacent neurons or astroglia themselves (Struzynska 2009).

13 Lead and Metabotropic Glutamate Receptors

Of the metabotropic glutamate receptor, mGluR5 has also been linked to Pb^{2+}-induced deficits in learning and memory. The impact of developmental lead exposure on hippocampal mGluR5 expression and its potential role in Pb^{2+}-induced neurotoxicity has been investigated both in vitro and in vivo (Xu et al. 2009a, b). Decreased expression of mGluR5 mRNA and protein by Pb^{2+} dose dependently suggests that mGluR5 might be involved in Pb^{2+}-induced neurotoxicity. Impairment of mGluR5-dependent long-term depression (LTD) (Huang and Hsu 2006) and decreasing NMDAR-dependent or protein synthesis-dependent long-term potentiation have been hypothesized as potential mechanisms of Pb^{2+}-induced neurotoxicity (Toscano and Guilarte 2005; Topolnik et al. 2006; Manahan-Vaughan et al. 2003; Manahan-Vaughan and Braunewell 2005; Naie and Manahan-Vaughan 2004; Neyman and Manahan-Vaughan 2008).

14 Protein Phosphatases and Lead-Induced NMDAR-Dependent Neurotoxicity

The major Ser/Thr protein phosphatases (PPs) in mammalian brain are PP1, PP2A, and PP2B (Liu et al. 2005). Overactivation/overexpression of these Ser/Thr PPs has been implicated in impairment of learning and memory. PPs are strong molecular constraints on learning and memory (Lee and Silva 2009). PPs are also involved in cognitive decline in aging (Mansuy and Shenolikar 2006; Knobloch et al. 2007) and in favoring forgetting (Genoux et al. 2002). Overactivation of PP1 is associated

with learning and memory impairment (Genoux et al. 2002, 2011; Koshibu et al. 2009, 2011; Graff et al. 2010; Haege et al. 2010). PP2A and PP2B also adversely affect learning and memory (Bennett et al. 2003; Havekes et al. 2006; Yamashita et al. 2006; Mauna et al. 2010; Oberbeck et al. 2010). Overactivation of PP2A induces LTD in vivo (Thiels et al. 1998), and inhibition of PP2A abrogates LTD induction (Mauna et al. 2010).

Whether the overactivation/overexpression of these PPs is involved in Pb^{2+}-induced impairment of learning and memory has largely remained uninvestigated until now. This issue was recently addressed by investigating the effect of Pb^{2+}-exposure on PPs both in cultured human neurons and in rats exposed to Pb^{2+} during early development. In the Pb^{2+}-exposed cultured human fetal neurons, a significant increase in total PPs and PP2A activities was observed. Pb^{2+} exposure significantly increased the expression of PP1 and PP2B but significantly decreased the expression of PP2A and PP5 in cultured human fetal neurons (Rahman et al. 2010). In rats exposed to Pb^{2+} during early development, learning, short-term memory (STM), and long-term memory (LTM) were significantly impaired at PND 21, and this impairment of learning and LTM was associated with decreased synaptogenesis and increased expression and activity of PP1 and PP2A in the hippocampus. On the other hand, at PND 30, learning and short-term memory (STM), but not the LTM, was impaired by Pb^{2+}. At this developmental stage, expression and activity of hippocampal PP1 was increased but that of PP2A was decreased. These results suggest that increased PP1 activity in hippocampus is involved in the impairment of learning and LTM, whereas, increased PP2A activity is involved in the impairment of STM (Rahman et al. 2012).

LTM involves protein synthesis, growth, and formation of new synapses (Martin et al. 1997; Ma et al. 1999; Toni et al. 1999; Bozdagi et al. 2000; De Roo et al. 2008). By contrast, STM involves covalent modification of proteins in the presynaptic or postsynaptic structures (Kandel 2001; Malinow and Malenka 2002). The major covalent modification underlying these long-lasting changes in synaptic communication is protein phosphorylation, which is regulated by a balance between protein kinases (PKs) and PPs. Increased activity of PKs results in increased protein phosphorylation which has been implicated in LTP. On the other hand, increased activity of PPs results in decreased protein phosphorylation, which has been implicated in LTD (Roberson et al. 1996; Winder and Sweatt 2001; Blitzer et al. 2005). Reversible protein phosphorylation regulates presynaptic and postsynaptic events in excitatory and inhibitory neurons. The major substrates for PPs at these synaptic sites include ligand-gated ion channels and G-protein-coupled receptors, whose functional properties, trafficking, and synaptic organization are controlled by reversible phosphorylation (Swope et al. 1999).

Several mechanisms have been proposed to explain the role of PPs in learning and memory. These include dephosphorylation and the subsequent deacetylation of histone proteins and chromatin remodelling and altered expression of CREB and NF-κB (Kandel 2001; Fischer et al. 2007; Miller et al. 2008; Koshibu et al. 2009, 2011; Oberbeck et al. 2010). Both PP1 and PP2A dephosphorylate CREB

(Mauna et al. 2010) and thereby reduce CREB-mediated gene expression (Wadzinski et al. 1993; Alberts et al. 1994; Genoux et al. 2002; Oberbeck et al. 2010). Other mechanisms include dephosphorylation by PP1 and PP2A of NMDA receptor and MAPK (Chan and Sucher 2001; Oberbeck et al. 2010), calcium-/calmodulin-dependent protein kinase IV (CaMKIV) (Westphal et al. 1998; Anderson et al. 2004), ERK (Davis et al. 2000; Norman et al. 2000; Silverstein et al. 2002; Ho et al. 2007), and the AMPA receptor (Thiels et al. 2002).

Of particular significance in the Pb^{2+}-induced excitotoxicity is the dephosphorylation and subsequent inhibition of the NMDARs-associated signaling pathways. Protein phosphorylation has been established as an important mechanism for the regulation of NMDAR function. LTP is accompanied by increased glutamate receptor phosphorylation through various protein kinases and a concomitant decrease in protein phosphatase activity (Bliss and Collingridge 1993; Mulkey et al. 1993; Soderling and Derkach 2000). In contrast, LTD has been shown to be dependent on glutamate receptor dephosphorylation mediated by an increase in the activity of protein phosphatases, possibly PP1 and PP2A (Lee et al. 1998, 2000; Thiels et al. 1998). Thus, coordination of kinase and phosphatase activities is crucial for the modulation of synaptic plasticity. Both kinases (PKA) and phosphatases (PP1 and PP2A) are located in physical proximity to NMDAR (Chan and Sucher 2001). Synaptic NMDA receptors are phosphorylated or dephosphorylated depending on synaptic stimulation. Phosphorylated NMDA receptors have enhanced channel openings and a consequent increase in Ca^{2+} influx, and this influx is necessary for inducing long-term neuronal changes (Levitan 1999; Prybylowski and Wenthold 2004; Raymond et al. 1994; Roche et al. 1994). Following excitatory neurotransmission and Ca^{2+} influx, NMDA receptors are phosphorylated by PKA then rapidly dephosphorylated by PP1, PP2A, or PP2B. This reversible phosphorylation controls synaptic strength, memory formation, and storage by the induction of LTP or LTD (Blitzer et al. 2005). Several PKs, including CaMKII, PKC, PKA, and ERKs, have been implicated in LTP induction and maintenance, whereas PPs are implicated in the induction of LTD. Previous studies have shown that LTD is dependent on the change of the phosphorylation state of glutamate receptors in general (Lee et al. 1998, 2000) and the activity of PPs, particularly PP1 and PP2A (Mulkey et al. 1993, 1994; Thiels et al. 1998). Stimulation of NMDARs activates PP1, PP2A, and PP2B whose substrate specificity is primarily determined through interaction with regulatory and targeting proteins (Mansuy and Shenolikar 2006).

NMDAR activity is attenuated by PP1, PP2A (Wang et al. 1994), and PP2B (Mulkey et al. 1994; Wang and Kelly 1997). PP1 diminishes NMDA-receptor-mediated synaptic currents in an activity-dependent manner in the hippocampus (Wang et al. 1994; Westphal et al. 1999). PP1 and PP2A appear to decrease the single channel open time in cultured rat hippocampal neurons and thus reduce NMDAR activity (Wang et al. 1994). PP1 has been reported to have more involvement than PP2A in dephosphorylating the NMDAR.

Both positive and negative effects of PP2B on glutamate receptor functions have been reported. PP2B reduces NMDA-receptor-mediated currents by

dephosphorylating the NR2A subunit of the NMDAR and reduction of the open time of individual channels (Lieberman and Mody 1994) and desensitization of the receptor (Krupp et al. 2002; Tong et al. 1995). On the other hand, PP2B has been reported to potentiate NMDAR-induced metabotropic mGluR5 receptor activity by dephosphorylating PKC-dependent sites on the mGluR5 C-terminus and attenuating mGluR5 desensitization (Alagarsamy et al. 2005). PP2B-mediated dephosphorylation also contributes to the developmental switch of NMDAR subunits and thus modulates NMDA receptor subunit composition. In the developing cerebellum, it counteracts the TrkB- and ERK1/2-dependent upregulation of the NR2C subunit, which then exchanges with NR2B to promote synaptic transmission from mature mossy fibers onto granule cells (Suzuki et al. 2005).

The role of PP2A in NMDAR regulation and functioning has been well-studied and best understood. There are intriguing functional similarities between PP2A and NMDAR. Both contribute to the regulation of neural functions such as synaptic transmission and plasticity. Immunoprecipitation studies indicated that the carboxyl domain of NR3A subunit of NMDAR forms a stable complex with the catalytic subunit of PP2A in the rat brain in vivo (Chan and Sucher 2001). Further studies demonstrated that NR3A constitutively associates with the PP2A holoenzyme but not the core enzyme in rat brain synaptic plasma membranes. A sequence of six amino acids between leucine 958 and histidine 974 of the NR3A is critical for binding to PP2A, as deletion or mutation of this sequence disrupted the NR3A-PP2A interaction (Ma and Sucher 2004). Association of PP2A with NMDARs leads to an increase in the activity of PP2A and the dephosphorylation of Ser 897 of the NMDAR subunit NR1. Stimulation of NMDARs leads to the dissociation of PP2A from the complex and the reduction of PP2A activity (Chan and Sucher 2001).

The NR1 subunit is phosphorylated by both PKA and PKC (Tingley et al. 1997). PKA is associated with NMDAR through the scaffold protein yotiao (Westphal et al. 1999), and this NMDAR-associated PKA has been shown to phosphorylate the Ser 897 of NR1 (Chan and Sucher 2001). PP2A associated with NR3A dephosphorylate this serine residue of NR1. PP1 has also been shown to be associated with NMDAR through the same scaffold protein. These PP2A- (and possibly, PP1-) induced changes in phosphorylation of NR1 decrease NMDA currents through the attenuated opening of the NMDAR-gated channels (Wang et al. 1994). PP2A may also indirectly modulate the phosphorylation of NR1 subunits by modulating the function of PKC. It has been reported that PP2A dephosphorylates and inactivates PKC in vitro, and inhibition of PP2A by okadaic acid prevents dephosphorylation of PKC and enhances the function of PKC (Hansra et al. 1996; Millward et al. 1999; Ricciarelli and Azzi 1998).

In addition to NR1, PP2A is also known to dephosphorylate NR2B subunit. It is known that CaMKII can bind to the C-terminal region of the NR2B subunit of NMDAR and phosphorylate it at serine-1303 (Mayadevi et al. 2002). PP2A may regulate the phosphorylation of this site of NR2B subunits by modulating the function of CaMKII. CaMKII autophosphorylated at Thr286 is active, whereas the activity is decreased by dephosphorylation of this site (Colbran 2004; Otmakhov et al. 2004). CaMKII autophosphorylated at Thr286 was first reported to be exclusively dephosphorylated by PP1 in isolated synaptosomes (Shields et al. 1985).

From the literature reviewed above, it is evident that our knowledge about the mechanism of Pb^{2+}-induced neurotoxicity is patchy, and there is a need to put these isolated pieces of information together to understand how the pathway(s) involved in learning and memory are affected by Pb^{2+}. Only when we understand the problem, we will be able to devise an effective intervention.

MS and Excitotoxicity

Chai K. Lim

Contents

Abstract

In this section, it will be studied how excitotoxicity contributes to neurodegeneration in the context of multiple sclerosis (MS). MS has long been regarded as an autoimmune inflammatory disease targeting oligodendrocytes of the central nervous system (CNS). However, recent advancement in research questioned whether MS is merely an inflammatory disease despite pathological evidences of degeneration are clearly present. More recent findings further challenge the research focus of MS which previously thought oligodendrocytes as the main target, whereas current debate points towards pathology of MS being primarily dysfunctional glial interaction, i.e., astrocytes and microglia. Herein, a brief overview will be provided on how various aspects of excitotoxicity are evident in MS pathology and its possible roles between interactions of cells in the CNS that ultimately lead to neurodegeneration in inflammatory condition of MS.

Excitotoxicity • Kynurenine pathway • Multiple sclerosis • Neurodegeneration • Quinolinic acid

1 Introduction

Multiple sclerosis (MS) is a chronic degenerative disease of the central nervous system (CNS) characterized by the presence of multifocal lesions with immune cells infiltration, inflammation, demyelination, and neural damages. Although the cause of MS is unknown, very often, MS begins with an autoimmune response to myelin components and progressively leads to oligodendrocytes and axonal degeneration in the chronic phase. The early stages of MS are often resembled by the cycle of inflammation described as relapsing-remitting (RR) phase where the recovery (remitting) period can generally occur from several months to years. About half of RRMS patients will experience exacerbation of the disease progression, of which the remitting period progressively shortens while the relapsing phase persists, leading to the secondary progressive (SP) stage. It remains unclear when and how this switch occurs, but the current hypothesis is that the early stage of MS is driven by the adaptive immunity through inflammation, whereas in the later stage of MS, the innate immunity mediating through neurodegeneration predominates.

2 MS, an Autoimmune Disease or Neurodegenerative Disease?

MS has long been considered an autoimmune demyelinating disease of the CNS. The concept of immune-mediated response in the pathogenesis of MS is indisputable. Presence of autoreactive antibodies and T-cell-mediated destruction on CNS myelin had been the core of this concept. Studies using immunized animals with myelin-related peptides known as experimental autoimmune encephalomyelitis (EAE) exhibiting similar phenotype to MS further highlight the importance of the immune regulation in MS progression. As a result, large number of transacted axons arises from inflammatory insult, but most of these demyelinated axons initially survive and subsequently the damages are reversed. However, in late stages of MS, i.e., SPMS, the brain undergoes continuous atrophy where new inflammatory demyelinating lesions are rare. Progressive neuronal and axonal loss provided a logical explanation for the transition from RRMS to SPMS and for continuous and irreversible neurological decline in SPMS. However, these observations present a more typical hallmark of neurodegeneration. More importantly, neuronal and axonal degeneration must continue in environments other than the inflammatory demyelinating lesion. Furthermore, the inflammatory microenvironment contains a variety of substances that could injure axons, such as proteolytic enzymes, cytokines, oxidative products, and free radicals produced by activated immune

and glial cells. Hence, mechanisms other than inflammatory demyelination of white matter, therefore, must contribute to axonal and neuronal degeneration. It has been well established that excitotoxicity has played a significant role in neurodegeneration, and the next few sections will look at past and recent evidences of excitotoxicity participating in MS pathogenesis.

3 Clinical Evidences of Glutamate-Induced Excitotoxicity in MS

It was notable that the concentration in one of the main excitatory amino acids, glutamate, was significantly elevated in the CNS of MS implicated from several clinical studies. Stover et al. showed that the glutamate level in the CSF of active relapsing phase of MS patients was significantly higher than those who are in the silent (remitting) phase of MS (Stover et al. 1997; Sarchielli et al. 2003). This increase was also associated with the severity and progression of the disease (Sarchielli et al. 2003; Barkhatova et al. 1998). More importantly, Srinivasan et al. demonstrated that the increase of glutamate levels was present in acute lesions and normal-appearing white matter but not in chronic lesions of MS patients using in vivo magnetic resonance spectroscopy imaging technique (Srinivasan et al. 2005). In consistent with the clinical data, MS animal model, EAE lesions are also primarily localized in rich glutamatergic area such as cerebellum and the subpial region of the spinal cord (Brown et al. 1982; Tran et al. 1997).

4 Focus on Oligodendrocytes

The potential role of glutamate-induced excitotoxicity in MS was observed in experimental data demonstrating the beneficial effect of NMDA and AMPA/kainate antagonist, memantine in rat EAE showing reduction of axonal and oligodendrocyte damage but do not dampen CNS inflammation (Wallstrom et al. 1996). This indicates that the mechanism of axonal damage and reversible neurological deficit is likely to act through NMDA receptor and independent of autoimmune neuroinflammation. In addition, two independent studies using NBQX, a selective inhibitor of AMPA/kainate, led to significant reduction in clinical impairment with increased survival of oligodendrocytes in EAE (Pitt et al. 2000; Smith et al. 2000). These data further indicate that AMPA/kainate receptor-mediated glutamate excitotoxicity is a chief factor in oligodendrocyte death in EAE. Indeed, oligodendrocytes express functional AMPA/kainate-type glutamate receptor (Holtzclaw et al. 1995; Steinhauser and Gallo 1996), and exposure to low concentration of AMPA, kainate, or glutamate results in death of oligodendrocytes which can be reversed by addition of NBQX (McDonald et al. 1998). Furthermore, the degree of vulnerability in oligodendrocytes to glutamate excitotoxicity is similar to cortical neuron cultures (McDonald et al. 1998). In addition, oligodendrocytes, like astrocytes, also express functional glutamate transporters for glutamate uptake

(Domercq et al. 1999) and glutamine synthetase (D'Amelio et al. 1990; Cammer 1990). This further subjects oligodendrocytes to glutamate excitotoxicity should their ability to regulate glutamate be compromised (Domercq et al. 2005).

It was found that GluR1, a calcium-permeable AMPA subunit, was elevated on oligodendrocytes in the borders and within active MS plaques in comparison with white matter reflected by positive GluR1-immuneopositive oligodendrocytes (Newcombe et al. 2008). This upregulation of GluR1 on oligodendrocytes around and within plaques may render these cells vulnerable to glutamate excitotoxic damage and death mediated by intracellular calcium ions. One possible mechanism for the increase in GluR1 may be due to presence of growth factor that is facilitated by recruitment of progenitor neural cells at the lesion sites. Growth factors can induce robust and selective enhancement of GluR1 expression in functional channel of oligodendrocytes (Chew et al. 1997). Hence, growth factor-induced upregulation of GluR1 may increase cell vulnerability to glutamate and indirectly limit remyelination at lesion sites.

5 Focus on Microglia and Astrocytes

During inflammation, glutamate is produced and released into the extracellular space by activated leukocytes and microglia in the CNS (Piani et al. 1991; Werner et al. 2001). Astrocytes, on the other hand, are the main glial cells capable of catabolizing glutamate within the CNS (Schousboe et al. 1993) and are thus strategically situated in the vicinity of neurons and oligodendrocytes to prevent damage caused by variation in glutamate extracellular level. Astrocytes express two critical glutamate transporters, GLAST and GLT-1, to maintain glutamate homeostasis in the CNS (Rothstein et al. 1996). In the course of EAE, although high astrocytic reaction is observed reflected by increased GFAP (marker for astrocytes), there is a decrease in expression of astrocytic glutamate catabolic enzymes, glutamine synthetase, and glutamate dehydrogenase, suggesting reduction in the capacity of astrocytes to break down glutamate (Hardin-Pouzet et al. 1997). Further, Ohgoh et al. also found significant downregulation of expression in the protein level of the glial glutamate transporter GLAST (EAAT1) and GLT-1 (EAAT2) in EAE, possibly contributing to increase extracellular glutamate (Ohgoh et al. 2002).

It is inevitable not to mention inflammatory cytokines in regard to microglia as these two entities are closely linked. Inflammatory cytokines can also fuel excitotoxicity in MS. Two proinflammatory cytokines of MS, interleukin (IL)-1β and tumor necrosis factor (TNF)-α, dose-dependently inhibited glutamate uptake in astrocytes, whereas treatment with interferon (IFN)-γ alone promotes glutamate uptake. Hu et al. showed that this paradigm can be antagonized by nitric oxide synthase (NOS) blocker, N^G-monomethyl-L-arginine, suggesting a mechanistic involvement of NO in IL-1β-mediated inhibition of glutamate uptake (Hu et al. 2000). In addition, anti-inflammatory cytokine IFN-β, a common treatment therapy

used in RRMS, was also found to mimic NOS inhibitor by limiting NO production while promoting glutamate uptake in astrocytes (Hu et al. 2000). This phenomenon may partly explain the beneficial effects of the current IFN-β therapy in MS. TNF-α had also shown to disrupt the glutamate homeostasis by promoting glutamate exocytosis in CXCR4-activated astrocytes (Bezzi et al. 2001). Bezzi et al. also showed that glutamate release is further enhanced by presence of activated microglia (Bezzi et al. 2001). TNF-α was also found to inhibit the uptake of glutamate in a dose-dependent fashion by human primary astrocytes; however, the exact mechanism remains to be resolved (Fine et al. 1996). Hence, it is likely that astrocytes-microglia interaction during MS inflammation, under the influences of proinflammatory cytokines, forms an amplification cascade leading to abnormal glutamate homeostasis. Indeed, Takahashi et al. showed that IL-1β and TNF-α are not detrimental in pure oligodendrocyte culture; however, in co-culture with astrocytes and microglia, they evoke apoptosis in oligodendrocyte mediating through glutamate excitotoxicity (Takahashi et al. 2003). Collectively, all the above evidences suggest that loss of ability to modify the local glutamate levels between glial-glial interactions is likely to contribute to neurodegeneration in MS.

6 Quinolinic Acid, Another Potential Endogenous Culprit in Excitotoxicity of MS

One of the NMDA receptor agonists that is worth mentioning and progressively received significant attention in the field of excitotoxicity is quinolinic acid (QUIN). This glutamatergic agonist acts preferentially on distinct population of NMDA receptors containing the NR2A and NR2B subunits. QUIN has had described to be the most potent agonist for NMDA receptors among the others such as NMDA, ibotenate, and glutamate (Monaghan and Beaton 1991). QUIN is one of the downstream metabolites of the kynurenine pathway (KP) which is a major catabolic route of the tryptophan metabolism. It is one of the several metabolites in the KP that are both neuroactive and neurotoxic. Under physiological condition, QUIN is present at nanomolar concentrations in human and rodent brain (Chen and Guillemin 2009). However, during inflammatory state, activation of the KP under the influence of proinflammatory cytokines in the presence of macrophages and microglia can lead to production of up to submicromolar concentration of QUIN (Guillemin et al. 2003, 2005). Hence, its endogenous level in the CNS may be of concern for excitotoxicity given its potency over any other agonists. Indeed, Schwarcz et al. showed that nanomolar concentrations of QUIN injected into rat striatum and hippocampus region of the brain resulted in axon-sparing lesions (Schwarcz et al. 1983). Several in vitro studies also demonstrated that neuronal cells are vulnerable to QUIN excitotoxicity similar to glutamate at pathophysiological concentration including neurons (Kerr et al. 1998), astrocytes (Ting et al. 2009), and oligodendrocytes (Cammer 2001). QUIN can further enhance glutamate excitotoxicity by increasing the release of glutamate by neurons,

decrease uptake by astrocytes (Tavares et al. 2002), and inhibit astroglial glutamine synthetase (Ting et al. 2009) consequently disrupting glutamate-glutamine cycle and ultimately leading to excitotoxicity. Detrimental effects of QUIN can be reversed either through increased endogenous of kynurenic acid (KYNA) (Miranda et al. 1997; Harris et al. 1998), an antagonist of the NMDA receptor, or using potent selective NMDA blocker, MK801 and memantine (Braidy et al. 2009). KYNA is also a KP metabolite and its endogenous level in the mammalian system plays a pivotal role in regulating QUIN excitotoxicity. KYNA was found to be present at subnormal concentration in several neurodegenerative diseases (Chen and Guillemin 2009) including MS (Rejdak et al. 2002). It was suggested that it requires twice as much KYNA to antagonist the same concentration of QUIN (Lekieffre et al. 1990). This further suggests that QUIN is a potent NMDA agonist mediating excitotoxicity at pathophysiological conditions such as inflammation. In the context of MS, QUIN had been implicated to be involved in the pathogenesis of MS associated with neurodegeneration (reviewed (Lim et al. 2010)). Flanagan et al. was the first to demonstrate that QUIN is elevated in EAE and is selective to CNS (Flanagan et al. 1995). They further showed that the time course of QUIN production was similar to the neurological signs of the disorder apart from the initial increased in QUIN before onset of any prominent abnormal behavioral sign of EAE. This suggests that QUIN may be involved in the pathogenesis of EAE. Another study reporting similar results further identified the source of QUIN to be coming from infiltrating macrophages resulting in an accumulation of QUIN at a level considered to be toxic to both neurons and glial cells (Chiarugi et al. 2001). In addition, treatment of EAE mice with a KP modulator (Ro61-8048) that selectively inhibits kynurenine monooxygenase (enzyme that breaks down upstream KP metabolite) results in decreased downstream production of QUIN, while upstream metabolite, KYNA, was significantly increased (Chiarugi et al. 2001). Interestingly, this paradigm was associated with reverse paralysis of the EAE which further suggests a detrimental role of QUIN in progression of EAE. These data implied that altered QUIN homeostasis is likely to contribute to MS pathogenesis. However, the level of QUIN in MS patients remains to be elucidated. Clinical data of QUIN involvement in MS may have pharmacological implication for late stages of MS (i.e., PMS) associated with neurodegeneration since there is currently no effective treatment.

7 Conclusion

This chapter presented various evidences on the roles of excitotoxicity in a complex multifactorial disease, MS. We have highlighted the various components involved in glutamate excitotoxicity and their interactions in cells and animal model of MS. We also looked at how excitotoxicity may interact with some of the immune components of MS. It is indisputable that all these evidences point towards the pivotal roles of excitotoxicity participating in MS pathogenesis. However, the presence of demyelination, the hallmark of MS, whether it is a cause or effect due to autoimmune response or neurodegeneration remains to be elucidated.

Neuroprotectants Targeting NMDA Receptor Signaling

Sandra M. Vetiska and Michael Tymianski

Contents

Abstract

N-Methyl-D-aspartate (NMDA) receptors are key mediators of fast excitatory synaptic transmission within the mammalian central nervous system (CNS) and play vital roles in learning, memory, and synaptic development. Overactivation of NMDA receptors (NMDARs) at glutamatergic synapses often results in excitotoxicity, which can cause neuronal injury and death, and is associated with many neurological disorders such as ischemic stroke, epilepsy, neuropathic pain, traumatic brain and spinal injuries; ocular disorders such as glaucoma; as well as neurodegenerative diseases, including amyotrophic lateral sclerosis, Parkinson's, Huntington's, and Alzheimer's

diseases. Numerous NMDAR antagonists have been developed that have been effective in reducing cell damage and death in both in vitro and in vivo experimental models of neurological disease, such as ischemia and traumatic brain injury. Unfortunately, clinical use of these NMDAR antagonists has been limited by intolerable side effects, likely due to the necessity of NMDARs in normal brain function. Intracellular signaling pathways that couple to NMDAR activation can promote either cell survival or cell death, depending on NMDAR subunit composition and/or subcellular localization. Ideal therapeutic strategies targeting NMDAR-mediated neurotoxicity should selectively block pro-death signaling, while sparing pro-survival signals. Neuroprotectants targeting downstream effectors of NMDAR-mediated cell death, rather than NMDARs directly, would maintain normal NMDAR function and minimize adverse effects commonly associated with traditional NMDAR antagonists in the treatment of neurological disorders.

1 Introduction

In the mammalian central nervous system (CNS), the principal excitatory neurotransmitter is glutamate. This neurotransmitter acts on two classes of receptors: ionotropic glutamate receptors that form a central ion channel pore and mediate fast excitatory synaptic transmission and metabotropic glutamate receptors, which are G protein-coupled receptors that play neuromodulatory roles within the CNS (Traynelis et al. 2010). Three types of ionotropic glutamate receptors have been identified and classified based on electrophysiological and pharmacological properties: *N*-Methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), and kainate, each being named for their preferred pharmacologic agonist (Nakanishi 1992; Hollmann and Heinemann 1994). Activation of ionotropic glutamate receptors leads to the opening of their associated ion channel, which, depending on receptor type, is permeable to sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}) ions. While AMPA and kainate receptors have modest Ca^{2+} permeability, NMDA receptors (NMDARs) are highly Ca^{2+}-permeable (MacDermott et al. 1986; McBain and Mayer 1994; Dingledine et al. 1999), and it is this Ca^{2+} influx that is thought to play a major role in both the physiological as well as pathophysiological functions of the NMDAR (Choi 1988a, b; Tymianski et al. 1993; Ghosh and Greenberg 1995).

The term "excitotoxicity," first coined by Olney (1969), refers to the overactivation of glutamate receptors due to excessive synaptic release of glutamate. Initial studies on glutamate toxicity were done by Lucas and Newhouse (1957), who showed that systemic injections of L-glutamate into mice destroy the inner neural layers of the retina. These observations of neuronal death following excessive glutamate administration were later extended to the brain (Olney 1969; Olney and de Gubareff 1978) and spinal cord (Regan and Choi 1991). Excitotoxicity is now considered an important mechanism involved in many acute CNS insults, such as ischemia and traumatic brain injury (TBI) as

well as in chronic neurodegenerative diseases, such as Parkinson's (PD), Huntington's (HD), and Alzheimer's (AD) diseases (Lipton and Rosenberg 1994; Arundine and Tymianski 2004; Lau and Tymianski 2010).

Glutamate-mediated neurotoxicity arises from excessive Ca^{2+} influx through NMDARs (Berdichevsky et al. 1983; Choi 1987, 1988a, b; Sattler and Tymianski 2000). Ca^{2+} overload can trigger many detrimental cellular processes, including activation of calcium-dependent proteases, mitochondrial dysfunction, and death signals (Pivovarova and Andrews 2010; Szydlowska and Tymianski 2010). Additionally, excessive cellular Ca^{2+} can induce the production of harmful reactive oxygen species. For example, nitric oxide (NO), synthesized by the Ca^{2+}-dependent enzyme neuronal nitric oxide synthase (nNOS), can react with the superoxide anion (O_2^-) to form the highly reactive species peroxynitrite, which can cause damage to proteins, lipids, and DNA (Radi et al. 1991a, b; Aarts et al. 2003b). NMDARs are key mediators of excitotoxicity in the CNS and have thus been the targets of many neuroprotective strategies.

2 NMDA Receptors and Their Antagonists

Structurally, NMDARs exist as heterotetramers, typically consisting of two obligatory NR1 subunits and two regulatory NR2 subunits and less commonly including NR3 subunits (Das et al. 1998; Chatterton et al. 2002; Paoletti and Neyton 2007; Cavara and Hollmann 2008; Pachernegg et al. 2012). Four subtypes of NR2 (NR2A-D) can assemble with the NR1 subunit, most commonly NR2A or NR2B in the forebrain. These receptors are typically diheteromeric in nature; that is, they are comprised of either NR1/NR2A or NR1/NR2B subunits. Some NMDARs can also incorporate two different NR2 subunits (Chazot et al. 1994; Chazot and Stephenson 1997); however, few studies have addressed the functional implications of these receptors.

The type of NR2 subunit determines the biophysical and pharmacological properties of NMDARs; furthermore, these subunits govern distinct protein-protein interactions and downstream signaling pathways, by way of the structural diversity of their carboxyl (C)-terminus (Hardingham and Bading 2003; Cull-Candy and Leszkiewicz 2004; Prybylowski and Wenthold 2004; Kohr 2006; Ryan et al. 2008). Alternatively spliced isoforms also exist for some subunits, such as NR1, creating additional functional diversity (Sugihara et al. 1992; Zukin and Bennett 1995). At resting membrane potential, the channel pore of the NMDAR is blocked by magnesium (Mg^{2+}) which prevents ion flow through the channel. Upon membrane depolarization, Mg^{2+} is expelled, allowing for the passage of ions through the channel. Thus, NMDAR activation requires not only the presynaptic release of glutamate but also the depolarization of the postsynaptic membrane. NMDARs also require simultaneous binding of glutamate and glycine (or D-serine) for activation (Johnson and Ascher 1987; Kleckner and Dingledine 1988; Lerma et al. 1990). The glutamate-binding site is located on the NR2 subunits, while the NR1 subunits provide the glycine-binding site (Furukawa and Gouaux 2003; Furukawa et al. 2005).

Evidence from preclinical research has demonstrated a critical role for NMDAR-mediated neurotoxicity in cellular and animal models of neurological disorders, such as ischemic stroke and TBI (Choi 1988a, b; Tymianski et al. 1993; Arundine et al. 2003). NMDA receptor antagonists targeting the glutamate-binding site, the glycine-binding site, or the channel pore, as well as NR2B subunit-selective antagonists, all showed neuroprotection in preclinical studies of excitotoxicity-related CNS diseases (Danysz and Parsons 2002; Wang and Shuaib 2005). Unfortunately, all clinical trials for neuroprotection in acute disorders including stroke and TBI using NMDAR antagonists, such as Selfotel, Aptiganel, and Gavestinel, have failed. This was largely due either to adverse effects or to limited clinical efficacy (Wood and Hawkinson 1997; Morris et al. 1999; Gladstone et al. 2002; Ikonomidou and Turski 2002; Hoyte et al. 2004; Muir 2006; Kalia et al. 2008; Lau and Tymianski 2010). In addition to undesirable side effects, a short therapeutic window may be a limiting factor with the use of NMDAR antagonists as neuroprotectants in stroke and TBI (Ikonomidou and Turski 2002; Roesler et al. 2003).

In the case of more chronic disorders, an anti-excitotoxic approach using NMDAR antagonists may have a role. For example, memantine is the only NMDAR antagonist currently approved for the treatment of moderate to severe Alzheimer's disease (AD) in most of Europe, the USA, and Canada, either as a monotherapy or in combination with cholinesterase inhibitors (Thomas and Grossberg 2009). Memantine is a moderate affinity, uncompetitive NMDAR antagonist with strong voltage-dependency and fast kinetics, which allow rapid binding to and quick dissociation from NMDARs. These properties allow memantine to be well tolerated and have few side effects, unlike other NMDAR channel blockers (Danysz and Parsons 2012); however, there is no clear benefit to date for the use of memantine in milder stages of AD and only a small beneficial effect on cognition in vascular dementia (Parsons et al. 1999; McShane et al. 2006; Rammes et al. 2008; Herrmann et al. 2011). Memantine has been studied in several other neurological diseases, both at the preclinical and clinical levels (Stieg et al. 1999; Rao et al. 2001; Volbracht et al. 2006; Rojas et al. 2008; Thomas and Grossberg 2009; Milnerwood et al. 2010), and may have clinical benefit in some disorders, including PD (Aarsland et al. 2009), HD (Beister et al. 2004; Ondo et al. 2007) and HIV-associated dementia (Schifitto et al. 2007; Zhao et al. 2010). Further work is required to establish the full potential of memantine in these diseases.

3 Dual Roles of NMDARs in Health and Disease: Implications for Neuroprotectants

3.1 Importance of NMDAR Subcellular Localization

The critical roles that NMDARs play in normal brain function may help explain why clinical treatment of stroke and brain trauma with NMDAR antagonists has failed. An ideal therapeutic approach to antagonize NMDAR overactivity in

neurological disorders would include blocking downstream excitotoxic signaling without directly blocking NMDARs or inhibiting normal excitatory neurotransmission. Recently, dual roles for the NMDAR in both neuronal death and survival have been increasingly appreciated. These depend, at least in part, on the subcellular NMDAR pool that is activated (Hardingham and Bading 2010). At the neuronal plasma membrane, NMDARs are localized to both the synapse and to extrasynaptic regions, and these two receptor populations may have different roles in physiological and pathophysiological processes. Although NMDARs at both locations can mediate excitotoxicity (Sattler et al. 2000; Liu et al. 2007), studies in cultured cortical and hippocampal neurons showed that stimulation of synaptic NMDARs promotes cell survival pathways, whereas extrasynaptic NMDAR activation is more strongly associated with neuronal death (Vanhoutte and Bading 2003; Soriano and Hardingham 2007; Leveille et al. 2008; Hardingham and Bading 2010). This dual role of NMDARs in cell survival and death stems from distinct intracellular signaling pathways that are coupled to synaptic and extrasynaptic NMDARs. Synaptically localized NMDARs promote cell survival by suppressing apoptotic gene expression (Leveille et al. 2010) and activating pro-survival factors such as cyclic AMP response element-binding protein (CREB), a transcription factor that induces expression of genes such as brain-derived neurotrophic factor (BDNF) that is important for survival (Hardingham et al. 2002). In contrast, extrasynaptic NMDARs can mediate cell death by attenuating the CREB pathway, blocking BDNF expression, and promoting mitochondrial dysfunction and cell death (Hardingham et al. 2002; Gouix et al. 2009). Recent work has demonstrated that, similar to cortical neurons, striatal medium-sized spiny neurons also show increased and decreased CREB signaling after stimulation of synaptic and extrasynaptic NMDARs, respectively (Kaufman et al. 2012).

Alterations in synaptic and extrasynaptic NMDAR localization, leading to an imbalance between pro-survival and proapoptotic signaling, have been associated with several neurological disorders (Gladding and Raymond 2011; Sanz-Clemente et al. 2012). For example, enhanced activity of extrasynaptically localized NMDARs was observed in cerebral ischemia (Tu et al. 2010) and Huntington's disease (HD; Okamoto et al. 2009; Milnerwood et al. 2010). In the striatum of transgenic HD mice, increased NR2B-containing extrasynaptic NMDAR expression, increased current, and associated reductions in nuclear CREB activation were found. Furthermore, this reduction in CREB activity, along with associated motor learning deficits, was reversed by treatment of HD mice with memantine, which was shown to preferentially block extrasynaptic NMDARs (Leveille et al. 2008; Okamoto et al. 2009; Xia et al. 2010). The selective block of extrasynaptic NMDARs by memantine may contribute to its clinical tolerability; that is, memantine may spare physiological synaptic transmission needed for normal brain function but selectively antagonize extrasynaptic NMDARs that are excessively activated under pathological conditions.

3.2 Importance of NMDAR NR2 Subunit Subtype

Seemingly contrary to the idea that neuronal survival and death pathways are mediated by synaptic and extrasynaptic NMDARs, respectively, the well-characterized synapse-specific protein PSD95 (postsynaptic density-95) is required for NMDAR-mediated excitotoxic neuronal death (Sattler et al. 1999; Aarts et al. 2002; Zhou et al. 2010). This apparent paradox may be explained by the temporally and spatially regulated expression of different NMDAR NR2 subunits (Traynelis et al. 2010). In adult forebrain neurons, NR2A-containing NMDARs are preferentially localized to synapses, while NR2B-containing NMDARs are primarily expressed at extrasynaptic sites (Tovar and Westbrook 1999; Liu et al. 2007; Groc et al. 2009). In addition, NR2A-containing NMDARs are thought to mediate cell survival signals, whereas NR2B-containing NMDARs are associated with cell death pathways, in both in vitro and in vivo models of stroke and TBI (DeRidder et al. 2006; Zhou and Baudry 2006; Liu et al. 2007; Chen et al. 2008; Terasaki et al. 2010). However, this distribution profile of NMDAR NR2 subunits is not absolute. NR2A-containing receptors can be found at extrasynaptic sites; likewise, NR2B-containing NMDARs are expressed in the postsynaptic membrane, where they associate with other postsynaptic density proteins, such as PSD95 (Groc et al. 2006; Thomas et al. 2006; Harris and Pettit 2007). Therefore, neuronal death pathways may be activated by either synaptic or extrasynaptic NR2B-containing NMDARs, while activation of either synaptic or extrasynaptic NR2A-containing NMDARs promotes neuronal survival (Liu et al. 2007).

NMDARs are localized in the cell membrane, including that of synapses, by an array of scaffolding proteins. Among these is the abundant PSD95 protein, discussed in greater detail in sections below. In synapses, PSD95 binds the C-termini of NMDAR NR2 subunits and links NMDARs to other proteins found in the multiprotein complex (MPC) with which NMDARs associate. In doing so, PSD95 links NMDARs to signaling proteins within the MPC that mediate excitotoxic neuronal death (Sattler et al. 1999; Aarts et al. 2002; Lai and Wang 2010; Zhou et al. 2010). The linkage between NMDARs and downstream toxic signaling pathways may be strongest with NR2B-containing NMDARs. Lending support to this idea is a recent study (Martel et al. 2012) that used chimeric constructs of NMDAR NR2A and NR2B subunits with reciprocal exchanges of their C-terminal domains to demonstrate that the NR2B C-terminal domain is important for NMDAR-mediated toxicity, regardless of receptor location. As discussed above in the case of PSD95, the precise mechanisms by which NMDAR subunit composition determines functional outcome of the receptor may lie in the specific intracellular signaling proteins that couple to NMDARs, most often via their C-terminal tails. Ideally, a therapeutic strategy for excitotoxicity-related neurological disorders would selectively target only those NMDARs or their downstream signaling components associated with neuronal death, while sparing the cell survival-promoting NMDAR population.

4 NMDAR Signaling at the Postsynaptic Density

At the postsynaptic membrane of central excitatory synapses, ionotropic glutamate receptors are localized into specialized MPCs in an electron-dense region termed the postsynaptic density (PSD) (Kennedy 1997; Sheng 2001). NMDARs are abundantly expressed in association with the PSD (Moon et al. 1994), which is composed of both membranous and cytoplasmic proteins (Ziff 1997; Okabe 2007). Scaffolding proteins, which are major components of the MPC, associate with each other and other MPC proteins via highly specific and often unique protein-protein interactions. Such interactions govern cell-to-cell adhesion, regulation of receptor clustering, and modulation of receptor function (Feng and Zhang 2009; Verpelli et al. 2012). PSD95 (also known as SAP90), the first PSD scaffolding protein to be identified (Cho et al. 1992), is a member of a larger group of scaffolding proteins known as membrane-associated guanylate kinase (MAGUK) proteins (Gardoni 2008; Zheng et al. 2011). MAGUKs contain modular protein interaction domains, such as SH3 (Src homology 3), GK (guanylate kinase), and PDZ (Postsynaptic density-95/Discs large homolog/Zona occludens-1) domains (Sheng and Sala 2001; Gardoni 2008; Zheng et al. 2011).

Many surface receptors, such as the NMDAR, bind to MAGUK PDZ domains via their C-terminal PDZ-binding domains. For example, through its first two PDZ domains, PSD95 can bind NMDAR NR2 subunits at their C-terminus PDZ-binding motif (ESDV) (Kornau et al. 1995; Niethammer et al. 1996). PSD95 connects NMDARs to intracellular signaling proteins, such as neuronal nitric oxide synthase (nNOS). PSD95 also binds directly to nNOS via a PDZ-PDZ interaction that involves the second PDZ domain of PSD95 (Brenman et al. 1996; Craven and Bredt 1998; Christopherson et al. 1999; Tezuka et al. 1999). By physically bringing together the NMDAR and nNOS, PSD95 allows Ca^{2+} that permeates through NMDARs to preferentially induce the activation of nNOS and thus couples NMDAR activity to the production of nitric oxide (NO), a signaling molecule that mediates NMDAR-dependent excitotoxicity (Dawson et al. 1991, 1993). Disrupting the NMDAR-PSD95-nNOS complex in cultured cortical neurons using antisense oligonucleotides against PSD95 selectively attenuated NMDAR-mediated excitotoxicity, without affecting NMDAR expression or function (Sattler et al. 1999).

5 NMDAR NR2B Signaling: Downstream Effectors of Excitotoxicity as Therapeutic Targets in Neurological Diseases

5.1 NR2B-PSD95-nNOS Signaling Complex

Because suppression of PSD95 using antisense oligonucleotides is impractical in the treatment of excitotoxicity-related disorders in humans, an alternative strategy

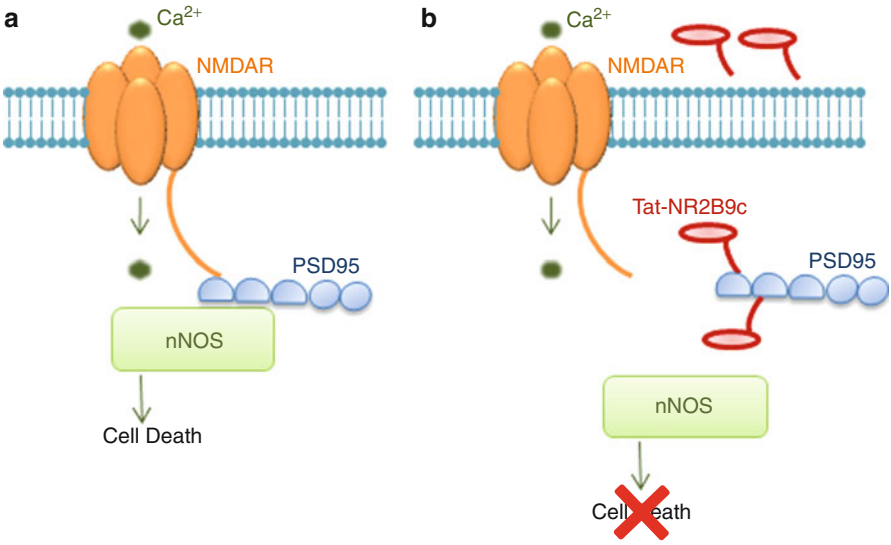

Fig. 1 The NMDAR-PSD95-nNOS signaling complex. (**a**) By binding to both the NMDAR and nNOS, PSD95 brings nNOS in close proximity to the NMDAR and allows Ca^{2+} entering the neuron through the NMDAR to preferentially induce the activation of nNOS, leading to cell death. (**b**) The Tat-NR2B9c peptide disrupts the NMDAR-PSD95-nNOS complex, dissociating NMDARs from downstream neurotoxic signaling, without blocking synaptic activity or calcium influx

for disrupting the NR2B-PSD95-nNOS signaling complex is to use drug compounds that block protein interactions within this complex. One such drug compound is NR2B9c (Aarts et al. 2002). The NR2B9c peptide, comprising the nine C-terminal residues of NR2B (KLSSIESDV), can be rendered cell permeant by fusion to the 11 residue protein transduction domain of the human immunodeficiency virus type 1 (HIV-1) Tat protein (Schwarze et al. 1999). This produces a 20-amino acid peptide termed Tat-NR2B9c. This peptide permeates through cell membranes and disrupts the intracellular interaction of NMDARs with PSD95 (See Fig. 1). This effectively dissociates NMDARs from downstream neurotoxic signaling. However, unlike NMDAR antagonists, this occurs without blocking synaptic activity or calcium influx. This approach is feasible in vivo: when applied either before, 1 or 3 h after an insult, Tat-NR2B9c protected cultured neurons from excitotoxicity and reduced transient middle cerebral artery occlusion (MCAO)-mediated ischemic brain damage in rats (Aarts et al. 2002; Sun et al. 2008).

A proteomic and biochemical analysis of the interactions of Tat-NR2B9c with most or all PDZs in the human genome revealed that the disruption of the NMDAR-PSD95-nNOS complex by Tat-NR2B9c was highly specific. Because the peptide targets the first and second PDZ domains of PSD95, where both the NMDAR and nNOS bind, Tat-NR2B9c inhibited the interaction between both PSD95 and NR2 subunits as well as between PSD95 and nNOS (Cui et al. 2007).

Importantly, Tat-NR2B9c administered 3 h after both permanent and transient focal ischemia reduced infarct volumes in rats and improved long-term neurobehavior, including sensorimotor function, emotionality, and cognition (Sun et al. 2008), raising the possibility for clinical usefulness in a wide therapeutic window. Further downstream, the consequences of administering Tat-NR2B9c are to ameliorate excitotoxic neuronal loss in vitro and ischemic cortical damage in vivo by impairing pro-death p38 signaling, without affecting NMDAR-mediated pro-survival pathways involving CREB or Akt (Soriano et al. 2008; Martel et al. 2009). Other studies have proposed that compounds other than Tat-NR2B9c that target the NMDAR-PSD95 interaction may also have neuroprotective effects. Disruption of the PSD95-nNOS interaction using a small molecule inhibitor (ZL006) is suggested to be neuroprotective in ischemia (Zhou et al. 2010). In addition, the use of a dimeric inhibitor, Tat-*N*PEG4(IETDV)$_2$ (Tat-*N*-dimer), which binds the tandem PDZ1-2 domain of PSD95, reduced infarct volume in mice subjected to cerebral ischemia (Bach et al. 2012).

Recently, Tat-NR2B9c was used for the treatment of stroke in cynomolgus macaques, higher-order gyrencephalic nonhuman primates, which bear anatomical and behavioral similarities to humans (Cook et al. 2012). Animals treated with Tat-NR2B9c up to 3 h after MCAO showed significant reduction in infarct volume, as measured by magnetic resonance imaging and histology. In addition, Tat-NR2B9c-treated macaques showed improved neurobehavioral outcomes assessed using the nonhuman primate stroke scale (NHPSS). This neuroprotection preserved cellular functionality, as gauged by the capacity for gene transcription in ischemic brain tissue. The 3-h time frame for neuroprotection with Tat-NR2B9c is significant as it suggests a broader clinical applicability. Tat-NR2B9c has already entered clinical trials; the ENACT (Evaluating Neuroprotection in Aneurysm Coiling Therapy) Phase 2 clinical trial (ClinicalTrials.gov number, NCT00728182) to determine the safety and efficacy of Tat-NR2B9c in reducing embolic strokes in patients undergoing endovascular repair of brain aneurysms was recently successfully completed (Hill et al. 2012). The encouraging results from this trial warrant further investigation of Tat-NR2B9c in the clinical treatment of stroke.

Since the first study (Aarts et al. 2002) utilizing blocking peptides against PSD95 in stroke, subsequent work using similar strategies has been carried out to investigate other excitotoxicity-mediated neurological diseases, such as epilepsy, AD, and neuropathic pain. Administration of Tat-NR2B9c in rats 3 h after the termination of status epilepticus reduced cell loss in regions of the hippocampus (Dykstra et al. 2009). Perturbing the NR2B-PSD95 association with Tat-NR2B9c ameliorated Aβ-mediated toxicity in vitro and was sufficient to prevent lethality and memory deficits in an AD mouse model (Ittner et al. 2010). The importance of the NR2B9c-PSD95-nNOS signaling complex in neuropathic pain has been demonstrated using a variety of genetic, biochemical, and proteomic techniques. These include the use of antisense oligonucleotides against PSD95 (Tao et al. 2001, 2003), small molecule inhibitors that block the interaction between PSD95 and nNOS (Florio et al. 2009), or Tat-fusion peptides comprising regions of PSD95 (Tao et al. 2008), nNOS (Florio et al. 2009), or the NMDAR NR2B subunit (D'Mello et al. 2011).

5.2 NR2B-ND2-Src Signaling Complex

NMDAR activity is governed in part by the balance between phosphorylation and dephosphorylation (Salter and Kalia 2004). Tyrosine phosphorylation upregulates the activity of NMDARs (Wang and Salter 1994; Zheng et al. 1998), and the nonreceptor tyrosine kinase Src (Ohnishi et al. 2011) can mediate this upregulation. Within the NMDAR complex, Src, along with the phosphotyrosine phosphatase STEP (striatal enriched tyrosine phosphatase), act in opposition to phosphorylate or dephosphorylate the NMDAR, respectively. $STEP_{61}$, the membrane-associated STEP isoform (Sharma et al. 1995; Bult et al. 1996), suppresses NMDAR activity by opposing the actions of Src (Pelkey et al. 2002). Src-mediated enhanced phosphorylation of NMDARs is associated with synaptic plasticity (Rostas et al. 1996; Salter 1998) as well as pathophysiological conditions such as ischemia (Cheung et al. 2003), HD (Song et al. 2003), epilepsy (Sanna et al. 2000; Moussa et al. 2001), and neuropathic pain (Salter and Pitcher 2012). Inhibition of Src activity may attenuate brain injury in ischemia (Jiang et al. 2008; Liang et al. 2009), supporting a role for Src in excitotoxic processes.

Src is anchored to the NMDAR via the adaptor protein NADH dehydrogenase 2 (ND2) (Gingrich et al. 2004). ND2 brings Src in close proximity to the NMDAR and allows Src to upregulate NMDAR function through phosphorylation of NR2 subunits. Disruption of the NMDAR-ND2-Src signaling complex has been shown to suppress pain behaviors. A 10-amino acid peptide, Src40-49, comprising the region of Src needed to bind ND2, was able to inhibit the binding of Src to ND2, thus releasing Src from the NMDAR complex and inhibiting Src-mediated enhancement of NMDAR activity (Liu et al. 2008). Importantly, uncoupling of Src from the NMDAR complex with the membrane-permeable Src40-49Tat fusion peptide suppressed pain hypersensitivity induced by inflammation and peripheral nerve injury (see Fig. 2). Thus, by regulating the function of NMDARs through phosphorylation and dephosphorylation, Src and STEP play vital roles in both physiological as well as pathophysiological glutamatergic neurotransmission. Furthermore, both Src and STEP themselves are subject to regulation. For example, differential regulation of $STEP_{61}$ may play an important role in mediating the dual roles of the NMDAR in cell survival and death (Xu et al. 2009). Synaptic NMDAR activation promotes the ubiquitination and degradation of $STEP_{61}$, concomitant with ERK1/2 activation and cell survival. In contrast, extrasynaptic NMDAR stimulation leads to calpain-mediated proteolysis of $STEP_{61}$, activation of p38, and cell death. Aberrant regulation of both Src and STEP may therefore be involved in NMDAR-mediated pathophysiological conditions (Hossain et al. 2012; Salter and Pitcher 2012). Although targeting STEP or the Src:ND2 interaction has not been tested in ischemia, it is another example of a protein-protein interaction that may be targeted therapeutically in disorders that depend on NMDAR overactivity.

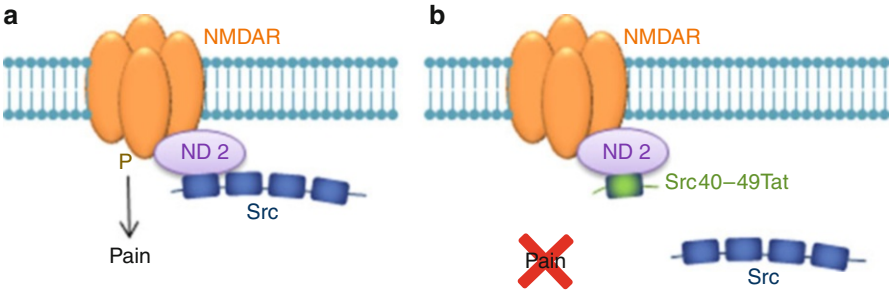

Fig. 2 The NMDAR-ND2-Src signaling complex. (**a**) Src is anchored within the NMDAR complex via the adaptor protein NADH dehydrogenase 2 (ND2). By bringing Src in close proximity to the NMDAR, ND2 allows Src to phosphorylate the receptor and enhance NMDAR activity, resulting in hypersensitivity to pain. (**b**) Using a Src40–49Tat peptide to block the interaction between Src and ND2 dissociates Src from ND2, thereby inhibiting Src-mediated upregulation of NMDAR activity and suppressing pain behaviors (Figure adapted from Liu et al. 2008)

5.3 Other Signaling Pathways Implicated in NMDAR-Mediated Neurotoxicity

Other signaling pathways downstream of NMDARs have been identified to play roles in excitotoxic signaling. For example, during cerebral ischemia, death-associated protein kinase 1 (DAPK1) is recruited to extrasynaptic NMDAR NR2B subunits in the cortex of mice (Tu et al. 2010). DAPK1 directly binds to NR2B, phosphorylates it, and enhances NMDAR channel conductance, leading to increased excitotoxic signaling. Peptides that inhibit the interaction between DAPK1 and the NMDAR NR2B subunit reduced brain infarction and improved neurological function in mice. DAPK1 itself is subject to regulation by other signaling molecules, such as ERK1/2, which may affect NMDAR activity (Liu et al. 2012). Another signaling protein involved in cell death downstream from the NMDAR is PTEN (phosphatase and tensin homolog deleted on chromosome 10). PTEN is recruited selectively to NMDAR NR2B subunits (Ning et al. 2004), potentiates neurotoxic NMDAR activity, and inhibits the PI3K (phosphatidylinositol 3-kinase) survival pathway, thus contributing to excitotoxic neuronal death in stroke. PTEN-induced kinase 1 (PINK1) in a ubiquitous kinase thought to function in cell survival-promoting pathways (Wilhelmus et al. 2012). Overactivation of NR2B-containing NMDARs may contribute to ischemic cell death by suppressing PINK1-dependent survival signaling (Shan et al. 2009). Thus, drug compounds that are able to increase PINK1 levels and activity may prove to be neuroprotective in NMDAR-mediated neurotoxicity.

Activation of NMDARs has been linked to the modulation of several transcription factors that can mediate either pro-survival or pro-death pathways (Hardingham et al. 2002; Zou and Crews 2006; Lai et al. 2011), and these may be useful targets for therapeutic intervention. One example is the transcription factor

SREBP-1 (sterol regulatory element-binding protein-1) (Taghibiglou et al. 2009), which typically controls lipid biosynthesis genes but whose activation is essential in NMDAR-mediated excitotoxic neuronal death in both in vitro and in vivo models of stroke. Therapies aimed at pro-death transcription factors downstream of NMDAR-mediated excitotoxic pathways may offer some novel therapeutic targets in the treatment of neurological diseases. Since activation of these transcription factors is often delayed, relative to NMDAR activation, neuroprotective strategies targeting these proteins may offer a wider therapeutic window if such pathways participate in the cell injury process.

Cell death pathways also exist that may occur in parallel with and converge upon NMDAR-mediated excitotoxic signaling mechanisms (Tymianski 2011). TRPM7 and TRPM2 are members of the transient receptor potential (TRP) channel superfamily (Nilius and Owsianik 2011) that are widely expressed and function in diverse cellular processes, including death, survival, and proliferation. Both TRPM2 and TRPM7 are nonselective cation channels that are activated by oxidative stress and are thought to play significant roles in ischemic cell death (Aarts et al. 2003a; MacDonald et al. 2006; Sun et al. 2009; Xie et al. 2010). TRPM2 and TRPM7 may represent additional Ca^{2+} influx pathways, other than NMDARs, in mediating neurotoxicity in ischemia. Neurotoxic signals such as reactive oxygen species downstream of NMDARs may in turn activate TRPM2 and TRPM7 channels to form a positive feedback loop that perpetuates ischemic cell death.

6 Conclusion

NMDARs have important physiological roles mediating synaptic plasticity and neurodevelopment. However, overactivation of NMDARs leads to excitotoxicity, common to many neurological diseases such as ischemic stroke, epilepsy, neuropathic pain, traumatic brain and spinal injuries; ocular disorders such as glaucoma; as well as neurodegenerative diseases, including amyotrophic lateral sclerosis, Parkinson's, Huntington's, and Alzheimer's diseases. Antagonists that directly inhibit NMDARs have limited use clinically, possibly due to intolerable side effects at anti-excitotoxic doses. Intracellular signaling pathways that couple to NMDAR activation can promote either cell survival or cell death, depending on NMDAR subunit composition and/or subcellular localization. Extrasynaptic NMDARs, and especially those receptors containing NR2B subunits, engage in cell death pathways upon excessive glutamate stimulation. Conversely, activation of synaptically localized NMDARs, and especially those receptors containing NR2A subunits, may result in neuroprotection. Therapeutic strategies targeting NMDAR-mediated neurotoxicity should preferentially block pro-death signaling while sparing pro-survival signals. Since neuroprotectants that selectively target the molecular components involved in pro-death signaling downstream of the NMDAR do not directly inhibit NMDARs themselves, they may be better tolerated than traditional NMDAR antagonists.

The last decade of scientific research has shed light on the molecular mechanisms involved in NMDAR-mediated excitotoxicity and has revealed additional targets for neuroprotective strategies in the treatment of neurological disorders; however, many questions remain unanswered. First, in addition to NR1/NR2A and NR1/NR2B diheteromeric NMDARs, triheteromeric receptors comprising NR1/NR2A/N2B are also believed to exist. The roles of these triheteromeric receptors, in both health and disease, have yet to be elucidated. Second, several signaling molecules downstream of NMDARs, such as nNOS, DAPK1, and PTEN, play roles in excitotoxic signaling to promote cell damage and death. Whether and how these signaling molecules cross talk with one another is not known. Third, in conditions such as ischemia, excessive Ca^{2+} influx through NMDARs leads to the formation of reactive oxygen species, which can activate other plasma membrane channels, such as TRPM2 and TRPM7 channels; these channels thus represent additional therapeutic targets. Lastly, a major part of our understanding about NMDAR-mediated cell death pathways comes from models of cerebral ischemia. Future work will need to determine whether these pathways also play a role in other neurological diseases that involve excitotoxic mechanisms and whether preclinical neuroprotective therapies can be translated to clinical use.

Abstract

The overexcitation of excitatory amino acid receptors generates excitotoxicity, which plays an important role in the pathophysiology of various neurodegenerative disorders such as Parkinson's and Alzheimer's diseases, stroke, and epilepsy. The prevention of excitotoxic neuronal damage is therefore a major

objective in neuroprotective strategies. The kynurenine pathway, the main route of the tryptophan metabolism, produces both neuroprotective and neurotoxic metabolites. Kynurenic acid is a broad-spectrum endogenous antagonist of ionotropic excitatory amino acid receptors, and hence it can prevent excitotoxic neuronal damage. The kynurenine metabolites are additionally involved in the regulation of glutamatergic and cholinergic neurotransmission. The pathogeneses of several neurodegenerative disorders have been shown to involve multiple imbalances in the kynurenine metabolism. Kynurenine pathway metabolites may provide important targets for future neuroprotective therapeutic strategies.

Keywords

Glutamate excitotoxicity • Kynurenine pathway • Neurodegeneration • Neuroprotection

List of Abbreviations

3-HANA	3-hydroxyanthranilic acid
AMPA	alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
ANA	anthranilic acid
3-HK	3-hydroxykynurenine
EAA	excitatory amino acid
IDO	indoleamine 2,3-dioxygenase
KAT	kynurenine aminotransferase
KMO	kynurenine 3-monooxygenase
KYNA	kynurenic acid
L-KYN	L-kynurenine
NAD	nicotinamide adenine dinucleotide
NMDA	*N*-methyl-D-aspartate
QUIN	quinolinic acid
TDO	tryptophan 2,3-dioxygenase

1 Introduction

The term excitotoxicity refers to pathological processes in which excitatory amino acid (EAA) receptors are overactivated, thereby initiating further pathological processes and ending with the death of neurones. This mechanism is involved in the pathophysiology of diverse neurological diseases such as stroke or epilepsy, traumatic brain injury, and various neurodegenerative disorders including Parkinson's disease and Huntington's disease. One of the most important substances participating in these processes is glutamate, which is also the most important excitatory neurotransmitter in the mammalian brain. The results of one of the first studies implicating the toxic effect of glutamate were published in 1957, when Lucas and Newhouse observed that the subcutaneous injection of monosodium glutamate destroyed the neurones in the inner layers of the retina in newborn mice (Lucas and Newhouse 1957). It was later

established that this phenomenon occurs not only in the retina but in several brain regions too: it is restricted to postsynaptic neurones, and glutamate agonists may induce the same effect (Olney 1969). These findings led to emergence of the term excitotoxicity. Glutamate acts on different types of ionotropic and G protein-coupled (metabotropic) receptors. These receptors play essential roles in the normal functioning of the brain, but their excessive stimulation may trigger an extensive influx of calcium (Ca^{2+}) to the neurones, setting into motion various pathological processes, which lead to damage to the cell structures and terminate in cell death (Arundine and Tymianski 2003; Krieglstein 1997). Excitotoxicity is known to be involved in the pathomechanism of a number of neurological diseases, and the search for neuroprotective agents which may prevent neuronal damage has long been an important aim in neuroscience. The kynurenine pathway, the main route in the tryptophan catabolism, involves both an EAA receptor antagonist and an agonist (Beadle et al. 1947), and kynurenines are involved in various physiological and pathophysiological processes, therefore standing at the focus of research interest (Schwarcz 2004).

2 Glutamatergic Excitotoxicity

Ionotropic receptors activated by glutamate can be divided into three major types identified by their preferred agonists: *N*-methyl-D-aspartate (NMDA), kainate, and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), each of them with several subtypes. All three families of ionotropic glutamate receptors allow the permeation of sodium (Na^+) and potassium (K^+), whereas the NMDA-type and some AMPA-type channels also display Ca^{2+} permeability. Metabotropic receptors activated by glutamate exert their effects through the activation of second messenger systems also leading to a cytosolic Ca^{2+} overload. The different receptor families contribute to the excitotoxic processes to different extents, and there is evidence that the NMDA receptors play a pivotal role. AMPA receptors have a heterotetrameric structure built up from four homologous subunits (GluR1-4) (Hollmann and Heinemann 1994). All of the subunits consist of a large extracellular N-terminal domain followed by four transmembrane domains ending in an intracellular C-terminal segment. The second transmembrane domain is responsible for the formation of the cation-permeable channel (Ozawa et al. 1998; Madden 2002). The glutamate-binding domain is formed by a part of the N-terminal domain together with the third membrane domain (Hollmann et al. 1994). The C-terminal domain is responsible for the interaction with the intracellular proteins and contains phosphorylation sites too (Carvalho et al. 2000). The subunits may exist in two distinct forms, flip and flop, which are formed through alternative splicing (Sommer et al. 1990). The activation of AMPA and kainate receptors allows the entry of Na^+ to the neurones, triggering rapid excitatory neurotransmission in the brain. Additionally in the hippocampus, cortex, and retina, various neurones express AMPA receptors which are also permeable to Ca^{2+}. Under physiological conditions, the number of Ca^{2+}-permeable AMPA receptors present in the hippocampal pyramidal neurones (HPNs) is relatively low, but in consequence of ischaemia, this number undergoes a significant increase (Pellegrini-Giampietro et al. 1997).

NMDA receptors are heteromeric complexes consisting of subunits of three major types: the NR1, NR2, and NR3 families. In mammalian tissues, functional NMDA receptors are expressed only when they contain at least one NR1 and one NR2 subunit (Moriyoshi et al. 1991; Ciabarra et al. 1995). NMDA receptors are slow-gating ion channels that are highly permeable to Ca^{2+}. The C-terminal domains of NMDA receptor subunits have an important role in NMDA receptor interactions with intracellular synaptic and cytoskeletal proteins, and these protein–protein interactions initiate various downstream signalling pathways (reviewed by Arundine and Tymianski 2004). It has been demonstrated experimentally that glutamate excitotoxicity has two components: immediate cell damage which is Na^+- and Cl^--dependent and a delayed neuronal degeneration process which can be related to the presence of Ca^{2+}. Na^+ influx causes neuronal damage even in the absence of Ca^{2+}, through the generation of toxic swelling in hippocampal and retinal cells (Rothman 1985; Olney et al. 1986). The neuronal swelling can be avoided by the removal of extracellular Na^+, but neurones exposed to glutamate will still develop neurodegenerative processes unless the extracellular Ca^{2+} is also removed (Berdichevsky et al. 1983; Choi et al. 1987). Other possible ways for Ca^{2+} to enter the cells are voltage-dependent Ca^{2+} channels and Na^+/Ca^{2+} exchangers. Release from internal pools may contribute to toxic Ca^{2+} concentrations. This can occur through mitochondrial damage or dysfunction. An increased intracellular Ca^{2+} level initiates pathological processes such as proteolysis, protein phosphorylation, lipolysis, the activation of nitric oxide synthases, and the generation of free radicals which may destroy neurones (Szydlowska and Tymianski 2010). The activation of proteases, lipases, and endonucleases results in damage to cell structures, degradation of the cytoskeleton and DNA and a mitochondrial dysfunction, and finally leads to cell death.

If neurones suffer an energy impairment, a partial membrane depolarization occurs, which leads to the removal of Mg^{2+} blocking the NMDA receptors, allowing glutamate to exert its downstream effects under physiological concentrations, contributing to neurodegenerative processes (Novelli et al. 1988).

As excitotoxic mechanisms are involved in pathological neurone loss, EAA receptor antagonism has long been at the focus of interest for neuroscientists searching for neuroprotective agents. The early experiments with NMDA antagonists revealed that they are able to prevent the neurotoxic effects of NMDA (Olney et al. 1979) and ibotenate (Schwarcz et al. 1982). In animal models, NMDA antagonism proved to have anticonvulsive properties (Croucher et al. 1982) and to be able to prevent neuronal damage in cerebral ischaemia (Simon et al. 1984). Subsequent to these convincing results, numerous experiments have demonstrated the neuroprotective efficacy of NMDA antagonism.

3 The Kynurenine Pathway and Its Metabolites

3.1 The Kynurenine Pathway

L-Tryptophan, one of the ten essential amino acids, serves as a precursor of several biologically active molecules. Besides its involvement in protein synthesis, it can be

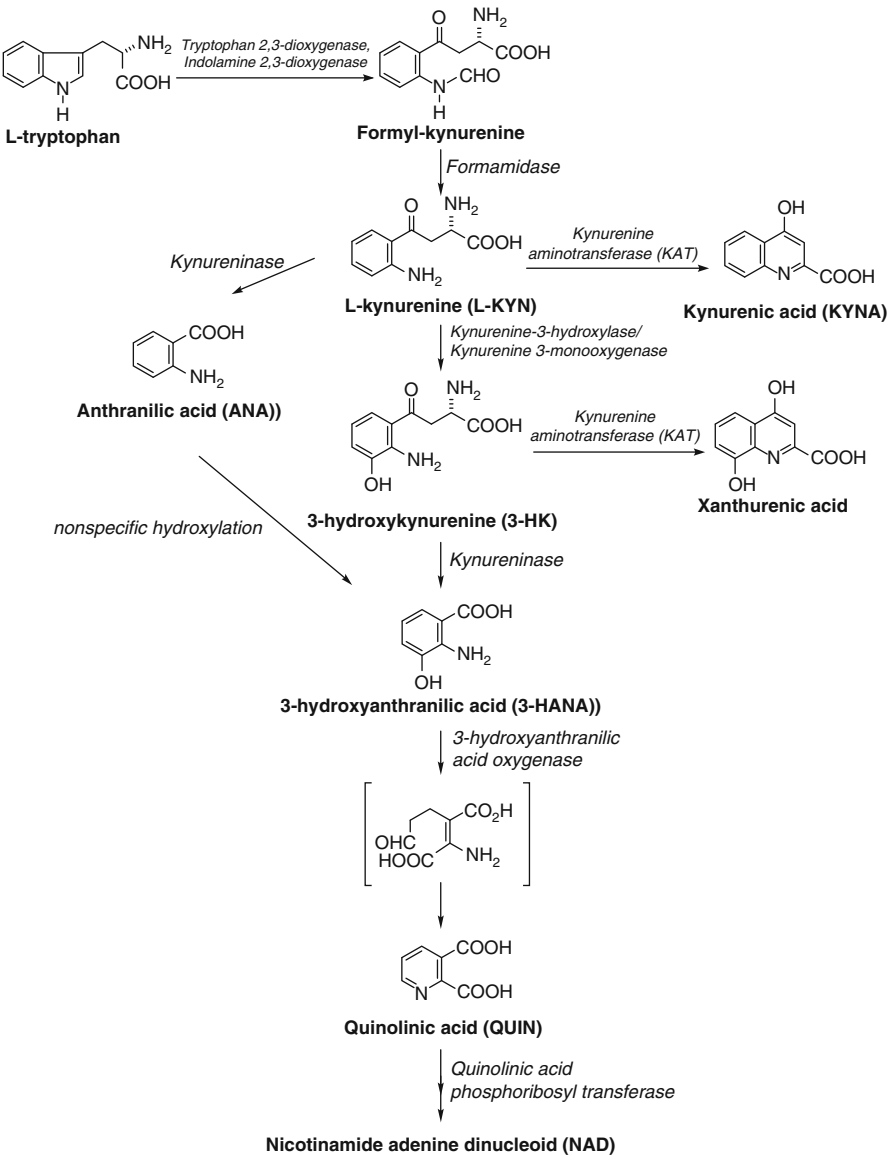

Fig. 1 The kynurenine pathway

metabolized in different pathways. The serotonin pathway is responsible for the synthesis of the important neurotransmitter serotonin, which can be converted to melatonin. In the human brain, as in most mammalian tissues, 95 % of tryptophan is catabolized through the kynurenine pathway (reviewed by Vamos et al. 2009) (Fig. 1). This metabolic cascade is responsible for the synthesis of nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), coenzymes which are essential for many

biological processes, such as the control of the energy metabolism of cells, DNA repair, and transcription. The other metabolites of this pathway, collectively termed "kynurenines," have been shown to play important roles in the nervous and immune systems and to be involved in the pathophysiology of a growing number of neurological diseases (Ogawa et al. 1992; Stoy et al. 2005; Hartai et al. 2005; Robotka et al. 2008b; Guidetti et al. 2006).

The first step in this cascade is the enzymatic degradation of tryptophan by indoleamine 2,3-dioxygenase (IDO) or tryptophan 2,3-dioxygenase (TDO) to formylkynurenine, which is converted by arylformamidase to L-kynurenine (L-KYN). The pathway then divides into three main branches. The first branch ends with the synthesis of kynurenic acid (KYNA) through the transamination of L-KYN, a metabolic step catalyzed by the kynurenine aminotransferases (KATs) (Rossi et al. 2008). It was first believed that there are two main KAT isoforms in the brain (Okuno et al. 1991). The KATs are mainly localized in the astrocytes (Du et al. 1992), but they are also present in neurones in the hippocampus, in the striatum (Knyihar-Csillik et al. 1999), and in most of the neurones in the medulla and spinal cord (Kapoor et al. 1997). Early studies indicated that under physiological pH conditions, KAT-II has higher substrate specificity for KYN than KAT-I and that in most brain regions, KYNA can be attributed primarily to KAT-II activity (Okuno et al. 1991; Guidetti et al. 1997; Kiss et al. 2003). The results of recent experiments relating to the pH profile of human KAT-I indicated that under physiological pH conditions, it is able to catalyze L-KYN to KYNA (Han et al. 2004); hence, it may also play an important role in kynurenine metabolism. Recently, another member of the KAT family was discovered, the KAT-III isoform, which exhibits a number of similarities to KAT-I but appears to have no activity in the human brain (Yu et al. 2006). Whereas the main enzyme of KYNA synthesis in the human and the rat brain is KAT-II, recent studies revealed that the most important enzyme in mice is KAT-IV, which has proved to be identical to mitochondrial aspartate aminotransferase (mtAAT) (Guidetti et al. 2007; Han et al. 2010). The four KAT isoforms have different pH optima and temperature preferences (Han et al. 2010).

L-KYN can also serve as a substrate for kynureninase, giving rise to anthranilic acid (ANA). The third main branch of the kynurenine pathway comprises a sequence of enzymatic steps which ends in the synthesis of NAD. This cascade is responsible for the formation of free radical generators 3-hydroxykynurenine (3-HK) and 3-hydroxyanthranilic acid (3-HANA) and the neurotoxic compound quinolinic acid (QUIN). The first of these steps is to yield 3-HK that involves the action of kynurenine 3-monooxygenase (KMO; kynurenine-3-hydroxylase), which is then degraded by kynureninase into 3-HANA. This metabolite, which may also be generated from ANA, is then converted by 3-HANA-oxygenase to 2-amino-3-carboxymuconate-semialdehyde, an unstable intermediate which is transformed nonenzymatically into QUIN. Finally, QUIN is transformed in consecutive steps involving the enzymatic action of phosphoribosyltransferase to furnish nicotinamide and NAD.

The enzymatic machinery for this pathway is present in both the brain and the periphery, but the metabolic activity differs under physiological and

pathophysiological conditions. Under physiological conditions, this pathway has a much higher capacity at the periphery, while during inflammatory processes localized to the central nervous system (CNS), more than 98 % of the L-KYN and QUIN result from local synthesis in the brain (Kita et al. 2002). KYNA and QUIN are present in nanomolar concentrations in the human cerebrospinal fluid (CSF) (Moroni 1999; Schwarcz and Pellicciari 2002; Erhardt et al. 2004), while the concentration of KYNA in the human brain tissue is assumed to be 0.2–1.5 μM (Moroni et al. 1988; Turski et al. 1988). The neuroactive metabolites KYNA and QUIN cross the blood–brain barrier to only a limited extent, whereas their precursor L-KYN is able to cross it well (Fukui et al. 1991).

Within the CNS, the enzymes are differently distributed between the different subtypes of glial cells. Many studies have indicated that the astrocytes harbor hardly any KMO and therefore contribute more significantly to the synthesis of KYNA. In contrast, the microglial cells contain little KAT and hence are primarily responsible for the formation of QUIN (Guillemin et al. 2001; Lehrmann et al. 2001; Kiss et al. 2003).

3.2 Quinolinic Acid and Other Kynurenines with Neurotoxic Properties

QUIN is a weak competitive agonist of the NMDA receptors containing NR2A and NR2B subunits (Stone and Perkins 1981; de Carvalho et al. 1996). QUIN has been reported to be involved in the pathogenesis of several neurodegenerative disorders (Schwarcz et al. 1984; Klivenyi et al. 2004). Early studies yielded evidence that the administration of QUIN leads to a neurotoxic effect and may result in neuronal death in cortical cell cultures (Kim and Choi 1987). In vivo it has been observed that QUIN produces axon-sparing lesions in the rat brain (Schwarcz et al. 1983), which are similar to those seen in Huntington's disease (Beal et al. 1986). Intrastriatal QUIN injection is therefore a widely used experimental animal model for the study of Huntington's disease. It has proved to be neurotoxic in a number of studies conducted in recent years, but its neurotoxic effect involves several processes besides NMDA receptor agonism. It has become clear from the results that QUIN causes endogenous antioxidant depletion, contributes to the generation of free radicals (Behan et al. 1999; Rodriguez-Martinez et al. 2000), and also induces lipid peroxidation (Rios and Santamaria 1991). Moreover, QUIN has been confirmed to influence the glutamate metabolism, as it can enhance presynaptic glutamate release and inhibit glutamate uptake by astrocytes (Connick and Stone 1988; Tavares et al. 2002). Plasma levels of QUIN are elevated in Parkinson's disease patients (Ravikumar et al. 2000). Human studies revealed that QUIN levels are also increased in early stages of Huntington's disease (Guidetti et al. 2004).

3-HK and 3-HANA are potent neurotoxic agents experimentally demonstrated to be able to induce apoptosis in cultured cells (Morita et al. 1999). 3-HK and 3-HANA also contribute to the production of free radicals and elevation of the oxidative stress level. Under physiological conditions, the concentration of 3-HK is

within the nanomolar range, but there is evidence that under certain pathological conditions, it can reach micromolar levels (Okuda et al. 1998; Pearson and Reynolds 1991). The level of 3-HANA, a metabolite produced from 3-HK or ANA, is elevated in Huntington's disease and Parkinson's disease (Ogawa et al. 1992; Pearson and Reynolds 1992).

3.3 The Endogenous Neuroprotectant Kynurenic Acid

KYNA, one of the neuroactive metabolites of the kynurenine pathway, displays broad-spectrum antagonistic properties of ionotropic EAA receptors (Stone and Connick 1985). KYNA is an endogenous glutamate receptor antagonist of AMPA, NMDA, and kainate types, with the highest affinity for NMDA receptors (Perkins and Stone 1985; Swartz et al. 1990). At low micromolar concentrations (EC50 = 7.9–15 μM), it has a high affinity for the strychnine-insensitive glycine-binding site of the NMDA receptors and blocks it in a competitive way, while at 10–20 times higher concentrations, it exhibits an antagonistic effect of the glutamate-binding site too (EC50 = 200–500 μM) (Birch et al. 1988; Kessler et al. 1989). High concentrations of KYNA exert an anticonvulsant effect and protect the neurones from excitotoxic injury.

In vitro studies have revealed that KYNA may be capable of the direct activation of the G protein-coupled receptor GPR35 (Wang et al. 2006; Ohshiro et al. 2008). KYNA was earlier recognized to display antagonistic properties at the AMPA receptors, and it has only recently become clear that, depending on its concentration, it may also have another mechanism of action. In micromolar concentrations, KYNA inhibits AMPA receptors, whereas in nanomolar concentrations, it acts as a facilitator, binding to a positive modulatory-binding site at the AMPA receptor (Prescott et al. 2006; Rozsa et al. 2008). This dose-dependent dual effect indicates that KYNA may play an important role in the regulation of neurotransmission. KYNA has proved to exert an antagonistic effect on the presynaptic α7-nicotinic acetylcholine (α7-nACh) receptor too, inhibiting its activity in a noncompetitive manner, while increasing the expression of non-α7-nACh receptors (Hilmas et al. 2001). This effect may contribute to the generation of the sensory deficit caused by KYNA (Shepard et al. 2003; Chess and Bucci 2006), and the evidence suggests that it is mediated by its binding to sites located on the N-terminal domain of the α7-nACh receptor subunit (Pereira et al. 2002). Recent studies have revealed that KYNA in low concentrations (30–100 nM) inhibits glutamate release at the presynaptic nACh receptors, thereby contributing to a neuroprotective effect (Carpenedo et al. 2001; reviewed by Zadori et al. 2011). These results support the assumption that the kynurenine pathway is involved in the regulation of glutamatergic and cholinergic neurotransmission in the brain.

An increased level of KYNA was earlier proved to have sedative and anticonvulsive effects (Carpenedo et al. 1994). It was later demonstrated that it is able to reduce neuronal damage in brain ischaemia (Cozzi et al. 1999). There is a growing body of evidence that alterations in the kynurenine metabolism play important roles in the pathomechanisms of neurodegenerative disorders. Human postmortem studies have revealed elevated 3-HK levels in the substantia nigra and the putamen of

Parkinson's disease patients, while the ratio L-KYN/3-HK is decreased (Ogawa et al. 1992). In Huntington's disease patients, the KYNA levels are significantly decreased in the striatum, cortex, and CSF (Beal et al. 1990, 1992). KYNA levels are elevated in Alzheimer's disease (Baran et al. 1999) and in schizophrenia (Schwarcz et al. 2001; Nilsson et al. 2005), playing a part in the cognitive decline. A number of experiments have demonstrated an elevated KYNA level or L-KYN exerts a neuroprotective effect in brain ischaemia (Nozaki and Beal 1992; Gigler et al. 2007; Robotka et al. 2008a; Sas et al. 2008).

4 Conclusion

Excitotoxicity is a major factor in the pathomechanism of several neurological disorders. The overstimulation of EAA receptors results in an excessive influx of Ca^{2+} into the cells, subsequently initiating downstream pathological processes, resulting in damage to the cell structure, mitochondrial dysfunction, and an energy impairment leading to apoptosis. The kynurenine pathway is the main route of the metabolism of tryptophan in the mammalian brain. This pathway generates various neuroactive compounds which play an important role in the regulation of neurotransmission. There is accumulating evidence that imbalances in the kynurenine metabolism are involved in the pathomechanism of several neurodegenerative disorders, thereby providing a valuable target for future therapeutic strategies.

Neuroprotective Strategies in Amyotrophic Lateral Sclerosis: Modulation of Neurotransmittory and Neurotrophic Input to Motor Neurons

Pierre-François Pradat and Luc Dupuis

Contents

Abstract

Amyotrophic lateral sclerosis (ALS) is an adult-onset degenerative disease characterized by the selective progressive death of lower and upper motor neurons. Although its primary cause remains unknown, multiple pathogenic pathways have been identified. The major pathological event in ALS is the degeneration of lower motor neurons (LMNs), and it is thought to be the ultimate cause of death. Thus, neuroprotection of LMNs is assumed to be a reasonable target for

treating ALS. This assumption guided most of research effort in the last 20 years to develop neuroprotective strategies able to preserve the remaining LMNs. Three major possibilities have been explored and are presented in this review. First, it is thought that LMN survival and degeneration are regulated by neurotransmittory inputs that LMN integrates. Several experimental and imaging studies have shown an impairment of multiple neuronal types innervating motor neurons, in particular glycinergic interneurons, glutamatergic input from proprioceptive type Ia fibers, and serotonergic neurons. The abnormalities in glutamatergic input proved especially fruitful since they led to the discovery of riluzole. A second potential neuroprotective strategy would be to modulate neurotrophic input to motor neurons. Indeed, studies of motor neuron development have shown that their survival is governed by neurotrophic input from its muscle target or from surrounding glia. Thus, modulating neurotrophic support to LMN might be a therapeutic strategy, although the multiple clinical trials based on this possibility were up to now unsuccessful. A last possibility to provide neuroprotection in ALS would be to indirectly modulate the motor neuron survival through action on events occurring outside this cell type, in particular inflammation or abnormal energy metabolism.

Keywords

ALS • GABA • Glutamate • Glycin • Interneuron • Motor neuron • MRI • Neurotrophic factor • PET • Serotonin

List of Abbreviations

^{1}H-MRS	Primary motor area, M1, proton magnetic resonance spectroscopy
5-HT	5-hydroxytryptamine
5-HTP	5-hydroxytryptophan
ALS	Amyotrophic lateral sclerosis
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
BDNF	Brain-derived neurotrophic factor
CNTF	Ciliary-derived neurotrophic factor
CSF	Cerebrospinal fluid
DTI	Diffusion tensor imaging
EAAT2	Excitatory amino acid transporter type 2
Exc.	Excitatory
GABA	Gamma-aminobutyric acid
GDNF	Glial cell line-derived neurotrophic factor
Glu	Glutamate
Gly	Glycine
IGF-1	Insulin-like growth factor-1
IN	Interneuron
inh.	Inhibitory
LMN	Lower motor neuron
mRNA	Messenger ribonucleic acid

MT	Magnetization transfer
NMDA	*N*-methyl-D-aspartate
PET	Positron emission tomography
PM	Premotor
SICI	Short-interval intracortical inhibition
SMA	Supplementary motor area
SOD1	Superoxide dismutase type 1
UMN	Upper motor neuron
VEGF	Vascular endothelial growth factor
VGLUT2	Vesicular glutamate transporter type 2

1 Introduction

Amyotrophic lateral sclerosis (ALS) is the major adult-onset motor neuron disease with an incidence of 2–3/100,000. ALS typically affects lower motor neurons (LMNs), which degenerate, leading to a progressively lethal paralysis. ALS symptoms might start in limbs (spinal onset, 2/3 of cases) or in muscles controlling speech and/or swallowing (bulbar onset, 1/3 of cases). Apart from LMN involvement, ALS is associated with degeneration of upper motor neurons (UMNs), and most patients develop UMN signs, in particular hyperreflexia and spasticity. A number of patients also display focal or more widespread frontal lobe disease (Schreiber et al. 2005). Other non-motor symptoms include major defects in energy metabolism, typified by weight loss, muscle wasting, and hypermetabolism (Dupuis et al. 2011). Death of ALS patients typically occurs within 2–5 years after diagnosis, but a huge heterogeneity among patients exists, with survival after diagnosis ranging from few weeks to more than 30 years (Chio et al. 2009).

The major pathological event in ALS being degeneration of LMNs, it is thought to be the ultimate cause of death, thus neuroprotection of LMNs is assumed to be a reasonable target for treating ALS. This assumption indeed guided most of research effort in the last 20 years to develop neuroprotective strategies able to preserve the remaining LMNs. Three major possibilities have been explored and will be developed sequentially in this chapter (Fig. 1). First, it is thought that LMN survival and degeneration is regulated by neurotransmittory inputs that LMN integrates, in particular glutamatergic input. This possibility proved especially fruitful since it culminated in the discovery of riluzole. Second, studies of LMN development have shown that LMN survival is governed by neurotrophic input from its muscle target or from surrounding glia. Thus, modulating neurotrophic support to LMN might be a therapeutic strategy. Third, most recent results in ALS field suggested that neuroprotection of LMN might be indirectly achieved through modulation of LMN independent events such as inflammation or nutrition.

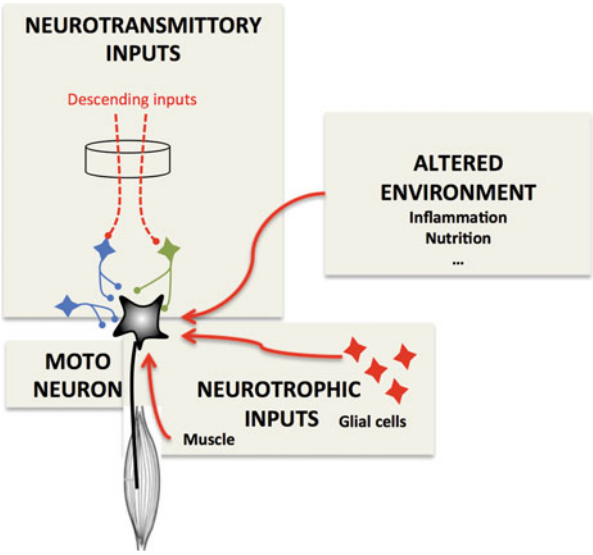

Fig. 1 Three ways to achieve neuroprotection in ALS. Lower motor neurons might be rescued by altering their neurotransmittory input, by improving their neurotrophic support, and/or by modifying their altered, potentially toxic environment

2 Neuroprotection Through Modulation of Neurotransmittory Inputs to Motor Neurons

In this first section, we will review how input to motor neurons might be modulated to achieve neuroprotection in ALS.

2.1 Major Inputs to Motor Neurons

Motor neuron activity is controlled by two types of inputs. First, activation of ionotropic receptors, either excitatory or inhibitory, will generate postsynaptic currents that summate at the soma. If the net resulting current is sufficient to elicit an action potential, then the motoneuron discharge, which triggers the muscle contraction. Second, neuromodulatory inputs, through metabotropic receptors, activate intracellular signalling pathways that modulate the responses to ionotropic receptors. Since electrical activity is critical in the survival of any neuron, it is likely that identifying the abnormalities of inputs to motor neurons and correct these through pharmacological means will provide therapeutic strategies.

Motor neurons receive inputs from the periphery (in particular proprioceptive neurons) and from central projections. A schematic drawing of inputs to LMNs is presented in Fig. 2. There are about 100,000 synaptic boutons per lumbar motor neurons in cat (Rekling et al. 2000). A majority of these boutons are inhibitory, either GABAergic or glycinergic. Such inhibitory connections come from Renshaw cells that mediate recurrent inhibition of motor neurons and from other spinal inhibitory interneurons, which integrate numerous descending and peripheral

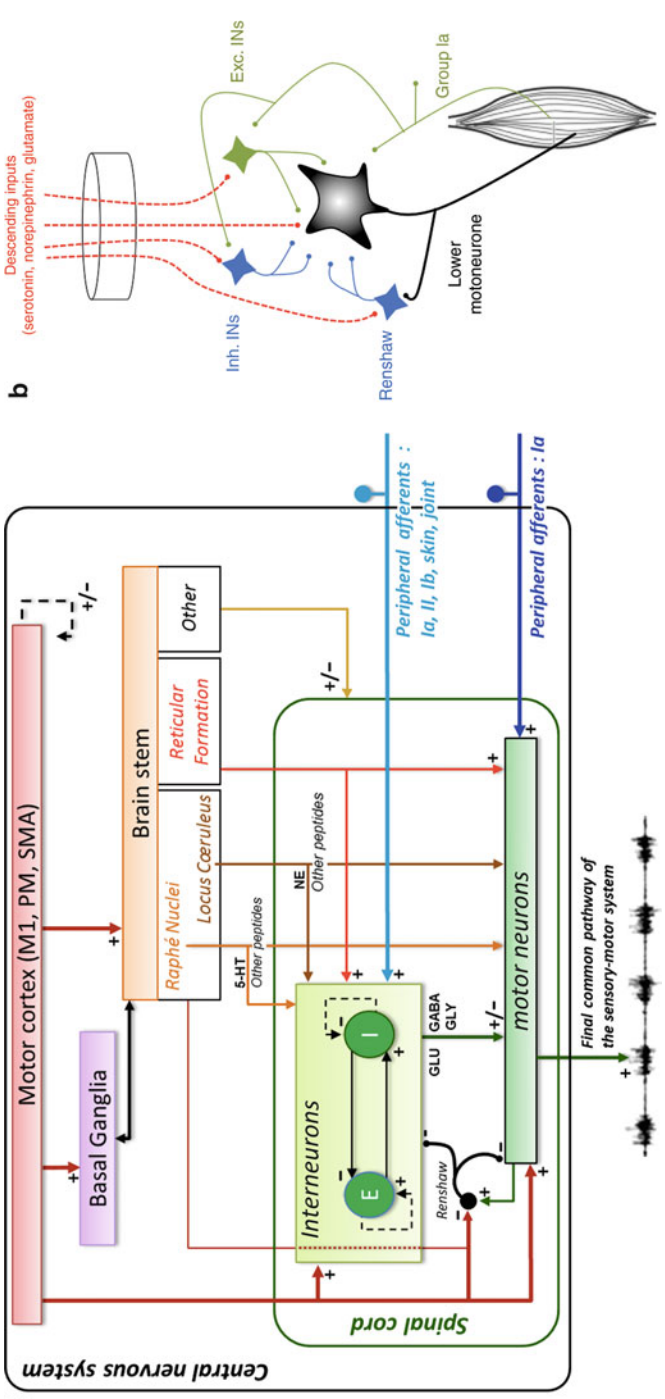

Fig. 2 Motor neurons receive afferences from the central and peripheral nervous system. These afferences project either directly to motor neurons (excitatory glutamatergic inputs) or indirectly through spinal interneurons. Inputs from interneurons are mainly inhibitory, either either GABAergic or glycinergic, or excitatory, glutamatergic. Inhibitory interneurons include the Renshaw cells, glycinergic, which are activated by upper motor neurons and the interneurons, either GABAergic or glycinergic, which are activated by peripheral sensory neurons from skin and muscle spindles. Type Ia fibers coming from muscle spindles are glutamatergic and directly innervate motor neurons.

inputs. Inhibitory projections from brainstem nuclei and nucleus tractus solitarius also innervate spinal motor neurons.

About one fifth of synaptic boutons are glutamatergic, and include projections from type Ia muscle spindles and rubrospinal neurons. In rodent, corticospinal neurons do not directly project to motor neurons, but to spinal cord interneurons, thus only indirectly modulating motor neuron activity. In contrast, corticospinal neurons directly innervate motor neurons in primates to control fine movements. Spinal motor neurons also receive extensive projections from monoaminergic neurons from the brainstem, mostly from noradrenergic and serotonergic neurons. Many peptides are co-localized with monoaminergic projections, suggesting that they might be co-released with either serotonin or norepinephrine.

2.2 Abnormalities of Inputs to Motor Neuron in ALS

A number of cell types innervating motor neurons have been shown to degenerate in ALS animal models and/or patients. In this section, we will present the abnormalities by neurotransmitter.

2.2.1 GABAergic Abnormalities

A number of GABAergic abnormalities have been documented in ALS.

Neuroimaging studies suggest that a loss of central nervous system inhibitory influence, in particular GABA, plays a role in ALS pathogenesis. Flumazenil binds to the benzodiazepine subunit of the GABA-A receptor present on neurons of the cerebral cortex. Using positron emission tomography (PET), a study showed a widespread loss of binding of [^{11}C]-flumazenil in sporadic ALS patients. The abnormalities were less extensive in patients with SOD1-linked familial ALS patients, suggesting that GABAergic neurotransmission may be less severely impaired in these cases (Lloyd et al. 2000). Recent advances in proton magnetic resonance spectroscopy (^{1}H-MRS) allow direct quantification of GABA in the cortex (Zhu et al. 2011). Using high resolution 3 Tesla edited ^{1}H-MRS, a study in a small number of subjects showed that decreased levels of GABA were present in the motor cortex of ALS patients compared to healthy controls (Foerster et al. 2012).

What could be the consequences of loss of cortical GABA? Studies with transcranial motor magnetic stimulation (TMS) suggest that the cortical hyperexcitability observed in ALS patients could be due to alterations in GABA-A signalling. In this technique, the intensity required to stimulate the motor cortex as well as the duration of the cortex silent period and the response to paired stimulation are measured, providing a good estimate of cortical excitability (Eisen and Weber 2001). The increased excitation observed in ALS patients may reflect a combination of an intrinsic hyperexcitability of the corticomotoneurons themselves and reduced inhibition due to dysfunction of cortical inhibitory neurons. Although there are some conflicting data (Attarian et al. 2009), a loss of inhibition is suggested by several studies using paired-pulse stimulation that showed a decreased short-interval intracortical inhibition (SICI)

attributed to GABA-A receptors (Zanette et al. 2002; Yokota et al. 1996; Vucic and Kiernan 2006; Desiato et al. 1999; Caramia et al. 2000).

The role of cortical hyperexcitability in ALS remains debated, in particular with respect to its timing. Some authors have suggested it is an early feature (Mills and Nithi 1997; Prout and Eisen 1994; Caramia et al. 2000) whether others argued that it was a late phenomenon (Zanette et al. 2002). At least in SOD1-linked familial ALS, results obtained using a threshold-tracking TMS technique suggested that reduction of SICI is an early phenomenon that may precede the development of clinical symptoms (Vucic et al. 2008). Indeed, reduction of SICI was observed in three asymptomatic SOD1-mutation carriers who subsequently developed typical clinical features of ALS. A question is whether changes in excitability have implications on clinical symptoms. A study using threshold-tracking TMS showed a correlation between the reduction of SICI and fatigue (Vucic et al. 2011). The authors concluded that maladaptation of cortical processes related to degeneration of inhibitory GABAergic intracortical circuits may have a role in the development of fatigue in ALS.

All the previous results were obtained in cortical regions. It would be of high interest to obtain PET imaging or MRS data on inhibitory activity at the level of the spinal cord in ALS patients. However, technical limitations render such data currently inaccessible.

The GABAergic system has been poorly studied in animal models of ALS. In the few studies existing, GABAergic projections to motor neurons appeared much less affected than glycine interneurons (Chang and Martin 2009; Petri et al. 2005). However, the response of motor neurons to GABA might be slightly abnormal (Carunchio et al. 2008).

2.2.2 Glycinergic Abnormalities

In patients, an impairment of Renshaw cells has been suggested by electrophysiological studies testing the mixed nerve silent period (Shefner and Logigian 1998) or using a conditioned H-reflex technique (Raynor and Shefner 1994). In contrast to spastic spinal cord-injured patients, spastic ALS patients showed strikingly reduced recurrent inhibition, suggesting that reduction of the recurrent inhibition suggested a different physiology for spasticity in ALS compared to spinal cord transection (Raynor and Shefner 1994). The role of Renshaw cells is however controversial in ALS since more distal muscles, more affected in ALS, lack recurrent inhibition (Mazzocchio and Rossi 2010).

The glycinergic system, and in particular the Renshaw cells, have been studied in more detail in experimental models of ALS. First, Renshaw cells lose connection with motor neurons in end-stage mice (Chang and Martin 2009; Wootz et al. 2012), and this might contribute to motor neuron hyperexcitability. Consistent with this, several authors described degeneration of glycinergic interneurons on spinal motor neurons of SOD1(G93A) mice and showed that glycinergic currents are decreased in SOD1(G93A) motor neurons (Chang and Martin 2009, 2011; Martin and Chang 2012). The pathology in glycinergic neurons appears however to follow the pathology of motor neurons, suggesting that it is either a very late event or a consequence of degeneration of motor neurons (Hossaini et al. 2011).

A recent study in worms however suggested that, at least in this model, glycinergic interneurons are early and strongly affected by the disease process (McGown et al. 2012). More research is needed to ascertain this point in vertebrates.

2.2.3 Glutamatergic Abnormalities

Glutamatergic abnormalities in ALS have been the subject of intense research in the last 30 years. Most research focused on abnormalities of glutamate release or reuptake by astrocytes as the source of increased glutamate in the cerebrospinal fluid (CSF). The contribution of neurons themselves has been scarcely studied. Direct glutamatergic innervation has been reported to be decreased in one study (Schutz 2005), but an opposite result has been recently published (Sunico et al. 2011). Consistent with an importance of glutamatergic innervation in motor neuron survival, decreasing vesicular glutamate transporter VGLUT2, responsible for a major part of glutamate release on motor neurons, decreased motor neuron degeneration, but did not have influence animals survival (Wootz et al. 2010). Although only indirectly innervating LMN in mice, it is clear that corticospinal motor neurons, a major glutamatergic population, degenerate in ALS mouse models (Ozdinler et al. 2011). It has been suggested a possible alteration of glutamatergic proprioceptive Ia afferents originating from muscle spindles primary endings, which have monosynaptic projections onto motor neurons. An impairment of the sensory pathways, with a degeneration of the dorsal funiculus, has been detected in animal model of SOD1-linked ALS (Guo et al. 2009). In a rat model of ALS, an impairment of dorsal roots was detected at an early and asymptomatic stage when motor neuron cell bodies did not appear to be compromised (Malaspina et al. 2010). Interestingly, sensory neurons that are functionally linked to muscle-spindle afferents by large-caliber myelinated fibers, corresponding to Ia fibers, were affected. The authors stated that these findings supported the pathogenic relevance in the development of the disease of sensory inputs coming from the muscles. Interestingly, two recent studies in a mouse model of another motoneuron degenerative disease, spinal muscular atrophy, demonstrated an early impairment of proprioceptive inputs to motor neurons. It was speculated that even a modest loss of proprioceptive function may have implications on motoneuron activity, since it has been estimated that one single Ia afferent can sprout collaterals and can develop over 2,700 synapses with up to 300 motoneurons in a motor neuron pool that innervates the medial gastrocnemius (Mendell and Henneman 1971).

Recently a spinal magnetic resonance imaging study showed that an impairment in the dorsal column, containing large myelinated sensory fibers, occurred at an early stage of the disease (Cohen-Adad et al. 2012) (Fig. 3). Together with findings in animal models, these in vivo findings in ALS patients suggest that the modifications glutamatergic input from type Ia muscle spindles to motoneurons may play a role in the pathogenesis of ALS.

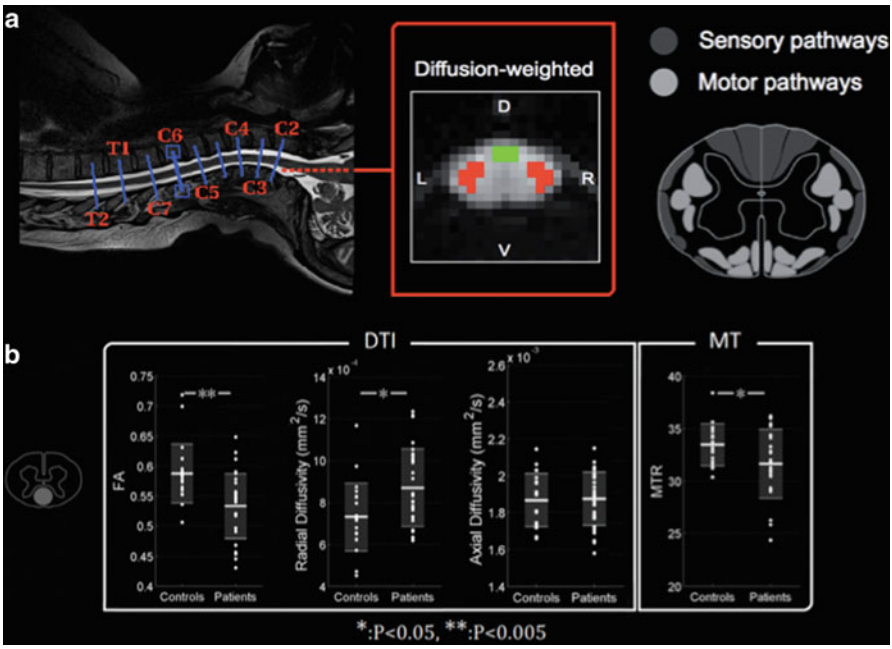

Fig. 3 Magnetic resonance imaging abnormalities of sensory pathways in ALS patients. (**a**) Regions of interest were selected in the lateral segment (turquoise blue) to include most of the lateral cortico-spinal tract and in the dorsal segment (purple) to include most of the dorsal columns (**b**) Individual plots of MRI metrics averaged in the dorsal columns. Differences were also detected in the lateral cortico-spinal tract (not shown). MTR stands for Magnetization Transfer Ratio.

2.2.4 Serotonergic Abnormalities

Besides glutamatergic neurons, other long projection neurons targeting the motor neurons are affected by the disease, although this area is still largely unexplored. In particular, it was recently shown that serotonergic neurons profoundly degenerate in both patients and animal models. This degeneration is variable between nuclei and is mostly neuritic, with some loss of cell bodies. Most importantly, this degeneration contributes to spasticity in animal models (Dentel et al. 2012). Other consequences of serotonergic loss in ALS are still unexplored.

2.3 Strategies Targeting Glutamate

Multiple therapeutic strategies have been designed to target glutamate in ALS (Van Den Bosch et al. 2006). Indeed, glutamate levels are increased in the CSF of ALS patients, and motor neurons are exquisitely sensitive to increased glutamate because they express calcium permeable AMPA receptors, due to the very low levels of the GluR2 subunit on motor neurons and to abnormal editing of its mRNA (Kawahara and Kwak 2005; Shaw and Eggett 2000). This high permeability to

calcium, combined with poor buffering capacity of calcium in the cytoplasm of motor neurons, likely causes high cytosolic calcium increases in motor neurons in response to excess of glutamate, leading to cell death through excitotoxicity (Van Den Bosch et al. 2006). Multiple antiglutamatergic strategies have been built on this framework.

2.3.1 Riluzole

Bensimon and collaborators demonstrated in 1994 that riluzole improved survival in ALS patients (Bensimon et al. 1994). A second larger confirmatory study published 2 years after this initial breakthrough confirmed this protective effect (Lacomblez et al. 1996a, b). Taking into account safety results, it was concluded from these two trials that the 100 mg dose of riluzole has the best benefit-to-risk ratio and that riluzole increases survival of patients with ALS. A meta-analysis of published riluzole trials in ALS has been recently performed and confirmed the increase in lifespan of ALS patients under riluzole (Miller et al. 2012). Taken together, interventional and population-based studies converge to demonstrate a consistent positive effect of riluzole on the survival of ALS patients. Apparently, this effect is stronger in patients treated early after symptom onset and in patients with bulbar onset. Although 3 months survival benefit is significant, there is no apparent slowing of disease progression. To our knowledge, riluzole is the only drug in the field of neurodegenerative diseases that proved increasing lifespan in multiple interventional trials. However, the underlying mechanism, long postulated to be glutamatergic, is extremely unclear, and multiple studies point to riluzole being rather an inhibitor of sodium persistent inward currents, rather than an antiglutamatergic drug (Bellingham 2011).

2.3.2 Other Antiglutamatergic Agents

Results of therapeutic trials testing other antiglutamatergic agents have been disappointing. Gabapentin, which presumably acts through inhibition of glutamate biosynthesis, showed promising preclinical effects in SOD1 mice (Gurney et al. 1996), but a randomized clinical trial was negative in ALS patients (Miller et al. 2001). Lamotrigine, which is thought to inhibit glutamate release, also failed to demonstrate a beneficial effect in ALS patients (Ryberg et al. 2003). A potential therapeutic strategy to target excitotoxicity consists in the blockade of selected glutamate receptors. However, phase III clinical trials were negative in ALS when testing AMPA receptors blockers such as talampanel or topiramate (Cudkowicz et al. 2003). Clinical trial with NMDA receptor antagonists, dextromethorphan (Blin et al. 1996) or memantine (de Carvalho et al. 2010), was unsuccessful as well. The excitatory amino acid transporter EAAT2 is one of the major glutamate transporters expressed predominantly in astroglial cells and is responsible for 90 % of total glutamate uptake. The beta-lactam antibiotic ceftriaxone was shown to increase EAAT2 levels and to prevent motor neuron death in an animal model (Rothstein et al. 2005). However, a therapeutic trial recently failed to show a therapeutic effect in ALS patients (Cudkowicz 2012).

2.4 Other Potential Strategies (Serotonin, Glycine)

To our knowledge, no drug based either on glycinergic transmission has been rigorously tested in an ALS clinical trial. Preclinical research is to be done. Concerning serotonergic transmission, serotonin levels are decreased in ALS blood (Dupuis et al. 2010), and decreased serotonin is responsible for the development of spasticity in ALS models (Dentel et al. 2012). Interestingly, providing ALS mice with serotonin precursor 5-hydroxytryptophan (5-HTP) increased their lifespan (Turner et al. 2003). However, here again, no drug targeting specific serotonin receptor subtype has been tested in models or patients.

3 Modulation of Motor Neuron Loss Through Increased Neurotrophic Activity

3.1 Neurotrophic Factors: A Potential Therapeutic Strategy

It is widely recognized that providing more trophic support to dying motor neurons might slow down their degeneration. This is supported by a number of observations suggesting that neurotrophic factor expression and/or activity might be abnormal in ALS. For instance, expression of glial cell line-derived neurotrophic factor (GDNF), a major neurotrophic factor, is increased in ALS muscle (Lie and Weis 1998), as a likely consequence of denervation. Indeed, there are reported abnormalities in c-Ret, the GDNF receptor, in ALS motor neurons (Mitsuma et al. 1999; Ryu et al. 2011). Last, overexpressing GDNF is protective in multiple ALS models, using various mode of administration (Li et al. 2003, 2007 Manabe et al. 2002, 2003; Suzuki et al. 2008).

A second example is vascular endothelial growth factor (VEGF): VEGF expression is decreased in ALS spinal cord (Anagnostou et al. 2010) and in mouse models, and such a decrease is on its own sufficient to trigger ALS-like disease in mouse. Moreover, overexpression of VEGF is able to provide strong protection to animal models (Azzouz et al. 2004; Devos et al. 2004; Lambrechts et al. 2003; Oosthuyse et al. 2001; Storkebaum et al. 2005; Van Den Bosch et al. 2004; Wang et al. 2007).

Besides documented alterations in ALS, trophic factors are in general of interest in the treatment of ALS. Indeed, during development, motor neurons are produced in excess, and those that are unable to contact efficiently skeletal muscles are eliminated (Kanning et al. 2010). It is thus possible that similar mechanisms of survival might slow down degeneration of LMNs in adults affected with ALS. During development, survival of motor neurons is strictly under the control of the innervated limb through the production of multiple trophic factors that include GDNF or ciliary-derived neurotrophic factor (CNTF). During the last 20 years, a plethora of motor neurotrophic factors have been identified which are able in vitro to provide protection to isolated cultured motor neurons. Each of these neurotrophins is thus a potential candidate for ALS therapy.

3.2 Treatment with Neurotrophic Factors in ALS Patients

Despite promising preclinical studies, direct administration of neurotrophic factor in human ALS patients failed to show a therapeutic effect in ALS patients. The major agent studied were brain-derived neurotrophic factor (BDNF) (BDNF Study Group 1999), CNTF (Miller et al. 1996), and insulin-like growth factor-1 (IGF-1) (Mitchell et al. 2007; Sorenson et al. 2008; Borasio et al. 1998; Lai et al. 1997). Clinical trial with xaliproden, an orally administered non-peptide compound that promotes the secretion of several endogenous motor neuron growth factors, failed to demonstrate a statistically significant therapeutic effect (Meininger et al. 2004). A human study with intraventricular injection of VEGF is currently in a phase I/II clinical trial.

4 Conclusion

The last 20 years of research in the field of neuroprotection in ALS have been very successful for identifying potential strategies to improve the survival of motor neurons in ALS mouse models. However, none of these potential treatments successfully translated to the clinics. This failure might be due to multiple causes, and we would like to highlight two of these potential causes.

First, research efforts were almost exclusively devoted to identify compounds and/or strategies to provide protection to motor neuron cell body. However, such a protection is now known to be largely insufficient (Dupuis and Loeffler 2009). For instance, we and others have shown that providing a complete protection of motor neuron cell bodies does not ameliorate profoundly the phenotype of ALS mice because the remaining LMNs are still denervated and do not reinnervate affected muscles (Dewil et al. 2007; Gould et al. 2006; Rouaux et al. 2007). Thus, it is critical to identify the mechanisms that cause synapse loss, rather than motor neuron loss.

Second, despite it is largely assumed that ALS patients die of motor neuron degeneration, multiple events, many of them not occurring in motor neurons, strongly contribute to disease pathogenesis. In particular, despite weight loss is a strong predictor of survival, its causes remain unknown (Dupuis et al. 2011). The recent examples of microglial (Boillee et al. 2006) or serotonergic (Dentel et al. 2012) contributions to clinical picture should illuminate our need to understand how non-motoneuronal cell types could be targeted by specific treatments to achieve neuroprotection.

Acknowledgments We thank Veronique Marchand and Caroline Iglesias (UMR-678, INSERM-UPMC, Groupe Hospitalier Pitié-Salpêtrière, Paris, France) for critical reading of the manuscript, particularly physiological and electrophysiological aspects, and for providing us Fig. 1.

Neurotoxicity and ALS: Insights into Pathogenesis

Steve Vucic and Matthew C. Kiernan

Contents

Abstract

Amyotrophic lateral sclerosis (ALS) is a rapidly progressive neurodegenerative disorder of the motor neurons in the spinal cord, brainstem, and motor cortex. While the mechanisms underlying the development of ALS remain to be fully elucidated, evidence is now emerging to suggest that the pathophysiological mechanisms underlying ALS are multifactorial, reflecting a complex interaction between causal genes and local environment. In particular, dysfunction of metabolic pathways including excessive oxidative stress, glutamate excitotoxicity, mitochondrial dysfunction, and defective axonal transport

systems along with abnormalities of nonneuronal supporting cells may cause critical injury to target proteins and organelles within the motor neuron, thereby leading to neurotoxicity and neurodegeneration in ALS. The clinical effectiveness afforded by anti-glutamatergic agents such as riluzole underscores the importance of glutamate excitotoxicity in the development of neurodegeneration in ALS, with anterior horn cell degeneration mediated by corticomotoneuronal hyperexcitability via an anterograde transsynaptic process. This chapter will review current understanding of the pathophysiological mechanisms underlying the development of ALS, with a particular focus on the role of neurotoxicity in mediating neurodegeneration in ALS.

Keywords
ALS • Glutamate excitotoxicity • Neurodegeneration • Neurotoxicity

1 Introduction

Amyotrophic lateral sclerosis (ALS) is a rapidly progressive neurodegenerative disorder of motor neurons in the spinal cord, brainstem, and motor cortex (Kiernan et al. 2011). The ALS phenotype is clinically characterized by the presence of upper and lower motor neuron abnormalities (Kiernan et al. 2011; Vucic et al. 2007; Winhammar et al. 2005), whereby lower motor neuron (LMN) features include fasciculations, muscle wasting, and weakness, while upper motor neuron features include weakness, slowness of movement, increased tone, and hyperreflexia. This unique combination of upper and lower motor neuron abnormalities, not encountered in other neurodegenerative diseases, led Charcot to postulate the mechanism of neuronal involvement in ALS pathogenesis (Charcot and Joffroy 1869). Despite Charcot's initial observations, the precise pathophysiological mechanisms, and even the site of disease onset, remain the subject of ongoing debate (Ravits et al. 2007).

Evidence is now emerging to suggest that the pathogenic mechanisms underlying ALS are multifactorial, reflecting interaction between causal genes and local environment (Boillee et al. 2006a; Kiernan et al. 2011; Vucic and Kiernan 2009; Winhammar et al. 2005). These complex pathways, including oxidative stress, glutamate excitotoxicity, mitochondrial dysfunction, and defective axonal transport systems (Fig. 1), combined with abnormalities of nonneuronal supporting cells such as the astrocytes, may cause injury of critical target proteins and organelles within the motor neuron, thereby resulting in neurotoxicity and degeneration in ALS (Gonzalez de Aguilar et al. 2007; Gros-Louis et al. 2006; Haidet-Phillips et al. 2011; Neusch et al. 2007; Pasinelli and Brown 2006; Patel and Maragakis 2002; Vucic and Kiernan 2009). As such, this chapter will review current understanding of the pathophysiological mechanisms underlying the development of ALS, with a particular focus on the role of neurotoxicity.

1.1 Glutamate-Mediated Excitotoxicity

Glutamate-mediated excitotoxicity appears to be an important mechanism in ALS pathogenesis (Boillee et al. 2006; Kiernan et al. 2011). Glutamate is the major excitatory neurotransmitter in the central nervous system (Heath and Shaw 2002; Watkins and Evans 1981), synthesized from reductive deamination of alpha-ketoglutarate or from the action of amino acids of aminotransferases (Heath and Shaw 2002). Approximately 20% of the total glutamate pool is stored in presynaptic nerve terminals, and during impulse transmission, glutamate is released from presynaptic neurons through the effects of depolarization, diffusing across the synaptic cleft to activate postsynaptic receptors. Their excitatory signal is terminated upon removal of glutamate from the synaptic cleft by specific glutamate reuptake transporters located on both neurons and astrocytes (Dong et al. 1999; Vandenberg 1998). Within presynaptic astrocytes, glutamate is converted into glutamine by the enzyme glutamine synthetase and then returned to the neuron for resynthesis of glutamate (Laake et al. 1995).

Glutamate receptors are broadly classified into ionotropic or metabotropic receptors (Heath and Shaw 2002). Binding of glutamate to its ionotropic receptors results in a conformational change within the receptor, thereby enabling a passage of Na^+ and Ca^{2+} ions through a central pore. Metabotropic glutamate receptors are linked via G-proteins to second-messenger enzymes, which in turn can regulate a host of cellular activities (Simeone et al. 2004). Based on pharmacological studies, glutamate ionotropic receptors are further classified as (i) *N*-methyl-D-aspartate (NMDA), (ii) α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA), and (iii) kainite receptors. This pharmacological classification is supported by cloning studies that have identified six different families of glutamate ionotropic receptors that conform to the original agonist studies (Simeone et al. 2004). *N*-methyl-D-aspartate receptors are permeable to influx of Na^+ and Ca^{2+} and efflux of K^+ (Simeone et al. 2004). An essential feature of NMDA receptors is their voltage-dependent blockade by Mg^{2+} binding within the channel pore, which can be alleviated by depolarization (MacDermott et al. 1986). NMDA receptors are involved in excitatory neurotransmission, which is characterized by a slow rise time and decay. As such, the NMDA receptors are involved in complex physiological processes, such as generation of rhythmic motor activity (Traven et al. 1993), regulation of neuronal migration during embryogenesis (Komuro and Rakic 1993), and memory (Bliss and Collingridge 1993).

The NMDA receptor complex is composed of different subunits derived from 6 genes: NMDAR1 (eight splice variants described), NMDAR2 (A–D), and NMDAR3 (A,B) (Heath and Shaw 2002; Simeone et al. 2004). While the NMDAR1 subunit forms the basic structure of the receptor (Heath and Shaw 2002), the NMDAR2 subunit determines ion channel properties and forms ligand-binding sites (Kutsuwada et al. 1992; Meguro et al. 1992; Michaelis 1998). Functional and pharmacological properties of NMDA receptors are determined through specific combination of NMDAR1 and NMDAR2 subunits (Kutsuwada et al. 1992;

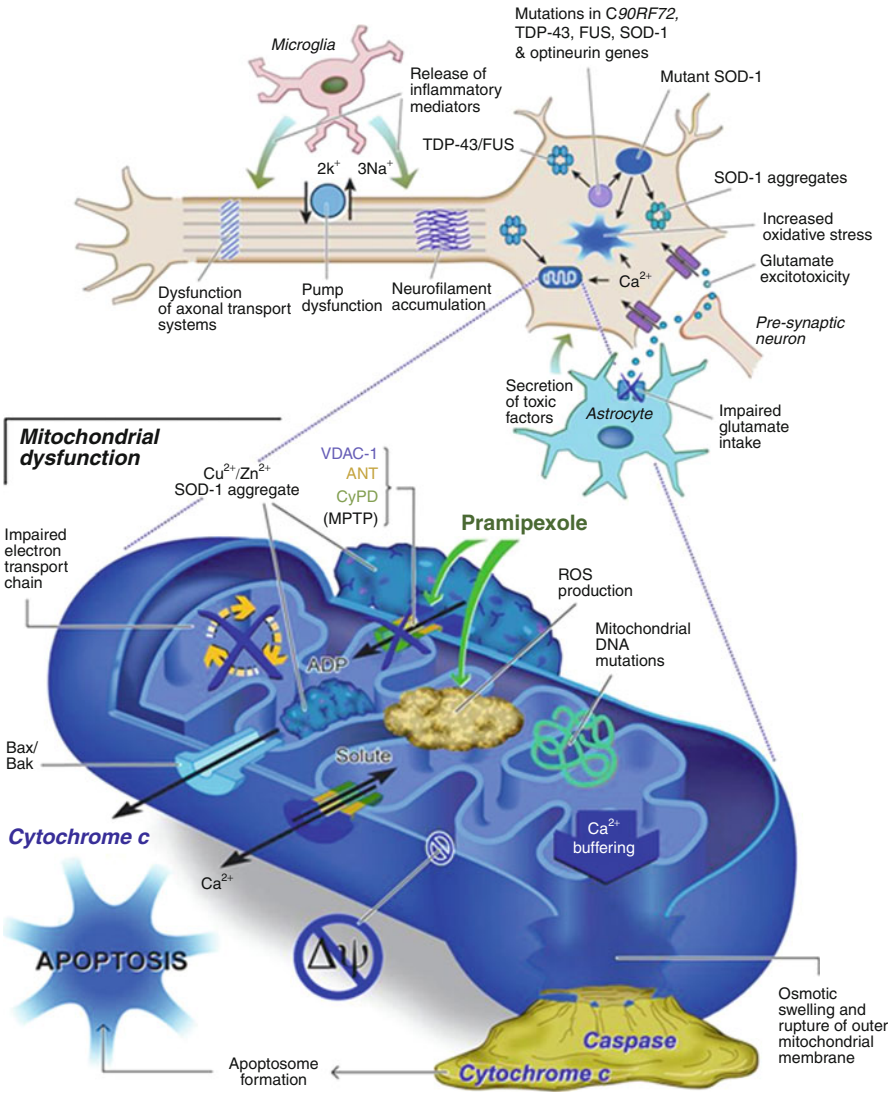

Fig. 1 Multiple interacting pathophysiological mechanisms appear to underlie the development of amyotrophic lateral sclerosis (*ALS*). Glutamate-mediated excitotoxicity is an important mechanism ALS progression and seems to precede the clinical development of ALS. Dysfunction of the excitatory amino acid transporter type 2 (EAAT2), located on astrocytes, in part induces the development of glutamate excitotoxicity via excessive extracellular accumulation of glutamate. In addition, activation of nonneuronal cells (astrocytes and microglia) in ALS results in secretion of proinflammatory cytokines and other cytotoxic factors that ultimately results in further neurotoxicity and degeneration. In conjunction with glutamate-mediated excitotoxicity, other molecular processes induce neurotoxicity via multifactorial mechanisms. Within the neuron, mutations in a host of ALS-related genes, including C9orf72, superoxide dismutase 1 (*SOD1*), TDP-43, and FUS, result in ALS via multiple mechanisms. Specifically, mutations in the SOD-1

Monyer et al. 1992). In addition, there are regional variations in the expression of NMDA receptor subtypes (Ciabarra and Sevarino 1997; Ishii et al. 1993; Kutsuwada et al. 1992; Monyer et al. 1992; Watanabe et al. 1993a, b, 1994a, b), with the NMDAR3B subunit heavily expressed in somatic motoneurons (Chatterton et al. 2002; Nishi et al. 2001).

AMPA receptors mediate a rapid influx of monovalent ions, such as Na^+, K^+, and chloride (Cl^-) but unlike NMDA receptors are impermeable to Ca^{2+} (Heath and Shaw 2002). Four AMPA receptor subtypes have been cloned (*Glu*R1-4) and are composed of three transmembrane domains (M1, M3, M4) and a fourth cytoplasmic hairpin loop (M2), which contributes to the pore-lining region (Dingledine et al. 1999; Simeone et al. 2004). The AMPA receptor exists as a pentameric structure in vivo, which is formed by the arrangement of subunits to create receptor diversity (Heath and Shaw 2002). The GluR2 subunit influences the Ca^{2+} permeability of AMPA receptors, whereby those receptors expressing an immature GluR2 subunit are more permeable to Ca^{2+} ions. Following activation of these AMPA receptors, excessive influx of Ca^{2+} results in neurodegeneration through activation of Ca^{2+}-dependent pathways (Heath and Shaw 2002; Simeone et al. 2004).

1.2 The Role of Glutamate in ALS Pathogenesis

As discussed, glutamate excitotoxicity is mediated by excessive activation of postsynaptic glutamate receptors (Heath and Shaw 2002). In ALS, glutamate excitotoxicity has been postulated to induce anterior horn cell degeneration via a transsynaptic anterograde process mediated by corticomotoneurons (Eisen et al. 1992). Support for such a mechanism has been provided by transcranial magnetic stimulation studies (TMS) which have demonstrated that cortical hyperexcitability, a biomarker of glutamate excitotoxicity, is an early feature in sporadic and familial ALS, linked to motor neuron degeneration (Blair et al. 2010; Caramia et al. 1991; Desiato et al. 2002; Eisen et al. 1993; Prout and Eisen 1994; Vucic and Kiernan 2006, 2009, 2010; Vucic et al. 2008). In addition, longitudinal studies in asymptomatic SOD-1 mutation carriers revealed that cortical hyperexcitability developed prior to the clinical onset of ALS (Vucic et al. 2008), a feature also evident in the G93A SOD-1 mouse model (Browne et al. 2006). Of relevance, loss of γ-aminobutyric acid (GABA) secreting parvalbumin-positive inhibitory interneurons in the motor cortex of ALS patients may further contribute

Fig. 1 (continued) gene result in toxic gain of function of the SOD1 enzyme which affects a host of critical cellular organelles, such as DNA/RNA metabolism. In addition, mitochondrial dysfunction is a feature of ALS, linked to glutamate excitotoxicity and SOD-1 gene mutations, resulting in a reduced production of ATP and calcium-sequestering ability, as well as an increase in free radical formation. Of further relevance, mitochondrial dysfunction may contribute to glutamate excitotoxicity. Ultimately, these multiple pathogenic processes result in critical cell dysfunction and motor neuron degeneration

to the development of cortical hyperexcitability (Nihei et al. 1993), a finding underscored by recent neuroradiological studies reporting a significant reduction of GABA within the motor cortex of ALS patients (Foerster et al. 2012).

Molecular-based studies have provided further evidence for glutamate-mediated excitotoxicity in ALS. Specifically, molecular studies established significant reduction in the expression and function of the astrocytic glutamate transporter (EAAT2), which mediates glutamate reuptake at synapses thereby reducing glutamate excitotoxicity, in the superoxide dismutase-1 (SOD-1) mouse model and the motor cortex and spinal cord of ALS patients (Boillee et al. 2006; Ionov 2007; Rothstein et al. 1993, 1995, Trotti et al. 1999). Of further relevance, dysfunction of the EAAT2 transporter appears to be a preclinical feature in the SOD-1 mouse model (Boston-Howes et al. 2006; Gibb et al. 2007), and an increase in the expression and transporter activity of EAAT2 increases the life span of mutant SOD-1 mice (Rothstein et al. 2005).

At a postsynaptic level, increased expression of AMPA receptors with the unedited GluR2 subunit has been reported in ALS (Kawahara et al. 2004; Kwak and Kawahara 2005; Takuma et al. 1999; Van Damme et al. 2002, 2005). This editing defect appears to be specific for ALS, thereby rendering the motor neurons more permeable to Ca^{2+}, potentially explaining the increased sensitivity of motor neurons to excitotoxicity (Cox et al. 2007; Heath and Shaw 2002). Further support for glutamate excitotoxicity has been provided by the clinical benefit of riluzole in ALS patients (Bensimon et al. 1994; Cheah et al. 2010; Gurney et al. 1996, 1998; Lacomblez et al. 1996). Specifically, riluzole is a glutamate antagonist that exerts effects in the central nervous system by reducing the release of glutamate from presynaptic nerve terminals and enhancing the reuptake of glutamate (Azbill et al. 2000; Cheah et al. 2010; Quinlan 2011; Wang et al. 2004).

For the glutamate hypothesis to be a plausible mechanism of motor neuron degeneration in ALS, it must explain how motor neurons became selectively damaged through overactivity of the glutaminergic system and provide a mechanism by which degeneration occurs. A number of cell-specific molecular features possessed by the motor neurons render them vulnerable to glutamate toxicity in ALS. Motor neurons affected in ALS preferentially express AMPA receptors lacking the functional GluR2 subunit, thereby rendering the motor neurons more permeable to Ca^{2+} (Kawahara et al. 2004; Kwak and Kawahara 2005; Van Damme et al. 2002, 2005). In addition, motor neurons vulnerable to degeneration lack the intracellular expression of proteins parvalbumin and calbindin D28k which are required to buffer intracellular Ca^{2+} (Ince et al. 1993). Of further relevance, increased expression of the inositol 1,4,5-triphosphate receptor 2 (ITPR2) gene was reported in ALS (van Es et al. 2007). The ITPR2 is involved in glutamate-mediated neurotransmission, whereby stimulation of glutamate receptors results in binding of inositol 1,4, 5-triphosphate to ITPR2, which subsequently increases intracellular calcium (Choe and Ehrlich 2006; van Es et al. 2007). Aberrant activity of ITPR2 results in higher intracellular concentration of Ca^{2+} leading ultimately to neurodegeneration (Gutstein and Marks 1997). Of further relevance, motor neurons in ALS, at least in animal

models, appear to be larger, with an increase in distal dendritic branching (Amendola and Durand 2008). Consequently, the input conductance of the motor neurons is increased rendering the motor neuron more vulnerable to electrical and metabolic stresses, in particular those imparted by glutamate excitotoxicity (Quinlan 2011).

Although details of the molecular mechanisms by which glutamate exerts neurotoxicity are still to be fully elucidated, several pathways have been defined. Initially, an influx of Na^+ and Cl^- ions occurs along with water molecules, resulting in acute neuronal swelling that is reversible with removal of agonist (Choi 1987; Shaw and Kuncl 2002; Stys 1998). Subsequently, an influx of Ca^{2+} ions occurs via activation of ionotropic receptors such as the NMDA and Ca^{2+}-permeable AMPA receptors, as well activation of voltage-gated Ca^{2+} channels (Choi 1987; Miller et al. 1989). Ultimately, activation of these ionic pathways results in increased intracellular Ca^{2+} concentration and activation of Ca^{2+}-dependent enzymatic pathways leading to neuronal death (Cox et al. 2007; Meldrum and Garthwaite 1990; Regan et al. 1995; Shaw and Kuncl 2002). Further, glutamate excitotoxicity results in production of free radicals that can further damage the intracellular organelles to thereby cause cell death (Bondy and Lee 1993; Lees 1993; Maher and Davis 1996).

In his original manuscript, Charcot concluded that ALS was a disorder of the brain and that lower motor neuron degeneration resulted from downstream effects (Charcot and Joffroy 1869). This view was not universal, and some of Charcot's contemporaries, such as Gower's, argued that upper and lower motor neuron degeneration were independent. Over the past two decades the site of ALS onset has been revisited to a large extent precipitated by the advent of modern noninvasive technologies such as TMS. Three schools of thought have developed pertaining to the role of the UMN and related pathophysiological processes in ALS: (i) "the *dying forward*" hypothesis; (ii) "the *dying back*" hypothesis, and (iii) "the *independent degeneration*" hypothesis (Fig. 2).

The dying forward hypothesis proposed that ALS was primarily a disorder of the corticomotoneurons, which connect monosynaptically with anterior horn cells (Eisen et al. 1992). Corticomotoneuronal hyperexcitability was postulated to induce anterior horn cell degeneration transsynaptically via an anterograde glutamate-mediated excitotoxic process (Eisen et al. 1992; Vucic and Kiernan 2009). This dying forward hypothesis was based on a number of poignant clinical observations including (i) relative preservation of extraocular and sphincter muscles in ALS, postulated to be due to a paucity of corticomotoneuronal projections onto the motor nuclei innervating these muscles; (ii) absence of an animal model of ALS, ascribed to a lack of direct corticomotoneuronal-anterior horn cell connections (Armand 1982; Lemon and Griffiths 2005); (iii) rarity of pure lower motor neuron forms of ALS, with subclinical upper motor neuron dysfunction invariably detected with TMS studies (Eisen and Shtybel 1990); and (iv) the specificity of dissociated muscle atrophy (Eisen and Kuwabara 2012; Kuwabara et al. 2008; Menon et al. 2011; Wilbourn 2000), termed the split hand phenomenon in ALS remains best explained by a dying forward mechanism (Eisen and Kuwabara 2012; Menon et al. 2011).

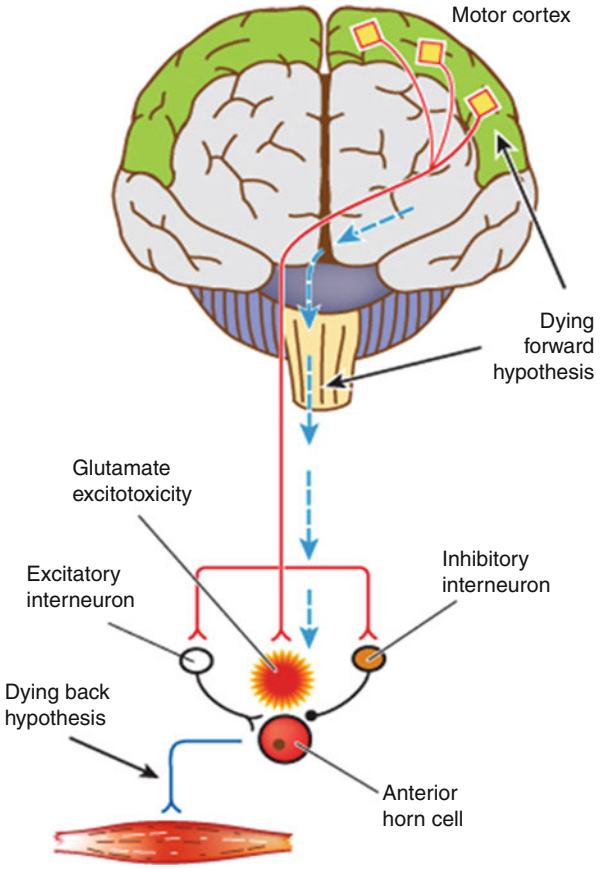

Fig. 2 The dying forward and dying back hypothesis of amyotrophic lateral sclerosis (*ALS*). The "dying forward" hypothesis proposed that ALS was primarily a disorder of the corticomotoneurons (highlighted in *red*), with anterior horn cell degeneration mediated via a transsynaptic anterograde glutamate-mediated excitotoxic process. In contrast, the dying back hypothesis proposed that ALS was primarily a disorder of the lower motor neurons with pathogens retrogradely transported from the neuromuscular junction to the cell body where these pathogens may exert their deleterious effects

Utilizing TMS technology, it is becoming increasingly apparent that cortical hyperexcitability develops as an early feature in sporadic and familial ALS, linked to the process of motor neuron degeneration (Caramia et al. 1991; Desiato et al. 2002; Eisen et al. 1993; Prout and Eisen 1994; Vucic and Kiernan 2006, 2009, 2010; Vucic et al. 2008). Furthermore, longitudinal studies in asymptomatic SOD-1 mutation carriers established that cortical hyperexcitability developed prior to the clinical onset of ALS (Vucic et al. 2008), a feature also reported in the G93A SOD-1 mouse model (Browne et al. 2006). In keeping with a cortical origin of ALS is the now accepted view that ALS and frontotemporal dementia (FTD) represent an overlapping continuum of the same disorder (Lillo and Hodges 2009; Neumann et al. 2006), an observation further underscored by recent genetic discoveries that increased hexanucleotide repeat expansions in the first intron of C9ORF72 gene (9p21) was associated with both ALS and FTD (DeJesus-Hernandez et al. 2011; Renton et al. 2011; Traynor 2012).

The dying back hypothesis proposed that ALS is primarily a disorder of the lower motor neurons, with pathogens retrogradely transported from the

neuromuscular junction to the cell body where they exert their deleterious effects (Chou and Norris 1993). Although some pathological studies have indirectly supported a dying back process (Gould et al. 2006; Pagani et al. 2006; Pun et al. 2006), no pathogens of any type has been identified in relation to ALS. The presence of widespread dysfunction within the frontal cortex, including the primary, supplementary, and prefrontal motor cortices in ALS, remains difficult to reconcile with any dying back process (Miller et al. 2009; Turner et al. 2009; Vucic et al. 2007). In addition, the absence of central pathology in other lower motor neuron disorders such as Kennedy's disease or poliomyelitis provides a further argument against a dying back process (Eisen and Weber 2001; Vucic and Kiernan 2008).

The independent degeneration hypothesis suggested that the upper and lower motor neurons degenerated independently (Gowers 1886–1888). Limited neuropathological studies provided indirect support for independent degeneration, whereby the degeneration of upper and lower motor neurons appeared to be independent (Kiernan and Hudson 1991; Pamphlett et al. 1995). These correlative morphological techniques, however, were significantly confounded by the anatomical and functional complexity of the corticomotoneuronal system (Flament et al. 1993). In particular, there remains considerable variability in the corticomotoneuronal to anterior horn cell ratio, due to synaptic changes, and as such, attempts to correlate upper and lower motor neurons as a "one-off" on autopsy studies are divorced from clinical and in vivo reality (Eisen and Weber 2001).

1.3 Neurotoxicity and the Role of SOD-1 Gene

Mutations in the SOD-1 gene, the first ALS gene reported and mapped to the long arm of chromosome 21 [21 q22.1] (Siddique et al. 1991), was postulated to exert pathogenic effects by resulting in acquisition of aberrant cytotoxic enzyme activity (Andersen 2006a; Dewil et al. 2004; Robberecht 2002). The SOD-1 gene spans 11 kilobases of genomic DNA, comprises five exons and four introns (Levanon et al. 1985), and encodes a highly conserved 153-amino acid long protein, which together with a catalytic copper (Cu) ion and a stabilizing zinc (Zn) ion form a subunit (Andersen 2006; Levanon et al. 1985). A disulfide bridge stabilizes each subunit, and the two identical subunits combine through non-covalent bonds to form the Cu-Zn SOD-1 enzyme. The main function of the SOD-1 enzyme involves free radical scavenging whereby the enzyme catalyses the conversion of the superoxide anion to molecular oxygen and hydrogen peroxide, which in turn is reduced to water by glutathione peroxidase and catalase (Andersen 2006; Fridovich 1986; Shaw and Kuncl 2002). The Cu-Zn SOD enzyme constitutes 0.5–1% of soluble protein in the brain and spinal cord and is located within the cytosol and nucleus and between two mitochondrial membranes (Andersen 2006; Bowling et al. 1995; Pardo et al. 1995).

To date, over 150 different mutations have been reported in the SOD-1 gene, with the majority of being missense mutations, resulting in changes in single amino acids but preserving the SOD-1 protein length. The remaining mutations are either nonsense or deletion mutations that either introduce novel nucleotides or remove existing

nucleotides resulting in alteration of the polypeptide length (Andersen 2006; Dewil et al. 2004; Gros-Louis et al. 2006). An autosomal dominant pattern of inheritance is evident with most mutations, except for the D90A mutation, which may be transmitted in an autosomal recessive manner. Compound heterozygosity has also been reported with SOD1 FALS, whereby two siblings with a slowly progressive ALS phenotype may be carriers of both the D90A and D96N mutations (Hand et al. 2001). The mutations are widely distributed throughout the gene with preponderance for exon 4 and 5 (Andersen 2006; Andersen et al. 2003; Cudkowicz et al. 1997; Radunovic and Leigh 1996). Globally, the most frequent mutation is the substitution of aspartate for alanine (D90A), followed by alanine to valine (A4V) and isoleucine for threonine (I113T) (Andersen 2006; Dewil et al. 2004).

Evidence for a neurotoxic gain of function of the SOD-1 enzyme has been provided by several lines of evidence. Specifically, increased activity of the SOD-1 enzyme was reported in the transgenic SOD-1 mouse models, supporting a toxic gain of function mechanism (Bruijn et al. 1997; Gurney et al. 1994; Ripps et al. 1995; Wong et al. 1995). Of further relevance, SOD-1 knockout mice failed to develop the ALS phenotype, thereby suggesting the importance of SOD-1 enzyme activity in ALS pathogenesis (Reaume et al. 1996). Aberrant biochemical activity of the SOD-1 enzyme has been reported to underlie this toxic gain of function (Andrus et al. 1998; Beckman et al. 1993; Bruijn et al. 1997, 1998, 2004). Specifically, SOD-1 gene mutations reportedly induced structural changes in the SOD-1 enzyme, enabling substrates other than the superoxide anion to gain access to the active center, thereby resulting in increased production of hydroxyl and free radicals (Bogdanov et al. 1998; Liu et al. 1998). In addition, the mutated SOD-1 enzyme also accepts peroxynitrate as a substrate, resulting in nitration of tyrosine residues on critical cellular proteins (Beckman et al. 1993; Beckman and Koppenol 1996; Crow et al. 1997). Ultimately, this aberrant biochemical activity of the SOD-1 enzyme resulted in cell injury and death (Beckman et al. 1993). Importantly, upregulation of protein-tyrosine nitration has been reported in anterior horn cells (Abe et al. 1997; Chou et al. 1996) as well as elevation of 3-nitortyrosine in the spinal cord of ALS patients and transgenic SOD-1 mice (Beal et al. 1997; Ferrante et al. 1997).

Mutations in the SOD-1 gene may also result in improper binding of zinc to the mutated SOD-1 peptide, thereby allowing reduction of SOD-1 bound copper, which in turn results in formation of superoxide anions and cell injury (Estevez et al. 1999). Diminished metal ion binding by the mutated SOD-1 peptide may also release zinc and copper ions, thereby further contributing to neurotoxicity and degeneration (Pasinelli and Brown 2006). Of further relevance, aberrant SOD-1 enzyme activity may result in oxidative stress via upregulation of proinflammatory cytokines (Hensley et al. 2006). Specifically, increased expression of proinflammatory mediators such as nitric oxide, interleukins 1, 6, and 12 has been reported in the SOD-1 mouse model with resultant neurotoxicity to motor neurons in spinal cord preparations (Kim et al. 2006). Importantly, antagonism of these agents with neutralizing antibodies resulted in increased motor neuron survival (Kim et al. 2006).

Alternatively, mutations in the SOD-1 gene may lead to conformational instability and misfolding of the SOD-1 peptide, resulting in formation of toxic

intracellular aggregates. In the transgenic SOD-1 mouse model and human ALS cases, immunoreactive SOD-1 aggregates were reported in motor neurons and glial cells (Bruijn et al. 1998; Jonsson et al. 2006; Zetterstrom et al. 2007). Whether the intracellular aggregates were neurotoxic to motor neurons remains unknown, although a number of possible cytotoxic mechanisms have been proposed, including (i) co-aggregating with vital cellular constitutes, (ii) inhibiting normal proteosome function, and (iii) exerting mechanical or biochemical effects on the cell, such as disruption of axonal transport systems (Bruijn et al. 1997, 1998; Pasinelli and Brown 2006; Williamson and Cleveland 1999).

1.4 Mitochondrial Dysfunction

In conjunction with glutamate excitotoxicity and oxidative stress, there is mounting evidence that mitochondrial dysfunction exerts an important role in the pathophysiology of ALS (Boillee et al. 2006; Chung and Suh 2002; Higgins et al. 2003; Kirkinezos et al. 2005; Lederer et al. 2007; Pasinelli and Brown 2006; Xu et al. 2004). Mitochondria are intracellular organelles whose main function is to generate energy for the cell in the form of ATP. Under conditions of excessive Ca^{2+} load, as may be evident with glutamate excitotoxicity (Dugan and Choi 1994), mitochondrial production of free radicals induces injury of critical neuronal cellular proteins and DNA. In addition, mitochondria remain sensitive to free radical damage at both the protein and DNA level, resulting in further mitochondrial dysfunction (Bowling and Beal 1995). Mitochondrial damage may in turn enhance glutamate excitotoxicity by disrupting the normal resting membrane potential, thereby resulting in a loss of the normal voltage-dependent Mg^{2+}-mediated block of NMDA receptor channels (Heath and Shaw 2002; Shaw and Kuncl 2002).

Mitochondrial degeneration and dysfunction has been reported in ALS patients and in the transgenic SOD-1 mouse model (Higgins et al. 2003; Kong and Xu 1998; Xu et al. 2004). Ultrastructural abnormalities of muscle mitochondria, paracrystalline inclusions, and abnormal cristae have been reported in ALS (Chung and Suh 2002; Comi et al. 1998; Lederer et al. 2007). Dysfunction of mitochondrial enzymes involved in energy generation, such as cytochrome C oxidase and respiratory chain complexes I and IV, as well as downregulation of nuclear genes encoding mitochondrial components within the motor cortex has been reported in ALS (Comi et al. 1998; Fujita et al. 1996; Jung et al. 2002; Kirkinezos et al. 2005; Lederer et al. 2007). Of further relevance, mitochondrial dysfunction including reduction in protein import, impairment in Ca^{2+} sequestering ability, and an exaggerated depolarizing response of the inner mitochondrial membrane to Ca^{2+} stimulation may occur in the presymptomatic stages of ALS (Bilsland et al. 2008; Damiano et al. 2006; Jaiswal et al. 2009; Li et al. 2010; Nguyen et al. 2009). Ultimately, severe damage to the mitochondrial membrane potential, respiration, and electron transfer chain ensues, resulting in reduced ATP synthesis and neurodegeneration (Quinlan 2011).

The transportation and distribution of mitochondria within the neurons appears to be impaired in ALS (Quinlan 2011). Mitochondria are normally highly mobile organelles, evident in both the axons and dendrites (MacAskill et al. 2010). The movement of mitochondria is regulated through Ca^{2+} signalling and synaptic activity (MacAskill et al. 2010). An increase in intracellular Ca^{2+} concentration, as occurs with glutamate excitotoxicity, interrupts the movement of mitochondria within the cell, in particular at the level of the synapse (MacAskill et al. 2009). Abnormalities of mitochondrial distribution and transport have been reported in ALS, with evidence of reduced distribution in the axons and more frequent pauses in mitochondrial movements (Bilsland et al. 2010). Importantly, the slow and fast axonal transport systems, vital for mitochondrial transport, seem to be impaired in ALS and have been linked to glutamate excitotoxicity (Bilsland et al. 2010; De Vos et al. 2007; Quinlan 2011). Ultimately, this interruption in mitochondrial mobility may result in depletion of energy supply in critical neuronal segments, essential for the maintenance of the resting membrane potential and generation of action potentials, with resultant neuronal degeneration.

From a therapeutic perspective, a recent phase II trial of dexpramipexole, a pharmacological agent that enhances mitochondrial function (Cheah and Kiernan 2010), was shown to be effective in slowing ALS disease progression and reducing mortality over a 24-week period (Cudkowicz et al. 2011). Currently, a phase III, multicenter international trial is underway to assess the clinical efficacy of dexpramipexole as add-on therapy to riluzole in ALS (ClinicalTrials.gov-NCT01281189).

2 Non-neuronal Cells and Neurotoxicity in ALS

Dysfunction of nonneuronal cells, astrocytes, and microglia also appears to be important in ALS pathogenesis (Boillee et al. 2006a, b; Haidet-Phillips et al. 2011; Neusch et al. 2007). Molecular studies in the SOD-1 mouse model have established that expression of the mutant SOD-1 protein in either the motor neurons or astrocytes in isolation failed to induce degeneration, thereby suggesting that the pathogenic process in ALS may involve a complex interaction between motor neurons interacting with nonneuronal cells (Gong et al. 2000; Lino et al. 2002; Pramatarova et al. 2001). Underscoring the importance of nonneuronal cells in ALS pathogenesis are findings that motor neuron toxicity appears to be modulated by expression of mutant SOD-1 in nonneuronal cells (Clement et al. 2003). However, mutant SOD-1 expressing nonneuronal cells seem to be more involved in the regulation of disease progression rather than onset of ALS (Beers et al. 2006; Boillee et al. 2006).

Similar to animal models, nonneuronal cells seem also to be an important pathogenic factor in the human disease. Specifically, astrocytes derived from postmortem spinal cord neural progenitor cells (NPCs) of sporadic and familial (SOD1) patients were selectively toxic to motor neurons (Haidet-Phillips et al. 2011). Upregulation of inflammatory genes encompassing chemokines, proinflammatory cytokines and components of the complement cascade, was evident in the neurotoxic astrocytes, further suggesting that neurotoxicity may in

part be mediated by an inflammatory mechanism. In addition, downregulation of mutant and wild-type SOD-1 expression in astrocytes derived from familial and sporadic ALS, respectively, was neuroprotective (Haidet-Phillips et al. 2011). Taken together, these findings suggest that astrocyte-mediated neurotoxicity contributed to neurodegeneration in familial (SOD-1) and sporadic ALS, thereby suggesting that novel cell-based approaches, particularly focusing on nonneuronal supportive cells, may be therapeutic in ALS.

3 Conclusion

Multiple interacting molecular and genetic mechanisms appear to underlie the development of motor neurodegeneration in ALS. Studies in animal models and human ALS have suggested an important role for glutamate neurotoxicity in ALS pathogenesis. Specifically, neurophysiological studies have suggested that cortical hyperexcitability, a biomarker of glutamate neurotoxicity, appears as a primary event in ALS, with motor neuron degeneration mediated via transsynaptic anterograde mechanisms. In conjunction with glutamate excitotoxicity, other molecular processes including mitochondrial dysfunction and abnormalities of axonal transport, together with neurotoxicity of the mutant SOD-1 enzyme, oxidative stress, and dysfunction of nonneuronal supporting cells, such as astrocytes, appear to contribute to ALS pathogenesis. From a therapeutic perspective, further insights into ALS pathogenesis will undoubtedly result in development of novel therapeutic strategies.

Neurotoxicity and Neuroprotection in Spinal Cord Injury

Renée Morris

Contents

Abstract

In the present chapter, the members of the neurotrophin family of neurotrophic factors and their receptors are first presented. This first section is then followed by a description of the neurotrophin-mediated signalling pathways that regulate cell survival, with particular emphasis on the "signalling endosome model" of intracellular signalling. The main functions of these neurotrophin-mediated signalling pathways are then described, and evidence that neurotrophic factors have the capacity to protect spinally projecting neurons against cell death and atrophy is subsequently examined. In this context, the neurotrophin-associated molecular

cascades of events that lead to the regulation of cell survival are presented. The protective role of the different neurotrophic factors for injured spinal cord-projecting neurons and their capacity to upregulate regeneration-associated genes is subsequently examined. The regenerative property of neurotrophins on lesioned sensory and motor axons is then introduced, and evidence that the delivery of neurotrophic factors, if available in sufficient concentration, can outweigh the effect of inhibitory molecules present in the scar tissue is reviewed. Finally, the different strategies currently under investigation to deliver neurotrophin to the injured spinal cord are reviewed. Here, special attention is given to the evidence for and against a potential role for neurotrophins in the recovery of motor function.

Keywords
Motor function • Neurotrophic factors • Neurotrophin • Regeneration • Spinal cord injury • Spinal cord-projecting neurons

1 Introduction

The propensity of the adult spinal cord to regenerate is only limited, and damage that disrupts the long myelinated fiber pathways within the cord results in permanent functional deficits. Over the last three decades, research in neuroscience has identified a set of pathophysiological events that occur within the injured spinal cord tissue and that contribute to halt axonal regeneration. One of the obstacles to axonal growth through the site of injury is the presence, in the glial scar, of potent growth inhibitory extracellular matrix molecules such as chondroitin and keratan sulfate proteoglycans (for a review, see Bradbury and Carter 2011). Another major impediment to axonal regeneration through traumatic damage to the cord is the existence of the myelin-associated axon growth inhibitory molecules Nogo-A, myelin-associated glycoprotein (MAG), and oligodendrocyte myelin glycoprotein (OMgp) (recently reviewed by Sharma et al. 2012). However, the presence of these inhibitory molecules within the damaged tissue is only part of the reason why injured axons fail to regenerate through a spinal cord injury. Indeed, a large population of spinal cord-projecting neurons that are axotomized after a spinal cord injury have been shown to exhibit a downregulation of genes that are directly involved in axonal regeneration (e.g., GAP-43 and Tα1 Tubulin), and this change in gene expression coincides with neuronal death and atrophy (Tetzlaff et al. 1991).

In the developing central nervous system (CNS), where they abound, neurotrophins contribute to neuronal growth and survival and to the formation of synaptic pathways. In the mature CNS, however, neurotrophin expression is downregulated, with the exception of brain regions that retain high levels of functional plasticity (Maisonpierre et al. 1990b). It has been suggested that the powerful role played by neurotrophins in development could be harnessed for the treatment of several neurological conditions including injury to the adult spinal cord. This present chapter will first present an overview of the neurotrophin family of neurotrophic factors and their receptors as

well as a brief description of the diverse neurotrophin-mediated signalling pathways that regulate cell survival. This chapter will also examine work that shows that neurotrophins have the capacity to protect spinally projecting neurons against cell death and atrophy as well as to revert the downregulation of regeneration-associated genes that occurs following a spinal cord injury. In this chapter, evidence that the delivery of neurotrophins to the injured spinal cord can outweigh the effect of growth inhibitory molecules present at the injury site will be subsequently reviewed. Moreover, data that demonstrate that the delivery of neurotrophins in the injured cord can promote axonal regeneration through scar tissue will be considered. Finally, this chapter will discuss issues related to recovery of function (or lack thereof) that is reported to accompany axonal regeneration after neurotrophin treatment of the injured spinal cord.

2 Members of the Neurotrophin Family of Neurotrophic Factors and Their Receptors

Some of the pro-survival signals that specifically act on neuronal cells belong to a family of target-derived regulatory proteins called neurotrophins, whose main members include nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4). Nerve growth factor (NGF), isolated from snake venom, was the first neurotrophin to be identified (Cohen et al. 1954). Decades later, brain-derived neurotrophic factor (BDNF) was subsequently purified from pig brain tissue (Barde et al. 1982). Years later, neurotrophin-3 (NT-3) was simultaneously characterized by several groups of researchers with the use of molecular cloning techniques (Enfors et al. 1990; Hohn et al. 1990; Rosenthal et al. 1990; Jones and Reichardt 1990; Kaisho et al. 1990; Maisonpierre et al. 1990a). With these techniques, another member of the neurotrophin family, neurotrophin-4/5 (NT-4/5), was identified the following year (Berkemeier et al. 1991; Hallböök et al. 1991). More recently, neurotrophic factor-6 (NT-6) and neurotrophic factor-7 (NT-7), both satisfying the structural criteria that characterize the neurotrophin family, were cloned from a genomic DNA of the platyfish *Xiphophorus maculatus* and the fish *Cyprinus carpio*, respectively (Götz et al. 1994; Lai et al. 1998).

Each of these small proteins exhibits a unique molecular profile that determines its particular affinity with one subtype of transmembrane tyrosine kinase (Trk) receptor (recently reviewed in Skaper, 2012a). For instance, TrkA is the specific receptor for NGF (Kaplan et al. 1991; Klein et al. 1991a), while TrkB binds BDNF and NT-4/5 (Klein et al. 1991b; Soppet et al. 1991). NT-3 preferentially interacts with TrkC (Lamballe et al. 1991), but it also bind to TrkA and TrkB although with considerably less efficiency (Glass et al. 1991; Squinto et al. 1991; Klein et al. 1991b; Ip et al. 1993). Thus, the neurotrophins exert their trophic activity through the interaction with transmembrane tyrosine kinase (Trk) receptors to which they bind with distinct as well as with some overlapping degree of specificity (see Ip et al. 1993). The biological action of the different members of the neurotrophin family can also be modulated by the low-affinity nerve growth factor receptor or $p75^{NTR}$. The $p75^{NTR}$ can bind neurotrophins either alone or as a co-receptor that

regulates ligand binding to Trk receptors (Rodriguez-Tébar et al. 1990; Hempstead et al. 1991; Frade and Barde 1998; Bibel et al. 1999).

3 Neurotrophin/Trk Receptor Intracellular Signalling

The binding of target-derived molecules of neurotrophins to the extracellular region of two Trk receptor molecules at nerve terminals causes the receptors to associate into active dimers (Ullrich and Schlessinger 1990). In this process, the two Trk dimers are cross-linked through the dimeric ligand but they do not make contact with each other directly (Wehrman et al. 2007). Ligand-induced dimerization of the receptor subsequently leads to phosphorylation of several tyrosine kinase residues within the intracellular domain of the receptor. This process results in the recruitment and activation of a number of downstream signalling effector molecules that initiate the intracellular signalling cascade leading to gene expression and activation (Stephens et al. 1994; Cunningham and Greene 1998).

How the neurotrophin/Trk signal triggered at distal nerve terminals is forwarded to the cell body to elicit neuronal responses has been the focus of much investigation. Although at least two alternative models have been proposed (e.g., Ginty and Segal 2002; Ibáñez 2007), there is mounting evidence in support of the "signalling endosome model" (for a recent review, see Chowdary et al. 2012). This model envisions that the activated receptors are internalized through an endocytosic pathway involving clathrin (Howe et al. 2001; Howe and Mobley 2005; Zheng et al. 2008). These ligand/receptor complexes are then packaged with their downstream signalling molecules into neurotrophic factor receptor-associated protein (NTRAP)-mediated specialized membrane-bound vesicles called signalling endosomes (Delcroix et al. 2003; Fu et al. 2010; for related recent articles, see Philippidou et al. 2010; Harrington 2011). These signalling endosomes, which serve as signalling platforms, are subsequently translocated in a retrograde fashion, i.e., from the distal end of axons to the cell soma by dynein-dependent motors along the microtubule tracks (Bhattacharrya et al. 2002; Ha et al. 2008). A similar endosome signalling mechanism has been proposed for the anterograde transport of BDNF from the dendrite to the nucleus (Cohen et al. 2010).

Endosome-bound neurotrophin/Trk receptors complexes mediate several signalling pathways. For instance, they activate the Ras/Erk pathway through the phosphorylation of the cytoplasmic "switch" G-protein Ras that subsequently binds and promotes the translocation of the Raf protein to the plasma membrane (Wennerberg et al. 2005; Reichardt 2006). Raf then activates MEK, which in turn recruits Erk (see Lemmon and Schlessinger 2010, Reichardt 2006 and Huang and Reichardt 2003, for detailed reviews on the Trk-activated signalling pathways). The PI3K/Akt signalling pathway is recruited by the activation of the cytoplasmic "switch" Ras and/or the adaptor protein Gab1 that in turn activates Pl3K (Rodriguez-Viciana et al. 1994; Holgado-Madruga et al. 1997). Activated Pl3K subsequently activates Akt (Franke et al. 1995). Neurotrophin-dependent Trk activation can also initiate other

intracellular signalling cascades such as phospholipase C (PLC-γ1). A downstream effect of the PLC-γ1 pathway is the release of Ca^{2+} from reticulum endoplasmic stores, therefore providing a point of convergence between neurotrophin and depolarization-induced cell signalling (Mizoguchi et al. 2002; Blanquet and Lamour 1997; Vaillant et al. 1999). On the other hand, cyclic AMP/protein kinase A (cAMP/PKA) signalling can also be activated by neurotrophin-recruited Trk receptors.

4 Neurotrophins as Cell Survival Regulators

Some of the critical functions of these neurotrophin-mediated signalling pathways are to mediate neuronal survival (Levi-Montalcini 1987; Gosh et al. 1994; Fagan et al. 1996), neurite outgrowth and differentiation (Segal et al. 1995; Barnabé-Heider and Miller 2003), and synaptic plasticity (Canossa et al. 2001; Yamada et al. 2002). A potent role of the PI3K/Akt pathway in neuronal survival (Barnabé-Heider and Miller 2003; Atwal et al. 2000; Vaillant et al. 1999; Holgado-Madruga et al. 1997; Dudek et al. 1997) and in synaptic plasticity (Lin et al. 2001) is well established. The Ras/ERK pathway also contributes to neuronal survival (Impey et al. 1998; Watson et al. 2001), although it seems to be involved mainly in neurogenesis, neuronal growth, and differentiation as well as in axonal elongation (Krishna and Narang 2008; Barnabé-Heider and Miller 2003; Markus et al. 2002; Atwal et al. 2000). The PLC-γ1 signalling pathway is not completely understood but there is evidence that it is involved in synaptic plasticity and in the release of neurotrophin-mediated neurotrophin (Canossa et al. 2001; Yamada et al. 2002; Choi et al. 2001; Stephens et al. 1994). As to the cAMP/PKA and Ca^{2+}/CaM signalling cascades, there is evidence to suggest that they play a role in neurite extension and outgrowth (Cai et al. 1999; Aglash et al. 2008; Spencer et al. 2008; for a recent review, see Tedeschi 2011).

How does neurotrophin signalling regulate cell survival? The neurotrophin-activated signalling pathways discussed above reach a point of convergence in the cell nucleus where they are potent activators of the nuclear transcription factor cyclic AMP response element-binding protein (CREB). Indeed, neurotrophin-activated Ras/Erk, PI3K/AKT, PLC-γ, cAMP/PKA, and Ca^{2+}/CaM pathways all mediate the phosphorylation of CREB at Serine 133 (Gonzalez and Montminy 1989; Du and Montminy 1998; Perkinton et al. 2002; reviewed by Lonze and Ginty 2002; Arthur et al. 2004; Spencer et al. 2008). Phosphorylation of CREB subsequently regulates the transcription of the antiapoptotic protein Bcl-2 (Riccio et al. 1999; Bonni et al. 1999; Saini et al. 2004) which, in turn, inhibits apoptosis (reviewed by Yuan and Yankner 2000 and Benn and Woolf 2004). Furthermore, survival is mediated by the activation of Akt, a key component of the PI3K/AKT pathway that leads to the phosphorylation of BAD and Forkhead, two potent effectors that inhibit the proapoptotic pathway (Datta et al. 1997; Brunet et al. 1999). Conversely, activation of the Ras/Erk pathway recruits protein kinase Rsk, the phosphorylation of which also results in the deactivation of the proapoptotic protein Bad (Nebrada and Gavin 1999).

Through their different intracellular signalling pathways, neurotrophins are able to promote cell survival in both a transcription-dependent (e.g., through the recruitment of the transcription factor CREB) and an independent (e.g., through the inhibition of the cell's intrinsic death machinery) manner, therefore shifting the survival/death equilibrium towards survival during ontogenesis as well as throughout adulthood (Finkbeiner et al. 1997).

5 Neurotrophins Confer Neuroprotection to Injured Spinal Cord-Projecting Neurons

Corticospinal neurons are located in the sensorimotor cortex and give rise to the corticospinal tract (CST). On the other hand, rubrospinal neurons are found in the red nucleus, a midbrain structure from which the rubrospinal tract (RST) originates. Injury to these long descending fiber tracts results in motor dysfunction below the lesion site. In the adult spinal cord, there is little evidence to suggest that spontaneous regeneration of these motor pathways occurs and that axotomized corticospinal and rubrospinal neurons reinnervate their former target fields (but see Hiebert et al. 2000). What are the response of corticospinal and rubrospinal neurons to axonal transection? It has been long been put forward that the neurons of origin of the rubrospinal tract undergo chromatolysis in reaction to axotomy (Egan et al. 1977). It has also been observed that, in both the sensorimotor cortex and in the red nucleus, the severity of the pathological response is distance specific with more severe pathological reaction, e.g., atrophy and death observed when axonal damage is closer to the cell soma (Egan et al. 1977; Kobayashi et al. 1997).

Giehl and Tetzlaff (1996) showed that axotomy at the level of the internal capsule (i.e., short distance from cell soma) induces death in nearly half the corticospinal neurons, with the surviving neurons displaying severe atrophy (see also Fernandes et al. 1999). However, there is now mounting evidence that the death of axotomized corticospinal neurons can be fully prevented by intraparenchymal delivery of BDNF and NT-3 during the first week after the injury. Indeed, application of BDNF completely alleviates atrophy of corticospinal, whereas the delivery of NT-3 only partially reverses it (Giehl and Tetzlaff 1996). In the same experimental paradigm, the delivery of BDNF, but not NT-3, during the first 2 weeks after the injury promotes the survival of corticospinal neurons for up to 42 days without further exogenous supply of neurotrophins (Hammond et al. 1999). These data suggest that early treatment with BDNF can trigger long-term downstream mechanisms that protect neurons from axotomy-induced death (Hammond et al. 1999).

Infusion of BDNF or NT-4/5 applied on transected rubrospinal fibers (Kobayashi et al. 1997; Bregman et al. 1998) or in the red nucleus (Bretzner et al. 2008) also prevents atrophy of rat rubrospinal neurons. Interestingly, the same group of co-workers have provided evidence that BDNF applied to the cell soma of axotomized rubrospinal neurons promotes their survival up to 1 year after the injury

(Kwon et al. 2002), whereas delayed application of BDNF on truncated rubrospinal fibers (i.e., 2 months after axotomy) failed to reverse atrophy (Kwon et al. 2004). The latter immunohistochemical analysis by Kwon and colleagues revealed that TrkB receptors remain present on the cell bodies of rubrospinal neurons, but not on their axons after axotomy, therefore providing one explanation as to why delayed application of BDNF on truncated rubrospinal axons failed to reverse atrophy (Kwon et al. 2004). The post-axotomy delivery of BDNF, either to the red nucleus or to its transected fibers, has also been reported to reverse neuronal atrophy (Liu et al. 2002; Tobias et al. 2003; Ruitenberg et al. 2004).

6 Neurotrophins Upregulate Regeneration-Associated Genes in the Injured Spinal Cord

Axotomy of rubrospinal and corticospinal neurons is accompanied by changes in expression of several genes that are directly involved in regeneration (for a recent review, see Gerin et al. 2011). These include the genes encoding for growth-associated proteins GAP-43 and SCG10, which are known to be involved in the regulation of actin (Frey et al. 2000) and microtubule (Reiderer et al. 1997) dynamics in growth cones during axonal regeneration. A study by Mason and co-workers has demonstrated by means of in situ hybridization that both Gap-43 and SCG10 were upregulated after intracortical lesions that axotomized corticospinal neurons (Mason et al. 2003). Increased GAP-43 mRNA expression in rubrospinal neurons was also reported shortly after axotomy performed at cervical level 3 (C3) (Tetzlaff et al. 1991; Fernandes et al. 1999; Storer and Houle 2003). GAP-43 upregulation is accompanied by an increase in the mRNA encoding both Tα1- and βII-tubulin (Tetzlaff et al. 1991; Storer and Houle 2003), two microtubule proteins that are essential for neurite growth in both developing and regenerating neurons (Hoffman 1989; Gloster et al. 1994; Fausett and Goldman 2006). In the second week after axotomy, however, rubrospinal neurons exhibit a decline in GAP-43 and Tα1-tubulin expression that coincides with neuronal atrophy (Tetzlaff et al. 1991). Interestingly, the delivery of BDNF and NT-4/5 can maintain the upregulation of GAP-43 and Tα1-tubulin mRNAs expressed by axotomized rubrospinal neurons (Kobayashi et al. 1997; Kwon et al. 2007). The upregulation of GAP-43 and βII- tubulin mRNAs in rubrospinal neurons has also been observed after the application of GDNF, but not BDNF, directly on the truncated axons (Storer et al. 2003). Together, these results show that corticospinal and rubrospinal neurons have the intrinsic capacity to upregulate genes that encode growth-associated proteins in a manner that is similar to that exhibited by neurons capable of regeneration (Hoffman and Cleveland 1988; Miller et al. 1989). These data also suggest that the application of neurotrophins to injured spinally projecting neurons can maintain the axotomy-induced expression of growth-associated genes beyond the second week after the injury.

7 Neurotrophins Outweigh the Effects of Inhibitory Molecules in Spinal Cord Injury

The inability of axotomized spinally projecting neurons to regenerate has been attributed, at least partly, to myelin-derived axonal growth inhibitory factors present at the injury site (for reviews, see Silver and Miller 2004; Chaudhry and Filbin 2007; Sharma et al. 2012). Indeed, several myelin-associated inhibitory molecules are able to limit neurite outgrowth and to mediate growth cone collapse. These include Nogo-A (Chen et al. 2000), myelin-associated glycoprotein (MAG) (McKerrecher et al. 1994; Mukhopadhyay et al. 1994), and oligodendrocyte myelin glycoprotein (OMgp) (Mikol and Stefansson 1988; Mikol et al. 1990; recently reviewed in Skaper 2012b). On the other hand, glial scar tissue represents a powerful obstacle to axonal elongation through the lesion, with potent inhibitory extracellular matrix molecules such as chondroitin- and keratan-sulfate proteoglycans produced by reactive astrocytes (Gallo et al. 1987; Gallo and Bertolotto 1990; but see Rolls et al. 2009) and the repellent proteins semaphorin 3 (Pasterkamp et al. 1999; Pasterkamp and Verhaagen 2006; for a recent review, see Pastekamp 2012) and ephrins (Xu et al. 1999; Mellitzer et al. 1999). Since the initial identification of these above-mentioned inhibitory molecules, a wealth of effort has been deployed to reverse the effect of myelin- and scar-derived inhibitory molecule, with strategies such as blocking the effect of Nogo with antibodies (Merkler et al. 2001; GrandPré et al. 2002; Li and Strittmatter 2003; Weinmann et al. 2006; for a review, see Onose et al. 2006), delivering MAG (Vyas et al. 2005) and ephrin (Goldshmit et al. 2004) antagonists and enzymatically digesting chondroitin-sulfate proteoglycans with chondroitinase ABC (Brückner et al. 1999; Starkey et al. 2012; for a recent review, see Bradbury and Carter 2011).

Once thought to be an impenetrable barrier to axonal regeneration, the action of the different inhibitory molecules above mentioned can be counteracted by enhancing the intrinsic growth capacity of axotomized neurons (for recent reviews, see Giger et al. 2010; Hollis and Tuszynski 2011). The regenerative effect of neurotrophins has been extensively studied in rat models of spinal cord injury (for a recent review, see Bo et al. 2011). In the majority of these studies, gene therapy is selected as the method of choice for the delivery of neurotrophins. Briefly, the gene encoding the neurotrophin of choice is cloned into replication-deficient viral vectors that can be directly delivered at the site of injury (Schnell et al. 1994; Houweling et al. 1998; Namiki et al. 2000; Blits et al. 2003; Koda et al. 2004). In most cases, however, vehicle cells such as fibroblasts (Grill et al., 1997a, b; McTigue et al. 1998; Tobias et al. 2003; Tuszynski et al. 2003; Zhou et al. 2003), permissive autologous bone marrow stromal cells (Koda et al. 2007; Lu et al. 2012), Schwann cells (Xu et al. 1995), neuronal and glial progenitors (Bonner et al. 2010), and olfactory ensheathing glial cells (e.g., Ruitenberg et al. 2003) are modified by viral-mediated transfer of the gene sequence for BDNF. Such virally transduced cells are known to produce biologically active neurotrophins in vitro (e.g., Liu et al. 1999;

Jin et al. 2002; Ruitenberg et al. 2003). These genetically engineered cells are then implanted acutely into the cavity created by the spinal cord injury where they are known to release the therapeutic agent (e.g., Lu et al. 2005). Such BDNF-expressing cell implants have been reported to fill the lesion cavity and to survive in the spinal cord and express the transgene for up to 4 months (Ruitenberg et al. 2003; Tobias et al. 2003).

8 Regenerative Property of Neurotrophins on Lesioned Motor Axons

Several groups of researchers have reported that grafts of cells genetically modified to express BDNF create a permissive environment for the injured spinal cord and in particular for the rubrospinal tract. The regenerative properties of engineered cell grafts can be observed even if they are transplanted several weeks after the injury (Tobias et al. 2003). However, the extent to which these BDNF-secreting cell grafts promote axonal growth is somewhat inconsistent. For example, extensive axonal growth has been reported (Lu et al. 2005), sometime extending well outside the boundaries of the BDNF-producing cell implant (Liu et al. 1999, 2002), whereas only modest axonal growth (i.e., within the limits of the implant) has been observed by others (Namiki et al. 2000; Jin et al. 2002; Tobias et al. 2003, 2005; Ruitenberg et al. 2003; Koda et al. 2007). Axons found within the cellular grafts have been shown to be positive for GAP-43 (Tobias et al. 2003, 2005; Koda et al. 2007) and for the marker for axonal neurofilaments TR-97 (Tobias et al. 2003, 2005), therefore providing evidence of motor axonal regeneration. It is worth mentioning that BDNF as well as NT-3-induced axonal regeneration has been associated with oligodendrocyte proliferation and enhanced myelination of ingrowing motor axons (McTigue et al. 1998).

Nearly two decades ago, Schnell and co-workers have reported that injections of NT-3, but not BDNF, result in modest regenerative sprouting of the CST (Schnell et al. 1994). Similar results were obtained a few years later with NT-3 dissolved into a collagen matrix that was implanted in the lesioned spinal cord (Houweling et al. 1998). As is the case for BDNF, viral-mediated gene therapy involving NT-3 as the transgene has been widely used in acute and chronic animal models of spinal cord injury. Grill and co-workers (1997b) implanted primary rat fibroblasts genetically modified ex vivo to express NT-3 in dorsal spinal cord hemisections that include the CST. Three months later, significant CST growth was reported at, as well as for up to 8 mm distal to, the lesion site, showing the therapeutic benefits of NT-3 in this descending motor fiber pathway (Grill et al. 1997b). Grafts of NT-3-expressing fibroblasts in the injured cord also induce proliferation of oligodendrocytes and encourage myelinogenesis (McTigue et al. 1998). In a study performed by Tuszynsky and co-workers (2003), primary fibroblasts genetically modified to express human NT-3 were implanted in and distal to the lesion cavity after chronic

spinal cord injury. With this dual implantation protocol (e.g., in and distal to the lesion), the elongation and arborization of CST axons was observed up to 15 mm distal to the injury site. Multiple combinational therapy, with cAMP injections into brainstem reticular motor neuron area to encourage their growth state, implants of bone marrow stromal cells to provide a cellular bridge through the spinal cord lesions, and the delivery of BDNF-expressing viral vectors caudal to the lesion sites to attract axonal growth, has recently been performed (Lu et al. 2012). This complex combinational treatment leads to motor axon regeneration through and beyond the limits of the implant, with some evidence of synapse formation with BDNF-expressing neurons caudal to the implant.

Retrograde neural tracers are known to be internalized by nerve endings and transported in a retrograde fashion to the corresponding spinal cord motor neurons (Tosolini and Morris 2012). The retrograde machinery of neurons can also be used to deliver different transgenes to spinal cord motor neurons (Morris et al. 2004). Intramuscular injections of viral vectors containing the gene sequence for diverse neurotrophins have been used as an alternative method to cell-mediated delivery of neurotrophic genes in the spinal cord (Ghage et al. 1995; Baumgartner and Shine 1998a, b; Nakajima et al. 2007; Uchida et al. 2008, 2012; Zhang et al. 2010). Interestingly, it is not necessary to target all motor neurons to achieve sustainable levels of chemoattractant, as non-transduced motor neurons in the vicinity have been shown to internalize neurotrophins through a paracrine mechanism (Baumgartner and Shine 1997). This "bystander" effect greatly enhances the efficacy of neurotrophin gene interventions that take advantage of the retrograde machinery of neurons (e.g., Aharoni et al. 2005). Virally mediated retrograde delivery of the gene sequence for BDNF has been reported to protect motor neurons from apoptosis after a spinal cord injury in rats (Nakajima et al. 2007, 2010) and mice (Uchida et al. 2008, 2012). However, although the delivery and expression of BDNF in motor neurons near a spinal cord lesion should presumably encourage axonal regeneration, no evidence supporting this assumption is currently available. On the other hand, adenoviral vector carrying the gene sequence for NT-3 has been delivered to level motor neurons at lumbar levels via injections in the sciatic nerve in a rat model of unilateral CST lesion at the level of the hindbrain (Zhou et al. 2003). In this study, sprouting from the intact CST (i.e., contralateral to the injection of NT-3-expressing viral vector) was reported to cross the midline at lumbar levels L3/6, suggesting that this particular observation is an instance of NT-3-mediated axonal plasticity rather than true regeneration. The effect of implant-mediated transgenic delivery of NGF, GDNF, and NT-4/5 has been less investigated. However, cellular implants secreting NGF (Grill et al. 1997a; McTigue et al. 1998; Jones et al. 2003), GDNF (Blesch and Tuszynski 2003), and NT-4/5 (Blesch et al. 2004) have been shown to produce significant regeneration of specific motor pathways through the implants. Taken together, these data provide evidence that the delivery of growth-promoting agents such as neurotrophins, if available in sufficient concentration, can outweigh the effect of inhibitory molecules present in the scar tissue.

9 Regenerative Properties of Neurotrophins for Lesioned Sensory Axons

Rhizotomy, or crush lesions of the dorsal roots, has been used extensively to study sensory axon regeneration within the spinal cord (for a recent review, see Smith et al. 2012). In these injury models, centrally projecting sensory axons regenerate rapidly until they reach the transition between the peripheral and central nervous system, an area called the dorsal root entry zone (DREZ). Several neurotrophin therapies have been conducted in an effort to encourage sensory axons to reenter the spinal cord after dorsal root crush. After such lesions, intraspinal infusion of NGF (Odega and Hagg 1996; Ramer et al. 2000), NT-3 (Zhang et al. 1998; Ramer et al. 2000, 2001), and GDNF, but not BDNF (Ramer et al. 2000), has been shown to promote extensive regeneration of sensory axons through the DREZ and in the spinal cord. Dorsal horn injections of adenovirus carrying the gene sequence for NGF have been reported to induce robust regeneration of dorsal root sensory axons through the DREZ and into former target laminae II and IV in the dorsal horn of the cord (Romero et al. 2001). In this study, however, sensory afferent axons were also observed to innervate laminae III and VI in the dorsal horn as well as ventral horn laminae VII–X. In a follow-up study, the same group of researchers was able to confine the regenerating sensory axons to the superficial layers of the dorsal horn by coupling the injection of the NGF-expressing vector with that of a vector encoding the gene for the negative guidance molecule semaphorin 3A in the ventral horn (Tang et al. 2007).

Another model to study regeneration of sensory axons is to create a partial spinal cord lesion that disrupts the ascending dorsal column. With this model, Taylor and colleagues (2006) have shown that a continuous gradient of lentivirus-mediated neurotrophin-3 (NT-3) in and immediately rostral to a lesion elicit modest axonal growth beyond the lesion. However, the sensory axons were found to stop elongating when they reach the rostral limit of the NT-3 gradient (Taylor et al. 2006). The same group of researchers has further demonstrated that axons have the potential to reach and reconnect with their former target if the distance between the lesion and the target is very small (2 mm) and is filled with a continuous gradient of NT-3 (Taylor Alto et al. 2009). Together, these findings show that damaged axons in the adult animal not only have the potential to elongate but also can form new synapses with former targets and that neurotrophins play a critical role in this process.

10 Functional Recovery After Neurotrophin Treatment of the Injured Spinal Cord

In the previous sections of this chapter, evidence that severed motor and sensory fiber pathways can regenerate through scar tissue, if neurotrophins are made available, has been reviewed. Is neurotrophin-mediated axonal regeneration associated with the recovery of function? Unfortunately, the answer is not

straightforward. Of the various experimental models of spinal cord injury, dorsal rhizotomy seems to be particularly amenable to recovery of function after neurotrophin treatment. In particular, the delivery of NGF after dorsal rhizotomy at lumbar levels 4 and 5 (L4/5) has been associated with near complete recovery of thermal nociception (Romero et al. 2001; Tang et al. 2007). Particularly, the report by Ramer et al. (2000) that deafferented dorsal horn sensory neurons can be synaptically driven by peripheral nerve stimulation after NGF, NT-3, and GDNF treatment is strong evidence of functional recovery. A therapeutic effect for BDNF on the recovery of thermal sensitivity has also been reported (Shumsky et al. 2003) (see Table 1).

Several teams of scientists have provided evidence that BDNF treatment after cervical lesions that involve the RST is accompanied by various degrees of recovery of function. After such lesions, BDNF delivery has been reported by different teams of researchers to enhance performance on the rope walking (Kim et al. 2001; Ruitenberg et al. 2003; Tobias et al. 2005) and cylinder tests (Liu et al. 1999; Tobias et al. 2005). Open-field testing with the BBB locomotor rating scale (Basso et al. 1995), on the other hand, has led to conflicting results. Indeed, significant improvement on the BBB open-field locomotor test has been reported in BDNF-treated animals (Koda et al. 2004), whereas complete recovery on this test has been shown to be independently of the nature of the treatment, i.e., fibroblasts expressing BDNF or control fibroblasts (Kim et al. 2001; Tobias et al. 2005). Together, these findings therefore suggest that BBB score is not useful to assess recovery of motor function after cervical lesions that target the RST. It is worthwhile to point out that the rope walking and the narrow beam tests as well as the BBB open-field locomotor test assess motor performance involving whole limb movement per se, or in relation to the intact limbs. However, evidence that lesions restricted to the RST do not lead to deficits in whole limb movement (Whishaw et al. 1998; Morris et al. 2011) suggests that these above-mentioned behavioral tasks are not particularly stringent to evaluate functional recovery of the RST. Moreover, the return of performance to, or near, preoperative values on some of these tests may therefore reflect compensation of function mediated by other motor pathways, particularly when recovery of function is not accompanied by evidence of RST growth in and through the BDNF-secreting implant.

Significant recovery on the gridwalk test has been reported after dorsal thoracic hemisections that include the main component of the CST, followed by treatment with NT-3-expressing cells (Grill et al. 1997b; Houweling et al. 1998). In both studies, amelioration of locomotor capacity on this test was accompanied by growth of CST axons in the cellular implants. However, the report by Grill and co-workers (1997) that smaller lesions that still abolish the CST are not sufficient to create a deficit on the gridwalk test (Grill et al. 1997b) indicates that the observed CST growth and recovery on the gridwalk test are two independent events. Furthermore, this observation also suggests that multiple pathways, possibly including the lateral aspect of the CST and the RST, contribute to locomotor function as measured by the gridwalk test.

Table 1 Compilation of several scientific reports that have addressed recovery of function after diverse neurotrophin treatments

Authors	Type of injury	Treatment	Anatomical outcome	Behavioral testing	Functional recovery after treatment
Tang et al. (2007)	Dorsal rhizotomy at L4/5	Ad-mediated NGF gene and semaphorin3A transfer in dorsal and ventral horns, respectively	Sensory axon growth across DREZ and into superficial dorsal horn laminae I and II	Response to noxious thermal stimulation	Functional restoration of nociception
Ramer et al. (2000)	Dorsal rhizotomy between C4 and T2	Delivery of NGF, NT-3, BDNF, and GDNF	Sensory axon growth across DREZ and into the spinal cord after treatment with NGF, NT-3, GDNF but not BDNF	Peripheral nerve stimulation	Dorsal horn neurons found to be synaptically driven with NGF, NT-3, GDNF but not BDNF
Romero et al. (2001)	Dorsal rhizotomy at L4/5	Delayed Ad-mediated NGF gene transfer in dorsal horn	Robust axonal growth in normal and aberrant locations with the dorsal horn	Plantar heat test and grid runway	Near complete recovery of hindlimb thermal nociception
Shumsky et al. (2003)	Unilateral hemisection at C3/4	Delayed delivery of BDNF and NT-3-expressing fibroblasts	Not reported	Battery of motor and sensorimotor tasks	No recovery on motor tasks but modest recovery of thermal sensitivity
Ruitenberg et al. (2003)	Unilateral DLF lesion involving the RST at C4	Acute delivery of BDNF-expressing OECs	Sprouting of RST axons in graft	Rope walking	Improved hindlimb performance
Liu et al. (1999)	Unilateral LF lesion involving the RST at C3/4	Acute delivery of BDNF-expressing fibroblasts	Growth of RST axons 3–4 segments below grafts	Cylinder test	Significant recovery
Tobias et al. (2005)	Unilateral DLF lesion involving the RST at C4	Acute delivery of BDNF-expressing fibroblasts	No evidence of growth of RST fibers in the implant	Rope walking test, cylinder test, BBB locomotor test	Complete recovery on BBB in treated and control rats, partial recovery in treated rats on cylinder test, partial recovery of rope walking in treated and control rats

(*continued*)

Table 1 (continued)

Authors	Type of injury	Treatment	Anatomical outcome	Behavioral testing	Functional recovery after treatment
Koda et al. (2004)	Complete transection at T8	Ad-mediated BDNF gene transfer in both stumps	Growth of RST axons through the lesion site	BBB locomotor test (Basso et al. 1995)	Significant improvement for at least 6 weeks
Kim et al. (2001)	Unilateral LF lesion at C3/4	Acute delivery of BDNF-expressing fibroblasts	Not reported	Swim test, patch-removal test, rope walking test, BBB locomotor test, narrow beam test,	No recovery on swim test, shorter latency to touch the patch, significant recovery on the rope walking test, complete recovery on BBB locomotor, and narrow beam tests in treated and control rats
Blits et al. (2003)	T9/10 excision	Schwann cell bridge and acute delivery of AAV-mediated BDNF and NT-3 gene transfer 5 mm caudal to bridge	Axonal growth in the cellular bridge but not beyond its caudal limits	BBB locomotor scale	Modest improvement of hindlimb function
Namiki et al. (2000)	Compression injury at T3	Infusion of BDNF and NT-3 for 14 days after injury	Smaller lesion size and regeneration through the injury	Inclined plane technique	Significant recovery at 1 week after injury. No significant recovery at later times
Houweling et al. (1998)	Dorsal hemisection between T8 and T10	NT-3 in a collagen matrix applied at the site of the injury	Growth of CST axons into, but not caudal to, NT-3-containing collagen matrix	Gridwalk test	Significant recovery
Grill et al. (1997b)	Dorsal hemisection at T7	Acute delivery of NT-3-expressing fibroblasts	Significant growth of CST axons in cellular implant	Gridwalk test	Significant recovery

(*continued*)

Table 1 (continued)

Authors	Type of injury	Treatment	Anatomical outcome	Behavioral testing	Functional recovery after treatment
Tuszynski et al. (2003)	Dorsal hemisection at T7	Delayed delivery of NT-3-expressing fibroblasts placed in, and caudal to the injury site	Significant growth of CST axons up to 15 mm distal to the injury site	BBB locomotor scale	Modest recovery

In an effort to encourage axonal growth below the cell implants, Blits et al. (2003) used Schwann cell implants to bridge thoracic spinal cord transections and subsequently delivered adeno-associated viral vectors containing the gene sequence for BDNF and NT-3 caudal to the cellular bridge. This surgical treatment, however, failed to promote growth caudal to the level of the NT-3-secreting bridge. Using a similar strategy, Tuszynski and co-workers (2003) observed growth of CST axons up to 15 mm distal to the injury level after the implantation of NT-3-expressing fibroblasts in, as well as caudal to a thoracic dorsal hemisection. Despite the considerable difference in the extent of axonal growth reported in these two studies, both procedures led to equally modest recovery on the BBB locomotor scale (Blits et al. 2003; Tuszynski et al. 2003). Thus, the striking difference in the extents of NT-3-mediated regeneration observed between these studies is by no means reflected in the level of performance on the BBB locomotor scale. In summary, that axonal regeneration after neurotrophin treatment has a direct impact on the recovery of function, at least with regard to the motor modality, is yet to be established.

11 Conclusion

In its infancy only a few decades ago, spinal cord regeneration has become a vast and dynamic field of research in neuroscience. Over the last 30 years, many groups of scientists have concentrated their efforts to identify growth inhibitors that are present in the damaged spinal cord and to develop strategies to counteract their action. Others have sought to design ways to increase the levels of growth-promoting neurotrophin expression at the site of injury in an attempt to offset the effect of these inhibitory molecules. There is now compelling evidence that neurotrophic factors can promote the survival of neurons giving rise to the different ascending and descending fiber pathways running in the spinal cord and that are axotomized after an injury. Moreover, it is well substantiated that the action of inhibitory signalling molecules that act as a barrier to axonal regeneration can be reverted by the delivery of neurotrophins to the injured spinal cord. Collectively, these key findings represent significant advances towards the development of

therapeutic strategies to promote axonal regeneration through a spinal cord lesion. Further work such as subjecting promising anatomical outcomes to independent replication is required before these preclinical data can be translated to clinical trials.

Recovery of function after spinal cord injury remains an enormous challenge for neuroscientists working in the field of spinal cord regeneration. Indeed, although the literature examined in the present chapter has reported axonal growth in and even several millimeters below the level of injury, there is no compelling evidence to show that the regenerative benefits of neurotrophin treatment are directly associated with functional recovery. Several factors may contribute to this unfulfilled endeavor. First and foremost, functional recovery must be supported by anatomical evidence of reinnervation of former postsynaptic target cells. This includes the demonstration that appropriate synaptic contacts (i.e., axodendritic synapses) with the postsynaptic target cells have been reestablished (e.g., Taylor Alto et al. 2009). Second, behavioral evidence for functional recovery gains significant strength if supported by electrophysiological data. In this regard, the report by Ramer et al. (2000) that deafferented sensory neurons in the dorsal horn can be synaptically driven by stimulation of the peripheral nerve after neurotrophin treatment constitutes powerful evidence of functional recovery. The years to come will certainly bring us closer to resolving this difficult task.

Contents

Abstract

Stroke is the clinical manifestation of the occlusion (ischemic stroke) or rupture of a blood vessel to the brain (hemorrhagic stroke). Neurotoxicity is triggered in stroke by the failure of oxygen delivery and the buildup of metabolites resulting in a cascade of harmful physiological events. Here, we review and contrast neurotoxicity and its corollary – neuroprotection – in the context of preclinical

(animal) and clinical (patient) drug trials. Preclinical tests are distinguished by greater homogeneity, earlier time windows for treatment, and greater probability of success. Many of the same processes have been targeted in preclinical and clinical trials – such as excitotoxicity, oxidation, inflammation, and trophic factors – however, it is not a seamless flow from bench to bedside and back. Current trends in stroke neuroprotection include combination neuroprotection and improved trial designs. Areas where drug development in stroke could be improved include better target identification, development of lead drug candidates prior to preclinical testing and use of computational tool for prediction of toxicity based on biochemical pathway and drug characteristics.

NMDA	*N*-methyl-D-aspartate
tPA	Tissue plasminogen activator
WHO	World Health Organization

1 Introduction to Stroke

1.1 Definition of Stroke

Stroke is the clinical manifestation of the occlusion (ischemic stroke) or rupture of a blood vessel to the brain (hemorrhagic stroke). It has been formally defined by the World Health Organization as "rapidly developing clinical signs of focal (or global) disturbance of cerebral function lasting more than 24 hours (unless interrupted by surgery or death) with no apparent cause other than a vascular origin" (WHO 1988). This review is limited to ischemic stroke which accounts for approximately 85 % of strokes in humans.

1.2 Pathophysiology of Ischemic Stroke

Knowledge of the mechanisms by which ischemic stroke causes brain damage has been derived from autopsy, from animal experiments, and more recently from

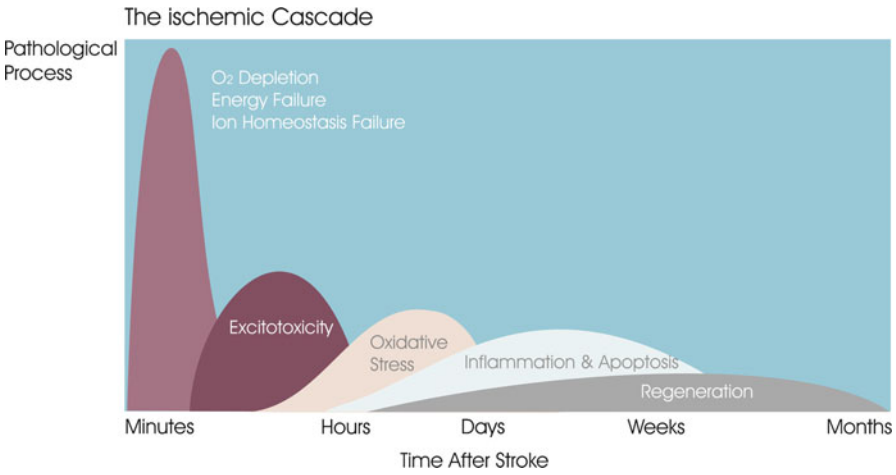

Fig. 1 The ischemic cascade (Adapted from Heiss et al. 1999)

imaging of the human brain. These data suggest that the extent to which blood flow is reduced in the brain is an important determinant of the response of cells (Astrup et al. 1981; Bandera et al. 2006).

Occlusion of a cerebral artery results in a reduction in oxygen, glucose, and nutrients in the territory of the brain supplied by the artery. The brain attempts to compensate for small reductions in blood flow (hypoperfusion) by recruiting blood flow through collateral vessels and by autoregulatory vasodilation (Derdeyn et al. 1999). Further reductions in blood flow are compensated for by increasing the amount of oxygen extracted from blood (Derdeyn et al. 1999). A failure to normalize perfusion pressure and blood flow will result in cellular swelling, disturbances in the redox state, lactic acidosis, loss of membrane dynamics, and ultimately cell death (Derdeyn et al. 1999).

On the basis of the degree to which blood flow and metabolism are compromised, brain tissue is often divided into normal healthy tissue, oligemic tissue, penumbral tissue, and infarcted tissue, in order of increasing severity of damage. Infarction initially occurs in the most severely hypoperfused region ("core"). The surrounding nonfunctional but potentially salvageable brain tissue ("penumbra") progresses to infarction with time as a result of a cascade of ischemia-induced biochemical changes resulting in cellular death (Markus et al. 2003).

Time is a critical determinant of the viability of brain tissue following a stroke. Evidence from animal models of stroke has demonstrated that the occlusion of a blood vessel sets in train a series of physiological events which have been termed the "ischemic cascade" (Dirnagl et al. 1999; Heiss et al. 1999). Primary damage following the loss of blood flow includes oxygen depletion, energy failure, and the failure of ion homeostasis (Fig. 1) (Heiss et al. 1999).

1.3 Neurotoxicity and Stroke

Ischemic stroke is a complex, multifaceted, and heterogeneous disease; thus, neurotoxicity is not easy to define in the context of stroke. Whilst the lack of oxygen and nutrients is the ultimate "neurotoxin," secondary damage may result from the following mechanisms: (1) "excitotoxicity," a surge in extracellular excitatory amino acids such as glutamate which become toxic because they are not buffered by normal cellular reuptake mechanisms (mainly astrocytes) (Benveniste et al. 1984; Benveniste 1991; Rothman and Olney 1986); (2) "oxidative stress," the massive release of free radicals that follow when endogenous production mechanisms become overactive (e.g., NOX enzymes) or when protective mechanisms (e.g., glutathione, superoxide dismutase) are swamped (Uenohara et al. 1988); and (3) inflammation and associated cell death, the inflammatory and apoptotic response marked by the migration and activation of microglia and macrophages at the lesion site and apoptotic signaling mechanisms (e.g., misplaced mitochondrial proteins which lead to further cell death) (Abraham and Lazar 2000; Mabuchi et al. 2000). Neurotoxicity may also result from disturbances in physiological processes such as acidosis, hyperthermia, blood sugar imbalance, and excessively high or low blood pressure.

Neurotoxicity may also be used to describe side effects of medications administered to manage stroke or a patient's comorbidities. For instance, tissue plasminogen activator (tPA) – expressed endogenously and administered in recombinant form therapeutically to break down clots – is a lifesaving therapy, but in animal models it has also been associated with neuronal damage, especially if the blood–brain barrier is not intact or if administered outside the vascular compartment (Wang et al. 1998, 1999; Kaur et al. 2004). Similarly, early agents targeting excitotoxicity (e.g., NMDA antagonists like MK-801) had poor profiles in terms of their effect on cognition (Muir and Lees 1995).

Neurotoxicity, however, is not the most common term designating damage in stroke research; when it does, it is often when implicating substances related to damage in other areas of medicine such as iron-induced neurotoxicity (Selim and Ratan 2004). Blood is neurotoxic if it gets outside of the vessels; the iron in hemoglobin is toxic to the brain and blood-signaling proteins like cytokines and chemokines. This causes inappropriate stimulation of the neuraxis and plays a role in directing invasion of inflammatory cells which themselves cause further damage but also help in regeneration. These regenerative responses are believed to be activated in the days and weeks following stroke onset (Wiltrout et al. 2007), but by this time most of the damage has been done.

One reason why endogenous substances upregulated during the ischemic cascade are not automatically designated as neurotoxic is that they might also take on neuroprotective roles, depending upon the time after iachemic onset and cell type. For instance, microglia has both neurotrophic and proinflammatory roles (Kim and de Vellis 2005) and may play a complex role after ischemia. Neuroprotection, rather than neurotoxicity, has therefore been the focus of intense interest in stroke research over the past 25 years.

2 Neuroprotection and Stroke

2.1 Clinical Management of Acute Stroke

Current evidence supports the use of a limited number of acute stroke interventions (Donnan et al. 2008): (1) management of patients in hospital stroke units, (2) reestablishment of blood flow using recombinant tissue activator (tPA) (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995), (3) aspirin (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1997; International Stroke Trial Collaborative Group 1997), and (4) hemicraniectomy (Vahedi et al. 2007). Of these treatments, the most significant and widely available gains during the acute phase of stroke have been secured through caring for patients in a dedicated hospital stroke unit (Donnan et al. 2008). The benefits of these interventions are not mutually exclusive; however, for patients in hospital stroke units are probably more likely to have access to the other three interventions.

Therapies that target the cerebral vasculature by restoration of cerebral blood flow (thrombolytics, mechanical embolectomy) and preventing clot formation (aspirin) have shown unequivocal benefit in clinical trials and are approved for use in clinical practice. Neuroprotective strategies targeting the injurious biochemical and molecular cascade are designed to restrict injury to the ischemic brain by preventing neuronal cell death, especially in the salvageable penumbral region. While the concept of neuroprotection has shown promise in experimental studies, thus far there has been failure of translation into clinical success.

2.2 Neuroprotection and Animal Models of Stroke

Over the past 50 years, animal models have been used to test the efficacy of potential neuroprotective stroke therapies both before and after they have gone to clinical trial. Most commonly, these animal models entail occlusion of the middle cerebral artery to induce a "focal" area of brain damage. The standard method of evaluating treatments has been by applying a dye or stain to fine slices of brain tissue after the animal has been sacrificed. Various functional tests for animals have been derived from their clinical counterparts and purport to measure sensory and motor deficits. Such tests have been the mainstay of preclinical testing of potential therapies to reduce the impact of stroke.

To obtain global estimates of efficacy in animal models, data were pooled from two systematic reviews (O'Collins et al. 2006, 2012), which identified studies reporting the efficacy of interventions in animal experiments published 1978–2010. Testing the effect of therapies on infarct size was undertaken in 3,288 acute ischemic stroke experiments (47,899 animals); 94 % of these experiments were undertaken in rats or mice. Data were combined using meta-analysis and meta-regression, partitioned on the basis of stroke model

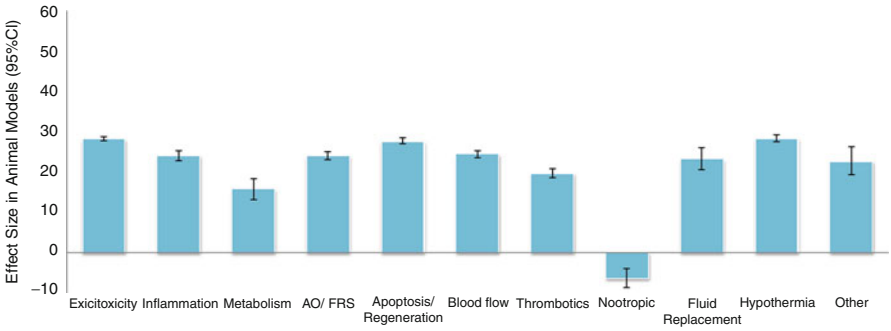

Fig. 2 Testing of acute stroke treatments in animal models. *Bar chart* of data from 3,288 controlled experimental tests of therapies in acute stroke in animal models (47,899 animals), subject to meta-analysis. A higher effect size indicates greater efficacy of the therapeutic class, compared to the control condition. Abbreviations: *AO* antioxidant, *FRS* free radical scavenger

and therapeutic target (e.g., excitotoxicity, thrombolysis, oxidative stress). Because of the heterogeneity, we used random effects meta-analyses (DerSimonian and Laird 1986).

Across all 502 potential therapies included in the dataset, the studies indicated on average a substantial reduction in brain damage (infarct) through use of a therapy (effect size = 25.1 ± .15, 95%CI 24–25.4). Of the 3,288 experiments, 24 % involved testing of excitotoxicity agents, 17 % involved agents targeting apoptosis or regeneration, 13 % involved free radical scavengers/antioxidants, and 12 % deployed hypothermia. The most effective of the therapeutic classes was hypothermia (effect size = 28.4 ± 0.4, 95%CI 27.6–29.3) and anti-excitotoxic drugs (28.3 ± 0.3, 95%CI 27.7–28.8) (see Fig. 2). However, classification of treatment mechanisms is notoriously difficult with treatments with multiple mechanisms of action and no objective measure of the strength of action in a domain.

2.3 Clinical Trials of Neuroprotection in Stroke Versus Animal Data

The Internet Stroke Center website provides a comprehensive database of neuroprotective agents that have been studied in humans (Internet Stroke Center 2013). Table 1 summarizes the key Phase III neuroprotection trials in humans, none of which have shown unequivocal clinical benefit (Table 1). Details of the drugs tested are given below. No neuroprotective strategy – in a narrow sense of the term – is currently approved for clinical use. By contrast, individual therapies tested in animal models and taken to Phase III clinical trial, estimates of efficacy from meta-analysis (Table 2) tend to suggest a positive effect. Note that these estimates are representative and not exhaustive of all animal model studies for each of the drugs listed below.

Table 1 Neuroprotection in acute ischemic stroke. Phase III trials in humans

Category	Drug name	Mechanism	Time window	Patients (drug/placebo)	Clinical Phase	Year	Trial	Reference
Antioxidant	NXY-059	Free radical scavenger	6	1,646/1,660	III	2007	SAINT II	(Shuaib et al. 2007)

[a]rhbFGF basic fibroblast growth factor. Time window is median time of drug delivery post occlusion. Control groups are adjusted for the number of comparisons

2.3.1 Glutamate Antagonists

Glutamate excitotoxicity is an important mediator of ischemia-induced neural injury via the *N*-methyl-D-aspartate (NMDA) and the 3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors.

NMDA Receptor Antagonists

Aptiganel (CNS-1102), a noncompetitive NMDA receptor antagonist (Albers et al. 2001), and Selfotel (CGS 19755) (Davis et al. 2000), a competitive NMDA receptor antagonist, have been studied in Phase III clinical studies. Although preclinical studies indicated that neuroprotection with these agents occurred only after very early administration, a time window of up to 6 h after stroke onset was utilized in human studies. Both agents exhibited significant neurobehavioral toxicity, resulting in a lower dosage being used in human studies than that predicted to provide neuroprotection from comparative preclinical animal studies. A higher mortality was observed in the Aptiganel group with a trend towards higher mortality in the Selfotel group, raising the possibility that NMDA receptor-mediated neuronal survival mechanisms were adversely affected by the delayed administration (Hoyte et al. 2004).

NMDA receptor antagonists have been relatively well studied in animal models of stroke compared with other classes, although even amongst these drugs, relatively few tests were published prior to clinical trial. Aptiganel has been studied in rat models of stroke and has been found to reduce infarct size when administered minutes after stroke onset with effects studied within the few days (Minematsu et al. 1993; Pitsikas et al. 2001; Zhao et al. 2010). When administered subcutaneously in Fisher 344 rats – as opposed to intravenously in more commonly used rat strains – beneficial effects were only seen in a narrow dose range (Pitsikas et al. 2001).

Selfotel has been investigated in focal ischemia models, global ischemia, and spinal cord ischemia, both in cat focal ischemia models (Okada et al. 1997) and in rat models (Jolkkonen et al. 1999; Simon and Shiraishi 1990; Minger et al. 1998), although testing in focal ischemia models is limited. Following adverse effects of NMDA antagonists in clinical trials, psychomimetic effects (e.g., hyperlocomotion, head weaving, and stereotyped sniffing) were studied in a small cohort of stroke rats and similar behavioral effects noted after administration (Loscher et al. 1998).

Gavestinel (GV150526), a NMDA receptor glycine site antagonist (Lees et al. 2000; Sacco et al. 2001) within 6 h of onset, showed no benefit in clinical outcome, mortality, or, in an imaging substudy, infarct attenuation in comparison with placebo (Warach et al. 2006). Gavestinel was tested in the Glaxo-Wellcome Research Laboratories, predominantly in permanent models of ischemia, and benefits on infarct measures of damage were found (Bordi et al. 1997; Di Fabio et al. 1999; Reggiani et al. 2001). Subsequent authors have hypothesized that NMDA receptor antagonists may hinder survival and regeneration (Hoyte et al. 2004); these outcomes were not typically measured in the studies.

AMPA Receptor Antagonists

Two clinical studies using YM872 (an AMPA receptor antagonist) within 6 h of stroke onset with and without concomitant rtPA, were prematurely terminated in 2003 after an interim futility analysis (Internet Stroke Center 2013). The study results have not been published. Animal studies have been undertaken in permanent and temporary occlusion models in rats (Kawasaki-Yatsugi et al. 1998; Shimizu-Sasamata et al. 1998; Haberg et al. 1998; Ni et al. 1998; Suzuki et al. 2003) and cats (Takahashi et al. 1998). While the overall result was positive, a number of individual trials showed minimal or no effect on infarct outcome in animal models.

2.3.2 GABA Agonists

Studies using clomethiazole, a GABA(A) agonist (Wahlgren et al. 1999; Lyden et al. 2002), and diazepam, a GABA-ergic agent (Lodder et al. 2006) within 12 h of stroke onset showed no clinical benefit in comparison with placebo. In contrast, preclinical studies of clomethiazole in rats and marmoset models of stroke conducted by AstraZeneca and others tended to show a reduction in infarct volume and edema compared to control groups (Baldwin et al. 1994; Sydserff et al. 1995, 1996, 2000; Green and Cross 1994; Snape et al. 1993; Marshall et al. 1999, 2000). Studies of diazepam in animal stroke models are few: Diazepam did not reduce infarct volume in a filament occlusion model of stroke (Kuhmonen et al. 2002) but did so in a photothrombotic model (Aerden et al. 2004).

2.3.3 Magnesium

The Intravenous Magnesium Efficacy in Stroke Trial (IMAGES) that randomized 2,589 patients within 12 h of stroke onset showed no clinical benefit for IV magnesium in comparison with placebo with a trend to higher mortality in the IV magnesium-treated group (Muir et al. 2004). The median time to treatment was 7 h, and only 3 % were treated within 3 h. The Field Administration of Stroke Therapy – Magnesium (FAST-MAG) Trial is currently recruiting to evaluate the safety and effectiveness of paramedic initiation of IV magnesium within 2 h of stroke onset (Internet Stroke Center 2013).

Magnesium has been relatively well characterized in investigator-sponsored trials in animal models of ischemia (Marinov et al. 1996; Lin et al. 2002; Westermaier et al. 2003; Meloni et al. 2006; O'Collins et al. 2011). It has been suggested that the effect of magnesium is via its effect on temperature, for where spontaneous hypothermia was prevented, no protective effect was seen (Zhu et al. 2004; Song et al. 2012; Campbell et al. 2008). A number of studies have found that magnesium is more effective when combined with other neuroprotective strategies (Schmid-Elsaesser et al. 1999; Zhao et al. 2010; Chung et al. 2004; Meloni et al. 2009; Campbell et al. 2008; Song et al. 2012; Wang et al. 2012), but not always (Lee et al. 1999). It has been argued that the sulfate salt is possibly more effective than the chloride salt (Izumi et al. 1991).

2.3.4 Antioxidants

NXY-059

NXY-059, a nitrone with free radical scavenging properties, was subjected to more extensive preclinical testing than most other agents prior to entering clinical trials in humans although subsequently several deficiencies were identified (Savitz 2007). The SAINT I (Lees et al. 2006) and SAINT II (Shuaib et al. 2007) studies randomized 1,722 and 3,306 patients, respectively, to receive a 72-h infusion of NXY-059 commencing within 6 h of stroke onset. The SAINT I trial reported a small but statistically significant shift of the modified Rankin score (mRS) at 3 months, but there was no change in the Barthel index or NIHSS scale. The SAINT II trial failed to confirm the data reported in SAINT 1. When taken together, the investigators concluded that NXY-059 was ineffective for the treatment of acute ischemic stroke.

NXY-059 is interesting from a preclinical perspective in that it was one of the first drugs said to have been conducted according to rigorous experimental standards (the STAIR guidelines) (Kuroda et al. 1999; Marshall et al. 2001; Zhao et al. 2001; Lapchak et al. 2002a, b; Sydserff et al. 2002; Yoshimoto et al. 2002a, b; Lapchak and Araujo 2003; Marshall et al. 2003a, b; Lapchak et al. 2004). There was much hope that it would succeed at clinical trial, and after this failed, it received criticism for falling short in terms of methodological quality (Macleod et al. 2008; Bath et al. 2009; Savitz 2007). Nevertheless, the preclinical literature is still stronger than many other drugs which have been taken to clinical trial.

Tirilazad

Tirilazad, an aminosteroid that inhibits free radical-induced lipid peroxidation, showed no clinical benefit in acute stroke when initiated within 6 h of stroke onset (The RANTTAS Investigators 1996). A subsequent meta-analysis revealed that tirilazad increased death and disability by about one-fifth when given to patients with acute ischemic stroke (Tirilazad International Steering Committee 2000). In animal models, tirilazad (U74006F) has reduced infarct size in a rat and rabbit model of stroke but not cat (Alessandri et al. 2000; Beck and Bielenberg 1991; Hellstrom et al. 1994; Orozco et al. 1995; Oktem et al. 2000; Park and Hall 1994; Schmid-Elsaesser et al. 1998, 1999; Scholler et al. 2004; Takeshima et al. 1994; Umemura et al. 1994; Wilson et al. 1992; Xue et al. 1992; Zausinger et al. 2003a, b; He et al. 1993).

2.3.5 Membrane-Stabilizing Agents

Citicoline

Citicoline is an exogenous form of cytidine 5′-diphosphate choline, which is essential for the biosynthesis of membrane phospholipids. The ICTUS study (Dávalos et al. 2012) that randomized 2,298 patients to receive citicoline or placebo within 24 h of stroke onset did not confirm the clinical benefits that had been suggested by a meta-analysis of four smaller trials using this agent (Dávalos et al. 2012). In animal models of stroke, citicoline is one of the best agents characterized,

second only to tissue plasminogen activator (Schabitz et al. 1996; Onal et al. 1997; Andersen et al. 1999; Shuaib et al. 2000; Katsumata et al. 2001; Ataus et al. 2004; Hurtado et al. 2005, 2007; Adibhatla et al. 2006; Ramos-Cabrer et al. 2011; Xu et al. 2011; Diederich et al. 2012).

Piracetam, a GABA derivative, is also used clinically to improve cognitive function. Although taken to clinical trial, only a few studies have reported its function in animal models (Tortiglione et al. 2002; Muley et al. 2012). Repinotan (BAY x 3702) is a selective 5-HT1A receptor agonist developed and tested in animal models by Bayer Health Care (Berends et al. 2005) and tested in focal models (Semkova et al. 1998; Mauler and Horvath 2005).

2.3.6 Calcium Modulators

Voltage-Gated Calcium Antagonists

A meta-analysis published in 2001 of 29 studies that included 7,665 patients with acute ischemic stroke treated with calcium antagonists reported no benefit with respect to clinical outcome or mortality (Horn and Limburg 2001). The calcium antagonists used were nimodipine in 23 studies, flunarizine in 3 studies, and isradipine and nicardipine in 1 study each. In 25 studies, including the Phase III TRUST (1,215 patients) and the American Nimodipine study (1,064 patients), treatment was started up to 48 h after stroke onset. There was no beneficial effect observed in the subgroup (660 nimodipine, 619 placebo) that received oral nimodipine within 12 h. Subsequent to this meta-analysis, the Very Early Nimodipine Use in Stroke (VENUS) trial reported the use of oral nimodipine within 6 h of stroke onset. This study was prematurely terminated by the steering committee because of sample size concerns. At the time 454 patients had been randomized and nimodipine was not associated with reduction of death or dependency at 3 months.

In animal studies, nimodipine was one of the earliest drugs trialed. More recently, it has been used a positive control against newer treatments, especially in studies of traditional Chinese medicines (Tian et al. 2005; Lu et al. 2011; He et al. 2012). It has been tested in mice, rats, and cats (Barnett et al. 1986; Gotoh et al. 1986; Hakim 1986; Sauter and Rudin 1986; Germano et al. 1987; Berger and Hakim 1988; Sauter et al. 1989; Jacewicz et al. 1990; Sakaki et al. 1991; Prehn et al. 1993; Herz et al. 1996; Cramer and Toorop 1998; Kawaguchi et al. 1999; Sobrado et al. 2003; Zausinger et al. 2003). In the 36 experimental comparisons included here, the median time for treatment was 5 minutes prior to ischemia.

Ginsenoside

Ginsenoside is a receptor-mediated calcium channel antagonist that does not lower blood pressure like voltage-gated calcium antagonists such as nimodipine discussed above. Liu et al. (2012) randomized 390 patients with acute ischemic stroke in a 3:1 ratio to receive a 14-day intravenous infusion of ginsenoside or placebo within 72 h after the onset of stroke. The primary outcome was positive with improved distribution of disability scores on the modified Rankin

scale (mRS) at 90 days in the group receiving ginsenoside. This is a promising result that needs verification in a larger RCT, bearing in mind that the initial NXY-059 trial reported a similar positive result based on shift of the mRS scores that was not confirmed in a second larger trial.

Ginsenosides (ginseng saponins) are the active component isolated from the traditional Chinese medicine ginseng, from the root of Panax ginseng. Over 30 different ginsenosides have been isolated, a number of these have been recently studied in animal models: ginsenoside Rb(1), ginsenoside Rd, ginsenoside Rh2, ginsenoside Rg(2), ginsenoside RG3, and fermented ginseng (Bae et al. 2004). Animal models suggest that the mode of action is on mitochondrial energy metabolism and altered activity of the mitochondrial permeability transition pore (Tian et al. 2009) and potentially via its effect on neural plasticity (Cheng et al. 2005) and angiogenesis (Yang et al. 2012). Rodent models have shown dose-dependent reductions in infarct size; however, sample sizes tend to have been small, and in many studies animals were treated prior to ischemia (Park et al. 2004; Tian et al. 2005; Zhang et al. 2006; Lu et al. 2011; Ye et al. 2011a, b, c; He et al. 2012; Yang et al. 2012; Zhu et al. 2012).

2.3.7 Anti-apoptotic and Trophic Factors

Cerebrolysin

First developed in Russia in the 1970s, cerebrolysin is a porcine brain-derived preparation of low-molecular-weight neuropeptides (10 kDa) and free amino acids that shows pharmacodynamic properties similar to those of naturally occurring neurotrophic factors. The CASTA study investigators randomized 1,070 patients to receive cerebrolysin or placebo within 12 h of stroke onset (Heiss et al. 2012). There was no difference in the primary outcome of a global functional scale, but there was a trend towards lower disability and reduced mortality in the cerebrolysin group for patients with more severe stroke (NIHSS >12). Cerebrolysin has demonstrated efficacy in a limited set of animal focal ischemia experiments (Schwab et al. 1998; Ren et al. 2007; Hanson et al. 2009; Zhang et al. 2010).

Erythropoietin, either alone or in combination with another agent after ischemic stroke, has attracted much interest in the last decade. Where animal tests have been undertaken, the time window for delivery tends to have been longer than other potential neuroprotectives and more emphasis has been placed on behavioral tests (Bernaudin et al. 1999; Brines et al. 2000; Wang et al. 2004, 2007; Esneault et al. 2008; Belayev et al. 2009; Fletcher et al. 2009; Jia et al. 2010; Zechariah et al. 2010).

2.4 Possible Reasons for Failure of Neuroprotection

With such positive data from animal experiments, how is it then that the promise of neuroprotection has thus far failed to translate into clinical benefit in human stroke studies (Ginsberg 2008; Sutherland et al. 2012)? There are numerous

preclinical and clinical reasons that could account for this failure. Failure of the initial clinical trials led to the development of the STAIR guidelines in 1999 for preclinical animal testing (STAIR Group 1999). In the wake of negative human clinical trials of compounds such as NXY-059 that had appeared promising in animal trials that fulfilled these guidelines, the criteria were revised in 2009 (Fisher et al. 2009).

A key issue in the human clinical trials is whether the agent actually reached the target tissue, the ischemic penumbra. The time window for effective thrombolysis in humans is 4.5 h after sstroke onset with greatest efficacy at earlier time points when the penumbra is maximal. By contrast, the completed Phase II/III studies of neuroprotective agents in humans had time windows of up to 48 h although efficacy was demonstrated at a shorter time window in the corresponding animal studies where there is no evidence of effective neuroprotection beyond 6 h. In the animal data surveyed above, the median time of treatment administration was 10 min after stroke onset.

Ischemic stroke in humans is heterogeneous with a multitude of subtypes and mechanisms. In contrast, animal studies have used relatively homogenous MCA occlusion models, but this particular stroke subtype accounts for only about 25 % of ischemic strokes in humans. Potential therapies have been tested almost exclusively in male animals (unless a female hormone is implicated in the mode of action) and in young animals (our data suggests that less than 1 % of testing occurs in middle-aged or old animals).

Neurotoxicity or neuroprotection may also occur as a covariate in animal models, e.g., anesthetic agents such as ketamine have effects on regional cerebral blood flow, EEG, sensation, and memory. Finally, there are important anatomical differences in gray and white matter distribution animal and human brains. The ischemic cascade has been studied primarily in gray matter that accounts for 90 % of rodent brain, but white matter accounts for approximately 50 % of human brain tissue involved by ischemic stroke (Ho et al. 2005).

3 The Future of Neuroprotection in Ischemic Stroke

3.1 Current Trends

The large numbers of negative clinical trials of neuroprotection in humans have led to calls for abandoning future trials, citing ineffectiveness of this strategy (The Lancet 2006). Others have reasonably argued for improved design of future trials of neuroprotectants in humans, primarily with shorter time windows and use in conjunction with thrombolytic therapy (Ginsberg 2008; Sutherland et al. 2012). Current ongoing trials of neuroprotection strategies in ischemic stroke incorporating these changes include intravenous magnesium within 2 h of onset (Internet Stroke Center 2013) and uric acid, an endogenous antioxidant in conjunction with rtPA (Amaro et al. 2010). In preclinical development, current trends

in neuroprotection include a focus on the microvasculature, inflammation, and the neurovascular unit and, secondly, a focus on endogenous neuroprotection and regeneration (stem cells, hormones, oxygen metabolism).

3.2 Improved Drug Development Procedures

Few of the agents tested in animal models of stroke have been developed specifically for treatment of ischemic stroke. This will reflect a bias against publication of potentially patentable drugs. However, it also suggests a need for better funding of stroke target identification and validation, together with better development of lead drug candidates before taking candidates to preclinical studies.

3.3 Toxicity in Animal Models of Stroke

Although toxicity is a frequent cause of drug failure at clinical trial, preclinical investigation of toxicity is generally looked at further down the preclinical pathway. Simultaneous optimization of drug efficacy and ADMET properties (absorption, distribution, metabolism, elimination, toxicology) is a strategy which could be looked at in greater detail in stroke drug development. To this end, improved computational tools for better prediction of toxicity based on biochemical pathways and drug characteristics may assist.

Expanding preclinical outcome measures beyond the standard measures of brain damage and neurological score may help identify potential neurotoxicity of drugs earlier. Cognitive deficit which has been noted following administration of NMDA antagonists could have been detected in animal models with tests typically deployed in other areas of neuroscience, for instance, locomotion (hyperlocomotion), prepulse inhibition disturbances, and disruptions to social interactions. Side effects of stroke drugs can include neurotoxicity but may also extend to genotoxicity, carcinogenicity, reproductive and developmental toxicity, and skin sensitization or irritation.

4 Conclusion

Ischemic stroke is a complex disease that straddles the vascular and nervous systems and is frequently confounded by comorbidities such as hypertension, diabetes and age-related degeneration. Thus, identifying and targeting individual causes of neurotoxicity in stroke is a great challenge for the clinical testing and laboratory development of novel therapeutics. The clinical and animal trials reviewed here have tended to focus on protecting the brain against damage caused by free radical scavengers and excitoxicity, or have used pharmacological means to target calcium modulation, membrane stabilization and trophic factors.

Acknowledgments Sources of funding: V. O'Collins was funded by an Australian Postgraduate Award scholarship. The work was also supported by an Australian National Health and Medical Research (NHMRC) Program Grant.

Disclosures/conflicts of interest: D. W. Howells has been the recipient of industry and government funding for research into neuroprotection.

Abstract

Huntington Disease (HD) is an autosomal dominant, progressive, neurodegenerative disorder, due to abnormal CAG expansion in the Chromosome 4 *Huntingtin* (*HTT*) gene. Typical age of onset is in the 30s-40s, and symptoms include involuntary movements, cognitive/behavioural symptoms and psychiatric disorders. As a monogenic disorder, the aetiology of HD is well established - however our understanding of the pathogenesis of HD is still evolving. In particular, mutation in the *HTT* gene confers neurotoxicity on multiple levels, ranging from the genetic/protein level, intracellular level, intercellular level, to the end-organ level. On a genetic/protein level, a *HTT* mutation is associated with toxic gain of function, loss of normal function and altered transcription of other genes. On an intracellular level, it is associated with mitochondrial dysfunction and impaired cytoskeleton/intra-cellular trafficking. On an intercellular level, it is associated with impaired synaptic transmission, excitoxicity and inflammation. On an organ level, both the brain and peripheral tissues are affected. We will review each of these areas in this article.

Keywords

Huntington disease • Molecular genetics • Neurodegeneration • Neurotoxicity • Polyglutamine • Tandem repeat disorder

1 Introduction

Huntington Disease (HD) is an autosomal-dominant, progressive, neurodegenerative disorder, due to abnormal CAG expansion in the chromosome 4 *Huntingtin (HTT)* gene. It is one of the most common neurogenetic disorders (MacMillan and Harper 1991), and has devastating consequences for patients and their families (Vamos et al. 2007). Typical age of onset is in the 30s–40s, and symptoms include involuntary movements, cognitive/behavioral symptoms, and psychiatric disorders (Walker 2007). While symptomatic treatments exist, these do not prolong survival, and median survival is about 20 years (Walker 2007). HD strikes at a productive period in work and family life, and requires a high level of complex care. Consequently, the direct and indirect cost of HD has been informally estimated to be two billion dollars per year, in the United States alone (Society for Neuroscience 2005).

2 Overview

As a monogenic disorder, the etiology of HD is well established (The Huntington's Disease Collaborative Research Group 1993), however our understanding of the pathogenesis of HD is still evolving. In particular, mutation in the *HTT* gene appears to confer neurotoxicity on multiple levels, ranging from the genetic/protein level, intracellular level, intercellular level, to the end-organ level (Table 1). We will review each of these areas in turn.

Table 1 Mutation in the Huntingtin gene leads to neurotoxicity on multiple levels

	Consequences of mutation in the *Huntingtin* gene
Neurotoxicity on a genetic/protein level	Toxic gain of function:
	1. Altered conformation
	2. Aberrant posttranslational modifications
	3. Impaired clearance
	4. Toxic proteolytic cleavage products
	5. Increased propensity to aggregate
	Loss of normal function
	Altered transcription of other genes
Neurotoxicity on an intracellular level	Role of the intranuclear inclusion body
	Mitochondrial dysfunction
	Impaired cytoskeleton and intracellular trafficking
Neurotoxicity on an intercellular level	Impaired synaptic transmission
	Excitotoxicity and the kynurenine pathway
	Inflammation (?)
Neurotoxicity on the end-organ level	Brain
	Peripheral tissues

3 Neurotoxicity on a Genetic/Protein Level

The *HTT* gene is located on the short arm of chromosome 4 (4p16.3) (Meyer et al. 2012). It has 67 exons and encodes a 348-kDa nuclear protein which is widely expressed in the human brain as well as other tissues (Strong et al. 1993). Exon 1 of the *HTT* gene contains a polymorphic CAG repeat, which is expanded among people with HD. The general population carries up to 26 repeats at this locus, and people carrying 40 or more repeats almost invariably develop clinical HD (ACMG/ASHG 1998). People with 36–39 CAG repeats have reduced penetrance. People with 27–35 CAG repeats do not develop clinical HD, but their offspring may do so, due to meiotic instability of the CAG repeat and further expansion across generations (Leeflang et al. 1995).

3.1 Toxic Gain of Function

From a genetic point of view, the prevailing hypothesis is that the expanded CAG repeats lead to a toxic gain of function. This is supported by: (1) the dominant mode of inheritance, (2) association of longer CAG repeats with earlier age of onset (Lee et al. 2012), and (3) no worsening of clinical HD phenotype among people

without a normal copy of *HTT* gene (i.e., people with homozygous HD mutations) (Wexler et al. 1987). In addition, a transgene expressing the human *HTT* Exon 1 with expanded CAG repeats was sufficient to cause a HD-like phenotype in the R6 lines of transgenic mice (Mangiarini et al. 1996).

Accordingly, the mutant huntingtin protein (mHTT) has been studied to elucidate a potential pathogenic mechanism for HD. Compared to wildtype huntingtin protein (wHTT), mHTT has (1) altered conformation, (2) aberrant posttranslational modifications, (3) impaired clearance, (4) toxic proteolytic cleavage products, and (5) increased propensity to aggregate (Ross and Tabrizi 2011).

3.1.1 Altered Conformation

In wHTT, the CAG expansion translates to an N-terminal polyglutamine tail which is flexible and can adopt a variety of conformations (Kim et al. 2009). However, when the CAG region is expanded into the pathogenic range, mHTT develops a compact two-strand hairpin conformation (Peters-Libeu et al. 2012). This hairpin epitope was identified using the 3B5H10 antibody, which also predicts the severity of neurodegeneration upon live cell imaging (Miller et al. 2011). Exactly how this hairpin structure leads to neurodegeneration is currently unclear, although early pathogenic processes are likely to include changes in protein solubility, aggregation, and protein–protein interactions.

3.1.2 Aberrant Posttranslational Modifications

Posttranslational modification (PTM) of mHTT is altered compared to wHTT. Examples of these PTM include phosphorylation, palmitoylation, ubiquitination, and acetylation. Huntingtin is constitutively phosphorylated at multiple sites (Schilling et al. 2006), and in general, mHTT is less phosphorylated than wHHT (Ehrnhoefer et al. 2011). For instance, in cell models, phosphorylation of Threonine-3 in HTT declines in a dose–response manner, with increasing CAG repeat length (Aiken et al. 2009). When phosphorylation was mimicked using site-specific mutagenesis for Serines-13 and -16, mHTT aggregation was reduced in vitro, and motor/psychiatric symptoms improved in a mouse model (Gu et al. 2009). Palmitoylation at Cysteine-214 of the HTT protein is also reduced, in the presence of a pathogenic CAG repeat (Yanai et al. 2006). Cells expressing mHTT resistant to palmitoylation are associated with faster inclusion body formation (Yanai et al. 2006). Ubiquitination is associated with protein targeting for proteasome degradation. Mutant HTT with expanded glutamine repeats have a slower rate of degradation in the proteasome (Jana et al. 2001). In addition, a protein specific to the striatum, the Ras Homologue Enriched in the Striatum (Rhes) protein, selectively increases SUMO-ylation (Small Ubiquitin-like modifier) of mHTT. This results in disaggregation of mHTT and cytotoxicity, and is consistent with the anatomical distribution of HTT (Subramaniam et al. 2009). Finally, acetylation at Lysine-444 of mHTT is associated with tagging for autophagy in vitro. This reverses toxic effects of mHTT in *C. elegans* and cell models, and is an example where alteration in posttranslational modification of mHTT is beneficial rather than deleterious (Jeong et al. 2009).

3.1.3 Impaired Clearance

Clearance of mHTT is impaired. In addition to the slower rate of degrading mHTT in the proteasome, N-terminal fragments of mHTT were found to directly impair functioning of the Uniquitin/Proteosome System (UPS) in a cellular model (Bence et al. 2001). More recently, this has been confirmed in vivo, using a UPS reporter/inducible HD mouse model (Ortega et al. 2010). UPS dysfunction was found transiently after expression of N-terminal mutant HTT, and recovered with appearance of inclusion bodies.

3.1.4 Toxic Proteolytic Cleavage Products

A number of experiments support the notion that neurotoxicity in HD arises from toxic proteolytic cleavage products of mHTT rather than the full mHTT molecule. These include: (1) sufficiency of *HTT* Exon 1 to cause an HD-like phenotype in a transgenic mouse model (Mangiarini et al. 1996), and (2) normal phenotype in a mouse model expressing caspase-6 resistant mHTT (Graham et al. 2006). In addition to caspases, calpains also play a role in proteolytic cleavage (Southwell et al. 2011). More recently, CAG repeat length-dependent aberrant splicing of the *HTT* gene has been found to be an alternative mechanism in generating N-terminal mHTT fragments (Sathasivam et al. 2013).

3.1.5 Increased Propensity to Aggregate

Early neuropathologic studies of the brains of people with HD found intranuclear inclusion bodies that contained protein aggregates immunoreactive to antibodies raised to the N-terminal 17 amino acids, but not an internal epitope for HTT (Becher et al. 1998). This raised the question as to whether these N-terminal HTT fragments, aggregated in inclusion bodies, were pathogenic. As evidence was generated showing that the inclusion bodies could be protective rather than pathogenic (Arrasate et al. 2004) (see Sect. 4.1 for further details), attention was shifted to polyglutamine monomers and oligomers, which may be more neurotoxic (Miller et al. 2011). Oligomer formation is faster and more extensive for HTT fragments with longer polyglutamine tracts (Legleiter et al. 2010). This increased propensity for mHTT to aggregate also provides an explanation for the inverse relationship between CAG repeat length and age of onset in HD. Interestingly, an aggregation kinetic study has found a static population of oligomers despite ongoing conversion of mHTT monomers to inclusion bodies in a cell models (Olshina et al. 2010). This suggests that neurotoxicity due to oligomers may be a constant process, and correlates poorly with inclusion body formation.

3.2 Loss of Normal Function

While the prevailing hypothesis for neurotoxicity of CAG expansion is a toxic gain of function, there is also an argument that loss of normal function may play a role (Cattaneo et al. 2005). Mouse models without a normal copy of the murine

HTT analogue gene are embryonically lethal (Duyao et al. 1995; Nasir et al. 1995). Inactivation of the murine *HTT* analogue genes postnatally also leads to a progressive neurodegenerative phenotype (Dragatsis et al. 2000). These underline the role of wHTT in normal neuronal functioning, which include: (1) upregulation of brain-derived neurotrophic factor (BDNF) (Zuccato et al. 2001), (2) interaction with the motor proteins and microtubules in BDNF transport (Gauthier et al. 2004), and (3) interaction with literally hundreds more proteins (Kaltenbach et al. 2007), including ones important for synaptic function (Milnerwood and Raymond 2010).

3.3 Altered Transcription of Other Genes

Wildtype HTT upregulates BDNF by sequestering repressor element-1 transcription factor/neuron restrictive silencer factor (REST/NRSF) in the cytoplasm, reducing its availability to bind neuron restrictive silencer element (NRSE) in the nucleus, thus allowing increased transcription (Zuccato et al. 2003). This mechanism also applies to a number of other NRSE-containing genes, and is impaired in mHTT. NRSE is only one of many pathways through which gene transcription is altered in HD. Other examples include nuclear receptor compressor (N-CoR) (Boutell et al. 1999), transcription factor Sp1 (Dunah et al. 2002), the Histone Acetyltransferase cAMP response element-binding protein (CREB) (Nucifora et al. 2001), and RNA-mediated gene silencing through association with the Argonaute (Savas et al. 2008). As a consequence, mHTT is associated with widespread alteration in gene transcription both in development (Feyeux et al. 2012) and diseased brains (Hodges et al. 2006). Drugs targeting some of these transcriptional changes, e.g., Histone Deacetylase Inhibitors, appear to be promising therapeutic agents (Steffan et al. 2001).

4 Neurotoxicity on an Intracellular Level

4.1 Role of the Intranuclear Inclusion Body

A characteristic feature of the neuropathology HD is the intranuclear inclusion body, which stains positive for ubiquitin and HTT. They also stain positive for antibodies raised to the N-terminal 17 amino acids, but not those raised to an internal epitope of HTT. This was the case in both the R6/2 mouse model (Mangiarini et al. 1996) and human archival tissue (Becher et al. 1998). The role of inclusion bodies in pathogenesis was clarified with automated microscopy and live cell imaging, where inclusion body formation was associated with improved neuron survival rather than death (Arrasate et al. 2004). Since then, the focus on mHTT has shifted to mHTT monomers and oligomers.

4.2 Mitochondrial Dysfunction

Mutant HTT can impair cellular mitochondrial function directly and indirectly. Direct effects of mHTT on the mitochondria include altered calcium handling and mitochondrial dynamics. Mitochondrial capacity to retain calcium is impaired in HD (Panov et al. 2002), where mHTT is thought to interrupt membrane integrity (Choo et al. 2004; Rockabrand et al. 2007). This, in turn, adds to the effect of glutamate/calcium-mediated excitotoxicity. Mutant HTT contributes toward increased intracellular calcium by sensitizing activation of the type 1 inositol-(1,4,5)-triphosphate receptor, thus increasing calcium release from the endoplasmic reticulum (Tang et al. 2003).

Mitochondria undergo continual fissure and fusion, and alteration of its dynamics can lead to neurodegeneration (Knott et al. 2008). Mutant HTT triggers mitochondrial fragmentation and arrests mitochondrial transport, through abnormal interaction with the GTPase dynamin-related protein 1 (DRP1) (Song et al. 2011). Interestingly these cellular changes can be rescued by reducing DRP1 activity.

Finally, mHTT also impairs mitochondrial function indirectly by inhibiting expression of peroxisome proliferator-activated receptor [PPAR]-gamma coactivator-1 alpha (PGC-1 alpha), a transcriptional coactivator that regulates mitochondrial function (Cui et al. 2006). The mechanism for this is likely to be through interference with the CREB transcription pathway.

4.3 Impaired Cytoskeleton and Intracellular Trafficking

Wildtype HTT binds to monomeric tubulin and microtubules, while mHTT disrupts integrity of microtubule filaments (Trushina et al. 2003). Mutant HTT is associated with neurite retraction in a cell culture model, indicating cytoskeletal collapse. Toxicity of mHTT can also be modulated by microtubule stabilization using low-dose taxol (Trushina et al. 2003).

Mutant HTT is associated with impaired axonal transport, with possible mechanisms including: titration of motor proteins such as kinesin from other cargoes (Gunawardena et al. 2003), direct blockage of axonal transport by aggregates (Lee et al. 2004), and by reducing kinesin-1 binding to microtubules through mHTT associated cJun N-terminal kinase (JNK) activation (Morfini et al. 2009).

Loss of normal function of wHTT, as an integrator of molecular motors, may also contribute toward the disrupted intracellular trafficking in HD (Caviston and Holzbaur 2009). An example of one such molecular binding partner for HTT is Huntingtin-Associated Protein 1 (HAP1) (Li et al. 1995). HAP1 is concentrated in axon terminals and promotes neurite extension (Li et al. 2000). Mutant HTT reduces HAP1 binding to molecular motors, resulting in decreased level of the

nerve growth factor receptor Tropomyosin-receptor kinase A (TrkA), and neurite outgrowth (Rong et al. 2006). Translating to human studies, an amino-acid substituting polymorphism in *HAP1* was found to be associated with a later age of onset in HD (Metzger et al. 2008). Finally, mHTT also impairs transport of mitochondria (Song et al. 2011) and vesicles (Gauthier et al. 2004).

5 Neurotoxicity on an Intercellular Level

5.1 Impaired Synaptic Transmission

In addition to vesicular transport, synaptic transmission is also affected in HD (Smith et al. 2005). In exocytosis, mHTT reduces the level of Complexin II, a protein involved in the transport vesicle/presynaptic protein-binding process (Edwardson et al. 2003). In that cell model, there was a corresponding reduction in calcium-triggered exocytosis of neurotransmitters.

Mutant HTT impairs endocytosis through interaction with caveolin-1, which has a role in forming invaginations of the plasma membrane (Trushina et al. 2006). There is some suggestion that mHTT could impair clathrin-mediated endocytosis; however, the data is conflicting (Trushina et al. 2006; Borgonovo et al. 2013).

These, together with other factors, have resulted in complex changes of glutamate and dopamine levels in the brain (Andre et al. 2010). Another neurotransmitter affected by mHTT is Gamma-AminoButyric Acid (GABA) (Pearson and Reynolds 1994).

5.2 Excitotoxicity and the Kynurenine Pathway

The association between excitotoxicity and HD was made prior to molecular characterization of HTT. This was based on the shared, extrinsic axon sparing phenotype, between the human HD brain and lesion models using excitatory amino acids (Schwarcz et al. 2010). In particular, the Quinolinic acid (QUIN) lesioned rats were found to have similar neurochemical profiles to human HD brains. These neurochemical profiles were characterized by depletion of GABA and Substance P, and relative sparing of Somatostatin/Neuropeptide Y neurons (Beal et al. 1986). QUIN level was also raised in early stage HD brains (Guidetti et al. 2004). QUIN is a downstream product of the kynurenine pathway (KP), which catabolizes the amino-acid tryptophan. It forms part of the neuroinflammatory response and acts as an excitotoxin through the *N*-methyl-D-aspartate (NMDA) receptor (Guillemin 2012). Recent interest in the KP for HD has grown, following reports that modulation of the KP led to improved life span in a mouse model (Zwilling et al. 2011), and a *Drosophila* model of HD (Campesan et al. 2011).

5.3 Inflammatory Response

There are a few lines of evidence, in addition to QUIN, that suggest a role of inflammation in HD (Soulet and Cicchetti 2011). In a mouse model where mHTT is selectively expressed in astrocytes only, the phenotype remained similar to the corresponding fully expressed HD mouse, albeit with a late onset (Bradford et al. 2009). Microglial activation measured on Positron Emission Tomography scans also correlated with clinical severity of people with HD (Pavese et al. 2006). Nonetheless, the exact role of inflammation in the pathogenesis of HD remains unclear.

6 Neurotoxicity on an Organ Level

6.1 Brain

Since Graveland et al.'s Golgi impregnation study in 1985, medium-sized spiny neurons in the striatum have been considered the primary cell type affected in HD (Graveland et al. 1985). Medium-sized spiny neurons require a high level of energy to maintain their unusually high transmembrane potentials. This makes them more vulnerable than other cell-types to the disrupted cellular respiration in HD (Mitchell et al. 1999).

However, the striatum is not the only brain region affected in HD. Recently, a large HD brain autopsy series ($N > 500$) (Hadzi et al. 2012) highlighted the role of the cerebral cortex. Forty-one neuropathologic ratings from various regions of the brain were categorised into two clusters: the striatal and cortical clusters. Neurodegeneration in the striatal cluster had a stronger correlation with HD CAG repeat size, but the cortical cluster had a stronger correlation with brain weight. These suggested that neurodegeneration in the striatum and the cortex do not necessarily proceed in a coupled manner.

6.2 Peripheral Tissues

Finally, the effect of mHTT reaches beyond the brain (Sassone et al. 2009; van der Burg et al. 2009). For instance, derangement in the hypothalamic–pituitary–adrenal axes is not the only potential mechanism for weight loss in HD. Other contributory mechanisms include the effect of mHTT on the gastrointestinal tract (impaired motility and malabsorption) (van der Burg et al. 2011), pancreas (altered glucose homeostasis) (Lalic et al. 2008), adipose tissue (Phan et al. 2009), and a hypermetabolic state (Mochel et al. 2007).

7 Conclusion

Given the complex and varied mechanisms leading to neurotoxicity in HD, it is unlikely that a therapeutic agent based on any single mechanism will be able to reverse all disease manifestations of HD. This makes oligonucleotides (RNA interference and antisense oligonucleotides) (Sah and Aronin 2011) a particularly attractive therapeutic approach, as they will be acting upstream of most other neurotoxic mechanisms. Animal studies using oligonucleotides have been promising (Kordasiewicz et al. 2012; Yu et al. 2012), and the first round of human safety trials is keenly awaited. However, complementary therapeutic approaches, addressing a range of pathogenic targets, need to be addressed in parallel, to combat this devastating disease.

Neurotoxicity: A Complex Multistage Process Involving Different Mechanisms

Ewa Niedzielska, Bartłomiej Rospond, Lucyna Pomierny-Chamioło, Anna Sadakierska-Chudy, and Małgorzata Filip

Contents

Abstract

Neurotoxicity is defined as alterations causing physical damage or disruption in functions of the cells (neurons, glial cells) of the nervous system. There are several mechanisms by which neurotoxic processes take place. These include high concentrations of glutamate and/or calcium ions, increased oxidative damage, and reactive species (RS) such as free radicals, mechanisms linked to execution of

apoptosis, glial dysfunction injury, and/or genetic-epigenetic defects in protein clearance. Each of these mechanisms reciprocally modulates their own actions and is capable of neuronal cell death followed by nervous system dysfunction.

Keywords

Apoptosis • Calcium ions • DNA damage • Epigenetic • Glia activation • Glutamate • Neurotoxicity mechanism • Neurotoxicity pathway • Oxidative stress

List of Abbreviations

5-HT	Serotonin
AIF	Proapoptotic inducting factor
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
Apaf-1	Apoptotic protease activating factor-1
ATP	Adenosine triphosphate
CAT	Catalase
CNS	Central nervous system
CpG	Cytosine-guanine dinucleotide
CREB	cAMP response element binding
CYP	Cytochrome P450
DISC	Death-inducing signaling complex
DNMT	DNA methyltransferase
EAAT	Excitatory amino-acid transporter
endo-G	Endonuclease G
esiRNA	Endogenous small interfering RNA (endo-siRNA)
FADD	Fas-associated death domain
FasL	Fas ligand
GABA	ɣ-aminobutyric acid
GPx	Glutathione peroxidase
GR	Glutathione reductase
GSH	Glutathione
GSSG	Glutathione disulfide
HAT	Histone acetyltransferase
HDAC	Histone deacetylase
HDM	Histone demethylase
HMT	Histone methyltransferase
IAP	Inhibitor of apoptosis protein
IL	Interleukin
JNK	c-Jun NH_2-terminal kinase
lncRNA	Long noncoding RNA
MAO	Monoamine oxidase
MDA	Malondialdehyde
miRNA	microRNA
MMP	Metalloproteinase
ncRNA	Noncoding RNA
NMDA	*N*-methyl-D-aspartic acid

NOS	Nitric oxide synthase
NSL	Nuclear localization signal
PARP	Poly-ADP ribose polymerase
piRNA	Piwi-interacting RNA
RBS	Reactive bromine species
RCS	Reactive chloride species
RIP	Receptor-interacting protein
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
RS	Reactive species
SMAC	Small mitochondria-derived activator of caspase
SOD	Superoxide dismutase
SODD	Silencer of death domain
TNF	Tumor necrosis factor
TRADD	TNF receptor-associated death domain
TRAF2	TNF-R-associated factor 2
TRPM	Transient receptor potential melastin
VGLUT	Vesicular glutamate transporter
xCT	Cystine-glutamate antiporter

1 Introduction

Neurotoxicity is defined as alterations in the normal activity of the nervous system to cause its physical damage (e.g., cell death) or disruption in functions (e.g., neurocognitive deficits, poor judgments, and diminished decision-making capacity). Within the central nervous system (CNS), neuronal cells are key factors for neurotoxicity and degeneration in many diseases. However, in the mid-1990s research has shown that glial cells (i.e., astroglia, microglia, and oligodendrocytes) also play a number of active roles in the brain and are sensitive indicators for pathology of the CNS (see also Clark et al. 2013). Thus, astrocytes – apart from provision of nutrients to the nervous tissue, maintenance of both extracellular ion balance and the blood–brain barrier, and a role in the repair and scarring process of the brain and spinal cord following traumatic injuries – are engaged in the release or absorption of neural transmitters (called gliotransmission) (Ben Achour and Pascual 2012; Santello et al. 2012). For example, astrocytes propagate intercellular calcium waves over long distances in response to stimulation and, similar to neurons, release transmitters in a Ca^{2+}-dependent manner (Zorec et al. 2012), while a new report indicates also that astrocytes from adult human brain are ɣ-aminobutyric (GABA)-ergic cells possessing enzymes and receptors and modulating microglial activity representing GABAceptive cells (Lee et al. 2011). The concept of a "tripartite synapse" referring to the relationship occurring at synapses among a presynaptic and a postsynaptic element as well as a glial element has been

introduced (Santello et al. 2012). On the other hand, microglial cells are activated due to neuronal damage leading to reactive gliosis and to cytoarchitectonic changes accompanied by alterations in surface receptor and channel expression as well as to release of neuroactive soluble factors (see below) that in turn exert actions on neuronal function and cell death. Recently, it was found that oligodendroglia in the CNS is not only linked to myelin formation and maintenance, but they actively participate in neuronal survival and development as well as in neurotransmission and synaptic function including neurotoxic processes (Deng and Poretz 2003).

Neurotoxicity can result from exposure to several factors (intrinsic and exogenous xenobiotics) that disturb the normal physiology and function of the nervous system. The exogenous and intrinsic factors influence each other's actions.

2 Intrinsic Factors Engaged in Neurotoxicity

There are several endogenous brain toxins which in high amount may lead to neurotoxicity. When present in high concentrations, glutamate, calcium ions, and reactive species (RS) such as free radicals, proinflammatory cytokines, tumor necrosis factor alpha (TNF-α), or neurotrophins released by microglia are potentially neurotoxic (Aloisi 2001; Aloisi et al. 2001; Hanisch 2002). All of them reciprocally modulate their own actions and are responsible for neuronal cell death followed by nervous system dysfunction (e.g., loss of motor control; cognitive deterioration; loss of memory, vision, and/or intellect; uncontrollable obsessive and/or compulsive behaviors; delusions; headache; or neurodegenerative diseases). The most common to damage cells within the CNS are glutamate, increased cell calcium concentrations, RS and increased oxidative damage, mitochondrial dysfunction linked to apoptotic pathways, glial dysfunction injury, and/or genetic-epigenetic defects in protein clearance (cf. Halliwell 2006).

2.1 Neurotoxicity Induced by Glutamate

Glutamate serves a principal brain neurotransmitter, while its neurotransmission impairment such as high concentrations (>μM in extracellular fluids) evokes excitotoxicity to neurons. The glutamate concentration equilibrium is extremely delicate and is under control of glutamate transporters that pump the glutamate back from the neuronal synapse into the glia and neurons and allow glutamate to be recycled for repeated release via glutamate-glutamine neuronal glial cycle.

There are two general classes of glutamate transporters, those that are dependent on a sodium ion gradient (so-called the excitatory amino-acid transporters; EAATs) and those that are not dependent (vesicular glutamate transporters (VGLUTs) and cystine-glutamate antiporter (xCT)). EAATs are also dependent on transmembrane K^+ and H^+ concentration gradients and are known also as "sodium- and potassium-coupled glutamate transporters" or "high-affinity glutamate transporters." In humans and rodents, five subtypes of EAATs have been identified: subtypes EAAT1–2 are

found in membranes of glial cells (astrocytes, microglia, and oligodendrocytes) and in endothelial cells, EAAT3–4 are located on neurons, while EAAT5 is found in the retina. Four VGLUTs (VGLUTs 1–3 and sialin) are found in the membrane of glutamate-containing synaptic vesicles. The xCT located to the plasma membrane of cells prefers cystine and glutamate as its substrates in the way that the anionic form of cystine is transported in exchange for glutamate to glial cells. The xCT protein is upregulated in glial cells upon oxidative stress and plays an essential role to protect neurons. The glial transporters – in particular the various splice variants of EAAT2 and xCT – play the largest role (>90 %) in regulating extracellular glutamate levels. Data suggest that astrocytes also signal to neurons through Ca^{2+}-dependent release of glutamate (Hua et al. 2004).

In the event of any disruption in the function of glutamate transporters, a high concentration of glutamate accumulates at the glutamate receptors. Exposing neurons to high glutamate concentrations results in the activation of ionotropic glutamate receptors such as the *N*-methyl-D-aspartic acid (NMDA) receptors or α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, which induce faster mitochondrial Ca^{2+} uptake (Rego and Oliveira 2003). NMDA receptor overstimulation allows high levels of calcium ions to enter to cells, causing formation of mitochondrial RS and lipid peroxidation (Maciel et al. 2001). Moreover, extrasynaptic NMDA receptor activation promotes a dominant CREB (cAMP response element binding) dephosphorylation pathway that leads to protective CREB function shutoff causing loss of mitochondrial membrane potential and finally apoptosis (Hardingham and Bading 2010).

It should be added that NMDA glutamatergic receptors are stimulated also by quinine, being a product of the autoxidative pathway of dopamine metabolism (Lieb et al. 1995) which was shown to be neurotoxic in striatal neurons (Ben-Shachar et al. 1995).

2.2 Neurotoxicity Induced by Calcium Ions

High Ca^{2+} cell concentration in the cytosol initiates apoptosis (a cell death that leads to the elimination of cells without releasing harmful substances into the surrounding area) through cleaved caspase processing and activation of a number of several intracellular enzymes (e.g., phospholipase A_2, nitric oxide synthase, calcineurin, endonucleases, and xanthine dehydrogenase) and proteases (e.g., calpain) which by themselves can induce the formation of RS or damage the cytoskeleton, membrane, or DNA (Rego and Oliveira 2003). Another damaging result of excess Ca^{2+} in the cytosol is the opening of the mitochondrial permeability transition pore. Opening this mitochondrial pore may cause release of reactive oxygen species (ROS), more Ca^{2+}, more proteins that can lead to apoptosis and finally to cessation of adenosine triphosphate (ATP) production (Court and Coleman 2012).

A rise in Ca^{2+} intracellular concentration is generated – among others – by glutamate high synaptic concentrations (see above) or products of lipid peroxidation (e.g., 4-hydroxynoneral; see below).

2.3 Neurotoxicity Induced by RS

RS include free radicals and non-radical molecules. A free radical means any species capable of independent existence ("free") that contains one or more unpaired valence shell electrons (Halliwell and Gutteridge 1988). These chemically reactive molecules include ROS, reactive bromine species (RBS), reactive chloride species (RCS), and reactive nitrogen species (RNS). It should be stated that the term ROS is usually used as a collective term for both oxygen radicals that include free radicals (e.g., superoxide $O_2^{\bullet -}$, hydroxyl $OH^{\bullet}$, hydroperoxyl $HO_2^{\bullet}$) and non-radicals (e.g., hydrogen peroxide H_2O_2, peroxynitrite $ONOO^-$). The collective definition exists also for RBS (free radical: atomic bromide Br and non-radicals: bromine gas Br_2, hypobromous acid, HOBr), for RCS (free radical: atomic chlorine Cl and non-radicals: hypochlorous acid HOCl, chloramines), and for RNS (free radicals: nitric oxide NO, nitrogen dioxide NO_2, and nitrate NO_3 and non-radicals: nitrous acid HNO_2, nitrosyl anion NO^-, peroxynitrite $ONOO^-$, and peroxynitrate O_2NOO^-). Among RS, the most neurotoxic are $O_2^{\bullet -}$, $OH^{\bullet}$, and H_2O_2 (Bartosz 2009; Matés et al. 2010), the first radical leaking from the respiratory chain in mitochondria, the second radical resulting from the dismutation of $O_2^{\bullet -}$ or directly from the action of oxidase enzymes, and the non-radical species causing modification of purine and pyrimidine bases that lead to DNA damage.

The most important source of RS for aerobic cells is O_2 due to its high consumption, especially by the mammalian brain (Halliwell 2006). When formed during the normal metabolism of oxygen, RS have important roles in cell signaling and homeostasis; however, strong environmental stressors (e.g., UV, heat exposure, ionizing radiation, chemical substances including addictive drugs) increase their brain levels. In the brain, formation of oxygen radicals is linked to an increase in the Ca^{2+} concentration inside a cell (via membrane Ca^{2+} exporters, transient receptor potential melastatin-related (TRPM)2 cation channels located on some neurons and glia or via Ca^{2+} pumps in the endoplasmic reticulum) due to damage of mitochondrial function by neurotoxins following disruption of ATP production. High intracellular Ca^{2+} levels can activate neuronal nitric oxide synthase (NOS), phospholipase A_2, and calpains and/or interfere with mitochondrial function. The interaction between the Ca^{2+} and Ca^{2+}-dependent NOS pathway results in the production of $NO^{\bullet}$ which reacts with O_2 forming $ONOO^-$. $ONOO^-$ and other RS may decrease glutamate transporter activity on glial cells and inactivate glutamine synthethase (Aksenov et al. 1997; Trotti et al. 1996; Noack et al. 1998; Koppal et al. 1999), while 4-hydroxynonenal (a major aldehydic product formed by peroxidation of ω-6-unsaturated fatty acids regarded as a specific marker of lipid peroxidation) can impair the function of glutamate transporters (Mattson and Chan 2003). Disturbances in glutamate clearance may promote the high Ca^{2+} intracellular levels and lead to mitochondrial and protein dysfunctions.

Other potential sources of RS are cytochromes P450 (CYPs) and activated microglia. CYPs are enzymes localized to almost every cell, including some brain regions (Miksys and Tyndale 2004). Among CYPs, the CYP2E1 leaks electrons during the catalytic cycle and is especially linked to RS production (Gonzalez 2005);

however, the CYP2E1-dependent RS generation is important following exposure to, e.g., solvents, tobacco, or ethanol, as these substances significantly increase the enzyme levels.

It was also found that neurotoxin-activated microglia can produce $O_2^{\bullet -}$, H_2O_2, and cytokines (interleukin (IL)-1, interleukin-6, and TNF α). In turn, cytokines lead to activation of microglia and then to production of more RS, inducible NOS and $NO^{\bullet}$ (Duncan and Heales 2005). Of note, cytokines may be also produce by activated astroglia (Duncan and Heales 2005).

RS are also generated by endogenous sources such as neurotransmitters. In fact, catecholamines such as dopamine, its precursor L-DOPA and norepinephrine, as well as indolamine serotonin (5-HT) react with O_2 to produce $O_2^{\bullet -}$ (Spencer et al. 1998). The best recognized is dopamine-induced generation of RS. Thus, dopamine metabolism includes either a nonenzymatic pathway (via molecular oxygen through autoxidation) to generate hydrogen peroxide (H_2O_2) and a superoxide anion ($O_2^{\bullet -}$) or an enzymatic pathway by monoamine oxidase (MAO) to form H_2O_2. Both of these radicals may react via the Haber-Weiss/Fenton reaction with transition metal ions to produce the highly toxic $OH^{\bullet}$ (Hermida-Ameijeiras et al. 2004).

As the brain is the most vulnerable to increased levels of RS due to its low oxidative capacity and because neurons are characterized as postmitotic cells, it means that neurons live with accumulated damage over the years. Harmful effects of RS on the cell include induction of apoptotic pathways, damage of DNA, oxidations of polyunsaturated fatty acids in lipids (lipid peroxidation and malondialdehyde (MDA) are widely studied; MDA is a product of polyunsaturated fatty acid peroxidation), oxidations of amino acids in proteins, and oxidatively inactivated specific enzymes by oxidation of their cofactors. Of note, there is positive feedback response between the mitochondrial production of RS and glutamate concentration at the synapse which further gives rise to postsynaptic Ca^{2+} levels via RS-mediated inhibition of glial EAAT2 function.

Whether RS will act as damaging or signaling molecules and whether "oxidative stress" occurs depends on the delicate equilibrium between RS production and scavenging/detoxification. There are several cellular or extracellular defensive mechanisms comprising of the nonenzymic as well as enzymic antioxidants to break down RS. The enzymic antioxidants include proteins such as superoxide dismutases (SOD), catalases (CAT), peroxiredoxins, glutathione peroxidase (GPx), glutathione reductases (GR), thioredoxin reductases, heme oxygenase-1, eosinophil peroxidase, and metallothionein (Matés et al. 2010). An essential defense role against oxidative stress in all aerobic organisms is played by SOD which converts O_2^- to H_2O_2 and molecular oxygen. Four classes of SOD have been identified: cytosolic Cu, Zn-SOD, mitochondrial Mn-SOD, extracellular-SOD, and mitochondrial Fe-SODs; the first three SODs exist in humans. CAT, GRx, or peroxiredoxins convert molecules of H_2O_2 into water and oxygen, while GR catalyzes the reduction of glutathione disulfide (GSSG) to glutathione (GSH) and, thus, maintains a cellular redox state (Matés et al. 2008).

A potent nonenzymatic antioxidant defense system is comprised of vitamin C (ascorbic acid), vitamin E (α-tocopherol), vitamin A, β-carotene, polyamines,

melatonin, NADPH, adenosine, urate, coenzyme Q-10 (ubiquinol), polyphenols, flavonoids, phytoestrogens, GSH, cysteine, homocysteine, taurine, methionine, *S*-adenosyl-L-methionine, nitroxides, and selenium (Matés et al. 2008). Among these small antioxidant molecules ascorbate, GSH and tocopherols are of special significance. Thus, ascorbic acid donates electrons in a number of enzymatic and nonenzymatic reactions, while GSH by reaction with $OH^{\bullet}$ or H_2O_2 can function directly as a free radical scavenger and protect proteins, lipids, or DNA either by the formation of adducts directly with reactive electrophiles or by acting as proton donor in the presence of RS. Tocopherols potently scavenge oxygen and protect lipids and lipid structures against peroxidation.

2.4 Neurotoxicity Induced by Apoptosis

Due to physiological as well as pathological conditions including intracellular rise in RS or Ca^{2+} levels as well as other strong stressors (e.g., hyperthermia, ionizing radiation, some toxic substances; (Bojes et al. 1999; Darzynkiewicz et al. 2009)), a programmed cell death (apoptosis) appears. Apoptosis is a multistep process characterized by biochemical events that lead to cell blebbing, cell shrinkage, nuclear fragmentation, chromatin condensation, chromosomal DNA fragmentation, and, finally, cell death. The process of apoptosis is controlled by diverse signals, which may originate either extracellularly (e.g., toxins, cytokines) that must cross the plasma membrane or transduce a response or intracellularly (Darzynkiewicz et al. 2009).

Apoptosis is executed by either caspases or noncaspase proteases (Wyllie 2010). Caspases are cysteine-dependent aspartate-specific proteases forming a family of over a dozen caspases. They function as initiator caspases (caspase 2, 8, 9, 10 leading to activation of effector caspases) and effector caspases (caspase 3, 6, 7 that proteolytically degrade intracellular proteins to kill a cell). Two intracellular caspase pathways have been recognized; one is triggered by message from a death receptor (so-called the extrinsic pathway) and the other activated by an intracellular message such as DNA damage and microtubule disruption (so-called the intrinsic or mitochondrial pathway) (Gabai et al. 2002).

The extrinsic pathway for caspase activation engages apoptotic mechanisms through stimulation of the TNR family, i.e., TNF receptors and Fas at the cell surface. TNF1 receptors are activated by TNF, and such linkage results in the release of silencer of death domains (SODD) and formation of a receptor-proximal complex containing the important adaptor proteins TNF receptor-associated death domain (TRADD), TNF-R-associated factor 2 (TRAF2), receptor-interacting protein (RIP), and Fas-associated death domain (FADD). These adaptor proteins enhance activity of the TNF pathway-specific enzymes (e.g., caspase 8 and IKKβ) to the TNF-R1 complex. These enzymes, in turn, initiate the activation of c-Jun NH_2-terminal kinase (JNK), a kinase that phosphorylates c-Jun and increases its transcriptional activity, while the protein kinase RIP is critical to the activation of the transcription factor NF-κB.

Fas are also stimulated by another death activator, Fas ligand (FasL). The interaction between Fas and FasL results in the formation of the death-inducing signaling complex (DISC), which contains the FADD, caspase 8 and caspase 10. Activation of caspase 8 initiates a cascade of caspase activation leading to cell phagocytosis.

The internal/mitochondrial pathway for caspase activation is initiated by proapoptotic (Bax, Bak, Bid, or Bad) homodimers of the *Bcl-2* family that inhibit antiapoptotic (Bcl-Xl and Bcl-2) Bcl-2 members. The proapoptotic proteins are required to allow the release of caspase activators such as cytochrome c and small mitochondria-derived activator of caspases (SMAC) out the mitochondrial membrane. The released cytochrome c binds to the apoptotic protease activating factor-1 (Apaf-1) forming apoptosomes that later activate caspase 9. Caspase 9, in turn, activates effector caspases 3 and 7. Caspase 3 destroys poly-ADP ribose polymerase (PARP), a protein which takes part in DNA repair; caspase 3 also initiates DNA fragmentation. SMACs are mitochondrial proteins released into the cytosol to bind to the inhibitor of apoptosis proteins (IAPs) such as caspases and deactivate them.

The noncaspase-related execution of apoptosis is linked to activation of calpains. The calpains exist in two isoforms (I and II) and are Ca^{2+}-dependent proteases. They degrade membrane, cytoplasmic, and nuclear substrates, leading to the breakdown of cellular architecture. Among others, they release proapoptotic factor (AIF) (Breckenridge and Xue 2004) from the mitochondria into the cytosol. AIF migration into the nucleus is mediated by its nuclear localization signal (NSL); in the nucleus AIF binds with DNA strands inducing its fragmentation and cell death. Of note, another effector of caspase-independent cell death is endonuclease G (Endo-G) released from mitochondria (Singh et al. 2004).

2.5 Neurotoxicity Induced by Glial Cell Activation

Among several glial cells, microglia are preferentially exposed to toxic factors and are strongly engaged in brain toxicity.

Microglia constitute 20 % of the total glial cell population within the brain and are the first form of active immune defense in the CNS responsible for maintaining homeostasis. There are several factors that activate microglia, such as glutamate and glutamate receptor agonists, proinflammatory cytokines, cell necrosis factors, lipopolysaccharide, and extracellular potassium changes (Nakajima and Kohsaka 2001; Graeber and Streit 2010). In turn, activated microglia via hemichannels within cell membranes (Orellana et al. 2012) can secrete a variety of neurotoxic substances, among them are (i) large amounts of H_2O_2 and $NO^{\bullet}$ – the process known as "respiratory burst" leads to neuronal cell death; (ii) proteases (i.e., cathepsins B, L, and S; the matrix metalloproteinases (MMP)-1, MMP-2, MMP-3, and MMP-9; the metalloprotease-disintegrin ADAM8 plasminogen; and elastase) that catabolize various proteins causing cellular damage; (iii) nuclear factor κB, a transcription factor that starts proinflammatory actions in microglia; (iv) proinflammatory chemokines (MCP-1, MIP-1α, and MIP-1β); (v) proinflammatory cytokines (IL-1α, IL-1β) and TNF-α that initiate demyelination of neuronal axons and/or

apoptosis through activation of caspase 8 and caspase 3; and (vi) excitatory amino-acid glutamate and aspartate that injury neurons (Block et al. 2007; Graeber and Streit 2010).

Another glial cell type, oligodendroglia, expresses a variety of ligand- and voltage-gated neurotransmitter receptors/ion channels, including NMDA and AMPA (Belachew et al. 1999; Rogister et al. 1999). The presence of functional neurotransmitter receptors/ion channels in glia indicates that there is glutamate-mediated cross talk between neurons and glia (Bergles et al. 2000; Gallo and Ghiani 2000) as well as that which oligodendrocytes share with neurons – a high vulnerability to glutamate excitotoxicity.

On the other hand, oligodendrocytes (as well as astrocytes) have the ability to protect themselves from RS as they contain high concentrations of antioxidant enzymes and GSH (Makar et al. 1994). However, in conditions where protective functions of astrocytes are impaired, oligodendrocytes may be vulnerable to oxidative and RS-mediated damage (e.g., following increased metabolism of catecholamine neurotransmitters that generates H_2O_2) (Noble et al. 1994).

2.6 Neurotoxicity Induced by DNA Damage

DNA is a genetic material, and any DNA damage can result in malfunctions or complete inactivation of encoded proteins. Genomic instability is an important mechanism leading to death of neurons. Several environmental factors (e.g., UV radiation, plant and chemical toxic substances, viruses) or endogenous sources (e.g., RS) are responsible for DNA damage that may occur during the synthesis of DNA precursors, DNA repair, and during various methylation events, including DNA methylation (see below). Both DNA repair and DNA methylation are critical for maintaining genomic stability. Several forms of DNA damage may appear including mutations, deletions, gene amplification, and rearrangements (Matés et al. 2008).

There is a relationship between oxidative stress and genomic instability (Matés et al. 2008). In fact, ROS (especially $OH^{\bullet}$) are a major source of DNA sequence changes leading to deoxyribose oxidation, a generation of a deoxyribose radical that further initiates strand breakage, removal of nucleotides, a variety of modifications in the organic bases of the nucleotides, and DNA-protein cross-linkages. Of note, the formation of 8-hydroxy-2′-deoxyguanosine is regarded as an index of oxidative DNA damage (Frenkel et al. 1991).

DNA damage may result in the initiation of signaling leading to neurotoxic consequences such as cell death or to the activation of several proto-oncogenes and/or the inactivation of some tumor suppressor genes such as p53 (Hetman et al. 2010; Raj et al. 2011). p53 gene is a suppressive gene coding a p53 protein – a tumor suppressor protein and its level in unstressed cells are kept low through a continuous degradation, but DNA damage and other stress signals trigger the increase of p53 protein levels and its activity. The major functions of p53 protein are (i) a growth arrest (a stop signal for progression of cell cycle) during DNA damage and

(ii) induction of DNA repair, and when unsuccessful, it directs cells on the road to apoptosis via an upregulation of Bax, Fas, and Apaf- 1 expression (Hetman et al. 2010; Raj et al. 2011).

2.7 Neurotoxicity Induced by Epigenetic Mechanisms

Apart from genetic material, epigenetic regulation of gene expression (=epigenetic processes) can change dynamically in response to external factors, providing a key mechanism by which the environment can influence gene expression and, hence, phenotype (Taft et al. 2007; Archer et al. 2010). Epigenetic mechanisms reflect the regulation of gene expression, occurring independently of DNA sequence (Henikoff and Matzke 1997). There were recognized – at least – three forms of epigenetic mechanism: DNA methylation, histone tail modifications, and regulatory noncoding RNA (ncRNA).

DNA methylation occurs primarily at cytosine-guanine dinucleotides (CpG) and requires DNA methyltransferases (DNMTs). The addition of a methyl group to CpG sites displaces the binding of transcription factors and attracts methyl-binding proteins that instigate chromatin compaction of DNA and gene silencing.

Histones are the basic proteins around which DNA is wrapped to form nucleosome. Covalent histone tail modifications, including methylation, acetylation, phosphorylation, sumoylation, and ubiquitylation, modulate gene expression via alterations in chromatin structure. Acetylation, one of the most frequent posttranscriptional modifications of histones, depends on histone-modifying enzymes, such as histone acetyltransferases (HATs) and histone deacetylases (HDACs). Generally, histone acetylation belongs to the active chromatin marks; it increases the accessibility of transcription complexes to genomic DNA. Histone methylation, controlled by several families of histone methyltransferases (HMTs), has been associated with both transcriptional activation and repression, depending on the particular residue and the extent of methylation (Su and Tarakhovsky 2006; Maze and Nestler 2011); this reaction can be reversed by equally diverse histone demethylases (HDMs).

Regulatory ncRNAs (encoded by part of DNA noncoding proteins) are able to control transcription and translation in an organ- and cell-specific manner; the disturbance of their function could lead to perturbation in cellular homeostasis. These include, inter alia, microRNAs (miRNAs), Piwi-interacting RNAs (piRNAs), endogenous small interfering RNAs (endo-siRNAs, esiRNAs), and long noncoding RNAs (lncRNAs).

miRNAs represent a class of short (∼18–25 nucleotides in length), single-stranded molecules which cause epigenetic changes in gene transcription, mediated by both DNA methylation and histone modifications (Kim et al. 2007, 2009). miRNA are expressed in the mature mammalian brain (Landgraf et al. 2007) and are thought to be involved in long-term potentiation and in regulating structural and functional aspects of synaptic plasticity (i.e., neuronal morphogenesis, activity-dependent translation during synapse formation, memory and synapse development, and plasticity (Schratt 2009)). miRNAs in the vertebrate system predominantly inhibit productive translation

of mRNAs in the cytoplasm (Schratt et al. 2006) and may regulate transcriptomic networks via the expression of other types of lncRNAs in the nucleus (Zhou et al. 2010). On the other hand, the expression of miRNAs is modulated by DNA methylation and histone modifications.

piRNAs are a class of small noncoding RNA, 24–31 nucleotides in length that forms RNA-protein complexes with Piwi proteins (Dharap et al. 2011). piRNAs are present in the polysomal fraction, but surprisingly they were also found in the nucleus. piRNAs play an important role in silencing pathways that regulate mRNA stability, heterochromatin formation, and genome integrity (Brower-Toland et al. 2007). They may guide DNA methylation and control transposon activity (Xu et al. 2008; Zhou et al. 2010), and in turn, impaired epigenetic regulation of transposons can interfere with the expression of neighboring genes. Recent studies confirmed their expression in somatic tissues (Spadaro and Bredy 2012) and in the epigenetic facilitation (chromatin remodeling) of long-term memory and neuronal plasticity (Lee et al. 2011; Rajasethupathy et al. 2012; Spadaro and Bredy 2012).

esiRNAs represent one of several classes of small noncoding RNAs involved in RNA interference. esiRNA is derived from repeated DNA elements and transposons (Obbard and Finnegan 2008). In addition to their role as posttranscriptional regulators, esiRNAs function as epigenetic regulators through either RNA-directed DNA methylation or RNA-mediated heterochromatin formation (Verdel et al. 2009; Lejeune and Allshire 2011). In both cases, esiRNAs may act as guide molecules to direct epigenetic factors such as site-specific MNMT1 or HMTs to target specific genomic regions (Song et al. 2011). Chen et al. (2012) have demonstrated that esiRNAs by silencing LINE-1 activity through DNA methylation in human cells can function as a link between the expression of esiRNAs and LINE-1 retrotransposons. The recent study has also showed that adult mouse hippocampus expresses esiRNAs that possibly play more specific roles in regulating synaptic plasticity and learning (Smalheiser et al. 2011).

lncRNAs are mRNA-like transcripts ranging in length from 200 nucleotides to ~100 kilobases that do not have functional open reading frames. Most lncRNAs are localized in nucleus, display low expression compared to protein coding genes, and are composed of both polyA+ and polyA− transcripts (Kaikkonen et al. 2011). lncRNA can be divided into five categories based on their proximity to coding genes: intronic, intragenic, bidirectional, sense, and antisense (Qureshi and Mehler 2011). They have been associated with various cellular processes, such as transcription regulation (in *cis* or *trans* loci), alternative splicing, control of the subcellular localization of transcription regulatory factors and proteins, chromosomal dosage compensation, as well as chromatin remodeling (Johnson et al. 2012; Li et al. 2012). lncRNAs recruit histone modification complex to target sites in chromatin and thus can function as epigenetic regulatory factors (Rinn and Chang 2012). They exhibit cell-specific patterns of expression within brain, suggesting their role in the modulation of genes associated with neuronal connectivity and synaptic plasticity (Bernard et al. 2010; Li et al. 2012). Recently, lncRNAs were shown as factors engaged in GABA neuron neurogenesis (Mercer et al. 2010).

3 Conclusion

Among endogenous brain toxins, high concentrations of glutamate, calcium ions, and RS are well-known factors that potently disturb the normal physiology and function of the nervous system. It was also established that glial cells (i.e., astroglia, microglia, and oligodendrocytes) and their released factors (e.g., proinflammatory cytokines and chemokines, excitatory amino acids, cell necrosis factors, RS) also play a number of active roles in the brain and are sensitive indicators for pathology of the CNS. Recently, genomic instability due to DNA damage and epigenetic mechanisms (such as DNA methylation, histone tail modifications, and regulatory ncRNAs) were recognized as important mechanisms leading to disturbances of neurons and finally to their death.

Abstract

There are many ways in which neuronal damage can be produced in the brain, including the overactivation of depolarizing receptors, exposure to high levels of pro-inflammatory proteins such as cytokines, or miscellaneous toxins, but the kynurenine pathway has emerged as a novel but potentially major factor in regulating neuronal viability or death. It is the major route for the metabolism of the essential amino acid tryptophan, which is oxidized by indoleamine-2,3-dioxygenase (IDO) to a series of compounds which can activate, block, or modulate conventional neurotransmitter receptors. Quinolinic acid is an agonist at *N*-methyl-D-aspartate receptors, kynurenic acid is an antagonist at these and other glutamate receptors, and other kynurenine metabolites are highly redox-active. Superimposed on the discovery of this neuromodulatory pathway have been observations that activity in the pathway is linked to neurological and psychiatric disorders, correlating with disease state (as in Huntington's disease) or cognitive function (as following bypass surgery). Together, the data accumulated to date make a strong case for this hitherto obscure pathway being a major factor in determining cell damage, death, or recovery in health and disease.

Keywords

Alzheimer's disease • Depression • Excitotoxicity • HIV-1-Associated neurocognitive disorder • Huntington's disease • Kynurenate • Kynurenine pathway • Multiple sclerosis • Neurodegeneration • Neuro-inflammation • Parkinson's disease • Quinolinic acid • Schizophrenia • Stroke

List of Abbreviations

3HA	3-Hydroxyanthranilic acid (3HA)
3HAO	3-Hydroxyanthranilic acid oxygenase
3HK	3-Hydroxkynurenine
AD	Alzheimer's disease
AIDS	Acquired immunodeficiency syndrome
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
Gly	Glycine
HD	Huntington's disease
HIV	Human immunodeficiency virus
IDO	Indole amine 2,3-dioxygenase
IFN	Interferon
KAT	Kynurenine amino transferases
LPS	Lipopolysaccharides
MAPK	Mitogen-activated protein kinase
mGluR	Metabotropic glutamate receptor
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MS	Multiple sclerosis
nAChR	Nicotinic acetylcholine receptor
NAD^+	Nicotinamide adenine dinucleotide

NMDA	*N*-methyl-D-aspartate
PD	Parkinson's disease
TDO	Tryptophan 2,3-dioxygenase
TNF	Tumor necrosis factor

1 Introduction

Quinolinic acid is a highly selective agonist at the population of glutamate receptors that respond to the synthetic amino acid *N*-methyl-D-aspartate (NMDA). In contrast to NMDA, however, quinolinic acid is an endogenous compound, generated via the kynurenine pathway for the oxidation of another amino acid, tryptophan (Stone and Perkins 1981). The discovery that quinolinic acid is able to produce depolarization by activating NMDA receptors (NMDARs) led to the demonstration that it also causes neurodegeneration (Schwarcz et al. 1983), consistent with the knowledge that glutamate itself can induce neuronal damage by promoting depolarization and an excessive influx of calcium. These discoveries launched the concept that the brain damage associated with stroke or degenerative disease might be attributable not only to the accumulation of glutamate or hyperactivity of its receptors, but also to abnormal function of the kynurenine pathway.

The kynurenine pathway also produces redox-active compounds (3-hydroxykynurenine and 3-hydroxyanthranilic acid) which cause neuronal damage by generating reactive oxygen species (Eastman and Guilarte 1989; Giles et al. 2003). A branch of the pathway generates kynurenate which is an antagonist of glutamate (Perkins and Stone 1982) and nicotinic cholinergic receptors (Hilmas et al. 2001; Stone 2007). As a result, kynurenate exhibits neuroprotective properties. A number of diseases have been associated with altered levels of quinolinic acid and other kynurenines in the CNS, including the AIDS–dementia complex, Alzheimer's disease, Huntington's disease, and Parkinson's disease. In addition, as the relevance of neuronal viability and damage become clear in the etiology of psychiatric disorders such as schizophrenia and depression, and inflammatory diseases such as multiple sclerosis, the pathological and therapeutic importance of kynurenine metabolism continues to expand, as indicated in the sections that follow.

2 Components of the Kynurenine Pathway

2.1 Tryptophan Cleavage and Immune System

L-tryptophan, the least abundant of the essential amino acids used for protein synthesis, is also a substrate for synthesizing the neurotransmitter serotonin via the methoxyindole pathway, or vitamin B3 (nicotinamide) and quinolinic acid via the kynurenine pathway (Fig. 1).

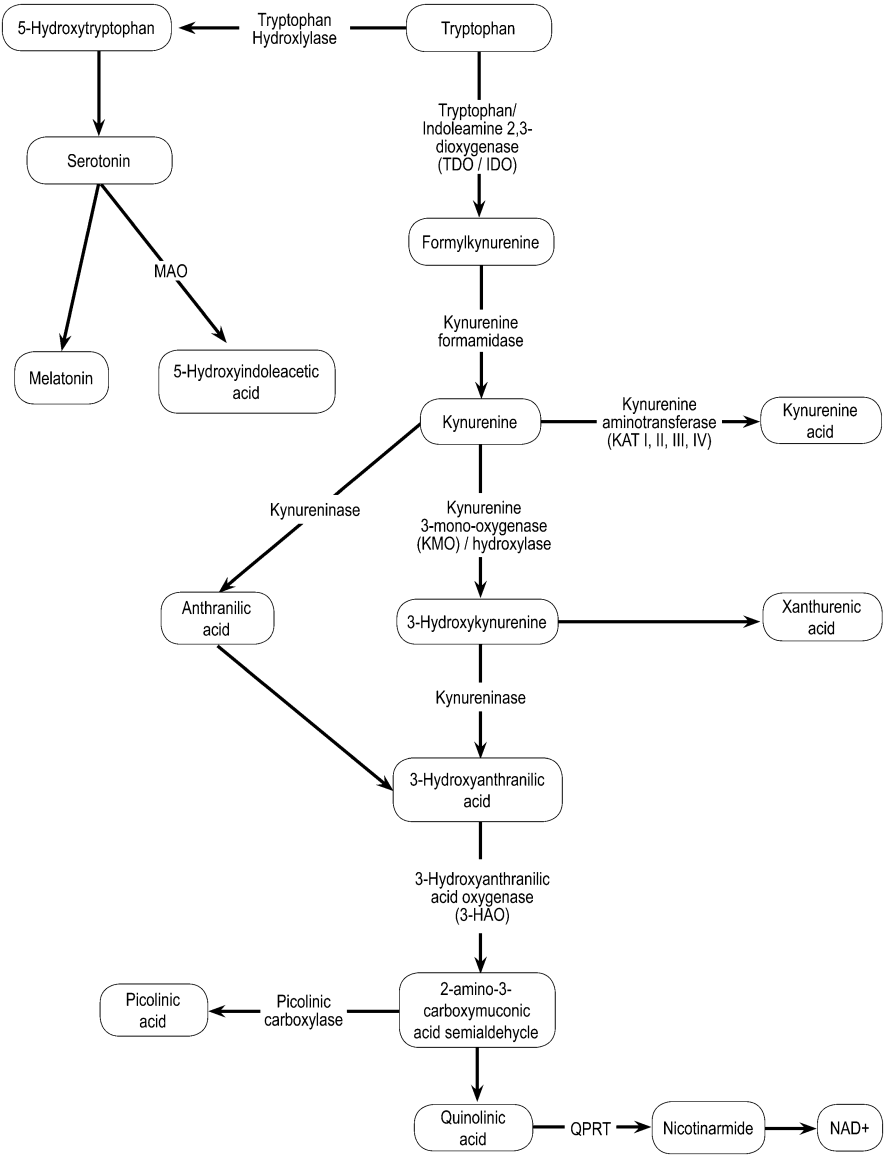

Fig. 1 A summary of the major compounds in the kynurenine pathway of tryptophan oxidation

Most of the ingested tryptophan (over 95 %) is catabolized in the kynurenine pathway (Stone 1993a; Takikawa 2007) and generates nicotinamide adenine dinucleotide (NAD^+) under physiological conditions. L-tryptophan is metabolized to kynurenine by oxidative cleavage of the indole ring by the enzymes tryptophan 2,3-dioxygenase (TDO) or indoleamine 2,3-dioxygenase (IDO), the activities of which may act as rate-limiting steps under some conditions (Takikawa et al. 1986;

Rafice et al. 2009). IDO, a heme-containing inducible enzyme, is found in the lungs, blood, and brain (Heyes et al. 1993; Banks et al. 1994) and has a higher affinity for tryptophan (Km = ~10 μM) than does TDO (Km = ~200 μM). IDO has recently been shown to exist in at least two isoforms, though little is yet known about IDO-2 (Ball et al. 2009).

A key aspect of the kynurenine pathway that is becoming increasingly recognized for its importance in neurodegeneration is its intimate relationship with the immune system. The IDO promoter has one interferon-γ (IFN-γ) activation site and two nonspecific IFN-stimulated response elements that respond to IFN-α, IFN-β, or IFN-γ, with IFN-γ being the most potent inducer (Puccetti 2007). Pro-inflammatory interleukins such as IL-10 activate T cells and natural killer cells to produce IFN-γ which acts synergistically with tumor necrosis factor-α (TNF-α) to increase expression of IDO (Robinson et al. 2003). During immune system activation, this sequence serves as a form of defense against infection by causing tryptophan depletion (Takikawa 2007). IDO can be activated also by some pro-inflammatory cytokines (IL-18, IL-12) independently of IFN-γ (Liebau et al. 2002).

In the CNS, IDO is found in microglia, macrophages, astrocytes, neurons, and microvascular endothelial cells (Guillemin et al. 2001, 2005, 2007). Activated microglia produce pro-inflammatory cytokines IL-1βb, IL-2, IL-6, TNF-α, and IFN-γ which cause further microglial activation to amplify the inflammatory response.

TDO is found mainly in the liver but is also present in several brain areas including the cerebral cortex, cerebellum, hypothalamus, and brainstem (Haber et al. 1993; Kanai et al. 2009). The enzyme is readily activated by IFN-γ or bacterial endotoxins (Yoshida et al. 1981).

2.2 Formation of 3-Hydroxy-Kynurenine, 3-Hydroxy-Anthranilic Acid, and Quinolinic Acid

Kynurenine is transported easily into the CNS across the blood–brain barrier by the large neutral amino acid transporter; hence, changes in the plasma level of kynurenine are reflected in CSF levels (Fukui et al. 1991; Jauch et al. 1993). Approximately 60 % of the brain kynurenine is from the systemic circulation (Gal and Sherman 1978). Brain immune cells take up kynurenine from the extracellular space via the Na^+-independent large neutral amino acid transporter (Speciale et al. 1989).

Kynurenine 3-monoxygenase (KMO) [also known as kynurenine 3-hydroxylase], which uses kynurenine as a substrate, is present mainly in the liver. It is also present in the brain albeit with a much lower activity than in peripheral tissues. KMO is located in the outer membrane of mitochondria and is not saturated under physiological conditions. The production of 3-hydroxkynurenine (3HK) can, therefore, be increased when there is increased supply of kynurenine, as, for example, from the periphery (Schwarcz et al. 2010). The cytokine IFN-γ activates KMO; hence, inflammatory states stimulate the expression of KMO and production of quinolinic acid (Heyes and Morrison 1997; Connor et al. 2008).

In the CNS, resident microglia and invading macrophages from the periphery express far more KMO and 3-hydroxyanthranilic acid oxygenase (3HAO) enzymes than astrocytes, and therefore are the major source of quinolinic acid (Heyes et al. 1996; Lehrmann et al. 2001).

2.3 Formation of Kynurenate

In mammalian brain, kynurenine amino transferases (KAT), the enzymes that convert kynurenine to kynurenate, are found mainly not only in astrocytes but also in neurons to some extent (Guillemin et al. 2000; Guidetti et al. 2007b). Kynurenate is produced by the irreversible transamination of kynurenine by four mammalian pyridoxal-5′-phosphate dependent enzymes – KAT I (glutamine transaminase or cysteine conjugate beta-lyase I), KAT II (alpha aminoadipate aminotransferase), KAT III (cysteine conjugate beta-lyase II), and KAT IV (glutamic-oxaloacetic transaminase or mitochondrial aspartate aminotransferase). KAT II accounts for most (50–60 %) of kynurenate formation in human and rat brains, whereas KAT IV, a more recent addition, is the dominant enzyme (60 %) in mouse brain (Guidetti et al. 2007a; Han et al. 2010).

Once formed, kynurenate cannot be metabolized further and is released into the extracellular compartment by a non-Ca^{2+} -dependent process (Turski et al. 1989; Kiss et al. 2003). Kynurenate is removed slowly from the brain by the probenecid-sensitive, nonspecific acid transporter and by passive diffusion (Moroni et al. 1988; Schwarcz and Pellicciari 2002). Although KMO is in the pathway that produces 3HK and quinolinic acid, its activity regulates the levels of kynurenine in the brain, and, hence, indirectly affects the rate of formation of kynurenate (Wonodi and Schwarcz 2010).

3 Neurodegeneration and Kynurenine Metabolites

Excitotoxicity was first described by Olney et al. (1975) as the damage to neurons that results from excessive stimulation of glutamate receptors (Olney et al. 1975). The neuronal damage caused by stimulation of glutamate receptors does not affect the axons of passage or the afferent nerve terminals. Endogenously released glutamate does not cause much excitotoxicity due to the very efficient uptake systems (Danbolt 2001); hence, quinolinic acid, being an endogenous excitotoxin with no efficient removal mechanism, has been of particular interest for several years.

The concentration of quinolinic acid in the brain is normally too low to cause acute toxicity although maintained high nanomolar concentrations may damage or kill particular groups of neurons (Giulian et al. 1990). During inflammation, quinolinic acid may increase from the normal nM levels to micromolar levels which can cause overt and rapid neurotoxicity (Heyes et al. 1998). Nonetheless, quinolinic acid has been reported to be toxic to neurons even at concentrations as low as 150 nM (Braidy et al. 2009).

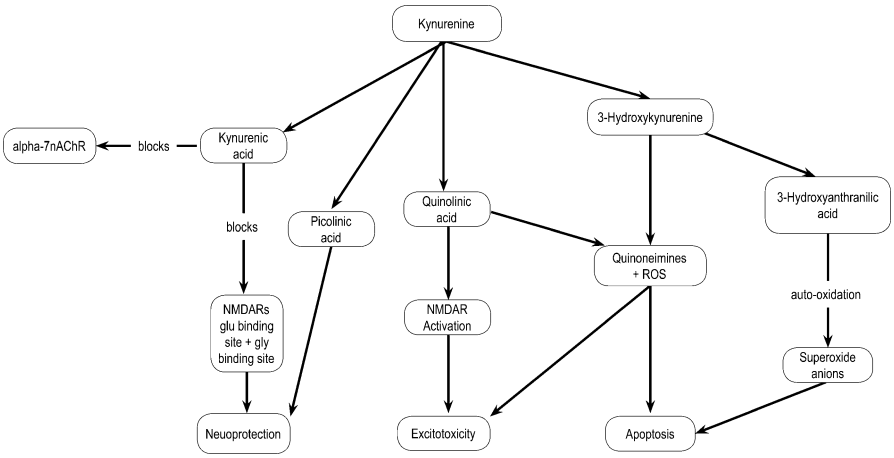

Fig. 2 A diagrammatic representation of how the role of the kynurenine pathway in regulating neuronal death or survival depends critically on the ratio between compounds such as quinolinic acid, which can be neurotoxic in excessive concentrations, and kynurenic acid, which is protective by blocking NMDA and nicotinic receptors. The contributions of redox-active compounds such as 3-hydroxykynurenine and 3-hydroxyanthranilic acid depend on their relative concentrations as well as the ambient redox state of the tissue

Quinolinic acid produced by microglia and infiltrating macrophages acts on NMDARs (Addae and Stone 1987; Stone 1993a), particularly those with NR1/NR2A or NR1/NR2B subunits (Perkins and Stone 1983; Stone 1993b; de Carvalho et al. 1996), and causes neurotoxicity partly via overactivation of these receptors (Fig. 2). Excessive stimulation of NMDARs causes influx of Ca^{2+} which overcomes cellular Ca^{2+} sequestration processes and leads to activation of proteases, endonucleases, generation of reactive oxygen species and nitric oxide that eventually cause neuronal death by lipid peroxidation or apoptosis. In addition, quinolinic acid stimulates hypertrophy and proliferation of astrocytes which then release increased amount of cytokines, leading to astrogliosis and inhibition of glutamate reuptake to cause further excitation of NMDARs (Tavares et al. 2002; Ting et al. 2009).

Two other products in the kynurenine pathway, 3-hydroxykynurenine (3HK) and 3-hydroxyanthranilic acid (3HA), cause neurodegeneration by generating superoxide and hydrogen peroxide under appropriate redox conditions (Goldstein et al. 2000). The axon-sparing excitotoxicity of quinolinic acid is potentiated by the presence of 3HK and reactive oxygen species; this synergistic effect is unique to quinolinic acid, because there is no such effect between NMDA and 3HK (Guidetti and Schwarcz 1999; Behan and Stone 2002). This synergistic effect explains why, although the potency of quinolinic acid on NMDARs is less than that of NMDA itself, the concentration of quinolinic acid that causes damage in the CNS is about the same as that of NMDA.

The activity of 3HAO, the oxygenase enzyme that converts 3-hydroxyanthranilic acid to quinolinic acid, is iron (Fe^{2+}) dependent. Hence,

excessive iron levels in the brain dramatically increase the levels of quinolinic acid which may contribute to the neurodegeneration caused by iron (Stachowski and Schwarcz 2011). Quinolinic acid itself may also cause neurotoxicity via formation of iron complexes, leading to lipid peroxidation (Platenik et al. 2001).

4 Neuroprotective Kynurenine Metabolites and Their Control

Kynurenate is the only known endogenous antagonist of NMDARs that preferentially blocks the glycine co-agonist binding site (Gly_2 or Gly_B) where it has a higher affinity for the glycine site than glutamate (Birch et al. 1988; Kessler et al. 1989). Kynurenate is normally present in the brain at average levels that are in the high nanomolar range (200–1,500 nM) (Turski et al. 1988), but at higher micromolar concentrations, which are likely to exist near the sites of production and cellular efflux, kynurenate blocks competitively all ionotropic glutamate receptors (Perkins and Stone 1982; Stone 1993a). This effect of kynurenate on non-NMDA glutamate receptors at synaptic sites enables it to effectively block thalamic projections to neocortical neurons (Addae and Stone 1988). Kynurenate also blocks noncompetitively the α7-nicotinic acetylcholine receptor (nAChR), and inhibits release of glutamate from presynaptic terminals by acting on this type of receptor (Hilmas et al. 2001; Carpenedo et al. 2001).

One consequence of the antagonistic activity of kynurenate at glutamate receptors is that a reduction in the levels of brain kynurenate promotes NMDAR-mediated excitotoxicity (Sapko et al. 2006). Such a reduction may occur when there are changes in extracellular ionic concentrations (e.g., high potassium) (Gramsbergen et al. 1997) or during a state of reduced cellular energy generation (e.g., hypoglycemia) which reduces the energy-dependent transport systems for kynurenine. Kynurenate formation is reduced also by compounds, such as the metabotropic glutamate receptor (mGluR) agonists and the sulfur-containing endogenous amino acid cysteine sulfinate, which inhibit KAT II (Battaglia et al. 2000; Kocki et al. 2003). Also, L-α-aminoadipate, a gliotoxic metabolite of the amino acid lysine, decreases the transamination of kynurenine to kynurenate and exerts its neuropathological effects partly by such an action on astrocytes (Wu et al. 1995). In contrast to the effects of the above compounds, pyruvate and other 2-oxoacids increase kynurenate levels by serving as co-substrates for the transamination process (Hodgkins et al. 1999).

Another important neuroprotective metabolite in the kynurenine pathway is picolinic acid, which is produced in neurons from 2-amino-3-carboxymuconic acid semialdehyde. The level of picolinic acid in the CSF declines with age which would contribute to the increasing prevalence of neurodegenerative diseases with age (Coggan et al. 2009). The neuroprotective properties of picolinic acid are achieved in part through its ability to promote chelation of iron and other metals (Testa et al. 1985; Jhamandas et al. 1990; Guillemin et al. 2007).

5 Diseases Associated with Kynurenines

5.1 HIV-1-Associated Neurocognitive Disorder (HAND)

Human immunodeficiency virus (HIV-1)-induced neuropathology (ranging from the most severe AIDS–dementia complex to mild cognitive impairment) does not result from direct infection of neurons by the virus but indirectly from the release of neurotoxins from activated immune cells (Glass et al. 1995; Adle-Biassette et al. 1999).

HIV-1 infection causes intestinal mucosal damage and elevated levels of lipopolysaccharides (LPS) in the blood arising from enteric bacteria (Brenchely et al. 2006) Infected monocytes in the blood cross through the blood–brain barrier which is breached in part by the LPS and pro-inflammatory mediators (Zhou et al. 2006). In the CNS, the monocytes not only release viruses that infect other monocytes, but also differentiate into macrophages and release viral proteins, for example, gp120 and Tat that activate microglia and, to a lesser degree, astrocytes. The chemokines and cytokines (e.g., TNF-α, IL-1β and monocyte chemo-attractant protein-1) produced by the activated brain immune cells promote further migration of monocytes across the blood–brain barrier (Boven et al. 2000; Fantuzzi et al. 2003; Persidsky and Gendelman 2003). Additionally, Tat activates IDO in peripheral and brain macrophages – a process that is mediated by p38 MAPK (mitogen-activated protein kinase) and enhanced by IFN-γ (Heyes et al. 1992; Sardar and Reynolds 1995; Smith et al. 2001; Fu et al. 2011). The increased expression of IDO eventually results in elevated quinolinic acid levels and neurotoxicity (Fig. 2). Additionally, the released quinolinic acid induces astrocytes to produce more chemokines, thus amplifying the neuropathology (Croitoru-Lamoury et al. 2003). Also, the neuronal damage is exacerbated by increased levels of glutamate due to the latter's impaired reuptake by the damaged astrocytes.

5.2 Alzheimer's Disease

The severity of Alzheimer's disease (AD) depends on the accumulation of two groups of molecules in the CNS – amyloid-β fragments and tau proteins. However, there are other pathological processes that contribute to the disorder including excitotoxicity and free radical damage caused by kynurenine pathway metabolites. For example, the kynurenine/tryptophan ratio is increased in AD (Widner et al. 2000), while increased levels of circulating IgA antibodies to IDO have been detected in the blood of AD patients, suggesting an increase in the production of the enzyme (Duleu et al. 2010). Also, amyloid-β activates microglia and induces IDO expression, leading to increased quinolinic acid production (Guillemin and Brew 2002; Guillemin et al. 2003a, b) and an associated decreased level of kynurenate (Hartai et al. 2007). NMDAR overactivation by quinolinic acid increases amyloid-β production, thus providing a positive feedback for disease progression (Lesne et al. 2005). In rodents, the level of quinolinic acid in the cortex increases with age, providing another mechanism for age-related predisposition to AD.

5.3 Huntington's Disease

Huntington's disease (HD) is an autosomal-dominant disease associated with neuronal loss in the striatum and neocortex. Beal et al. (1986) were the first to report that injection of quinolinic acid to the striatum of rodents produces a pattern of neuronal damage similar to that seen in human postmortem HD tissue. In HD, the evidence points strongly to an over-expression of the abnormal huntingtin gene and consequent neuronal damage by the huntingtin protein (Carter et al. 1999; Usdin et al. 1999). Interestingly, quinolinic acid has also been shown to induce expression of huntingtin in the striatum (Tatter et al. 1995). Additionally, huntingtin increases expression of the NR1/NR2 subunit combination of NMDA receptors in some types of neurons in the striatum, and the resulting increase in cellular sensitivity to quinolinic acid and glutamate (Fan et al. 2007) promotes disease progression.

The huntingtin protein triggers microglial activation (Haass and Selkoe 2007; Thakur et al. 2009) and in the R6/2 mouse, a well-established animal model of HD, the levels of quinolinic acid and 3HK are increased in the cortex and striatum (Guidetti et al. 2006). The increased level of 3HK is due to the combined increased activity of the synthesizing enzyme, KMO, and decreased activity of its degradative enzyme, kynureninase (Giorgini et al. 2005; Sathyasaikumar et al. 2010). Increased 3HK and quinolinic acid levels have also been observed in the striatum and cortex of other animal models of HD, for example, YAC128 and Hdh^{Q92}/Hdh^{Q111} mice (Guidetti et al. 2006).

In humans, there is an increased plasma kynurenine:tryptophan ratio in HD patients (Stoy et al. 2005; Forrest et al. 2010). Also, the levels of quinolinic acid and 3HK are increased in the brain of low-grade HD patients, but the levels tend to be similar to those of age-matched controls as the disease progresses (Pearson and Reynolds 1992; Guidetti et al. 2004). The severity of HD is linked to the number of glutamine residues (coded by CAG nucleotide triplets) close to the N-terminal of the huntingtin protein. The increased conversion of tryptophan to kynurenine by IDO in HD patients is further supported by the finding of a positive association between the plasma kynurenine:tryptophan ratio and the severity of HD, as determined by the clinical state or the degree of CAG triplet repeats (Stoy et al. 2005; Forrest et al. 2010). The correlation between kynurenine pathway activity and both disease severity and CAG repeat length represents one of the few known instances of a biochemical parameter which can act as a reliable marker of the disease and, potentially a predictor of disease progression. It also remains a strong possibility that these correlations reflect a causative role for the kynurenine pathway in the severity of the disease (Stone et al. 2012a, b). Thus, one consequence of the extended glutamine repeat sequences in huntingtin may be a change in one or more of the kynurenine pathway enzymes, as a result of which there is an altered susceptibility to neuronal damage.

A more detailed discussion of kynurenines and Huntington's disease, together with some of the issues associated with viewing the kynurenine pathway as

a potential therapeutic target for the prevention, delay, and treatment of the disorder, may be found in recent reviews (Stone et al. 2012a, b).

5.4 Parkinson's Disease

Parkinson's disease (PD) is associated with neuro-inflammation: Microglial activation forms part of the pathobiology of PD induced in rodents by 1-methyl-4-phenyl-tetrahydroyridine (MPTP) or LPS (Wu et al. 2002; Liu and Hong 2003). Also, PD patients exhibit microglial activation in the basal ganglia and cortex (Gerhard et al. 2006), with a resulting increase in 3HK and quinolinic acid and subsequent neuronal damage (Ogawa et al. 1992; Zinger et al. 2011). In addition, the antagonist activity of kynurenate at glutamate receptors is reduced in PD, since there is decreased expression of KAT1 in the substantia nigra of a rodent model of PD (Knyihar-Csillik et al. 2004) and there are lowered levels of kynurenate in the basal ganglia and cortex of PD patients (Ogawa et al. 1992). Overall, kynurenine pathway activation in PD seems to be such that the production of neurotoxic metabolites (quinolinic acid, 3HK) by microglia and infiltrating microphages outweighs the production of neuroprotective metabolites kynurenate (by astrocytes) and picolinic acid (by neurons) (Zinger et al. 2011) (Fig. 2).

5.5 Schizophrenia

Patients with schizophrenia have increased plasma levels of the pro-inflammatory cytokines IFN-γ, TNF-α, and IL-6 (Kim et al. 2009) and an associated activation of the kynurenine pathway (Barry et al. 2009). There is increased expression of IDO which is accompanied by a relatively greater activation of astrocytes than microglia, thus leading to the observed increase in levels of kynurenate in the cortex and CSF (Schwarcz et al. 2001; Erhardt et al. 2001; Muller et al. 2011). The blockage of NMDARs by kynurenate in the cortex could account for the glutamatergic hypofunction that is now believed to be a major factor in creating the established dopaminergic dysfunction in schizophrenia. For example, since glutamate and nicotinic acetylcholine receptors (nAChRs) are essential for cognitive processing, their blockage by kynurenate explains the cognitive deficit in schizophrenics (Zmarowski et al. 2009; Wu et al. 2010). Additionally, the sensory gating deficits in schizophrenia can be explained by kynurenate decreasing excitability of CA1 stratum radiatum interneurons via its blockade of NMDARs and nAChRs (Alkondon et al. 2011).

5.6 Depression

Depression is associated with an activated immune system (Maes et al. 1995; Maes 1999). For example, pro-inflammatory cytokines produced by activated

macrophages induce symptoms of depression when given to volunteers (Smith 1991; Dantzer et al. 2011) and patients receiving IFN-α for hepatitis C infection develop symptoms of depression. Also, depression is associated with increased IDO activity (which is reflected in an increased plasma kynurenine:tryptophan ratio), and a reduced level of the neuroprotective compound kynurenate (Wichers et al. 2005; Myint et al. 2007). The activity of TDO also is increased by pro-inflammatory cytokines, and by cortisol (Leonard and Myint 2006). Hence, the increased levels of cortisol during depression augment the activation of the kynurenine pathway by the cytokines to cause the neurodegenerative changes in susceptible brain regions – such as the subgenual anterior cingulate cortex, hippocampus, and amygdala – that are linked to the symptoms of depression.

Depression has an established association with low levels of serotonin for synaptic transmission, a link which has led to the widespread use of serotonin uptake inhibitors for treating depression. However, the diversion of tryptophan to the kynurenine pathway following immune system activation is likely to reduce the availability of tryptophan for serotonin synthesis. Changes of serotonergic neurotransmission may, therefore, be secondary consequences of kynurenine pathway activity, a hypothesis that could partly explain the association between activation of the kynurenine pathway and depression (Mackay et al. 2009).

5.7 Stroke

Cerebral ischemia induced by 10 min of bilateral carotid occlusion in gerbils results in increased levels of brain quinolinic acid at 4 days post ischemia (Heyes and Morrison 1997). In stroke, there is increased production of pro-inflammatory cytokines including IFN-γ, IL-1β, IL-8, IL-6, and IL-17 (Tarkowski et al. 1995; Kostulas et al. 1999; Hoshi et al. 2009); a subsequent localized increase in IDO expression (Taguchi et al. 2008; Hoshi et al. 2009); and increased kynurenine metabolites in the brain (Saito et al. 1993).

In humans, activation of the kynurenine pathway in stroke is supported by the finding of an association between stroke and an early onset decrease in plasma tryptophan levels and 3-hydroxyanthranilic acid:anthranilic acid ratio. Stroke also causes increases in the plasma kynurenine:tryptophan ratio (a measure of IDO expression), neopterin (a major inflammation marker), S100B protein (a marker of brain injury), and lipid peroxidation products (malondialdehyde and 4-hydroxynonenal). The levels of S100 and peroxidation products, as well as aspects of kynurenine metabolism, correlate with the infarct volume, as determined by CT scans (Darlington et al. 2007). Furthermore, the degree of IDO expression is well correlated with mortality risk following a stroke (Darlington et al. 2007) and with the subsequent degree of cognitive impairment following acute stroke (Gold et al. 2011). The latter observation is consistent with data showing very strong correlations between kynurenine pathway activity and cognitive function following cardiac bypass or thoracic surgery, to the extent that the biochemical changes may be used to predict cognitive outcome (Forrest et al. 2011).

5.8 Multiple Sclerosis

In multiple sclerosis (MS), there are parenchymal infiltrates associated with the multifocal areas of demyelination, macrophages and microglia being the main cell types found in the infiltrates. The activated macrophages and microglia release cytokines (IL-6, TNF-α, IL-1β, IL-12 and IL-23) that are capable of activating the kynurenine pathway.

Patients with MS have low tryptophan levels in serum and CSF (Sandyk 1996; Rudzite et al. 1996), suggesting activation of the kynurenine pathway. There have also been reports of decreased kynurenate levels in the CSF (Rejdak et al. 2002) and increased levels of plasma kynurenate (Hartai et al. 2005). The difference is unlikely to be due to the sample used since kynurenate easily crosses the blood–brain barrier. However, the difference might be due to the stage of the disease with increased kynurenate production during the active phase and a decreased production during the chronic non-active phase (Lim et al. 2010).

It seems that activation of microglia and perivascular macrophages in MS causes increased amounts of quinolinic acid that overwhelm the neuroprotective actions of kynurenate and contribute to the axonal demyelination. The oligodendrocytes that are damaged in MS lack IDO-1 activity and hence play an insignificant role in the kynurenine pathway; however, they do have NMDAR on their processes and AMPA/kainate receptors on the cell bodies (McDonald et al. 1998), making them susceptible to quinolinic acid– and glutamate-mediated excitotoxicity.

6 Therapeutic Possibilities

Acyclovir, an established drug against herpes virus infection, has been shown to inhibit quinolinic acid–induced lipid peroxidation in rat brain (Muller et al. 2005a), making it a potential treatment for quinolinic acid–mediated neurodegenerative diseases even when viral infection is not a primary factor.

A number of other compounds such as Necorostatin-1, Annulin, and Exigamine A have been shown to be effective IDO inhibitors in experimental models (Muller et al. 2005b; Brastianos et al. 2006; Pereira et al. 2006). That activity may make the compounds suitable for use as anticancer therapy or to inhibit the production of quinolinic acid, 3HK, and 3-hydroxyanthranilic acid in order to reduce excitotoxicity. However, they have not yet been shown to effective and safe enough to enter general clinical use (Takikawa 2007).

Because kynurenate production takes place in astrocytes, whereas 3HK and quinolinic acid are produced in microglia, the two branches of the kynurenine pathway are anatomically segregated. Additionally, these two branches are functionally segregated since the enzymes KAT II and KMO can be blocked selectively: Blocking of KAT II has no effect on 3HK/quinolinic acid levels, while blocking KMO decreases 3HK/quinolinic acid levels but increases kynurenate levels (Amori et al. 2009). Selective KMO inhibitors have been shown to produce neuroprotection against neuronal cell death in hippocampal slices (Carpenedo et al. 2002), brain

ischemia in gerbils (Cozzi et al. 1999), and dystonia in hamsters (Hamann et al. 2008). The therapeutic use of KMO inhibitors as neuroprotectants may be particularly effective when immune system activity is responsible for the changes in kynurenine pathway activation. Examples of this situation include parasitic disorders with CNS involvement. Infection of appropriate strains of mice with *Plasmodium* species, able to produce cerebral involvement similar to that encountered in humans, leads to ataxia and death within a few days; KMO inhibition reduces symptom severity and prevents mortality (Clark et al. 2005). Protection against brain damage has also been shown in a murine model of cerebral trypanosomiasis ("sleeping sickness"), a disease which is almost invariably fatal in humans (Rodgers et al. 2009). Despite these successes, the compounds used to date as KMO inhibitors penetrate the blood–brain barrier only poorly, and even greater success is likely to be achieved with the development of compounds that effectively cross this barrier more effectively (Zwilling et al. 2011).

6.1 Diet

Finally, it should be noted that in the fields of neurodegeneration and neuroprotection, as with several other major areas of central and peripheral pathology, dietary and nutritional factors may not only play a part in determining the extent of brain damage, but may also point toward potential therapeutic strategies for the reduction of damage. For example, there is accumulating evidence that a ketogenic diet (high in fat, low in carbohydrate) can increase plasma levels of acetoacetate, β-hydroxybutyrate, and acetone. The high levels of these ketone bodies may then provide neuroprotection against a number of CNS disorders in which brain damage occurs (in animal models or patients) including epilepsy, Alzheimer's disease, Parkinson's diseases, stroke, and traumatic brain injury (Gasior et al. 2006). Mice on a 4-week ketogenic diet exhibited smaller increases in brain TNF-α induced by the potent exogenous excitotoxin kainate (Jeong et al. 2011); the dietary effect would lead to reduced production of endogenous excitotoxins. Other studies have reported that ketone bodies induce the expression of KAT I and II in glial cells (Chmiel-Perzynska et al. 2011), leading to increased kynurenate levels in areas such as the hippocampus and striatum (Zmarowski et al. 2009).

Since some lifestyle activities including fasting or strenuous exercise can mimic ketogenic diets by promoting the formation of ketone bodies, it is likely that these or similar interventions will be examined closely as potential means by which the incidence and severity of CNS damage can be minimized, or recovery enhanced.

7 Conclusion

The key message from the work described above is that pharmacological interference with the kynurenine pathway should have importance in the treatment of a wide range of neuro-inflammatory and neurodegenerative disorders, including

those with primarily neurological or psychiatric symptomatology. This strategy would represent a major conceptual advance over the use of general receptor antagonists, since glutamate is the most widely used excitatory neurotransmitter in the mammalian CNS. A general blocker of glutamate receptors (or the major subdivisions of NMDA, AMPA, and metabotropic receptors) is, as a result, likely to induce a plethora of unwanted side effects that may include neurological manifestations such as paralysis, loss of memory, and compromised function of controlling output systems to the cardiovascular and respiratory systems. Interference with the kynurenine pathway should only affect those neurons and glia affected by the brain insult and thus should produce a locally directed modification of dysfunction with correspondingly fewer associated problems – one of the gold standard objectives of modern drug development.

Abstract

Despite years of research, the pathophysiology of depression and the mechanism of action in antidepressant drugs largely remain unknown. The subsequent hypotheses examining depression witnessed attention being paid to the decrease of the serotonin and noradrenaline synaptic concentrations, adaptive changes in the neurotransmitters receptor, activation of the immune system, hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis, and enhanced glutamatergic activity. Current research suggests that disturbed neuronal plasticity and the degeneration of neurons and glia cells may be involved in the pathogenesis of depression. In fact, in depressed patients, structural changes are observed in several brain regions, mainly in the hippocampus. Also, in various animal models of depression, morphological alteration in neurons and glial cells is present besides depression-like behavioral changes. A lot of evidence indicates that an increased amount or activity of glucocorticoids, glutamate, and proinflammatory cytokines is the reason for these changes. In both animal models of depression and postmortem studies, a reduced neurogenesis in the dentate gyrus of the hippocampus; a decrease in the total number of neurons and astrocytes; a reduction of the dendritic length, branching density, or the number of synapses; and a decrease in the brain-derived neurotrophic factor were observed. Moreover, activation of microglia, a source of proinflammatory cytokines and reactive oxygen species, has a disadvantageous effect on neurons and astrocytes. However, it should be noted that not all of the studies demonstrate neurodegenerative changes in depression, or the glucocorticoids' detrimental action, so further studies are needed in order to clearly determine the contribution of neurotoxic agents in the pathogenesis of depression and also the importance of the neuroprotective properties of some antidepressant drugs in their therapeutic effect.

Keywords

Animal models of depression • Antidepressant • Depression • Neurotoxicity

List of Abbreviations

5HT	Serotonin
ACTH	Adrenocorticotropic hormone
BDNF	Brain-derived neurotrophic factor
CMS	Chronic mild stress
CREB	Cyclic AMP response element-binding protein
CRF	Corticotropin-releasing factor

CRP	C-reactive protein
CUS	Chronic unpredictable stress
GFAP	Glial fibrillary acidic protein
HPA	Hypothalamic-pituitary-adrenal
LPS	Lipopolysaccharide
mPFC	Medial prefrontal cortex
NA	Noradrenaline
NMDA	*N*-methyl-D-aspartate
NOS	Nitric oxide synthase
PFC	Prefrontal cortex
ROS	Reactive oxygen species
SSRI	Selective serotonin reuptake inhibitors
TCA	Tricyclic antidepressant

1 Introduction

The first effective antidepressant drugs were introduced around 50 years ago, although their mode of action remained unclear (Charney et al. 1981). The investigation into the mechanism of action of antidepressants (iproniazid, imipramine) showed that these substances increase the central serotonin and norepinephrine transmission. Using these results as the basis, it was hypothesized that the cause of depression is the decrease in the level of monoamines such as serotonin or norepinephrine in the synaptic space, as well as a reduction in nerve conduction (Berton and Nestler 2006). It has been also shown that antihypertensive drugs such as reserpine, which cause monoamine depletion, sometimes lead to depression (Freis 1954). However, the hypothesis concerning monoamine has been recently questioned. It has been observed that not all drugs that increase monoamine concentration exert an antidepressant effect, and drugs such as monoamine oxidase inhibitors (tranylcypromine), and inhibitors of selective serotonin reuptake (fluoxetine), act immediately through the enhancement of monoaminergic conduction, yet their therapeutic effect in the improvement of mood is observed after a few weeks of therapy (Ruhé et al. 2007). Both the clinical and etiological heterogeneities of depression make it hard to define its pathophysiology (Hasler 2010). The last few years have paid witness to a variety of theories explaining the etiology of this disease. A decrease in the synaptic levels of monoamines, changes in neurotransmitter receptors, protein kinases, proinflammatory cytokines, neurotrophic factors, and hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis in the pathophysiology of depression were postulated as being potentially involved. Studies conducted in recent years have provided abundant evidence that the disturbance of molecular and cellular regulation of neuronal plasticity may be involved in the pathogenesis of depressive disorders (Nestler et al. 2002; Pittenger and Duman 2008). A considerable amount of data has suggested that degeneration of neurons and glia cells evoked by

a disturbance in neurotrophic factor pathways and enhanced glutamate, glucocorticoids, and proinflammatory cytokines' action play an important role in the pathogenesis of this disease. However, it has not presently been conclusively established whether morphological and functional brain changes observed in depression are one of the causes of disease or if they are the result of depression.

2 The Evidence for Brain Structures Changes in Depression: Clinical Data

Several changes have been noted in the structures anatomically linked with depression, such as the prefrontal cortex, hippocampus, amygdala, or nucleus accumbens. First of all, the structure which is the most vulnerable to atrophy is the hippocampus. The hippocampus is an area of the brain responsible for learning, memory, mood, and emotions. It plays an important role in the consolidation of information from short-term memory to long-term memory and spatial orientation. Volume reduction of this structure in depression, observed in postmortem studies, might be the result of many processes, including the remodeling of cellular elements, retraction of dendrites, reduction of neurogenesis in the dentate gyrus, and loss of glial cells (McEwen 1999; Rajkowska 2000; Czéh et al. 2001). In depressed patients, it was observed that the size of pyramidal neurons decreased, whereas the packing density of glial cells, pyramidal neurons, and granule cell neurons was significantly greater (Stockmeier et al. 2004; Tsopelas et al. 2011). The hippocampus is the most extensively studied region in depression by neuroimaging, and the resulting findings seem to suggest that hippocampal volumetric reductions are associated with depression (Bremner et al. 2000; Frodl et al. 2002b; MacQueen et al. 2003).

There were also reports that the volume of other brain structures have also decreased in postmortem research. Patients with depression had a significantly smaller medial orbitofrontal cortical volume, without smaller volumes of other frontal regions. These findings are consistent with other studies where the reduced volume of the orbitofrontal cortex, as well as the reduction of the entire frontal lobe, was shown (Bremner et al. 2002; Shah et al. 2002; Frodl et al. 2006). This change occurs in a more severely ill patient group, but not in those who were less severely ill (Bremner et al. 2000; Lacerda et al. 2004). Similar to the hippocampus, the decreased volume of the orbitofrontal cortex is caused by an increased density of glial cells and neurons (Rajkowska 2000). Depression was also associated with neuronal loss in some of the subcortical structures investigated (nucleus basalis, substantia nigra, raphe nucleus) (Tsopelas et al. 2011).

Examination of the brain of depressives showed an enlargement of the cerebral ventricles (Kellner et al. 1986). With this increase in ventricular volume, it was noted that the surrounding tissue shrinks (mammillary bodies, thalamus) and there are changes in formations that are connected to structures that pass through the third ventricle, such as the hippocampus (via the fornix) and the amygdala, which is connected via the stria terminals (Baumann et al. 1997; Dasari et al. 1999; Bernstein et al. 2008).

There were also noted changes in the volume of the amygdala. The amygdala is a structure that contains an extensive system of neuronal connections. It is involved in the analysis and processing of incoming information and with then comparing them to the stored patterns of emotional memory. Patients with depression have impaired functioning in emotional tasks involving the amygdala and, furthermore, they have an abnormal resting amygdala blood flow (Ledoux 2000; Phan et al. 2002). Depressed patients had reduced amygdala core nuclei volumes, without any differences in the total amygdala volumes. Studies indicate that reduction of the hippocampal volume was often accompanied by the volume reduction of amygdala (Caetano et al. 2004). It seems that glucocorticoid-induced neurotoxicity has been mediated by the glutamatergic connections in these closely cooperating structures (Sheline et al. 1998). It was noted that the initial stage of the disease was characterized by increased volume of this structure (Frodl et al. 2002a, b; Lange and Irle 2004; Weniger et al. 2006), and during the development of the depression, the volume reduction was observed, especially in females (Bremner et al. 2000; Caetano et al. 2004; Hastings et al. 2004).

3 The Evidence for Changes in Brain Structures in Depression: Experimental Data

Depression is a very diverse disease, with mostly different symptoms amongst individuals, and its etiology is still poorly recognized despite extensive investigation (Table 1). More importantly, it is not possible to reproduce some of the symptoms characteristic of major depression in animals, such as suicidal thoughts, a depressed mood, or the feeling of guilt. This is the reason why it is hard to delineate the most accurate animal model of depression.

The majority of the presently applied models are based on different stress paradigms and in different stress patterns (chronic, acute, unpredictable). Chronic mild stress (CMS), which consists of the long-term exposure of animals to a series of unpredictable, mild stressors, produces depression-like behavioral changes, including anhedonia. In this model of depression, a decrease in the total number of granule cells in the ventral hippocampus, an enhanced blood corticosterone level, and an increase in the number of caspase-3 positive neurons in the cerebral cortex were observed (Jayatissa et al. 2006; Bachis et al. 2008; Nowak et al. 2010). In chronic unpredictable stress (CUS), which has been conducted on rabbits, glial atrophy in the PFC has been confirmed (Banasr and Duman 2008). In prenatal restraint stress, which, similar to CMS, exhibits face, predictive and construct validity, a decrease in hippocampal cell neurogenesis in the dentate gyrus and impairment in the hippocampal-related spatial tasks were indicated (Lemaire et al. 2000). A decrease in hippocampal neurogenesis has also been observed in the olfactory bulbectomy (Jaako-Movits et al. 2006). In another examination, with chronic or acute restraint stress, there were a decrease in the total number of neurons and the structure volume and a decrease of the neurogenesis of the CA3 field dentate gyrus (Pham et al. 2003). In chronic, social stress in tree shrews,

Table 1 Summary of structural alterations related to neurodegenerative processes demonstrated in animal models of depression

Animal model of depression	Structural changes	References
Chronic mild stress	▼Granular cell number in hippocampus	(Bachis et al. 2008; Nowak et al. 2010)

a model with high validity for depression, a reduced hippocampal volume, a decreased hippocampal neurogenesis, and an increased number of apoptotic cells in the temporal cortex occur (Czéh et al. 2001; Lucassen et al. 2001). A decrease in cell proliferation and enhanced apoptosis in the dentate gyrus of the hippocampus were reported in the maternal separation rat model (Lee et al. 2001). The expression of antiapoptotic proteins (Bcl-2, Bcl-xL) was lower in the cingulate and frontal cortex, hippocampus, and central nucleus of the amygdala in CUS (an animal model of depression) (Kosten et al. 2008). In the restraint model of psychological stress in mice, the increased proliferation of microglia cells was observed (Nair and Bonneau 2006).

4 The Involvement of the HPA Axis in Neurodegenerative Processes in Depression

Amongst the possible mechanisms involved in the brain's morphological changes observed in depression, hyperactivity of the HPA axis, itself leading to prolonged hypercortisolemia, has been considered. This mechanism may play an important role in the volumetric and neurodegenerative alteration of several brain areas, especially in those with a high concentration of glucocorticoid receptors, such as

the hippocampus (Herman et al. 2003). It has been observed that, on the one hand, stress-induced neurotoxicity can cause volumetric changes in different brain structures, while, on the other hand, these changes may in turn induce an increase in HPA axis activity (Cerqueira et al. 2005). This results from the fact that stress and glucocorticoids induce neuronal loss mainly in the hippocampus, a structure which exerts an inhibitory effect on HPA axis activity. Thus, hippocampal damage disinhibits the HPA axis and, as a result, additionally enhances glucocorticoid synthesis and release. This "glucocorticoid cascade hypothesis," formulated by Sapolsky et al. (1986), was proposed as an explanation of hippocampal damage in both some neurodegenerative disorders and depression.

Psychological studies conducted in patients affected by depression at the end of the 1970s revealed the role of psychological stress as a factor contributing to the development of depression (Brown and Harris 1978). At the same time, HPA axis abnormalities, including an increased cortisol serum level, were shown to be one of depression's features. In addition, it has been observed that dexamethasone administration suppresses the cortisol level in the blood of depressed patients less potently than in healthy people (Carroll 1982). The participation of the HPA axis dysfunction in the pathogenesis of depression has been also supported by the observations that patients suffering from Cushing's syndrome, characterized by elevated levels of serum cortisol, often exhibit symptoms of depression (Sonino et al. 1993). Similarly, it has been shown that the administration of chronic glucocorticoids evoked depression-like symptoms in rodents (Gourley et al. 2007). A HPA axis dysfunction in depression can manifest in a variety of ways, including excessive sensitivity of the adrenal gland to the adrenocorticotropic hormone (ACTH) (Parker et al. 2003), increased secretion of the corticotropin-releasing factor (CRF) (Nemeroff and Owens 2002), or the reduction in negative feedback exerted via the glucocorticoids' receptor (Brown et al. 2004).

Glucocorticoids regulate metabolism and immune system activity and are essential for maintenance, homeostasis, and adaptation to stress, but their long-term increased level or disturbance in the circadian rhythm can have a deleterious effect on the brain's morphology and function. Glucocorticoid receptors are present in many brain regions which are affected by depression, such as the prefrontal cortex (PFC), hippocampus, nucleus accumbens, striatum, limbic system, and ventral midbrain (Herman 1993; Van Craenenbroeck et al. 2005). It was discovered that when corticosterone concentration increases for a long time, it causes neuronal damage in the CA1 and CA3 hippocampal region and enhances neurodegenerative processes evoked by excitatory amino acids, hypoxia, hypoglycemia, seizures, or age. One of the long established changes caused by chronic stress or long-term administration of glucocorticoids is the reorganization of the apical dendrites of pyramidal cells in the CA3 region of the hippocampus. Stress or glucocorticoid treatment induces an extensive reduction of the total dendritic length, a reduction in the distal dendritic branching density, and a reduction of the number of synapses in the hippocampal CA3 region in rats (Magariños et al. 1999; Sousa et al. 2000). Apart from the hippocampus, atrophy of the dendrites was also witnessed in the prefrontal cortex in experimental animals after chronic stress (Magariños and McEwen 1995; Wellman 2001; Duman 2002).

It seems that one of the reasons for hippocampal volume reduction observed in depression is an impairment in the process of neurogenesis. A lot of data indicated that glucocorticoids, stress, and glutamate inhibited neurogenesis in the dentate gyrus of the hippocampus, while physical and mental activity, insulin-like growth factor, serotonin, estradiol, and adrenalectomy enhanced this process in experimental animals. It seems that glucocorticoids and glutamate regulate neurogenesis by a common mechanism, because *N*-methyl-D-aspartate (NMDA) receptor antagonists inhibit corticosterone action, while NMDA activation blocks the effect of adrenalectomy (Cameron et al. 1998). Since glucocorticoids enhance extracellular glutamate concentration in the hippocampus, their inhibitory effect on the process of neurogenesis may result from the enhancement of glutamate activities.

The mechanisms of glucocorticoids' deleterious action on brain cells are unclear, but most probably are connected with enhancing glutamate action, inhibition of astrocyte glucose uptake, and decreasing the synthesis of neurotrophic factors. For example, stress or glucocorticoids reduce synthesis of the brain-derived neurotrophic factor (BDNF), a compound responsible for the growth, maturation and survival of nerve cells as well as for the processes of arborization and brain plasticity. It has been shown that chronic stress decreases the synthesis of BDNF in the hippocampus, whereas antidepressants lead to an increase in its production in the hippocampus and PFC (Shimizu et al. 2003). It has also been found that stress reduces the BDNF and tyrosine kinase B (*TrkB*) (BDNF-specific receptor) genes' expression and phosphorylation of the cyclic AMP response element-binding protein (CREB), which is the transcription factor that regulates the expression of BDNF (Nibuya et al. 1995, 1996; Duman et al. 1997, 2000).

The role of glucocorticoids in the pathogenesis of depression is evidenced by the data indicating the antidepressant effect of GR antagonists and glucocorticoid synthesis inhibitors in animal models (Baez and Volosin 1994; Healy et al. 1999). Clinical data also showed the antidepressant action of glucocorticoid synthesis inhibitors, and clinical trials with specific glucocorticoid and CRF receptor antagonists as potential antidepressants are in progress (Wolkowitz and Reus 1999; Mathew et al. 2008).

5 The Involvement of Enhanced Glutamate Transmission in Neurodegenerative Processes in Depression

The hypothesis that dysfunction of the glutamatergic system may be involved in the pathophysiology and treatment of depression was proposed in 1996 (Skolnick et al. 1996), following several discoveries concerning the importance of the NMDA receptor in antidepressant action (the first article by Trullas and Skolnick evidenced that NMDA receptor functional antagonists exhibit antidepressant-like activity, Trullas and Skolnick 1990). Many studies demonstrated that patients with depression have an elevated glutamate level in the blood (Kim et al. 1982; Altamura et al. 1993) and a positive correlation between the blood glutamate level and the severity of depressive symptoms was discovered (Mauri et al. 1998; Mitani et al. 2006). Similarly, it was

demonstrated that the glutamate level in the cerebrospinal fluid of patients with depression is higher than in the healthy controls (Levine et al. 2000). The disturbance of glutamatergic neurotransmission in depression is also supported by postmortem studies. Alterations in [^{3}H]CGP39653 (an antagonist of the glutamate binding site of the NMDA receptor) binding and its modulation by glycine were demonstrated in both the frontal cortex and hippocampus in suicide/depressed humans (Nowak et al. 1995; Beneyto et al. 2007). Furthermore, a decrease of [^{3}H]L-689,560 binding (an antagonist of the NMDA receptor glycine site), as well as the reduction in the NR1 subunit of NMDA receptor immunoreactivity in the superior temporal cortex of depressed patients was reported (Nudmamud-Thanoi and Reynolds 2004). Also, changes in mRNA/protein concentrations of the glutamate receptor subunits (NMDA, metabotropic) in the brain regions of depressed subjects were described (e.g., Law and Deakin 2001; Feyissa et al. 2009; Deschwanden et al. 2011).

Elevated concentration of extracellular glutamate is considered to be the main reason for the degeneration of neurons and/or cell death observed in neurodegenerative diseases (Hardingham and Bading 2010). Environmental stress, which increases both glutamate and glucocorticoids, has a huge impact on the morphology of the brain tissue and is also a risk factor for mood/anxiety disorders (de Kloet et al. 2005). Studies in rats using the microdialysis technique indicated an increase in extracellular levels of excitatory neurotransmitters (glutamate and aspartate) within the striatum, hippocampus, nucleus accumbens, and medial prefrontal cortex (mPFC) after acute restraint stress (for 20 min). The highest glutamate level increase was observed in the mPFC, when compared to other structures. The same result was obtained in swimming stress, conducted in the same period of time. Glucocorticoids, which inhibit glutamate uptake into glia cells, are probably responsible for an enhanced intracellular glutamate level and, consequently, the increase of excitotoxicity processes. It has been reported that an elevated level of glucocorticoids in the hippocampus and mPFC increased glutamate concentration and that both of these compounds are responsible for the retraction of dendrites in the CA3 region of the hippocampus (McEwen 2005; Pittenger and Duman 2008; Gorman and Docherty 2010). In glutamatergic synapses, the typical mechanisms of the synaptic plasticity affecting their activity are changes in the shape and size of the synaptic shafts and spines (Sorra and Harris 2000). Stress can affect the processes of the synaptic plasticity of various brain structures, and different forms of stress may induce atrophy, retraction, and remodeling of dendrites of the pyramidal neurons in the hippocampal CA3 region (Watanabe et al. 1992; Magariños and McEwen 1995). It has been demonstrated that certain intracellular processes, associated with glutamatergic receptor stimulation, may be involved in the pathophysiology of depression and neuronal degeneration. Stimulation of the NMDA receptor leads to an increase in intracellular calcium concentration in postsynaptic neurons. Ca^{2+} bind to and stimulate the Ca^{2+}/calmodulin-dependent protein kinase, which via action on the nitric oxide synthase (NOS) may then enhance the synthesis of the nitric oxide (II) (Southam and Garthwaite 1993; Li and Poulos 2005). Nitric oxide is a membrane-permeable molecule associated with the processes of cellular signaling and communication in various systems. In the brain, nitric oxide regulates

many physiological processes, including neurotransmission, synaptic plasticity, neuromorphogenesis, gene expression, and the perception of pain and learning (Esplugues 2002), suggesting that its enhanced level may contribute to the etiology of depression. Clinical studies have shown increased immunoreactivity for nNOS in the hippocampal CA1 and subiculum region in patients suffering from major depression and bipolar disorder (Oliveira et al. 2008). Administration of 7-nitroindazole, an inhibitor of neuronal nitric oxide synthase (nNOS), into the dorsal hippocampus, induces an antidepressant-like effect in rats (Joca and Guimarães 2006). Moreover, paroxetine, a selective serotonin reuptake inhibitor, inhibits the activity of constitutive nitric oxide synthase (cNOS) (Finkel 1996).

6 The Involvement of the Immune System in Neurodegenerative Processes in Depression

Patients suffering from depression have a higher incidence of immune system disorders when compared to the total population, and also depression often occurs as a side effect of cytokine therapies that are used in the treatment of hepatitis C, multiple sclerosis, Kaposi's sarcoma, and many other cancer types. Depression occurs most frequently in therapies using IFN-α and IL-2, less frequently during IFN-β administration, and has not been recorded in the case of IFN-γ (Valentine et al. 1998; Gohier et al. 2003). Patients with depression often exhibit increased activity of the immune system, which is reflected in the increase of the level of "positive" acute phase proteins – C-reactive protein (CRP), haptoglobin, ceruloplasmin – as well as in the reduction of the "negative" acute phase proteins' concentration (albumin, transferrin, retinol-binding protein). Depression is also more common in patients suffering from disease connected with immune component disturbances (Kronfol 2002). Studies conducted in experimental animals have shown that administration of lipopolysaccharide (LPS) or IL-1 evoked "sickness behavior" syndrome, which has symptoms that are similar to those observed in depression (Kent et al. 1994). Similarly, administration of LPS to healthy volunteers resulted in the appearance of symptoms of anxiety and depression (Reichenberg et al. 2001). A lot of data especially indicates the important role of TNF-α, IL-1, and IL-6 in the pathogenesis of affective disorders. Under physiological conditions, these cytokines positively affect the central nervous system, through neurogenesis enhancement and trophic action on neurons. However, excessive stimulation of signal transduction pathways through the proinflammatory cytokines in the central nervous system can have a disadvantageous effect (Miller et al. 2009). Peripheral administration of LPS causes an increase in the concentration of TNF-α and IL-1 in the hippocampus, which is associated with a decreased expression of BDNF and TrkB in this brain structure. This leads to a decrease in the neurogenesis processes, impairs cognitive function and may also cause an increase in glutamatergic transmission, enhances oxidative stress, and induces apoptosis of astrocytes and oligodendrocytes, thus, the processes that are most likely involved in the pathogenesis of depression (Wu et al. 2007; Miller et al. 2009). Apart from enhancing neurodegenerative processes, proinflammatory

cytokines can modify the level of neurotransmitters. Animal studies suggest that proinflammatory cytokines alter the turnover of serotonin (5HT) in different brain regions (Dunn et al. 1999), lead to the downregulation of serotonin receptor $5HT_{1A}$ (Cai et al. 2005), and inhibit serotonin synthesis through activation of the indoleamine 2,3-dioxygenase enzyme that converts the tryptophan (precursor of serotonin) into kynurenine (Schwarcz and Pellicciari 2002). Additionally, proinflammatory cytokines, especially IFN-α, increase the kynurenine-3-monooxygenase enzyme and in this way shift kynurenine metabolism toward the synthesis of 3-hydroxykynurenin and quinolinic acid, NMDA receptor agonists which can contribute to the neurotoxic processes observed in depression (Zunszain et al. 2012). Cytokines also affect dopamine neurotransmission by upregulation of the dopamine receptor and an increase of the nitric oxide (II), which in turn inhibits the synthesis of dopamine (Kitagami et al. 2003; Moron et al. 2003). Proinflammatory cytokines were also indicated as modulating the function of the HPA axis. For example, administration of IL-1 and IL-6 enhances CRF secretion and consequently activates the HPA axis (Besedovsky and del Ray 1996). Cytokines can activate the HPA axis acting on the hypothalamus, pituitary, or adrenal cortex and can also modulate glucocorticoid receptor action (Pariante et al. 1999).

7 The Disturbed Glucose Metabolism in Depression

Functional neuroimaging research of depressed patients showed anatomical differences in the glucose metabolism in the brain. In 1985, and for the first time, scientists described reduced glucose metabolism in the prefrontal cortex in bipolar depressives (Baxter et al. 1985). These findings were confirmed in other investigations, which then also demonstrated hypometabolism in unipolar patients (Baxter et al. 1989; Hurwitz et al. 1990; Martinot et al. 1990). Further reports indicate the coexistence of reduced blood flow and impaired glucose metabolism in the prefrontal cortex in patients with a reduced cortical volume (Drevets et al. 1997). Moreover, alterations of brain glucose metabolism are stronger in patients with hyperactivity of the HPA axis, which suggests that the impaired glucose metabolism can result from elevated glucocorticoid action.

On the other hand, numerous studies have shown a correlation between an increased severity of depressive symptoms and increased use of glucose in the subgenual anterior cingulate cortex (Drevets et al. 1999; Osuch et al. 2000), although the opposite result has also been reported (Price and Drevets 2010). It is probable that the increase of glucose metabolism in this brain region is the compensatory mechanism acting at the initial stage of this disease and in unmedicated patients. In another research, an increased perfusion in the medial orbitofrontal cortex was observed during the induction of sadness in healthy controls (Liotti et al. 2002). Glucose hypermetabolism has also been used as a potential indicator of treatment response during the antidepressant therapy (Mayberg et al. 1997, 2000). Most frequently in antidepressant respondents, the increased dorsolateral and decreased ventrolateral prefrontal metabolism have been reported (Kennedy et al. 2007).

Interestingly, researchers have also found a correlation between the amygdala volume and glucose metabolism in the human brain in vivo (Johansen-Berg et al. 2008). Reduction in gray matter volume in the amygdala is probably compensated by an increased glucose metabolism at the beginning of a depressive episode. This prolonged compensation could provoke neuroplastic changes in the brain structure.

8 The Role of Glial Cells in Neurodegenerative Processes in Depression

Changes in the structure or function of neurons may be the result of disturbed action of glial cells (astrocytes, oligodendrocytes, and microglia). Astrocytes regulate many brain functions, including extracellular concentration of ions and neurotransmitters, glucose uptake, synthesis of neurotransmitters, synaptic function, neuronal metabolism, and migration. Astrocytes and microglia are also a source of many neurotrophic factors and cytokines.

Many studies have indicated the role of glial elements in the pathophysiology of various neurodegenerative disorders, including depression (Rajkowska and Miguel-Hidalgo 2007). It has been shown that glial ablation in the PFC evoked by an astrocyte-specific toxin, L-alpha-aminoadipic acid, can sufficiently induce depressive-like behaviors in rodents (Banasr and Duman 2008). Numerous studies reported a decrease of the glial density in various brain structures in depression. For instance, it has been revealed in layers 3 and 5 of the dorsolateral prefrontal cortex and in the deeper layers of the caudal orbitofrontal cortex (Rajkowska et al. 1999). Reduction of glial cell density was also observed in the subgenual part of the anterior cingulate cortex and in the supracallosal part of the anterior cingulate cortex in depressive subjects (Ongur et al. 1998; Cotter et al. 2001). By contrast, in hippocampal CA subfields and in the granule cell layer of the dentate gyrus, the glial cell density was increased in subjects with depression (Stockmeier et al. 2004).

Experimental data indicated that glucocorticoids, which appear to be elevated in depression, reduce the activation of astrocytes in the hippocampus (Sonino et al. 1993; Laping et al. 1994). According to this, concentration of glial fibrillary acidic protein (GFAP), a protein expressed in astrocytes, is also decreased in the hippocampus after chronic psychosocial stress (Czéh et al. 2006). Since a decreased number or function of astrocytes attenuates synaptic glutamate uptake and in the end enhances synaptic glutamate concentration, it may be one of the mechanisms responsible for neurodegenerative changes observed in depression. Glial cells are the main source of proinflammatory cytokines, which then regulate the kynurenine pathway, the main pathway for brain tryptophan metabolism (Schwarcz and Pellicciari 2002). Microglia cells, macrophages, and monocytes produce quinolinic acid, which is an agonist of the NMDA receptor, while astrocytes synthesize kynurenic acid, which is its antagonist (Guillemin et al. 2000, 2001, 2005). Increased quinolinic acid levels were found in blood and cerebrospinal fluid in major depression and in the cytokine-induced animal model of this disease

(Myint et al. 2007; Dantzer et al. 2008; Raison et al. 2010), while higher kynurenic acid production was linked to schizophrenia (Erhardt et al. 2001; Nilsson et al. 2005; Linderholm et al. 2012). In this context, quinolinic acid may be the link between immune and neurotransmitter changes that are specific to depression and involved in neurodegenerative changes (Steiner et al. 2011). Moreover, glial cells are also the source and the target of various cytokines, e.g., interleukins, tumor necrosis factor, whose level appears to be elevated in depression (Müller and Ackenheil 1998; Howren et al. 2009; Dowlati et al. 2010).

An important function of astrocytes is glucose metabolism and providing energy to neurons. The majority of research with positron emission tomography and functional magnetic resonance, which is based on the activities of glucose uptake, glycolysis, and oxidative phosphorylation, indicated hypometabolism in the prefrontal cortex in depression patients. As such, these changes might be evoked by either a reduced number or weaker activation of astrocytes.

Properly functioning glial cells are necessary for the appropriate function of the neurons, including resistance to damage. It has been found that brain injury is associated with activation of astrocytes and manifested by the increase of the GFAP expression (Krohn et al. 1999). Activated astrocytes may promote neuronal survival by enhanced release of trophic factors but, conversely, they may also inhibit the process of regeneration by forming a glial scar.

Microglia, similar to astrocytes, regulate the extracellular concentration of ions and neurotransmitters and via the release of the trophic factor act on neuroprotective/neurodegenerative processes. However, overstimulation of microglia seems to be harmful for brain cells. Microglia is activated mainly in response to immunity stimulation and brain damage, and this process is associated with the transition of microglia cells into the amoeboid form, which promotes phagocytosis and mobility (Streit et al. 1988; Kreutzberg 1996; Streit et al. 1999; Liu and Hong 2003). Activation of microglia, in response to proinflammatory triggers such as LPS (Pei et al. 2007; Qin et al. 2005a, b), β-amyloid (Aβ) (Bamberger and Landreth 2001), and HIV-Tat (Turchan-Cholewo et al. 2009), is associated with the liberation of cytotoxic agents, including TNF-α (Sawada et al. 1989; Lee et al. 1993), inflammatory prostaglandins (Wang et al. 2005), or reactive oxygen species (ROS) such as superoxide ($O2^{\bullet -}$) (Colton and Gilbert 1987) and NO (Moss and Bates 2001; Liu et al. 2002), for the neutralization of pathogens (Oehmichen and Gencic 1975; Graeber et al. 1988). These compounds, besides the hydrogen peroxidase and hydroxyl radicals also produced by microglia, may injure neurons and glial cells (Chao et al. 1992; Boje and Arora 1992). Several studies revealed that antidepressant drugs (selective serotonin reuptake inhibitors, SSRI) modulate the ability of microglia to produce TNF-α and NO in mice (Hashioka et al. 2007, 2009; Hwang et al. 2008; Horikawa et al. 2010). Fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram have been reported to strongly inhibit the production of TNF-α and NO in LPS-stimulated microglial cells (Tynan et al. 2012). The above reports support the hypothesis of the role of activated microglia in the pathogenesis of depression. Furthermore, activation of microglia and an increased corticosterone level can appear together. In the restraint model of psychological stress in mice, the elevated corticosterone level was accompanied by an increased proliferation of

microglia cells. The inhibition of glucocorticoid synthesis or antagonists of either the glucocorticoid receptor or NMDA receptor resulted in suppression of the stress-induced microglia cell proliferation (Nair and Bonneau 2006).

9 Effects of Antidepressant Drugs on Neurodegenerative Processes in Depression

Currently used antidepressants show a large variation in the mechanism of their action. Most registered drugs are based on the monoaminergic hypothesis of depression. According to this, the effect is acquired by increasing noradrenergic and/or serotonergic transmission through inhibition of monoamine's reuptake, the influence on adrenergic and serotonergic receptors, or inhibition of enzymatic degradation of monoamines. Tricyclic antidepressants, being the oldest group of drugs with a particularly broad spectrum of activity, have a number of adverse effects. The pharmacological action of antidepressants, as well as their toxicity, should be considered always in terms of two processes: changes after a single dose of the substance and the activity of the drug after prolonged use, due to changes in quantity/activity of the receptors, the intracellular molecular changes, and the process of plasticity. In this chapter, we focus on the effect and mechanism of action of antidepressant drugs on neuronal maintenance, the process of neurogenesis, and their influence on the morphological changes that occur during the state of depression. Although some antidepressant drugs exerted neuroprotective action on neurons and glial cells, some of these drugs, especially at higher doses, may exert a cytotoxic effect. For example, amitriptyline, desipramine, and fluoxetine induced in in vitro studies at μM concentrations cell death in hippocampal neurons and PC12 pheochromocytoma cells, and some antidepressants from the TCA and SSRI group induce apoptosis in neurons and glia cells (Španová et al. 1997; Post et al. 2000; Bartholomä et al. 2002).

9.1 Effects of Antidepressants on Proinflammatory Cytokines

The neuropharmacology of tricyclic antidepressants (TCA) cannot be described only in the example of noradrenaline (NA) and 5-HT reuptake inhibition because it has transpired that the profile of these drugs is much broader. The neuroprotective effect of tricyclic antidepressants has been described in the case of imipramine and clomipramine in in vitro studies. It has been shown that these drugs decrease the concentration of nitric oxide, TNFα, and IL-1β, as well as neurotoxic changes, observed in microglia cells and astrocytes stimulated with LPS (Hwang et al. 2008). This data is in line with the inflammatory and neurodegenerative theory of depression, whereby an increased level of proinflammatory cytokines and reactive oxygen species is purportedly involved in the pathogenesis of depression and the inhibition of microglia activation in the brain has a neuroprotective effect (e.g., Hwang et al. 2008; Maes et al. 2012). Similarly, it was reported that fluvoxamine, reboxetine, and imipramine inhibited the production of

NO and IL-6 by microglial cells activated with IFN-γ (Hashioka et al. 2007). In the in vivo experiment, it has been found that a 2-week administration of paroxetine inhibited, when stimulated by IFNα, IL-1β and IL-10 concentrations in the hypothalamus, while desipramine decreased the IL-1β and TNFα concentration in the rat cortex after LPS administration (Myint et al. 2007; O'Sullivan et al. 2009). When stimulated by LPS, the production of proinflammatory cytokines was also inhibited by an atypical antidepressant – tianeptine, but only in the hypothalamus and not in the hippocampus (Castanon et al. 2004). These studies indicated that antidepressant drugs showing a different action on monoamines inhibit the synthesis of proinflammatory cytokines.

9.2 Effects of Antidepressant Drugs on Neurogenesis

Recently, a lot of data has indicated that depression is associated not only with the process of neurodegeneration but also with reduced neurogenesis in the brain. Although the function of new neurons generated in the adult mammalian brain, especially in the dentate gyrus of the hippocampus, is poorly established, studies in animals suggest a relation between neurogenesis and some hippocampus-dependent learning task. Experimental data indicated that the administration of long-term antidepressants increases hippocampal neurogenesis and prevents the fall in this process induced by different factors, most often by various kinds of stress. For example, in chronic mild stress – an animal model of depression – a decrease in the total number of granule cells in the ventral hippocampus was observed, and long-term treatment with escitalopram blocked this reduction (Jayatissa et al. 2006). Also, in the olfactory bulbectomy model of depression, citalopram reversed inhibition of the new cells' creation in the dentate gyrus of the hippocampus (Jaako-Movits et al. 2006). Different classes of antidepressants (selective serotonin reuptake inhibitors, selective noradrenaline reuptake inhibitors, monoamine oxidase inhibitors, atypical antidepressants) and electroconvulsive seizures have been found to increase neurogenesis acting on the process of proliferation or survival of newborn neurons.

9.3 Effects of Antidepressant Drugs on the Brain Derived Neurotrophic Factor

The BDNF regulates the growth, survival, and function of brain cells and is involved in both the formation of memory traces and learning process. Some data has evidenced the involvement of BDNF in the pathogenesis of depression and in the action of antidepressant drugs. Chronic stress and glucocorticoids decreased BDNF expression in the hippocampus, whereas antidepressant drugs increase its concentration or prevent the stress effect. For example, it has been shown that in an animal model of chronic unpredictable stress, venlafaxine, mirtazapine, and fluoxetine raised the level of the BDNF in the hippocampus (Zhang et al. 2010). Also, desipramine, sertraline, and tianeptine, in some experimental models, increase the

levels of BDNF. Chronic treatment with various antidepressant drugs also increases the expression or activity of TrkB (BDNF receptor), and BDNF/TrkB-signaling seems to be employed not only in the survival and differentiation of neurons but also in depression's etiology and the action of antidepressant drugs. It was revealed that in the TrkB knockout animals, antidepressant therapy has no effect, whereas application of BDNF into the hippocampus exerted an antidepressant-like effect (Shirayama et al. 2002; Saarelainen et al. 2003). In patients with depression, decreased levels of BDNF in the blood were normalized after long-term escitalopram treatment (Serra-Millàs et al. 2011). Also, postmortem studies showed decreased brain BDNF concentration in unmedicated depressed subjects (Pittenger and Duman 2008). A lot of data, but not all, indicated that BDNF is an important factor in the prevention of neuronal degeneration, the inhibition of neurogenesis, and may be essential for the action of antidepressants.

9.4 Effects of Antidepressant Drugs on the Atrophy of Hippocampal Neurons

Postmortem studies show that patients with depression have a significant atrophy of neuronal cells in the hippocampus (particularly area CA3 pyramidal neurons) and in the amygdala. In experimental animals, neurodegeneration is reversed after the application of antidepressant drugs belonging to different classes, such as fluoxetine, imipramine, tranylcypromine, rolipram, and reboxetine, plus also following electroconvulsive treatment or transcranial magnetic stimulation (Madsen et al. 2000; Mayberg et al. 2000; Czéh et al. 2002; Duman et al. 2004). In the inhibition of stress- or glucocorticoid-induced hippocampal neurodegeneration, tianeptine especially exerts a protective function. This drug inhibits stress- or glucocorticoid-induced atrophy of apical dendrites of the hippocampal Ca3 pyramidal neurons (Magariños and McEwen 1995). Also, a stress-related decrease in the hippocampal volume, inhibition of cell proliferation, and a decreased level of *N*-acetylaspartate in the hippocampus and amygdala were prevented by tianeptine (Czéh et al. 2001; McEwen and Chattarji 2004). Tianeptine is an atypical antidepressant drug, which in contrast to other antidepressants increases serotonin uptake, and its neuroprotective action perhaps results from both the inhibition of NMDA receptor function and the increasing serotonin reuptake in the hippocampus, monoamine, whose release in the hippocampus is increased under many types of stress (Kole et al. 2002).

10 Zinc Deficiency-Induced Neurodegeneration in Depression

Recently, much attention has been paid to the role of zinc in the pathophysiology and treatment of depression (Szewczyk et al. 2010; Szewczyk et al. 2011b). The first strong evidence indicating hypozincemia in human depression was demonstrated by Maes and co-workers (Maes et al. 1994). On the other hand, zinc exhibits

antidepressant activity in preclinical and clinical studies (Szewczyk et al. 2010, 2011a, b). Zinc deficiency is currently examined in experimentally induced depression in rodents (by a zinc deficient diet) and assessed in humans (e.g., Szewczyk et al. 2011a, b). Zinc deficiency induces depressive-like behavior and biochemical alterations similar to that observed in the animal models of depression (resembling human depression). The biochemical changes include reductions of brain BDNF, NGF concentrations, enhanced activity of the NMDA receptor, increased glucocorticoid and glutamate actions, and reduced neurogenesis processes (e.g., Szewczyk et al. 2011a). Examinations of zinc deficiency as a model of depression are in progress.

11 Conclusion

Major depression is one of the most common psychiatric disorders whose etiology, despite long and intensive studies, remains unclear. Because about 30 % of patients do not respond to the therapy with currently available antidepressants, there is a great need to investigate new hypotheses explaining the cause of depression, plus create new drugs. Previous research on depression was focused on changes in the concentration of neurotransmitters and their receptors. Actually, increasing evidence indicates that an impaired neuronal plasticity, especially observed in the hippocampus and frontal cortex, plays a role in the pathogenesis of depression. In turn, the disruption of cellular mechanisms regulating neuronal plasticity is most often connected with prolonged, damaging effects of the glucocorticoids, glutamate, and proinflammatory cytokines. Thus, it seems that in the pathophysiology of depression, all of the main systems involved in homeostasis maintenance, namely, neurotransmitters, glucocorticoids, and cytokines, interact in a complex way. To study the role of one factor in the pathogenesis of depression is relatively easy, while the influence of several compounds and the determination of their interactions remain difficult. For example, even the interaction between glucocorticoids and proinflammatory cytokines is complex and depends on the duration of action and their actual concentration, plus involves the inhibitory action of glucocorticoids on cytokine synthesis, modulation of the cytokine receptor function, the stimulatory effect of some cytokines on cortisol synthesis, or their influence on glucocorticoid receptors. Moreover, it must be noted that the role of glucocorticoids, cytokines, and glutamate in the pathogenesis of depression has not yet been fully determined and that other factors may be also involved, while, furthermore, the pathogenesis of depression should not be connected only with cell neurodegeneration/death.

Abstract

The accumulation of amyloid-β is widely considered the primary neurotoxic insult leading to Alzheimer's disease. Although the precise mechanism of this toxicity is not well understood, amyloid-β-induced downregulation of brain-derived neurotrophic factor may be one of the most important contributors to amyloid-β toxicity. Brain-derived neurotrophic factor has diverse neurotrophic effects on the nervous system, including promoting synaptic plasticity and neurogenesis, and it is essential for cognition and memory. Early in the progression of Alzheimer's disease, prior to significant plaque and tangle deposition, declining brain-derived neurotrophic factor expression induced by amyloid-β is associated with mounting impairments in cognition and memory. A variety of approaches have demonstrated that increasing brain-derived neurotrophic factor levels improves learning and memory, highlighting the possibility that therapeutically restoring brain-derived neurotrophic factor levels may prevent or reverse the memory impairments and cognitive decline seen in Alzheimer's disease.

Keywords

Alzheimer's disease • Amyloid-β • BDNF • CREB • Learning and memory • LTP

1 Introduction

Alzheimer's disease (AD) is a progressive neurodegenerative disorder that is the most common cause of dementia in the elderly. AD presents as global cognitive decline with associated memory loss and altered personality. The neuropathological hallmarks of AD include extracellular amyloid-β (Aβ)-containing plaques, intracellular neurofibrillary tangles formed by hyperphosphorylated tau protein, synaptic loss, and resulting neurodegeneration (Hyman et al. 2012; Coleman & Yao 2003; Coleman and Flood 1987; Hyman 1997; Scheff and Price 2003; McKhann et al. 1984). AD primarily affects several regions of the brain that are known for their role in learning and memory, namely, the basal forebrain, hippocampus, cortex, and entorhinal cortex (Hyman et al. 1984; Coyle et al. 1983; Gomez-Isla et al. 1996).

Several theories exist to explain the molecular mechanisms that could lead to this devastating disease. One predominant theory suggests that an imbalance between Aβ production and clearance produces the accumulation of Aβ that is the driving force behind AD neuropathology (Hardy and Selkoe 2002; Iqbal and Grundke-Iqbal 2008). Amyloid-β has many neurotoxic effects; however, the precise mechanism by which Aβ results in the neurodegeneration seen in AD is unclear. The ability of Aβ to downregulate the critical neurotrophic factor brain-derived neurotrophic factor (BDNF) is the main focus of this chapter, as the promotion of synaptic integrity and function by BDNF is of utmost importance throughout life and for the prevention of learning and memory impairments.

2 Characteristics of Alzheimer's Disease

2.1 Pathological Features

Alzheimer's disease (AD) exhibits characteristic pathological features such as senile or amyloid plaques composed of precipitated Aβ and neurofibrillary tangles composed of hyperphosphorylated tau; the presence of these pathologies is necessary for a definitive AD diagnosis (Hyman et al. 2012). The amyloid cascade hypothesis states that the accumulation of toxic Aβ is the upstream driving force behind subsequent pathology and synaptic degeneration (Hardy and Selkoe 2002; Iqbal and Grundke-Iqbal 2008). Nevertheless, amyloid plaques do not correlate well with cognitive decline; neurofibrillary tangles correlate better (Guillozet et al. 2003). However, it is the loss of functional synapses in AD that correlates most strongly with loss of cognitive abilities (Terry et al. 1991).

A significant decline in synaptic connections in AD is followed by the pronounced loss of neurons in the basal forebrain, entorhinal cortex, hippocampus, and cortex. AD has been characterized as a disconnection of the hippocampus, as projections from the basal forebrain, entorhinal cortex, and cortex to the hippocampus are lost in AD (Hyman et al. 1984). Among these brain areas, the entorhinal cortex is one of the earliest areas vulnerable to synaptic degeneration, and because of its connection with the hippocampus and cortex, entorhinal cortex damage in AD significantly impacts learning and memory (Van Hoesen et al. 1991). In addition, studies have indicated that the memory deficits seen in AD are also directly related to the degree of basal forebrain cholinergic atrophy (Coyle et al. 1983). The basal forebrain is the major cholinergic output of the central nervous system, and these neurons as well as their projections to hippocampal and cortical regions are critical for learning, memory, and attention (Baxter and Chiba 1999). The loss of basal forebrain innervation is associated with aging and age-related memory loss (Terry and Katzman 2001; Ypsilanti et al. 2008). In fact, the most common drugs for AD on the market today are cholinergic enhancers.

In addition to loss of connectivity, there may be a loss of functional neurogenesis associated with AD. In many different AD transgenic mouse models, significantly less proliferation of new neurons is present in the hippocampal formation compared to control animals (Mu and Gage 2011). Without the generation of new neurons, the synaptic degeneration resulting from AD is not compensated and learning and memory are impaired. The case is not so clear in human hippocampus, however, where immunostaining with different markers of immature neurons suggests that there is either increased (Jin et al. 2004), no change (Boekhoorn et al. 2006), or decreased (Crews et al. 2010) neurogenesis in AD. More research is clearly needed to determine whether reduced hippocampal neurogenesis contributes significantly to memory loss in AD.

2.2 Clinical Presentation

2.2.1 Impaired Cognition, Learning, and Memory

Perhaps the most clinically apparent symptom of the synaptic loss and neurodegeneration characteristic of AD is the decline of declarative memory, including both episodic and semantic memories (Aronoff et al. 2006). Initially, the loss of synaptic connections in the hippocampus and entorhinal cortex is evident as an early and significant decline in cognitive function and episodic memory (Devanand et al. 2007), which are hallmarks of AD. Episodic memory loss is not only an early event in AD, but in mild cognitive impairment (MCI), it is associated with an increased risk for conversion to AD (Aggarwal et al. 2005; Devanand et al. 2007). MCI is considered a preclinical stage of AD, since as many as 8 % of people with MCI progress to AD per year (Mitchell and Shiri-Feshki 2009). Transgenic mouse models of AD are also significantly impaired on tests of episodic-like memory compared to control animals (Davis et al. 2012). In addition, animal models of AD are impaired in long-term potentiation (LTP), a model for synaptic plasticity and a major cellular constituent underlying learning and memory processes. Aβ, when injected into rat hippocampus or added to hippocampal slices, abolishes LTP without affecting baseline synaptic transmission (Cullen et al. 1997; Chen et al. 2000). Like episodic memory in humans, the LTP deficit in rodent models of AD occurs early; it occurs prior to plaque formation and is accompanied by deficits in spatial learning and memory (Liu et al. 2008; Jacobsen et al. 2006).

2.3 Molecular Pathway for Learning and Memory

2.3.1 CREB

A molecular pathway essential for learning and memory that is disrupted in AD involves the transcription factor cAMP response element binding protein (CREB) (Barco et al. 2003). Aβ interferes with hippocampal LTP via signaling pathways including the Ca(2+)-dependent protein phosphatase calcineurin, Ca(2+)/calmodulin-dependent protein kinase II (CaMKII), and CREB (Yamin 2009). Active, phosphorylated CREB is reduced in the AD brain (Yamamoto-Sasaki et al. 1999) and is also decreased in neurons following treatment with Aβ in vitro (Tong et al. 2001; Garzon and Fahnestock 2007). CREB phosphorylation recruits transcriptional coactivators which are required for the transcription of genes involved in learning and memory. Aβ-induced suppression of transcription induced by the CREB coactivator CRCT1 has been demonstrated in transgenic AD mice, and this suppression is mediated by blockade of L-type voltage-gated calcium channels, reduced calcium influx, and disruption of PP2B/calcineurin-dependent CRTC1 dephosphorylation (España et al. 2010). Restoration of CREB activity in AD transgenic mice by inducing expression of another coactivator, CREB binding protein (CBP), ameliorates learning and memory deficits (Caccamo et al. 2010). Among the genes induced by CREB and its coactivators that are required for learning and memory, the most important for AD may be brain-derived neurotrophic factor (BDNF).

3 BDNF Is a Powerful Neurotrophic Molecule with Pleiotropic Effects on the Nervous System

3.1 Neuronal Survival

BDNF supports the survival of neurons and their connections that are vulnerable in aging and in diseases of the aging brain such as AD, including the hippocampus, entorhinal cortex, neocortex, and basal forebrain (Hyman et al. 1984; Alderson et al. 1990; Knusel et al. 1991; Ghosh et al. 1994; Lindholm et al. 1996; Lowenstein and Arsenault 1996). Early studies demonstrated a more than twofold increase in survival of septal cholinergic neurons following BDNF treatment as measured by acetylcholinesterase (AChE) histochemical staining (Alderson et al. 1990). Further, blocking BDNF signaling either using antibodies or BDNF gene knockdown decreases survival of cortical (Ghosh et al. 1994), hippocampal (Lindholm et al. 1996), and dorsal root ganglion neurons (Korte et al. 1995). Although these results demonstrate that BDNF is a survival-promoting factor for critical neuronal populations during development, conditional knockdown of BDNF in the adult suggests that BDNF is not required for postmitotic neuronal survival, but rather for dendritic maturation and growth of specific neuronal populations such as medium spiny neurons of the striatum (Rauskolb et al. 2010). Furthermore, the high-affinity BDNF receptor, tropomyosin-related kinase B (TrkB), unlike the related receptors TrkA or TrkC, is unable to trigger cell death in the absence of ligand (Nikoletopoulou et al. 2010), suggesting that decreases in BDNF may trigger altered spine morphology, reduced dendritic complexity, synaptic dysfunction, and degeneration but not outright neuronal loss.

3.2 Neurogenesis

BDNF promotes neurogenesis. Direct infusion of BDNF into rat hippocampus increases the number of developing neurons compared to saline injections in both the ipsilateral and contralateral hemispheres, suggesting a widespread effect (Scharfman et al. 2004). This hippocampal neurogenesis is directly related to subsequent cognitive functions, as new neurons are integrated into neural circuitry and play an important role in specific learning and memory tasks such as learning in the Morris water maze, a spatial memory task (Zhao et al. 2008).

Studies investigating the exact molecular mechanisms underlying BDNF-mediated increases in neurogenesis are still underway; however, by signaling through the TrkB receptor, BDNF activates three signaling cascades, namely, the phosphatidyl-inositol-3-kinase (PI3K)/Akt, Ras/extracellular-regulated kinase (ERK), and phospholipase C gamma (PLCγ) pathways, all of which are implicated in BDNF's ability to activate CREB. Specifically, PLCγ promotes the release of intracellular Ca(2+) stores (Berninger et al. 1993) which induce the activation of the CREB kinase, CaMKIV (Finkbeiner et al. 1997; Blanquet and Lamour 1997), and subsequently lead

to the activating phosphorylation of CREB. Further, activation of the Ras/ERK signaling pathway is reportedly sufficient to promote Ca(+2)-/CRE-dependent transcription (Finkbeiner et al. 1997). Lastly, protein kinase A (PKA), which is activated by BDNF signaling predominantly via the PI3K/AKT pathway, can activate CREB by phosphorylating its activation site Ser133 (Gonzalez and Montminy 1989). In support of the latter pathway, the PKA activator rolipram increases the survival of new neurons in a CREB-dependent manner (Fujioka et al. 2004; Merz et al. 2012). The activation of CREB is associated with hippocampal neurogenesis, as phosphorylated CREB is consistently found in newborn hippocampal neurons (Nakagawa et al. 2002a, b; Jagasia et al. 2009). These findings support the possibility that BDNF promotes neurogenesis via mechanisms that rely on its ability to activate the neurogenesis-promoting transcription factor CREB.

3.3 Dendritic Modulation

BDNF regulates dendritic growth, branching and spine maturation through a balance between BDNF and its precursor form, proBDNF. Both mature and proBDNF signal through the TrkB receptor and the pan-neurotrophin receptor $p75^{NTR}$; however, BDNF has a greater affinity for TrkB while proBDNF preferentially binds to $p75^{NTR}$ (Fayard et al. 2005; Teng et al. 2005). Signaling through TrkB promotes dendritic growth and spine maturation via activation of the PI3K/Akt/mTOR signaling pathway, which has been long associated with axonal growth and dendritic complexity (Atwal et al. 2000; Kuruvilla et al. 2000; Markus et al. 2002; Kumar et al. 2005). Therefore, the preferential binding of BDNF to TrkB promotes synaptic development through increased dendritic growth and spine maturation. Conversely, proBDNF inhibits neurite outgrowth through its preferential binding to $p75^{NTR}$, which negatively alters dendrite and spine morphology in addition to spine density (Yamashita et al. 1999; Zagrebelsky et al. 2005; Singh et al. 2008; Koshimizu et al. 2009). $p75^{NTR}$ reduces dendritic growth and branching through activation of a Rho-GTPase, RhoA (Sun et al. 2012), by releasing RhoA from its inactivating Rho-GDI (Yamashita and Tohyama 2003). Thus, the balance between proBDNF and BDNF plays a critical role in the regulation of spine maturation, dendritic growth/retraction, and synaptic density, which underlie learning and memory processes.

3.4 BDNF Plays a Critical Role in LTP

The cleavage of proBDNF to mature BDNF can take place extracellularly by plasmin or matrix metalloproteinases (MMPs) or intracellularly by furin or proprotein convertase 1 (PC1) (Mowla et al. 2001; Lu et al. 2005). The extracellular conversion by plasmin is specifically controlled by the extracellular serine protease tissue plasminogen activator (tPA) (Pang et al. 2004). tPA proteolytically cleaves inactive plasminogen to plasmin which can then cleave proBDNF into

mature BDNF (Lee et al. 2001). This conversion of plasminogen to plasmin by tPA takes place at hippocampal synapses, where subsequent conversion of proBDNF to mature BDNF occurs (Pang et al. 2004). Plasminogen−/− mice are impaired in late-phase long-term potentiation (L-LTP) (Pang et al. 2004). Addition of mature BDNF to these mice was able to rescue L-LTP, while addition of proBDNF was not, implicating proBDNF cleavage to mature BDNF in the mechanisms of LTP.

This ability of BDNF to rescue LTP is related to its preferential signaling through TrkB. Signaling through TrkB activates molecular cascades vital for synaptic integrity and for the production of LTP (Figurov et al. 1996). LTP is induced by the activation of protein kinases such as MAPK, PKA, PI3K, PKC, and CaMKII, which converge at the activation of ERK and modulate the activation of proteins involved in gene transcription and protein synthesis such as CREB (Lynch 2004). BDNF effectively activates protein kinases upstream of ERK through the PI3K/AKT, PKA, and Ras signaling pathways, which play a central role in the activation of CREB and subsequently contribute to neuronal survival and synaptic plasticity. CREB in turn plays a substantial role in upregulating the effector genes necessary for L-LTP (Pittenger and Kandel 1998) such as Arc, a member of the immediate-early gene (IEG) family that has been critically implicated in the maintenance of LTP (Ying et al. 2002; Guzowski et al. 2000), and BDNF itself. Additionally, BDNF is essential for maintaining the phenotype of VP16-CREB mice, which contain a constitutively active form of CREB and prime cells for L-LTP by activating CRE-mediated transcription (Barco et al. 2005). Conversely, proBDNF signaling through $p75^{NTR}$ favors long-term depression (LTD) (Lu 2003; Pang et al. 2004). Although the precise mechanism by which proBDNF signaling via $p75^{NTR}$ promotes LTD is still unknown, it may involve NMDA receptor subtype NR2B. NR2B activation is reportedly required for LTD (Massey et al. 2004), and proBDNF signaling through $p75^{NTR}$ directly potentiates the NR2B component of NMDA synaptic currents in hippocampal slices (Woo et al. 2005). Taken together, current research supports the model that regulation of BDNF/proBDNF processing modulates the balance of LTP/LTD, which underlies learning and memory.

3.5 BDNF Is Essential for Cognition and Memory

Multiple studies have shown that decreases in BDNF such as in heterozygous BDNF knockout mice or BDNF knockdown result in learning and memory deficits (Linnarsson et al. 1997; Gorski et al. 2003; Heldt et al. 2007). A Val66Met polymorphism in the pro-domain of proBDNF which interferes with BDNF secretion results in episodic memory impairments and reduced hippocampal volume, key endophenotypes of AD (Egan et al. 2003; Hariri et al. 2003). This finding shows that an alteration in BDNF levels is sufficient to affect hippocampal activity and that BDNF is critically involved in hippocampal learning and memory processes.

4 BDNF Is Significantly Downregulated in Alzheimer's Disease

4.1 BDNF Loss Is an Early Event in the Progression of AD

Amyloid plaques correlate poorly with cognition, and evidence suggests that cognitive decline precedes Aβ pathology (Van Dam et al. 2003; Westerman et al. 2002; Hanna et al. 2009). This is supported by transgenic mouse models of AD, where deficits in novel object recognition and spontaneous alternation performance in a "Y" maze occur prior to the deposition of Aβ plaques (Holcomb et al. 1998; Francis et al. 2012). Loss of BDNF also occurs prior to plaque deposition in these transgenic mice and coincides with memory deficits (Francis et al. 2012). Further, BDNF is lost early in the progression of AD, as demonstrated by a significant decline in BDNF in individuals with MCI. More than a 30 % reduction in cortical BDNF expression was found in MCI subjects compared to age- and gender-matched, noncognitively impaired controls (Peng et al. 2005), with expression levels nearly as low as in AD subjects. Lastly, like humans, canines develop cognitive impairment and amyloid deposition as they age and are an excellent model of MCI (Cotman & Berchtold 2002; Cotman & Head 2008). BDNF mRNA levels were significantly decreased and correlated with cognitive status in aged, cognitively impaired canines as well, supporting human findings that BDNF loss coincides with memory impairments (Fahnestock et al. 2012). Thus, in both animal models and humans, BDNF is lost early, coinciding with memory loss and prior to the appearance of significant plaque deposition typical of AD.

4.2 BDNF Is Indicative of Cognitive Status

The expression of BDNF is strongly correlated with cognitive status. BDNF mRNA and proBDNF and mature BDNF protein are decreased in the entorhinal, frontal, temporal, and parietal cortices as well as the hippocampus of AD subjects compared to controls (Ferrer et al. 1999; Phillips et al. 1991; Murray et al. 1994; Narisawa-Saito et al. 1996; Connor et al. 1997; Holsinger et al. 2000; Hock et al. 2000; Fahnestock et al. 2002; Michalski and Fahnestock 2003; Peng et al. 2005). Lower levels of both mature BDNF and proBDNF protein correlate with decreased cognitive test scores as measured by the Mini Mental State Examination (MMSE) and Global Cognitive Score (GCS) (Peng et al. 2005).

4.3 Increasing BDNF Levels Can Counteract Memory Impairments

The strong correlation between lowered BDNF and diminished cognition, learning, and memory makes the possibility of rescuing these behavioral symptoms of AD with BDNF an enticing undertaking. Knocking down BDNF in mice results in loss

of synapses, learning and memory deficits, and diminished LTP, whereas BDNF administration rescues or increases LTP and synapses and restores learning and memory (Blurton-Jones et al. 2009; Nagahara et al. 2009; Patterson et al. 1996; Korte et al. 1995). Early studies substantiated findings that BDNF is necessary for LTP: mice with a deletion in the BDNF gene exhibited significantly weakened hippocampal LTP expression (Korte et al. 1995), whereas treating hippocampal BDNF knockout tissue with recombinant BDNF completely restored LTP (Patterson et al. 1996). Similarly, knockdown of the BDNF receptor TrkB can significantly reduce hippocampal LTP (Minichiello et al. 1999). These early studies led to efforts in recent years to deliver exogenous BDNF as a method of restoring cognitive abilities in animal models of AD. However, expression of truncated TrkB receptors in the ventricular ependyma effectively prevents diffusion of BDNF to target tissues when it is administered by intracerebroventricular infusion (Anderson et al. 1995). Furthermore, BDNF does not readily cross the blood–brain barrier. Fusions of BDNF with factors that allow it to be transferred across the blood–brain barrier such as an antibody to the transferrin receptor (Zhang and Pardridge 2001a, b; 2006) or to the insulin receptor (Boado et al. 2007) have facilitated entry of intravenously administered BDNF into brain tissue.

The brain is exquisitely sensitive to BDNF levels, which presents another significant barrier to the successful use of this trophic factor in vivo. Microinjections of microgram levels of BDNF into the hippocampus increase neuronal excitability and can even cause seizures, whereas chronic infusions of similar amounts decrease the TrkB receptor and TrkB activation, resulting in loss of responsiveness to BDNF (Scharfman 1997; Xu et al. 2004). Furthermore, delivery of BDNF can result in impairment of spatial learning rather than improvement if BDNF expression is too high (Pietropaolo et al. 2007). Therefore, more physiological delivery of low doses of BDNF via viral vectors has been extensively investigated.

In the entorhinal cortex-lesioned aged rat, BDNF gene delivery enhanced LTP and partially restored cognitive function (Ando et al. 2002). BDNF gene delivery via lentiviral injection to the entorhinal cortex in a transgenic mouse model of AD not only increased synaptic density (synaptophysin-IR) and synaptic function (p-Erk signaling) but, importantly, improved spatial memory performance in the Morris water maze task (Nagahara et al. 2009). BDNF treatment did not affect neuronal number in this model, although it did rescue neurons from cell loss in a perforant path transection model. BDNF administration also exerted similar effects and rescued learning and memory in the aged, cognitively impaired nonhuman primate. Importantly, this lentiviral expression system has been used to maintain delivery of NGF for up to 1 year in primate basal forebrain, eliminating transient expression as a disadvantage of the system. These experiments were carried out after the onset of disease symptoms and pathology in transgenic mice and after cognitive impairment appeared in aged primates, suggesting that BDNF may be an effective therapy for reversal of cognitive deficits as well as prevention.

However, this delivery method suffers from poor viral diffusion within the parenchyma. This complication is somewhat ameliorated by the implantation of neural stem cells (NSC) which can migrate within brain parenchyma. NSC delivery

into hippocampus of the triple-transgenic (Tg3x-AD) mouse model of AD increased synaptic density and improved hippocampal-dependent learning and memory (Blurton-Jones et al. 2009). BDNF knockdown in these NSCs eliminated the beneficial effects of the cells, demonstrating that BDNF secreted by the NSCs was the active factor (Blurton-Jones et al. 2009).

Alternative approaches to gene delivery include methods of increasing endogenous BDNF levels or signaling. For instance, viral delivery of CREB activators (Caccamo et al. 2010; Espana et al. 2010), successfully reverses synaptic atrophy and learning and memory impairments in transgenic mice. Rolipram, a phosphodiesterase inhibitor and CREB activator, increases BDNF expression (DeMarch et al. 2008) and therefore may have therapeutic effects in AD. Additionally, small molecule BDNF mimetics or TrkB agonists which promote signaling through the TrkB receptor can restore synaptic plasticity and cognitive function (Massa et al. 2010). Moreover, natural products and their derivatives such as certain flavonoids are under active investigation as potential neuroprotective agents, LTP enhancers and activators of CREB, TrkB, and its downstream signaling pathways PI3K/Akt and MAPK/Erk (Maher et al. 2006; Jang et al. 2010). Finally, lifestyle adjustments such as exercise, environmental enrichment, and dietary restriction increase BDNF expression in both animal models and human studies (Mattson et al. 2004b). An enriched environment has been shown to increase BDNF mRNA in rats (Falkenberg et al. 1992), while an exercise routine can regulate transcript-specific BDNF mRNA and protein (Berchtold et al. 2002; Cotman and Berchtold 2002; Zajac et al. 2010). Recently, the combination of an antioxidant-rich diet and environmental enrichment was shown to significantly increase BDNF expression and was correlated with an improvement in memory scores in old, cognitively impaired canines (Fahnestock et al. 2012). Although a variety of molecular, pharmacological, and lifestyle interventions are under investigation and may pave the way for future clinical trials in subjects with AD, increasing brain BDNF levels safely and effectively is not yet a reality. A greater understanding of BDNF regulation and expression may provide additional targets or modalities.

4.4 BDNF Transcriptional and Posttranslational Regulation

The human BDNF gene is 70 kb long and consists of 11 exons and 9 functional promoters, which by alternative splicing result in at least 17 different BDNF transcripts (Pruunsild et al. 2007). This variation in transcript expression allows for tissue-specific regulation of BDNF in response to a variety of developmental and environmental cues (Timmusk et al. 1993; Pruunsild et al. 2007). BDNF transcripts II, III, IV, V, and VII are exclusively localized to the brain, while other BDNF transcripts are expressed in neuronal as well as nonneuronal tissues (Pruunsild et al. 2007). Within the brain, BDNF transcript IV accounts for approximately half of the total BDNF mRNA found in the cortex (Garzon and Fahnestock 2007). BDNF transcript IV is regulated at least in part by CREB (Shieh et al. 1998; Pruunsild et al. 2007; Timmusk et al. 1995).

BDNF protein is synthesized as 36 kDa precursor proBDNF, which can be cleaved by enzymes including plasmin, furin, and matrix metalloproteases to produce 14 kDa mature BDNF (Mowla et al. 2001; Lee et al. 2001; Lu et al. 2005). ProBDNF is expressed widely in the human brain, where it is only partially cleaved to its mature form. Both BDNF and proBDNF are found in relatively high amounts in the hippocampus, cortex, and basal forebrain (Michalski and Fahnestock 2003), areas that are particularly vulnerable in AD.

4.5 BDNF mRNA and Protein Decrease in AD

BDNF levels are dramatically altered in individuals with AD and MCI. BDNF mRNA expression in the hippocampus is decreased nearly twofold in individuals with AD (Phillips et al. 1991), and BDNF mRNA is reduced approximately threefold in the AD parietal cortex (Garzon et al. 2002; Holsinger et al. 2000). This decrease in BDNF mRNA is due to a decrease in four BDNF transcripts: I, II, IV, and VI (Garzon et al. 2002). Of particular interest is transcript IV, since it is the most prevalent transcript in human cortex (Garzon and Fahnestock 2007) and is specifically decreased in human and mouse models of AD (Garzon et al. 2002; Peng et al. 2009).

The decreased BDNF mRNA in AD corresponds to a similar decrease in BDNF protein. Mature BDNF protein is significantly reduced in AD hippocampus (Narisawa-Saito et al. 1996; Connor et al. 1997; Hock et al. 2000), frontal cortex (Ferrer et al. 1999), temporal cortex (Connor et al. 1997), and parietal cortex (Hock et al. 1998; Peng et al. 2005) compared to controls, and proBDNF protein is reduced in AD parietal cortex (Michalski and Fahnestock 2003; Peng et al. 2005). The molecular mechanisms in AD that could lead to this substantial decrease in BDNF expression are beginning to be understood.

5 Amyloid-β Toxicity in Alzheimer's Disease

Although Aβ has been recognized as having non-disease associations, such as acting as an antimicrobial agent (Soscia et al. 2010), it is most well studied as the precipitating insult in AD. Early studies suggested that it was the formation of Aβ plaques that was the primary neurotoxic insult in Alzheimer's disease. However, plaques do not correlate well with decreased cognition, and more recent evidence suggests that soluble forms of Aβ may be more toxic (Ferreira et al. 2007; Walsh and Selkoe 2007; Lacor et al. 2007; Hardy and Selkoe 2002; Garzon and Fahnestock 2007).

5.1 Formation of Toxic, Soluble Aβ

Amyloid-β is a peptide formed by the proteolytic processing of the amyloid precursor protein (APP) (Hardy and Selkoe 2002; Haass et al. 1992; Citron et al.

1992; Shoji et al. 1992). APP is a single-pass, transmembrane protein with a small intracellular C-terminus and a large extracellular segment which contains part of the Aβ sequence (Mattson 2004). APP is initially proteolytically cleaved by α- or β-secretase (also known as beta-site APP cleaving enzyme 1; BACE-1), which releases a soluble fragment of APP (DeStrooper and Annaert 2000). Following primary cleavage by β- or α-secretase, a secondary cleavage of the transmembrane domain, or C-terminal fragment, of APP by γ-secretase results in the formation of either the Aβ peptide or the p3 fragment of APP, respectively (DeStrooper and Annaert 2000; Haass et al. 1992). Gamma-secretase is a complex of integral membrane proteins that includes presenilin-1 (PS-1) or presenilin-2 (PS-2), which when mutated can dramatically alter the production of Aβ. Gamma-secretase cleavage following cleavage by β-secretase can result in Aβ peptides of various lengths (Haass et al. 1992; DeStrooper and Annaert 2000). $A\beta_{1–40}$ is most commonly produced following the successive cleavage of β- and γ-secretases; however, it is $A\beta_{1–42}$ that is of particular interest in the progression of AD because of its greater propensity to aggregate (Tabaton et al. 2010; Glabe 2001). The aggregation of Aβ involves several conformational states from dimers and trimers to high-molecular-weight oligomers and protofibrils and finally insoluble Aβ fibrils (Glabe 2004) and requires a structural change from an α-helical conformation to a more organized β-sheet configuration characteristic of Aβ aggregation (Xu et al. 2005).

Formation of soluble Aβ is increased by mutations in APP, PS-1, and PS-2, hallmarks of familial forms of AD (Citron et al. 1992; Haass et al. 1994; Hutton and Hardy 1997; Scheuner et al. 1996). Such mutations result either in Aβ overproduction or in an increase in the aggregation-prone $A\beta_{1–42}$ (Burdick et al. 1992; Jarrett et al. 1993; Hardy and Selkoe 2002; Selkoe 1994). Increased levels of Aβ increase aggregation and toxicity prior to plaque deposition. Levels of soluble Aβ oligomers in the frontal cortex of individuals with AD are up to 70-fold higher than in control brains (Gong et al. 2003) and correlate with the degree of dementia and of synaptic loss (Lue et al. 1999).

5.2 Mechanisms of Aβ Toxicity

Aβ has many proposed toxic effects that could result in the neuronal dysfunction and neurodegeneration characteristic of AD. Aβ enhances tau hyperphosphorylation and the subsequent formation of neurofibrillary tangles in animal models (Gotz et al. 2001; Lewis et al. 2001; Masliah et al. 2001; Hardy and Selkoe 2002) and in human neuroblastoma cells in vitro (Pennanen and Gotz 2005). This suggests that Aβ may exert its neurotoxic effects via tau hyperphosphorylation and subsequent neurofibrillary tangle formation (Iqbal and Grundke-Iqbal 2008). Another well-studied toxic effect of Aβ accumulation is altered calcium homeostasis: soluble Aβ oligomers have been shown to alter calcium regulation by modulating ion channels, including voltage-gated calcium and potassium channels and nicotinic and NMDA receptors, and by forming its own calcium-conducting

pores, thereby increasing levels of cytosolic calcium (Green et al. 2007; Mattson et al. 1993; Ferreiro et al. 2006; Demuro et al. 2005; Resende et al. 2007). Oligomeric Aβ has also been shown to promote increased reactive oxygen species (ROS) production in primary cortical and hippocampal neurons (Sponne et al. 2003; DeFelice et al. 2007), which has been associated with inflammation and neurodegeneration. Amyloid-β may also indirectly induce neurotoxicity through the activation of proinflammatory responses (Akiyama et al. 2000; Giovannini et al. 2002; Lukiw and Bazan 2000), which may have a role in inhibiting hippocampal memory formation (Tancredi et al. 1992, 2000; Murray and Lynch 1998; Heneka and O'Banion 2007). However, Aβ has its most direct effect on synaptic degeneration through its action on specific signaling cascades.

6 BDNF May Mediate Aβ Toxicity in Alzheimer's Disease

Aβ toxicity results in neurodegeneration by altering signaling pathways upstream and downstream of CREB. CREB phosphorylation and signaling are reduced by exposure to soluble, oligomeric Aβ in vitro (Tong et al. 2001; Garzon and Fahnestock 2007). Aβ treatment inhibits the Ras/ERK and PI3K/AKT signaling pathways (Tong et al. 2004), which are downstream of BDNF/TrkB but are also essential for the phosphorylation of CREB and subsequent expression of BDNF. It has recently been shown that inhibiting glycogen synthase-3β (GSK3β), which can be activated by Aβ, is an effective way to decrease inhibitory phosphorylation of CREB and increase BDNF protein (DaRocha-Souto et al. 2012). Additionally, Aβ has been shown to inactivate PKA in vitro, and increasing PKA activity reverses decreased CREB activation induced by Aβ treatment (Vitolo et al. 2002). Therefore, Aβ disrupts several kinase cascades, leading to a reduction in activity of CREB and in BDNF expression.

Soluble, oligomeric Aβ, but not the fibrillar Aβ found in plaques, decreases CREB activation and downregulates BDNF in vitro, largely via transcript IV (Garzon and Fahnestock 2007). In transgenic mouse models of AD, which also exhibit downregulation of transcript IV, BDNF expression is inversely proportional to the amount of soluble, high-molecular-weight Aβ oligomers (Peng et al. 2009). Thus, inactivation of CREB by soluble, aggregated Aβ may downregulate BDNF transcript IV, resulting in the diminished synaptic connections and memory loss characteristic of AD.

A major consequence of Aβ-induced CREB reduction that is mediated by BDNF is diminished LTP. Soluble Aβ oligomers have been shown to effectively inhibit hippocampal LTP (Lambert et al. 1998; Walsh et al. 2002). Aβ inhibits LTP by specifically interfering with CaMKII and CREB signaling pathways (Yamin 2009), and Aβ-induced reductions in LTP are rescued by BDNF (Zeng et al. 2010). These effects on LTP provide a mechanism for Aβ's interference with learning and memory. Therefore, although Aβ has many proposed mechanisms of toxicity, its modulation of kinase pathways affecting transcription of genes involved in learning and memory, particularly BDNF and CREB, is perhaps the most significant for AD.

7 Conclusion

Alzheimer's disease, which increasingly affects our aging population, is primarily a disease of synaptic dysfunction. Soluble, aggregated amyloid-β is thought to be the primary neurotoxic insult leading to synaptic loss. However, the exact mechanisms that lead from Aβ aggregation to the pathological and physical symptoms of AD are not clear. Aβ accumulation, among other toxic effects, alters kinase cascades, leading to reduced CREB activation and to BDNF downregulation, primarily through transcript IV. This downregulation of BDNF is an early damaging event in the progression of AD and occurs in MCI and prior to plaque deposition in transgenic mice. BDNF promotes the integrity and function of synaptic connections and the function of neuronal circuits required for cognition, learning, and memory, and it is one of the most powerful neural repair molecules known. BDNF administration in animal models of AD can reverse morphological and behavioral symptoms even when administered late in the disease process. This suggests that the therapeutic use of BDNF might arrest or even correct the cognitive decline seen so early in the progression of AD. Methods to deliver or enhance BDNF and its signaling cascade are under investigation. A deeper understanding of the mechanisms that regulate BDNF in AD may provide additional therapeutic options.

Contents

Abstract

Brain derived neurotrophic factor (BDNF) plays important roles in neuronal survival, axonal and dendritic growth, synaptic plasticity, learning and memory and emotional behavior. Recently, a single nucleotide polymorphism (SNP) in the BDNF gene leading to a valine to methionine substitution at position 66 in BDNF prodomain (Val66Met) has been found to decrease activity-dependent BDNF secretion and to be associated with increased susceptibility to neuropsychiatric disorders. BDNF Val66Met polymorphism only exists in human and represents the first genetic alteration in a neurotrophin that has been linked to a human disease. In this chapter, we will focus on the biological consequences of BDNFVal66Met polymorphism in the context of central nervous system structure and function with combined molecular and cellular, human behavioral and imaging, and transgenic mouse studies.

1 Introduction

Brain-derived neurotrophic factor (BDNF), a molecule known to regulate neuronal survival and differentiation, plays an important role in activity-dependent plasticity processes, such as long-term potentiation (LTP), learning, and memory (Huang and Reichardt 2001; Chao 2003). BDNF is widely expressed in the development and adult mammalian brain and has been implicated in the actions of both antidepressants and mood stabilizers, as well as the pathophysiology of affective disorders (Schuman 1999; Castren and Rantamaki 2010; Krishnan and Nestler 2010). Therefore, BDNF plays a significant role in regulating specific synaptic functioning in learning, memory, and neuropsychiatric disorders. Recently, a single nucleotide polymorphism (SNP) in the BDNF gene leading to a valine-to-methionine substitution at position 66 in BDNF prodomain (Val66Met) has been identified and shown to influence human hippocampal volume and memory (Egan et al. 2003). This BDNF polymorphism is found to be associated with altered susceptibility to neuropsychiatric disorders including bipolar disorder, Alzheimer's disease, and depression (Neves-Pereira et al. 2002; Sklar et al. 2002; Ventriglia et al. 2002; Nederhof et al. 2010). BDNF Val66Met polymorphism only exists in human and represents the first genetic alteration in a neurotrophin that has been linked to a human disease. This chapter will be focused on the biological consequences of BDNF Val66Met polymorphism in the context of central nervous system structure and function.

2 $BDNF_{Met}$ SNP and Mental Disorders

The human BDNF gene is located on the short arm of chromosome 11 (11p14.1). One frequent, nonconservative polymorphism in the human BDNF gene (dbSNP number rs6265) has been identified, a single nucleotide polymorphism (SNP) at nucleotide 196 (G/A) producing an amino acid substitution (valine to methionine) at codon 66 (Val66Met). The frequencies for the alleles of the Val66Met polymorphism were A = 20–30 % and G = 70–80 % in Caucasians (Neves-Pereira et al. 2002; Egan et al. 2003). However, the frequency of $BDNF_{Met}$ SNP varies depending upon ethnicity. The frequency of healthy individuals who carried G/G (Val/Val) was significantly decreased in Japanese (33.8 %) than that in Italians (48.7 %) or in Americans (68.4 %) (Shimizu et al. 2004), which suggests that BDNF might act to produce ethnic traits.

Accumulating evidence suggests that BDNF plays a role in the pathophysiology of psychiatric diseases. A recent series of studies have linked BDNF Val66Met polymorphism with memory impairments as well as altered susceptibility to neuropsychiatric disorders, such as bipolar disorders, Alzheimer's disease, Parkinson's disease, depression, and eating disorders (Neves-Pereira et al. 2002; Ventriglia et al. 2002; Masaki et al. 2003; Ribases et al. 2003; Schumacher et al. 2005). This BDNF polymorphism represents the first alternation in a neurotrophin gene that has been linked to clinical pathology. Anxiety is a

common symptom among most psychiatric disorders. Several recent studies have looked at the relationship between the $BDNF_{Met}$ variant and the anxiety traits. The results have been conflicting, with the Val allele associated with vulnerability in one study and the Met allele designated as the "risk" allele in another study (Sen et al. 2003; Jiang et al. 2005; Lang et al. 2005). Inconsistency across genetic studies may be attributable to sampling and measurement issues, genetic heterogeneity due to differential sampling of populations, or low frequency of homozygous Met carriers, which may lessen the effect size of any particular association. It may also relate to a failure to take into account relevant gene-by-gene and gene-by-environment interactions. A recent investigation found the association between incident stroke and depression with the strongest association for Met/Met genotype participants (Kim et al. 2008), which provides evidence for a gene-environment interaction with respect to the impact of stroke on depression. Other studies revealed that BDNF interacted with childhood adversity or stressful life events that predicted greater likelihood of depression among Met carriers and did not influence Val/Val carriers, which further confirmed that the association of $BDNF_{Met}$ SNP with depression was modified by the environment factor such as stress (Bukh et al. 2009; Carver et al. 2011). A significant three-way interaction between BDNF genotype, 5-HTTLPR, and maltreatment history in predicting depression was also reported (Kaufman et al. 2006). Children with the Met allele of the BDNF gene and two short alleles of 5-HTTLPR had the highest depression scores, but the vulnerability associated with these two genotypes was only evident in the maltreated children. To further elucidate the role of $BDNF_{Met}$ variant in psychiatric disease, the $BDNF_{Met}$ knock-in mouse would be an ideal tool since the transgenic mouse would provide a more homogeneous gene background and the gene-by-gene and gene-by-environment effects will be more easily controlled in mouse behavior study.

3 Molecular Mechanism Underlying $BDNF_{Met}$ Variant

Brain-derived neurotrophic factor (BDNF) has been shown to play significant roles in neuronal survival, axonal and dendritic growth and guidance, synaptic structure and connections, neurotransmitter release, LTP, and synaptic plasticity (Chao 2003). Thus, the influence of BDNF spans from developmental neurobiology to neurodegenerative and psychiatric disorders. The actions of BDNF are dictated by two classes of cell surface receptors, the TrkB receptor tyrosine kinase and the p75 neurotrophin receptor ($p75^{NTR}$), a member of the TNF receptor superfamily (Chao et al. 2006). BDNF binding to TrkB receptor triggers receptor dimerization, transphosphorylation of intracellular tyrosine residues, and subsequent activation of the PI-3 kinase, Ras/MAPK, and PLC-γ pathways, thus influencing transcriptional events that have a multitude of effects on cell cycle, neurite outgrowth, and synaptic plasticity (Huang and Reichardt 2003; Teng and Hempstead 2004; Chao et al. 2006). Signal transduction through p75 independently gives rise to increase

in JNK (c-Jun N-terminal kinase), NF-κB (nuclear factor κB), and ceramide, thus triggering apoptosis (Roux and Barker 2002). Consistent with the critical role of BDNF in synaptic plasticity, BDNF is synthesized and released in a manner that is dependent on neuronal activity (Lessmann et al. 2003; Lu 2003; Bramham and Messaoudi 2005). In the mammalian brain, BDNF is synthesized as a precursor called proBDNF, which is proteolytically cleaved to generate mature BDNF. ProBDNF may preferentially bind $p75^{NTR}$, whereas mature BDNF preferentially binds TrkB receptor (Teng et al. 2005; Nagappan et al. 2009; Yang et al. 2009).

The molecular mechanisms underlying altered $BDNF_{Met}$ function have begun to be studied primarily in vitro cell culture systems. The Met substitution in BDNF prodomain was shown in neurosecretory cells and primary cultured neurons to lead to four trafficking defects: (1) decreased variant $BDNF_{Met}$ distribution into neuronal dendrites, (2) decreased variant $BDNF_{Met}$ targeting to secretory granules, (3) subsequent impairment in BDNF-regulated secretion, and (4) impaired dendritic targeting of BDNF mRNA (Egan et al. 2003; Chen et al. 2004; Chen et al. 2005; Chiaruttini et al. 2009). The molecular mechanisms underlying the trafficking defects associated with $BDNF_{Met}$ variant are described in detail below.

When expressed together in the same cell, $BDNF_{Met}$ alters the trafficking of wild-type BDNF ($BDNF_{Val}$) through the formation of heterodimers that are less efficiently sorted into the regulated secretory pathway (Chen et al. 2004). These findings are consistent with previous studies indicating that the prodomain of neurotrophins plays important role in regulating their intracellular trafficking to secretory pathways (Suter et al. 1991; Mowla et al. 1999). These in vitro studies with $BDNF_{Met}$ point to the presence of a specific trafficking signal in the BDNF prodomain region encompassing the Met substitution that is required for efficient BDNF sorting. Following this hypothesis, a trafficking protein, sortilin, was identified to be necessary for the efficient sorting of BDNF to the regulated secretory pathway. Sortilin interacts specifically with BDNF in a region encompassing the Met substitution (Chen et al. 2005). Replacement of Met at this position led to decreased interaction of BDNF with sortilin and suggests that decreased protein-protein interaction between BDNF and the trafficking machinery is one plausible molecular model for the secretion defect observed with the variant BDNF. Targeting of BDNF mRNA to dendrites also plays a key role in mediating synaptic plasticity (An et al. 2008; Tongiorgi and Baj 2008). Constitutive dendritic targeting of BDNF mRNA is mediated by translin, an RNA-binding protein implicated in RNA trafficking (Chiaruttini et al. 2009). $BDNF_{Met}$ mutation blocks dendritic targeting of BDNF mRNA by disrupting its interaction with translin (Chiaruttini et al. 2009). A $BDNF_{Met}$ knock-in transgenic mouse was recently generated and provided a unique tool to study the in vivo consequences of $BDNF_{Met}$ SNP (Chen et al. 2006). The transcription of $BDNF_{Met}$ is regulated by endogenous BDNF promoters in the $BDNF_{Met}$ knock-in mouse, which fully mimics the human $BDNF_{Met}$ polymorphism. When hippocampal neurons were cultured from $BDNF_{Met}$ mice, a significant decrease in the BDNF-regulated secretion was detected, which suggested an insufficiency in available BDNF in $BDNF_{Met}$ mice (Chen et al. 2006). In $BDNF_{Met/Met}$ mice, pilocarpine-induced dendritic trafficking

of BDNF mRNA was also blocked, which further confirmed the in vitro study (Chiaruttini et al. 2009). Thus, the in vitro findings of the trafficking defects associated with $BDNF_{Met}$ variant were verified in $BDNF_{Met}$ knock-in mouse.

It also remains possible that there are additional defects in $BDNF_{Met}$ processing, although in vitro studies in neurons suggest no defect in $BDNF_{Met}$ processing (Egan et al. 2003; Chen et al. 2004). It has been reported that tissue plasminogen activator, by activating the extracellular protease plasmin, converts proBDNF to the mature BDNF and that such conversion is critical for late-phase long-term potentiation expression in the mouse hippocampus (Pang et al. 2004). Given that proBDNF preferentially activates $p75^{NTR}$ over TrkB receptor, it is likely that proteolytic conversation of proBDNF may be implicated in the BDNF function. Whether $BDNF_{Met}$ affects BDNF processing should be further examined in vivo in the $BDNF_{Met}$ knock-in mice.

4 Brain Structure Alterations Associated with $BDNF_{Met}$ Polymorphism

The fundamental question is what the in vivo consequences of $BDNF_{Met}$ SNP are. One of the most reliable effects observed in carriers of the Met allele is a reduction in hippocampal volume. In studies of human brain morphometry using structural MRI scans, Val/Met individuals have repeatedly been shown to have a smaller hippocampal volume relative to controls who are homozygous for Val allele (Val/Val) (Pezawas et al. 2004; Szeszko et al. 2005; Bueller et al. 2006). This difference may be related to the role that BDNF and its receptors play in the development as well as continued plasticity of the brain (Huang and Reichardt 2001; Lu et al. 2005). In addition to hippocampus, studies have shown decreased volume in the dorsolateral prefrontal cortex, an area associated with planning and higher-order cognitive functioning, in carriers of the Met allele (Pezawas et al. 2004). It was also found that Met allele carriers have smaller temporal and occipital lobar gray matter volumes (Ho et al. 2006). Interestingly, the effect of $BDNF_{Met}$ SNP on brain structure is modified by neuropsychiatric disorders. The bipolar disorder patients who carried the $BDNF_{Met}$ allele had the smallest hippocampus volumes compared to individuals without bipolar disorder and Val/Val homozygotes, and these decreases are most prominent in left anterior hippocampus (Chepenik et al. 2009; Matsuo et al. 2009). Within the bipolar cohort, individuals with one or more BDNF Met alleles showed greater losses in prefrontal gyrification index (GI) over time (Mirakhur et al. 2009). These studies suggest that the $BDNF_{Met}$ SNP may play a more prominent role in brain structure differences in subjects affected with bipolar disorder. Within schizophrenia patients, Met allele carriers had significantly greater reductions in frontal gray matter volume than Val-homozygous patients (Ho et al. 2007). Major depression patients had significantly smaller hippocampal volumes compared with controls and significantly smaller hippocampal volumes were observed for patients carrying the Met-BDNF allele compared with subjects homozygous for

the Val-BDNF allele, which suggest that Met-BDNF allele carriers might be at risk to develop smaller hippocampal volumes and may be susceptible to major depression (Frodl et al. 2007).

Brain structure alterations associated with $BDNF_{Met}$ SNP were further analyzed in $BDNF_{Met}$ knock-in mouse. Using Cavalieri volume estimation, a significant decrease (about 14 %) in hippocampal volume in $BDNF_{Met}$ mice was observed, which was comparable to the decrease in the humans carriers of Met allele (Pezawas et al. 2004; Chen et al. 2006). Ventromedial prefrontal cortex (vmPFC) volume was also found to be significantly decreased in $BDNF_{Met/Met}$ mice compared with wild-type mice (Yu et al. 2009). Golgi staining and fractal dimension analyses further revealed a significant decrease in dendritic complexity in the dentate gyrus and vmPFC neurons from $BDNF_{Met}$ mice (Chen et al. 2006; Yu et al. 2009), which might in part account for the decreased volume in $BDNF_{Met}$ carriers.

5 Behavior Phenotypes Associated with $BDNF_{Met}$ Polymorphism

One of the common clinical symptoms among the psychiatric disease affected by the $BDNF_{Met}$ variant is the impairment of higher cognitive abilities. Individuals with the Val/Met genotype have been shown to be associated with poorer episodic memory in comparison with Val homozygotes, which rely heavily on the hippocampus (Egan et al. 2003; Hariri et al. 2003). Moreover, functional magnetic resonance imaging (fMRI) studies showed Met carriers exhibited relatively diminished hippocampal activation compared with Val/Val individuals during both the encoding and retrieval processes of a declarative memory task (Egan et al. 2003; Hariri et al. 2003). These findings taken together suggest that carriers of the Met allele have a selective impairment in hippocampal-dependent memory. In bipolar patients, the performance in Wisconsin card sort task (WCST) was significantly better in subjects with Val/Val-BDNF genotype compared with Val/Met genotype, which suggests a role of $BDNF_{Met}$ SNP in prefrontal cognitive function in bipolar illness (Rybakowski et al. 2003). In both patients with schizophrenia and healthy volunteers, Met allele carriers had poorer verbal memory performance than their Val-homozygous counterparts. In visuospatial abilities, Met allele-associated visuospatial impairment was specific to patients with schizophrenia but not healthy volunteers (Ho et al. 2006). These studies suggest that the association between the $BDNF_{Met}$ variant and poor medial temporal lobe-related memory performance and that the $BDNF_{Met}$ variant may have a specific role in conferring visuospatial dysfunction in schizophrenia (Ho et al. 2006). However, $BDNF_{Met}$ variant did not appear to impact general intellectual abilities or affect attention, problem solving, and language skills (Ho et al. 2006). A recent study also showed that $BDNF_{Met}$ polymorphism is associated with differences in brain motor system function, altered short-term plasticity, and greater error in short-term motor learning (McHughen et al. 2010).

The $BDNF_{Met}$ knock-in mouse provided a unique tool to assess the behavior phenotypes associated with $BDNF_{Met}$ polymorphism in a controlled genetic and environmental background which was not feasible in humans. In the fear conditioning test, $BDNF_{Met}$ mice showed significant less context-dependent memory than wild-type mice (Chen et al. 2006), which was consistent with the hippocampal-dependent learning defect in human carriers of the $BDNF_{Met}$ allele. When placed in conflict settings, $BDNF_{Met/Met}$ mice display increased anxiety-related behaviors in three separate tests (elevated plus maze, open field, and novelty-induced hypophagia) and thus provide a link between $BDNF_{Met}$ SNP and anxiety (Chen et al. 2006). Interestingly, the elevated anxiety in $BDNF_{Met/Met}$ mice could not be rescued by a common serotonin reuptake inhibitor (SSRI) fluoxetine, which suggests that humans with the $BDNF_{Met}$ allele may not have optimal responses to this class of antidepressants. The $BDNF_{Met/Met}$ mouse may serve as a valuable model to identify novel pharmacologic approaches to treat anxiety symptoms that underlie many neuropsychiatric disorders. $BDNF_{Met/Met}$ mouse was further found to exhibit abnormalities in aversive memory extinction (Yu et al. 2009). This abnormality in extinction learning may be explained by alterations in neuronal morphology, as well as decreased neural activity in the vmPFC. Recently, Soliman et al. reported the impaired extinction learning in human $BDNF_{Met}$ allele carriers relative to non-Met allele carriers, which was paralleled by atypical frontoamygdala activity in humans (Soliman et al. 2010). Understanding the effect of $BDNF_{Met}$ allele on impaired learning of cues that signal safety versus threat provided insight into the role of $BDNF_{Met}$ SNP in anxiety disorders. In $BDNF_{Met/Met}$ mouse, D-cycloserine (DCS), a partial agonist of NMDA receptor, was effective in rescuing the extinction defect (Yu et al. 2009), suggesting that when coupled with behavior therapy, DCS may be an effective treatment option for anxiety disorders in humans with this genetic variant BDNF.

6 Conclusion

Brain-derived neurotrophic factor (BDNF) plays important roles in activity-dependent plasticity processes and has been implicated in the pathophysiology of affective disorders. The human genetic variant BDNF (Val66Met) represents the first example of neurotrophin family member and has been linked to psychiatric disorders. Combined molecular and cellular, human behavioral and imaging, and transgenic mouse approaches were employed to assess the impact of $BDNF_{Met}$ SNP on brain structure and function. The mouse model provides the opportunity to test dose-dependent effects of the $BDNF_{Met}$ allele in a controlled genetic and environmental background not feasible in humans. The human behavioral and imaging findings provide confidence that cross-species translation is biologically valid. $BDNF_{Met}$ variant has been associated with cognitive impairment and anxiety; drug discovery strategies to increase BDNF release from synapses, prolong the half-life of secreted BDNF, or directly activate TrkB receptors may provide greater therapeutic responses for human populations with this common BDNF polymorphism. In addition, the $BDNF_{Met/Met}$ mouse may serve as a valuable model to evaluate novel pharmacologic strategy in humans with this polymorphic allele and may ultimately guide personalized medicine for related clinical disorders.

Blood Brain-Derived Neurotrophic Factor Levels and Mood Disorders

Reiji Yoshimura and Jun Nakumura

Contents

Abstract

Blood levels of brain-derived neurotrophic factor (BDNF) plays an important role in mood disorders. It is considered that blood (serum or plasma) BDNF could be a candidate biological state marker for depressive state. In addition, blood BDNF levels might also reflect psychological job stress in healthy workers.

Brain-derived neurotrophic factor • Serum • Plasma • Mood disorders • BDNF gene Val66Met

1 Introduction

Depression is heterogeneous and is diagnosed on the basis of a patient's symptoms, not on the basis of a laboratory test. Therefore, it is important to search for biological markers for depression due to the need of finding diagnostic adjuncts. Brain-derived neurotrophic factor (BDNF), a major neurotrophic factor, has been found to play a critical role in long-term potentiation, a cellular mechanism of learning and memory, suggesting that it can influence neuroplasticity (Fignov et al. 1996). BDNF is also needed for the survival and guidance of neurons during development as well as the survival and function of neurons during adulthood (Duman et al. 2000). The atrophy and loss of hippocampal or cerebral cortical neurons or of glia could result from a stress-induced loss of neurotrophic factors, from other processes that compromise neuronal function and activity, or from other insults depending on the patient's genetic background (Shelton 2000). There is growing evidence that BDNF might have a crucial role in depression (Duman et al. 2000; Mowla et al. 2001). The source of circulating BDNF remains unknown. Platelets, brain neurons, and vascular endothelial cells are currently considered to be putative sources. It was demonstrated that BDNF crosses the blood–brain barrier (Pan et al. 1998) and that BDNF levels in the brain and serum have been shown to undergo similar changes during the maturation and aging process in rats (Karege et al. 2002). Furthermore, Lang et al. reported that serum BDNF concentrations reflect some aspects of neuronal plasticity, as indicated by the association of BDNF levels with those of *N*-acetyl-aspartate, which reflects neuronal damage in the cerebral cortex (Lang et al. 2007). These results indicated that blood BDNF levels might in part reflect the BDNF levels in the brain. Moreover, Klein et al. (2011) recently reported that measures of blood and plasma BDNF levels reflect brain-tissue BDNF levels. We reported that serum BDNF levels are approximately 20 times greater than those in platelet-poor plasma, and a close correlation was found between plasma and serum levels (Yoshimura et al. 2010a). Platelets are the major source of serum BDNF, as they sequester large quantities of it for release during clotting. Sources of circulating plasma BDNF include vascular endothelial cells as well as brain cells (Lommatzsch et al. 2005). Platelets have a life span of approximately 10 days, whereas plasma BDNF is minimally affected by the amount stored in platelets, and therefore is likely to be a more suitable index of brain BDNF levels (Marano et al. 2007) (Fig. 1).

In this chapter, the role of serum BDNF and its association with mood disorders predominantly will be discussed mainly based on our previous findings.

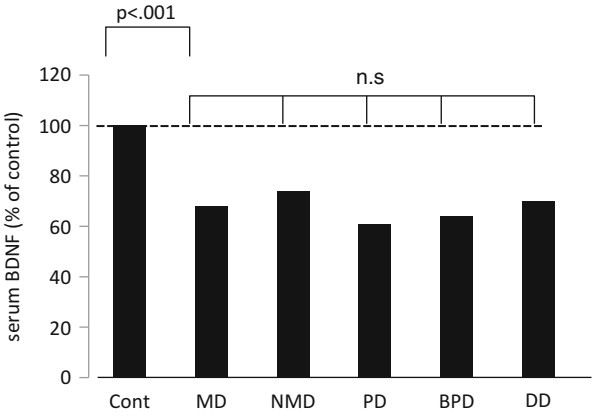

Fig. 1 Serum BDNF levels in various depressed types. Abbreviations: Cont, control; MD, major depression with melancholia; NMD, major depression without melancholia; PD, major depression with psychotic features; BPD, depressive episode with bipolar disorder; DD, double depression

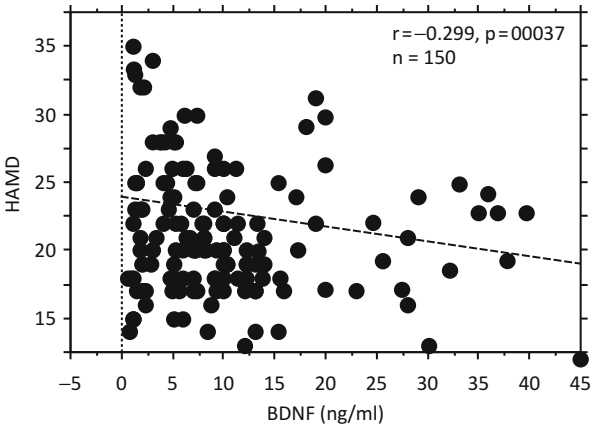

Fig. 2 HAMD scores and serum BDNF levels

2 Blood BDNF Levels in Patients with Major Depressive Disorder

The serum BDNF levels were significantly lower in those patients than in the healthy subjects: No difference in serum BDNF levels between with melancholia and without melancholia. In addition, no difference was observed in serum BDNF levels between the patients with psychotic features (psychotic depression) and without ones. There have been at least three meta-analyses of studies of blood BDNF levels in patients with major depressive disorder (Bocchio-Chiavetto et al. 2010; Brunori et al. 2010; Sen et al. 2008). The results of those investigations have consistently revealed that blood BDNF levels in patients with major depressive disorder are significantly lower than those of healthy subjects. A negative correlation was also found between the scores of Hamilton Rating Scale for Depression (HAMD) and serum BDNF levels, which means serum BDNF levels reflect the severity of depressive state (Yoshimura et al. 2011; Shimizu et al. 2003). From these findings, it is deduced blood BDNF level is a candidate biomarker for depression (Fig. 2).

3 Blood BDNF Levels in Patients with Bipolar I Disorder

Plasma BDNF levels in depressive episodes were significantly lower than those in manic episodes in patients with bipolar I disorder or healthy subjects (Yoshimura et al. 2006). Fernandes et al. recently performed meta-analysis including our study, and they concluded that blood BDNF levels are consistently reduced during maniac and depressive episodes, but not during euthymic state in patients with bipolar I disorder (Fernandes et al. 2011).

4 Blood BDNF Levels in Patients with Dysthymic Disorder

Dysthymic disorder has a number of typical characteristics such as low drive, low self-esteem, and a low capacity for pleasure. They will usually find little pleasure in usual activities and pastimes (Griffiths et al. 2000). In addition, BDNF levels among patients with dysthymic disorder, major depressive disorder, and healthy controls were measured. Serum BDNF levels in the dysthymic disorder group were significantly lower than those in the healthy controls. Moreover, no difference was found between the dysthymic disorder group and the major depressive disorder group (Yoshimura et al. 2011). On the other hand, Aydemir et al. (2007) reported that serum BDNF concentrations of the dysthymic group were significantly higher than that of the major depressive disorder group, and it was not different from the level of the control group. One of the reasons of the discrepancy of the results might be due to the difficulty of the diagnosis of dysthymic disorder. Actually, it is difficult to diagnose patients with dysthymic disorder because of the subtle nature of the symptoms and the patients often can hide them in social situations, making it challenging for others to detect symptoms. Additionally, dysthymic disorder often occurs at the same time as other psychological disorders which adds a level of complexity to determine the presence of dysthymic disorder, particularly because there is often an overlap in the symptoms of other psychiatric disorders (Sansone et al. 2009).

5 Blood BDNF Levels in Patients with Major Depressive Disorder with Alcohol Dependence

Alcohol dependence is often comorbid with major depressive disorder (Regiet et al. 1990). Alcohol use in depression patients increases their severity of depressive state and suicidal risk. Zanardini et al. (2011) reported that serum BDNF levels were decreased in patients with alcohol dependence However, no reports have been found comparing blood BDNF levels with and without alcohol dependence in depressed patients. Serum BDNF levels in the patients with or without alcohol dependence were significantly lower than those in the healthy controls. There was however no difference in serum BDNF levels between the depressed patients with and without alcohol dependence (Umene-Nakano et al. 2009).

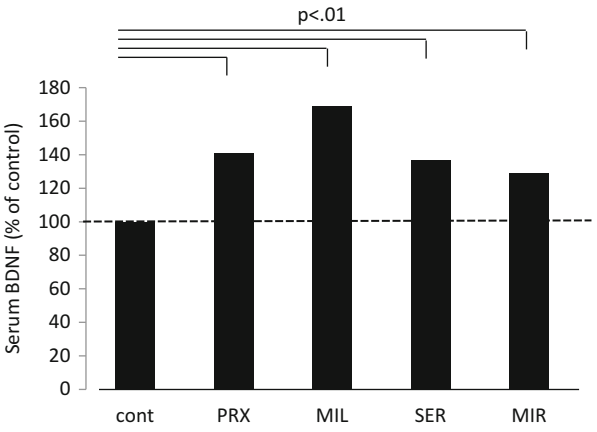

Fig. 3 Effects of various antidepressants on serum BDNF levels. Abbreviations: Cont, control; MIL, milnacipran; MIR, mirtazapine; PRX, paroxetine; SER, sertraline

6 Effects of Antidepressants on Serum BDNF Levels in Depressive Patients

Recent review by Molendijk et al. demonstrated that St John's wart and selective serotonin reuptake inhibitor (SSRI), but not serotonin noradrenaline reuptake inhibitor (SNRI), tricyclic antidepressant (TCA), or noradrenergic and specific serotonergic antidepressants (NaSSAs) increased serum BDNF levels (Molendijk et al. 2010). Effects of paroxetine, a SSRI, and milnacipran, a SNRI, on serum BDNF levels in patients with major depressive disorder were investigated. Treatment with paroxetine and milnacipran for at least 8 weeks, but not 4 weeks, both increased serum BDNF levels in responders, but not in nonresponders to the same degree (Yoshimura et al. 2007). Taken together, serotonin rather than noradrenaline might play an essential role for increasing BDNF (Molendijk et al. 2010) (Fig. 3).

7 Effects of Repetitive Transcranial Magnetic Stimulation (rTMS) or Electrical Convulsive Therapy (ECT) on Blood BDNF Levels

rTMS or ECT is effective for treatment-resistant depression. A systematic review by Lam et al. (2008) reported that the pooled response and remission rate rates were 25 % and 17 %, respectively. ECT is widely used for treatment in major depressive disorder, bipolar disorder, and schizophrenia. The mechanisms of rTMS and ECT have not been fully elucidated. To the best of our knowledge, this is the first report that rTMS increased plasma BDNF levels at least 5 weeks in responders with treatment-resistant depressed patients (Yukimasa et al. 2006). Furthermore, ECT also increased serum BDNF levels in responders with refractory patients within 4 weeks (Okamoto et al. 2008). Taking these findings into account, it can be deduced that rTMS or ECT rapidly and robustly might increase blood BDNF levels

in depressed patients. Bocchio-Chiavetto et al. have demonstrated that ECT significantly increased serum BDNF levels in paralleled with clinical improvement of depressive symptoms (Bocchio-Chiavetto et al. 2006). On the other hand, Fernandes et al. (2009) reported that no changes were observed in the serum BDNF before and after the ECT treatment. Zanardini et al. (2006) reported that a significant increase of serum BDNF was found after rTMS treatment. It still remains controversial: How rTMS or ECT increased blood BDNF levels in depressed patients. Farther replications in larger sample will be performed.

8 Polymorphism of BDNF Gene Val66Met and Response to SSRIs

The relationship between the BDNF gene polymorphism (Val66Met) and the clinical response of patients with major depressive disorder to selective serotonin reuptake inhibitors (SSRIs; paroxetine and sertraline) was investigated. In addition, serum BDNF levels in these patients were considered together with the clinical response. A negative association was found between the serum BDNF levels and the Hamilton Rating Scale for Depression (HAMD) scores. No correlation was observed between BDNF gene Val66Met polymorphism and response to SSRIs or between BDNF Val66Met polymorphism and serum BDNF levels. These results suggest that serum BDNF level is a state biomarker for depression, but that in depressed patients, presence of the BDNF Val66Met polymorphism is independent of both the response to SSRI treatment and serum BDNF levels (Yoshimura et al. 2011). In contrast, recent meta-analysis by Zou et al. (2010) demonstrated that the association between BDNF Val66Met polymorphism and treatment response in patients with major depressive disorder, and Val66Met heterozygous patients has a better response rate in comparison to Val66Val homozygote patients, especially in the Asian population.

9 Adding an Atypical Antipsychotic Drug to an Antidepressant Increased Rapidly Plasma BDNF Levels in Treatment-Resistant Depressed Patients: Preliminary Findings

Only two-thirds of depressive patients respond to antidepressant treatment. Addition of an atypical antipsychotic drug to ongoing treatment with an antidepressant has been considered effective and well-tolerated, and that the improvements of depressive symptoms were related with the increase of plasma BDNF levels after adding the atypical antipsychotic drug to the antidepressant (Yoshimura et al. 2010b). No relationship was however observed between BDNF gene Val66Met polymorphism and the response to the atypical antipsychotic drug to the antidepressant. To the best of our knowledge, this is the first report demonstrating an atypical antipsychotic drug to an antidepressant enhances plasma BDNF levels in refractory depressive patients.

10 Longitudinal Follow-Up Study of Serum BDNF Levels and the Relapse of Depressive Episodes

Long-term study of serum BDNF levels in patients with major depressive disorder. A longitudinal follow-up study measuring serum BDNF levels after remission of depressive episodes. Serum BDNF levels at relapse were significantly lower than those at remission or after 6 months after remission. No difference was observed between levels at remission and at 6 months after remission. These results indicate that serum BDNF levels at 6 months after remission might not be associated with subsequent depressive episodes.

11 No Association Between Responses to the Addition of an Atypical Antipsychotic Drug to a SSRI or SNRI and BDNF (Val66Met) Polymorphism in Refractory Major Depressive Disorder: Preliminary Study

The association between the BDNF (Val66Met) polymorphism and the response to the addition of an atypical antipsychotic drug to a SSRI or SNRI in treatment-refractory depression was observed. Forty-two patients meeting the DSM-IV criteria for major depressive disorder and who were treated with at least two courses of a single antidepressant, but whose HAMD-17 scores were 15 points or more and were reduced less than 50 % over at least a 4-week treatment periods, were enrolled in the study. No correlation was found between the BDNF (Val66Met) polymorphism and a positive response to the atypical antipsychotic addition. In addition, patients who experienced remission were followed up 1 year after discontinuation of the atypical antipsychotic drug at least within 3 months. Eleven of 19 patients (47 %) relapsed within a year. These results suggest that the BDNF (Val66Met) polymorphism is not associated with the response to the augmentation of a SSRI or SNRI with an atypical antipsychotic drug, and the combination regimen of an atypical antipsychotic drug and a SSRI or SNRI should be continued for 3 months or more in refractory depressed patients in the Japanese population (Fig. 4).

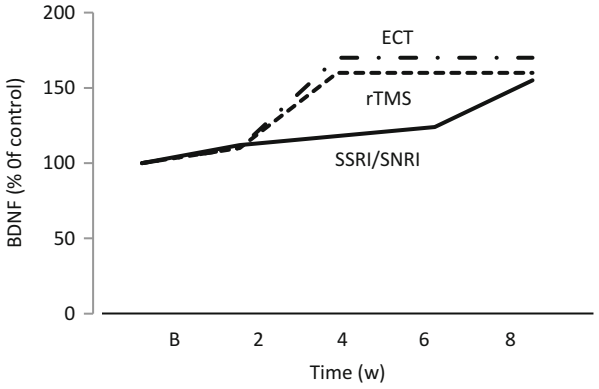

Fig. 4 Time courses of blood BDNF levels in different treatments for depression

12 Mental Stress, Personality Trait, and Blood BDNF Levels

Lang et al. first reported a negative correlation between the BDNF serum concentration and the depression-related factor neuroticism (Yoshimura et al. 2011). These results indicate that low BDNF levels in healthy humans with depressive personality traits might constitute a risk marker, reflecting a personality profile that is linked to vulnerability to mood disorders. Recently, Terracciano et al. also reported that serum BDNF might represent a biological correlate of neuroticism and not just of transient depressive state (Lang et al. 2004). Associations between plasma BDNF levels and personality trait evaluated by using NEO-FFI (neuroticism, extroversion, openness, agreeableness, and conscientiousness) also were examined. A positive correlation was observed between plasma BDNF levels and extroversion, but not neuroticism (Terracciano et al. 2011). The discrepancy of our results and those in other two studies remain controversial. One of the reasons might be the difference in the ethnicity. An association between psychological job stress and serum BDNF levels in Japanese hospital employee also was examined. Psychological job stress was evaluated. A negative correlation was observed between the scores of psychological stress and serum BDNF levels (Mitoma et al. 2008; Okuno et al. 2011). In other words, subjects with high psychological job stress had low BDNF levels. These results suggest that serum BDNF levels reflect psychological job stress in healthy workers.

13 Conclusion

Blood (serum and plasma) BDNF levels are useful state biomarker for depressive stateon. Blood BDNF levels reflect the severity of depressive state. SSRIs and SNRIs increased serum BDNF levels in the responders with major depressive disorder. Adding an atypical antipsychotic drug to a SSRI or a SNRI improved clinical symptoms in patients with refractory depression, which was accompanied with the increase plasma BDNF levels. The polymorphism of BDNF gene Val66Met was neither associated with the response to SSRIs nor an atypical augmentation to SSRIs or SNRIs. Further research should be done to reconfirm our preliminary findings.

Neuroprotection in Demyelinating Diseases: The Therapeutic Potential of the Neurotrophins

Junhua Xiao, Richard A. Hughes, and Simon S. Murray

Contents

Abstract

The myelin sheath has evolved to exert critical influences upon the central and peripheral nervous systems. Recently, the neurotrophins have been implicated in influencing the dynamic and complex signals that occur between neurons and myelinating glial cells – Schwann cells in the peripheral nervous system and oligodendrocytes in the central nervous system – that regulate myelination. Somewhat surprisingly, the neurotrophins have been found to influence

myelination in a complex manner involving both promyelinating and inhibitory signals that can be directed against either neuronal or glial cells that ultimately regulate central and peripheral myelin formation in distinct ways. The neurotrophins and their receptors have also been shown to influence the severity and affect remyelination in distinct in vivo models of demyelinating disease. Together, these data indicate that the selective targeting of neurotrophin receptors to promote remyelination offers an exciting prospect for the treatment of demyelinating diseases.

List of Abbreviations

CGRP	Calcitonin gene-related peptide
CNS	Central nervous system
DPN	Diabetic peripheral neuropathy
DRG	Dorsal root ganglion
EAE	Experimental autoimmune encephalomyelitis
EAN	Experimental autoimmune neuritis
Erk	Extracellular signal-regulated kinase
GPCR	G Protein-coupled receptor
MAPK	Mitogen-activated protein kinase
MS	Multiple sclerosis
NRG	Neuregulin
NTR	Neurotrophin receptor
OPCs	Oligodendrocyte progenitor cells
PNS	Peripheral nervous system
TrkB	Tropomyosin-related kinase B

1 Introduction

The myelin sheath is critical for normal nervous system function. Its evolution has effectively given the nervous system enhanced compactness, reduced its metabolic demands, improved action potential synchrony, and allowed the rapid processing of complex information. This has been achieved via at least two distinct and critical influences on the nervous system. The first is to increase the speed at which the action potential is propagated along the axon, by permitting saltatory conduction. Electrophysiological studies have clearly shown the impact this has on nervous system function, demonstrating that nervous system demyelination results in slowing of the conduction velocity of action potentials and in more severe cases can actually lead to conduction block (McDonald and Sears 1969). While these studies theoretically accounted for the neurological deficits encountered in people suffering from demyelinating diseases, the clinical picture appeared more complex. Brain imaging studies revealed that white matter lesion load did not necessarily correlate with the extent of neurological deficit. Indeed,

histological studies have now revealed that injured and transected axons are present within both demyelinated and actively demyelinating lesions and that progressive axonal loss resulting from demyelination is a key contributor to clinical decline (Trapp et al. 1997; Bitsch et al. 2000). It is now increasingly apparent that the second critical influence that myelinating glial cells exert is to confer protective and trophic support to the axons which they ensheathe (Yin et al. 2006). Collectively, these studies indicate that there is an intimate relationship between damage to either the myelinating glial cell or the myelin sheath itself and axonal degeneration. The evolution of the myelin sheath and saltatory conduction reduced the metabolic demands and energy expenditure required by the nerve cell to relay the action potential down its axon, and perhaps this at least in part contributes to the axonal-protective properties of myelin. However it is also clear that the myelinating cells support axonal integrity and survival independent of the myelin sheath itself (Lappe-Siefke et al. 2003; Lee et al. 2012; Oluich et al. 2012). Thus, the protective influences that myelinating glial cells and the myelin sheath exert on axonal integrity suggest that any successful therapy against demyelinating diseases must consider both survival of myelinating glial cells and myelin regeneration.

In human demyelinating diseases such as multiple sclerosis (MS) and some peripheral demyelinating neuropathies, the myelinating glial cells progressively die, disrupting these myelin sheaths and placing axonal integrity at risk. The body has an innate mechanism for remyelination, whereby myelin sheaths are restored to the damaged axons, protecting them from further degeneration (Irvine and Blakemore 2008; Franklin et al. 2012). In MS, this is affected by regenerating oligodendrocytes through the generation, recruitment, and differentiation of OPCs resident within the CNS. However, remyelination is often incomplete, becomes less efficient with age, and following successive demyelinating events is ultimately insufficient and invariably leads to irreversible axonal damage and progressive and extensive disability (De Stefano et al. 1998).

In these diseases an autoimmune response is commonly observed, which is generally believed to contribute to the extent of demyelination. While immune-targeted therapies are available to limit demyelination, no treatments are currently available to directly promote myelin repair. Intuitively, studies that examine the growth factors and molecular mechanisms that promote myelination during development and remyelination following injury are essential if the therapeutic targets that promote myelin repair and thereby limit axonal injury and ultimately disability are to be identified. Recent reviews have examined the neurotrophin family of growth factors and the roles they play in regulating myelination during development in detail (Rosenberg et al. 2006; Xiao et al. 2009a). We briefly review here the current understanding of the mechanisms that the neurotrophins and their receptors utilize to influence myelination during development and identify the protective roles they exert in demyelinating diseases. Finally we discuss the evolving potential for the selective targeting of neurotrophin receptors for therapeutic benefit in the context of myelin repair following a demyelinating insult.

2 The Neurotrophins, Their Receptors, and Myelination During Development

2.1 The Neurotrophins and Their Receptors

The neurotrophin family of growth factors comprises nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). They are widely expressed and exist in two distinct forms. They are initially synthesized as larger precursor proteins, known as proneurotrophins, which subsequently undergo proteolytic cleavage either intracellularly or extracellularly to yield the mature neurotrophins. It is generally accepted that the proneurotrophins modulate cell death (Teng et al. 2010); however, there is emerging evidence they can also exert distinct influences including modulating synaptic plasticity and axonal competition at developing neuromuscular synapses (Woo et al. 2005; Je et al. 2012). To date, there is no evidence to indicate that the proneurotrophins directly influence myelination, whether central or peripheral.

In contrast, it is well established that the mature neurotrophins exert profound and diverse effects upon neural development as well as in maintaining and modulating the adult mature nervous system. The mature neurotrophins signal through two distinct classes of structurally unrelated transmembrane receptors: the receptor tyrosine kinase tropomyosin-related kinase (Trk) family and p75NTR (Chao 2003). These receptors exhibit a distinct capacity to interact with the neurotrophins. Whereas all the neurotrophins can bind nonselectively and with approximately the same affinity to p75NTR, they display selectivity in their interaction with Trk receptors: NGF binds selectively to TrkA, BDNF and NT4/5 to TrkB, and NT-3 to TrkC (Chao 2003; Huang and Reichardt 2003). Increasing the complexity of these ligand-receptor interactions, when Trk and p75NTR are co-expressed on the same cell, they can also form a receptor complex wherein p75NTR modulates the affinity of Trk receptor binding and selectivity of Trk receptor activation (Esposito et al. 2001). Despite this complexity, genetic analysis of mice deficient in either the neurotrophins or their receptors reveals that, by and large, Trk receptor signalling transduces the key influences of the neurotrophins (Conover and Yancopoulos 1997; Huang and Reichardt 2003).

2.2 The Neurotrophins Regulate Schwann Cell Myelination

It is well established that both peripheral neurons and Schwann cells express a variety of neurotrophin receptors, as well as expressing and secreting neurotrophins. Analyses of either neurotrophin or neurotrophin receptor knockout mice reveal the absolute requirement of the ligands and their receptors for peripheral neuron development, showing that ~80 % of DRG neurons are dependent on NGF for survival (Crowley et al. 1994), ~30 % are dependent on BDNF (Jones et al. 1994), and ~70 % are dependent on NT-3 (Liebl et al. 1997; Tessarollo et al. 1997).

Consequently, while it is clear that the neurotrophins and their receptors exert critical influences on the development of the peripheral nervous system, analysis of the precise effects that these molecules have on peripheral myelination in vivo has been problematic. However, development and manipulation of in vitro myelination assays has provided insight into the roles the neurotrophins and their receptors are playing in this context. Somewhat surprisingly, despite Schwann cells expressing several neurotrophin receptors, the key influences that the neurotrophins exert on peripheral myelination appear to be directed through neuronally expressed receptors that ultimately regulate axonal receptivity to myelination by Schwann cells.

Chan and colleagues were the first to identify that NGF exerts a positive influence upon Schwann cell myelination. Through the use of in vitro myelination assays, they identified that NGF enhanced Schwann cell myelination specifically of TrkA-expressing DRG neurons. This influence of NGF was specific to TrkA, as NGF also promoted myelination of neurons not expressing p75NTR and exerted no influence on TrkB-expressing DRG neurons (where TrkA expression is absent) (Chan et al. 2004). Thus, NGF exerts its promyelinating influence selectively through neuronally expressed TrkA receptors (Fig. 1). Contextually this fits well developmentally, as ~80 % of DRG neurons express TrkA during the early postnatal period when peripheral nerves are actively being myelinated. Thus, TrkA is well placed to direct key influences upon DRG neurons to regulate their myelination in vivo (Wiggins et al. 1975; Silos-Santiago et al. 1995; Molliver and Snider 1997; Xiao et al. 2009a). Interestingly, TrkA expression is strikingly developmentally regulated, in that while ~80 % of DRG neurons express TrkA during embryogenesis and early postnatal life, the expression of TrkA is remarkably downregulated in adult DRG neurons (Molliver and Snider 1997). This suggests that the utility of NGF as a potential remyelination therapy in adults may be limited.

The influence that BDNF exerts upon peripheral myelination is considerably more complex, with evidence demonstrating that BDNF can promote or inhibit the myelination of distinct subsets of DRG neurons. Like NGF, BDNF regulates Schwann cell myelination through activation of neuronally expressed receptors. However, the precise influence that BDNF exerts is dependent on the subset of neurotrophin receptors expressed on the particular DRG neuron. BDNF inhibits Schwann cell myelination of TrkB+ DRG neurons; however, in the absence of neuronal TrkB, BDNF can promote the myelination via activation of neuronal p75NTR (Chan et al. 2001; Cosgaya et al. 2002; Xiao et al. 2009b). The contrasting influence that BDNF exerts upon Schwann cell myelination is therefore context specific, due to BDNF activating distinct neuronal receptors – p75NTR to promote myelination and TrkB to inhibit it (Xiao et al. 2009b) (Fig. 1). For this reason, the utility of BDNF itself as a potential remyelination therapy in adults may also be limited. This also reveals a fundamental difference as to how NGF and BDNF promote Schwann cell myelination: NGF promotes myelination via activation of neuronal TrkA receptors (Chan et al. 2004), whereas BDNF promotes myelination via activation of neuronal p75NTR receptors (Xiao et al. 2009b) (Fig. 1).

In contrast to the situation for NGF and BDNF, there have been relatively few studies that have attempted to identify the precise influence that NT-3 exerts on

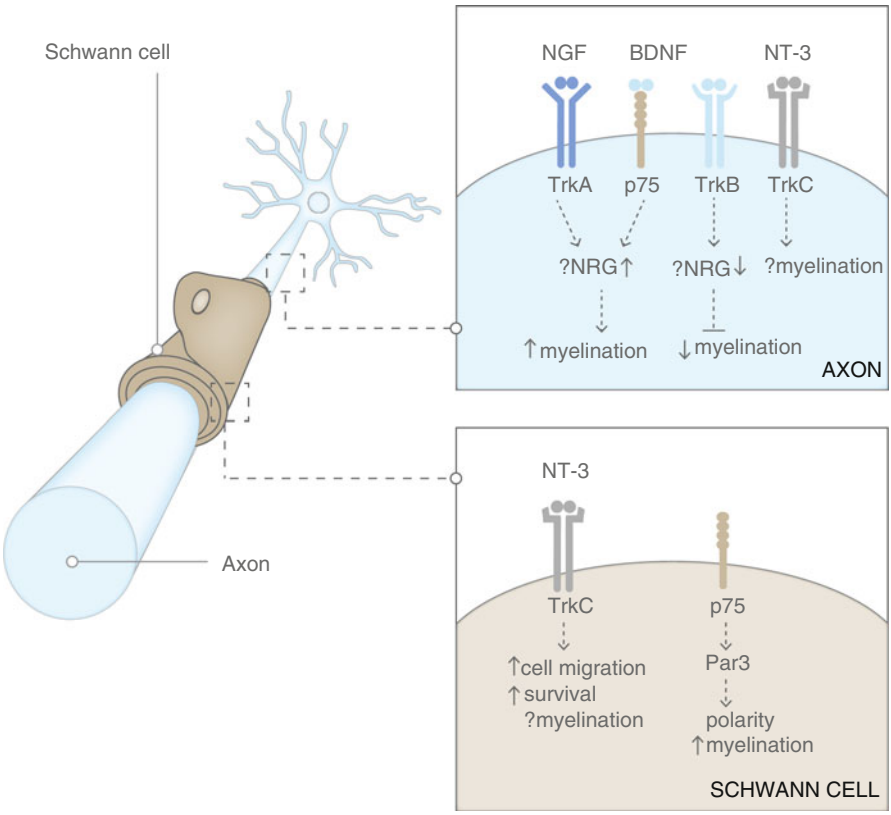

Fig. 1 Neurotrophin influences on Schwann cell myelination. Top panel: Neuronal influences of the neurotrophins. NGF exerts a promyelinating influence via TrkA activation. BDNF promotes myelination via p75NTR activation, but inhibits myelination via TrkB. NGF and BDNF putatively differentially regulate neuregulin (*NRG*) expression to regulate myelination. The precise influence that neuronal TrkC receptors exert is unclear. *Bottom panel*: Neurotrophin influences on Schwann cells. NT-3 effects Schwann cell migration and survival, whereas BDNF influences Schwann cell polarity in a p75NTR-dependent manner. The precise role these influences exert on myelination is unclear

Schwann cell myelination. In vitro, exogenous NT-3 inhibits myelin formation, and injection of NT-3 adjacent to the sciatic nerve of neonatal mouse pups also results in reduced myelin protein formation, supporting an inhibitory role for NT-3 upon peripheral myelination, most likely via activation of the TrkC receptor (Chan et al. 2001; Cosgaya et al. 2002) (Fig. 1). However, as Schwann cells and some DRG neurons express TrkC, the precise mechanism that NT-3 utilizes to influence myelination remains unclear.

Collectively, these data demonstrate that the influences the neurotrophins exert upon the myelination of peripheral axons are highly dependent on the complement of neurotrophin receptors expressed at critical times in development. It is clear that

at least NGF and BDNF direct neuronal events that alter axonal receptivity to Schwann cell myelination. Importantly, the critical neuronal event that determines the ensheathment fate of peripheral axons is the expression of neuregulin-1 type III (Taveggia et al. 2005; Nave and Salzer 2006; Birchmeier and Nave 2008). Thus, it is likely that neurotrophin signalling within the distinct subsets of DRG neurons differentially regulates the expression of neuregulin-1 type III. However, this has yet to be definitively demonstrated.

It is intriguing that Schwann cells also express several neurotrophin receptors, including p75NTR, TrkC, and truncated TrkB receptors. Emerging data identify that the neurotrophins also exert direct influences on Schwann cells. BDNF can regulate Schwann cell migration (Yamauchi et al. 2004) as well as Schwann cell polarity and alignment to axons in a p75NTR-dependent manner (Chan et al. 2006) (Fig. 1). NT-3, acting through Schwann cell-expressed TrkC receptors, also promotes Schwann cell migration (Yamauchi et al. 2003; Yamauchi et al. 2005a, b), and analysis of NT-3 mutant mice suggests it also promotes survival of maturing Schwann cells (Woolley et al. 2008) (Fig. 1). These events all ultimately impact upon the process of myelination and clearly suggest that neurotrophins exert distinct influences directly upon both neurons and Schwann cells that collectively contribute to the orchestration of peripheral myelination.

2.3 The Neurotrophins Regulate Oligodendrocyte Myelination

As in the peripheral nervous system, a variety of neurotrophins and neurotrophin receptors are expressed by both the neurons and oligodendrocytes of the central nervous system. Analyses of central nervous system myelination in either neurotrophin or neurotrophin receptor knockout mice have also proven largely problematic, as many of these mice die in the embryonic or early postnatal period prior to CNS myelination being complete. In any case, analyses of these mice are confounded by the global deletion, whereupon the potential selective influences that neuronal and oligodendroglial receptors exert upon myelination cannot be discriminated. In vitro myelination assays have again proved critical here, providing insight into the influences that the neurotrophins and their receptors exert upon oligodendrocyte myelination. Perhaps surprisingly, the data here clearly indicate that the neurotrophins exert quite distinct influences upon peripheral and central nervous system myelination.

The first indication that the neurotrophins did not exert uniform influences upon peripheral and central myelination came with the study of NGF. Chan and colleagues, adopting the same approach that demonstrated that NGF promoted Schwann cell myelination, found that NGF inhibited oligodendrocyte myelination (Chan et al. 2004). Mechanistically NGF was shown to be acting via the activation of neuronally expressed TrkA receptors in both cases but with starkly contrasting outcomes (Fig. 2, top panel). This reaffirmed what had been known for some time – that axonal control over peripheral and central nervous system myelination is mediated via unique and mutually exclusive mechanisms – but surprisingly

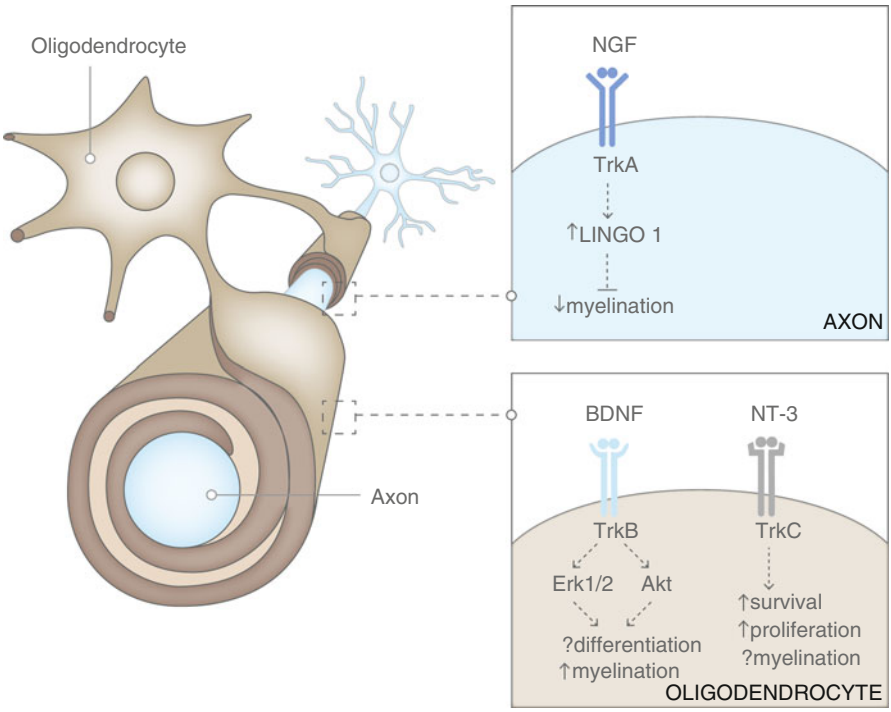

Fig. 2 Neurotrophin influences on oligodendrocyte myelination. Top panel: Neuronal influences of the neurotrophins. NGF inhibits oligodendrocyte myelination via regulating LINGO-1 expression. *Bottom panel*: Neurotrophin influences on oligodendrocytes. BDNF activates TrkB to promote oligodendrocyte myelination, potentially via Erk1/Erk2 or Akt activation. NT-3 effects oligodendrocyte survival and proliferation; however, the precise influence it exerts on myelination is unclear

revealed that a common growth factor could exert opposite effects upon myelination. In this context, NGF regulates axonal expression of LINGO-1, a membrane-bound protein that acts as a negative regulator of oligodendrocyte but not Schwann cell myelination (Mi et al. 2005; Lee et al. 2007) (Fig. 2, top panel). As an aside, LINGO-1 exerts profoundly negative influences on oligodendrocyte myelination (Mi et al. 2005), and LINGO-1 antagonists have been found to promote remyelination in animal models of CNS demyelination (Pepinsky et al. 2011a, b). A phase 1 clinical trial utilizing a LINGO-1 antagonist has recently been completed.

Analysis of the impact that BDNF exerted on oligodendrocyte myelination also revealed marked differences to its influence on Schwann cell myelination. Both BDNF knockout and heterozygous mice display a hypomyelinated phenotype in the CNS (Cellerino et al. 1997; Vondran et al. 2010; Xiao et al. 2010), suggesting a key role for BDNF in promoting oligodendrocyte myelination. This was verified in vitro, with BDNF found to promote myelination via a direct effect upon

oligodendrocyte-expressed TrkB receptors (Cohen et al. 1996; Du et al. 2003; Xiao et al. 2010) (Fig. 2). This was the first demonstration that a neurotrophin exerted its promyelinating influence by directly activating receptors expressed by the myelinating glial cell. This was subsequently verified in vivo through the analysis of mice in which TrkB had been deleted specifically in oligodendrocytes. This deletion significantly disrupted normal myelination in the CNS, resulting in a significant reduction in myelin protein expression and myelination of CNS white matter tracts during development (Wong et al. 2013). Interestingly, analyses revealed significantly reduced myelin thickness without oligodendrocyte number being affected, indicating that TrkB exerts an important influence in selectively promoting myelin ensheathment. These conditional knockout mice also exhibited an increased density of oligodendrocyte progenitor cells (OPCs) in CNS white matter tracts, which in vitro analyses suggested was dependent upon TrkC and p75 expression (Wong et al. 2013). This is another exemplar demonstrating the complexity of the neurotrophin signalling.

As the signalling by the Trk receptors is reasonably well characterized (Huang and Reichardt 2001), this had the potential to provide novel insight into the molecular control of myelination. Indeed, several canonical signalling pathways downstream of TrkB have been implicated in promoting oligodendrocyte myelination. Activation of both the MAPK (Chew et al. 2010; Fyffe-Maricich et al. 2011; Ishii et al. 2012) and Akt (Narayanan et al. 2009; Tyler et al. 2009) signalling pathways promote oligodendrocyte differentiation and myelination. Through screening candidate signalling pathways in in vitro myelination assays, it was found that BDNF-induced activation of extracellular signal-regulated kinase 1 and 2 (Erk1/Erk2) signalling in oligodendrocytes positively correlated with myelination (Xiao et al. 2012). Indeed, Erk1/Erk2 has been identified as a key signalling pathway that regulates the promyelinating effect of BDNF (Xiao et al., 2012; Ishii et al., 2012).

NT-3 is well known as an oligodendrocyte survival factor and was in fact one of the first growth factors identified to support the survival and proliferation of oligodendrocyte progenitor cells in vitro and in vivo (Barres et al. 1993, 1994; Kumar and de Vellis 1996; Kumar et al. 1998; Saini et al. 2004) (Fig. 2). It is important to note though that in addition to these effects upon progenitor cell survival, exogenous NT-3 also promotes oligodendrocyte myelination in vitro (Yan and Wood 2000; Rubio et al. 2004). The phenotype of the NT-3 knockout mouse supports a promyelinating role for NT-3 in vivo (Kahn et al. 1999). However, insufficient attention has been paid to NT-3 in this context, and whether its primary influence in the central nervous system in vivo is the generation and proliferation of OPCs or as a distinct promyelinating factor or both remains to be definitively established.

Similar to that observed for Schwann cell myelination, the influences the neurotrophins exert upon oligodendrocyte myelination are highly dependent on the complement of neurotrophin receptors expressed by the different cell types. While NGF initiates neuronal events that alter axonal receptivity to oligodendrocyte myelination, BDNF and NT-3 directly target oligodendrocyte-expressed

receptors to influence myelination. Somewhat surprisingly, despite p75NTR being expressed by both neurons and oligodendrocytes, it does not appear to exert a significant influence upon central nervous system myelination (Xiao et al. 2010), unlike that observed with Schwann cell myelination (Cosgaya et al. 2002; Chan et al. 2006; Xiao et al. 2009b).

Collectively, identification of the key influences that the neurotrophins exert on both peripheral and central nervous system myelination has revealed that their actions are highly contextual, with no unified response apparent. This is at least in part reflected in the complex nature with which the neurotrophins interact with their respective receptors but also reflects the distinct mechanisms that have evolved to generate central and peripheral myelin. From a therapeutic perspective this is potentially problematic, demanding that any potential neurotrophin-based approach be selective for central or peripheral remyelination, with the caveat that what might promote remyelination in the CNS could inhibit remyelination in the PNS. Nevertheless, neurotrophin-based approaches have been adopted to investigate their efficacy in promoting remyelination following a demyelinating injury to both the CNS and PNS.

3 The Neurotrophins, Their Receptors, and Remyelination Following Injury

Demyelination is the pathological process in which myelin sheaths are lost from around axons (Franklin and Ffrench-Constant 2008), with MS and Guillain-Barre syndrome (GBS) being the most common demyelinating diseases of the central and peripheral nervous systems, respectively (Miller 1996). Demyelination can result from a direct insult targeted at the myelin forming glial cells, which commonly occurs in CNS demyelination (Franklin and Ffrench-Constant 2008). The process of remyelination, in which entire myelin sheaths are restored to demyelinated axons, can reinstate saltatory conduction, resolve functional deficits, and promote axonal integrity and neuronal survival (Jeffery and Blakemore 1997; Liebetanz and Merkler 2006; Zawadzka and Franklin 2007). In recent years, multiple studies have examined the influence that the neurotrophins exert upon models of CNS autoimmune demyelination and remyelination. In contrast, there have been relatively few studies examining the influence that the neurotrophins exert upon models of peripheral nervous demyelination.

3.1 The Neurotrophins Promote Peripheral Nervous System Remyelination

Peripheral neuropathy encompasses complex neurological conditions, covering many disorders of the peripheral nervous system (Hughes 2008). The causes of peripheral neuropathy are protean: they can be either genetic in origin or acquired, with acquired neuropathies having either metabolic, ischemic, inflammatory,

or toxic precipitants (Hughes and Cornblath 2005; Hughes 2008). Peripheral neuropathies are also usefully classified as either axonal or demyelinative in origin. In axonal neuropathies the primary insult is directed to the neuron, and demyelination follows as a secondary consequence, whereas in demyelinative neuropathies the insult is directed to the Schwann cell that ensheathes the axon with myelin. Neuropathies are nevertheless not always pure; for example, there are circumstances in which the pathogenic insult is directed to both the axon and the Schwann cell; furthermore, in severe demyelinative neuropathy there is often secondary axonal degeneration because of the loss of trophic support that the Schwann cells otherwise provide.

Axonal peripheral neuropathy is most commonly caused by diabetes but can also result from a range of metabolic disorders, infectious agents, vasculitis, toxins, drugs, autoimmune and paraproteinemia neuropathies, and inherited polyneuropathies (McHugh and McHugh 2004). In experimental models of peripheral polyneuropathy, a reduction in the availability of the neurotrophins and alterations in the expression of their receptors has been observed, affecting both neuronal survival and maintenance of a myelinated phenotype (Apfel 1999a; Pittenger and Vinik 2003). The most widely utilized model of peripheral neuropathy is diabetic peripheral neuropathy (DPN) (Apfel et al. 1994, 1998; Apfel 1999a, b; Fressinaud et al. 2003; Pittenger and Vinik 2003). While DPN itself represents a heterogeneous variety of disorders affecting the peripheral nervous system, it is modelled by inducing diabetes in rats by administration of streptozocin.

DPN is characteristically described as degeneration of both small- and large-diameter sensory fibers, axonal degeneration, demyelination and atrophy, and ultimately associated with failed axonal regeneration, remyelination, and synaptogenesis (Pittenger and Vinik 2003). There is altered expression of neurotrophins and their receptors, as well as neuronal trafficking of neurotrophins in experimental models of DPN. It has been suggested that such changes could in fact contribute to the pathogenesis of DPN, but the data are far from definitive (Fressinaud et al. 2003; Pittenger and Vinik 2003). While large myelinated fibers can be affected in this model, it is the neuropathy associated with the small thinly myelinated fibers and sympathetic neurons that causes the majority of symptoms that adversely affect quality of life (Apfel 1999b). In this context, experimental depletion of NGF or its receptors duplicates many of the neuronal abnormalities observed in this model (Pittenger and Vinik 2003). So perhaps unsurprisingly NGF, which selectively supports the survival of the subset of smaller DRG and sympathetic neurons, was trialled as a potential therapy for DPN due to the consequences associated with degeneration of these neuronal populations (Apfel 2002). A number of animal studies initially demonstrated benefit following NGF treatment for toxic and diabetic peripheral polyneuropathy, which lead to the first clinical trials using neurotrophin-based strategies (Apfel 1999a, b). However, while significant improvement was seen in early trials, studies were discontinued at the phase III stage due to painful side effects (Apfel 2001, 2002). As NT-3 supports the survival of larger DRG neurons, by adopting a similar rationale, it too was trialled as a therapy in animal models of DPN. Utilizing an adenovirus-based vector approach

for the delivery of NT-3 in drug-induced diabetic rats, the slowing of motor nerve conduction velocity and muscle denervation was prevented, suggesting NT-3 retards the development of DPN (Pradat et al. 2001). Combination studies with both NGF and NT-3 in animal models of peripheral neuropathy including DPN suggested that these factors can ameliorate neuronal degeneration (Apfel 1999a). However, as indicated above, this is not a true demyelinating neuropathy, so the lessons learned here in the context of remyelination are unclear.

The contemporary view is that NGF promotes peripheral nerve myelination via activation of neuronal TrkA receptors (Chan et al. 2004). In the adult, no motor neurons and relatively few DRG neurons express TrkA, which tend to be thin and nonmyelinated anyway, so the rationale for utilizing NGF as a strategy to promote peripheral remyelination has limited basis. In fact the pain associated with this clinical trial may be attributable to NGF producing peripheral sensitization of nociceptive DRG neurons through the activation of TrkA. Indeed recent work has demonstrated that increases in peripheral nerve sensitization and pain are due to TrkA activation, p38 phosphorylation, and TRP channel expression (Bron et al. 2003; Obata et al. 2006).

With NGF being an unsuitable therapeutic candidate, what of BDNF? It is certainly implicated in remyelination, as endogenous BDNF has been shown to promote peripheral nerve regeneration and remyelination after sciatic nerve crush injury (Zhang et al. 2000). Electrical stimulation enhanced the remyelination of injured peripheral nerves by inducing BDNF expression and promoting Schwann cell polarization (Wan et al. 2010). However, recent findings have identified that the influence BDNF exerts upon peripheral myelination is more complex, due to BDNF activating distinct receptors: p75NTR to promote myelination and TrkB to inhibit it (Xiao et al. 2009b). On the simple basis of these contrasting influences, BDNF also presents as a less than ideal therapeutic candidate. Nevertheless the identification that BDNF promotes peripheral myelination via neuronal p75NTR is of some interest (Xiao et al. 2009b), as p75NTR has been identified as a global positive regulator of peripheral myelination during development (Cosgaya et al. 2002). In a sciatic nerve injury model in vivo, remyelination was found to be impaired in p75NTR−/− mice (Song et al. 2006). However, it is important to note that approximately 50 % of the DRG neurons are lost in the p75NTR−/− mouse (Murray et al. 1999), complicating this analysis. In a similar sciatic nerve injury model but in nude mice, nerve grafts derived from p75NTR−/− or wild-type mice were transplanted, supplying a source of Schwann cells for remyelination. Analysis of these mice identified that those receiving p75NTR−/− grafts had poorer motor performance, reduced myelin sheath thickness, decreased axonal diameter, and reduced myelin protein expression (Tomita et al. 2007). Collectively these data suggest that p75NTR also plays an important role in the remyelinating process, albeit in a nerve injury model.

Thus, the potential that the neurotrophins hold in promoting peripheral myelination is far from clear, and two issues stand out as requiring attention. The first is the choice of model. Clearly models that utilize nerve injury as the primary pathology are complex, and identifying the selective influence that any putative

therapy exerts on remyelination is confounded. There is a demonstrated need to assess any potential neurotrophin-based therapeutic strategy in a targeted primary demyelinating model, such as experimental autoimmune neuritis (EAN), an autoimmune disease model induced by inoculation with PNS antigen (Gold et al. 2000). The second standout issue is the complexity in the interactions between neurotrophins and their receptors. The cell biology has identified that the neurotrophins exert differing and at times contrasting influences on peripheral myelination, dependent on the complement of neurotrophin receptors expressed by the peripheral neuron. Thus, the therapeutic potential of the neurotrophins per se maybe functionally limited, yet it remains plausible that the selective molecular targeting of p75NTR may, in principle, exert a unified promyelinating response in the PNS. A couple of research groups have recently identified compounds that act as putative selective p75NTR modulators (Massa et al. 2006; Fletcher et al. 2008; Fletcher and Hughes 2009), so the potential of a selective agonist that uniformly promotes the myelination of distinct subsets of peripheral neurons remains a distinct possibility.

3.2 The Neurotrophins Promote Central Remyelination

There are two major groups of CNS demyelinating diseases. The first is the leukodystrophies, a group of genetic disorders that affect the production or metabolism of one of several of the component molecules of myelin. The second is inflammatory demyelinating diseases, caused by autoimmune mediated damage to myelin and oligodendrocytes, with MS being by far the most significant of these diseases. Experimental models of CNS demyelination, including experimental autoimmune encephalomyelitis (EAE) and toxic models of demyelination such as lysolecithin, ethidium bromide, and cuprizone models, have been widely used to examine the therapeutic potential of candidate molecules and to assess the affect they exert upon oligodendroglial and immune cells, as well as their influence on the extent of demyelination and remyelination (Rodriguez 2007).

While the roles that the neurotrophins exert on CNS myelination have been extensively studied in the context of development (Barres et al. 1993; Cellerino et al. 1997; Chan et al. 2004; Xiao et al. 2010), the influence that they exert upon demyelination and remyelination has received substantially less attention. BDNF is the neurotrophin most widely expressed in the CNS and unsurprisingly has been the focus of most attention.

In the normal CNS, BDNF is primarily derived from neurons (Lewin and Barde 1996). However, in inflamed areas in the CNS, such as occurs in MS and EAE, activated astrocytes express increased levels of endogenous BDNF (Stadelmann et al. 2002; Burbach et al. 2004; Linker et al. 2010). Moreover, BDNF is also produced by several immune cell subtypes in vitro, such as activated T cells, B cells, and monocytes (Kerschensteiner et al. 1999; Stadelmann et al. 2002). Thus, BDNF is well placed to exert a modulatory effect upon myelination in this context (Stadelmann et al. 2002). Interestingly in the EAE model, the MS

immune-modulatory drug glatiramer acetate causes a sustained increase in BDNF expression in the brain, which its protective effects are dependent upon (Aharoni et al. 2005; De Santi et al. 2009; Lee et al. 2011).

Several recent studies have implicated BDNF in exerting a functionally protective role following CNS demyelination. In response to the cuprizone model of demyelination, BDNF heterozygote mice exhibit greater demyelination and reduced remyelination in the absence of any change to the total number of oligodendroglia, microglia, astrocytes, or extent of axonal injury (VonDran et al. 2011). In mice in which BDNF has been selectively deleted under the influence of the GFAP promoter, and thus theoretically deleted in oligodendrocytes, astrocytes, and some neurons, a more severe course of EAE and increased axonal loss was observed (Linker et al. 2010). Interestingly, the protective effect of BDNF in this model is temporally restricted, as an inducible conditional knockout strategy demonstrated that BDNF exerts its protective effects primarily during the initial phases of EAE, reducing clinical symptoms and structural damage, whereas deletion of BDNF in later stages of the disease had no significant effect on either disease course or axonal integrity (Lee et al. 2011). This suggests there may be an early window of therapeutic opportunity for the modulation of BDNF levels, at least in EAE.

It appears that not only central nervous system-derived BDNF is important, as mice deficient for BDNF in T cells exhibited progressive disability and enhanced axonal loss in EAE, while mice overexpressing BDNF in T cells exhibited less severe EAE and axonal protection (Linker et al. 2010). Despite this, however, CNS-derived BDNF appears more critical than immune cell-derived BDNF. Experiments utilizing bone marrow chimeras reveal that following CNS deletion of BDNF, immune cell-derived BDNF cannot influence disease severity (Lee et al. 2011). This suggests that while immune cell-derived BDNF can modulate disease, CNS resident cells are the major source of biologically relevant BDNF in autoimmune demyelination. Whether in this context BDNF exerts its influence directly on the myelinated axon/neuron-oligodendrocyte interface remains an open question. In an alternate strategy, treatment with BDNF-engineered bone marrow stem cells also resulted in a significant delay to EAE onset, reduced clinical severity, reduced expression of pro-inflammatory cytokines TNF-α and IFN-γ, and increased expression of anti-inflammatory cytokines such as IL-4, IL-10, and IL-11 (Makar et al. 2009). In addition, immune cell expression of TrkB has been shown to play an important role in EAE immunopathogenesis by modulating autoreactive T cell survival and behavior (De Santi et al. 2009). This indicates that BDNF may also influence the immune response, suggesting its protective effect at least in part could be indirect. Ultimately the identity of the cells that BDNF targets for its protective effect may not be absolutely identified until a new strategy is taken, whereupon the EAE model is undertaken in mice in which the BDNF receptor is conditionally targeted in distinct candidate cell types.

In the CNS, TrkB expression is present in various cell types including neurons, oligodendroglial cells, astrocytes, as well as infiltrating immune cells (Cahoy et al. 2008; De Santi et al. 2009), so there is no shortage of potential BDNF targets.

Interestingly, the detection of phosphorylated TrkB was increased in the neurons of EAE-diseased mice compared to the intact axons of control mice, suggesting BDNF is at least exerting a neuronal effect in this context (Linker et al. 2010). As both in vitro and in vivo analyses have identified that oligodendroglial TrkB potentiates CNS myelination (Xiao et al. 2010; Wong et al. 2013), it would be interesting to investigate directly whether oligodendrocyte expression and phosphorylation of TrkB is altered in models of demyelination/remyelination. This would provide some insight into whether the selective promyelinating influence that oligodendroglial TrkB signalling exerts during development is also relevant to remyelination. What is beyond dispute however is that regardless of the model or the strategy to manipulate BDNF or TrkB expression, the effect they exert is a uniformly promyelinating one. Future studies aimed at identifying the cellular and molecular basis of the protective and regenerative effects that BDNF exerts in the context of animal models of demyelinating diseases are critical now in order to establish how these responses might ultimately be targeted and modulated for therapeutic benefit.

4 The Therapeutic Potential of Targeting Neurotrophin Receptors for Promoting Remyelination

Despite substantial increases in our understanding of the mechanisms of myelination, demyelination, and remyelination, current therapeutic interventions for demyelinating diseases are suboptimal. These advances in knowledge have yet to be translated into the clinic, meaning that current therapies focus on reducing inflammation rather than directly promoting remyelination. However, as discussed above, there is now a strong body of evidence from preclinical studies pointing to the therapeutic potential of neurotrophins in preventing or slowing demyelination and promoting remyelination.

Human clinical trials assessing the efficacy of human recombinant NGF as a treatment for peripheral neuropathy were undertaken over a decade ago and were discontinued due to side effects including pain (Apfel et al. 1994; Apfel 1999b; Apfel et al. 2000; Apfel 2001, 2002). While the effect on pain sensitization is likely to be an NGF-specific side effect, the complexity of neurotrophin receptor interactions and the more recent identification of the context-dependent influences the neurotrophins exert upon peripheral myelination described above confound the clinical use of recombinant neurotrophins for this purpose. In addition the pharmacokinetic behavior of the neurotrophins is generally not optimal for pharmaceutical use. BDNF, for example, has a half-life in the circulation of less than 1 min in the rat (Poduslo and Curran 1996), and, as one would expect with a protein, there is no strong evidence that it can cross the blood–brain barrier.

Given the difficulties inherent with using recombinant neurotrophins themselves to treat demyelinating and other CNS disorders, increasing attention has turned to the development of alternative strategies to harness neurotrophic action for clinical use. One means of doing this is to use functional mimetics of the neurotrophins.

These compounds would have the advantage of being able to selectively target p75NTR or Trk receptors and could be tailored to have appropriate pharmacokinetic properties. Moreover, exciting recent data describing G protein-coupled receptor (GPCR) transactivation of Trk receptors and their downstream signalling pathways raise the possibility of using an even wider range of small molecules to elicit promyelinating effects.

4.1 Putative p75NTR Agonists

Unlike NGF, BDNF does not induce painful side effects and is safe and well tolerated in both animals and humans (Mitsumoto et al. 1994; Ikeda et al. 1995). Based on published data (Chan et al. 2001; Cosgaya et al. 2002; Xiao et al. 2009b), BDNF itself could be considered as a suitable promyelinating candidate to test in the context of peripheral neuropathy. However, as described above, while BDNF promotes myelination of peripheral axons via activation of neuronally expressed p75NTR, it also inhibits the myelination of TrkB-expressing neurons (Xiao et al. 2009b). Thus, at least in the context of peripheral myelination, compounds that selectively activate p75NTR, without concomitantly activating TrkB, would be expected in principle to produce a unified promyelinating response in the periphery.

Recently, two different classes of selective modulators of p75NTR have been described. Structure-based design approaches have been used to obtain conformationally constrained, low molecular weight peptides based on the solvent-exposed loops of BDNF involved in binding to its receptors (Fig. 3). Using this approach, monomeric mimetics of loop 4, exemplified by the cyclic pentapeptide cyclo-[DPro-Ala-Lys-Lys-Arg] (cyclo-DPAKKR), have been developed (Fletcher et al. 2008; Fletcher and Hughes 2009), consisting of the cationic "Lys-Lys-Arg" motif shown to be required for the binding of BDNF to p75NTR (Ryden et al. 1995), presented in a highly conformationally constrained cyclic template. Like BDNF, cyclo-DPAKKR promotes the survival of embryonic chick sensory neurons in culture (Fletcher et al. 2008). However, its mechanism of action is distinct to BDNF, in that it does not cause TrkB autophosphorylation, nor does it lead to phosphorylation of MAPK, a downstream mediator of TrkB signalling, consistent with an effect through p75NTR (Fletcher et al. 2008). In addition, cyclo-DPAKKR has low molecular weight (580) and is highly resistant to proteolysis. These properties of cyclo-DPAKKR and analogues render them unique pharmacological tools to investigate the influence of selective modulation of p75NTR on PNS myelination.

Indeed, recent data indicate the effects that cyclo-DPAKKR exerts upon peripheral myelination are entirely consistent with it acting as a selective p75NTR activator: *promoting* the myelination of distinct subsets of DRG neurons in vitro and requiring neuronal expression of p75NTR. Importantly, local injection of cyclo-DPAKKR adjacent to the developing sciatic nerve in vivo also significantly enhanced myelin protein expression and increased the number of myelinated axons (Xiao et al. 2013). It was also identified that the promyelinating effect of cyclo-DPAKKR was coincident with an increase in the expression of neuregulin-1

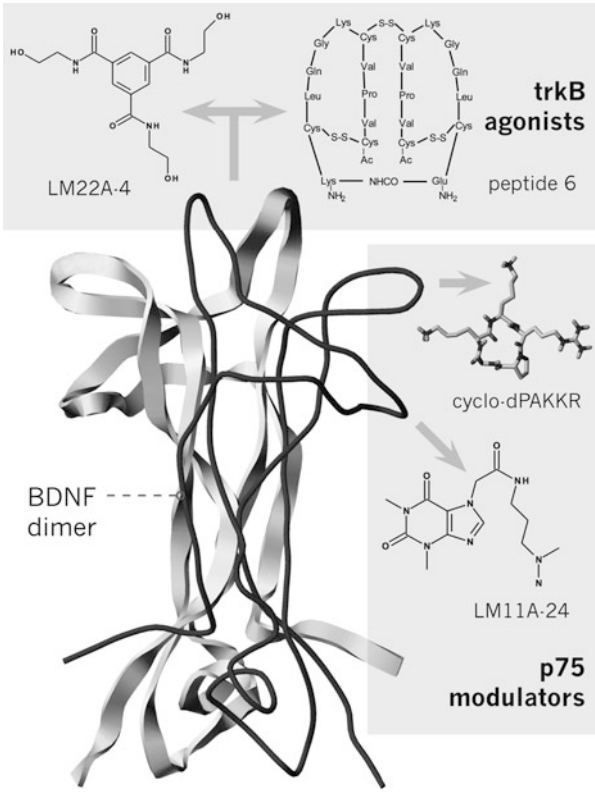

Fig. 3 Molecular structure of BDNF and mimetics. The central image is the three-dimensional structure of the BDNF dimer (*ribbon representation*). The TrkB agonists, mimicking the loop 2 region of BDNF, are shown above: LM22A-4 (Massa et al. 2010) and the tricyclic dimeric peptide 6 (O'Leary and Hughes 2003). The p75NTR modulators are shown to the right: cyclo-DPAKKR (3D depiction of an NMR-derived structure in solution; (Fletcher et al. 2008)) derived from loop 4 of BDNF and LM11A-24 (2D structure; (Massa et al. 2006)) derived from loop 1 of NGF (Images not drawn to scale)

type III which provides the key instructive axonal signal that initiates myelination (Michailov et al. 2004; Taveggia et al. 2005). Collectively, these data demonstrate that cyclo-DPAKKR promotes peripheral myelination in vitro and in vivo, suggesting it is a strategy worthy of further investigation for the treatment of peripheral demyelinating diseases.

Recently, Frank Longo's group described a tandem in silico and in vitro approach that leads to the identification of a novel p75NTR ligand, LM11A-24 (Massa et al. 2006). This small molecule, a derivative of caffeine that was selected as a mimic of loop 1 of NGF, has been found to inhibit Aß-induced neurodegeneration and synaptic impairment, block proNGF-induced cell death, and prevent the death of motor neurons in vitro (Pehar et al. 2006; Yang et al. 2008). As a putative selective p75NTR modulator, it would be interesting to investigate the effect that LM11A-24 exerts on Schwann cell myelination in vitro. In particular, it will be intriguing to see if it is able to uniformly promote myelin formation of distinct populations of DRG neurons in vitro and whether this influence can be replicated on peripheral myelin development in vivo. Ultimately, the logical extension of this approach would be to investigate whether both cyclo-DPAKKR and LM11A-24 have the ability to reduce the severity/promote remyelination in an animal model of peripheral nerve demyelination such as EAN.

4.2 Putative TrkB Agonists

In contrast to its apparent inhibitory influence upon PNS myelination, TrkB signalling has been shown to play a key role in promoting CNS myelination. Thus, the selective targeting of TrkB offers a potential means of promoting CNS remyelination. A version of the structure-based design approach has been used to obtain conformationally constrained, low molecular weight peptides that mimic solvent-exposed loop 2 of BDNF, the region involved in binding TrkB (Fig. 3). Using this approach, monomeric mimetics of loop 2 that act as TrkB antagonists (O'Leary and Hughes 1998) and dimeric mimetics of loop 2 that are highly potent putative TrkB agonists (O'Leary and Hughes 2003) have been successfully developed. Like BDNF itself, the putative TrkB agonists promote neuronal survival in cell culture (O'Leary and Hughes 2003). The best of these dimeric peptides, the conformationally constrained tricyclic dimeric peptide 6, is highly potent with an EC50 for the survival of sensory neurons in culture of 11pM (O'Leary and Hughes 2003), that is, the same order of magnitude as BDNF itself, despite being less than one-tenth the molecular weight of the parent protein.

Similarly, an in silico screen with a BDNF pharmacophore followed by low-throughput in vitro screening in mouse fetal hippocampal neurons led to the discovery of small molecules with nanomolar neurotrophic activity specific to TrkB, typified by LM22A-4 (Massa et al. 2010). LM22A-4 prevents neural cell death with an efficacy equal to BDNF in vitro and causes hippocampal and striatal TrkB activation and improved motor learning in an in vivo model of traumatic brain injury (Massa et al. 2010). It also improves functional recovery and increases neurogenesis following hypoxic-ischemic stroke (Han et al. 2012) and rescues TrkB phosphorylation and improves respiratory function in a model of Rett syndrome (Schmid et al. 2012). Together, these studies demonstrate the potential utility of BDNF – particularly its solvent-exposed loops – as a template for the discovery of novel low molecular compounds that mimic the action of the parent protein.

Adopting a distinct approach, 7,8-dihydroxyflavone was identified in a cell-based screen as a high-affinity TrkB agonist and provokes receptor dimerization, autophosphorylation, and activation of downstream signalling (Jang et al. 2010). Dihydroxyflavone protects neurons from apoptosis in vitro in a TrkB-dependent manner and is neuroprotective in several models of neuronal injury such as kainic acid-induced apoptosis, the transient MCAO occlusion model of stroke, and the MPTP model of Parkinson's disease. It also exerts positive influences in in vivo models of Rett syndrome (Johnson et al. 2012) and depression (Liu et al. 2010, 2012).

The discovery of these small molecules that function as specific TrkB ligands has made modulating selected components of neurotrophin signalling possible for the first time. As the selective modulation of TrkB could achieve more favorable effects than those mediated by BDNF, which also stimulates other neurotrophin receptors, these small molecules provide a potentially powerful therapeutic tool for the treatment of demyelinating disease. The scene is now set to examine the effects

that these compounds exert upon oligodendrocyte myelination in vitro and if successful to extend this work to identify whether they exert a protective influence in animal models of CNS demyelination.

4.3 Transactivation of Trk Neurotrophin Receptors by GPCR Ligands

One final strategy for the targeting of neurotrophin receptors lies in the discovery that Trk receptors can be transactivated by GPCRs (Lee and Chao 2001). Transactivation of receptor tyrosine kinases by GPCRs is now recognized as an important signalling mechanism allowing the cell to respond to a vast array of extracellular stimuli (Daub et al. 1996; Luttrell et al. 1999; Rajagopal et al. 2004). Both TrkA and TrkB receptors can be activated, in the absence of NGF or BDNF, via a GPCR-dependent mechanism. At least two GPCR ligands, adenosine and pituitary adenylate cyclase-activating peptide (PACAP), can activate Trk receptors to promote neuronal survival in vitro, an effect dependent upon Trk-mediated activation of Akt activity (Lee and Chao 2001; Lee et al. 2002; Rajagopal et al. 2004). The effect of adenosine and PACAP upon Trk receptor activation is unusual in that it displays very slow kinetics and selectively activates intracellular receptors. Nevertheless, this effect has been shown to be therapeutically relevant in vivo, as transactivation of the TrkB receptor by adenosine agonists promotes motor neuron survival after facial nerve lesioning (Wiese et al. 2007). While studies to date have focussed selectively on neuronal survival, in principle GPCR transactivation of Trk receptors could also exert a promyelinating influence, as not only is the Akt pathway activated by Trk receptors following transactivation but it is also implicated in promoting oligodendrocyte myelination (Lee and Chao 2001; Narayanan et al. 2009; Tyler et al. 2009). Thus, in the context of oligodendrocyte myelination, further studies are clearly warranted to investigate the influence that GPCR transactivation of Trk receptors exerts. However, for Schwann cell myelination the case is less clear, as in vitro studies have revealed that Trk receptor signalling in peripheral neurons exerts contrasting effects upon Schwann cell myelination and the signalling mechanisms that mediate these distinct responses have yet to be elucidated. In totality, a more complete understanding of the potential influences that GPCR transactivation exerts upon models of both central and peripheral myelination in vitro is required in order to establish an evidence-based rationale for future investigations aimed at determining the therapeutic potential of this mechanism of neurotrophin receptor activation.

5 Conclusion

It has proven useful to identify the precise influence and the cellular and molecular basis of how the neurotrophins regulate myelination in vitro. Based on these findings, it is now important to attempt to verify these conclusions through the specific conditional targeting of the neurotrophins and their receptors in vivo, in order to

develop a clear understanding of the key influences the neurotrophins exert upon myelination. Future studies aimed at identifying whether these mechanisms are relevant not only to development but also in the context animal models of demyelinating diseases will afford specific insight into potential therapeutic approaches that may effect remyelination. The fact that the neurotrophins can exert positive as well as negative influences on myelination in vitro highlights another challenge. However, the evolving development of small molecule neurotrophin mimetics that selectively target distinct neurotrophin receptors affords a degree of hope that ultimately evidence-based rational approaches that enhance these responses will provide therapeutic benefit in the context of human demyelinating disease.

Neurotrophic Factors and Ethanol Neurotoxicity

Margaret I. Davis

Contents

Abstract

Neurotrophins are essential for the growth, differentiation, and survival of neurons during development and in the adult. Considerable data have accumulated over the last few decades implicating classical neurotrophins, Nerve Growth Factor (NGF), Brain-Derived Neurotrophic Factor (BDNF), and Neurotrophins 3 and 4 (NT-3/4), in many aspects of ethanol addiction, neurotoxicity, and repair after ethanol withdrawal. Genetic screens in *Drosophila* have identified novel neurotrophic factors and signaling intermediates involved in acute tolerance and pharmacodynamic adaptation to prolonged exposure in rodent. Ethanol modulates neurotrophic factor expression in vivo in a time- and

region-specific fashion. Ethanol inhibits neurotrophin signaling acutely in vivo and in vitro in many brain regions. Conversely, acute and chronic ethanol exposure can upregulate neurotrophin-associated signaling pathways, particularly in brain nuclei associated with anxiety and addiction. Cell death induced by high concentrations of ethanol can be mitigated by exogenous neurotrophins indicating that neurotrophin induction in vivo may also be neuroprotective but ultimately fails over time. Neurotrophin levels in serum and plasma of patients with alcohol use disorders are dynamic and may serve as a surrogate for central nervous system levels. The kinetics suggest that increased levels during withdrawal may be involved in repair, but these analysis are complicated by genetic polymorphisms and the blood component analyzed, particularly with BDNF which is polymorphic in human populations and also produced by platelets. Neurotrophins are intricately involved in pharmacodynamic compensation with prolonged ethanol exposure, addiction-related plasticity, and neurotoxicity, but considerable work remains to be performed and replicated. Recent pharmacological advances targeting neurotrophins and neurotrophin signaling may ultimately be useful for treating ethanol-induced neurodegeneration and aberrant plasticity associated with addiction.

List of Abbreviations

AD	Alcohol dependence
ALK	Anaplastic lymphoma kinase
ARND	Alcohol-related neurodevelopmental disorders
BAC	Blood alcohol concentration
BDNF	Brain-derived neurotrophic factor
BFCN	Basal forebrain cholinergic nuclei
cAMP	3′-5′ cyclic adenosine monophosphate
ChAT	Choline acyltransferase
E	Embryonic
ERK	Extracellular signal regulated kinase
FAS	Fetal alcohol syndrome
GABA	Gamma amino butyric acid
GDNF	Glial-derived neurotrophic factor
GENSAT	Genetic nervous system Atlas
ICV	Intracerebroventricular
IGF	Insulin-like growth factor
JNK	Jun N-terminal kinase
MAPK	Mitogen-activated protein kinase
MSN	Medium spiny neuron
NAc	Nucleus accumbens
NGF	Nerve growth factor
NMDA	*N*-Methyl D-aspartate
NT	Neurotrophin
PACAP	Pituitary adenylate cyclase activating peptide

PI3K	Phosphatidyl inositol 3-OH-kinase
PKA	Protein kinase A
PKC	Protein kinase C
PN	Postnatal
RACK	Receptor for activated C kinase
Trk	Tropomyosin-related protein kinase
VTA	Ventral tegmental area

1 Introduction

The majority of heavy drinkers who consume ethanol daily for years to decades show some form of brain pathology either as a result of alcohol-associated neurodegeneration or secondary to nutritional deficiencies, vascular damage, and hepatotoxicity (see Harper 2009; Zahr et al. 2011; Welch 2011; de la Monte et al. 2012 for excellent reviews). Ethanol is even more detrimental to the developing fetus, with Fetal Alcohol Syndrome (FAS) and Alcohol-Related Neurodevelopmental Disorders (ARND) occurring at a combined rate of <0.7 % in the United States to as high as 5 % in places like South Africa with high per capita alcohol consumption (de Sanctis et al. 2011; May et al. 2009). Chronic and developmental ethanol exposure clearly causes neurodegeneration and cognitive deficits; therefore, it seems intuitive that factors which mediate neuronal survival would be involved in ethanol-induced neurotoxicity. In models of ARND/FAS and in the adult, neurotrophins play a role in cell death, aberrant synaptogenesis, perturbed migration, tolerance, and repair but may also regulate the selective plasticity that occurs with addiction (reviewed by Ghitza et al. 2010; Castren 2004). Whether neurotrophin expression is the result of or induces subsequent changes in synaptic activity is not always clear, but neurotrophins are integral to many ethanol-sensitive processes.

Neurotrophins are a family of proteins initially characterized for the ability to provide trophic support to developing neurons but also regulate synaptic plasticity and survival in mature neurons (reviewed by Reichardt 2006). Nerve Growth Factor (NGF) was the first neurotrophic factor described which supported the growth of chick sensory ganglia neurons (Levi-Montalcini and Cohen 1960). This was followed by isolation and cloning of a family of proteins that includes Brain-Derived Neurotrophic Factor (BDNF), Neurotrophin-3 (NT-3), and NT-4/5 in mammals and their respective Trk receptors (Leibrock et al. 1989; Klein et al. 1989; Lamballe et al. 1991; Maisonpierre et al. 1990b). Since these initial discoveries, many other factors have been isolated that are also trophic for neurons, but these factors do not contain regions of significant homology with the NGF family. Trophic factors explored in alcohol toxicology belonging to the latter group include Insulin-like Growth Factor 1 (IGF-1), Pituitary Adenylate Cyclase Activating Peptide (PACAP), and Glial-Derived Neurotrophic Factor (GDNF).

Classical neurotrophins of the NGF family are cysteine knot proteins that function as dimers. Neurotrophins are expressed as pro-proteins and cleaved to form active proteins, primarily through activity-dependent secretion and protease activation. Neurotrophins can be target-derived, transported trans-synaptically in a retrograde or anterograde direction, or signal through local mechanisms, depending on the brain region and neurotrophin (see Ginty and Segal 2002; Chowdary et al. 2012; Ascano et al. 2012 for reviews). Classical neurotrophins bind to Tropomyosin Related Kinase (Trk) receptors with picomolar affinity. TrkA is the full-length receptor for NGF, TrkB for BDNF and NT-4, and TrkC is the NT-3 receptor, although neurotrophins can bind other Trks with reduced affinity or differential coupling to signaling pathways (Schecterson and Bothwell 2010; Reichardt 2006). Trks also exist as splice variants that result in truncated receptors without signaling capacity, or with only the Shc binding domain (reviewed by Schecterson and Bothwell 2010). Trk receptors can also be transactivated by G protein–coupled receptors, adding further complexity to the signaling repertoire, potential for cell specific signals, and cross-regulation. Activation leads to dimerization and autophosphorylation of tyrosine residues in the full-length Trk receptors, creating docking sites for signaling intermediates (reviewed by Reichardt 2006). Modulation of signaling by ethanol exposure has been demonstrated for many of the major signaling pathways downstream of these trophic factors either individually, sequentially, or in parallel, including Extracellular signal Regulated Kinase (ERK), phosphatidylinositol 3-kinase (PI3K), phospholipase C, Protein Kinase C (PKC), small molecular weight GTPases, calcium, Nuclear Factor (NF) kB, and cyclic AMP (reviewed my Ron and Messing 2013). Neurotrophins are subject to activity-dependent, promoter-specific regulation and therefore regulated by synaptic activity, which is also directly regulated by ethanol exposure. In addition, novel and growth factor-convergent pathways have been identified in *Drosophila* that regulate ethanol sensitivity, tolerance, and toxicity that remain to be fully explored in mammalian systems (Devineni et al. 2011; Bhandari et al. 2009). Collectively, these data implicate neurotrophins as integral mediators that are regulated by, or regulate, nearly all neuronal processes, albeit with relative selectivity.

Classical neurotrophins also bind p75 with lower affinity, but pro-neurotrophins bind p75 with high affinity (reviewed by Koshimizu et al. 2009). p75 dimerized with sortilin family members to regulate Rho, NF-kB, and Jun N-terminal Kinase (JNK)-p53-Bax pathways, resulting in both survival and apoptosis (reviewed by Friedman 2010). Apoptosis through p75 is mediated by JNK while survival is signaled via NFkB in some cell types (Yeiser et al. 2004). p75 expression declines with age, indicating an active role in development. p75 can also dimerize with Trks to regulate activity, acting as dominant-negative receptors or enhancers of Trk signaling depending on the context, cell type, and neurotrophin concentration (reviewed by Schecterson and Bothwell 2010). For example, intracerebroventricular (ICV) injection of pro-NGF induces degeneration of the cholinergic system (Fortress et al. 2011) and mediates hippocampal growth cone collapse through p75-sortilin signaling to Trio-GEF-mediated Rac inhibition (Deinhardt et al. 2011).

Pro-BDNF and cleavage-resistant BDNF induce apoptosis and inhibit migration in cerebellar granule cells (Koshimizu et al. 2009, 2010). Cleavage-resistant pro-BDNF reduces cholinergic hippocampal innervation and hippocampal dendritic spines but does not appear to induce apoptosis in hippocampal neurons (Koshimizu et al. 2009, 2010). Pro-BDNF also mediates long-term depression (Woo et al. 2005). Thus, the maturation state of the neurotrophin, which is activity-regulated, may dramatically influence the receptor selectivity and the subsequent response of the cell.

This chapter will review the background on neurotrophin signaling, expression in animal models of ethanol exposure, and in patients with alcohol dependence. Each section will provide the necessary background information to evaluate the data. While not exhaustive in detail, these sections will provide references to the primary literature and more extensive reviews. Many studies differ in the presentation of dose or concentration and that should be considered. The LD50 for a single intraperitoneal dose of ethanol is ~3.5 g/kg for most mouse strains and range from less than 0.4 g/dL for some rat studies (Prado Carvalho and Izquierdo 1977) to as high as 7–9 g/kg in others (Material Safety Data Sheet). Concentrations are also given in percent (g/dL or mg/dL) or as millimoles per liter depending on the laboratory. Humans become unconscious at Blood Alcohol Concentrations (BACs) ~0.35 g/dL, and death is likely at concentrations ~100 mM or 0.5 g/dL. Therefore, LD50 should be considered in experimental situations where tolerance is not a factor. Besides the obvious complexities of dose, duration, tolerance, and withdrawal, several experimental caveats in inconsistencies must also be considered when reviewing 30 years of data speckled on a background of exponential scientific discovery and technological advances. These concerns will be addressed as they arise. Current data collectively suggest that work remains to be performed and replicated to gain a better understanding of how temporal changes in neurotrophin expression regulate, and are regulated by, physiological responses within the nervous system and how these influence neurotoxicity, plasticity, and repair after ethanol exposure.

2 Neurotrophin and their Receptors after Ethanol Exposure In Vivo: Animal Models

2.1 Nerve Growth Factor

2.1.1 NGF-TrkA Expression and Distribution

NGF was the first neurotrophin to be examined in models of alcohol-induced neurodegeneration and fetal alcohol syndrome. NGF is expressed in targets of sympathetic neurons and throughout the periphery, with high levels submaxillary gland, heart, prostate, stomach, endocrine system, skin, mast cells, intestine, spleen, lung, skin, and kidney (Korsching and Thoenen 1983; Heumann et al. 1984; Shelton and Reichchardt 1986). Within the CNS, NGF is trophic for Basal Forebrain Cholinergic Neurons (BFCN) where it upregulates choline acyltransferase (ChAT)

activity with an EC50 of ~3 ng/mL (Honegger and Lenoir 1982; Hefti et al. 1984; Mobley et al. 1986; Korsching et al. 1985). Functional studies and developmental expression indicate an essential role for NGF in hippocampal-dependent learning and expression of cholinergic markers in afferent structures (Conner et al. 2009; Conner and Varon 1997; Houeland et al. 2010). NGF also enhances communication between the nucleus basalis and the amygdala (Moises et al. 1995). Functional studies and the expression pattern implicate NGF as a candidate for modulation of ethanol-induced toxicity in the BFCN, hippocampus, and striatum, leading to cognitive deficits and addiction.

NGF mRNA expression (Fig. 1, Allen Institute) and GFP expression from the NGF promoter (Fig. 1, GENSAT) show the general distribution of NGF-producing cells in the adult mouse brain. Expression is sparse in comparison to BDNF shown in the adjacent panels. The highest level of NGF mRNA and protein is detected in the hippocampus within the mossy fiber terminal fields (hilus and stratum lucidum of CA3 and CA2) followed by cortex and olfactory bulbs (Fig. 1, Allen Institute and Gibbs et al. 1989; Maisonpierre et al. 1990a; Conner and Varon 1992; Altar et al. 1997; Conner and Varon 1997). Within the hippocampus, mRNA is localized primarily to interneurons of the hilus, but is also observed scattered in dentate granule cells, scattered interneurons within the CA fields, and interneurons in distal pyramidal cell synaptic fields after colchicine treatment (Ceccatelli et al. 1991). NGF mRNA is also detected in anterior olfactory nucleus, magnocellular preoptic nucleus, nucleus of the horizontal limb of the diagonal band, supramammillary nucleus, striatal interneurons, bed nucleus of the stria terminalis, ventral pallidum, mediodorsal thalamic nucleus, paraventricular hypothalamic nucleus, supraoptic nucleus, lateral and medial septum, substantia innominata, and nucleus basalis. Within the brainstem, NGF is localized to oculomotor, nucleus, facial nucleus, ambiguus nucleus, gigantocellular reticular nucleus, gigantocellular, reticular nucleus (alpha part), inferior olive, reticular nucleus, nucleus of the solitary tract, and vestibular nucleus (Maisonpierre et al. 1990a; Conner and Varon 1992; Altar et al. 1997).

The exact concentration of NGF (and all neurotrophins) in brain regions when measured by ELISA is variable due to extraction procedures, buffer composition, pH, fraction assayed, and the presence or absence of tissue homogenates in the standard curve (see Larkfors et al. 1987; Hoener et al. 1996; Fawcett et al. 1999; Zhang et al. 2000; Soderstom and Ebendal 1995; Whittemore et al. 1986). Calculated value from the studies cited above estimate NGF protein levels at (ng/g wet weight): hippocampus 1.34–6, cortex 0.57–3.5, olfactory bulb 0.85–5.3, basal forebrain 0.672–4.77, cerebellum 0.42–1.86 and striatum 0.16–1.0. Protein levels increase during development in the CNS with a peak that is approximately twice the adult level at postnatal day (PN)14 in cortex, PN14-21 in the striatum and BFCN, and PN7 in the cerebellum (Whittemore et al. 1986; Das et al. 2001; Mobley et al. 1986).

NGF is notoriously sensitive to fixation, pH, and post-fixation times; therefore, many studies purporting to measure NGF by immunohistochemistry may not be measuring NGF. Earlier studies discussed above are replicated in the mouse

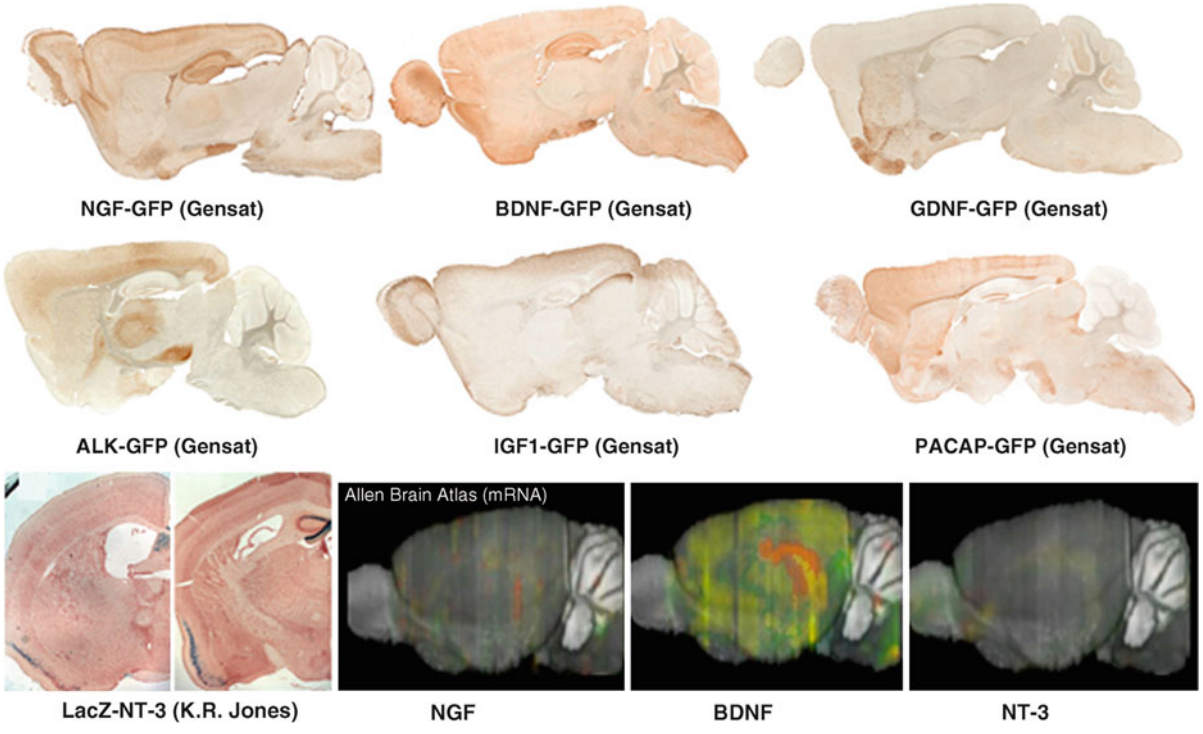

Fig. 1 Neurotrophic factor localization in the mouse brain using promoter-driven GFP expression and in situ hybridization. Immunohistochemistry for GFP in sagittal sections is shown for each neurotrophic factor to show the distribution of cells that produce the factors within the brain. Lac-Z expression from the NT-3 promoter in an adult mouse is shown in the *bottom left*. Rendered images from the Allen Brain Atlas mRNA series are shown for NGF, BDNF, and NT-3 in the *bottom row*. For more detail and immunohistochemical detection of each neurotrophin, see citations discussed in the text, GENSAT (www.gensat.org), and The Allen Brain Atlas (www.brain-map.org/) (Lac-Z images were generously provided by Dr. Kevin R. Jones and were generated as described in Vigers et al. [2000])

expressing GFP from the NGF promoter produced by GENSAT (Fig. 1). NGF immunoreactivity is particularly strong in hippocampal mossy fibers in mature and developing animals with transient production in other dentate lamina during development (Conner et al. 1992; Conner and Varon 1992, 1997). Cells in the stratum radiatum and stratum oriens contain NGF, while a few larger interneurons in the pyramidal cell layer contain NGF immunoreactivity (Conner and Varon 1992; Rocamora et al. 1996; Pascual et al. 1998). Cortical neurons immunoreactive for NGF were generally small (<12 um), but occasional NGF+ cells could be observed that were 13–17 μm in diameter, consistent with NGF expression primarily in interneurons (Conner and Varon 1992; Conner et al. 1992; Rocamora et al. 1996).

Regions of neurotrophin expression detected by mRNA frequently do not overlap with the protein distribution measured by immunohistochemistry. This is because NGF is produced in the target region or by local interneurons and retrogradely transported to the cell bodies of the "consumer" neurons (Seiler and Schwab 1984; Conner et al. 1992; Conner and Varon 1992). Colchicine treatment increases somatic immunoreactivity, allowing refined localization of NGF by allowing accumulation of protein in the cells that produce it and blocking retrograde transport to cells that stain for NGF because of uptake from postsynaptic sources. Under these conditions, NGF-expressing cells were detected in the olfactory bulb, tenia tecta, striatum, cortex, septum, BFCN, bed nucleus of the stria terminalis, diagonal band magnocellular preoptic region, ventral pallidum, and substantia innominata. Cholinergic cells with previous immunoreactivity in the septum and BFCN disappeared, thereby segregating the NGF "consumers" from "producers" (Conner and Varon 1992). Thus, many forebrain neurons will contain NGF protein but do not express NGF mRNA, instead obtaining NGF from cortical, hippocampal, and local interneurons (Conner et al. 1992; Conner and Varon 1992; Lauterborn et al. 1995; Whittemore et al. 1986). Similarly, much of the septal NGF is the result of retrograde transport from the hippocampus where it is expressed by cells in the target region for septohippocampal afferents (Conner and Varon 1992; Seiler and Schwab 1984). GFP expression from the NGF promoter also found NGF expression by Fananas astrocytes in the cerebellum and by cerebellar interneurons (Kawaja et al. 2011; GENSAT Fig. 1).

TrkA is widely expressed within the nervous system (see Sobreviela et al. 1994; Altar et al. 1991; Cohen-Cory et al. 1989 for detailed anatomy), including neurons of the striatum, ventral premammillary nucleus, mesencephalic trigeminal nucleus, vestibulocochlear ganglion, prepositus hypoglossal nucleus, raphe nucleus, nucleus ambiguus, glomeruli of the olfactory bulb, area postrema, and nucleus tractus solitarius. TrkA is not present in hippocampal pyramidal cells but is expressed by hippocampal interneurons. The suprachiasmic nucleus, olivary pretectal nucleus, and spinal trigeminal nuclei only contain TrkA immunoreactive fibers. TrkA immunoreactivity is also detected in the leptomeninges, ventricles, and ependymal cells (Gibbs et al. 1989). Iodinated NGF binding is highest in the interpeduncular nucleus and spinal trigeminal tract followed by striatum (higher in lateral striatum), amygdala, diagonal band, nucleus accumbens (NAc), olfactory tubercle, cerebellum, hippocampus, cortex, and subiculum. p75 is notably absent from striatal

cholinergic neurons that express TrkA (Sobreviela et al. 1994). Conversely, TrkA is not generally detected in mature cerebellar Purkinje cells that express p75 (Sobreviela et al. 1994; Larkfors et al. 1987, 1996). However, GFP expressed from the TrkA promoter does label a subset of Purkinje cells developmentally, suggesting that some transiently express TrkA. Interestingly, p75 regulates autophagy in Purkinje cells (Florez-McClure et al. 2004). NGF is also trophic for cholinergic interneurons of the striatal matrix in vivo (Van Vulpen and Van Der Kooy 1999) and in vitro (Studer et al. 1994) but has no effect on the survival of striatal medium spiny neuron (Ventimiglia et al. 1995), Purkinje cells (Larkfors et al. 1996), or hippocampal pyramidal cells (Ip et al. 1993).

Genetic deletion of NGF reduces acetylcholine esterase, causes a loss of sympathetic preganglionic neurons, reduces cholinergic septal and striatal neurons, leads to atrophy of BFCNs, and reduces hippocampal innervation by cholinergic afferents (Smeyne et al. 1994; Sanchez-Ortiz et al. 2012), while overexpression of NGF increases the size of septal neurons (Kawaja et al. 1998) and increases cholinergic neuron number and size without altering the innervation of the hippocampus (Fagan et al. 1997; Kawaja et al. 1998). Trk A knockout mice die by 1 month of age, exhibiting severe sensory neuropathies with smaller trigeminal, sympathetic, and dorsal root ganglia (Smeyne et al. 1994).

2.1.2 Ethanol and NGF Expression in Animal Models

NGF levels are sensitive to dose, duration, and withdrawal state, suggesting a dynamic role for NGF (and all neurotrophic factors) in intoxication, tolerance, and toxicity. Ethanol administered acutely via liquid diet causes an increase in NGF and TrkA protein and mRNA in the cerebellum (Wang et al. 2010). Chronic exposure via drinking water also produced a transient increase in NGF in the hippocampus, septum, striatum, cortex, BFCN, and olfactory bulbs (Gericke et al. 2006). After 9 months of exposure, there was a slight reduction in cortical NGF, but no differences in the other regions examined. Shorter exposures (2–4 weeks) of ethanol increased NGF in hippocampus and cortex with a return to control values after 3 months of ethanol exposure (Nakano et al. 1996). Chronic intermittent exposure produced an increase in hippocampal NGF protein levels (Miller 2004), but, in contrast to Gericke and colleagues, chronic exposure for 8 or 24 weeks reduced NGF in most cortical regions cortex and basal forebrain at most time points (Miller and Mooney 2004). Chronic ethanol exposure via liquid diet also reduced TrkA mRNA in the basal forebrain (Miller et al. 2002) and NGF can induce TrkA expression (Holtzman et al. 1992), suggesting failure of NGF to signal with chronic exposure. Combined with reduced basal forebrain TrkA (Miller et al. 2002), this increase in cortical and hippocampal NGF may reflect failure of NGF to transport or a neuroprotective induction that eventually fails with prolonged exposure. In contrast to chronic forced exposure, no differences in striatal NGF levels were observed by McGough and colleagues (2004) after 4 weeks of drinking using the 2 bottle choice model, suggesting some selectivity, depending on the model. The reason for these differences is unclear but may be the result of differential neurotoxicity, the choice to drink, or other environmental factors.

Bruns and Miller (2007) also observed an increase in NGF in the somatosensory cortex in layer V pyramidal cells, not interneurons, with repeated episodic exposure that correlated with the duration of exposure. NGF is generally not generally observed in pyramidal cells (Conner et al. 1992; Conner and Varon 1992; in contrast, see Pitts and Miller 1995; Pitts and Miller 2000), and only pyramidal cells were shown in the micrographs presented by Bruns and Miller; therefore, it is uncertain whether it is ethanol-specific ectopic expression, different pools of NGF, cellular uptake, or resulting from fixation procedures that were significantly different from Conner and colleagues (See Conner 2001 for detailed methods).

While the induction of NGF (i.e., Miller 2004; Gericke et al. 2006; Wang et al. 2010) may correlate with protective capacity and plasticity at early time points, many reports agree that long-term exposure to ethanol decreases NGF levels in the mature rodent hippocampus and cortex (De Simone and Aloe 1993; Aloe et al. 1993; Miller and Mooney 2004; Gericke et al. 2006). Furthermore, reduced hippocampal NGF after prolonged ethanol exposure is associated with atrophy cholinergic cells in the medial septum; similarly reduced cortical levels are associated with atrophy of septal neurons (De Simone and Aloe 1993; Aloe et al. 1993; Arendt et al. 1988; Cadete-Leite et al. 2003; Ehrlich et al. 2012). This atrophy and reduced NGF are accompanied by reduced ChAT activity in the hippocampus, septum, and striatum, which can be reversed by administered of NGF via osmotic pump (Cadete-Leite et al. 2003).

NGF-sensitive cells in the developing BFCNs and striatum show transient sensitivity to ethanol that parallel observations in the adult with variable resiliency. Initial studies used chick embryos to show that ethanol was toxic to cholinergic neurons, which was reversed by NGF, and established a window of vulnerability for these neurons (Rahman et al. 1993; Brodie and Vernadakis 1992). A similar window may exist in rodents; a single binge exposure on E15 resulted in a transient increase in hippocampal NGF at PN15 followed by a decline below control values in adulthood and parallel changes in ChAT (Angelucci et al. 1997, 1999).

Rats exposed prenatally to ethanol throughout gestation also have a transient reduction in ChAT activity in the BFCN, striatum, cortex, hippocampus, and septum neonatally (Swanson et al. 1995, 1996; De Simone and Aloe 1993; Fiore et al. 2009a, b). Reversal was associated with an increase in hippocampal NGF (transiently at PN7 and robustly at PN21) and repair in some studies (Heaton et al. 1996). In contrast, others (De Simone and Aloe 1993; Tsuji et al. 2008; Fattori et al. 2008) did not detect any differences in NGF in cortex with prenatal or postnatal exposure but reported a transient decrease in NGF in the hippocampus at PN7 that correlated with reduced cholinergic activity. Similarly, constant gestational exposure to ethanol (but not wine) reduced hippocampal and cortical NGF (Fiore et al. 2009a, b). This was correlated with a reduction in cholinergic neurons in the septum. The survival of cholinergic neurons and NGF induction differs with exposure paradigms, but each outcome is associated changes in NGF levels correlated with cholinergic neuron activity. Whether repair succeeds or fails may depend on the dose and duration of exposure, with binge exposure at a defined window being more toxic to developing BFCNs. As with the pattern in the adult where the ability to

upregulate NGF with intermittent exposure may be protective, variability in these data may be the result of the populations that survive the insult and their ability to produce NGF.

NGF levels are acutely increased in the cerebellum in mature mice by ethanol, suggesting a role in adaptation or repair (Wang et al. 2010), but NGF-ethanol interactions have primarily been addressed in the developing cerebellum. Cerebellar Purkinje cells are particularly vulnerable to ethanol toxicity during the first postnatal week but resistant to ethanol-induced cell death during the second postnatal week (West 1993), a period that coincides with the rise to the peak of developmental NGF expression (Das et al. 2001; Maisonpierre et al. 1990a). High dose ethanol (6.6 g/kg/day, peak BAC 336 mg/dL, cyclic exposure) PN4-10 via artificial rearing did not change NGF levels as detected by ELISA in neonatal cerebellar homogenates but reduced both p75 and TrkA in Purkinje cell dendrites and in cerebellar homogenates (Dohrman et al. 1997; also see Moore et al. 2004a). When this window was further subdivided, Heaton and colleagues (2003) found a transient reduction in NGF only when animals were exposed to ethanol at PN4 (correlating with the developmental period when Purkinje cells are sensitive to ethanol) but an increase at PN7 immediately after exposure and a delayed decrease at 12 h. Surprisingly, exposure on PN7-8 did not change NGF levels, suggesting some form of compensation with prolonged exposure, as was noted in the cholinergic populations. (The levels reported in this study (2003c) are two orders of magnitude greater than previously reported by this lab (i.e., Heaton et al. 2000c) and higher than classical reports. It is possible that this is calculation error, but no correction has been issued.) Furthermore, NGF overexpression from the GFAP promoter rescued Purkinje cells from ethanol toxicity in the neonatal cerebellum without hypertrophy (Heaton et al. 2000b). Purkinje cell number was slightly reduced in the control transgenic mice, suggesting that NGF overexpression alone in a non-activity dependent way may reduce Purkinje cell viability since hypertrophy resulting in fewer neurons per area is excluded but this was not evaluated. NGF overexpression induces aberrant cholinergic sprouting in the cerebellum that might also contribute to the increased survival in this paradigm through cholinergic systems positively coupled to survival pathways and independent of direct NGF effects on Purkinje cells (Kawaja and Crutcher 1997). Furthermore, the locus of NGF action in these studies has not been adequately established and again may suggest robust, dynamic changes in interneurons (Kawaja et al. 2011) or cerebellar afferent fibers since which then modulate Purkinje cell activity. Purkinje cells have not traditionally shown TrkA-mediated survival (Sobreviela et al. 1994; Larkfors et al. 1996) but this does not exclude a role for p75.

Upregulation of NGF at earlier time points after withdrawal or from low levels of ethanol may represent an attempt to compensate for the effect of ethanol on synaptic transmission that fails as producer neurons degenerate. Alternatively, the NGF measured may represent increased pro-NGF, leading to neurodegeneration. In addition, the effect of ethanol on the NGF system specifically in hippocampal and cortical interneurons has not been selectively evaluated in this context, but collectively these data suggest that interneurons may be a central mediator of

ethanol effects on NGF-mediated processes, perhaps secondary to reduction in synaptic activity, or death, with prolonged ethanol exposure. As discussed above, neurotrophic activity cannot be examined independent of the chronic and pharmacodynamic effects of ethanol on neural activity and circuit function.

2.1.3 NGF and In Vitro Models of Ethanol Exposure

Cell culture models have provided insight into ethanol pharmacology and toxicology, but many of the in vitro studies discussed below require supraphysiological concentrations of ethanol to induce cell death. These concentrations are generally more than 100 mM or 0.4 g/dL. Many dose–response curves in the studies discussed below range from 0.4 to 6 g/dL and require high concentrations of ethanol to decrease neurite outgrowth and induce cell death. Ethanol impairs neuronal function in vivo at much lower concentrations; therefore, the events leading to cell death in vivo are possibly more subtle, linked to developmental events such as migration and synaptogenesis, may be distinct from the overt toxicity observed over 24–48 h in vitro, and take longer to develop. Therefore, cell death may not be the result of immediate toxicity but may occur secondary to more subtle impairment in the developmental program that leads to cell death at a later developmental stage as the result of aberrant synapse formation or impaired migration. This caveat applies to similar sections on direct toxicity throughout this chapter.

As the prototypic neurotrophin, NGF was the first to be examined for direct modulation of ethanol toxicity in vitro. Chick sympathetic ganglia developed fewer neurites in response to ethanol in combination with NGF in vitro (Dow and Riopelle 1985) and impaired development of NGF-supported structures in ovo that could be reversed by exogenous NGF (Brodie et al. 1991; Brodie and Vernadakis 1992; Rahman et al. 1993). Dow and Riopelle (1985) used ethanol at concentrations ranging from 0.01 to 0.25 g/dL and evaluated neurite formation as a measure of toxicity but found no evidence for cell death at these concentrations. Follow-up in vitro studies replicated the decrease in neurites but extended the concentrations to include doses up to 6 g/dL (Heaton et al. 1993). Ethanol (0.25 g/dL) combined with NGF caused a slight (∼20 %) increase in processes in this model but higher concentrations reduced process formation and concentrations above 5 g/dL were required to kill dorsal root ganglia neurons. Similarly, cell death in cultured hippocampal and septal neurons did not occur at concentrations below 2.4 and 1.8 g/dL, respectively (Heaton et al. 1994). NGF was protective against toxicity, even at these extreme concentrations. When cultures were prepared from embryos exposed to ethanol in vivo, they were resistant to cell death at 1.8 g/dL but not 2.4 g/dL (Heaton et al. 1995), suggesting that exposure to ethanol increased resistance to subsequent exposure. In cortical organotypic cultures, NGF has region-specific effects, with neuroprotection only evident within the lower cortical layer developmentally (Mooney and Miller 2007). NGF-mediated neuroprotection is more dramatic in dispersed cultures of cortical, hippocampal, and cerebellar granule neurons (Heaton et al. 2000a; Mitchell et al. 1998; Seabold et al. 1998; Luo et al. 1997; Bonthius et al. 2003), although pyramidal cells and cerebellar granule cells do not respond to NGF through TrkA (Ip et al. 1993; Collazo et al. 1992;

Segal et al. 1992; Barker-Gibb et al. 2001; Courtney et al. 1997; Nonomura et al. 1996; Larkfors et al. 1996). These effects may instead be mediated by p75 in granule cells (Courtney et al. 1997). Alternatively, this may also be due to the relatively high concentration of NGF used, which can nonspecifically activate other Trks. While many neurotrophins are capable of increasing survival in ethanol-exposed cultures, some may be increasing baseline survival without a specific protective effect from ethanol (Bonthius et al. 2003).

PC-12 cells, an immortalized pheochromocytoma cell line with sympathetic neuron-like properties, express TrkA and show enhanced neurite formation, increased microtubule content, and enhanced differentiation in response to 100 mM ethanol (~0.48 g/dL) and NGF (Wooten and Ewald 1991; Messing et al. 1991; Roivainen et al. 1993; Roivainen et al. 1995). Enhancement was not seen with forskolin and ethanol, but FGF-induced neurite outgrowth was enhanced (Messing et al. 1991). This was accompanied by an increase in Thy-1 expression and subsequently determined to be mediated by PKC- and ERK-dependent pathways (Roivainen et al. 1993, 1995). PKC epsilon, a calcium-independent PKC isoform, was shown to mediate this enhancement of ERK (Hundle et al. 1997), while PKC delta, not epsilon, is responsible for the increase in polymerized microtubule content (Reiter-Funk and Dohrman 2005). Interestingly, PKC epsilon can induce neurite formation independent of catalytic activity (Zeidman et al. 1999) and inactive kinase induces more neurites than wild type PKC epsilon (Ling et al. 2004). Cell cycle arrest and enhanced differentiation were also observed in PC-12 cells, as determined by an increase in neuron-specific enolase expression, a decrease in ^{3}H-thymidine incorporation, and increased acetylcholine esterase expression with 87 mM ethanol in combination with NGF (Wooten and Ewald 1991). NGF-differentiated PC-12 cells are less sensitive to ethanol-induced cell death in the absence of serum (Oberdoerster and Rabin 1999) and, when specifically induced to differentiate with NGF, became less sensitive to ethanol inhibition of calcium channels (Mullikin-Kilpatrick and Treistman 1995). Therefore, ethanol causes cell cycle arrest and cell death in mitotic PC-12 cells, but once induced to differentiate by NGF, the signaling to ERK is enhanced by ethanol and neurite formation is enhanced, potentially protecting the cell from toxicity but with a potentially detrimental outcome if this were to occur in differentiating neurons.

Recent work using explant cultures of the nucleus basalis suggests more subtle effects than cell death in cholinergic neurons in response to ethanol (Ehrlich et al. 2012). Ethanol reduced ChAT immunoreactivity in neonatal explants without causing cell death or inflammatory cytokine induction which was reversible upon withdrawal. NGF (10 ng/mL) reversed the 100 mM ethanol-induced reduction in ChAT but did not reverse the reduction observed with 50 mM ethanol. Induction of trophic factors with the lower concentration could occlude an NGF effect since NGF was used near the EC50 in these experiments. Perhaps the ability of the cells to produce their own trophic factors is impaired at 100 mM, unmasking the effect. Furthermore, Erlich and colleagues implicate the nitric oxide synthase-p38 MAPK pathway in the reduction in ChAT with both 50 and 100 mM ethanol. These are

intriguing findings and support a role for NGF in repair after prolonged (7 days) ethanol exposure. The time course of NGF inductions varies significantly between studies and duration of ethanol exposure, but collectively, these data suggest induction of NGF that may mitigate some of the toxic effects of ethanol. NGF can be trophic, but if it is induced without concurrent neuronal activity and not cleaved, then pro-NGF can signal cytoskeletal changes or apoptosis through p75. Replicative experiments could focus on determining levels of pro and mature NGF, take advantage of newer technologies to determine the contribution of ethanol-induced changes in NGF and NGF signaling in survival, adaptive plasticity, addiction, and apoptosis.

2.1.4 NGF in Patients with Alcohol Dependence

Genetic polymorphisms and haplotypes in neurotrophins and their receptors in psychiatric and neurodegenerative disorders is an area of active research. The role of neurotrophin polymorphisms in neuropsychiatric disorders is controversial, and many initial association studies were not replicated. Others have reported no association with the underlying disorder but instead indicate a role for genotype in response to treatment (see Table 1). A few definitive associations of neurotrophin mutations with overt neurological disorders have been made, while most associations are weak or only relevant in subsets of patients. This applies to BDNF and other neurotrophic factors as well. Mutations and polymorphisms in NGF or TrkA have been associated with cancer (Scaruffi et al. 1999; George et al. 1998), hypertension (Kapuscinski et al. 1996), Alzheimer's disease (Di Maria et al. 2012; Nagata et al. 2011), anxiety (Lang et al. 2008), white matter structure (Braskie et al. 2012) and congenital insensitivity to pain (Mardy et al. 2001); however, unlike BDNF, no genetic associations with NGF polymorphisms have been reported with alcohol dependence.

Neurotrophins can be measured in the periphery and may be proportional to central levels as well as a surrogate for sympathetic dysfunction and peripheral neuronal activity. Table 1 details measurements of plasma and serum neurotrophin levels in patients with alcohol dependence and during withdrawal. The majority of the reports detailed in Table 1 indicate that ethanol increases peripheral NGF, regardless of the source (plasma vs. serum), in patients still drinking and during early withdrawal (Aloe et al. 1996; Lee et al. 2009; Heberlein et al. 2008; Jockers-Scherubl et al. 2007). NGF levels were found to be an order of magnitude higher in patients that had previously suffered delirium tremens and were not correlated with Korsakoff's Syndrome (Jockers-Scherubl et al. 2007). NGF levels decline toward normal during prolonged withdrawal but remain elevated for as long as 8 months (Aloe et al. 1996; Heberlein et al. 2008; Jockers-Scherubl et al. 2007). Furthermore, downregulation of NGF toward control levels was associated with methylation of the NGF promoter (Heberlein et al. 2011). In contrast, Yoon and colleagues (2006) reported decreased NGF after only 3 months of withdrawal. Ethanol produced a more dramatic decrease in NGF in patients with a family history of alcohol dependence. The patient demographics may contribute to these disparate

observations. Patients were European in the first three studies, while the patients were Asian in the Yoon study and the control population varied by 11 years in age. While peripheral sources, concurrent anticonvulsant therapy, and systemic inflammation contribute to serum and plasma NGF levels, these do not appear to be significant covariates when measuring NGF levels in alcohol-dependent patients, nor does the blood component assayed. The well-established association between

stress and peripheral NGF levels (reviewed by Berry et al. 2012) also provides an intriguing link to alcohol dependence and NGF induction. The relative consistency among these studies implies global effects involving elevated NGF in homeostasis, withdrawal hyperexcitability, and repair after prolonged alcohol exposure that parallel observations in rodent models.

2.2 BDNF

2.2.1 BDNF-TrkB Expression and Distribution

While BDNF was the second neurotrophin to be characterized, BDNF distribution and functions are more widespread than NGF. Figure 1 shows the wide distribution of BDNF promoter–driven GFP expression and mRNA in the mature mouse. BDNF expression is regulated by multiple promoters that are differentially methylated and transcribed developmentally, regionally, by activity, pathologically, and upon exposure to xenobiotics (Pruunsild et al. 2007; Aid et al. 2007; Timmusk et al. 1993). BDNF mRNA targeting and translation are also regulated by 5′ and 3′ UTR sequences (Tongiorgi et al. 2006). BNDF expression level coincides developmentally with synaptogenesis and begins weakly at E13 in the brain (reviewed by Bartkowska et al. 2010). Levels of BDNF remain low until the second postnatal week which coincides with a peak in apoptosis for many structures (Das et al. 2001; Maisonpierre et al. 1990a; Katoh-Semba et al. 1997). BDNF levels are highest in the hippocampus (5.4 ng/g wet weight) followed by hypothalamus (4.33). All other brain regions contain less than 1.5 ng/g wet weight.

BDNF is expressed at high levels by cells in the cortex and hippocampus but is notably absent in the striatum, NAc, and striatal-derived amygdaloid structures (see Maisonpierre et al. 1990a; Ernfors et al. 1990a, b; Conner et al. 1997; Altar et al. 1997 for detailed expression and anatomy). Within the hippocampus, CA3 pyramidal cells and granule cells show the highest mRNA expression with lower expression in CA1 while hilar polymorph cells produce moderate levels of BDNF. BDNF-immunoreactive fibers populate the hippocampal strata oriens, radiatum, lucidum, and lacunosum moleculare, avoiding the stratum pyramidale. High levels of BDNF mRNA are also detected in the thalamus while both immunoreactive fibers and cell bodies containing mRNA are detected in the cortex, septum, BFCN, and the lateral and basal nuclei of the amygdala (Altar et al. 1997; Conner et al. 1997). As with NGF, BDNF is often synthesized in one area and transported, frequently anterograde (Conner et al. 1997; Altar et al. 1997; Li et al. 2012), but also retrograde as is observed in cerebellar granule cells (Bhattacharyya et al. 1997). Notable in addiction research, the medial habenula, striatum, NAc, central amygdala, and bed nucleus of the stria terminalis do not contain significant amounts of BDNF mRNA detected by in situ hybridization or BDNF-immunoreactive cell bodies but contain BDNF-immunoreactive fibers and cells expressing TrkB, consistent with anterograde transport to these (and other) regions (Altar et al. 1997; Conner et al. 1997; Baquet et al. 2004; Li et al. 2012),

The BDNF receptor TrkB is a family of proteins with thirty-six potential splice variants (Luberg et al. 2010), three of which have been well-characterized. TrkB.FL refers to the full-length receptor with tyrosine kinase activity. TrkB-Shc is truncated but retains Shc binding and coupling to the ERK and PI3K pathways. The truncated TrkB.T1 lacks tyrosine kinase activity and was thought to serve as a "decoy" to sequester and inhibit BDNF signaling, but TrkB.T1 coupling to Rho also regulates cytoskeletal dynamics (reviewed by Fenner 2012). TrkB splice variants are also believed to differentially regulate signaling intermediates, with full-length TrkB coupling to transcription through CREB and truncated variants signaling to the cytoskeleton. Both full-length and TrkB.T1 receptors are expressed throughout the brain, but the full-length receptor is exclusively associated with neurons, while TrkB.T1 is expressed by neurons, glia, choroid plexus, and ependymal cells (Altar et al. 1994). Iodinated BDNF and NT-4/5 binding sites were widely distributed similar to in situ hybridization (Altar et al. 1994). The highest levels of TrkB are in hippocampus, cerebellum, and cortex. Diencephalic, hypothalamic, and midbrain monoaminergic neurons express TrkB, and BDNF increases neurotransmitter synthesis and survival in these cells (Altar et al. 1992, 1994; Madhav et al. 2001; Akbarian et al. 2002; Baquet et al. 2004). TrkB is expressed on the majority of mesencephalic dopaminergic neurons, while many of these neurons also produce BDNF (Li et al. 2012; Numan and Seroogy 1999).

Homozygous BDNF knockout mice are not viable and die as neonates. Heterozygous mice exhibit a motor/balance phenotype by 2 weeks of age due to loss of vestibular ganglia (Klein 1994; Ernfors et al. 1994a; Jones et al. 1994). TrkB knockout mice do not eat and also die at birth (Klein et al. 1992). Reduced BDNF impairs taste (Liebl et al. 1997), resulting in abnormal appetitive behaviors in BDNF haploinsufficient mice (Kernie et al. 2000; see Krimm 2007) and, while controlled for and not observed in all experimental cohorts (Hensler et al. 2003; McGough et al. 2004), could contribute to increased alcohol consumption by BDNF haploinsufficient mice in some substrains. Deletion of BDNF also reduces neuropeptide expression in cortical interneurons but does not decrease parvalbumin- and NPY-expressing interneuron numbers (Jones et al. 1994). Recent work has employed region-specific Cre-recombinase-mediated gene deletion strategies and drug-inducible promoters to circumvent the developmental lethality of the full knockout. Combined, both of these strategies validate that deletion of, or reduction in, BDNF impairs hippocampal function, decreases striatal neuron survival, decreases spine density, and induces hyperactivity and hyperphagia (Lyons et al. 1999; Kernie et al. 2000; Rios et al. 2001; Zorner et al. 2003; Gray et al. 2006; Gorski et al. 2003; Li et al. 2012; Baydyuk et al. 2011). Cortex-specific and nigra-cortex double deletion of BDNF causes degeneration of striatal medium spiny neurons due to the loss of anterograde trophic support (Baquet et al. 2004; Strand et al. 2007; Li et al. 2012). Selective deletion of TrkB from medium spiny neurons impairs motor function, reduces striatal volume, MSN size, spine density, and impairs MSN dendritic development that is accompanied by a reduction in dopaminergic innervation (Baydyuk et al. 2011; Li et al. 2012). Interestingly, a human mutation in the TrkB gene is associated with developmental delay and severe obesity, a phenotype quite similar to the deficient mice (Yeo et al. 2004).

2.2.2 BDNF and Ethanol in Animal Models

A detailed review of ethanol and BDNF interactions in addiction and anxiety was recently published (Davis 2008); therefore, this section will concentrate on toxicity and recent controversial reports. BDNF has been extensively studied in the mature brain after acute and chronic ethanol exposure, but the results have varied significantly, often with disparate results in the same species, with the same exposure paradigm and over the same time course. For example, a few studies report no change in hippocampal BDNF levels (Miller et al. 2002; Okamoto et al. 2006), while most find a decrease in hippocampal BDNF with chronic exposure (MacLennan et al. 1995; Miller and Mooney 2004; Tapia-Arancibia et al. 2001; Hauser et al. 2011; Rueda et al. 2012). Still others report a transient increase in hippocampal BDNF with shorter exposure models (Kulkarny et al. 2011; Kalev-Zylinska and During 2007; McGough et al. 2004) and others see increased BDNF during withdrawal (Tapia-Arancibia et al. 2001) or with chronic intermittent exposure (Miller 2004). Disparate results were observed in BDNF mRNA in the hippocampus with intraperitoneal injection, the simplest of exposure paradigms. McGough and colleagues (2004) found an increase at 30 min while Raivio and colleagues (2012) examined levels at 3 h, implicating time as a factor; however, McGough did not observe a change in BDNF mRNA at this time point but found a reduction at 24 and 48 h. Raivio and colleagues conversely did not observe any differences in hippocampal BDNF at 24 h. Much of the discordant data are clustered around the acute time course as most studies agree that doses and exposure times sufficient to cause degeneration decrease BDNF but periods of withdrawal with intermittent exposure may be associated with attempts at repair (Miller 2004). These disparate results are observed in the same brain region and over the same time course, but collectively suggest that BDNF induction eventually fails in the hippocampus with prolonged exposure while upregulation during withdrawal may contribute to excitotoxicity and withdrawal-associated seizures.

Observations are inconclusive in other regions as well. Both increased and decreased BDNF protein levels have been observed in the cortex after chronic ethanol exposure and vary with region and pattern of exposure (Pandey et al. 1999; Miller and Mooney 2004; Miller 2004; Rueda et al. 2012). BDNF protein and mRNA levels in the cerebellum are acutely reduced by ethanol (Wang et al. 2010). BDNF mRNA levels in amygdala and NAc were also acutely reduced in rats after a single intraperitoneal dose of 2.5 g/kg of ethanol (peak BAC 58 mM); levels remained reduced in the frontal cortex at 24 h but returned to control values in the amygdala and hippocampus. The acute phase of this response is consistent with a decrease in excitatory transmission. BDNF mRNA in the NAc was initially reduced but increased in the ventral tegmental area (VTA) at 3 h, rebounding to increase at 24 h in both structures (Raivio et al. 2012). Kerns and colleagues (2005) also observed an increase in BDNF in NAc by microarray with acute exposure that was mouse strain specific. The acute increase in the VTA could result from direct excitation, reduced inhibition, or accumulation of mRNA that fails to transport but suggest that the VTA may be a source for accumbal BDNF mRNA levels since cortical levels remained lower. Microarray analysis also identified BDNF as a gene

with reduced expression in the prefrontal cortex after chronic intermittent ethanol exposure (Melendez et al. 2012). Interestingly, the array analysis also detected increased Oprl1 and extensive modulation of mRNA species belonging to the actin dynamics and MAPK signaling nodes consistent with a pharmacodynamic process. Consistent with a decrease in cortical BDNF mRNA, Bosse and Mathews (2011) measured BDNF protein levels in the striatum after acute ethanol exposure in both wild type and BDNF haploinsufficient mice. Both exhibited a decrease in BDNF; furthermore, the deficient mice did not respond to ethanol with a robust increase in dopamine when measured by in vivo microdialysis.

This is in contrast to work from the Ron/Janak laboratory that did not detect changes in cortical or NAc BDNF with acute exposure or self-administration (Logrip et al. 2009; McGough et al. 2004). Hippocampal BDNF was also elevated by ethanol through a Receptor for Activated C Kinase (RACK1) dependent pathway after both acute and prolonged (4 weeks) ethanol exposure (McGough et al. 2004; Jeanblanc et al. 2009, 2006; He et al. 2010). The data contrast the observations discussed above in extended striatum, implicating an acute increase in dorsolateral striatal BDNF that is negatively correlated with ethanol consumption (McGough et al. 2004; Logrip et al. 2009; Jeanblanc et al. 2009). This is supported by the observation that BDNF haploinsufficient mice voluntarily consume more ethanol than wild type litter mates, but these cohorts do not exhibit generalized hyperphagia, as discussed above (Hensler et al. 2003; McGough et al. 2004). Furthermore, viral mediated expression of BDNF siRNA in the dorsolateral striatum clearly transduced medium spiny neurons identified with GFP and replicated the phenotype of increased drinking (Jeanblanc et al. 2009). RACK1 mediated the ethanol-induced BDNF expression since Tat-RACK1 administration increased BDNF, reduced ethanol intake through TrkB, and reversed the phenotype in haploinsufficient mice when administered in the dorsolateral striatum (McGough et al. 2004; Jeanblanc et al. 2006). BDNF induction by ethanol was also observed in vitro with immunofluorescence in striatal neurons (Logrip et al. 2008), neuroblastoma cells (He et al. 2010), and in hippocampal pyramidal cells (McGough et al. 2004; He et al. 2010), requiring RACK1 for gene expression in each cell type. RACK1 activation of BDNF transcription is purported to be mediated by cAMP (Yaka et al. 2003b, c; He et al. 2010; Neasta et al. 2012), 14-3-3 association (Neasta et al. 2012) and epigenetic modulation of BDNF promoter IV (He et al. 2010). Interestingly, cAMP signaling via PACAP also appears to use this pathway to induce BDNF (Yaka et al. 2003a, b). Cyclic AMP causes dissociation of RACK1 from the NMDA/Fyn complex, thereby increasing Fyn phosphorylation of the NMDA receptor and increased NMDA activity. Collectively, these data place cAMP upstream of many key events involved in adaptation to ethanol exposure but implicate RACK1 and not CREB as the key transacting factor in this pathway.

Similarly, BDNF induction was observed in MSNs of the central and medial amygdala by Pandey and colleagues, where interference with BDNF expression using antisense oligonucleotides increased anxiety-like behavior and ethanol consumption (Pandey et al. 2005). Furthermore, alcohol-preferring rats produced less central amygdala and BNST BDNF mRNA and protein and exhibited higher

anxiety-like behavior (Moonat et al. 2011; Prakash et al. 2008). In this case, CREB appears to be a key intermediate in the behavioral response but Pandey and colleagues place CREB and ERK downstream of BDNF induction. While Pandey's group did not detect strain differences in BDNF in the NAc, Yan and colleagues found a reduction in accumbal BDNF in the preferring strain (Yan et al. 2005). Together, these data implicate reduced BDNF in the basal ganglia in alcohol appetite, but the anatomical locus is not resolved. As with MSNs in the striatum, BDNF protein should be delivered to the central amygdala via afferents (Conner et al. 1997) but the source of the mRNA and efficacy of BDNF siRNA and antisense oligonucleotides were unequivocally shown to be locally mediated within medium spiny neurons in the dorsal striatum and striatal-like nuclei of the amygdala. This was not concluded by Riovio (2012) and colleagues whose data and discussion suggest afferent or rare local sources in the accumbens. These data are difficult to reconcile and will require further anatomical, pharmacological, and molecular investigations.

Variable results have also been reported in developing animals with BDNF expression, likely amplified by the low levels of BDNF in neonates and stress. Many fetal alcohol experiments focus on the developing cerebellum because the ontogeny of specific neuronal populations, their migration, synaptogenesis, and the factors modulating these processes have been well-characterized (reviewed by Sotelo 2004). The majority of studies examining BDNF levels, TrkB, or BDNF signaling have shown that ethanol inhibits the neurotrophic activity of BDNF in the cerebellum, and this may contribute to cerebellar apoptosis and impaired foliation. Ge and colleagues (2004) performed a detailed dose–response, time-course analysis and found a rapid decrease in BDNF and TrkB mRNA in the cerebellum after exposure on PN4 but not PN9, suggesting a role for BDNF in the selective vulnerability at this time point when levels are low. In a follow-up study (Light et al. 2002), TrkB was detected in cerebellar Purkinje cells during the vulnerable first postnatal week; ethanol decreased TrkB immunoreactivity as well as TrkB.T1 and TrkB mRNA in these experiments. Moore and colleagues found an increase in TrkB in the cerebellum of females exposed prenatally but no other alterations in cerebellar TrkB with prenatal or postnatal exposure (Moore et al. 2004a, b). Moreover, Heaton and colleagues did not observe significant regulation of BDNF protein levels in cerebellum with numerous exposure windows that span postnatal development but subsequently reported a transient increase in BDNF immediately after exposure on PN4 that normalized by 2 h (Heaton et al. 1999, 2003a). Exposure on PN7 increased BDNF levels at 2 h and decreased levels at 12 h in this study. Observations made in juvenile rats after a single binge of ethanol indicate no changes in cerebellar BDNF mRNA (Kulkarny et al. 2011), suggesting modulation may be more dynamic in younger animals.

Multiple lines of evidence support a role for BDNF expression and signaling in the cortex and hippocampus in the development of FASD, but the sequence and mechanisms have not been fully resolved. A few reports have suggested an increase in BDNF (and related TrkB agonist NT-4) immediately following exposure. Increased BDNF/NT-4 levels were measured in combined "cortex/striatum" at

PN1 after prenatal exposure and at PN10 after PN4 -10 (Heaton et al. 2000c). Surprisingly there was no significant developmental increase detected in BDNF between PN10 and PN21. By contrast, Heaton and colleagues (2003a) reported bidirectional changes in BDNF cortex after exposure on PN7 and increased BDNF on PN10 after neonatal exposure that resolved by PN21. It should be noted that the levels of BDNF measured in these assays were very low (50–80 pg/g wet weight) and may have been below linear detection with the dilutions given in the text (100-fold). Others have found that fetal exposure decreases BDNF in the cortex (Climent et al. 2002; Fattori et al. 2008; Feng et al. 2005; Caldwell et al. 2008). In addition, Caldwell and colleagues (2008) found decreased BDNF and specific decreases in transcripts III, IV, and VI in the medial frontal cortex and hippocampus.

Similar differences were observed in the hippocampus where Heaton and colleagues (2000c) find a transient increase in hippocampal BDNF at PN10 with neonatal exposure and no change with prenatal exposure. However, Fattori found a decrease in BDNF after PN5-8 exposure. Feng and colleagues (2005) and Caldwell colleagues (2008) also report a decrease in BDNF after gestational exposure. Miki et al. (2008) exposed animals from PN10-15 via vapor inhalation and also noted a transient increase in hippocampal BDNF mRNA from PN16-PN30 that varied in duration depending upon the control group comparison. These observations were less robust in older animals and complicated by differential BDNF expression between the maternally reared control group and the separation control group such that BDNF levels were reduced when compared to the separation control animals but unchanged relative to the maternally reared animals at 60 days of age (Miki et al. 2008). Similarly, separation of PN5 pups increased PKC activity in the hippocampus, which correlated with increased ERK signaling (Davis et al. 1999). These observations illustrate how stress significantly affects signaling in the developing brain and may be another variable contributing to the differential effects of ethanol on neurotrophin levels and signaling between laboratories and exposure paradigms. While it is difficult to draw firm conclusions from the current data, combined, these studies suggest that ethanol may acutely and transiently increase BDNF in some brain regions developmentally. Correlations with cell death suggest that the increase may reflect an attempt at repair, but may ultimately lead to a reduction in BDNF production in the mature structure if administered during a vulnerable window.

Ethanol also produces variable effects on TrkB that may be dependent not only on timing but also on gender (Moore et al. 2004a, b). However, in spite of this overwhelming confound, others have found that prenatal exposure increases TrkB/TrkB-T1 ratios as neonates (Climent et al. 2002). Baseline neurotrophin levels and BDNF levels are responsive to multiple environmental and experimental factors that can make accurate measurements difficult. More experiments examining acute effects on signaling during exposure and compensatory regulation over time and after in specific cell types are required. It is also unclear whether these changes result in a decrease in activity-dependent BDNF release or represent differences in synaptic complexity. Examination of BDNF signaling (discussed below) suggests that ethanol causes a decrease in the ability of TrkB to transduce signal and desensitize, which may lead to compensatory regulation of both BDNF and TrkB

in vivo. There is considerable data to indicate a role for aberrant BDNF modulation during post-exposure development, but this may be secondary to impaired synaptogenesis, activity, and neuronal apoptosis (Bhave et al. 1999; Feng et al. 2005; Miki et al. 2008; Caldwell et al. 2008; Climent et al. 2002).

2.2.3 BDNF and In Vitro Models of Ethanol Exposure

As with NGF in the previous section, BDNF diminishes ethanol-induced hippocampal and cerebellar granule cell death in vitro (Heaton et al. 2000b; Bonthius et al. 2003). The neuroprotective effects of NMDA in cerebellar granule neurons are also mediated by BDNF induction (Marini et al. 1998; Bhave et al. 1999) and likely involve PI3K since the survival-promoting effects of BDNF were blocked by PI3K inhibition (Bhave et al. 1999). Ethanol also decreased Akt phosphorylation in the developing, but not adult, brain (Chandler and Sutton 2005), implicating PI3K/Akt in the selective vulnerability of the developing brain to ethanol.

Neurotrophins also reverse many of the effects of ethanol on synaptic activity. Exogenous BDNF reverses ethanol attenuation of GABA-A responses in cerebellar granule cells (Ericson et al. 2003). Ethanol also reverses BDNF-mediated long-term plasticity at developing hippocampal CA3 GABAergic synapses through inhibition of voltage-gated calcium channels (Zucca and Valenzuela 2010). At excitatory synapses, ethanol blocks BDNF enhancement of NMDA (NR2B-containing), but not AMPA, responses in hippocampal neurons (Kolb et al. 2005). As a control, the authors show that NGF and NT3 do not alter synaptic transmission, indicating cell type selectivity in the ion channels modulated by specific neurotrophins as would be expected from the anatomical distribution discussed above. Kolb and colleagues further dissected the effect of ethanol on the channel from the BDNF enhancement by using ethanol concentrations that did not have an impact on NMDA signaling, indicating that the effect of the effect of ethanol is independent of NMDA receptor inhibition.

In contrast to the experiments discussed above where chronic ethanol enhanced NGF-stimulated ERK activity in PC-12 cells, acute and chronic ethanol administration decreases activation of ERK in primary neurons and in the rodent brain (Davis et al. 1999; Kalluri and Ticku 2002, 2003; Tsuji et al. 2003; Chandler and Sutton 2005; Han et al. 2006; Ohrtman et al. 2006; Fattori et al. 2008 however, see Chen and Charness 2012 and Acquaah-Mensah et al. 2001). Regulation of ERK by ethanol also contributes to reduction in hippocampal LTP (Roberto et al. 2003). Ethanol acutely reduces TrkB signaling to ERK in cerebellar granule cells (Li et al. 2004; Ohrtman et al. 2006), but does not change TrkB phosphorylation state (Li et al. 2004), indicating an intracellular site of action downstream of the receptor. Neonatal hippocampal slices stimulated with BDNF displayed reduced nuclear translocation of phosphorylated ERK in hippocampal pyramidal cells in CA1 (Davis et al. 1999). Inhibition of BDNF-stimulated ERK phosphorylation by ethanol in cerebellar granule cells is dependent upon BDNF concentration and not modified by NMDA receptor antagonists (Ohrtman et al. 2006). Low concentrations of ethanol inhibit ERK activation only when BDNF was present at concentrations in the rising portion of the high affinity concentration–response curve (<5 ng/mL), while high concentrations of ethanol also block the desensitization of the ERK response at longer times (30–60 min), and at high BDNF

concentrations (>10 ng/mL). Thus, there was no apparent inhibition with 50 ng/mL of BDNF after 20 min, but the peak was never reached in the ethanol-exposed cells while the control curve is declining (Ohrtman et al. 2006). This was also reported recently by Chen and Charness (2012) who did not observe ethanol inhibition of BDNF-stimulated ERK activity with 50 ng/mL of BDNF, but this study did not perform the same pharmacological analysis as Ohrtman and colleagues. Both PKA and PKC regulate ERK, and reduced ERK activity correlates inversely with PKA activity and positively with a concurrent decrease in calcium-sensitive protein kinase C activity in the developing hippocampus (Davis et al. 1999); therefore, acute inhibition of TrkB signaling to ERK may be independent of Trk activation and ultimately cross-regulated by other pathways with different concentrations of ethanol.

In addition to mediating survival, BDNF also regulates migration and synaptogenic processes. Mutations that either upregulate or downregulate signaling through growth factor pathways and their associated GTPases cause a myriad of neurodevelopmental disorders resulting from accelerated or decelerated development (Stornetta and Zhu 2011). Perturbation of signaling that results in subtle changes in the rate of migration and synaptogenesis might also contributes to the development of alcohol-related neurodevelopmental disorders without inducing overt cell death. Numerous reports indicate that concentrations of ethanol as low as 25 mM inhibit neuronal migration neurite outgrowth through the adhesion molecule L1 (Charness et al. 1994; Bearer et al. 1999), and inhibition of ERK and Src and implicated in inhibition of L1-mediated neurite formation by ethanol (Tang et al. 2006; Yearney et al. 2009). In contrast, a few studies report increased migration and increased neurite formation in response to ethanol, as discussed above, and increased basal spines on pyramidal cells treated with chronic intermittent ethanol (Kroener et al. 2012). Developmentally, Powrozek and Olson (2012) observed increased dendrite formation in cortical explant cultures treated with ethanol. Proliferating neuroepithelial precursors exposed to ethanol display a differentiation-associated increase in migration (Camarillo and Miranda 2008) and ethanol increased the rate of axon formation in hippocampal pyramidal cells (Lindsley et al. 2011). This overall increase in axon growth rate was associated with ethanol inhibition of BDNF-stimulated Rac1/Cdc42 activation and increased Rho activity in hippocampal axonal growth cones, leading to increased growth cone surface area (Lindsley et al. 2011). Although ethanol increased the surface area of growth cones, the levels of active Rho GTPases in axonal growth cones were not affected in the absence of exogenous BDNF. These observations are in contrast to a recent study from Chen and Charness (2012), detailing reduced axon growth that was not mediated by BDNF and was dependent on Src, albeit with different substrates. We have also observed an increase in BDNF-stimulated migration/dendrite formation in cerebellar granule cells using a Boyden chamber assay (Hassoun et al. 2007a; See Hassoun et al. 2007b for detailed methods). As discussed above, ethanol also enhances differentiation in some cells, therefore cell cycle arrest, possible through ERK inhibition in cycling cells, and premature differentiation would increase the pool of migration-competent precursors if administered during the correct developmental window. This does not necessarily have to increase the rate

of migration, which has been shown to be reduced in the cerebellum after ethanol exposure (Jiang et al. 2008), but may simply increase the number of cells that migrate toward BDNF.

Oxidative stress, also known to modulate neurotrophin signaling, has recently been implicated in the etiology of some forms of autism (Rossignol and Frye 2012; Sajdel-Sulkowska et al. 2011) as well as the development of FAS/ARND (Brocardo et al. 2011). A target that has been suggested to mediate the toxic effects of ethanol is cJun N-terminal Kinase (JNK), a member of the mitogen-activated protein kinase family, which is induced by ethanol, genotoxicity, and oxidative stress (reviewed by Weston and Davis 2007). p75 also activates the JNK pathway (Koshimizu et al. 2010). JNK, as the name implies, phosphorylates c-Jun, a member of the AP-1 (Fos/Jun) transcription factor complex. "JNK" represents 3 families and as many as 16 splice variant isozymes that do not always correlate with molecular weight but is generally divided into 3 molecular weight categories of 58, 54, and 46 kDa. Suppression of Akt activates JNK (Shimoke et al. 1999), but apoptosis in cerebellar granule cells induced by growth factor withdrawal, glutamate, and beta amyloid is not mediated by JNK (Gunn-Moore and Tavare 1998). Some reports suggest that JNK with an apparent molecular weight near 60 kDa is involved in ethanol-induced apoptosis and ethanol-induced oxidative stress, but only one isoform was observed by western blot (Heaton et al. 2003a, 2012). Han and colleagues (2006) observed ethanol-induced increases in p46 and p54 phosphorylation that are associated with apoptosis in PN7 rat pups. However, when phosphorylated cJun is measured as a surrogate for JNK activity after ethanol exposure, there is no overlap between cells undergoing apoptosis and phospho-cJun in immunostained brain sections (Young et al. 2008). Moreover, JNK activation induces genes associated with protection in *Drosophila* in response to oxidative stress (Wang et al. 2003) and mutations that enhance JNK signaling in Drosophila can extend lifespan (Karpac and Jasper 2009). BDNF stimulation of AP1 DNA binding activity is also reduced by ethanol in cerebellar granule cells (Li et al. 2004). The effects of JNK activation may therefore be isozyme or splice variant, specific as these data suggest reduced genomic signaling through Fos/Jun after ethanol in cerebellar granule cells and a non-genomic, possibly protective, isoform-specific, role for JNK in ethanol toxicity which has not been explored.

The JNK pathway stimulates both dendrite and axon formation through phosphorylation of proteins such as MARKS and doublecortin that are associated with cytoskeletal dynamics (Oliva et al. 2006; Bjorkblom et al. 2012; Jin et al. 2010). JNK1 is associated with microtubules where it regulates axodendritic length (Tararuk et al. 2006), and genetic deletion of JNK or intermediates in the JNK pathway leads to axonal growth defects (Chang et al. 2003; Koushika 2008). Immunohistochemical staining for phospho-JNK in the neonatal mouse brain labels primarily developing axon pathways and not apoptotic cell populations (Davis, unpublished observations). A role for JNK regulating migration and axon outgrowth in response to ethanol is further supported by the observations that ethanol increases integrin and NCAM levels (Vangipuram et al. 2008; Miller et al. 2006), increases laminins (Vangipuram et al. 2008), increases Fyn activity (Yaka et al. 2003b), increases PKC, and increases FAK phosphorylation in cerebellar granule cells (Sivaswamy et al. 2010), which all regulate

cytoskeletal dynamics (Becchetti and Arcangeli 2010). JNK may therefore be an overlooked contributor to ethanol effects on the neuronal cytoskeleton and may serve protective as well as apoptotic functions.

2.2.4 BDNF in Patients with Alcohol Dependence

Variability in peripheral BDNF levels in alcohol-dependent patients is more extreme than NGF, making it difficult to deduce trends from the current data. The levels of BDNF reported in Table 1 are variable, often with standard deviations greater than the mean. Stress, depression, hematologic parameters, xenobiotics, age, and gender are all known to influence peripheral BDNF levels (reviewed by Autry and Monteggia 2012; Lommatzsch et al. 2005). BDNF levels detailed in Table 1 do not correlate with the source (plasma vs. serum), method used, or duration of abstinence. The source of the variability could be innate, due to simultaneous use of anticonvulsants during withdrawal, or due to sample preparation. Many experiments used serum, which includes BDNF released by thrombocytes, and is orders of magnitude higher than the plasma concentration (Lommatzsch et al. 2005). Two studies state different sources in the methods compared to the results section, although the levels reported suggest the source (ng vs. pg concentrations). In other studies, it is not clear that the centrifugation steps are sufficient to remove the thrombocytes, while others use sedimentation forces likely to rupture the cells. Zanardini and colleagues (2011) and D'Sa and colleagues (2012) directly compared serum and plasma BDNF. The first study reported a small increase in both components, while the second study only detected an increase in BDNF in serum in alcohol-dependent patients. Heberlein and colleagues (2010) also addressed this confound by simultaneously measuring thrombocyte activity and serum BDNF levels, observing a positive correlation between serum BDNF levels and both gamma glutamyl transferase levels and thrombocyte function. In addition, Costa and colleagues (2011) found a nonsignificant but suggestive association of BDNF levels with platelet count. Alcohol dependence and withdrawal are known to alter thrombocyte levels and coagulation cascades with robust rebound upon withdrawal (Schmitt et al. 1999; Chanarin 1982). BDNF is also produced and released by the vascular endothelium (Nakahashi et al. 2000), further complicating any correlation between central function and peripheral levels in patients with underlying cardiovascular disease.

Peripheral levels may provide valuable information since the production and release mechanisms regulating plasma and serum levels are likely to be similar to mechanisms governing central production and release, even if they are not the same pools of BDNF. Interestingly, this was predicted by Chinarin in 1982: "After platelet aggregation the platelets contract and squeeze various metabolites out of the platelet; this is called the 'release reaction'. This phase is also curtailed or even absent in platelets from alcoholics". BDNF polymorphisms also have the potential to regulate peripheral levels, but these reports are similarly variable and primarily examine serum BDNF. The Met allele of the Val66Met BDNF polymorphism decreases neuronal BDNF secretion (Egan et al. 2003; Chen et al. 2004, 2006). Some evidence supports an association between the homozygosity for the Met or

Val allele with lower or higher BDNF levels, respectively (Ozan et al. 2010; Cirulli et al. 2011). In contrast, no association between genotype and serum levels were found in the majority of patient populations examined thus far (Yoshimura et al. 2011; Trajkovska et al. 2007; Terracciano et al. 2011) and, paradoxically, patients with the Met allele were even found to have higher serum BDNF concentrations (Lang et al. 2009). Thus, factors other than genotype may be responsible for the majority of the variability in serum and plasma BDNF.

BDNF is highly polymorphic and linkage analysis identified an alcoholism susceptibility gene that mapped near the BDNF locus, 11p13 (Uhl et al. 2001). The human BDNF gene is encoded by 11 exons and 9 promoters (Pruunsild et al. 2007) and is polymorphic between different human populations, further complicating association analysis (Petryshen et al. 2010). Three polymorphisms have been examined in alcohol-dependent patients; these polymorphisms change BDNF secretion and activity-dependent processing (Egan et al. 2003; Chen et al. 2004, 2006). The first is a missense change (G196A, rs6265) that results in a valine to methionine substitution (Val66Met). The Met allele shows impaired trafficking and activity-dependent secretion, and humans homozygous for the Met allele have reduced hippocampal and amygdalar volume, increased anxiety, increased heart rate, and poor working memory (Egan et al. 2003; Hariri et al. 2003). Humans homozygous for the Met allele have recently been reported to have higher anxiety, increased cortisol, and consume more alcohol (Colzato et al. 2011). Abstinent Met/Val and Val/Val patients differ in their rate and locus of recovery measured by MRI, with Val/Val homozygotes showing more gray matter recovery while heterozygotes had more recovery in white matter measures (Mon et al. 2012). Transgenic mice carrying the human Met allele and their human counterparts were also impaired in models of extinction learning, with human Met/Met homozygotes demonstrating impaired fronto-amygdaloid activity by functional magnetic resonance imaging (Soliman et al. 2010). A second polymorphism (C270T) is present in the 5′ noncoding region that can regulate transcription or translation. The third genotype examined is a G712A polymorphism that has not been extensively investigated molecularly but may be associated with Parkinson's Disease (Chen et al. 2011). Initial studies suggested BDNF polymorphisms were associated with psychiatric disorders; however, subsequent studies and meta-analysis have failed to support associations for most major neuropsychiatric disorders, while studies contain too few patients to asses validity in less common disorders at this point (reviewed by Hong et al. 2011).

Anxiety is a precipitating factor for alcohol abuse. Association between the Met allele and higher anxiety-like behavior has been observed in both humans and transgenic mice expressing the human Met allele (Jiang et al. 2005; Montag et al. 2010; Chen et al. 2006). BDNF polymorphisms have been examined by several groups and the associations with alcohol dependence have been weak and variable in spite of promising initial observations. Matsushita et al. 2004 found that G196A (Val66Met) BDNF polymorphism frequency did not differ significantly from controls but alcohol-dependent patients with violent tendencies and a history of delirium tremens had an increased frequency of Met/Met genotype. Antisocial

alcohol behavior and alcohol dependence may also segregate with a TrkB variant (Xu et al. 2007). The Met allele was also associated with earlier disease onset in this study. Met carriers were subsequently shown to consume more alcohol than Val66Val or Val66Met patients which segregated with alcohol use disorders (Shin et al. 2010; Colzato et al. 2011). Reduction of BDNF is associated with aggression in mice (Chen et al. 2006), but the genetic association between aggression, Met/Met, and alcoholism was not observed in the majority of replicate analyses (Tsai et al. 2005; Muschler et al. 2011; Wojnar et al. 2009; Grzywacz et al. 2010). In a subgroup analysis, the Met allele was overrepresented in alcohol-dependent patients with depression compared to controls or dependent patients without depression (Su et al. 2011). While no association was found with dependence, Wojnar and colleagues (2009) found an association between the Val66Val genotype and relapse that was greater when restricted to analysis of those with a positive family history of alcohol use disorders. In support of this phenotypic association, the Val/Val is also associated with impulsivity (Gatt et al. 2009), which can contribute to relapse. A modest association between SNP G712A and substance dependence was also described but did not specifically examine the alcohol-dependent subgroup (Zhang et al. 2006). These data do not suggest a strong association between the BDNF polymprphisms and alcohol dependence but may identify a subgroup of patients and indicate response to treatment. Interestingly, over 60 polymorphisms in the BDNF gene have been identified to date, so lack of association at two loci does not exclude a role for BDNF genotype as a modifying factor in alcohol abuse, dependence, and toxicity.

2.3 NT-3

2.3.1 NT-3-TrkC Expression and Distribution

NT-3 is widely expressed in the periphery, with high levels in the kidney, spleen, heart, and muscle (Maisonpierre et al. 1990a; Ernfors et al. 1990b). As with NGF and BDNF, NT-3 supports survival and neurite outgrowth from peripheral ganglia (Maisonpierre et al. 1990a; Ernfors et al. 1990b). With the exception of hippocampal dentate granule cells, NT-3 mRNA is not highly expressed in the mature CNS (Fig. 1, Allen Institute and LazC expression from the NT-3 promoter generously provided by Dr. Kevin Jones at the University of Colorado). NT-3 is present at low levels in mature animals in the indusium griseum, tenia tecta, olfactory bulb, substantia nigra, medial locus coeruleus, and scattered paraventricular (IV) brain stem nuclei (Ernfors et al. 1990b; Vigers et al. 2000). Other structures such as the retrosplenial and visual cortices with low NT-3 expression and a developmental peak were also identified in a mouse strain expressing LacZ from the NT-3 promoter (Vigers et al. 2000). LacZ expression is more sensitive than in situ hybridization, but this essentially replicated the earlier mRNA studies with respect to relative expression levels, including lack of NT-3 expression by cells in striatum and globus pallidus (Maisonpierre et al. 1990b; Friedman et al. 1991).

Adult NT-3 protein levels range from 1 to 1.5 ng/g wet weight with hippocampus, cerebellum, and piriform cortex having the highest levels and superficial and deep cortical layers containing the greatest immunoreactivity (Anderson et al. 1994). Acid treatment has been shown to increase NT-3 detection by 30–50 %, depending on the region (Okragly and Haak-Frendscho 1997). NT-3 is detected in the internal granule cell layer of the cerebellum and ELISA estimates the concentration is around 500 pg/g wet weight in mature rats (Söderström and Ebendal 1995). Levels in neonatal animals reach 9 ng/g wet weight transiently in cingulate cortex (2.5 ng/g in hippocampus) and peak expression in the hippocampus, cerebellum, piriform cortex, and entorhinal cortex occurs at birth and declines over the first 2 postnatal weeks (Ernfors et al. 1990b; Söderström and Ebendal 1995; Das et al. 2001).

NT-3 regulates the development of discrete neuronal populations during early, middle, and late periods of CNS neurogenesis and synaptogenesis. NT-3 regulates neural crest development and is expressed at the earliest steps in neurulation (Maisonpierre et al. 1990b). NT-3 has a developmental peak in mRNA expression that coincides with the arrival of perforant path afferents into the hippocampus (Maisonpierre et al. 1990b, Ernfors 1990b; Friedman et al. 1991; Lauterborn et al. 1994), and NT-3 is transiently expressed in the hilus of the hippocampus at birth (Friedman et al. 1999). Similarly, late expression of NT-3 mRNA in the visual cortex and lateral geniculate nucleus coincides with eye opening and decreases after the critical period for ocular dominance column formation to undetectable levels in the adult (Lein et al. 2000). Follow-up studies using Cre-mediated deletion in cortex establish a role for NT-3 in thalamocortical innervation (Ma et al. 2002). NT-3 expression in the thalamus is transient, and targeted deletion of NT-3 in the mouse cortex selectively perturbs the development of thalamocortical axons projecting to retrosplenial and visual cortex (Ma et al. 2002). In organotypic cultures, NT-3 induces cortical, axon fiber branching and is an attractive signal for layer 6 axons while repelling layers 2/3 axons (Castellani and Bolz 1999).

Cerebellar granule neurons switch trophism from BDNF to NT-3 after they enter the internal granule layer (Segal et al. 1992). Conditional deletion of NT-3 results in a dramatic reduction in foliation of the cerebellum with normal Purkinje cell arborization, normal EGL proliferation, and normal lamination (Bates et al. 1999). Deletion of IGF-1 receptor in the cerebellum reduces NT-3 and results in a similar foliation phenotype (de la Monte et al. 2011). In addition to scattered pre- and post-migratory cerebellar granule cells expressing mRNA (Rocamora et al. 1996; Ernfors et al. 1990a), NT-3 immunoreactivity is detected in cerebellar Purkinje cells, cerebellar interneurons, deep cerebellar nuclei, medial vestibular nuclei, and the inferior olive (Friedman et al. 1991; Zhou and Rush 1994). Purkinje cells have not been shown to express NT-3 mRNA (Ceccatelli et al. 1991; Ernfors et al. 1994a), suggesting that NT-3 may accumulate in Purkinje cells via retrograde or anterograde transport.

TrkC has limited distribution in the CNS of mature animals but is highly expressed early in development. TrkC binding, TrkC mRNA, and NT-3 expression are similar, with the highest receptor levels in superficial cortical layers, stratum oriens, stratum radiatum, the molecular layer of the dentate gyrus, the nucleus of the

lateral olfactory tract, entorhinal cortex, the anterior olfactory nucleus, and the anteromedial thalamic nucleus. Neocortical deep layers, striatum, amygdala, dorsal root ganglia, and the central gray of spinal cord show moderate iodinated-NT-3 binding and TrkC expression, while expression is low in the cerebellum (Altar et al. 1993, 1994; Tessarollo et al. 1993).

2.3.2 NT-3 and Ethanol: Animal Models

It is not surprising that few studies have examined the effect of ethanol on NT-3/TrkC expression after ethanol exposure in mature animals, given the low, limited, and discrete regional expression in the adult. Recent studies of human postmortem tissue have suggested a role for ectopic induction of NT-3 induced by oxidative stress in the etiology of autism, particularly in cerebellar dysfunction (Sajdel-Sulkowska et al. 2011), but studies on NT-3 in developing and adult animals have been equivocal. NT-3 administered into the ventricles did not rescue vasoactive intestinal peptide-immunoreactive neurons in the suprachiasmic nucleus of withdrawn animals (Paula-Barbosa et al. 2003). Similarly, Baek and colleagues (1996) did no observe any changes in hippocampal NT-3 mRNA normalized to cyclophilin A after 28 weeks of constant ethanol exposure via liquid diet. Miller (2004) used a repeated episodic vapor exposure model, while Miller and Mooney (2004) exposed rats chronically to ethanol via liquid diet for 8 or 24 weeks and measured NT-3 levels by ELISA in parietal and entorhinal cortices, hippocampus, septum, and basal forebrain. Episodic exposure increased hippocampal NT-3 levels (from ~100 to 155–195 pg/mg protein) and reduced in basal forebrain NT-3 (from ~500 pg/mg protein to ~200 pg/mg). Chronic exposure increased NT-3 in entorhinal cortex and septum at both 8 and 24 weeks but transiently increased levels in basal nuclei and hippocampus. Both Miller and Mooney (2004) and Miller (2004) report the highest NT-3 content in the septum (600–700 pg/mg protein) with hippocampal levels ranging from 100 to 150 pg/mg protein and entorhinal cortex slightly higher at ~200 pg/mg protein. These data are given normalized to total protein but assuming 10 % protein, a value of 100 pg/mg is roughly 10 ng/g wet weight and regions such as septum contain 45+ ng/g wet weight. It should be noted that these concentrations are higher and not in the regional proportions previously observed in the adult, even upon acid treatment (see above) but may be the result of different sample preparation methods or, alternatively, significant transport.

When measured in homogenates after a variety of exposure paradigms, ethanol exposure either prenatally or postnatally changed NT-3 mRNA (Fattori et al. 2008; Light et al. 2001; Tsuji et al. 2008) and protein levels measured by ELISA (Heaton et al. 2000c). Heaton and colleagues (2000c) showed a trend toward increased "cortex/striatum" NT-3 on PN10 with PN4-10 vapor exposure (~90 pg/g wet weight to ~140 pg/g wet weight) in pups, but this did not reach statistical significance and NT-3 levels did not differ in other regions examined. When the telencephalon was further dissected (Heaton et al. 2003b), exposure to ethanol at PN14, but not the vulnerable PN3 exposure, increased NT-3 from ~8 ng/g to ~14 ng/g of striatal wet weight in rats at 24 h after exposure; NT-3 levels did not vary between

PN3 and PN14 (Heaton et al. 2003b). These levels are perplexing, given the variable concentrations observed between experiments and the lack of a developmental decrease in NT-3 postnatally (i.e., Das et al. 2001). NT-3 mRNA and NT-3 promoter–driven LacZ is not detected in the striatum in developing or mature animals (Maisonpierre et al. 1990b; Vigers et al. 2000; Soderstrom and Ebendal 1995; Das et al. 2001; Ernfors 1990b; Friedman et al. 1991; Lauterborn et al. 1994). Moreover, mRNA and LacZ expression also indicate low level of expression from the resident cells in the septum and basal forebrain. Therefore, the source of striatal NT-3 is unclear in these experiments as well. As discussed above, NT-3 is transiently produced in many structures including the thalamus, visual, cingulate, and retrosplenial cortex. NT-3 also regulates thalamocortical axon development during the critical stage with a peak in mRNA expression at PN8 (Ma et al. 2002). Again, NT-3 protein measured in striatum could be in retrograde transit through the striatum since the PN3 and PN14 time points in Heaton (2003b) flank the peak at PN5-8 but levels have not been shown to vary by orders of magnitude within a few days developmentally.

When the cerebellum is subdivided or immunoreactivity evaluated in situ, NT-3 and TrkC are sensitive to ethanol exposure in selected regions. TrkC immunoreactivity is reduced when examined specifically on Purkinje cells in pups exposed to ethanol during the vulnerable PN4-6 window (Light et al. 2002), but global mRNA for TrkC, likely representing mRNA from mature granule cells as well, was unchanged (Light et al. 2001). When the vermis was selectively assayed by ELISA, Parks and colleagues (2008) found increased cerebellar NT-3 and an increase in hippocampal NT-3 in mature animals after prenatal exposure, which could reflect compensation within the system. The high dose (6 g/kg/day by gavage) increased NT-3 in both regions while only the vermis was sensitive to the lower dose (4 g/kg/day). In addition, NT-3 levels in the vermis were higher in animals exposed to an enriched environment after prenatal alcohol exposure at both doses, again suggestive of a role in plasticity. The NT-3 concentrations measured were again higher than earlier reports in normal rats, but the relative levels, with the hippocampus having the highest NT-3 content, followed by cerebellum, were consistent.

The discrepancy between these studies and the classical descriptions is unclear as is the source of the high NT-3 levels measured in tissues not shown previously to have high levels of NT-3, suggesting the source of the NT-3 may be external to the structure. Acid treatment has been shown to increase NT-3 detection, but this should be uniform and not change the relative levels from region to region. Neutralization can also cause the reformation of NGF protein complexes. The samples in Miller and Mooney (2004) and Miller (2004) were fractionated by centrifugation, which may have concentrated specific pools of NT-3, and acid treated prior to assay; the samples in the Heaton studies were also acid treated. Parks and colleagues report higher levels than previously observed, but ratios consistent with the classical studies and those using in acid treated/neutralized samples in normal rodents.

2.3.3 NT-3 and Ethanol: In Vitro Models

The role of NT-3 in development is similarly time- and population-selective, and the effect of NT-3 on ethanol toxicity is similarly selective. Seabold and colleagues (1998) did not observe a protective effect of NT-3 on differentiated cortical neurons treated in vitro with a high (400 mg/dL) concentration of ethanol. Earlier in development, exposure of embryo cultures to ethanol for 3–10 h in vitro reduced proliferation of cephalic neural crest cells that was prevented by the addition of NT-3 to the medium (Jaurena et al. 2011). These studies are consistent with the limited cortical responsiveness to NT-3 and the early developmental peak in expression (see Sect. 2.3). Recent studies indicate that NT-3 may have a larger role in cerebellar development than previously appreciated. Cerebellar foliation is impaired when the insulin or IGF-1 system is perturbed in the cerebellum by siRNA; NT-3 levels are also reduced (de la Monte et al. 2011). This treatment reduces cerebellar foliation, suggesting role for NT-3 in this process, and developmental ethanol exposure similarly impairs cerebellar foliation (Cragg and Phillips 1985; Sakata-Haga et al. 2001).

3 Nonclassical Neurotrophic Factors: IGF-1, GDNF, and PACAP

3.1 The Insulin Family: IGF and ALK

IGF-1 is known to be involved in ethanol toxicity both centrally and peripherally. IGF-1 is produced in the liver in response to growth hormone secretion from the pituitary and thereby links IGF-1 levels to ethanol-induced growth restriction. Circulating IGF-1 levels in adults may also be involved in ethanol-induced vascular damage due to a lack of IGF-1-mediated repair, either directly by inhibiting signaling or secondary to hepatotoxicity, thereby compromising the blood–brain barrier. IGF-1 is bound in vivo to IGF Binding Proteins (IGFBPs) that further regulate bioavailability. Acute ethanol exposure results in a dramatic increase in IGFBP-1 and a decline in IGF-1 in healthy adults, while chronic ethanol exposure decreases IGF-1 bioavailability and growth hormone levels in patients (Passilta et al. 1999; Rojdmark et al. 2000; Rojdmark and Brismar 2001). After 4 days of withdrawal, IGF levels increase and IGFBP-1 levels decrease (Passilta et al. 1998). IGF-I and IGF-II are both upregulated in children exposed prenatally to ethanol, indicative of compensatory induction and a potential biomarker for FAS/ARND (Aros et al. 2011). The significance of alterations in peripheral IGF-1 to brain pathology is uncertain, but IGF-1 crosses the blood–brain barrier (Pan and Kastin 2000) and transport is activity dependent (Nishijima et al. 2010). Moreover, reduced IGF-1 levels are associated with depressive-like behavior (Mitschelen et al. 2011). Circulating IGF-1 levels are sensitive to hepatic function, thereby providing a link between hepatotoxicity and neuronal toxicity and repair processes. The GH-IGF-1 axis, neural activity, vascular integrity, and hepatic function are intimately linked, particularly during development.

IGF-1 is active in the early stages of neurogenesis, regulates stem cell proliferation, and enhances survival after ethanol exposure (Tateno et al. 2004). Ethanol blocks IGF-1-stimulated proliferation in vitro (Resnicoff et al. 1996) and ERK activation (Hallak et al. 2001) but, while trophic, does not significantly protect cerebellar granule cells from ethanol toxicity (Bonthius et al. 2003). Interestingly, in vivo siRNA-mediated reduction in insulin or IGF-1 receptor signaling produces cerebellar malformations that resemble fetal alcohol syndrome (de la Monte et al. 2011). McClure and colleagues (2011) used *Drosophila* to model fetal alcohol syndrome and implicate *Drosophila* insulin-like peptide and reduced insulin receptor expression in the teratogenic effects of ethanol. Another related molecule, ALK, was also recently suggested to be ethanol-sensitive in fly and mouse experiments (Lasek et al. 2011a, b). ALK is proapoptotic in the absence of ligand, but signals survival in presence of ligand (Yanagisawa et al. 2010). ALK promotes sensitization and cocaine reward (Lasek et al. 2011a) in flies and is involved in ethanol tolerance and reward in mice (Lasek et al. 2011a, b). ALK knockout mice show enhanced loss of righting reflex in response to high doses of ethanol, and this is not explained by reduced ethanol metabolism. ALK expression in striatum is negatively correlated with ethanol sensitivity. While knockout mice were more sensitive to the sedating effects, they were less sensitive to ataxia. These data implicate multiple intermediates in the IGF pathway as potential modulators of ethanol sensitivity and toxicity.

3.2 GDNF

GDNF is also a target derived factor that was originally described as a trophic factor for dopaminergic, sensory, and motor neurons (reviewed by Pascual 2011). GDNF is a member of a larger family that includes Artemin, Neurturin, and Persephin. While trophic for dopaminergic neurons, genetic ablation of GDNF does not affect genesis or survival of dopaminergic neurons (Sanchez et al. 1996; Jain et al. 2006), but Ret deletion cause late degeneration of the substantia nigra pars compacta (Kramer et al. 2007). GDNF is also produced in peripheral tissues, with high levels detected in kidney, ovary, testes, stomach, skin, and lung (Trupp et al. 1995). Like neurotrophins, GDNF signals through tyrosine kinase coupled pathway. GFR-alpha 1 binds GDNF and recruits the Ret tyrosine kinase; neurturin preferentially activates alpha 2, and artemin preferentially activates alpha 3 (reviewed by Mason 2000). Ret activation leads to ERK, Akt, phospholipase C, and Src activation to promote survival and differentiation. GDNF is also a potent regulator of anti-apoptosis pathways and NFkB. As with classical neurotrophins, alternative signaling pathways also exist for GDNF. GDNF can signal through NCAM to activate Fyn and focal adhesion kinase which mediate neurite outgrowth and survival (Sariola and Saarma 2003). Homophilic transsynaptic binding of GFR-alpha has also been described during hippocampal synaptogenesis (Ledda 2007).

GDNF is expressed at high levels in the striatal fast spiking interneurons, olfactory bulb, ventral mesencephalon, and septum with lower expression in the cerebellum and colliculi (see Fig. 1 and Hidalgo-Figueroa et al. 2012;

Pochon et al. 1997; Golden et al. 1999 for detailed anatomy). Receptors for GDNF are more widely expressed with Ret mRNA detected at high levels in diencephalic structures, cerebellum, brain stem, and olfactory bulb. Ret expression is low in the hippocampus, cortex, and striatum. GFR-alpha 1 is expressed at high levels in the septum, hippocampus, and colliculi, but at lower levels in the olfactory bulb, diencephalon, and brainstem. GFR-alpha 2 is high in cortex, hypothalamus, and colliculi, with low expression in the cerebellum and brainstem. GFR-alpha 3 expression is limited to the developing CNS and cerebellum (Masure et al. 1998) but is expressed in peripheral tissues such as heart, lung, and trigeminal ganglia. Interestingly, the striatal FSIs, not medium spiny neurons, produce GDNF while the receptors are produced by, and GDNF is accumulated in, mesencephalic dopamine neurons (Hidalgo-Figueroa et al. 2012; Barroso-Chinea et al. 2005). As with other neurotrophins, the differential distribution of GDNF and its receptors is consistent with target-derived factors and the consumer-producer model of neurotrophin action.

As with BDNF, GDNF was also identified for having the ability to reduce alcohol consumption in rodents (Carnicella et al. 2008, 2009a, b). The locus for this effect is the VTA since infusion of GDNF shRNA into the VTA blocks the effect (Barak et al. 2011) so it does not appear to involve fast spiking interneuron in the striatum, which also produce GDNF. Examination of the effects of ethanol on GDNF-mediated survival is limited. Fiore and colleagues (2009b) observed a decrease in cortical GDNF after a diet of chronic red wine (but not ethanol). Hippocampal GDNF does not appear sensitive to ethanol in mature animals (Okamoto et al. 2006).

Developmental studies in vivo indicate that GDNF protects developing chick spinal motor neurons from ethanol, but ethanol exposure did not reduce muscle GDNF levels in rats (Bradley et al. 1999; Barrow Heaton et al. 1999). However, Wentzel and Ericksson (2009) found a decrease in GDNF in trunk, but not cranial, neural crest–derived cells from the E10 rat embryo. Interestingly, this paper also reported a decrease in GAPDH mRNA in cranial neural crest cells exposed to ethanol. McAlhany and colleagues (1999) also found a reduction in GDNF protein, but not mRNA, with developmental ethanol exposure but a paradoxical increase in GDNF signaling to Shc. Neonatal brain growth restriction in response to high dose (5 g/kg gavage) ethanol during the postnatal brain growth spurt (PN6-8) is similarly correlated with a transient reduction in GDNF (Tsuji et al. 2008). (Exposure on PN 2–4 or PN 13–15 also reduced BDNF levels, but this did not correlate with microcephaly, as discussed above.) Interestingly, the ERK pathway was similarly sensitive regardless of age but inhibition of the Akt pathway was only observed with PN6-8 exposure, correlating with the temporal decrease in GDNF in these experiments.

In vitro, GDNF reverses Purkinje cell ethanol toxicity in cerebellar explants (McAlhany et al. 1997, 1999) and ethanol blocks GDNF-stimulated process outgrowth in granule cells (Chen and Charness 2012). GDNF reversed ethanol-induced JNK activation in SK-N-SH neuroblastoma cells and associated cell death (McAlhany et al. 2000). Interestingly, these cells underwent DNA fragmentation at 34 and 68 mM ethanol but displayed signs of necrosis at concentrations above 100 mM. GDNF can also protect glial-type transformed cells from ethanol toxicity

in vitro (Villegas et al. 2006). In contrast, Mitchell and colleagues (1999) found no neuroprotective effects of GDNF against cell death in hippocampal cultures, induced by high concentrations (>100 mM, 0.4–1.6 g/dl) of ethanol combined with hypoglycemia and hypoxia.

3.3 PACAP

PACAP is a member of the vasoactive intestinal peptide/glucagon/growth hormone releasing hormone superfamily and is active in stress, anxiety, consummatory behavior, metabolism, and thermoregulation (Adams et al. 2008). PACAP receptors exists as splice variants that stimulate adenylate cyclase and phosphoinositol hydrolysis with different kinetics (Spengler et al. 1993). PACAP also signals through Ca^{++}, PCK; Src family kinases, and by transactivation of Trks through the PAC1 receptor, with Gq-coupled pathways predominating in the hippocampus (Macdonald et al. 2005; Rajagopal et al. 2004; Shi et al. 2010). PACAP may also regulate BDNF levels through receptor-coupled activation of RACK1 through cAMP (Yaka et al. 2003a) placing BDNF downstream of PACAP. PACAP-deficient mice display hyperlocomotion, decreased body mass, novelty-seeking behavior, jumping, impaired hippocampal associative learning, and mossy fiber LTP. PACAP in the arcuate nucleus of the hypothalamus stimulates NPY neurons to regulate carbohydrate intake (Nakata et al. 2004) but inhibits food intake via the POMC arcuate neurons (Mounien et al. 2009). Peripherally, PACAP is coupled to catecholamine secretion from adrenal chromaffin, providing a peripheral link to the stress response (Kuri et al. 2009).

The initial evidence for involvement of PACAP in ethanol sensitivity came from *Drosophila* where an allele of the *Drosophila* PACAP homologue amnesiac called cheapdate was identified as a gene regulating ethanol sensitivity (Moore et al. 1998). Rutabaga, another cAMP pathway mutant, is required in mushroom bodies for ethanol consumption in *Drosophila* (Xu et al. 2012). As with flies, PACAP knockout mice are less sensitive to the hypothermic and hypnotic effects of ethanol (Tanaka et al. 2004). Cerebellar granule cells from PACAP knockout mice are more sensitive to ethanol and peroxide toxicity, while addition of PACAP or dibutryl cyclic AMP reversed this effect (Vaudry et al. 2005). PACAP administered to neonatal rats mitigated the ethanol-induced loss of righting and apoptosis, possibly through caspase 3 and cJun inhibition (Botia et al. 2011). As with BDNF, PACAP also protected cerebellar granule cells from ethanol toxicity by the activation of PI3K (Bhave and Hoffman 2004).

3.4 Nonconventional Neurotrophic Factors in Patients with Alcohol Dependence

To date only one study has examined peripheral GDNF levels in alcohol-dependent patients. Heberlein and colleagues (2010) found GDNF levels significantly

depressed in the serum of alcohol-dependent patients which remain decreased for up to 2 weeks after withdrawal. Interestingly, serum levels were also inversely related to subjective assessment of tolerance. Those with high serum GDNF levels reported lower tolerance and may therefore be more likely to limit their alcohol intake. This is consistent with observations in rodents, suggesting that GDNF negatively regulates ethanol consumption (Carnicella et al. 2009a, b).

4 Neurotrophic Therapies in Alcoholism, FAS, and ARND

Neurotrophins-based therapies for both addiction and repair of ethanol-induced brain damage may be on the horizon. Small interfering RNA and other expression-based strategies have been used experimentally to dissect the pathways involved in ethanol self-administration in rodents, but this strategy will not be immediately useful for treating patients. Direct activation of Trks with ICV neurotrophin infusion has been used experimentally. For example, neurotrophin infusion can maintain ethanol tolerance (Szabò and Hoffman 1995) and infusion of NGF can restore cholinergic function in the mature brain after chronic ethanol exposure in rodents (Cadete-Leite et al. 2003; Lukoyanov et al. 2003). Unfortunately, ICV infusion of NGF is also not feasible for human treatment, but intranasal delivery of IGF-1 is being investigated for ameliorating ischemia and hypoxia-induced damage in developing mice (Lin et al. 2009, 2011) and in adult stroke models (Kooijman et al. 2009). Intranasal IGF-1 also protects Purkinje cells in spinocerebellar ataxia type 1 and improves roto-rod function (Vig et al. 2006). Given the trophic role of IGF-1 in the CNS, IGF-1 might also be useful in FAS/ARND and it readily crosses the blood–brain barrier. While not protective against the insult, IGF-1 may enhance recovery in the child.

Neurotrophic peptides and peptidomimetics are also being developed, which may reverse ethanol-induced neurodegeneration and withdrawal-associated anxiety. Cyclotraxin-B was recently isolated from a peptidomimetic screen as a TrkB allosteric antagonist that reduces anxiety-like behavior (Cazorla et al. 2010, 2011). Such molecules may reduce anxiety-associated drinking and withdrawal hyperexcitability but may also pose a toxicity risk. Conversely, mimetic and small molecule agonists of TrkA and TrkB reverse cell death and enhance recovery in experimental models (Scarpi et al. 2012; Massa et al. 2010; Jang et al. 2010) and may therefore be useful for treating ethanol-induced neurodegeneration and cognitive dysfunction. Activity-Dependent Neurotrophic Factor and related peptides enhance survival in moderate (Zhou et al. 2008) and extreme (Incerti et al. 2010) fetal alcohol models. Interestingly, the ADNF peptides SAL and NAP reversed the deficits observed after a single exposure on day 8 of gestation to a dose of ethanol that produces BACs in excess of 500 mg/dL. This protective effect was attributed to normalization of ethanol-induced upregulation of BDNF at E9 and E18. Thus, NAP and SAL can influence events prior to the onset of CNS neurogenesis and normalize BDNF expression without off target teratogenesis; however, recent studies have excluded a direct role for BDNF in NAP effects on axon formation

(Chen and Charness 2012). The efficacy of NAP and related peptides may therefore be related to cytoskeletal interactions (Gozes 2011), or inhibition of apoptosis (Zemlyak et al. 2009) and not a direct interaction with BDNF signaling.

Small molecule pharmacological strategies that indirectly modulate neurotrophin levels have also been proposed and tested in rodent models. Antidepressants increase BDNF in the hippocampus and can reverse ethanol-induced reductions in BDNF in the hippocampus (Hauser et al. 2011), which may increase recovery after long-term ethanol exposure. The anti-addiction compounds Ibogaine and noribogaine may also interact with GDNF to reduce ethanol drinking (He et al. 2005; Carnicella et al. 2010). Neurotrophin-based therapeutics need not involve administration of a drug, however. Exercise in mature animals can induce hippocampal neurogenesis and increase BDNF levels, which ameliorates many of the effects of prenatal ethanol exposure (Boehme et al. 2011). Antioxidants provide neuroprotection in fetal alcohol models, in part through modulation of neurotrophins (reviewed by Brocardo et al. 2011). Dietary supplementation with omega-3 fatty acids also reverses behavioral deficits in fetal alcohol models and increases BDNF, possibly through antioxidant modulation (Patten et al. 2012). Similarly, choline supplementation modulates neurotrophins and choline is being examined in preclinical models as a treatment for alcohol-related birth defects (Ryan et al. 2008; Monk et al. 2012). These interventions, while subtle, may increase neurogenesis and plasticity, ultimately involving regulation of neurotrophins. The strategies vary but all ultimately increase neurotrophic activity to influence survival and plasticity.

5 Conclusion

Alterations in neurotrophins and neurotrophin signaling mediate the acute toxic effects, plasticity that occurs with pharmacodynamic tolerance, plasticity that occurs with addiction, and repair that occurs after withdrawal. The temporal and cell specific activation and inhibition of neurotrophins and their associated pathways have not been conclusively determined, and the data on ethanol and neurotrophic factors summarized in this chapter clearly do not outline a cohesive story. Neurotrophin levels can increase, decrease, or not change depending on the brain region, time of exposure, and presence or absence of drug upon analysis. Neurotrophin signaling is dependent upon concentration, with full-length receptors desensitizing, high concentrations activating p75, and related receptors being nonspecifically activated at higher concentrations. In addition, neurotrophin levels and signaling to not occur in isolation; therefore, it is important to consider the physiological changes that result from neurotrophin action. For example, an increase in glutamatergic synaptic activity during withdrawal would be expected to increase BDNF but the place of BDNF in this sequence is not well defined in most studies. Does BDNF drive these changes or, more likely, does BDNF increase as a result of excess NMDA receptor activation? The sequence is different early in exposure and with low ethanol concentrations where ethanol can reduce signaling

in BDNF independent of effects on ion channels (Kolb et al. 2005; Ohrtman et al. 2006). In this case, neurotrophin signaling may be directly involved in the regulation of subsequent events and not vice versa. When concentrations of ethanol become too high, none of these adaptive responses are likely to occur, however, as is observed with suprapharmacological concentrations. More subtle effects are likely to contribute to ethanol-induced teratogenesis and chronic toxicity.

The expression data for receptors and neurotrophin levels measured after ethanol exposure also frequently do not agree. It is possible that ethanol induces ectopic expression in specific cell types, but this has not been specifically addressed since the control cells in these regions also frequently show expression of neurotrophins they are not believed to express. This may be partially due to the fixation procedures used to detect immunoreactivity in situ since neurotrophins are difficult to detect with immunohistochemistry. In situ hybridization and protein detection with and without colchicine treatment and global mapping may also help resolve some of these discrepancies and locate the "producer" neurons where neurotrophins are sensitive to ethanol treatment. The availability of genetically tagged mice will also aid in dissecting these issues anatomically, functionally, and allow for separation of specific populations by cell sorting. In addition, Cre-recombinase-mediated deletion in specific cell types, for example, BDNF deletion in cortex versus medium spiny neurons, could be combined with self-administration behavioral experiments to define the loci for specific effects. The pharmacological tools described in the previous section will aid in dissection of the actions of neurotrophins in ethanol toxicity, tolerance, addiction, withdrawal, and the development of FAS/ARND.

Neurotrophic Factors and NeuroAIDS: A Lesson from Brain-Derived Neurotrophic Factor

Contents

Abstract

Human immunodeficiency virus type 1 (HIV) causes mild or severe neurological problems, termed HIV-associated neurocognitive disorder (HAND), even when HIV patients receive antiretroviral therapy. Thus, novel adjunctive therapies are necessary to reduce or abolish the neurotoxic effect of HIV. However, new therapies require a better understanding of the molecular and cellular mechanisms of HIV-induced neurotoxicity. HAND subjects are characterized by being profoundly depressed, and they experience deficits in memory, learning, and movements. These deficits resemble those occurring in premature brain aging.

Thus, it appears that HIV diminishes neuronal survival, along with reduced neuronal connections. These two phenomena should not occur in the adult brain when synaptic plasticity is promoted by neurotrophic factors. In particular, synaptic plasticity is enhanced by brain-derived neurotrophic factor (BDNF), a potent neurotrophic factor that is present in abundance in the adult synapses. This chapter will outline experimental evidence as well as present emerging concepts for the use of BDNF as an adjunct therapy to prevent HIV-mediated neuronal degeneration and restore the loss of synaptic connections.

1 Introduction

Human immunodeficiency virus type 1 (HIV) which depletes the immune system causing *acquired immunodeficiency syndrome* (AIDS) also infects the central nervous system (CNS) and promotes neurological problems in more than 50 % of patients not receiving any form of antiretroviral therapy. Symptoms include profound motor and behavioral/psychosocial abnormalities that disrupt work or other activities of daily living. Abnormalities that can be manifested as attention deficit can also be seen in children.

The introduction of combined antiretroviral therapy (cART) has improved immune recovery and decreased the gravity of neurological signs and the more severe form of cognitive impairment (Sacktor et al. 1999) or *HIV-associated dementia* (HAD). By controlling the viral load, cART allows an individual with HIV to typically live longer with milder medical symptoms. Indeed, recent estimates of AIDS subjects after the advent of cART place HAD in the 1–2 % of the HIV cohort (Woods et al. 2009). Yet, cART has not eliminated mild neurocognitive deficits and asymptomatic neurocognitive impairments (McArthur et al. 2003). These deficits are referred to as *HIV-associated neurocognitive disorders* (HAND). Current estimates find that nearly 50 % of HIV patients in the United States demonstrate neuropsychological testing performance that is below expectations compared to age-, education-, gender-, and ethnicity-matched reference groups. The reason why HAND persists among treated individuals is still under debate. Some of the drugs used in cART may not reduce HIV infection in the CNS because they poorly penetrate the blood–brain barrier (BBB) or because the virus develops drug resistance. It is noteworthy that neurologically impaired individuals have a higher viral load in the cerebrospinal fluid

(CSF) than in plasma. Indeed, clinical evidence has shown that the CNS of these individuals is an HIV sanctuary site (Masliah et al. 2000) unless they initiate a highly CNS-penetrating antiretroviral regimen (Letendre et al. 2004).

HIV does not infect neurons; nevertheless, postmortem brains of HAD subjects have shown neuronal loss accompanied by synaptic simplifications (Everall et al. 2005). Thus, our great hope lies in our ability to develop alternative adjunct therapies that can provide a more efficient treatment of HIV-mediated neuronal degeneration. The search for pharmacological compounds that prevent HIV neurotoxicity must rely on the general concept of the so-called biological therapies, which are defined by two principal features: they require a better understanding of the molecular and cellular mechanisms of HIV neurotoxicity, and, ideally, they use physiological compounds utilized by the CNS to prevent neuronal injury. These compounds include *neurotrophic factors*, which are naturally occurring diffusible polypeptides that promote survival of a variety of CNS cells and are equally essential for inducing differentiation of surviving neurons into their mature phenotypes (Reichardt 2001). This chapter will introduce new emerging concepts and principles in the use of neurotrophic factors as an adjunct therapy to prevent HIV-mediated neuronal degeneration and restore the loss of synaptic connections.

2 Brain-Derived Neurotrophic Factor: The Most Abundant Neurotrophin in the Adult Brain

2.1 Neurotrophins

HAND pathology includes loss of both synaptic connections and neuronal differentiation (Ellis et al. 2007). In addition, HIV promotes neuronal apoptosis, especially in children (Gelbard and Epstein 1995). Thus, this disease is an excellent target for a neurotrophic factors-based therapy. In fact, neurotrophic factors have been shown to reduce synaptic and axonal degeneration mediated by a number of neurotoxins and to interfere with the fundamental mechanism of apoptotic cell death in numerous conditions (Reichardt 2001). One of the most potent neurotrophic factors is *brain-derived neurotrophic factor* (BDNF) (Barde et al. 1982), the most abundant member of the neurotrophin family of trophic factors in the adult CNS that also includes *nerve growth factor* (NGF) (Levi-Montalcini 1987), neurotrophin-3, and neurotrophin-4 (Maisonpierre et al. 1990).

BDNF exerts multiple neurotrophic activities during development as well as in the adult CNS. After its initial discovery by Barde et al. (1982), interest in BDNF grew due to its potent effect on cortical (Cabelli et al. 1995) and subcortical plasticity (Lyons et al. 1999; Mamounas et al. 1995). Neurotrophic effects include modulation of dendritic branching and spines in the cortex and long-term potentiation in the hippocampus (Patterson et al. 1996; Zakharenko et al. 2003). Through these properties, BDNF plays a critical role in learning and memory and preservation of cortical circuits. Conversely, a reduction of BDNF secretion/activity is

responsible for the loss of cortical and hippocampal synapses and fear learning. This has been demonstrated not only in animals but also in humans. In fact, impaired learning and memory have been observed in both human subjects (Egan et al. 2003) and mice (Soliman et al. 2010) in which the regulated BDNF secretion is reduced due to a single nucleotide polymorphism in the BDNF gene that encodes a valine (Val) to methionine (Met) substitution at codon 66 (Val66Met). In addition, correlative studies of human chronic neurodegenerative diseases characterized by reduced BDNF levels/activity have confirmed the role of BDNF in adult plasticity. For instance, a deficiency in BDNF synthesis has been described in postmortem brains (Phillips et al. 1991) or cerebrospinal fluid (Laske et al. 2007) of patients with Alzheimer's disease (AD), which is categorized as a disease with reduced number of neurons and connections in the cortex and hippocampus as well as impaired short-term memory (Scheff and Price 2006).

BDNF is also decreased in *nigrostriatal dopamine neurons* in Parkinson's disease (PD) (Howells et al. 2000; Nagatsu et al. 2000), cortical neurons in Huntington's disease (HD) (Zuccato et al. 2001), and schizophrenia (Durany and Thome 2004). Nevertheless, results obtained from these studies may reflect secondary effects of the main pathological process rather than primary pathological events. This limitation is especially problematic for the *neurotrophins* whose expression and availability is regulated by synaptic activity (Ghosh et al. 1994). However, BDNF treatment has the potential to reduce or abolish neuronal death in several brain areas. Indeed, early experimental studies in animal models have shown a remarkable neuroprotective effect of BDNF against various neurotoxins that mimic human chronic neurodegenerative diseases such as PD and HD (Alberch et al. 2002; Frim et al. 1994; Hyman et al. 1991). Similar neuroprotection has been observed in rodents and nonhuman primates after the lesion of the perforant path, an animal model of AD (Nagahara et al. 2009). These and other experimental evidence have prompted the suggestion that BDNF could be a potential therapeutic agent for the treatment of these diseases. Most importantly, these observations suggest that an environment characterized by lower BDNF levels or activity (and other neurotrophic factors) could be a common risk factor for the development of neurological diseases. This issue rarely receives the attention it deserves, a problem that may have a negative impact on the success of future clinical trials.

2.2 Neurotrophin Receptors: Dual Mechanism of Action

The biological activity of the neurotrophins begins when they bind to a receptor complex composed of two different receptors. The first neurotrophin receptor that was characterized was a member of the tumor necrosis factor receptor family that was named p75 NGF (Johnson et al. 1986; Radeke et al. 1987); however, p75 binds to all neurotrophins with a similar affinity (Rodriguez-Tebar et al. 1990) and was therefore named *p75NTR*. The other component of the neurotrophin receptor complex is the proto-oncogene Trk. This is a receptor tyrosine kinase which, like other tyrosine kinase receptors, is activated by ligand-induced formation of non-covalently

associated receptor dimers (Kaplan et al. 1991). There are three structurally related Trks and each neurotrophin binds selectively to Trk: BDNF binds to *TrkB*, NGF to TrkA, and NT-3 to TrkC (Chao and Hempstead 1995); however, at high concentrations BDNF can also bind to TrkC (Klein et al. 1991). Both Trk and p75NTR are necessary to confer high-affinity binding to the neurotrophins and to influence their biological activities (Brennan et al. 1999; Hempstead et al. 1991). When activation of p75NTR occurs without a concomitant activation of Trk, p75NTR promotes death of oligodendrocytes (Gu et al. 1999) as well as axonal degeneration in the peripheral (Kenchappa et al. 2006) and CNS (Park et al. 2010). In addition to Trk, p75NTR can also form a complex with the so-called truncated Trk (or Trk.T1), an isoform of Trk generated from an alternative splicing which does not contain the tyrosine kinase domain. In certain neuronal populations, TrkB.T1 or TrkC.T1 can function as inhibitors of full-length Trk through a dominant-negative mechanism. Nevertheless, Trk isoforms and p75NTR also exhibit some neurotrophic properties such as neuronal crest proliferation and differentiation (Hapner et al. 1998) and regulation of neuronal branching as well as BDNF signaling (Carim-Todd et al. 2009).

p75NTR can also bind the larger precursor protein for the neurotrophins or *proneurotrophins* including proBDNF (Hempstead 2002). Proneurotrophins are abundant in the mature brain (Fahnestock et al. 2001) and can be released from neurons (Yang et al. 2009). Proneurotrophins can be cleaved in the endoplasmic reticulum by the proconvertase furin (Seidah et al. 1996) or extracellularly by proteases such as plasmin and matrix metalloproteases to be converted to mature neurotrophins (Mowla et al. 1999). Conversion of proneurotrophin to mature neurotrophin is an important process for synaptic plasticity. In fact, when processing is impaired, proNGF or proBDNF can accumulate outside neurons and induce neuronal loss by binding to p75NTR (Harrington et al. 2004; Teng et al. 2005). The mechanisms of p75NTR-mediated cell death include several "toxic" signaling pathways that are unrelated to tyrosine kinase activation but that produce ceramide (Dobrowsky et al. 1994) and activate nuclear factor kB and Jun kinase (Bhakar et al. 2003; Carter et al. 1996). Given the fact that at high concentrations neurotrophins can indiscriminately activate p75NTR, caution must be exerted in delivering neurotrophins into the mature injured brain where there is a possibility of an upregulation of p75NTR without a concomitant increase in Trk (Beattie et al. 2002; Brunello et al. 1990; Volosin et al. 2006).

3 BDNF and HIV Dementia: Basic Tenets

Subjects with the most severe form of HAND or HAD exhibit depression and mania (Grant 1990; Pumpradit et al. 2010), combined with all degrees of cognitive and motor impairments. In fact, the clinical manifestations of HAD include tremor, gait ataxia, loss of fine motor movement, mental slowing, forgetfulness, poor concentration, and behavioral abnormalities (McArthur et al. 2010). Neuroimaging studies of HAD patients have revealed generalized white matter reduction, with additional grey matter loss particularly in the basal ganglia and posterior cortex

(Aylward et al. 1995; Dal Pan et al. 1992). Neuronal loss has been confirmed in postmortem brains in the *basal ganglia* and other regions of the brain including the hippocampus and *frontal cortex* (Davies et al. 1998; Everall et al. 1993). Pathological alterations of the basal ganglia in HAD include neuronal loss in the putamen (Everall et al. 2005) and the globus pallidus (Fox et al. 1997), degeneration of nigrostriatal dopamine (DA) neurons (Itoh et al. 2000; Reyes et al. 1991), and dysfunctional DAergic transport (Wang et al. 2004). Thus, it is not surprising to note clinical features in HAD resembling those found in PD, such as the postural instability, involuntary movements, bradykinesia, and impairment in fine motor skills (Berger and Nath 1997; Koutsilieri et al. 2002; McArthur 2004).

HAD also exhibits a number of striking similarities with AD in terms of clinical manifestations and neuropathology. Indeed, cognitive impairments (moderate to severe) in HAD are similar to those observed in AD. Higher cognitive functions depend on a highly complex synaptodendritic network in the frontal cortex, and damage to this network results in abnormal output, measured as deficiencies in cognitive skills and behavior. Granted that memory and attention alterations could be also due to the high prevalence of CNS comorbidities in HIV populations (e.g., drug abuse), it is important to keep in mind that these cognitive alterations correlate with the loss of synaptodendritic networks in the cortex and hippocampus. Moreover, neuroimaging studies have revealed microstructural abnormalities in the cerebral white matter, supporting the theory of *synaptodendritic pathology* as the main cause of neuronal loss.

The notion that BDNF limits the neuronal pathology of brain diseases such as AD, PD, depression, and schizophrenia has been extensively established (Zuccato and Cattaneo 2009). Yet, very little is known about a possible role of this neurotrophin in HAD, the most severe form of HAND. As presented above, AD (Kunugi et al. 2001; Phillips et al. 1991), PD (Howells et al. 2000; Nagatsu et al. 2000), depression, and other psychiatric disorders (Duman 2004; Post 2007; Toyooka et al. 2002) have in common a decrease in *BDNF synthesis*. Thus, while BDNF treatment could be a beneficial therapeutic approach in these diseases (Nagahara and Tuszynski 2011), at the same time, it is appealing to suggest that HIV may promote neuronal degeneration by lowering BDNF levels. This hypothesis has recently been tested in animal models of HAD as well as in HIV-positive subjects. It was found that HIV reduces BDNF both in rodents (Nosheny et al. 2004) and humans (Avdoshina et al. 2011). These data pose the question as to whether HIV promotes synaptic simplification by reducing BDNF or other neurotrophic factors whose physiological role is to support and maintain synapses (Fig. 1). This theory was first developed for sensory and sympathetic neurons in which the neurotrophins regulate the density of their innervation to a target cell. Consequently, the extent of neuronal loss is regulated by interactions with postsynaptic targets producing NGF (Johnson et al. 1980; Levi-Montalcini 1987). Nevertheless, such concept can also be applied to the CNS. Indeed, low levels of BDNF have been shown to impair the innervation of the cortex by serotonergic neurons (Lyons et al. 1999).

BDNF can avidly be transported in axons and released upon activation of neuronal activity (Conner et al. 1997; Marini et al. 1998). When such transport is interrupted, the release diminishes, and, consequently, neurons do degenerate as

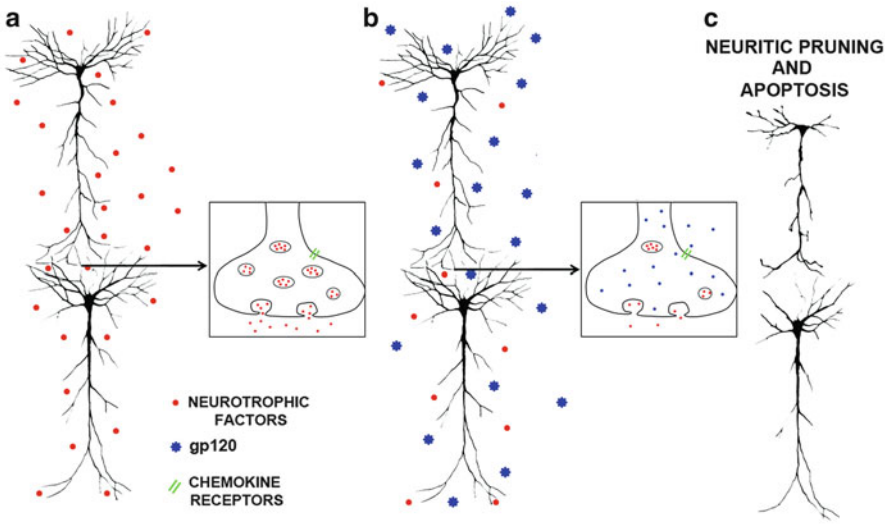

Fig. 1 *Model illustrating how HIV induces neuronal degeneration.* (**a**) Physiological environment. BDNF, released in an activity-dependent manner, promotes maintenance of neuronal architecture. BDNF can also signal back to the cell body to keep it from undergoing apoptosis. (**b**) Infected CNS. HIV infects the brain and sheds gp120. The viral protein binds to chemokine receptors and reduce BDNF trafficking and release. (**c**) Pathological brain. The lack of trophic support evokes short processes and elimination or pruning of processes that eventually culminate in apoptosis

BDNF profoundly affects neuronal homeostasis (Fig. 1) and the ability of neurons to counteract naturally occurring neuroinflammatory responses. This is applicable to different neuronal populations that express TrkB (Chao 2003), such as striatal (Zuccato et al. 2001), hippocampal (Erickson et al. 2011), and cortical (Mamounas et al. 1995; Xie et al. 2010) neurons. Conversely, BDNF inhibits neuronal *apoptosis* and cell loss in animal models of HAD both in vitro (Bachis et al. 2003) and in vivo (Nosheny et al. 2007). The neuroprotective property of BDNF raises the question of how this neurotrophin interacts with membrane receptors to avoid the destructive process of HIV. The next section reviews some experimental evidence that illustrates a unique molecular mechanism of BDNF action that might allow for the suppression of the main neurotoxic pathway of HIV. In order to fully comprehend this mechanism, a brief overview of how HIV infects cells is necessary.

4 HIV in the Brain

4.1 HIV and Chemokine Receptors

The most likely route for brain invasion by HIV is across the blood–brain barrier (BBB) (Price et al. 1988) although the choroid plexus and CSF pathway may also be

implicated (Petito et al. 1999). The primary CNS cell types that are vulnerable to HIV infection are the parenchymal microglia and the perivascular microglia/macrophages (Kramer-Hammerle et al. 2005). These monocyte lineage cells express the primary HIV receptor, CD4, a member of the immunoglobulin superfamily essential for activating helper cells, and chemokine co-receptors *CCR*5 or CXCR4 (Clapham and McKnight 2001). Chemokines represent a subset of cytokines with chemoattractant properties that are particularly important in HIV-related pathology. Indeed, both *CXCR*4 and CCR5 mediate entry of different strains of HIV into macrophages and T lymphocytes, respectively (Berger et al. 1999). Resident macrophages and microglia are the only indigenous CNS cell types to express both CD4 and CXCR4/CCR5, while neurons and astrocytes only express chemokine receptors (Albright et al. 1999). Consequently, macrophages and microglia are the primary target cells that are infected by a chemokine receptor-mediated mechanism (He et al. 1997). Infection of microglia by HIV has two potential effects: firstly, production of new virions and viral proteins and, secondly, induction of aberrant cytokine expression within the CNS (Anderson et al. 2002). Apart from microglia, astrocytes are also a possible target but are thought to be capable of only a restricted form of HIV infection in vivo (Brack-Werner 1999). The mechanism by which astrocyte infection occurs is unclear, as these cells do not express CD4, although, as stated above, they do express the chemokine receptors CCR5 and CXCR4. Recent reports have suggested a CD4-independent viral entry into astrocytes which is mediated either by mannose receptors (Liu et al. 2004) or through a gap junction mechanism (Eugenin et al. 2011). Regardless of whether astrocytes are infected or not, it is likely that these cells play a key role in the neuropathogenesis of HIV infection if their crucial functions in supporting neurons and maintaining BBB integrity are disrupted. These functions include the production of neurotrophic cytokines and buffering of substances such as glutamate which are neurotoxic at high concentrations.

There have also been occasional reports of neurons being infected with HIV, though neurons, like astrocytes, do not express CD4 but do express the chemokine receptors CCR5 and CXCR4 (Lavi et al. 1997; van der Meer et al. 2000). Given the lack of evidence for significant neuronal infection, it is thought that neuronal damage and death in AIDS is an indirect result of HIV infection of other cells in the brain. However, the mechanism(s) by which HIV infection of the CNS leads to neurocognitive disorders is not well understood and it is, therefore, the subject of intense research. The next chapters will briefly review some of the theories about HIV neurotoxicity that were obtained mostly from animal studies. The caveat is that simple animal models of AIDS/HAD needed to be carefully reevaluated in terms of relevance to the condition observed in humans.

4.2 Viral Proteins

HIV may promote neuronal injury by distinct series of events. HIV infection causes *HIV encephalitis* (Everall et al. 2005) which is characterized by neuroinflammation, astrogliosis, and microgliosis and results in an overall production and release of

pro-apoptotic chemokines, such as interleukin-1β (IL-1β) and tumor necrosis factor-α (TNFα), and overexpression of CXCR4 (Mocchetti et al. 2008) and its ligand CXCL12 (Langford et al. 2002). These findings have led to the notion that activated microglia play a role in the pathogenesis of HIV encephalitis and suggested that neurodegeneration is triggered by host factors generated from the infection (Kaul et al. 2001). However, this theory does not take in account that activated (proliferating) microglia and released chemokines could be beneficial to recruit other cells in order to prevent any further damage to the infected brain (Cardona et al. 2006). An alternative mechanism of HIV-mediated neurodegeneration involves toxic proteins derived directly from the virus. The HIV genome codes for nine proteins that, apart from their roles in the viral life cycle, can damage neuronal cells and/or interfere with CNS function. One *viral protein* that can cause neuronal injury is the transactivator of transcription, or Tat, which has been shown to be released from HIV-infected cells (Ensoli et al. 1993). Tat can reduce neuronal survival by several indirect and direct mechanisms, among others the production of inflammatory cytokines such as tumor necrosis factor-α (Chen et al. 1997), impairment of mitochondrial function (Norman et al. 2007), activation of NMDA receptors (Haughey et al. 2001), and apoptosis (Kruman et al. 1998). These effects occur at concentrations lower than those needed to support viral replication. Additional viral proteins that evoke neuronal cell death include the accessory proteins Nef and Vpr (Li et al. 2005). These proteins are not released (Tornatore et al. 1994) but can cause neurotoxicity by a number of mechanisms including activation of potassium and calcium channels (Piller et al. 1996; Zegarra-Moran et al. 1999). Thus, a new theory of neurotoxicity has been suggested that calls for a direct interaction of these proteins with membrane-associated receptors and activation of a signaling pathway that promotes cell death.

One important viral protein that has been linked to the pathogenesis of HAD is the envelope protein *gp*120. This protein is necessary for infectivity as it allows the virus to change conformation after binding to chemokine co-receptors CXCR4 and CCR5 (Scarlatti et al. 1997). During viral entry gp120 can be shed from the virus and bind to CCR5 and CXCR4. This binding activates a cytotoxic pathway in both T cells and neurons (Grivel and Margolis 1999; Kaul et al. 2007). Indeed, activation of neuronal CXCR4 and CCR5 has been shown to promote neuronal loss/atrophy that is relevant to explain the neuropathology of HAD (Hesselgesser et al. 1998; Meucci et al. 1998; Zheng et al. 1999). Proof of this theory has also been obtained in transgenic mice expressing gp120 or in rats infused intracerebroventricularly with gp120. In fact, transgenic mice exhibit neuronal loss and *dendritic simplification* (Toggas et al. 1994), pathological features seen in postmortem brains of HAD subjects. Infusion of gp120 into rat brains causes apoptosis and neuronal loss (Acquas et al. 2004; Bagetta et al. 1995). Moreover, gp120 has also been shown to cause axonal degeneration (Melli et al. 2006) and dendritic injury (Everall et al. 2002; Iskander et al. 2004), two key pathological events that may account for the synaptodendritic atrophy observed in HAD (Masliah et al. 1997). These data are significant from the standpoint of experimental therapeutics because they allow the speculation that gp120 signal transduction could be a valid target for an

adjunct therapy to prevent HIV neurotoxicity. Most importantly, they indicate that experimenters can recreate an animal model of HIV neurotoxicity without the need to deal with HIV infection.

5 Chemokine Receptors and Neurotrophins: From Experiments to Therapy

5.1 Chemokine Receptors and Synaptic Injury

As described above, CXCR4 and CCR5 are crucial for gp120-induced neurotoxicity. Therefore, inhibitors of the expression/signaling of these receptors may have an important therapeutic property against HIV-mediated neurological impairment caused by CXCR4/CCR5 activation. These receptors are abundant in neurons and areas of the CNS that also express TrkB, such as the cortex, hippocampus, and striatum (Ahmed et al. 2008). CXCR4 and CCR5 are G-protein-coupled receptors that can be desensitized by tyrosine kinase intracellular signal crosstalk (Daub et al. 1996). Thus, TrkB activation may downregulate CXCR4 and CCR5. Indeed, experimental evidence has shown that BDNF and the other neurotrophins modulate the expression of CXCR4 and CCR5. This evidence includes the ability of BDNF to reduce CXCR4 in vitro (Bachis et al. 2003) and in vivo (Nosheny et al. 2007). Conversely, BDNF heterozygous animals exhibit increased levels of CXCR4 and CCR5 mRNA in the cortex, hippocampus, and striatum when compared to wild type (Ahmed et al. 2008). Moreover, in BDNF heterozygous mice, increased CXCR4 correlates with a more robust neurotoxic effect of gp120 (Nosheny et al. 2004), supporting the role of CXCR4 in gp120-mediated neuronal degeneration. Thus, from a pharmacological point of view, BDNF is particularly important as a neuroprotective compound against HIV or gp120 neurotoxicity that occurs through CXCR4 or CCR5 receptors.

The neuroprotective effect of BDNF against gp120 relies on TrkB-mediated activation of the extracellular-signal-regulated kinase (ERK) pathway (Mocchetti and Bachis 2004). Conversely, BDNF does not prevent gp120 toxicity in neurons that do not express TrkB (Ahmed et al. 2008), suggesting that BDNF may not be suitable to reduce CXCR4 and HIV toxicity in all brain cells. However, from a therapeutic perspective, this is not an issue, as trophic factors can promote plasticity on overlapping as well as dissimilar neuronal populations/compartments. For example, cholinergic neurons of the basal forebrain express TrkB as well as TrkA. These neurons are more responsive to NGF than BDNF (Koliatsos et al. 1994). Thus, NGF could be used to modulate the plasticity of cholinergic neurons and control their function in learning and memory in HAD. Moreover, basic fibroblast growth factor, another neurotrophic factor that binds to tyrosine kinase receptors and has been shown to downregulate CXCR4 (Sanders et al. 2000), could also be used to rescue Trk-negative neurons and therefore overcome the toxic effects of HIV in neurons that do not respond to the neurotrophins. Based on all the experimental data collected so far, it is clear that specific neurotrophins may be necessary to stimulate growth in a defined population of CNS neurons. The functional significance of the ability of the

neurotrophins to modulate CXCR4 remains to be established as well as whether neurotrophins act on more than one chemokine receptor.

The survival of neurons exposed to HIV is greatly enhanced by CXCR4 or CCR5 receptor antagonists (Bachis et al. 2009). Moreover, as discussed before, several groups have demonstrated that gp120 binding to chemokine receptors evokes *caspase*-3-mediated apoptosis. This is relevant for HAD because cortical neurons of HIV subjects are caspase-3 positive (Garden et al. 2002). Thus, the ability of BDNF to prevent gp120 activation of caspase-3 (Bachis et al. 2003) suggests that this neurotrophic factor will also be neuroprotective against HIV. However, post-mortem studies of HAD have also indicated that neuronal apoptosis does not correlate with dementia and that loss of dendritic spines and synaptic densities may be the primary cause leading to apoptosis (Adle-Biassette et al. 1999). Consistent with this hypothesis, gp120 reduces dendritic arborization and dendritic volume in human neurons in vitro (Iskander et al. 2004). However, such pathological changes can also be reproduced in rodent neurons in vitro by HIV. In fact, a dramatic alteration of axonal processes, characterized by fragmentation and varicosities, can be seen as quickly as 6–8 h after exposure to HIV (Fig. 2). Most importantly, the axonal disruption is preventable by BDNF. Thus, BDNF can also help neurons to survive by inhibiting the disruption of axons caused by HIV.

5.2 Delivery of BDNF

Of particular theoretical importance is the use of BDNF in HIV-positive patients as an adjunct therapy combined with cART. As discussed above, the physiological role of BDNF in promoting the survival and plasticity of adult neurons adds credence to the experimental data supporting such therapy. Moreover, in vitro models of HIV neuropathogenesis have indicated that HIV infection of the brain triggers the release of glutamate (Bezzi et al. 2001). Glutamate, through excitotoxicity, may help propagate the initial "injury" caused by inflammation to adjacent neurons. BDNF is a strong inhibitor of *excitotoxicity* whether it is induced by neurotoxins (Marini et al. 1998; Martinez-Serrano and Bjorklund 1996) or ischemia (Han and Holtzman 2000). Thus, BDNF may also be a potential therapeutic agent in preventing HIV-mediated excitotoxicity, especially considering the side effects of glutamate receptor antagonists.

A crucial question to be considered is what constitutes a safe way of administering BDNF into the CNS. A major concern is the degree of penetration of BDNF into the CNS. BDNF is a charged protein that does not efficiently cross the BBB. When delivered by direct infusion into the ventricles, its parenchymal diffusion is limited; thus, the delivery must be constant. More recently, viral vectors have been designed to deliver the gene encoding for BDNF into the CNS (Klein et al. 1998). These vectors, such as *adeno-associated viruses* (AAVs), use viral backbones to transduce host cells in a brain area of interest. AAVs are safe and capable of sustaining long-term BDNF expression in neurons (Klein et al. 1998). Using an AAV-expressing BDNF, it was shown that BDNF prevents gp120-mediated

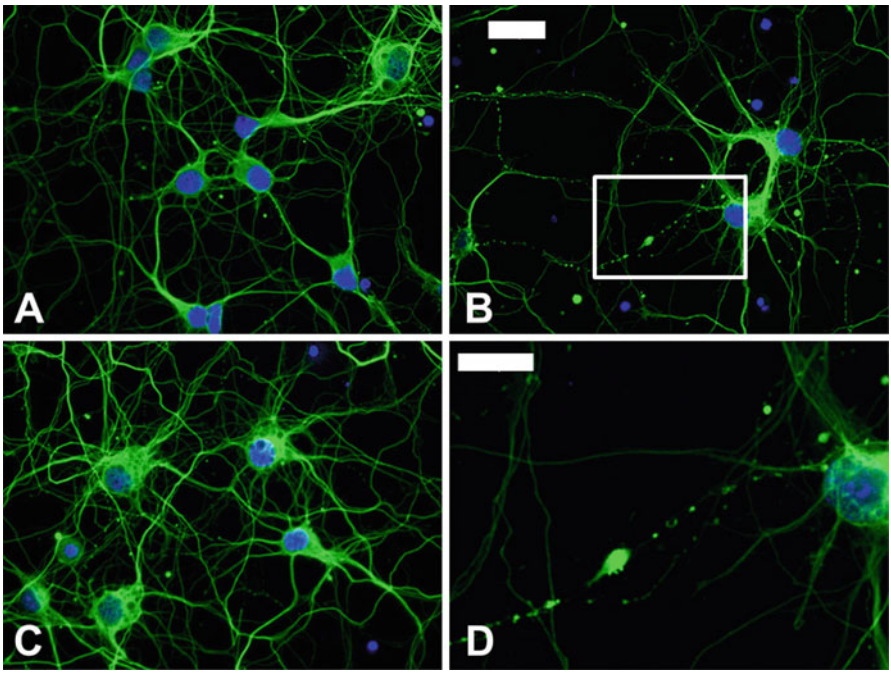

Fig. 2 *BDNF prevents HIV-mediated axonal damage*. Examples of rat cortical neurons grown for 7 days in vitro and then exposed for 6 h to (**A**) control medium (0.1 % BSA); (**B**) medium containing HIV; (**C**) medium containing BDNF and HIV; and (**D**) higher magnification of the *square* shown in (**B**) to show typical axonal varicosities. *Blue* DAPI to visualize cells, *green* βIII-tubulin to visualize neuronal processes. *Bar*: A, B, and C = 20 μm and D = 10 μm. Immunofluorescence was analyzed using a FV300 laser confocal scanning system attached to an Olympus IX70 upright microscope. Please note the lack of axonal swelling and varicosities, the hallmarks of diffuse axonal injury (Tang-Schomer et al. 2010), in BDNF-treated cultures

neuronal apoptosis in vivo (Nosheny et al. 2007), raising the possibility of using BDNF in clinical trials in the near future. However, caution must be exerted as clinical effects could be accompanied by undesired effects. For instance, BDNF also promotes sprouting of dendrites of dopaminergic neurons in gp120-treated rats (Nosheny et al. 2007). Although, in general, this is a trophic effect of the neurotrophins on neuronal processes, it may be a negative side effect of overdosing. Indeed, according to the classical view of trophic molecules, a trophic factor must be delivered in small amounts and only to specific populations of neurons to avoid such side effects.

5.3 BDNF and Immune Responses

There are other effects of BDNF that can be beneficial for HIV-positive subjects. For instance, in the immune system, BDNF decreases apoptosis of T cells

(De Santi et al. 2009; Maroder et al. 1996). These cells are depleted in AIDS. Thus, one may envision the use of BDNF in conjunction with cART to maintain the appropriate number of immune cells and delay AIDS. This effect also has a broader implication for the CNS function. In fact, as progressive neurological deficits occur after the onset of severe immunodeficiency (McArthur et al. 2010), keeping healthy immune cells will reduce "inflammation" of the immune system that can amplify nervous system damage via inflammatory cytokines. These may enter the CNS either from the periphery or produced locally by *microglia*. For example, in a state of chronic inflammation induced in a nonhuman primate by infection with simian immunodeficiency virus, the brain was positive for peripheral circulating monocytes trafficking from bone marrow. This event correlates with the severity of encephalitis (Burdo et al. 2010). Abnormal activation of cytokine and chemokine receptors in the context of HIV infection results in dendritic beading and loss of dendritic spines. These changes are accompanied by failure of long-term potentiation (LTP), which might underlie impaired learning and memory. Given the well-known property of BDNF in promoting dendritic branching and spine morphology (Horch and Katz 2002; Tanaka et al. 2008) which are key for the BDNF-mediated LTP (Figurov et al. 1996; Gartner and Staiger 2002), BDNF could be used to prevent atrophy of *dendrite branching* and memory loss. Of course such treatment will require an early diagnosis of cognitive impairments.

6 Conclusion

The dividing line between viral- and host-mediated neurotoxicities in HIV infection is neither precise nor rigid. An effective therapy aimed at treating HIV-induced CNS diseases will require both cART and adjunctive therapies that include neuroprotective and neuro-regenerative agents. Neurotrophic factors are large hydrophilic molecules that do not cross the BBB. Therefore, these molecules need to be delivered within the CNS, which lowers the enthusiasm for a chronic instrumentation in a nonclinical setting. In addition, when infused into the CNS, BDNF has limited diffusion. The delivery problems may not be severe for AIDS patients with neurodegeneration of peripheral neurons (i.e., peripheral neuropathy) as these neurons are located outside the CNS and are capable of retrogradely transporting BDNF to the soma. However, the efficiency of terminal uptake and axonal transport of trophic molecules is uncertain as there is evidence of impaired axonal transport in AIDS. One strategy, still under experimentation in humans, is the delivery of BDNF via viral vectors. A major concern about a clinical approach to increase BDNF in the CNS by this method is that an abnormal overproduction of BDNF may cause side effects that may be intolerable over a long period of time. Such effects may be seen locally (fiber spouting around the site of BDNF production) or systemically (weight loss). Thus, additional strategies must be applied to circumvent these problems. Ongoing research has demonstrated more safe and reliable methods to increase endogenous BDNF and consequently influence neuronal survival. This could replace the need for delivering BDNF by invasive approaches. For instance, physical exercise has been reported to increase BDNF

levels in the hippocampus (Cotman and Berchtold 2002) which, in turn, promotes hippocampus-based learning, synaptic plasticity, and neurogenesis (Vaynman et al. 2004). Antidepressant drugs, which are safely used in humans, also increase BDNF synthesis (Hashimoto et al. 2002; Nibuya et al. 1996). Thus, there are alternatives to minimize the use of chronic instrumentation.

Besides its traditional role as a molecule promoting survival and regeneration, BDNF is seen as a potent mediator of synaptic plasticity in the adult CNS. These effects could play a role in limiting AIDS-mediated neuronal degeneration and stimulating neuronal function. Although still tested only in animal models of HAD, the powerful properties of BDNF provide incentive for further research and raise hope for the therapeutic possibilities in the near future.

disease that results in death of motor neurons. This has led to a considerable number of clinical trials undertaken involving neurotrophic therapy for ALS, although none have shown benefit. This chapter will review the cause and pathology of ALS and how neurotrophic factors relate to neurotoxicity in this disease. The treatments targeted at neurotoxicity and results of trials will be discussed, in particular neurotrophic factors. This will include glial cell-derived neurotrophic factor (GDNF), brain-derived growth factor (BDNF), neurotrophin-3 (NT-3), ciliary neurotrophic factor (CNTF), insulin-like growth factor (IGF), vascular endothelial cell growth factor (VEGF), fibroblast growth factor (FGF), and hepatocyte growth factor (HGF). Also highlighted is the potential for reexamining neurotrophic factors as treatments for ALS, including new delivery methods.

Keywords
ALS • BDNF • CNTF • FGF • GDNF • IGF • NGF • NT-3 • NT-4 • NT-4 • VEGF

List of Abbreviations

ALS	Amyotrophic lateral sclerosis
BBB	Blood–brain barrier
BDNF	Brain-derived growth factor
CNTF	Ciliary neurotrophic factor
CNS	Central nervous system
FGF	Fibroblast growth factor
GDNF	Glial cell-derived neurotrophic factor
HGF	Hepatocyte growth factor
IGF	Insulin-like growth factor
NGF	Nerve growth factor
NMJ	Neuromuscular junction
NT-3	Neurotrophin-3
NT-4	Neurotrophin-4
NT-5	Neurotrophin-5
SOD1	Superoxide dismutase 1
SOD1G93A	Mutated SOD1 glycine to alanine position 93
TDP-43	Transactivation response DNA-binding protein of 43 kDa
VEGF	Vascular endothelial cell growth factor

1 Introduction: What Are the Neurotrophic Factors and How Do They Relate to Neurotoxicity in ALS?

The story of neurotrophic growth factors in the nervous system began when Rita Levi-Montalcini, Viktor Hamburger, and Stanley Cohen discovered the actions of nerve growth factor (NGF) in the 1950s (Levi-Montalcini and Hamburger 1951; Levi-Montalcini and Cohen 1960). In 1986, both Levi-Montalcini and Cohen

received the Nobel Prize for the "discovery of growth factors" and at that time were already acknowledged for opening up a large area of research and potential therapeutic approaches for these agents within and outside the nervous system. The list of proteins regarded as neurotrophic growth factors has grown, and a lot has been learned about common and specialized activities of these factors. Some of them, the four-member neurotrophin family that includes NGF, were first described as acting on neuronal cells, whereas other more recently described neurotrophic factors were initially discovered in a nonneuronal context.

Neurotrophic factors have an array of activities in the nervous system that consist of functions in development, plasticity, neurogenesis, disease, and injury. In the context of amyotrophic lateral sclerosis (ALS), it has long been hypothesized that *lack* of neurotrophic growth factors *is one of the neurotoxic* contributors to the disease that results in death of motor neurons. This has led to a considerable number of clinical trials undertaken involving neurotrophic therapy for ALS, although none have shown benefit. In retrospect this may be due to inadequate dosing and/or route of application of the growth factor in question. This chapter will review the general contributors to neurotoxicity in ALS including withdrawal of neurotrophic support and then the therapies trialled which are aimed at correcting neurotoxicity including neurotrophic therapy, highlighting the potential for reexamining neurotrophic factors as treatments.

The first neurotrophic factor to be discovered was NGF (Levi-Montalcini and Hamburger 1951). Subsequent systematic search of mammalian tissues revealed that male mouse salivary glands contained substantial amounts of NGF (Cohen 1960; An odd finding that has never been clearly understood!). Thirty years after the discovery of NGF, another neurotrophin that demonstrated neuronal growth-promoting properties was purified from pig brain, and later called brain-derived neurotrophic factor (BDNF; Barde et al. 1982). A third member of the family called neurotrophin 3 (NT-3) was identified in 1990 (Hohn et al. 1990) and neurotrophin 4 (NT-4) in 1991 (Hallböök et al. 1991), with neurotrophin 5 (NT-5) later identified as identical to NT-4 (Ip et al. 1993). After the discovery of NGF, a number of other, unrelated neurotrophic factors in the nervous system were discovered that have a similar scope of activities, including ciliary neurotrophic factor (CNTF; Barbin et al. 1984; Lin et al. 1989) and the glial cell line-derived neurotrophic factor (GDNF; Lin et al. 1993). Members of the insulin-like growth factor (IGF; Shemer et al. 1987; Rotwein et al. 1988) fibroblast growth factor (FGF; (Emoto et al. 1989)) and vascular endothelial growth factor (VEGF; Alvarez et al. 1992) families are known to have roles in the nervous system additional to those outside the nervous system. In addition, hepatocyte growth factor (HGF), which was found in the liver, has further actions in the nervous system (Jung et al. 1994).

2 Searches for the Cause and Pathophysiology of ALS

In 1869, the French neurologist Jean-Martin Charcot described a fatal and progressive paralysis that he termed amyotrophic lateral sclerosis (ALS) (Rowland 2001). This devastating neurodegenerative disease, also known as Lou Gehrig's disease

in the USA or motor neuron disease in the UK and Australia, has a worldwide incidence of 2 per 100,000 and prevalence of 7 per 100,000 (Ferraiuolo et al. 2011). ALS is characterized by progressive, debilitating paralysis. Patients experience muscle weakness and atrophy, leading to inevitable paralysis, due to the selective and progressive loss of motor neurons of the cerebral cortex, brain stem, and spinal cord that is characteristic of the disease. Most often, patients succumb to the disease because of denervation of muscles involved in respiration (Vande Velde et al. 2011). ALS/MND occurs mainly in adults (45–60 years of age), and only 50 % of patients survive 2–3 years after diagnosis. There is only one therapeutic option for patients, riluzole, which offers a modest 3- to 6-month extension in survival. However, in the last 3 years, real progress has been made in the identification of genetic causes of the disease, such as expanded GGGGCC hexanucleotide repeats in a noncoding region of C9ORF72 (Renton et al. 2011; Zinman and Cudkowicz 2011; Ludolph et al. 2012).

Around 5–10 % of ALS patients have inherited a mutation that can cause familial ALS (Andersen and Al-Chalabi 2011), with the remaining 90 % developing the disease sporadically through environmental and lifestyle risk factors (Sutedja et al. 2009). The highest proportion of familial ALS patients identified is that with expanded GGGGCC hexanucleotide repeats in the noncoding region of C9ORF72 (Renton et al. 2011), followed by patients that carry Cu/Zn superoxide dismutase 1 (SOD1), mutations (Ludolph et al. 2012). Other rarer mutations leading to ALS occur in genes such as alsin, senataxin, dynactin, transactivation response DNA-binding protein of 43 kD (TDP-43), fused in sarcoma/translated in liposarcoma (FUS), optineurin, and ubiquilin 2 (Deng et al. 2011; Andersen and Al-Chalabi 2011; Ludolph et al. 2012). Over 160 SOD1 mutations have been identified (Gurney et al. 1994; Al-Chalabi et al. 2012) in humans.

Transgenic rodents carrying SOD1 mutations have been essential to understanding the mechanisms of ALS in humans (Peviani et al. 2010; Kanning et al. 2010). All mimic human familial and sporadic ALS, with a dominant gain of toxic function resulting in motor symptoms and death, due to the neurotoxicity of the mutant SOD1 protein (Reaume et al. 1996; Turner and Talbot 2008; Peviani et al. 2010; Kanning et al. 2010). Transgenic mice that carry 23 copies of the human mutant SOD1G93A transgene are used for preclinical testing of ALS treatments (Scott et al. 2008; Ludolph et al. 2010). Mice that overexpress normal or human mutant TDP-43 have been produced (Cohen et al. 2011), but they have not yet lived up to their promise as a model for ALS. Several groups have generated TDP-43 knockout mice and in each instance all die during embryonic life, indicating the importance of TDP-43 in multiple biological processes (Wu et al. 2010; Kraemer et al. 2010). Issues with mice expressing mutant TDP-43 have been identified such as inconsistent pathology and disease progression across TDP-43 mouse models and most recently the TDP-43 A315T mutant mice dying from neuropathy-linked bowel obstruction (Igaz et al. 2011; Guo et al. 2012). Conversely, evidence supports the continued relevance of SOD1G93A animal models to sporadic disease. Misfolding of SOD1 into a disease-specific and toxic conformation has been found in both sporadic and familial ALS (Bosco et al. 2010). Moreover, SOD1G93A mice replicate features of human MND including progressive limb

paresis, respiratory failure, and reduced life span (Gurney et al. 1994; Turner and Talbot 2008). Behavioral symptoms appear around 90–110 days, but pathological changes occur much earlier (Peviani et al. 2010; Kanning et al. 2010).

Although we are yet to understand how the disease initiates, there is a large body of data on mechanisms that cause the pathology in motor neurons such as oxidative stress, protein aggregation, excitotoxicity, impairment of axonal transport, mitochondrial dysfunction, altered DNA/RNA processing, endoplasmic reticulum stress, and apoptosis (reviewed in Ferraiuolo et al. 2011). A common feature is ubiquitin-positive inclusions, most of which contain TDP-43 (Geser et al. 2011) that does not appear to be related to TDP-43 mutations. The pathophysiology of the disease includes a reduced secretion of neurotrophic factors, protein aggregations, malfunctioning of the mitochondria, rupture in the axonal passage, destruction in the calcium metabolism, changes in the skeletal proteins, high levels of glutamate, and oxidative damage (Ferraiuolo et al. 2011). Preventing and slowing down motor neuron degeneration and death in ALS are critical goals of future therapies, as are means of enhancing axonal regeneration.

Axonal transport has long been implicated in ALS. Axonal transport uses microtubule-dependent kinesin and cytoplasmic dynein molecular motors, which mediate transport towards the neuromuscular junction (anterograde transport) and towards the cell body (retrograde transport), respectively. Given the extremely long axons of motor neurons and their dependence on axonal transport for the delivery of ATP-producing mitochondria and other essential constituents, including neurotrophic factors, it comes as no surprise that transport deficiencies cause debilitating effects. Tumor necrosis factor elevated in SOD1G93A mice disrupts kinesin function via a mechanism involving p38 mitogen-activated protein kinase (p38 MAPK; De Vos et al. 2000), activation of which has been demonstrated in models of ALS (Holasek et al. 2005; Dewil et al. 2007). Mutant SOD1 also inhibits anterograde fast axonal transport of mitochondria and enhances the retrograde movement resulting in a depletion of axonal mitochondria content (De Vos et al. 2007). A study suggested that alterations in retrograde signalling contribute to neurodegeneration in ALS, by shifting from the transport of survival-promoting to death-promoting signalling cargo molecules (Perlson et al. 2009), suggesting less neurotrophic factors can be transported. Point mutation of the p150 subunit of dynactin has been detected in both sporadic and familial ALS patients (Munch et al. 2004). Mutations in dynactin lead to a reduction in retrograde transport in SOD1G93A mice (Puls et al. 2003).

Peripherin and neurofilament are intermediate filament (IF) proteins that can be abnormally found in inclusion bodies of the perikaryon and axon of motor neurons in ALS. Rare mutations in peripherin have been identified in a small number of people with ALS (Gros-Louis et al. 2004; Corrado et al. 2011). In addition to being found in inclusion bodies, neurofilaments are transported by axons and disruption of neurofilament transport occurs in ALS. Neurofilaments comprise three major proteins, neurofilament light, middle, and heavy chains (NFL, NFM, and NFH), that are synthesized within cell bodies and then usually transported into and through axons by “axonal transport.” Decreased amounts of normal NFH in axons of

SOD1G93A mice are correlated to shrinkage of axons in the ventral root and precede symptoms in SOD1G93A mice (Zhang et al. 1997). Abnormal phosphorylation of the side-arm domain of NFH by the stress-activated kinase p38alpha has been reported in sporadic and familial ALS and SOD1G93A mice (Ackerley et al. 2000, 2004). This work indicated the speed of neurofilament transport through axons is altered (Ackerley et al. 2004) with a slowing of transport proportional to the increase in phosphorylation (Ackerley et al. 2000). Excitotoxic damage by glutamate is thought to contribute to motor neuron injury in ALS. In cultured neurons, glutamate reduces axonal transport of neurofilaments via activation of protein kinases that phosphorylate NFM such as p38 (Ackerley et al. 2000), and riluzole protects against glutamate-induced slowing of neurofilament axonal transport (Stevenson et al. 2009). An association of neurofilaments with ALS is also represented by rare mutations in the neurofilament gene in ALS patients (Al-Chalabi et al. 1999). There is a significant increase in NFM in CSF and serum of humans with ALS and SOD1G93A mice (Brettschneider et al. 2006; Ganesalingam et al. 2011), especially in the late stage of disease (Lu et al. 2012). Thus, axonal transport defects are an important feature of ALS that may precede motor neuron degeneration and clinical symptoms.

At the tissue level, it is clear that cells beyond motor neurons are involved in ALS pathophysiology (Ilieva et al. 2009). Cells such as glia and immune cells are proposed to be involved in non-cell-autonomous toxicity. For example, astrocytes are reactive and apparently toxic in ALS (Ince et al. 2011). Also, reactive microglia and T-cell infiltration have been noted as players in non-cell-autonomous toxicity (Ilieva et al. 2009). Most of this data has come from studies in which human mtSOD1 is expressed in rodents. There is evidence that the onset of ALS in mutant SOD1 mice results from mutant SOD1 action in the motor neurons, whereas progression of the disease is a result of the action of SOD1 mutant protein in glia (Ilieva et al. 2009). Selective reduction of mutant SOD1 from astrocytes or microglia using cre-lox system slowed disease progression in SOD1G37R mice (Yamanaka et al. 2008; Boillee et al. 2006). A complimentary approach replacing microglia/macrophage via bone marrow transplantation demonstrated that wild-type microglia/macrophages slow disease progression in SOD1G93A mice although inflammation may be a consequence, not an initiator of disease (Kano et al. 2012).

Advances in identification of upstream mechanisms that might contribute to the death of motor neurons in ALS and compounds directed at these potential targets are being developed. Ongoing research is addressing the question of where the motor neuron disease process is initiated, candidates being the neuromuscular junction (NMJ), the axon, mitochondria, proteasome, or the cell nucleus (Dupuis and Loeffler 2009; Bilsland et al. 2010; Shi et al. 2010; Dupuis et al. 2004; Baron et al. 2007; Daoud and Rouleau 2011; Keller et al. 2012). Progress in understanding this etiology has led to therapies being trialled to target the various candidates that are causative in the disease. In addition, although ALS is a motor neuron disease, interventions directed towards improving muscle function such as muscle troponin activators, myostatin inhibitors, and reticulon 4 (Nogo-A) inhibitors are also proposed as therapies (Zinman and Cudkowicz 2011).

3 Treatments for ALS Targeted at Neurotoxicity

3.1 Treatments Targeted at Downregulation of SOD1 Mutations

For the approximately 20 % of familial patients with SOD1 mutations leading to familial ALS, a phase 1 human trial of safety, tolerability, and pharmacokinetics of antisense SOD1 oligonucleotides administered intrathecally to patients with SOD1 familial ALS is underway (ISIS 333611/clinicaltrials.gov/NCT01041222). The trial enrolled 21 patients with SOD1 mutations who were randomized into either three ascending dose cohorts or a placebo group. Some patients elected to enroll a second time. The phase 1 trial was completed in Jan 2012 with no significant adverse effects (Robinson 2012). However, some concerns were raised that the antisense oligonucleotide used in the trial targeted the mRNA of the non-mutated portion of SOD1 and that there may be a risk of inflammation in long-term, high-dose treatments. Isis the pharmaceutical company involved in this trial has recommended further animal trials with a redesigned antisense SOD1 oligonucleotide (Robinson 2012). The development of vaccine or passive infusion delivery of immunoglobulin to remove misfolded protein in ALS is a novel therapeutic strategy under investigation. Bosco et al. (2010) found misfolding of SOD1 into a disease-specific and toxic conformation underlies both sporadic and familial MND. Subsequently, vaccination with SOD1 mutant protein or antigenic peptide directed to monomer/misfolded SOD in the ALS SOD1 transgenic mouse model delayed disease onset and significantly extended survival (Takeuchi et al. 2010; Liu et al. 2012).

3.2 Treatments Targeted at Excitotoxicity

Glutamate-mediated excitotoxic effects have long been postulated to have an important role in motor neuron degeneration, with riluzole an example of a glutamate inhibitor used to treat ALS patients (Bensimon et al. 1994; Lacomblez et al. 1996). In an ALS SOD1 mouse model of ALS, lithium showed reduced aggregates of alpha-synuclein, ubiquitin, and SOD1 in motor neurons, and in addition to its known effects on protein clearance, lithium was found to increase the number of mitochondria and suppressed reactive astrogliosis (Fornai et al. 2008). However, lithium by itself failed in human clinical trials (Verstraete et al. 2012), and more recently in combination with riluzole, although well tolerated had no benefit (Aggarwal et al. 2010). Arimoclomol is an oral compound that amplifies the heat-shock response leading to induction of endogenous cellular cytoprotective mechanisms (Kieran et al. 2004) that might prevent motor neuron degeneration under conditions of stress. Arimoclomol delayed disease progression and extended survival by 22 % in the SOD1G93A transgenic ALS mice (Kieran et al. 2004; Kalmar et al. 2008; Lu et al. 2012). Efficacy studies in patients with familial ALS are underway with promising early results indicating this drug is safe in human beings, and it crosses the blood–brain barrier (BBB) following oral administration (Cudkowicz et al. 2008).

3.3 Treatments Targeted at Mitochondria

Results from ongoing trials using dexpramipexole, a drug that improves mitochondrial health, showed initial promise in ALS trials. Dexpramipexole is an optical enantiomer of pramipexole, a Parkinson's disease drug that maintains prolonged survival of ALS SOD1 transgenic mice (Danzeisen et al. 2006). A large, Phase 3 international study of treatment of ALS patients with dexpramipexole (EMPOWER) has been completed with disappointing results. There was initial promise with the first reports from a carefully controlled Phase 2 study indicating subjects show a slower rate of decline in measures of motor function and a lower level of mortality over the course of the study (Bozik et al. 2010; Cudkowicz et al. 2011; Rudnicki et al. 2013). However, in January 2013, the Phase 3 trial was suspended due to lack of effect (alsa.org/news/archive/biogen-discontinues.html). Some compounds proposed to improve mitochondrial function, such as minocycline and creatine, have had beneficial effects in the SOD1 transgenic mouse model (Zhu et al. 2002) but have yet to prove beneficial in human trials (Klopstock et al. 2011; Gordon et al. 2007). A new trial of creatine in combination with tamoxifen is underway (www.clinicaltrials.gov: NCT01257581b). Other agents targeting mitochondrial function have been identified. Olesoxime (previously TRO19622) is a mitochondrial pore modulator that improves SOD1G93A mice survival and attenuates activation of surrounding glial cells. A phase 2/3 study of olesoxime is underway in Europe (NCT00868166).

4 Neurotrophic Factor Withdrawals and Neurotrophic Factors as Treatments

4.1 Rationale

ALS is a complex disease and cannot be explained by the occurrence of a single event or the disturbance of a single gene or protein. The disease is likely to be the result of a multistep process, ultimately leading to motor neuron degeneration and clinical symptoms. Currently there are two hypotheses to explain the etiology of ALS. The first is the "dying-forward" hypothesis which proposes that ALS is mainly a disorder of cortico-motor neurons, which connect monosynaptically with anterior horn cells, mediating anterograde degeneration of anterior horn cells via glutamate excitotoxicity (Kiernan et al. 2011). The second is the "dying-back" hypothesis where pathological changes in motor axons and nerve terminals appear to precede motor neuron degeneration and clinical symptoms. Moreover, this second hypothesis raises the possibility that the disease process may start distally at the nerve terminal or at the neuromuscular junction (NMJ) and progress towards the cell body (Dadon-Nachum et al. 2011). The main therapeutic strategy for ALS directed to the dying-back hypothesis is the use of neurotrophic factors.

No genetic defects have been identified to date that interfere with any of the growth factor genes in ALS. The lack of trophic support appears to be a downstream

consequence of axonal transport of neurotrophic factors in ALS rather than expression. A deficiency of growth factor support could provoke motor neuron death in patients with ALS. In early stages of the disease, nerve terminals and neuromuscular junctions are partially degraded, while cell bodies in the spinal cord are mostly intact. This is clearly shown by Fischer and colleagues (Fischer et al. 2004) who demonstrated, in autopsy material from an ALS patient who died from an unrelated cause only 6 months after symptom onset, that denervation and reinnervation were pronounced, while the spinal motor neurons were not yet affected. The concept is further supported by recent work showing progressive motor axonal changes play a significant role in the course of disease including clinical impairment (Cheah et al. 2012). Studies in animal models of spinal muscular atrophy (SMA), a pure lower motor neuron disease, have shown that the first event to be observed is withdrawal of the axon terminals from the adjacent muscle fibers (Simon et al. 2010). In SOD1G93A mice axonal degeneration also precedes onset of symptoms as well as spinal motor neuron loss. Disease progression in these animals follows the dying-back principle characterized by an ascending neuronal degeneration from the terminals of the motor axons to the motor neuron cell body (Gould et al. 2006). Retrograde transport of neurotrophic factors such as BDNF and GDNF is impaired, whereas death-promoting signalling molecules are enhanced in axons of motor neurons of presymptomatic SOD1G93A mice (Perlson et al. 2009). Both retrograde transport and anterograde axonal transport are impaired in human ALS and in mouse models. This is supportive of the dying-back hypothesis that leads to loss of muscle function and the inability of neurotrophic factors, such as glial cell-derived neurotrophic factor (GDNF), to be transported to the motor neuron cell body.

4.2 Glial Cell-Derived Neurotrophic Factor

GDNF can be efficiently transported by motor neurons both retrogradely (Leitner et al. 1999) and anterogradely (Rind and von Bartheld 2002). In a study where stem cell-derived motor neurons were transplanted into paralyzed rat spinal cord and GDNF-secreting cells implanted into the sciatic nerve, axonal outgrowth and attachment to the muscle could be achieved. This thus supports the notion that combining protection of motor neuron cell body and support of nerve terminals in the muscle by GDNF may be beneficial in ALS (Deshpande et al. 2006). A study examining the overexpression of GDNF either centrally (astrocytes) or peripherally (muscle) showed that overexpression of GDNF in skeletal muscle, but not in the central nervous system (CNS), improved survival in the SOD1G93A model of ALS (Li et al. 2007). When stem cell-derived GDNF was expressed in astrocytes at disease onset, there was no improvement in survival in SOD1G93A mice although there was some improvement in health of motor neurons (Park et al. 2009). The outcomes of studies in SOD1G93A mice argued for a benefit of GDNF treatment. GDNF-treated motor neurons of SOD1 animals are clearly protected (Mohajeri et al. 1999; Acsadi et al. 2002; Suzuki et al. 2007). Some studies report a benefit for disease progression and/or survival (Acsadi et al. 2002; Li et al. 2007). Others

found GDNF has no effect on disease progression and integrity of neuromuscular junctions (Suzuki et al. 2007; Park et al. 2009), although Park et al. (2009) were the only ones to initiate treatment at the onset of disease.

Although GDNF has been used in clinical trial for Parkinson's disease, the factor has not yet been tested clinically for the treatment of ALS patients. Clinical observations demonstrated that the level of GDNF is increased in the CSF of ALS patients (Grundstrom et al. 2000) and that its receptor is expressed in the spinal cord, even at late stages of the disease (Mitsuma et al. 1999). Due to its in vivo neuroprotective effects on motor neurons, GDNF remains a potential candidate for a clinical trial in ALS, despite controversial efficacy data on survival. However, as there is evidence that GDNF does not cross the blood–brain barrier (Kastin et al. 2003), a future challenge remains in developing a protocol to resolve this issue, such as using an intrathecal delivery device for GDNF. Intraventricularly, GDNF has been trialled as a treatment for Parkinson's disease, but a clinical trial was halted because of adverse effects. Subsequent trials involving continuous intraputamenal infusion had no adverse effects but are inconclusive (Yasuda and Mochizuki 2010). Alternate routes for GDNF delivery include coupling to proteins that do cross the BBB. For example, intravenous, nonviral GDNF gene therapy in a rat model of Parkinson's disease was highly effective because the nonviral agent contained antibodies to the transferrin receptor that allowed entry across the BB (Zhang and Pardridge 2009). In another example, delivery of plasmid GDNF in neonatal rats was achieved using a nonviral complex containing antibodies to p75NTR receptor that enabled retrograde entry to motor neuron cell bodies from terminals in muscles (Barati et al 2006). GDNF gene therapy via direct delivery into the brain using a viral vector (AAV2-GDNF) is underway (clinicaltrials.gov).

4.3 Brain-Derived Neurotrophic Factor (BDNF)

BDNF was originally isolated as a trophic factor for neurons from brain extract (Barde et al. 1982). Expression of BDNF (Henderson et al. 1993) and the high-affinity BDNF receptor tropomyosin-related kinase B receptor (TrkB; Yan et al. 1993) is observed in skeletal muscle and motor neurons during motor neuron-programmed cell death. BDNF/TrkB kinase signalling is required for maintenance of the cholinergic phenotype of adult motor neurons and prevents embryonic and postnatal motor neuron cell death in a variety of experimental paradigms. For example, BDNF rescues motor neurons from embryonic-programmed cell death and neonatal axotomy-induced death (Oppenheim et al. 1992; Yan et al. 1992; Koliatsos et al. 1993). Research has shown BDNF and NT-3 slow motor neuron degeneration and increase lifespan in two models of inherited motor neuron disease, the wobbler and progressive motor neuropathy (pmn) mice (Ikeda et al. 1995; Haase et al. 1997). BDNF can also protect neurons from in vivo excitotoxicity (Bemelmans et al. 2006), a situation relevant to ALS.

In several clinical trials BDNF has failed to show any beneficial effect for ALS. A trial where 1,136 patients were given 25–100 μg/kg/day subcutaneously

for 9 months was reported in 1999 (The BDNF Study Group 1999). In this trial, the tolerability of BDNF was shown to be acceptable, despite some adverse effects such as diarrhea. While the results failed to show an effect on survival after treatment with BDNF, it appeared that a subgroup of patients responded positively to the treatment and demonstrated a higher survival rate. This subgroup consisted of patients having the lowest vital capacity and receiving the highest dose of BDNF, suggesting that BDNF could be beneficial for patients in advanced stages of the disease. The investigators suggested use of higher doses or intrathecal delivery to deliver BDNF to the diseased spinal cord. 1 year later, a phase I trial was published, showing the feasibility of intrathecal delivery of BDNF. Indeed, delivering BDNF with this method showed that BDNF leads to a detectable level of BDNF in the CSF, especially at the lumbar level (Ochs et al. 2000). The method being feasible, two clinical trials were conducted in 2003 and 2005. In 2003, 11 ALS patients were enrolled in a trial to receive an intrathecal delivery of BDNF. Another trial with intrathecal delivery was conducted in 2005 with 13 patients (Kalra et al. 2003; Beck et al. 2005). Both trials were too small to detect any meaningful efficacy signal.

What have we learned? Failure of BDNF therapy has been attributed to factors such as short half-life, inadequate dosage, and limited bioavailability. The first issue is the short half-life; BDNF has a half-life of 0.92 min in the circulation (Poduslo and Curran 1996). Bioavailability is a major issue with new methods of delivery being sought. Since Tetanus toxin C (TTC) is effectively retrogradely transported to motor neurons following intramuscular delivery (Moreno-Igoa et al. 2010) it seemed that fusion proteins containing TTC may improve delivery of neurotrophins including BDNF to motor neurons. However, TTC and BDNF share the same internalization pathways and localize in the same endocytic compartments, suggesting that addition of TTC to the neurotrophins does not improve their bioavailability to motor neurons and may even prevent their entry (Roux et al. 2006). Indeed, when plasmids expressing recombinant fusion proteins containing BDNF and TTC were given to SOD1G93A mice there was no improvement of motor neuron health or survival above that of TTC (Calvo et al. 2011), suggesting that TTC competes more effectively than BDNF for entry into motor neurons. Lessons can also be learned from the signalling that is generated from activation of the TrkB receptor and its truncated form, TrkB.T1 One study showed that TrkB phosphorylation in ALS patients is decreased although the number of receptors is increased (Mutoh et al. 2000) suggesting a mechanism affecting the TrkB response to BDNF. In addition, knocking out the TrkB variant receptor TrkB.T1 receptors in SOD1G93A mice delayed the onset of motor neuron loss and functional symptoms (Yanpallewar et al. 2012) suggesting physiological or pathological imbalances in TrkB receptor isoform levels can also affect motoneuron survival.

4.4 Neurotrophin-3

Neurotrophin-3 (NT-3) is important for maintaining the integrity of neuromuscular junctions. It is well described that NT-3 increases retrograde transport within

degenerating motor neurons (Sagot et al. 1998) and enhances synaptic transmission (Poo 2001), in addition to stimulating neuronal survival. Importantly, muscles of NT-3-knockout mice lose neuromuscular innervation postnatally (Woolley et al. 2005) reflecting the requirement of peripherally derived NT-3 for neuron survival (Meier et al. 1999; Riethmacher et al. 1997) as well as for the maintenance of the neuromuscular junction (Reddy et al. 2003). NT-3 has not been trialled as a potential treatment. Importantly, it should be noted that NT-3, like BDNF, has an exceptionally short half-life in the circulation of only 1.28 min (Poduslo and Curran 1996).

4.5 Ciliary Neurotrophic Factor

The history of CNTF in ALS is similar to that of BDNF. CNTF was one of the earliest neurotrophic factors to be shown to have a direct neuroprotective effect on degenerating motor neurons in stress-induced conditions. Two studies in 1990 demonstrated that CNTF protects motor neurons in cell culture (Arakawa et al. 1990) and in vivo after axotomy-induced apoptosis in the rodent (Sendtner et al. 1990). Those results were strengthened by the beneficial effect of CNTF in a mouse model of neuronopathy (pmn) with motor neuron degeneration (Sendtner et al. 1992) and by increased vulnerability of spinal motor neurons in a knockout mouse line for CNTF (Masu et al. 1993). These results were published in the early 1990s, prior to the development of SOD1G93A mouse model of ALS (Gurney et al. 1994); today the most frequently employed model for ALS. Because of these promising effects on motor neurons, CNTF went directly to the clinic and became the first growth factor investigated clinically for ALS. Two clinical trials were conducted in 1996 and enrolled 570 and 730 patients, respectively (Miller et al. 1996; ALS CNTF Treatment Study Group 1996). The investigators focused mainly on daily living activities outcomes and survival. Unfortunately, both of those trials reported no observable benefit of treatment. Moreover, adverse effects, especially for the doses over 5 μg/kg, were severe, leading to the cessation of treatment in many patients. What could be the reasons to explain the lack of efficiency of CNTF after such promising preclinical findings? Firstly, despite CNTF's ability to cross the BBB (Pan et al. 1999), a pharmacokinetic study in the rodent showed that CNTF has a half-life of only 3 min after intravenous injection (Poduslo and Curran 1996). Due to this low half-life, subcutaneous application of CNTF does not appear appropriate to target the CNS. Secondly, the doses used in animals were about 1 mg/kg, whereas the highest safe dose in the human is 200 times lower (5 μg/kg). This limited dose and short half-life of CNTF could easily account for the lack of observable efficacy of CNTF in patients. No further clinical projects were pursued with CNTF in ALS after these two trials. A recent article from Sendtner's group (Selvaraj et al. 2012) has highlighted the promise of CNTF in stabilizing neuromuscular endplates and improving axon health. The action of a cytoplasmic protein called stathmin that destabilizes microtubules was inhibited by the activated signal transducer and activator of transcription-3 (STAT3). Importantly, STAT-3 was

itself activated specifically by CNTF. This was done with motor neurons isolated from the pmn mouse model of neuronopathy; the same model used to show CNTF improves motor neuron health (Sendtner et al. 1992).

4.6 Insulin-Like Growth Factor-1

The action of IGF-1 in the nervous system (Shemer et al. 1987; Rotwein et al. 1988) was described long after its multitude of actions and targets in the body were known. Neurons in the central nervous system (CNS) express functional receptors of IGF-1 throughout the nervous system (Shemer et al. 1987; Rotwein et al. 1988; Bilak et al. 2001). IGF-1 is able to rescue motor neurons (Caroni 1993; Li et al. 1994) and reduce glutamate excitotoxicity (Nakao et al. 1996) both in vitro and in vivo. Therefore IGF-1 became an important drug candidate for ALS. Several clinical studies with IGF-1 in ALS were conducted early, before testing of IGF-1 in SOD1G93A rodents. In the late 1990s, two investigations were published with different conclusions (Lai et al. 1997; Borasio et al. 1998). Lai et al. enrolled 266 patients and administrated IGF-1 subcutaneously (Lai et al. 1997). The conclusion of the investigators was that IGF-1 is safe, slows progression of motor impairment, and increases quality of life. In a second trial, (Borasio et al. 1998) 183 patients were enrolled with the same mode of administration. The investigators focused on disease progression but found no improvement after treatment. Indeed, IGF-1 treatment appeared to be safe but did not improve quality of life of the patients nor motor functions. Additionally, a pilot study was conducted with intrathecal delivery of IGF-1 (Nagano et al. 2005b). Investigators claimed that the treatment was beneficial for the patients. Two groups of patients were compared, patients with a high and a low dose of IGF-1, and it was observed that the decline in motor function was slowed with the high dose of IGF-1, but not the low dose. However, as this study was not placebo controlled, the results should be considered with caution.

Many years after the first trials of IGF-1 in humans, preclinical reports investigating the effects of IGF-1 in SOD1 animals were published. The majority of the reports argue in favor of a potential protective effect in ALS, with an increase in survival and motor function parameters (Kaspar 2003; Nagano et al. 2005a; Lepore et al. 2007; Dodge et al. 2008; Franz et al. 2009). Also, IGF-1 mediates neuromuscular junction regeneration in a non-ALS-related animal model (Apel et al. 2010), although some contradictory results were published (Messi et al. 2007; Grumbles et al. 2009). For example, Messi et al. (2007) generated a transgenic form of SOD1G93A mice that overexpress IGF-1 in skeletal muscle but found no improvement of survival. The work of Franz et al. (2009) suggests that IGF-1 effects were only observed in male mice. At the same time, a new clinical trial was initiated with subcutaneous administration of IGF-1. This clinical trial enrolled 330 patients and studied the effects of IGF-1 on muscular strength and survival (Sorenson et al. 2008). Unfortunately, IGF-1-treated patients did not improve relative to the control patients.

There are a variety of reasons why IGF-1 failed at clinical trials. IGF-1 is increased at the spinal level of ALS patients (Wilczak et al. 2003) and in the

serum (Corbo et al. 2010). Conversely, muscle expression of IGF-1 and IGF-binding proteins was decreased in ALS patients (Lunetta et al. 2012), suggesting IGF-1 within the muscle tissue could participate in motor unit degeneration. However, as discussed above animal trials where IGF-1 is overexpressed in skeletal muscle in SOD1G93A mice did not improve survival (Messi et al. 2007). This may suggest the lack of success of the human clinical trial could be related to the transport of IGF-1 from muscle to the effected motor neurons and NMJ. In addition, it is hard to relate the preclinical trials involving viral gene delivery of IGF-1 (Kaspar 2003; Lepore et al. 2007; Dodge et al. 2008) or intrathecal administration (Nagano et al. 2005a) to the clinical trials where subcutaneous injections were used (Lai et al. 1997; Borasio et al. 1998; Sorenson et al. 2008). A genetic approach cannot be translated into subcutaneous delivery in patients, due to the high and constant expression of IGF-1 over time. Nor can the intrathecal administration that delivers IGF-1 to the CNS be directly comparable to subcutaneous injections. Indeed, IGF-1 has a half-life of only 4 min in the circulation (Pan and Kastin 2000), and intravenous IGF-1 enters the CNS by a saturable transport system at the BBB, which functions in synchrony with IGF-binding proteins in the periphery to regulate the availability of IGF-1. Therefore subcutaneous IGF-1 would seem unlikely to be an adequate mode of delivery. As Howe et al. (2009) observed it is highly unlikely that meaningful levels of IGF-1 were reached in the CSF and CNS tissue with the route and dose of IGF-1 used in the most recent clinical trial (Sorenson et al. 2008).

4.7 Vascular Endothelial Growth Factor

Discovered in the late 1980s as a growth factor for vascular endothelial cells, vascular endothelial growth factor (VEGF) induces endothelial cell growth and angiogenesis (Connolly et al. 1989). The first evidence for neurotrophic proprieties of VEGF arose with studies on neuronal regeneration (Sondell et al. 2000; Hobson et al. 2000). Shortly after, VEGF was implicated as a growth factor possibly involved in ALS by the discovery that mice with deletion of the HIF-response element in the VEGF promoter developed an ALS-like phenotype (Oosthuyse et al. 2001). Subsequent genetic analysis however failed to produce clear evidence for an effect of VEGF polymorphisms on the risk of developing ALS in humans (Gros-Louis et al. 2003; Lambrechts et al. 2003; Fernandez-Santiago et al. 2006; Chen et al. 2006; Zhang et al. 2006). A combined meta-analysis of American and European data showed the 2578AA VEGF genotype as a candidate for male ALS (Lambrechts et al. 2009). However, independent of the genetic discussion, VEGF promotes survival of cells overexpressing a mutated SOD1G93A protein (Li et al. 2003) and ameliorates the effects of glutamate excitotoxicity (Tolosa et al. 2008; Bogaert et al. 2010). In SOD1G93A rodents, VEGF treatment leads to a delay of disease onset, an improvement of motor functions, protection of motor neurons and neuromuscular junctions, and increase in survival (Zheng et al. 2004; Azzouz et al. 2004; Storkebaum et al. 2005; Wang et al. 2007; Hwang et al. 2009).

The preclinical data supports further clinical investigation of VEGF as a treatment target for ALS. Besides the animal studies, clinical observations show that VEGF is downregulated in the late stage of ALS (Devos et al. 2004), and restoring its level therefore could bring benefit for patients. The potential of VEGF as a therapeutic agent is further strengthened by its ability to cross the BBB (Wang et al. 1996; Dobrogowska et al. 1998; Ay et al. 2008). VEGF has an effective half-life of 10.7 min in the circulation (Wu et al. 2009). There are no published data on VEGF treatments for human ALS so far, but a clinical trial involving intracerebroventricular infusion of VEGF (NCT0080050) with 28 patients is now at phase I/II. Another trial using plasmid-encoding zinc finger protein transcription factor that upregulates VEGF-A expression (NCT00748501) has completed phase II testing involving the treatment of 40 patients, but no outcomes have yet been published. Clearly, the angiogenic side effects of VEGF treatment will have to be monitored closely.

4.8 Fibroblast Growth Factors

The fibroblast growth factors (FGF) proteins are growth factors with homologous structure that promote angiogenesis and the proliferation of fibroblasts. It was demonstrated that both FGF-1 and FGF-2 can protect motor neurons after axotomy-induced apoptosis and that they support neuronal regeneration (Cuevas et al. 1995; Piehl et al. 1995; Grothe et al. 1991; Klimaschewski et al. 1999). No disease-specific alterations in the expression pattern of FGF-2 were found in post-mortem spinal cord of ALS patients (Petri et al. 2009), but increased FGF-2 levels were measured in serum and cerebrospinal fluid of ALS patients (Johansson et al. 2003). Dependent on activation of different receptors, FGF-1 and FGF-2 can either promote cell survival or death (Grothe et al. 2006; Cassina et al. 2005). One report points out that FGF-1 might activate motor neuron apoptosis by astrocytes, thereby possibly contributing to ALS pathophysiology (Cassina et al. 2005). Subcutaneous administration of FGF-2 had no effect on the survival in transgenic SOD1G93A mice (Upton-Rice et al. 1999), but this may reflect the instability of native FGFs without heparin protection. A recent study where SOD1G93A mice were produced lacking endogenous FGF-2 showed increased lifespan of mice and upregulation of GDNF and CNTF (Thau et al. 2012). This supports the idea that endogenous FGF-2 contributes to the pathophysiology of SOD1G93A mice. Clearly, more work is needed to establish if the FGFs can be considered as drug candidates for ALS.

4.9 Hepatocyte Growth Factor

Hepatocyte growth factor (HGF) was discovered as growth factor acting on the liver (Nakamura et al. 1985). This growth factor exerts antiapoptotic activity in the liver after endotoxin-induced hepatic failure (Kosai et al. 1999). Neuronal effects consist of activity in the guidance and survival of neurons in the developing nervous

system (Ebens et al. 1996). Moreover, HGF is protective on motor neurons in culture and in vivo after axotomy (Wong et al. 1997; Okura et al. 1999). In rodent models of ALS, HGF reduces motor neuron degeneration and increases survival (Sun et al. 2002; Ishigaki et al. 2007; Kadoyama et al. 2007).

While HGF appears to be a good candidate for the treatment of ALS, especially since HGF levels in ALS patients appear to be dysregulated (Tsuboi et al. 2002), additional preclinical work is required. Indeed, more insight at the level of the NMJ is needed since it seems that HGF can have an influence on the formation of NMJs (Madhavan and Peng 2006; Tatsumi et al. 2009) but appears to be inefficient on their regeneration unless used in conjunction with other neurotrophic factors (Grumbles et al. 2009; Casella et al. 2010). There is work suggesting this may be because of pool-specific responsiveness of motor neurons to different neurotrophic factors. When the HGF receptor Met is turned off in mid-embryonic life, there is pool-specific loss of motor neurons at the NMJ within the pectoralis muscle from lack of Met (Lamballe et al. 2011). It will also be of interest for the design of a clinical trial to investigate whether a systemic delivery of HGF can reproduce the promising results observed after intrathecal administration in rodents (Ishigaki et al. 2007). HGF prevents the decline of choline acetyltransferase (ChAT) expression after adult hypoglossal nerve axotomy and also reduces motor neuron death in response to excitotoxic stress (Okura et al. 1999). Delayed disease onset and improved lifespan is observed when SOD1G93A mice overexpress transgenic HGF (Sun et al. 2002; Kadoyama et al. 2007). Reduced levels of the HGF receptor, Met, are found in the spinal cord of familial SOD1 patients over the course of disease, indicating disruption of the HGF-Met system contributes to neuronal degeneration in familial ALS (Kato et al. 2003). A recent study showed motor neuron development and maintenance are unaffected in mice with conditional enhancement of neuronal Met, whereas SOD1G93GA mice with the same enhancement of neuronal Met had a delayed disease onset (Genestine et al. 2011). Intrathecal HGF extends the lifespan of SOD1G93A mice, overcoming the HGF-Met deficit (Ishigaki et al. 2007). Another study showed in mice that the half-life of HGF is 10 min in the circulation, with 30 % of HGF crossing the BBB (Pan et al. 2006). A phase 1 clinical trial was intended to assess the safety and pharmacokinetics of single and multiple doses of rhHGF intrathecally in patients with ALS at Tohoku University Hospital (Japan) but was delayed because of the 2011 tsunami.

4.10 The Future of Neurotrophic Therapy for ALS

The demonstration of beneficial effects of neurotrophic factors for various CNS disease conditions raised great enthusiasm about their use as therapeutic agents for ALS. The clinical failure of neurotrophic factors is in no way ascribable to one single reason, especially in ALS.

Because of the failure to find clinical efficacy so far, the value of preclinical data has been questioned. There are two aspects to this issue. First, the models used may not be predictive for the working of a drug in the human system. This is of course an

irrefutable argument, which cannot be proven or disproven in the absence of any clinical positive outcome seen so far. Second, animal models may be predictive but have not been conducted with sufficient rigor and diligence to really tell us the truth about efficacy of a drug candidate in the rodent system. Reasons for this include insufficient blinding procedures, neglect of copy number issues in transgenic models, insufficient number of animals used, inadequate statistical methods, and inadequate independent replication of study results (Scott et al. 2008). An example may have been BDNF, where preclinical studies were not done in SOD1G93A rodent models of ALS as they were not available at the time but were achieved using axotomy models, pmn and wobbler mice. After reports were published on the failure of the large clinical trial of BDNF (The BDNF Study Group 1999), there have been no effective BDNF-based treatments reported for the SOD1G93A ALS rodent models but one failure (Park et al. 2009).

Since there is insufficient proof that any one ALS animal model produced so far can be used to predict the effectiveness of human treatments, a combination of different animal models could be trialled. This could include different animal models that monitor different aspects of ALS disease pathophysiology, for example, two different SOD1-mutant models, possibly mouse and rat models, but with rodents that have adequate checks on copy number and preclinical trials using carefully designed studies. Ideally, a dose-effect relationship should be established. All tests have to be conducted in a rigorously blinded and randomized manner and ideally be performed in at least two independent laboratories. If novel animal models become available, they should be immediately tested using a variety of preclinical approaches.

In all major clinical trials performed so far, it appears the dosing was inadequate. Examples of this include BDNF, CNTF, and IGF-1 (The BDNF Study Group 1999; Ochs et al. 2000; Miller et al. 1996; ALS CNTF Treatment Study Group 1996; Lai et al. 1997; Borasio et al. 1998). For CNTF, the dose showing benefit for motor neurons in vivo was three orders of magnitude lower in the human case. In addition, subcutaneous-injected CNTF has a plasma half-life time of only a few minutes (Poduslo and Curran 1996) and does not reach the target tissues. A similar scenario can be drawn for BDNF, with questionable delivery to the CNS. For IGF-1, CSF levels reached with the chosen subcutaneous dose of 0.05 mg/kg twice daily, more than an order of magnitude below endogenous levels in the CSF, and thus are likely to be therapeutically meaningless (Howe et al. 2009).

The relevance of neurotrophic factor treatment for ALS should be pursued with a thorough understanding of how the neurotrophic factors work and if they address mechanisms relevant to ALS. For example, neurotrophic factors should show some efficacy against cell death either or both apoptotic and excitotoxic cell death demonstrated on motor neurons, other primary neurons, and/or motor neuron lines. Also, effects on the integrity of the NMJ should be ascertained. Only VEGF is known to preserve innervation to the NMJs in ALS (Zheng et al. 2007), although IGF-1 has shown benefit in preserving the NMJ after nerve transection (Apel et al. 2010). Addressing additive or synergistic effects of neurotrophic factors on NMJ as well as axonal and cell body health is an area yet to be adequately

explored as a treatment for ALS. However, there is an indication that some neurotrophic factors in combination improve NMJs; for example, cells transplanted with a combination of IGF-1, HGF, and GDNF appear to improve NMJs after transection, the combinatorial approach being better than individual factors (Grumbles et al. 2009; Casella et al. 2010). A recent article supports the notion of growth factor combinations having positive synergistic effects (Krakora et al. 2013). Mesenchymal stem cells were implanted into three muscle groups of SOD1G93A rats and secreted either GDNF, VEGF, IGF-1, or BDNF and compared to those implanted with cells secreting a combination of GDNF and VEGF (Krakora et al. 2013). The results indicated that rats treated with cells secreting both VEGF and GDNF have improved NMJ health and extended survival compared to rats treated with cells secreting individual neurotrophic factors. This indicates the need to further understand the cross talk between neurotrophic factors to improve their therapeutic effect in ALS.

For a chronic CNS disease like ALS, the application and dose chosen should guarantee a therapeutic level of the drug in the brain and spinal cord. For a motor neuron-supportive principle like neurotrophic factor support, the drug level should likely be held constant over time. Options for this include gene-based delivery of recombinant protein, including viral and nonviral methods, stem cell-based treatments that include secretion of relevant neurotrophic factors, or constant infusion pumps.

There is a good rationale for using other methods of delivery besides administration of the naked molecules, including half-life, getting to the site of action and prolonged neurotrophic factor production. For example, virally delivered genes for VEGF and IGF-1 have all shown promise in SOD1G93A rodents (Azzouz et al. 2004; Kaspar 2003; Lepore et al. 2007; Dodge et al. 2008). There is also a strong rationale for using nonviral delivery methods of targeting neurotrophic factors to specific sites of action such as motor neurons, NMJs, and glia. A nonviral gene delivery treatment capable of generating small quantities of therapeutic protein such as GDNF or HGF over a limited time targeting specific cells could have significant therapeutic value (Rogers and Rush 2012). This has been demonstrated for GDNF in an axotomy model in rats (Barati et al. 2006).

Stem cell-based delivery of neurotrophic factors has been suggested as an alternative method of delivering neurotrophic factors for ALS. Several studies report stem cell production of neurotrophic factors when transplanted into SOD1G93A rodents, including VEGF, IGF-1, GDNF, and BDNF (Hwang et al. 2009; Suzuki et al. 2007; Park et al. 2009). Cortical human neural progenitor cells engineered to secrete GDNF confer motor neuron protection after transplantation into the spinal cords of SOD1G93A transgenic rats (Suzuki et al. 2007). Intramuscular delivery of GDNF or GDNF-/VEGF-producing mesenchymal stem cells in SOD1G93A transgenic rats also increases neuromuscular contacts, motor neuron survival, and lifespan (Suzuki et al. 2008; Krakora et al. 2013). Coadministration of embryonic spinal cord cells with GDNF, HGF, and IGF-1 after sciatic nerve resection resulted in increased number of reinnervated muscle fibers and improved

motor neuron health (Grumbles et al. 2009). Human spinal stem cells (HSSC) that differentiate into both neurons and glia have been transplanted into SOD1G93A rodents and shown to secrete endogenous neurotrophic factors that may improve functional outcome. Following transplantation, HSSC express excitatory amino acid transporters that potentially restore functional glutamate reuptake around vulnerable motor neurons and also release neurotrophic factors such as GDNF and BDNF. Grafted HSSC express several neurotrophic factors, including GDNF and BDNF, and form synaptic contacts with host motor neurons (Xu et al. 2009). Moreover, intraspinal HSSC transplantation delays symptom onset and extends the lifespan in SOD1G93A rodents (Yan et al. 2006; Xu et al. 2006, 2011). Some caution has to be included as a recent study (Koh et al. 2012) has indicated that bone marrow mesenchymal stromal cells (BM-MSC) from ALS patients have a lower capacity to proliferate and secrete neurotrophic factors, indicating using autologous stem cells may be not be an effective in ALS patients.

5 Conclusion

It is nearly 20 years since the first trial of neurotrophic factors was reported for ALS. Since this time we have not only made significant inroads into understanding the pathophysiology and genetic cause of the disease, but we have gained more knowledge on the potential action of neurotrophic factors in ALS and proposed potentially smarter ways to deliver effective therapy. This provides reason for cautious optimism that a truly effective treatment is on the horizon.

Neurotrophins and p75NTR in Axonal Regeneration and Myelination

Matt S. Ramer, Simon A. Bedard, and Angela L. M. Scott

Contents

Abstract

The neurotrophins are powerful, secreted signaling molecules that regulate the survival, proliferation, and function of neural cells. Neurotrophin-dependent signaling is not only critical during neurodevelopment but also plays an important role in the adult, where it mediates processes of plasticity and repair in both the central and peripheral nervous systems. The roles that the four known neurotrophins and their receptors play in regulating the cellular processes required for repair has been the subject of a significant body of research and has produced several promising avenues for treatment. This chapter reviews the current understanding of Neurotrophin-dependent signaling and how this evolving understanding can facilitate the development of future strategies to address

neurodegeneration and neurotrauma. Of particular interest in this context is the p75 pan-neurotrophin receptor, a mercurial molecule that binds not only the neurotrophins but also the other neurotrophin receptors in order to modulate these signaling cascades. P75-dependant signaling has been shown to be essential in the regulation of processes such as neurite outgrowth, axonal regeneration, cell survival, cellular proliferation, and myelination; these processes are critical to successful neural repair. As we learn more about the neurotrophins and p75 through future research, novel therapeutic targets for the treatment of damage to the nervous system will continue to be revealed.

Keywords

Brain-derived neurotrophic factor • Dorsal root entry zone • Dorsal root ganglion • Eph/ephrin • LINGO-1 • Myelination • Nerve growth factor • Nerve growth factor receptor • Neurotrophin-3 • NogoA receptor • Oligodendrocyte • Semaphorin • Sortilin • Trk receptor

1 Introduction

Since the discovery of nerve growth factor (Cohen et al. 1954), neurotrophins (NTs) have been touted as potential remedies for neurotrauma. For injuries involving peripheral nerves or the spinal cord, the problem is inefficient or ineffective growth of damaged axons. The promise of NTs stems from the notion that disability may be reversed by providing neurons and their associated glia with adequate trophic support. While much work has been aimed at exploiting the function of spared axons as a possible solution to incomplete neurotrauma (Ramer 2010), true functional recovery entails regeneration of damaged axons and their reconnection with appropriate targets. This is not all, however, since regenerated axons must be myelinated to reliably conduct action potentials. It is therefore not insignificant that NTs provoke multiple responses from myelinating glia.

In this chapter the biology of NTs and their receptors will be reviewed, with a particular emphasis on the pan-NT receptor p75NTR, given its pivotal role in a growing number of signalling mechanisms. The effects of NTs and their receptors on regeneration and myelination, mainly in the context of sensory neurons of the dorsal root ganglion (DRG), will be discussed. By virtue of their anatomical arrangement (with axons in both the peripheral and central nervous systems) and well-characterized responses to NTs, DRG neurons have proven particularly informative with respect to the mechanisms by which NTs mediate both regeneration and myelination.

2 The Neurotrophins

Neurotrophic factors are characterized by their ability to support the survival and growth of specific neuronal populations. The neurotrophic hypothesis holds that

target-derived neurotrophins, retrogradely transported to cell bodies, are responsible for maintenance of neuronal phenotype in adulthood. The most complete existing data relates to the NTs (Bradbury et al. 2000; Boucher et al. 2000). There are four known NTs: nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4), all of which form homodimers (Chao 2003). Each NT is derived from a precursor molecule (pro-NT) that can be cleaved by a furan or convertase to produce a mature NT which is subsequently released into the extracellular space. Although this posttranslational modification occurs intracellularly, unprocessed pro-NTs are also released to the extracellular space via the constitutive secretory pathway and – in the case of pro-BDNF – via a regulated secretory pathway (Mowla et al. 2001). The mature forms are non-covalently bound dimers that share 90 % homology, including a cysteine-rich motif within the structural core of the dimer and three beta hairpin loops forming the distinctive regions involved in determining receptor specificity (Wiesmann and de Vos 2001).

3 Neurotrophin Receptors

3.1 Trk Receptors

NT signals are received and transduced by the tropomyosin-related kinase (Trk) A, B, and C receptors as well as the p75 neurotrophin receptor (p75NTR), the latter being a member of the tumor necrosis factor receptor (TNFR) family. Each Trk receptor is a cell surface transmembrane protein that possesses ligand-dependant tyrosine kinase activity. However, alternative splicing of TrkB (TrkBT1, TrkBT2, and TrkBT4) and TrkC ($TrkCTK^-$) produces additional truncated isoforms of these receptors that lack the tyrosine kinase domain (Squinto et al. 1991; Valenzuela et al. 1993; Forooghian et al. 2001). Each full-length receptor and truncated isoform share a conserved extracellular domain that includes two immunoglobulin-like C2 domains that not only prevent the autoactivation of the full-length receptors (Arevalo et al. 2000) but also determine neurotrophin binding specificity (Urfer et al. 1995, 1997). This specificity has translated into high-affinity interactions of NGF with TrkA, BDNF and NT-4/5 with TrkB isoforms, and NT-3 with TrkC isoforms (Chao 2003). Thus in the majority of cases, the cellular sensitivity and responsiveness to neurotrophins is dictated by the expression of their respective Trk receptors (although NT-bound p75NTR can participate in NT signalling through alternate pathways (Naska et al. 2010)).

3.2 p75NTR

Perhaps the most interesting member of the neurotrophin-signalling suite is p75NTR, whose many roles in cellular signalling continue to emerge. p75NTR was first identified in 1973 (Herrup and Shooter 1973) and was originally named the nerve growth factor receptor (NGFR); the name was later changed when it was

realized that p75NTR had affinity not only for NGF but also for the other NTs. p75NTR was subsequently characterized as a 75 kDa, type I transmembrane protein (Grob et al. 1985). p75NTR has been simplistically described as a regulator of cell survival or death, but in reality its biological function is much more subtle and nuanced. In fact, p75NTR signalling can have effects as wide reaching as cell death, proliferation, differentiation, survival, neurite outgrowth/collapse, and even the modulation of synaptic connectivity, plasticity, and pruning (Skeldal et al. 2011; Garcia et al. 2011).

3.3 p75NTR Signalling Partners

There are several signalling modules in which p75NTR participates. First, p75NTR has been shown to greatly increase the binding affinity of the Trk receptors for their cognate NTs (Esposito et al. 2001). The Trk receptors form receptor dimers upon ligand binding, as do most receptor tyrosine kinases, and trans-autophosphorylate one another to activate downstream signalling pathways (Chao 2003). The association of p75NTR with these Trk dimers creates high-affinity binding sites, increasing both the sensitivity and degree of Trk signalling. In this way p75NTR is capable of positively regulating Trk signalling. The converse, however, is also possible. With proteolytic cleavage at a juxtamembrane α-secretase site, the extracellular domain of p75NTR is released into the extracellular space where it can bind competitively with available NTs. The consequent dearth of NTs available for the Trk receptors results in decreased Trk signalling.

Depending on the NTs present, the Trk receptors being expressed, and the type of cleavage (if any) that p75NTR undergoes, a whole multitude of functional outcomes is possible. Each of the different Trk receptors activates different downstream signalling pathways, which are often dependent on p75NTR. For example, TrkA is not able to activate a PI3-kinase/Akt signalling cascade without associating with p75NTR, but can activate a MAP-kinase cascade with or without p75NTR (Nykjaer et al. 2005). The Trk receptors are broadly involved in cell proliferation, differentiation, and survival, and p75NTR serves to enhance or mute these effects when it does or does not associate with them.

The Trk receptors are not p75NTR's only bedfellows, however. p75NTR also forms a complex with sortilin, a protein usually involved in intracellular vesicle trafficking, at the plasma membrane (Nykjaer et al. 2004). The association of sortilin with p75NTR greatly increases the affinity of p75NTR for the pro-NTs over mature NTs. It was shown that the interaction between p75NTR and sortilin is necessary for pro-NGF- and pro-BDNF-induced apoptosis (Nykjaer et al. 2004). In this context p75NTR is no longer a peripheral player, serving to modulate the signalling of another receptor, but is rather the receptor that transduces the signal to the cytosol. Upon binding of a pro-NT by the p75NTR/sortilin complex, the intracellular domain of p75NTR is cleaved and induces apoptosis via a Jun N-terminal kinase (JNK)-dependent mechanism (Barker 2004; Kenchappa et al. 2010).

A third signalling module that p75NTR is involved in is a membrane-bound complex with *LINGO-1* and, in neurons, the NogoA receptor (NgR) (Mi et al. 2004). This complex does not signal in response to NT or pro-NT signals, but rather responds to myelin-associated inhibitors (MAIs). These include Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte myelin glycoprotein (OMgp) (Wang et al. 2002). In this circumstance p75NTR (or the related molecule Troy) (Park et al. 2005; Shao et al. 2005) is again required for signalling. Although LINGO-1 possesses a tyrosine kinase phosphorylation site in its cytoplasmic aspect – indicating that it is likely able to interact with downstream intracellular signalling cascades (Mi et al. 2008) – it is unable to induce signalling in the absence of p75NTR, despite being able to bind its ligands. In neurons, the functional effect of signalling through the p75NTR/NgR/LINGO-1 complex is inhibition of neurite outgrowth via collapse of extending axons' growth cones (Yamashita and Tohyama 2003). In recent work, Park et al. (Park et al. 2010) showed that developmental MAI-dependent axonal pruning is also p75NTR dependent.

p75NTR is also connected to a fourth receptor complex, involved in Eph/ephrin signalling. In 2001, Kong et al. (Kong et al. 2001) cloned a novel transmembrane protein they called ARMS (ankyrin repeat-rich membrane spanning) downstream of Eph and neurotrophin signalling. ARMS interacted with both TrkA and p75NTR and could be phosphorylated following NT or ephrin B treatment of cultured cells. This was an exciting result, particularly since ephrin B3 was subsequently shown to be another MAI (Benson et al. 2005): p75NTR/ephrin B signalling may participate in ephrin B3-mediated neurite growth inhibition. Bolstering this notion, in sympathetic neurons p75NTR is required for ephrin B-mediated growth cone collapse (Naska et al. 2010). Other recent and compelling evidence of inhibitory p75NTR/ephrin A "reverse" signalling has emerged (Lim et al. 2008). Ephrin A lacks a transmembrane domain, but in the retinotectal system, it couples with p75NTR to mediate retinal axon repulsion during topographic map formation.

Inhibitory semaphorin signalling in growing axons also seems to involve p75NTR, although the data are not as clear-cut. p75NTR has been reported to bind plexins and neuropilins, both receptor components for semaphorin family members (Ben Zvi et al. 2007, but see Naska et al. 2010). In the absence of p75NTR, sensory neurons are hypersensitive to Sema 3A, an effect thought to be the result of enhanced association of neuropilins with plexins. Hypersensitivity of p75NTR sympathetic axons to Sema 3A was also shown in p75NTR−/− hearts, where the high-to-low gradient of sympathetic innervation from epi- to endocardium – shaped by endocardial Sema 3A expression during development (Ieda et al. 2007) – was greatly exaggerated (Lorentz et al. 2010). This same study also showed increased Sema 3A-mediated inhibition of outgrowth from p75NTR−/− sympathetic ganglion explants. These findings stand in contrast to another showing that functional p75NTR, bound to a NT ligand, is actually required for the growth cone collapsing effects of Sema 3 family members on sympathetic neurons (Naska et al. 2010). Although it seems clear that p75NTR participates in semaphorin signalling, there is not yet a complete picture of how it does so.

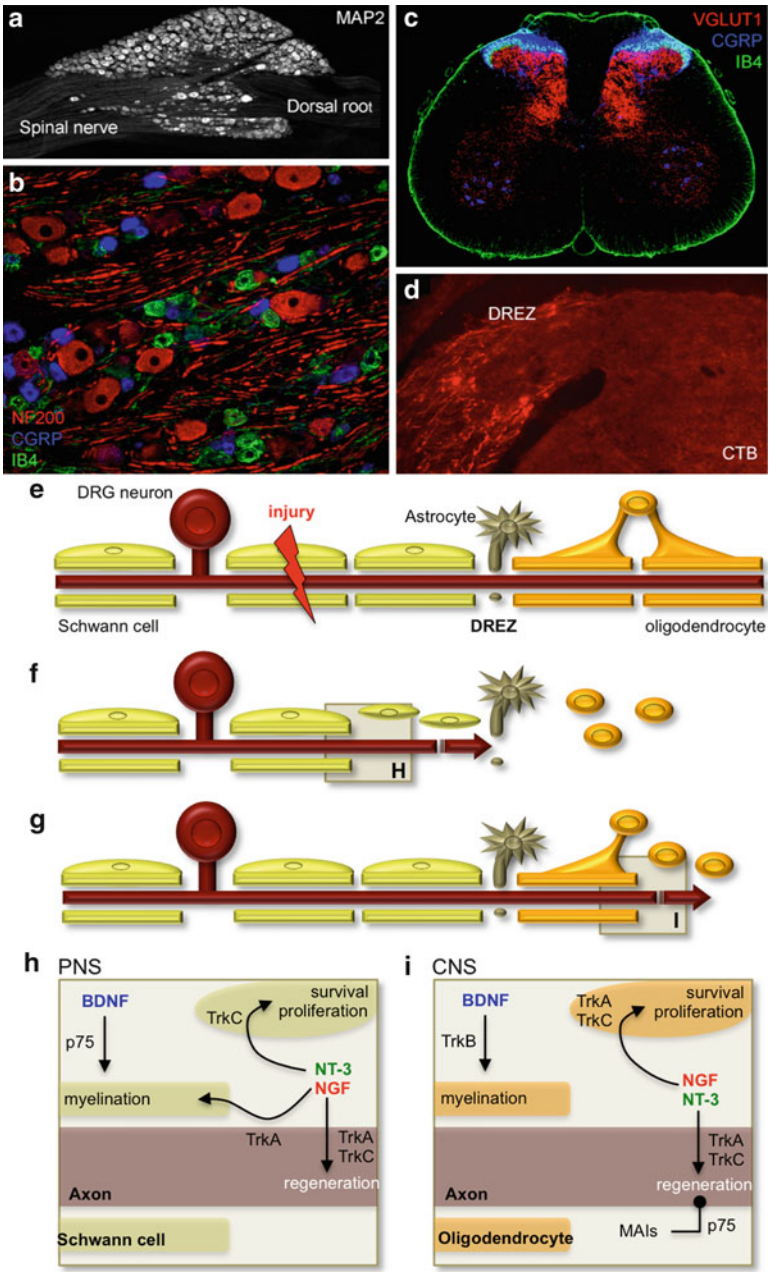

Fig. 1 Anatomy and selected NT responses of sensory neurons and associated glia. (**a**) A lumbar DRG section from a rat. (**b**) Subtypes of DRG neurons. Blue and green neurons, nociceptors; red neurons, mechano-/proprioceptors. (**c**) Central projections of sensory neurons. Terminal projections of subpopulations correspond to colors used in **B** (pia mater also binds IB4, and some motoneurons also express CGRP). (**d**) Large-diameter DRG neurons injured in the dorsal roots 1

4 Neurotrophins and Sensory Axon Regeneration

The tenets of the neurotrophic hypothesis have been most extensively demonstrated for sensory neurons of the dorsal root ganglion (DRG) (McMahon et al. 1995; Verge et al. 1995; Munson et al. 1997). As such, DRG neurons are ideal for assessing the role of neurotrophic factors and their receptors in regeneration. The anatomical arrangement of DRG neurons makes them ideal for experimental manipulation: they are pseudounipolar in that each has a single axon which emanates from the soma and bifurcates within the DRG, sending one branch peripherally in the peripheral nerves and the other centrally in the dorsal roots (Fig. 1). The dorsal root axons pass from the PNS into the CNS at a well-defined border, the dorsal root entry zone (DREZ). Once beyond the DREZ, most axons bifurcate again, forming longitudinal bundles. These are the ascending dorsal columns, large myelinated axons which terminate in the brainstem, and Lissauer's tract, a primarily unmyelinated propriospinal tract. From the longitudinally projecting axons extend branches which terminate in the grey matter of the dorsal and ventral horns. These are clustered around the axon's point of entry into the cord, but can occupy several segments rostrally and caudally. Thus, sensory axons can be injured in the peripheral nerve, in the dorsal roots (by rhizotomy), or within the spinal cord (Bradbury et al. 2000).

Sensory neurons come in several phenotypes, and this heterogeneity has been investigated in exquisite detail. About two thirds of all DRG neurons have unmyelinated or thinly myelinated axons, and more than 90 % of these innervate nociceptors peripherally. Roughly half of these are "peptidergic," as they express peptide neurotransmitters substance P and calcitonin gene-related peptide (CGRP). The remaining third of DRG neurons have rapidly conducting myelinated axons and subserve mechanoreception and proprioception.

All of the receptor components for neurotrophins are expressed in the adult DRG. Interestingly, small, substance P and CGRP-expressing nociceptive neurons virtually all express NGF receptor components – TrkA and p75NTR. The non-peptidergic group expresses none of the full-length Trk receptors, nor p75NTR (Molliver et al. 1997; Bennett et al. 1998). More than half of the large light neurons express TrkC and p75NTR, while few adult DRG neurons express TrkB (McMahon et al. 1994). Thus, the majority of sensory neurons respond to either NGF or NT-3.

NTs promote outgrowth of the expected phenotypes of adult sensory neurons (based on receptor expression in vivo) in dissociated culture (Lindsay 1988;

Fig. 1 (continued) week earlier and halted at the DREZ. (**e–g**) Stages in successful regeneration across the DREZ following dorsal root injury (indicated in **G**). (**h, i**) NT responses of axons, Schwann cells, and oligodendrocytes (and their precursors) and the NT receptors involved. Abbreviations: MAP2, microtubule-associated protein 2; NF200, 200 kDa neurofilament; CGRP, calcitonin gene-related peptide; IB4, lectin from *Bandeiraea simplicifolia*; VGLUT1, vesicular glutamate transporter 1; CTB, cholera toxin B fragment; MAIs, myelin-associated inhibitors

Hu-Tsai et al. 1994; Tuttle and Matthew 1995; Kimpinski et al. 1997; Gavazzi et al. 1999): NGF and NT-3 enhance outgrowth from peptidergic nociceptors and NF200-positive mechano-/proprioceptors, respectively. BDNF seems to have varied effects on sensory neurons in vitro, in some cases promoting outgrowth and in others inhibiting it (Gavazzi et al. 1999). In vivo, BDNF is ineffective at promoting regeneration of large-diameter axons (Bradbury et al. 1999; Ramer et al. 2000); furthermore, it inhibits intraspinal collateral sprouting of most primary afferent phenotypes (Ramer et al. 2007; Soril et al. 2008).

While the in vitro data show that NTs are clearly sufficient to elicit neurite outgrowth, there appears to be little necessity for endogenous NTFs in naturally occurring regeneration of peripheral nerves. For example, axotomized TrkA- and TrkC-expressing nociceptive and mechanosensitive axons reinnervate their peripheral targets normally in the presence of antibodies which block NGF and NT-3 signalling (Diamond et al. 1987; Yasargil et al. 1988; Diamond et al. 1992). Surprisingly little is known about the efficacy of exogenous NTs in enhancing regeneration of sensory axons following peripheral nerve injury. This is possibly because peripheral nerve regeneration actually happens, making subtle increases in regeneration distance or numbers of regenerating axons difficult to detect.

The dorsal rhizotomy model is particularly attractive for studying regeneration by virtue of the fact that regeneration proceeds in the permissive Schwann cell environment of the injured dorsal root, but halts upon contact with the astrocytic glia limitans at the PNS-CNS interface. Thus the role of neurotrophins and their receptors can be examined on a background of unequivocal regeneration failure. Using this model, Ramer et al. (Ramer et al. 2000) found that intrathecal delivery of NGF and NT-3, but not BDNF, resulted in regeneration of injured sensory axons beyond the DREZ and into the spinal cord. As might be expected from prior in vitro work, the phenotype of regenerating axons corresponded to Trk expression: NGF resulted in ingrowth of CGRP-expressing (TrkA-positive) primary afferents, and NT-3 resulted in regeneration of (TrkC-expressing) NF200-positive axons. The axons which regenerated were able to synaptically drive second-order neurons (Ramer et al. 2000, 2002), and at least in the case of NT-3, there was ultrastructural evidence of new synapses with neurons in the dorsal grey matter (Ramer et al. 2002). NGF administration was accompanied by the reemergence of responses to heat and noxious pressure (Ramer et al. 2000), and in NT-3-treated animals, behaviors requiring proprioception such as paw placement and walking across a beam and across a horizontal ladder returned (Ramer et al. 2002).

5 p75NTR and NT-Mediated Sensory Axon Regeneration

An attractive model for p75NTR/Trk interactions in axonal regeneration was posited in the late 1980s (Johnson, Jr. et al. 1988). This involved a "presentation" mechanism, by which Schwann cell-expressed p75NTR generated an NT gradient which could be followed by axons. This hypothetical framework led to the widely accepted notion that the powerful chemotactic effects of NTs on axons are mediated

by p75NTR (Huang and Reichardt 2003). However, several studies have pointed to a negative role of p75NTR in NT signalling and neurite outgrowth. Most notably, regeneration of motor axons following peripheral nerve injury is more robust in p75NTR knockouts than in wild-type mice (Ferri et al. 1998; Boyd and Gordon 2001, but see Song et al. 2009).

These data, combined with the possibility that α-secretase disrupts any substrate-bound gradient by liberating the ECD of p75NTR (Zampieri et al. 2005), led to questions regarding the validity of the presentation model. In fact, in p75NTR−/− mice (exon III deletion), injured sensory axons were able to not only penetrate the dorsal root entry zone and enter the CNS following dorsal rhizotomy but also drive CNS neurons and restore sensory function (Scott and Ramer 2010). Successful regeneration was dependent on endogenous NGF and NT-3, as the regeneration of both small-caliber and large-diameter axons was prevented in p75NTR−/− mice by NGF- and NT-3 sequestration by TrkA-Fc and TrkC-Fc, respectively. Importantly, p75NTR−/− axons could not penetrate the astrocytic scar unless their associated Schwann cells were also p75NTR−/−, and in tissue culture experiments of Schwann cells and DRG neurons, it was shown that Schwann cell-expressed p75NTR reduced NT-dependent neurite outgrowth. Since NGF and NT-3 levels were equivalent in wild-type and p75NTR−/− mice, these data showed that rather than presenting neurotrophins to regenerating axons, Schwann cell p75NTR restricts NT availability and limits regeneration into the cord.

It is important to contrast this work with studies on the effects of p75NTR following injury to sensory axons within the CNS. Since p75NTR transduces inhibitory signalling by MAIs, it is reasonable to hypothesize that its absence might relieve inhibition. However, Song et al. (Song et al. 2004) showed that sensory axons injured in the dorsal columns of p75NTR−/− mice (the same exon III null mutants used in the rhizotomy studies) failed to regenerate beyond the glial scar. The crucial difference between this and the rhizotomy model is the lack of reactive and NT-producing Schwann cells following direct CNS lesions. That is, regeneration did not fail following dorsal column injury because p75NTR was unable to mediate MAI signalling, but because trophic support was inadequate. Indeed, grafts of p75NTR−/− peripheral nerve are better able to support growth of injured dorsal column axons than are wild-type grafts (Scott and Ramer 2010). Together, these studies cast doubt on the role of all known p75NTR-interacting inhibitory molecules produced in the injured spinal cord (including NogoA, MAG, OMgp, ephrin B3, and Semaphorin 3A) in blocking regeneration of injured axons. In fact, a recent study using mice lacking all three known NgR ligands showed a frank absence of regeneration, reinforcing these uncertainties (Lee et al. 2010).

6 Neurotrophins, p75NTR, and Myelination

Successful establishment of axonal conduction during development, and successful recovery of function following neurotrauma, requires myelination. Some of the most

promising experimental strategies for promoting axonal outgrowth following CNS injury include manipulating neurotrophic factor levels and antagonizing signalling by MAIs (although in the latter case "outgrowth" is restricted to plasticity of spared fibers rather than regeneration of injured axons (Lee et al. 2010)). Despite its importance to functional recovery, it has yet to be determined in any meaningful way whether myelination accompanies the axonal regeneration induced by these manipulations.

In the PNS, axonal internodes are myelinated by Schwann cells (One Schwann cell per internode), and in the central nervous system (CNS), this task is performed by oligodendrocytes (multiple internodes per oligodendrocyte). Although similar in many respects, there are some very marked differences between these two cell types beyond their location and structure. One such difference is the expression of p75NTR following injury (Zhou and Li 2007). In Schwann cells p75NTR is dramatically upregulated following injury and remains so until axon/Schwann cell contact is reestablished, while in oligodendrocytes this is not the case. It has been suggested throughout the literature that this difference may be one key aspect that prevents CNS damage from being repaired in the same way as damage to the PNS, although the proposed mechanisms by which this might be accomplished vary.

6.1 Schwann Cells

In Schwann cells, Trk signalling is responsible for regulating proliferation and differentiation, as well as elongation and axon ensheathment. Cosgaya et al. (2002) demonstrated that NT-3, via TrkC, has a powerful inhibitory effect on myelination, maintaining Schwann cells in a proliferative state. NT-3 signalling via p75NTR also negatively affects Schwann cell migration (Bentley and Lee 2000; Yamauchi et al. 2004; Skeldal et al. 2011). Once NT-3 levels begin to drop, however, BDNF is able to upregulate myelin-specific genes in Schwann cells. BDNF is central to myelination by Schwann cells both in development and after injury: BDNF derived from sensory axons promotes Schwann cell myelination during development (Tolwani et al. 2004; Ng et al. 2007), and, following peripheral nerve injury, BDNF is required for myelination of regenerating axons (Zhang et al. 2000). Crucially, in all cases BDNF exerts its effects on Schwann cells via p75NTR (Cosgaya et al. 2002; Song et al. 2006).

NGF also promotes myelination in DRG-Schwann cell cocultures (Chan et al. 2004), although this is mediated not by a direct action of NGF on Schwann cells, but via TrkA expressed on sensory axons. It was speculated that some of the effects might have been due to an increase in axonal diameter, but it is well known that NGF potently upregulates BDNF selectively in TrkA-expressing DRG neurons and their processes (Michael et al. 1997). The potent effects of BDNF on myelination by Schwann cells probably underpin these indirect effects of NGF.

Schwann cell p75NTR not only is involved in the initiation of the glial myelination program and the maintenance of cell survival but appears to be involved in the actual act of ensheathment as well. Chan and colleagues (Chan et al. 2006) demonstrated that p75NTR is actively recruited to the axon-glial junction by the

polarity protein Par-3 at the commencement of ensheathment. Moreover, they showed that axon-Schwann cell contact was necessary to induce this recruitment and localization of p75NTR and proposed that this positions p75NTR precisely on the plasma membrane of the Schwann cell to receive pro-myelinating signals.

6.2 Oligodendrocytes

Neurotrophin signalling also operates in the oligodendrocyte lineage. Functional Trk receptors are expressed on these cells (Barres et al. 1994; Condorelli et al. 1995; Cohen et al. 1996; Kumar and de Vellis 1996); NGF and NT-3 promote oligodendrocyte precursor cell (OPC) survival in vitro and, when combined with platelet-derived growth factor, NT-3 induces their proliferation (Barres et al. 1994). NGF inhibits oligodendrocyte myelination of sensory axons in culture, but this occurs through modulating the "receptivity" of TrkA-expressing axons rather than via direct effects on OPCs (Chan et al. 2004). NT-3 withdrawal from culture results in OPC differentiation into pre-myelinating oligodendrocytes, and this is generally accepted to be the result of a cell-autonomous cycle-counting mechanism (Barres and Raff 1994; Durand and Raff 2000). In contrast to the survival- and proliferation-enhancing effects of NT-3, BDNF initiates the myelination program (via TrkB), and, accordingly, BDNF heterozygous mice exhibit delayed developmental myelination (Xiao et al. 2010). Unlike in Schwann cells, BDNF promotes oligodendrocyte myelination equally well in the presence or absence of p75NTR (Du et al. 2006; Xiao et al. 2010).

This is not to say that NGF and NT-3 never push oligodendrocytes toward differentiation. NT-3 and NGF have been shown to increase the expression of myelin basic protein and proteolipid protein, both components of mature myelin, in basal forebrain oligodendrocytes (Du et al. 2006). Unlike BDNF, they do so in part via p75NTR. For NT-3 at least, this occurs through activation of myelin protein translation, rather than by increasing myelin gene transcription (Coelho et al. 2009). Additionally, high concentrations of NT-3 are capable of transiently inducing OPC differentiation into oligodendrocytes (Heinrich et al. 1999).

Much of what is known about NT effects on oligodendrocytes comes from in vitro studies and developmental assessment of myelination in transgenic mouse studies; very little is known about NT effects on oligodendrocytes, their progenitors, or myelination of axons in the adult animal following neurotrauma. The dorsal rhizotomy model may again be particularly informative here, since Schwann cells do not invade the CNS when the injury occurs in the dorsal roots. In quantitative stereological TEM studies on rhizotomized rats, it was shown that 1 week's intrathecal NT-3 treatment, which promotes regeneration of sensory axons into the spinal cord, also results in a near doubling of oligodendroglial tissue in the CNS part of the DREZ (Hanna-Mitchell et al. 2008). How NT treatment affects myelination of regenerated axons in this model has not yet been worked out, but this task should be made easier by the fact that rhizotomy – unlike direct CNS trauma– does not result in oligodendrocyte progenitor death or demyelination of spared axons (Sun et al. 2010).

p75NTR/LINGO-1 signalling also has a role to play in oligodendrocytes, but it is distinct from that in neurons. In oligodendrocytes this signal inhibits differentiation of OPCs into pre-myelinating oligodendrocytes (Mi et al. 2005). LINGO-1 signalling via p75NTR seems to be essential to oligodendrocyte process outgrowth (and by extension, myelination), since the inhibitory effects of LINGO-1 are reversed by p75NTR antagonists (Bourikas et al. 2010). Intriguingly, axonal LINGO-1 also inhibits oligodendrocyte differentiation, an effect that is potentiated by NGF acting through axonal TrkA (Lee et al. 2007). LINGO-1 is expressed in white matter of the injured spinal cord (Barrette et al. 2007), so it is reasonable to speculate that myelin-derived inhibitory proteins released into the extracellular space following injury inhibit nearby OPCs from differentiating into myelinating oligodendrocytes. This intriguing hypothesis has yet to be tested, however.

7 Conclusion

The literature reviewed in this chapter illustrates the wide-ranging effects of NTs on axonal regeneration and myelination, both prerequisites for functional recovery in the wake of neurotrauma. These have largely been examined in isolation, however, and the time has come to develop strategies aimed at optimizing both processes. Although details vary, the following generalizations can be safely made (Fig. 1): NGF and NT-3 promote regeneration of sensory axons, and while NGF promotes peripheral myelination, NT-3 inhibits it. NGF and NT-3 also tend to enhance OPC survival and proliferation. BDNF, on the other hand, not only promotes myelination by both Schwann cells and oligodendrocytes but also inhibits plasticity of sensory axons. p75NTR is required for appropriate peripheral myelination, but may act to prevent oligodendrocyte myelination through its association with LINGO-1. For regeneration in the CNS – one of the toughest challenges in neuroscience – one might envision a sequential approach using NTs, first targeting sensory axonal regeneration and then initiating the myelination program.

The hope that neurotrophins hold for repairing the damaged nervous system must be tempered by the understanding that developmental mechanisms underlying neurotrophin-mediated axon growth and myelination are unlikely to be faithfully recapitulated in the adult. However, manipulations involving powerful experimental models – such as primary afferent neurons and their processes – will continue to shed light on how neurotrophin treatment might be refined to achieve all requirements of functional restoration.

Neurotrophins and Pain

Ru-Ping Dai and Xin-Fu Zhou

Contents

Abstract

There is ample evidence suggesting that neurotrophins in particular nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) regulate pain processing as the modulators. NGF released from local tissue and dorsal root ganglia (DRG) binds to tropomyosin-related kinase (Trk) A receptors and

regulates many membrane receptors, ion channels, and signaling molecules contributing to pain processing. Molecules antagonizing NGF-TrkA signaling have been developed and attenuate chronic pain in the patients. However, anti-NGF therapy leads to bone death in some patients suggesting that the therapy antagonizing NGF-TrkA signaling should be cautious to control pain in patients with chronic pain. On the other hand, brain-derived neurotrophic factor (BDNF) may regulate pain as a central modulator. BDNF is released when nociceptors are activated and regulated by NGF. This chapter reviews the roles and the underlying mechanisms by which NGF and BDNF regulate pain processing. The clinical trial of anti-NGF therapy is also discussed.

Keywords

Brain derived neutrophic factor • Central sensitization • Nerve growth factor • Neurotrophin • Pain • Spinal cord

List of Abbreviations

5-HT receptor	5-Hydroxytryptamine receptor
ASIC	Acid-sensing ion channels
B_2R	Bradykinin (BK) receptors
BDNF	Brain-derived neurotrophic factor
CGRP	Calcitonin gene-related peptide
CREB	cAMP response element-binding protein
DRG	Dorsal root ganglia
EPSCs	Excitatory postsynaptic currents
ERK	Extracellular regulated kinase
GABA	γ-aminobutyric acid
NGF	Nerve growth factor
NMDA receptor	*N*-methyl-D-aspartate receptor
NSAID	Nonsteroidal anti-inflammatory drugs
NT	Neurotrophin factor
$p75^{NTR}$	p75 neurotrophin receptor
SP	Substance P
TNF-α	Tumor necrosis factor-α
TRK	Tropomyosin kinase
TRPV	Transient receptor potential vanilloid

1 Introduction

Pain is an unpleasant feeling often caused by noxious stimuli such as trauma, stubbing a toe, or burning the finger. As defined by the International Association for the Study of Pain, pain is "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such

damage" (Bonica 1979). It can motivate the individual to withdraw from the damaged situation and is essential for the avoidance of tissue injury and promotes healing after injury (Lynn 1983). Pain is usually transitory and disappears once the noxious stimuli are removed or the injured tissue is healed. However, in many situations, pain can be persistent even after removal of the noxious stimuli or the healing of the body. The development of pathological or chronic pain will severely affect the patients' life quality and general functions (Raj 2007). As a matter of fact, pain is the most common reason for physician consultation in the United States and Europe, and management of pathological pain is still a major health challenge throughout the world (Breivik et al. 2006; Hardt et al. 2008). This is because there is still a lack of effective treatments of chronic pain without unwanted side effects and/or abusive liability.

Currently, nonsteroidal anti-inflammatory drugs (NSAID) such as ibuprofen and cyclooxygenase-2 inhibitors and opioids such as tramadol or morphine are most widely used for pain control in clinical practice. However, the concerns of gastrointestinal and renal side effects of NSAIDs and of cardiovascular risk of cyclooxygenase-2 inhibitors limit their use in many medical conditions (Whelton 2000). On the other hand, despite the fact that opioids are an effective treatment in the many types of chronic pain, their side effects and liabilities, including loss of drug effectiveness, constipation (the most common long-term side effect causing noncompliance), drug diversion, respiratory depression and accidental death caused by overdose, are major concerns in clinical practice (Chou et al. 2009). Therefore, development of new agents for chronic pain control without severe side effects remains a significant, unmet clinical need.

Neurotrophins are a family of growth factors containing the following members: nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin factor (NT), and NT-4/5. All neurotrophins are synthesized as a proform of approximately 30 kDa and cleaved to a mature form of approximately 13 kDa (Barbacid 1995; Reichardt 2006). Each neurotrophin binds with high affinity to their specific receptors, one of the tropomyosin kinase (Trk) family of transmembrane receptors. For example, NGF binds to TrkA, BDNF and NT-3/4 bind to TrkB, and NT-3 binds to TrkC (and to TrkA with lower affinity). Conversely all neurotrophins have a common low-affinity binding transmembrane receptor, p75 neurotrophin receptor ($p75^{NTR}$). Through binding to their high-affinity receptors and activating the downstream signaling, neurotrophins can regulate the survival, development, and function of neuronal subpopulations that express appropriate receptors (Barbacid 1995). In the absence of Trk or if the ratio of p75/TrkA is high, neurotrophins can activate $p75^{NTR}$ and subsequently the downstream signaling (JNK, Nf-kB) and promote apoptosis. In addition to regulating the survival and function of the nervous system, there is ample evidence indicating that NGF and BDNF play important roles in development of various types of pain (Pezet and McMahon 2006; Mantyh et al. 2011). In this chapter, the evidence that NGF and BDNF act as the pain mediators and modulators will be discussed (Fig. 1a). In addition, the clinical trials of management of chronic pain by neutralizing NGF are also introduced.

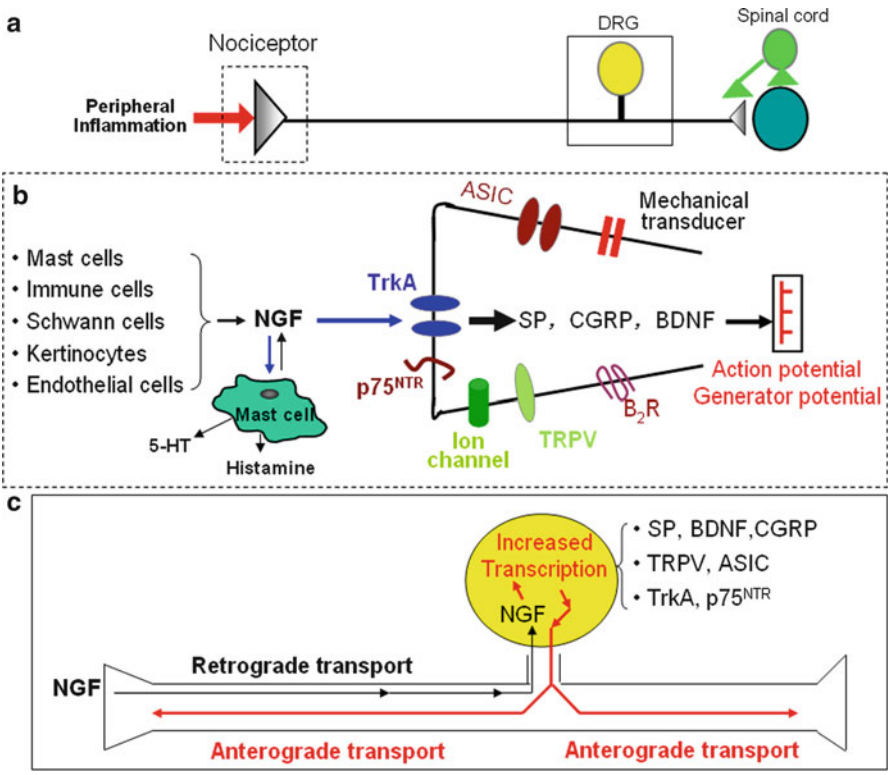

Fig. 1 Summary of the mechanisms by which NGF exerts its neuromodulator in pain processing. (**a**) Schematic summary of pain processing from nerve terminals, the primary sensory neuron (DRG), and spinal cord (second-order neuron). (**b**) Acute phase of NGF exerting pain hypersensitivity through peripheral sensitization. In response to peripheral inflammation, NGF released from many types of cells sensitizes many membrane surface receptors (TRPV, ASIC, etc.) and releases pain mediators (SP, CGRP, and BDNF), resulting in mechanical allodynia and thermal hyperalgesia. (**c**) Later phase of NGF exerting pain hypersensitivity through peripheral and central sensitizations. Released NGF can transport to DRG through a retrograde transport way. In the DRG, many genes are activated and the increased pain mediators such as SP, BDNF, and TRPV can anterogradely transport to peripheral tissue or spinal cord which contributes to central sensitization. The process may take hours to days

2 Nerve Growth Factor

Nerve growth factor is the first identified neurotrophin and can be isolated into two forms, 7S or 2.5S (S is defined as the sedimentation coefficient) from male mouse salivary gland. Mature NGF is an approximately 12.5 kDa protein and usually forms homodimers after being cleaved from pro NGF which may have independent biological activity through activating $p75^{NTR}$. NGF binds to TrkA, which directly

activates the downstream signaling (Levi-Montalcini 1998). The complexity of NGF-TrkA can be internalized and retrogradely transported to the cell bodies from the nerve terminals (Mantyh et al. 2011).

2.1 Deprivation of NGF Results in Pain Insensitivity

NGF as a pain modulator has been identified by the finding that selective mutations in NGF or TrkA genes cause congenital insensitivity to pain in humans and loss of pain behaviors in genetically altered mice (Crowley et al. 1994; Einarsdottir et al. 2004). In NGF or TrkA knockout mice, most sensory neurons expressing TrkA die and are profoundly unresponsive to pain noxious stimuli (Crowley et al. 1994; Smeyne et al. 1994; Einarsdottir et al. 2004). In addition, patients with a mutation in TrkA gene have normal proprioception and normal sensation to innocuous pressure but present pain insensitivity to thermal stimuli (Indo 2002). Other studies observed that immunization against NGF in the critical period of the development, i.e., in the utero or prenatal period, results in depletion of substance P in dorsal root ganglia (DRG) neurons in animals (Ross et al. 1981; Johnson et al. 1989). Delivery of anti-NGF antibody in the early postnatal development causes a developmental switch of high-threshold mechanoreceptors to sensitive mechanoreceptors (Ritter et al. 1991).

Together, deprivation of NGF using genetic or immunological methods shows that NGF is essential for the survival of the sensory neurons in the prenatal development phase. However, NGF is not required for the survival of sensory neurons in the postnatal phase; instead, NGF mainly maintains the peptidergic phenotype of primary neuronal afferents.

2.2 NGF in Inflammatory Pain

Ample evidence shows that NGF is involved in the induction and persistence of various types of pain including inflammatory pain, cancer pain, neuropathic pain, and surgical pain. In these types of pathological pain, NGF and its high-affinity receptor TrkA are upregulated in the local region and DRG. Manipulating NGF or TrkA and downstream signaling could attenuate pain hypersensitivity in pathological pain. Given that the role of NGF signaling has been extensively studied in the inflammatory pain, thus the role of NGF as an inflammatory mediator that regulates pain process firstly and then its role in other types of pain will be discussed.

In inflammatory pain including carrageenan, formalin, and complete Freund's adjuvants as well as in models of autoimmune arthritis (Shelton et al. 2005) and ultraviolet B radiation-induced acute inflammation (Bishop et al. 2007), NGF and TrkA are increased in the inflamed tissue and DRG. The local increase of NGF is mainly released from the inflammatory cells, immune cells, Schwann cells, as well as noninflammatory cells such as keratinocytes and endothelial cells (Tron et al. 1990). The released NGF binds to TrkA on mast cells resulting in the release of inflammatory mediators such as histamine, serotonin (5-HT), and NGF

itself (Fig. 1b). When NGF binds to TrkA on the peptidergic fiber terminals, it activates the downstream intracellular signaling pathways, which subsequently activate or modulate many membrane surface receptors including bradykinin receptors; ion channels including transient receptor potential vanilloid 1 (TRPV1), acid-sensing ion channels (ASIC) 2/3, voltage-gated sodium (Na_v) or calcium (Ca_v) ion channels, and delayed rectified potassium (K^+) currents; and putative mechanotransducers (Mantyh et al. 2011). The rapid modification of membrane surface receptors in the primary afferent terminals leads to sensitization of primary afferent terminals to mechanical or thermal stimuli (Bennett et al. 1998; Shu and Mendell 1999). The peripheral sensitization is rapid taking from minutes to hours (Fig. 1b). When the inflammation is persistent (e.g., inflammation induced by complete Freund's adjuvant), NGF and TrkA are transported to the DRG in a retrograde way (Ji et al. 2002). There NGF-TrkA signaling results in the production and release of neuropeptides such as substance P (SP) and calcitonin gene-related peptide (CGRP) and the other neurotrophin, BDNF, some of which are transported to peripheral tissue or the spinal cord (Lindsay and Harmar 1989; Woolf and Costigan 1999; Ji et al. 2002). The procedure of central sensitization may take several hours to days since it is involved in the retrograde transport, gene expression, anterograde transport, phenotype switch, and so on (Woolf and Costigan 1999) (Fig. 1c). A typical example is that NGF-induced pain hypersensitivity is selectively blocked by MK 801, a noncompetitive antagonist of *N*-methyl-D-aspartate (NMDA) receptor, which plays a critical role in the development of windup and central sensitization (Woolf 1996; Yaksh et al. 1999).

2.3 NGF in Other Types of Pain

NGF not only acts as an inflammatory mediator and results in peripheral and central sensitization in inflammatory pain but is also involved in other types of pain. In a mouse model of bone cancer, sustained delivery of anti-NGF antibody could inhibit the development of cancer pain, along with blocking the pathological sprouting of sensory and sympathetic nerve fibers, the formation of neuroma-like structures (Halvorson et al. 2005; Mantyh et al. 2010). This study suggests that NGF is released during the development of cancer pain. The released local NGF induces a remarkable reorganization of sensory and sympathetic nerve fibers, resulting in the formation of neuroma-like structure and sympathetic sprouting (Mantyh et al. 2010). Further study demonstrates that the source of NGF may be mainly from tumor-associated stromal, inflammatory, and immune cells (Ehrhard et al. 1993; Artico et al. 2008; Jimenez-Andrade et al. 2010). In this regard, injection of prostate cells which do not express detectable levels of NGF gene results in sclerotic bone lesions. In this model of bone cancer, TrkA-positive sensory and sympathetic nerve fibers are also observed to undergo the reorganization of pathological sprouting. Administration of anti-NGF to sequester the increased NGF in the early phase of prostate-induced bone cancer pain could block the nerve fibers sprouting and dramatically attenuate the development of cancer pain (Jimenez-Andrade et al. 2010). The findings that NGF

contributes to the sprouting of sensory and sympathetic nerve fibers in cancer pain suggest that preemptive anti-NGF therapy not only attenuates the attendant pain but also inhibits the pathological changes of sensory and sympathetic nerve fibers, which may be critical for the development of chronic pain hypersensitivity. Therefore, anti-NGF therapy may be effective in treating various types of cancer pain which predicts the occurrence of tissue/nerve injury.

Recent studies have shown that NGF also regulates the postsurgical pain (Zahn et al. 2004; Wu et al. 2007). Hind paw incision (a common animal model of surgical pain) results in the increased NGF in the incised tissue, but not DRG. Anti-NGF treatment could attenuate the guarding pain- and heat hyperalgesia induced by hind paw incision although it would not affect the C-fiber sensitization (Zahn et al. 2004; Wu et al. 2007). Further study showed that the increased NGF after hind paw incision is mainly localized in nerve bundles including Schwann cells and axons (Wu et al. 2007). Thus, NGF may be taken up by the axon and transported into the DRG and exerts its biological function, similar to that in inflammatory pain. These findings suggest that NGF may be a potential target to treat postsurgical pain (Wu et al. 2007).

The role of NGF in the neuropathic pain has not been well established. Neuropathic pain is one of the greatest challenges in clinical practice and refractory to current therapies. Neuropathic pain is normally caused by nerve injury induced by various etiologies including diabetes, infection such as postherpetic neuralgia, drug treatment-induced neuropathy, and traumatic injury in the peripheral nerves or spinal cord (Pezet and McMahon 2006). In the traumatic injury-induced neuropathic pain models such as spinal nerve ligation or sciatic constriction injury, some axons have lesions while the other axons are intact. The role of NGF may be distinct in the development of this type of neuropathic pain. This is because in the injured axons, it undergoes Wallerian degeneration which may lead to the retrograde neurodegeneration to the spinal cord and loss of the contact with their peripheral target. NGF has been reported to exert neuroprotective effect on small-diameter nociceptive sensory neurons and therefore reverse sensory hyperalgesia (McMahon and Cafferty 2004). However, the clinical trial in diabetic neuropathy does not show any neuroprotective effect (Apfel 2002). In contrast, the injured Schwann cell or recruited immune cells may release NGF which would sensitize the intact axons or transport to the DRG in a retrograde way (Pezet and McMahon 2006). Thus, blocking NGF may be able to attenuate neuropathic pain. Several studies indeed have shown that anti-NGF could attenuate the pain hypersensitivity in rat models of sciatic constriction injury and spinal cord injury (Ramer and Bisby 1999; Deng et al. 2000; Gwak et al. 2003). Further studies are needed to elucidate how NGF is involved in the development of neuropathic pain.

2.4 Anti-NGF Therapy in Clinical Trials

Ample experimental evidence has shown that blocking NGF or its high-affinity receptor TrkA could greatly inhibit the progress of chronic pain, in particular pain

induced by inflammatory injury. For example, systemic anti-NGF treatment prevents thermal and mechanical hyperalgesia in a complete Freund's adjuvant-induced inflammatory pain (Woolf et al. 1994). Administration of Trk-IgG fusion protein attenuates pain hypersensitivity induced by carrageenan (McMahon et al. 1995; Koltzenburg et al. 1999). In visceral inflammatory pain model, administration of anti-NGF antibody or Trk-IgG fusion protein markedly reduced the pain hypersensitivity. In addition, anti-NGF therapy also reversed the prolonged hyperalgesia in autoimmune arthritis (Shelton et al. 2005). Further studies have shown that anti-NGF therapy reduces pain caused by bone fracture or incisional pain suggesting that anti-NGF therapy is also effective for other types of pain (Jimenez-Andrade et al. 2007; Wu et al. 2007; Ghilardi et al. 2011).

The encouraging data of anti-NGF therapy in animal studies drive the scientists to investigate the role of NGF in humans. In the patient with chronic pain including arthritis, fibromyalgia, or peripheral nerve injury, NGF expression is increased locally (Aloe et al. 1992; Anand et al. 1997; Sarchielli et al. 2007). In addition, subcutaneous injection of NGF leads to persistent mechanical hyperalgesia in humans (Svensson et al. 2003; Rukwied et al. 2010). These studies suggest that increased local NGF may be involved in the development of chronic pain. There are several strategies to develop the anti-NGF-TrkA signaling for the treatment of chronic pain. These include NGF sequestration by anti-NGF antibody, inhibiting NGF binding to TrkA, blocking TrkA kinase activity by TrkA-Fc fusion protein (Shelton et al. 1995; Winston et al. 2003).

One typical molecule is a humanized anti-NGF monoclonal antibody tanezumab (RN-624, PF-04383119) (Cattaneo 2010). An early study has shown that, as compared to the placebo, tanezumab dose-dependently reduces the knee pain whilst walking in the patients with osteoarthritis, a form of arthritis in which the cartilage breaks down in the joint (Lane et al. 2010). The clinical trial of 450 patients shows that tanezumab along with NSAIDs reduces pain by 45–62 %, while a placebo only reduces pain by 22 % (Lane et al. 2010). In addition, tanezumab was also associated with dramatically greater improvement as measured by the patients' global assessment. However, phase 3 osteoarthritis trial was halted because 16 patients taking tanezumab were observed to have bone tissue death in their hip and knee joints and required the joint replacement (Garber 2011). Several possibilities are raised including the combined use of tanezumab and NSAIDs and reduced pain leading to much more movement of the joints (Lane et al. 2010; Garber 2011). Thus, it is still an important issue to address the safety of anti-NGF therapy in patients with chronic pain (Ackermann 2012).

3 Brain-Derived Neurotrophic Factor

Another neurotrophin involved in pain is brain-derived neurotrophic factor (BDNF). BDNF is a 12.4 kDa basic protein and the second identified neurotrophin isolated from pig brain in 1982 (Barde et al. 1982). It is well known that BDNF plays a critical role for cell differentiation, neuronal survival, migration, dendritic

arborization, synaptogenesis, and activity-dependent synaptic plasticity in the central nervous system (Greenberg et al. 2009). Dysfunction of BDNF in the central nervous system would lead to cognitive dysfunction and anxiety/depression behaviors (Greenberg et al. 2009). There is ample evidence showing that BDNF also regulates pain processing as a central modulator (Pezet and McMahon 2006).

3.1 Expression Pattern of BDNF and TrkB

Besides widely expressed in the brain, BDNF is also expressed in the tissues involving in the pain processing including the DRG and spinal cord. In the DRG, BDNF is constitutively expressed in the small- and medium-sized peptidergic neurons, which accounts for 10–40 % in the DRG neurons (Wetmore and Olson 1995; Luo et al. 2001). The synthesis of BDNF in the DRG neurons anterogradely transports into central terminals of primary afferent fibers in spinal cord dorsal horns. In the spinal cord, BDNF is mainly located in the large vesicles which also contain substance P, the common pain mediator. The BDNF contained in the sensory neurons and terminals in the spinal cord are believed to be released with activity. TrkB is also expressed in a subpopulation of DRG and the terminals in the dorsal horns of spinal cord (Zhou et al. 1993; Kashiba et al. 2003). In addition, TrkB is also expressed in nodose and trigeminal neurons and their terminals in trigeminal nucleus (Behnia et al. 2003). TrkB immunoreactive cells are also observed in the neurons of spinothalamic tract, which is associated with the transmission of painful information to supraspinal regions (Slack et al. 2005).

In addition to its expression in sensory neurons and central nervous system, BDNF gene is also expressed in the peripheral tissue. The expression of BDNF is higher in visceral tissues (such as the bladder, lung, and colon) than in the somatic tissues (Braun et al. 1999; Lommatzsch et al. 1999). In inflammatory or disease situations, BDNF is upregulated locally. For example, in the lung by allergen challenges, BDNF level is increased and expressed in the inflammatory infiltrates in subsets of T cells and the activated alveolar macrophages (Braun et al. 2004). Sequestration of the upregulated BDNF blocked the enhanced airway reactivity and persistent airway obstruction (Braun et al. 2004). In patients with chronic pancreatitis, BDNF is also greatly increased in ductural complexes and perineurium of the enlarged nerve. The increased level of BDNF is well correlated with the intensity of pain in the patients (Zhu et al. 2001).

3.2 Effect of Exogenous BDNF in Pain

There is accumulating evidence showing that BDNF regulates various types of pain states in different anatomical sites including peripheral tissues, DRG, spinal cord, and supraspinal levels. First, intrathecal delivery of exogenous BDNF could induce mechanical allodynia and hyperalgesia (Coull et al. 2005). Second, BDNF superfusion dramatically increases C-fiber-mediated reflexes which is greatly

inhibited in the BDNF-deficient mice (Kerr et al. 1999). In the inflammatory state, BDNF significantly increases the frequency of miniature excitatory postsynaptic currents (EPSCs) of the neurons in the spinal dorsal horns suggesting that BDNF activates nociceptive second-order neurons (Matayoshi et al. 2005). Third, BDNF-TrkB signaling activates the signaling closely associated with pain sensitization. For example, BDNF, after binding to TrkB, could potentiate glutaminergic neurotransmission, in particular *N*-methyl-D-aspartate (NMDA) receptor response (Slack et al. 2004). NMDA receptor is an ionotropic glutamate receptor and is believed to play a central role in central sensitization (South et al. 2003). Furthermore, intraspinal injection of BDNF can release the neuropeptide SP and induce the activation of extracellular regulated kinase (ERK) in the spinal cord (Kawasaki et al. 2004). Activation of ERK in the DRG and spinal cord has been reported to contribute to the development of pain such as inflammatory pain and neuropathic pain (Obata et al. 2004). BDNF may be able to activate cAMP response element-binding protein (CREB) and early gene c-fos, both of which are sensitive and specific markers in the spinal cord for the noxious stimuli (Obata et al. 2004; Jongen et al. 2005). More recent study suggests that the increased BDNF in the spinal microglia induces the depolarizing shift in the anion reversal potential and subsequently converts the GABA (γ-aminobutyric acid) inhibitory neurons to excitatory neurons (Coull et al. 2005).

3.3 Role of BDNF in Inflammatory Pain

As described above, pharmacological, biochemical, and neurophysiological evidence demonstrates that exogenous BDNF promotes pain processing. Extensive studies have shown that endogenous BDNF is increased in the DRG and spinal cord, and contributes to pain hypersensitivity in inflammatory pain. First, BDNF is increased in the DRG and spinal cord following peripheral inflammation including intraplantar formalin, CFA, and carrageenan (Pezet et al. 2002). The upregulation of BDNF is partly mediated by NGF since anti-NGF antibodies prevent the activation of BDNF in the spinal cord (Michael et al. 1997). In addition, a recent study also reports that TNF-α also contributes to the upregulation of BDNF and TrkB in the DRG (Onda et al. 2004). In DRG primary culture, chronic TNF-α treatment also upregulates the expression of BDNF and TrkB accompanied by the increased expression of CGRP and SP (Lin et al. 2011). In addition, tooth pulp inflammation increases BDNF expression in trigeminal ganglion (Kashiba et al. 2003). The increased BDNF is co-localized with CGRP and TRPV1 (Duric and McCarson 2007; Lin et al. 2011). Second, intrathecal injection of TrkB-IgG fusion protein dramatically ameliorates the pain behavior in response to peripheral inflammation suggesting that BDNF-TrkB signaling in the DRG and spinal cord contributes to inflammatory pain hypersensitivity (Lin et al. 2011). BDNF-TrkB signaling exerts their pro-nociceptive effect through multiple signaling such as activation of ERK1/2 signaling and CGRP, the well-known inflammatory pain mediator (Pezet and McMahon 2006) (Fig. 2).

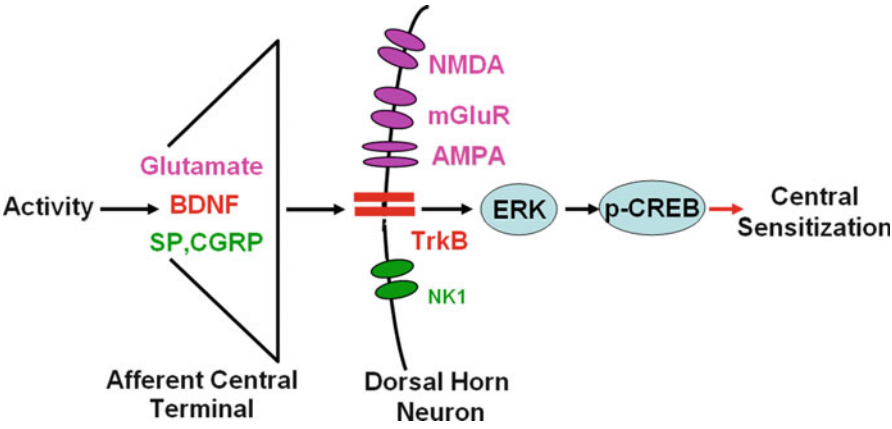

Fig. 2 Schematic summary of the mechanisms by which BDNF regulates pain processing as a central modulator in the spinal cord. Noxious stimuli induce the release of BDNF and neurotransmitters including glutamate, SP, and CGRP. BDNF can bind to TrkB and subsequently activate ERK which contributes to the central sensitization. Glutamate can bind to its receptors including NMDA, mGluR, and AMPA receptors. BDNF also phosphorylates the subunit of NMDA receptor, NR1. SP binds its receptor, NK1. These pain neurotransmitters also play critical role for the central sensitization

BDNF-TrkB signaling is also observed in the spinal cord or peripheral tissue in the inflammatory visceral pain. In a bladder inflammation model, TrkB is increased in the bladder, pelvic ganglion, and DRG (Qiao and Vizzard 2002). In addition, BDNF level is increased in the rectosigmoid biopsies which correlates with the pain score in the patients with irritable bowel syndrome (Yu et al. 2012). In experimental inflammation of mouse gut, BDNF is upregulated in the DRG in the experimental colitis (Yang et al. 2010). The pain intensity in this inflammatory visceral pain is reduced in BDNF (+/−) mice as compared with BDNF (+/+) mice (Yu et al. 2012). Our recent study showed that the modulation of BDNF in visceral pain is sex specific. Anti-BDNF antibody pretreatment attenuates the nocifensive response in the males, whilst exacerbates the nocifensive response in the females in visceral pain induced by acetic acid intraperitoneal injection (Li et al. 2010). The upregulation of BDNF in the pancreas has also been reported in the patients with chronic pancreatitis, and the level of BDNF correlated with pain intensity (Zhu et al. 2001). All of these studies strongly indicate that BDNF regulates inflammatory pain through peripheral and central mechanisms.

3.4 Role of BDNF in Neuropathic Pain and Surgical Pain

In neuropathic pain, BDNF expression is also dysregulated in the sensory neurons. However, the expression of BDNF in the sensory neurons is different in the different neuropathic pain models. For example, in the axotomy model induced by sciatic nerve section, BDNF level is upregulated in the medium- and large-diameter DRG

neurons and the central terminals in the deep layers of the dorsal horns in the spinal cord (Michael et al. 1999). However, the expression of BDNF in the small-diameter neurons is decreased probably due to the neurodegeneration induced by the axotomy. In another neuropathic pain model induced by sciatic nerve constriction injury, BDNF is upregulated in the small-diameter neurons. The increased BDNF in the small-diameter neurons may be mediated by TNF-α through inducing NGF expression (Onda et al. 2004). A series of studies have shown that the activated microglia can release BDNF in the spinal nerve ligation-induced neuropathic pain model (Onda et al. 2004). The increased BDNF in microglia activates TrkB, which, subsequently, converts inhibitory neurons to excitatory function through inverts the polarity of currents induced by γ-aminobutyric acid (GABA) (Coull et al. 2005). The disinhibition of GABA receptor-mediated neurons would contribute to the peripheral nerve injury-induced tactile allodynia (Coull et al. 2005). The upstream signaling of microglial BDNF includes ATP receptors, in particular P2X4 receptors through P2X4R-evoked increase in $Ca^{(2+)}$ and the activation of p38 mitogen activation protein kinase (Trang et al. 2009a). Thus, in peripheral nerve injury-induced neuropathic pain, the upregulation BDNF can be from the neurons or microglia and maintains the persistent pain hypersensitivity after nerve injury.

Our previous study has shown that BDNF is also increased in the DRG and spinal cord after surgical incision. The increased BDNF is mainly localized in the neurons as well as glial cells. Intrathecal delivery of anti-BDNF could dramatically reduce the incision-evoked pain hypersensitivity suggesting that BDNF in the DRG and spinal cord also contribute to pain hypersensitivity in surgical pain (Li et al. 2008). BDNF is also reported to be involved in cancer-induced pain through modulating NMDA receptors (Wang et al. 2012). Minocycline, a potent microglia inhibitor, could prevent the activation of BDNF in the model of bone cancer pain (Wang et al. 2012). This suggests that BDNF released from microglia contributes to cancer-induced bone pain.

3.5 Antinociceptive Effect of BDNF

Interestingly, in inflammatory pain, the expression of BDNF in the hippocampus is downregulated (Duric and McCarson 2007). Midbrain injection of BDNF, but not NGF, significantly exerts analgesia by elevating the tail-flick response latency and the latency in the hot-plate experiment (Siuciak et al. 1994, 1995). In addition, midbrain injection of BDNF also reduces the paw flinch response in the formalin intraplantar injection-induced pain (Siuciak et al. 1994, 1995). The analgesic effect of BDNF in the midbrain is associated with serotonergic neurons and can be prevented by naloxone (Siuciak et al. 1994, 1995). In addition, heterozygous BDNF(+/−) mice develops the hyperalgesia accompanied with the premature age-associated decreased forebrain 5-HT level and fiber density (Lyons et al. 1999). These findings suggest that supraspinal BDNF may exert antinociceptive effect through regulating the function of serotonergic neurons and levels of endogenous opioid receptors.

4 The Involvement of P75^{NTR} in Pain

Unlike TrkA and TrkB, p75^{NTR} is a low-affinity binding receptor for the whole family of neurotrophins. However, p75^{NTR} is the high-affinity binding receptor of precursor of neurotrophins such as pro NGF or proBDNF (precursor of BDNF). p75^{NTR} has been reported to exert multiple neuronal functions in the presence of Trk receptors (see review (Lu et al. 2005)). In the absence of Trks, neurotrophin acts on p75^{NTR} and promotes apoptosis. In a neuropathic pain model, p75^{NTR} expression is increased in the axon transport and uninjured primary afferents (Obata et al. 2006). Functional inhibition of p75^{NTR} in the DRG could reverse neuropathic pain after nerve injury. Further study shows that p75^{NTR} promotes neuropathic pain through enhancing TrkA signaling and activating p38 mitogen-activated protein kinase and TPRV1. These findings indicate that p75^{NTR} contributes to nerve injury-induced neuropathic pain (Obata et al. 2006). More recent study shows that morphine tolerance is attenuated in the wild-type but not p75^{NTR} (−/−) mice in which the induction of opioid physical dependence is not developed.

5 Conclusion

Neurotrophins, in particular NGF and BDNF, regulate and drive acute and chronic pain as pain modulators in adults. NGF contributes to pain processing mainly acting as peripheral inflammatory mediators. It can directly sensitize the peripheral nociceptive afferents and lead to peripheral sensitization rapidly. It can also retrogradely transport to sensory neurons and activate downstream signaling and gene expression. Anti-NGF therapy for treatment of chronic pain represents a novel class of analgesic therapy, but its safety is still a major challenge for the clinical application.

BDNF regulates pain processing as central modulators. BDNF is increased in the primary sensory neurons and spinal cord in the various types of pain. BDNF binds to TrkB and activates many pain mediators such as NMDA receptors, neuropeptides, and ERK, leading to the central sensitization. Sequestration of the increased BDNF through intrathecal delivery attenuates most types of pain. BDNF in the supraspinal level is downregulated in inflammatory pain, and midbrain infusion of BDNF exerts analgesic effect.

Neurotrophin Signaling in Cancer

Fei Tan, Carol J. Thiele, and Zhijie Li

Contents

Abstract

Neurotrophins are growth factors that play a major role in neuron survival, proliferation, differentiation, and apoptosis. There are four neurotrophins, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5) which function by interacting with Trk (tropomyosin-related kinase) tyrosine kinase receptors,

TrkA, TrkB, TrkC, or p75NTR receptor. Binding of neurotrophins with their cognate Trk receptors activates Ras/mitogen-activated protein kinase (MAPK) pathway, Phosphatidylinositol-3 kinase (PI3K)/Akt pathway, and Phospholipase C-γ (PLC-γ) pathway which are involved in cell survival, proliferation, differentiation, and apoptosis. Activation of the pan-neurotrophin receptor, p75NTR, leads to JNK pathway activation that induces cell apoptosis or activates a NF-κB cell survival pathway. Although neurotrophins were originally found to act on neurons, studies indicate they also have activities in nonneuronal cells. Trk activation or mutation occurs in tumors of neuronal origin, like neuroblastoma and medulloblastoma, as well as in nonneuronal tumors like thyroid, breast, lung, and prostate cancer. In neuroblastoma, expression of TrkA occurs in tumors that are biologically favorable and prone to spontaneous regression or differentiation which may be due to the absence or presence of its ligand (NGF) in the microenvironment. Expression of TrkB and/or its ligand BDNF in neuroblastoma tumors is often associated with chemo-resistance, metastasis, and a poor prognosis. In breast cancer, overexpression of TrkA promotes cell growth, migration and invasion in vitro or tumor growth, metastasis, and angiogenesis. Based on these studies, small molecule inhibitors targeting Trk receptors or downstream targets in their signaling pathways have been developed. The Trk selective inhibitor CEP-701 (Cephalon) or the Akt inhibitor perifosine are both in phase 1 and 2 clinical trials. The effects of these small molecule inhibitors, alone or in combination with chemotherapeutic drugs, are discussed.

List of Abbreviations

BDNF	Brain-derived neurotrophic factor
ERK	Extracellular signal-regulated kinase
Grb2	Growth factor receptor-bound protein 2
HGF	Hepatocyte growth factor
JNK	c-Jun N-terminal kinase
MAPK	Mitogen-activated protein kinases
MEK	MAP kinase kinase
mTOR	Mammalian target of rapamycin
NGF	Nerve growth factor
NSCLC	Non-small cell lung cancer
NT-3	Neurotrophin 3
NT-4/5	Neurotrophin 4/5
P75NTR	P75 neurotrophin receptor
PI3K	Phosphatidylinositol-3 kinase
PLC-γ	Phospholipase C-γ
PTB domain	Phosphotyrosine-binding domain
SCLC	Small cell lung cancer
Shc	Src-homology collagen protein
SOS	Son of sevenless
Trk	Tropomyosin-related kinase

1 Introduction

Neurotrophin are growth factors implicated in several different functions in the nervous system, including survival, proliferation, differentiation, myelination, apoptosis, axonal growth, and synaptic plasticity. In mammals, the neurotrophin family consists of nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3), and neurotrophin 4/5 (NT-4/5) (Snider 1994). With the exception of NT-4/5, which is not detected in avian species, the neurotrophin sequences are evolutionarily conserved in vertebrates. The *nt-6* and *nt-7* genes encode neurotrophins NT-6 and NT-7 and have been identified only in fish, and do not appear to have mammalian orthologs (Gotz et al. 1994; Nilsson et al. 1998).

The signal transduction pathways that mediate the diverse biological functions of the neurotrophins are initiated through interactions with two categories of cell surface receptors: the selective tropomyosin-related kinase (Trk) tyrosine kinase receptors and the "shared" p75 neurotrophin receptor (p75NTR). These two types of receptors share no sequence similarity in either ligand-binding or cytoplasmic domains, and activate distinct neurotrophin-dependent signaling pathways. In many instances, Trk receptors and p75NTR not only activate autonomous pathways but also collaborate to mediate effects of the neurotrophins. There are three Trk receptors: TrkA, TrkB, TrkC. The Trk receptor was originally discovered as a rearrangement of non-muscle tropomyosin and a then unknown tyrosine kinase. This tyrosine kinase was referred to as Trk and subsequently identified as a receptor for NGF. Trk became TrkA with the indentification of TrkB and TrkC which were based on their DNA sequence similarity to Trk (Hempstead et al. 1991; Klein et al. 1989, 1991; Lamballe et al. 1991). Each neurotrophin binds with high affinity to Trk receptors (Fig. 1): NGF to TrkA, BDNF to TrkB, NT-3 to TrkC. NT-4/5 binds TrkB, too. NT-3 also binds to TrkA and TrkB receptors that contain an additional short insert in the extracellular domain (Clary and Reichardt 1994; Strohmaier et al. 1996). The p75NTR belongs to the tumor necrosis factor (TNF) superfamily and was the first identified receptor for NGF (Chao et al. 1986; Radeke et al. 1987). All neurotrophins bind to the common p75NTR receptor with low affinity. Recently, pro-neurotrophins (the precursors of the neurotrophins: pro-NGF, pro-BDNF, pro-NT-3, pro-NT-4/5) have been identified as high-affinity ligands for p75NTR in complex with a co-receptor, sortilin (Lee et al. 2001; Nykjaer et al. 2004; Teng et al. 2005) (Fig. 1).

Disturbances in neurotrophins, their receptors, or neurotrophin/receptor-initiated signaling pathways have been associated not only with various neurodegenerative disorders (e.g., Alzheimer's disease, Parkinson's disease), but also to several types cancers of neuronal (e.g., neuroblastoma, medulloblastoma, gliomas) and nonneuronal origin (e.g., breast, lung, prostate cancers).

This chapter will describe neurotrophins, their receptors, and the signaling pathways initiated by binding of neurotrophins to Trk or p75NTR receptors. The expression of neurotrophins and/or their receptors in neuronal and nonneuronal cancers, as well as the potential to target these neurotrophins/receptors signaling pathways in the treatment of cancers, will be described.

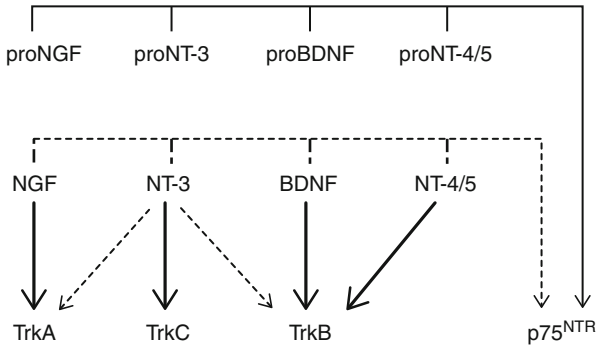

Fig. 1 Neurotrophins and their receptors: Neurotrophins preferentially bind to Trk receptors: NGF binds specifically to TrkA; BDNF and NT-4/5 recognize TrkB; NT-3 activates TrkC. NT-3 is also able to activate TrkA and TrkB with less efficiency. Neurotrophins bind p75NTR with equal affinity. Pro-neurotrophins bind p75NTR with high affinity

2 Neurotrophins

NGF was the first member of the neurotrophin family to be identified. NGF activity was initially observed in a mouse sarcoma that induced the dramatic growth of peripheral nerve fibers when transplanted into chick embryos. NGF was purified from mouse submandibular gland, which expressed extremely high levels of the factor. A dimer of 13.3 kDa polypeptides, termed the β subunit, was found to contain the biological activity of NGF. The β-NGF polypeptide chain is produced as a larger propeptide that is proteolytically cleaved to generate the mature form of a homodimeric polypeptide of about 26 kDa. A major biological function of NGF is the maintenance and survival of post-mitotic neurons; it is normally produced by the synaptic target field in limiting amounts to attract susceptible growth cones to functional site. NGF is a major player in the development of several peripheral nervous system subpopulations, as well as several central nervous system regions; as such, it has been considered a strong candidate for the treatment of several neurodegenerative conditions. In addition to its role in the maturation and maintenance or neuronal cells, NGF also has significant effects on nonneuronal cells. For example, it triggers chemotaxis in melanocytes, inhibits the migration of Schwann cells, has been reported to stimulate the proliferation of chromaffin cells, and is also an autocrine survival factor for B lymphocytes (Butte 2001; Reichardt 2006; Sofroniew et al. 2001; Wiesmann and de Vos 2001).

BDNF was the second neurotrophin to be discovered after its purification from pig brain in 1982. BDNF was produced initially as pro-BDNF (M.W. ~30 kDa), then cleaved to generate the mature form (M.W. ~14 kDa) which shared about 50 % amino acid identity with NGF. BDNF has survival- and growth-promoting actions on a variety of neurons, including dorsal root ganglion cells and hippocampal and cortical neurons. Certain peripheral sensory neurons, especially those in vestibular and nodose-petrosal ganglia, depend on

the presence of BDNF because BDNF homozygous (−/−) knockout mice lack these neurons. Unlike NGF, neither sympathetic or motor neurons are affected by BDNF. BDNF also plays a role in brain development and synaptic plasticity (Binder and Scharfman 2004; Reichardt 2006). As neural crest cells coalesce to form sympathetic ganglia, TrkB-positive cells are seen in both chicken and mouse embryos. The coexpression of TrkB and HNK-1 confirms that they are migrating neural crest cells. Subsequently, TrkB-positive cells begin to express the neural-specific markers Hu C/D and Islet-1, eventually commence neural differentiation (Straub et al. 2007).

NT-3 was identified using degenerate oligonucleotides to amplify by PCR novel cDNA sequences related to NGF and BDNF. The NT-3 cDNA encoded a mature polypeptide of predicted molecular weight 13.6 kDa. Recombinant NT-3 supports the survival of and neurite outgrowth from chick embryonic neurons, a result that established its neurotrophic activity. A PCR strategy similar to that used for NT-3 was used to identify a fourth mammalian neurotrophin, NT-4 (also known as NT-4/5), which was also shown to possess neurotrophic activity (Reichardt 2006).

3 Neurotrophin Receptors

3.1 Trk Receptors

Trk receptors are prototypical receptor tyrosine kinases that contain an extracellular domain, a transmembrane domain, and an intracellular domain. The extracellular domain is composed of a cysteine-rich domain followed by three leucine-rich domain, another cysteine-rich domain, and two immunoglobulin-like C2 type domains (Ig-C2). The cytoplasmic region contains a kinase domain (Fig. 2)(Brodeur et al. 2009; Gills and Dennis 2009; Reichardt 2006; Thiele et al. 2009). Binding of neurotrophins to Trk receptors occurs mainly through the Ig-C2 domains, with the domain closer to the transmembrane region playing a more prominent role in binding. The leucine-rich domains and the cysteine domains may also be involved in binding with neurotrophins. In addition to ligand binding, the Ig-C2 domains can also stabilize the monomeric form of the Trk receptor to prevent spontaneous dimerization and activation in the absence of neurotrophins. Deletions, chimeric receptors, or point mutations that disrupt the structure of the first or second Ig-C2 domain allow ligand-independent receptor activation. Differential splicing that leads to a loss of the first Ig-C2 domain of TrkA exhibits ligand-independent signaling and transformation activity when transfected into NIH-3T3 cells (Tacconelli et al. 2004).

The generation of alternatively spliced isoforms of Trk genes leads to functionally distinct receptors (Fig. 2). TrkA has three isoforms, TrkA-I, TrkA-II, and TrkA-III. TrkA-II is the isoform which is expressed in neuronal cells. TrkA-I is a nonneuronal TrkA isoform that lacks exon 9. Exon 9 encodes 6 amino acids in the extracellular domain near the transmembrane region (insertion) in TrkA and does not alter the reading frame. This does not affect NGF binding or receptor activation, but the TrkA-II isoform has enhanced responsiveness to NT3. TrkA

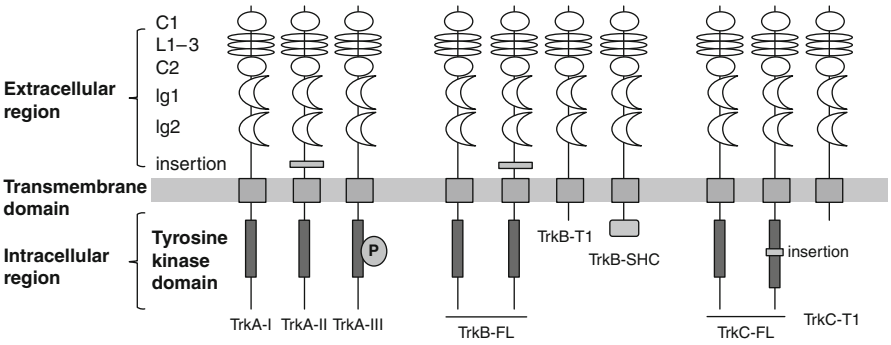

Fig. 2 Structures of the Trk receptors: The domain structures of the Trk receptors are schematized. Each Trk receptor has an extracellular domain, transmembrane domain, and an intracellular tyrosine kinase domain. The locations of two cysteine-rich domains (C1, C2), three leucine-rich domains (L1-3), and two immunoglobulin-like C2 type domains (Ig1, Ig2) in the extracellular domain of Trk receptors are depicted. There is an insert in the extracellular domain near the transmembrane region in TrkA or TrkB receptor. The insert of TrkC receptor is in the intracellular tyrosine kinase domain. Several truncated isoforms of TrkB and TrkC that lack the tyrosine kinase domain have been identified

isoforms lacking this sequence interact normally with NGF but show reduced NT-3 binding (Clary and Reichardt 1994). There is also an isoform, TrkA-III that is expressed early during development and splices out exons 6, 7, and 9. TrkA-III is constitutively active, independent of ligand (Tacconelli et al. 2004). Enhanced expression of TrkAIII occurs under hypoxia. TrkB is expressed as both full-length (kinase-intact) and truncated (kinase-deleted) isoforms. Full-length TrkB receptors have alternatively spliced product lacking 6–9 amino acids in the extracellular juxtamembrane region, like TrkA. TrkB variants lacking this region bind BDNF normally but show decreased affinity for NT-3 and NT-4/5. There are at least two kinase-deleted isoforms of TrkB that are truncated just beyond the transmembrane domain and differ by the absence (TrkB-T1) or presence (TrkB-SHC) of the SHC-binding site (Brodeur et al. 2009; Reichardt 2006; Thiele et al. 2009). Studies indicating that expression of truncated TrkB receptors inhibits BDNF induced neurite activity suggest that such isoforms may act as dominant-negative inhibitors of the TrkB kinase. This inhibition may occur by ligand sequestration or by formation of functionally inactive heterodimers. TrkC has full-length and truncated isoforms. Full-length TrkC receptors can be produced with amino acid inserts (14, 25, or 39 residues) in their kinase domain. Forms of TrkC containing insertions within the kinase domain retain their ability to autophosphorylate in response to neurotrophin-3, but cannot mediate proliferation in fibroblasts or neuronal differentiation in PC12 cells (Valenzuela et al. 1993). Truncated TrkC is the isoform without the intracellular kinase domain which may act as a dominant-negative inhibitor of kinase-intact TrkC. Thus, alternative splicing of the Trk receptors affects the specificity of neuronal responsiveness to neurotrophins.

3.2 p75NTR receptor

p75NTR is a 399-amino acid Type I transmembrane receptor which contains an extracellular, transmembrane, and intracellular domain. The extracellular domain contains four cysteine-rich domains (CR1-4). The intracellular domain contains a death domain which made it the first identified but last accepted member into the Death Receptor Family (TNF and TRAIL) (Fig. 3). Experimental and structural modeling studies have suggested that CR3 may be primarily responsible for interaction with neurotrophins (Yan and Chao 1991). p75NTR has both full-length and truncated isoforms. The p75ntr gene gives rise to a full-length receptor (p75NTR.FL) and an alternatively spliced isoform (p75NTR.T) lacking exon 3 (CR2-4). The full-length p75NTR receptor is also cleaved by a constitutively active metalloproteinase to generate a soluble extracellular domain that is capable of binding neurotrophins, and a receptor fragment containing transmembrane and intracellular domain (Fig. 3) (Zupan et al. 1989). The soluble form of p75NTR is produced at very high levels during development and following peripheral nerve injury, but the biological role(s) of the proteolytic products remain poorly defined (Zupan et al. 1989).

All neurotrophins bind to p75NTR receptor with similar affinity. The affinity of neurotrophins to TrkA and TrkB receptors is modulated by the presence of p75NTR, which enhances specificity for their primary ligands NGF and BDNF, respectively (Benedetti et al. 1993). Formation of high-affinity binding sites for NGF requires the presence of a correct ratio of full p75NTR and Trk receptors, as mutations of the cytoplasmic or transmembrane domains of either TrkA or p75NTR abolish the configuration of high-affinity binding sites. At the same time, p75NTR reduces the ability of NT-3 to activate TrkA, and NT-3 and NT-4 to activate TrkB.

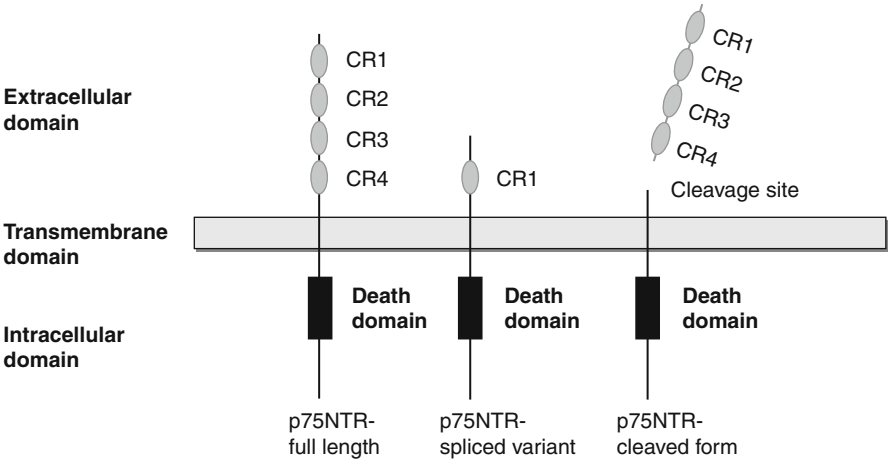

Fig. 3 Structure of p75NTR: p75NTR has an extracellular domain which consists of four cysteine-rich domain (CR1, CR2, CR3, CR4), a transmembrane domain, and an intracellular death domain. p75NTR has a spliced variant that lost the CR2 to CR4, and a cleaved form

This effect has been recently demonstrated in vivo in sympathetic neurons, where NT-3 can signal locally via TrkA receptors in the absence of p75NTR. Once axons reach their final target and receive NGF, TrkA retrograde signaling upregulates p75NTR, and the cells no longer respond to NT-3.

4 Neurotrophin Signaling Pathways

4.1 Neurotrophin Signaling Pathways Mediated by Trk Receptors

Binding of neurotrophin homodimers causes receptor dimerization, autophosphorylation on tyrosine (Y) residues within the activation loop (Y670, Y674, and Y675 relative to human TrkA), recruitment of different cytosolic adaptor proteins and enzymes which leads to the activation of several different signaling pathways. Among the signaling pathways activated by Trk receptors in response to neurotrophins, the Ras/mitogen-activated protein kinase (MAPK) pathway, phosphatidylinositol-3 kinase (PI3K) pathway, and PLCγ-protein kinase C (PLCγ) pathways are primarily studied (Fig. 4) (Kaplan and Miller 2000; Reichardt 2006). Most of the work describing these signaling pathways has been performed in PC12 cells, a rat adrenal pheochromocytoma cell line that responds to NGF and in many respects resembles sympathetic neurons. These signaling pathways have also been studied largely in the context of NGF activation of TrkA and extrapolated to the other Trk receptors.

4.1.1 Ras/MAPK Signaling Pathway

After binding to neurotrophins, Trk receptor tyrosine kinases are autophosphorylated and activated which recruits the adaptor protein Shc (Src-homology collagen protein) to phospho-Y490 on Trk receptors via interactions with the Shc PTB (phosphotyrosine binding) domain. Trk-mediated phosphorylation of Shc creates a phosphotyrosine site on Shc that recruits the adaptor Grb2 (growth factor receptor-bound protein 2), which is bound to the Ras exchange factor son of sevenless (SOS). These adaptors promote Ras activation which phosphorylates and activates Raf. Raf then phosphorylates and activates MEK (MAP kinase kinase), which in turn induces the phosphorylation and activation of ERK (extracellular signal-regulated kinase) (Fig. 4). Activated ERK translocates to the nucleus and transactivates transcription factors such as STAT1/3, Elk1, Myc, modulating gene expression to promote growth, differentiation, or development (Arevalo and Wu 2006; Reichardt 2006).

4.1.2 PI3K/Akt Pathway

PI3-kinases are activated through Ras-dependent and Ras-independent pathways, and the comparative importance of these two mechanisms differs in various subsets of neurons. In many neurons, Ras-mediated activation of PI3-kinase initiates the major pathways through which survival signals are conveyed. In addition, PI3-kinase can

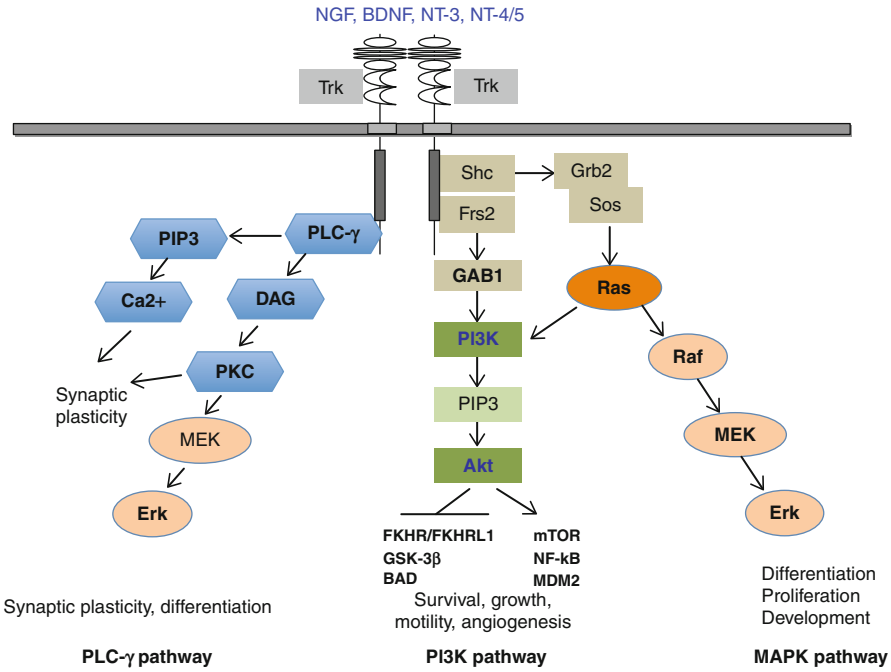

Fig. 4 Neurotrophin signaling pathways mediated by Trk receptors: Binding of neurotrophins to their Trk receptors leads to dimerization of the receptors, activation of tyrosine kinases, and the recruitment of different adaptors proteins and enzymes, resulting in activation of several signaling pathways, including Ras/MAPK pathway, PI3K/Akt pathway, and PLC-γ pathway. These signaling pathways are involved in the cell differentiation, proliferation, survival, motility, and synaptic plasticity

also be activated through Ras-independent pathways. Recruitment of Gab1 and Frs2 permits subsequent binding and activation of PI3K. Activated PI3-kinase generates phosphatidylinositol 3,4-bisphosphate (PIP2). PIP2 acts as a substrate to generate the second messenger phosphatidylinositol-3,4,5-triphosphate (PIP3), which recruits and binds AKT to the cell membrane via its pleckstrin homology domain. Akt is then phosphorylated and activated by PDK1 and PDK2. Phosphorylated Akt is translocated to the cytoplasm, nucleus, or mitochondria where it functions to phosphorylate downstream targets, leading to their activation or inactivation. Akt inactivates the FKHR/FKHRL1 (FOXO1) transcription factor, glycogen synthesis kinase (GSK-3β), and the Bcl-2 pro-apoptotic family member BAD known to play a pro-apoptotic role. Akt activates a number of proteins important for cell survival such as mTOR (mammalian target of rapamycin) which is important in protein synthesis, MDM2 which is an important negative regulator of the p53 tumor suppressor, and the transcription factor NF-κB (Fig. 4) (Arevalo and Wu 2006; Brodeur et al. 2009; Reichardt 2006; Thiele et al. 2009). Aside from a role in cell growth and survival, neurotrophin-mediated activation of the PI3K signaling pathway stimulates cell motility and increases production of VEGF. BDNF-mediated activation of TrkB in

cerebellar granule neurons, as well as NGF-mediated activation of TrkA in dorsal root ganglion neurons, stimulates an increased production of VEGF that are mediated by increases in HIF-α (Nakamura et al. 2011). Neurotrophin-stimulated increases in VEGF may mediate communication between the vasculature and neurons during development, cell stress, or hypoxia.

4.1.3 PLC-γ Pathway

Following Trk kinase activation, PLC-γ is recruited to a docking site surrounding phosphorylated Y785 on TrkA and to similar sites on TrkB and TrkC. Docked PLC-γ is activated through Trk-mediated phosphorylation and then hydrolyzes PIP2 to generate PIP3 and DAG. The presence of PIP3 results in Ca2+ release from cytoplasmic stores. DAG stimulates DAG-regulated isoforms of protein kinase C. Together, these signaling molecules activate a number of intracellular enzymes, including almost all PKC isoforms, Ca2+ -calmodulin-dependent protein kinases, and other Ca2+ -calmodulin-regulated targets. The proteins activated as a result of PLC-γ activation include PKC-δ, which is required for NGF-induced activation of MEK1 and Erk (Fig. 4). Signaling through this pathway controls expression and/or activity of many proteins, including ion channels and transcription factors (Arevalo and Wu 2006; Brodeur et al. 2009; Reichardt 2006; Thiele et al. 2009).

4.2 Neurotrophin Signaling Pathways Mediated by p75NTR Receptor

Binding of p75NTR to neurotrophins initiates opposing pathways, the pro-apoptotic signaling pathway and the pro-survival signaling pathway. The pro-survival effect of p75NTR/neurotrophins is mediated by the activation of the transcription factor, NF-κB (Karin and Lin 2002). The prototypic NF-κB molecule consists of a p65/p50 heterodimer, which is normally sequestered in the cytoplasm via binding to the inhibitory protein IκB. In response to neurotrophin binding to p75NTR, IκB is phosphorylated by the upstream IKK complex, leading to ubiquitination and degradation. Without the inhibition of IκB, NF-κB translocates into the nucleus where it regulates transcription of target genes (Fig. 5). Among the genes induced by NF-κB are several that promote survival, including members of the inhibitor of apoptosis family, IAP, and Bcl-2 homologs (Pahl 1999).

The pro-apoptotic effecter of activated neurotrophin/p75NTR is the JNK (c-Jun N-terminal kinase) signaling pathway. Activation of p75NTR induces activation of ASK1 and MEKK which in turn activates JNK. JNK either directly, or through the phosphorylation of c-jun, activates p53 which induces apoptosis by regulating its targets such as pro-apoptotic Bcl-2 family members Bax, Bad, Puma. In addition, activation of JNK induces expression of Fas ligand in neuronal cells, promoting apoptosis through activation of the Fas receptor (Fig. 5).

As mentioned early, p75NTR binds the unprocessed pro-neurotrophins with high affinity, stimulating an apoptotic signal. The pro-neurotrophins actually bind with high affinity to a complex of p75NTR with sortilin, a Vps10-domain

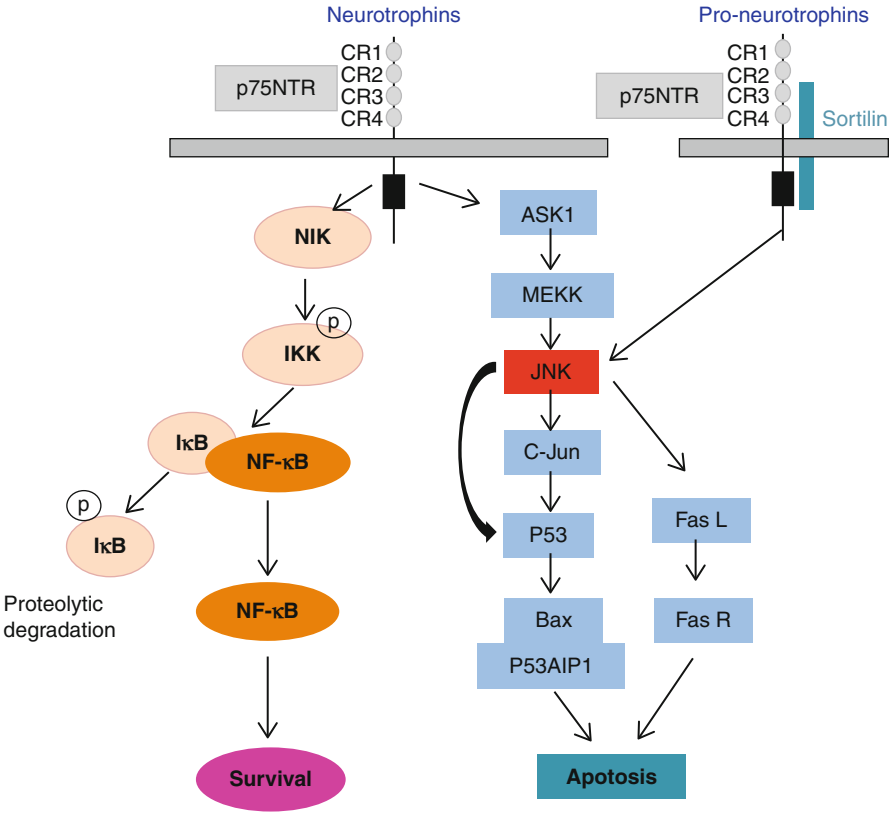

Fig. 5 Neurotrophin signaling pathways mediated by p75NTR receptor: Binding of neurotrophins to p75NTR either activates NF-κB signaling pathway to mediate cell survival, or activates JNK signaling pathway to induce cell apoptosis. Pro-neurotrophins bind to p75NTR to initiate cell apoptosis via the JNK signaling pathway

containing protein. Both sortilin and p75NTR participate directly in binding to the pro-neurotrophins. The presence of sortilin is required to generate apoptosis following engagement of p75NTR by the pro-neurotrophins. The JNK signaling pathway mediates the p75NTR/pro-neurotrophins-induced apoptosis.

5 Neurotrophins and Their Receptors in Cancers

5.1 Neurotrophins and Their Receptors in Neuronal Origin Cancers

Neuroblastoma is the most common extracranial solid tumor in children. It arises from neural crest precursor cells. The correlation between the expression levels of neurotrophins/neurotrophin receptors in tumors and the biological/clinical

characteristics of tumors has been extensively studied in neuroblastoma. The prognosis of neuroblastoma patients is varied. In some neuroblastoma patients, the tumors can regress or are very sensitive to the current cytotoxic regimens and they have a 90 % overall survival. In contrast, some neuroblastoma patients have tumors that are very resistant to chemotherapy, readily metastasize, and these patients have a poor prognosis. Differential Trk/neurotrophin expression has been used to correlate these clinical features.

TrkA (I, II) is expressed at high levels in biologically favorable neuroblastoma, and associated with favorable clinical features, so TrkA expression in tumors of neuroblastoma patients becomes a strong predictor of good prognosis (Nakagawara et al. 1993; Suzuki et al. 1993). Consistent with this observation, high TrkA expression in neuroblastoma cell lines is associated with decreased invasiveness, slow tumor cell growth, and low expression of angiogenic growth factors (Eggert et al. 2002; Lucarelli et al. 1997). Low-stage neuroblastomas usually express high TrkA and respond to NGF by enhanced survival and terminal differentiation (Nakagawara et al. 1993). TrkA expression is low or absent in most advanced stage tumors, and they do not undergo terminal differentiation in response to NGF, consistent with a model in which the NGF/TrkA pathway is responsible for differentiation and/or regression of favorable neuroblastoma. However, the recently identified isoform of TrkA (TrkA-III) was found to be more highly expressed in neuroblastoma tumors of patients with a poor prognosis (Tacconelli et al. 2004).

Most neuroblastomas express very low or undetectable levels of NGF. A limited amount of NGF may be supplied from the stromal-infiltrating cells such as schwannian cells and fibroblasts. One model posits that in regressing neuroblastoma, tumor cells expressing TrkA receptor are dependent on limiting amounts of NGF which would lead to differentiation in the presence of NGF or apoptosis in its absence. This model is based on the observation that normal developing sympathetic neurons survive and differentiate in the presence of target-derived supplement of neurotrophins or die in its absence (Nakagawara 1998a, b). Recently, a study found CCM2 as a key mediator of TrkA-dependent cell death. CCM2 is the protein product of the *cerebral cavernous malformation* 2 gene, it interacts with the juxtamembrane region of TrkA via its PTB (phosphotyrosine binding) domain. Coexpression with TrkA, CCM2 mediates TrkA-induced cell death, while CCM2 knockdown attenuates TrkA-dependent cell death. Furthermore, increased TrkA and CCM2 transcript expression correlates strikingly with positive clinical outcome in a large cohort of neuroblastoma patients (Harel et al. 2009).

Full-length TrkB and BDNF are expressed individually or co-expressed in more aggressive, unfavorable neuroblastoma (Nakagawara et al. 1994), Whereas truncated TrkB is expressed in more differentiated tumors, such as ganglioneuroblastoma. Addition of BDNF to the TrkB-expressing neuroblastoma cells enhanced the survival of cells exposed to serum-free media (Nakagawara et al. 1994), or chemotherapeutic drugs (etoposide, cisplatin, and vinblastin) (Jaboin et al. 2002; Scala et al. 1996). The survival of neuroblastoma tumor cells exposed to most chemotherapeutic drugs is mainly mediated by activation of the BDNF/TrkB

via activation of PI-3kinase/Akt and inactivation of GSK-3β(Jaboin et al. 2002; Li et al. 2005, 2007a). But for some chemotherapeutic drug (paclitaxel), the survival of neuroblastoma cells is mediated by activation of MAPK pathway and inhibition of Bim (Li et al. 2007b). Such studies also demonstrated that the effects of chemotherapeutic agents are attenuated even if a tumor cell with high levels of TrkB expression is in an environment with low levels of BDNF. More importantly, if tumor cells express low levels of TrkB receptor, and are in a BDNF-rich environment, the effects of cytotoxic agents were decreased (Jaboin et al. 2002). These findings indicate that sites of relatively high levels of TrkB ligands (BDNF and NT-4) may serve as sanctuary sites for TrkB-expressing tumor cells. BDNF also stimulates tumor cell disaggregation and increases the ability of TrkB-expressing neuroblastoma tumor cells to degrade and invade through extracellular matrix proteins. The BDNF/TrkB-mediated invasiveness in neuroblastoma cells may be due to upregulation of Hepatocyte Growth Factor (HGF), originally described as Scatter factor and its receptor, c-met. The siRNA-mediated silencing of c-met or antibodies to HGF diminishes BDNF/TrkB-induced invasiveness. Whether this is the generalized mechanism by which TrkB mediates motility/invasiveness awaits evaluation in other model systems. Additionally, BDNF activation of TrkB increases tumor cell production of VEGF and this is enhanced in hypoxic conditions (Nakamura et al. 2006). Thus, the expression of both BDNF and full-length TrkB may represent an autocrine or paracrine survival pathway that is important for the aggressive behavior of some neuroblastoma (Acheson et al. 1995).

TrkC was first reported to be expressed predominantly in biologically favorable neuroblastomas (Ryden et al. 1996). Full-length TrkC is expressed in about 25 % of primary neuroblastomas, and these tumors essentially represent a subset of the TrkA-expressing tumors (Svensson et al. 1997; Yamashiro et al. 1996). So TrkC expression in neuroblastoma has been associated with good prognosis. The TrkC ligand NT-3 is recently reported to be overexpressed in 38 % of stage 4 neuroblastoma and also in a fraction of neuroblastoma cell lines mainly derived from stage 4 neuroblastoma tumor materials. Tumors with high NT-3 levels showed a high NT-3/TrkC ratio (Bouzas-Rodriguez et al. 2010). This observation is consistent with the theories of TrkC being a dependence receptor, which can initiate two completely opposite signaling pathways, depending on ligand availability (Tauszig-Delamasure et al. 2007). In the presence of ligand, a positive differentiation, guidance, or survival signal is transduced, while in the absence of ligand, receptors mediate an active process of apoptotic cell death. TrkA may also function as a dependence receptor (Nikoletopoulou et al. 2010). So autocrine NT-3 expression in stage 4 neuroblastoma may be a mechanism developed by a large fraction of tumor cells to bypass TrkC-induced cell death that would occur in regions of limited NT-3 concentrations.

Medulloblastoma is a central nervous system tumor which arises from the external granule cell layer of the cerebellum. TrkC expression was detected in medulloblastoma, and elevated TrkC expression is associated with favorable clinical outcome (Segal et al. 1994). Studies show that overexpression of TrkC inhibits the growth of intracerebral xenografts of a medulloblastoma cell line in nude mice

(Muragaki et al. 1997). NT-3 mRNA was also detected in medulloblastoma specimens, and in vitro studies find that adding NT-3 to TrkC-expressing medulloblastoma cells induces apoptosis as well as activation of multiple parallel signaling pathways, like PI3K, ERK, JNK/SAPK, p38MAPK. Of these, p38MAPK activity appears necessary for NT-3-/TrkC-induced apoptosis, based on experiments using pharmacological inhibitors. BDNF and TrkB were also detected in some medulloblastoma specimens. Treatment with BDNF of TrkB-expressing medulloblastoma cells significantly inhibited the cell viability in vitro. Besides, NGF treatment of TrkA-expressing medulloblastoma cells results in massive apoptosis (Muragaki et al. 1997), and this NGF/TrkA-induced apoptosis is mediated through Ras/Raf signaling pathway. Thus, activation of the neurotrophin/Trk signaling pathways plays a pro-apoptotic role in medulloblastoma.

5.2 Neurotrophins and Their Receptors in Nonneuronal Origin Cancers

5.2.1 Colorectal Cancer

In colorectal cancer, BDNF and TrkB are overexpressed in the patients' tumors relative to levels in their adjacent normal tissues and this is more pronounced in advanced stages of colorectal cancer (Akil et al. 2011; Brunetto de Farias et al. 2010; Yu et al. 2010). In colorectal cancer cell lines, TrkB protein and BDNF mRNA expression are detected under basal (10 % serum) culture conditions, and BDNF mRNA levels and mature BDNF protein levels increase under stress condition (serum starvation) (Akil et al. 2011). Furthermore, in basal culture conditions, TrkB and BDNF have a cytosolic location in colorectal cell lines, but serum starvation induces a relocation of TrkB to the cell membrane and a colocalization of TrkB and BDNF on the membrane. BDNF induces cell proliferation and stimulates a TrkB-dependent anti-apoptotic effect under serum starvation condition. However, pro-BDNF, also detected in colorectal cancer cells, is co-expressed with p75NTR and sortillin at the cell membrane. In contrast to BDNF, exogenous pro-BDNF-induced colorectal cancer cell apoptosis, which suggests that a counterbalance mechanism is involved in the control of colorectal cancer cell survival (Akil et al. 2011). In human colorectal tumors, mutations in the TrkB kinase domain at two different sites (T695I, 751 N) have been found. The mutated TrkB displayed reduced activity compared to that of wild-type TrkB that indicated no gain-of-function of these mutations (Geiger et al. 2011). It is not known how these mutated TrkB receptors affect colorectal tumor cell biology. TrkA and TrkC were not detected in tumor tissues or in cell lines (Akil et al. 2011).

5.2.2 Breast Cancer

High levels of TrkA and phospho-TrkA are expressed in breast cancer tumors (compared to normal breast tissues) and in breast cancer cells (Davidson et al. 2004; Lagadec et al. 2009). Overexpression of TrkA induces constitutive activation of its tyrosine kinase activity. This promotes cell growth, migration, and

invasion in vitro via the activation of PI3K/Akt and MAPK signaling pathways which are required for the maintenance of a more aggressive cellular phenotype. TrkA overexpression enhances tumor growth, angiogenesis, and metastasis of breast cancer xenografts in immunodeficient mice (Lagadec et al. 2009).

NGF expression is detected in most breast tumors as well as in breast cancer cell lines, but no direct relationship between NGF overexpression and any known prognostic factor has been observed. Inhibition of NGF with neutralizing antibodies, or small interfering RNA, strongly reduces angiogenesis and tumor xenograft development in immunodeficient mice (Adriaenssens et al. 2008). Since NGF activation of TrkA has been shown to increase VEGF production by neuroblastoma tumor cells (Nakamura et al. 2011), it is possible that the decreased angiogenesis results from decreased tumor cell production of VEGF when NGF is inhibited. The mitogenic effect of NGF on breast cancer cells requires the tyrosine kinase activity of TrkA as well as the mitogen-activated protein kinase (MAPK) cascade, but is independent of p75NTR. In contrast, the anti-apoptotic effect of NGF is not dependent on TrkA but rather p75NTR and the activation of the transcription factor NF-κB (Descamps et al. 2001).

Truncated TrkB (TrkB.T1) and p75NTR, as well as BDNF and NT-4/5, are detected in breast cancer specimens and breast cancer cells. Full-length TrkB (TrkB.FL) has only rarely been reported (Vanhecke et al. 2011). Blocking endogenous NT-4/5 and BDNF using neutralizing anti-NT-4/5 or anti-BDNF antibodies inhibits the cell survival. Adding exogenous BDNF or NT-4/5 has an anti-apoptotic effect in breast cancer cells, but little effect on cell proliferation and invasion. Targeted decrease in p75NTR or TrkB-T1 using siRNAs abolishes the NT-4/5 and BDNF anti-apoptotic effect. Moreover, the Trk pharmacological inhibitor K252a has no impact on the BDNF- and NT-4/5-mediated survival, suggesting the involvement of p75NTR and TrkB-T1, and not Trk kinase activity. Treatment of mice bearing breast cancer xenografts with anti-BDNF, anti-NT-4/5, anti-p75NTR, or anti-TrkB-T1 inhibits tumor growth and this is accompanied by an increase in cell apoptosis and no changes in cell proliferation. A study showed that higher expression of BDNF is significantly associated with unfavorable pathologic parameters and poor prognosis (Patani et al. 2011). This indicates that an autocrine loop of BDNF and NT-4/5 stimulates breast cancer cell survival.

TrkC is also detected in breast cancers, and there is an inverse relationship between tumor grade and TrkC expression. The expression of TrkC is higher in Grade I tumors that have a good prognosis compared to that in Grade III tumors which have a poor prognosis. Rise in TrkC expression could indicate good prognosis (Blasco-Gutierrez et al. 2007).

5.2.3 Prostate Cancer

TrkA receptor is expressed in normal prostate, and expression is retained or significantly overexpressed in prostate cancer (MacGrogan et al. 1992; Mahadeo et al. 1994). TrkB and TrkC receptors are only expressed in malignant prostate cells. p75NTR is expressed in normal human prostate epithelial cells, and its expression is progressively lost during progression of prostate cancer. There is an

inverse relationship between low p75NTR expression and high prostate cancer growth and metastasis. So p75NTR may function as a prostate tumor-suppressor and metastasis-suppressor gene (Krygier and Djakiew 2002). TrkA activation increases cell proliferation, while p75NTR expression is associated with apoptosis. So an imbalance between p75NTR and TrkA-mediated signals may be involved in the progression of prostate cancer through increased proliferation and reduced apoptosis.

Human prostate is the second most abundant source of NGF after central nervous system. NGF is detected in prostate cancer specimens and cell lines. NGF secreted by the prostate stromal cells stimulates the growth of prostate cancer cells, and some specific prostate tumor cell lines secrete NGF in an autocrine manner (Djakiew 2000). Thus, NGF contributes to prostate cancer growth in both a paracrine and an autocrine manner.

5.2.4 Lung Cancer

Trk receptors but not p75NTR are readily detected in multiple types of human lung cancer (Koizumi et al. 1998; Ricci et al. 2001). High levels of TrkA are observed in adenocarcinomas and squamous cell carcinomas, while TrkB is detected primarily in small cell lung cancers (SCLC). Some tumors also express neurotrophin ligands. In particular, NGF is expressed in a high proportion of bronchioloalveolar and squamous cell carcinomas, while BDNF is expressed in SCLC. Approximately one third of bronchioloalveolar carcinomas express both NGF and TrkA, an observation that raises the possibility of autocrine effects of neurotrophins in this cancer type. Such autocrine loops may also exist as BDNF and TrkB expression is co-expressed in adenocarcinomas, squamous cell carcinomas, and small cell lung cancers. NT-3 and its corresponding TrkC receptor are found in a small number of squamous cell carcinomas (Ricci et al. 2001).

Studies with lung tumor cell lines indicate that NGF inhibits the growth of SCLC cells, and this is accompanied by an upregulation of TrkA, p75NTR, and NGF expression. NGF markedly inhibits cellular proliferation, colony formation, and invasiveness in vitro. NGF-treated cell lines do not form tumors in nude mice, whereas the untreated cell lines are highly tumorigenic. Administration of NGF to mice bearing established xenografts inhibits tumor growth.

In non-small cell lung cancers (NSCLC), TrkB enhances cell migration, invasion, and transformation (Harada et al. 2011), and a higher expression of TrkB in NSCLC primary tumors is closely correlated with lymph node metastasis (Zhang et al. 2010).

6 Clinical-Translational Advances

After the discovery of the involvement of neurotrophins and their receptors in the biological and clinical behaviors of cancers, it was appreciated that inhibition of neurotrophins, their receptors, or their targets might be beneficial in the clinical oncology setting. One well-studied strategy targets the Trk tyrosine kinase domain. Since there is a high degree of homology among Trk tyrosine kinase domains, there

are currently no inhibitors reported that selectively block TrkA or TrkB kinase activity. The earliest Trk inhibitors to reach clinical trials were Cephalon's CEP-751 and CEP-701 (lestaurtinib). These compounds were modeled on the indolocarbazole K252a from *Nocardiopsis* species and were relatively nonselective in inhibiting Trks, as well as Flt3, JAK2, and protein kinase C (PKC). CEP-751 and CEP-701 reduced tumor burden in xenograft models of prostate and pancreatic cancer, neuroblastoma, medulloblastoma, and medullary thyroid carcinoma (Camoratto et al. 1997; Evans et al. 1999, 2001; George et al. 1999; Miknyoczki et al. 1999). In prostate cancers, CEP-701 also inhibits the metastasis of both primary and metastatic sites of prostate cancer. A phase 1 study of CEP-701 established the maximum tolerated dose and identified that toxicities such as nausea, gastrointestinal events, and dyspepsia were relatively well tolerated (Marshall et al. 2005). Recently, a phase 1 study indicated that CEP-701 was well tolerated in patients with refractory neuroblastoma, and a dose level sufficient to inhibit TrkB activity was established (Minturn et al. 2011). CEP-701 phase 2 studies are in progress. Given the important role Trk signaling plays in normal neurons, it is encouraging that neural toxicity has not been a dose-limiting toxicity.

Another series of Trk inhibitors came from the optimization of 4-aminopyrazolylpyrimidines (AstraZeneca, Inc). One such compound, AZ-23, inhibits TrkA/B in the nanomolar range and has reasonable pharmacodynamics and oral bioavailability in toxicology studies. Phase 1 testing in adults was initiated but recently halted as a result of poor pharmacodynamic properties (Wang et al. 2008). Study on another compound named AZ623 showed that AZ623 inhibits BDNF-mediated signaling and neuroblastoma cell proliferation in vitro, as well as also inhibits the growth of human neuroblastoma xenograft tumors in vivo (Zage et al. 2011). Other congeners of 4-aminopyrazolylpyrimidines remain poised for clinical development.

Another strategy suggested by preclinical modeling is to use Trk kinase inhibitors in combination with standard chemotherapy. In a preclinical neuroblastoma xenograft model, CEP-701 (or the active precursor CEP-751) significantly enhanced the activity of cyclophosphamide, as well as other cytotoxic drug combinations currently used in the treatment of high-risk neuroblastoma (Evans et al. 1999). A clinical trial of CEP-701 with gemcitabine was undertaken assessing drug interactions in patients with advanced pancreatic cancer (Chan et al. 2008). The combination was well tolerated with no unexpected toxicities, but because the trial was limited and not designed to assess efficacy, further studies are planned. A study in a combination of AZ623 with topotecan, a topoisomerase inhibitor that is currently used for neuroblastoma treatment, indicated that a combination of AZ623 and topotecan has much higher effect on the inhibition of xenograft tumor growth compared to either individual agent, and inhibits the regrowth of tumors after cessation of the treatment where either individual agent alone is ineffective (Zage et al. 2011).

Additional therapeutic options to block the effects of activated Trk receptors can be developed by moving downstream and targeting the key intracellular mediators of activated Trk's pro-survival and prometastatic signals, PI3K and Akt. Pharmacologic inhibitors of these "nodal" kinases have been extensively pursued. Perifosine is an oral alkyl-phospholipid Akt inhibitor. Unlike most kinase

inhibitors, which target the adenosine triphosphate–binding region, perifosine targets the pleckstrin homology domain of Akt. Phase I and II clinical trials have indicated that the side effect of perifosine is limited to dose-limiting gastrointestinal toxicity, such as nausea, diarrhea, fatigue, and dehydration, which can be ameliorated with the use of prophylactic medicine and well tolerated (Gills and Dennis 2009). As Akt is a key downstream target in PI3K pathway initiated by many growth factors and their receptors, including neurotrophins/Trk, perifosine as an Akt inhibitor has been evaluated in many types of tumors with elevated activity of Akt, and has showed antitumor growth effect either alone or in combination with chemotherapeutic drugs/other small molecular inhibitors. The role of perifosine in tumors with BDNF/TrkB-initiating activation of Akt has been evaluated in neuroblastoma. Perifosine alone inhibits tumor growth, but is most effective in combination with cytotoxic drugs such as etoposide. Combinations of Akt inhibition and etoposide cause tumor regression of TrkB-expressing neuroblastoma tumor xenografts (Li et al. 2011). Strategies targeting Akt may offer a broader spectrum of inhibitory activity than Trk kinase–targeted agents and may avoid resistance due to feedback suppression that has been seen when targeting some receptors.

7 Conclusion

Neurotrophins and their receptors were originally found to play important roles in the survival, proliferation, differentiation, apoptosis, and synaptic plasticity of neurons, with aberrant expression being associated with neurodegenerative diseases. However, increasingly studies have indicated that the neurotrophin/neurotrophin receptors play an important role during the genesis of tumors where oncogenic events may subvert the normal functions of neurotrophins and their receptors and influence biologic features of tumors that may impact tumor cell aggressiveness. Neurotrophins activate different signaling pathways based on binding to their Trk receptors or p75NTR receptor, and they may exert pro- or anti-tumorigenic activity, depending on the activation status of other cellular receptors and the presence or absence of ligands in the environment. For most types of cancers, expression of TrkA or TrkC in tumor tissues is associated with good prognosis, such as neuroblastoma, medulloblastoma, lung cancer; expression of TrkB and/or its ligand BDNF is associated with poor prognosis, such as neuroblastoma and colorectal cancer. One exception is breast cancer where overexpression of TrkA and NGF in breast cancer cells stimulates cell proliferation and invasion but not cell differentiation or apoptosis. These findings provide support for the development of small molecular inhibitors that target on Trk or the downstream targets in the neurotrophin/neurotrophin receptor-initiating signaling pathways in the treatment of cancers. The preclinical and clinical evidence of efficacy as a single agent or in combination with chemotherapy, as well as the well-tolerated limited toxicities, suggests the usage of these small molecular inhibitors as a potential strategy for the treatment of cancers.

NGF and Immune Regulation

Luisa Bracci-Laudiero and Luigi Manni

Contents

Abstract

For some time after its discovery, the action of nerve growth factor (NGF) was considered restricted to the nervous system. Instead, a variety of experimental data indicate that NGF can influence the activity of both the nervous and immune systems. This should not be surprising since these two systems are responsible both for maintaining homeostasis and for adapting the body to the environment. To orchestrate strictly integrated responses, they need to have close anatomical connections and to share common chemical signals and specific receptors. The well-known effects of NGF on peripheral neuron survival and maintenance and dynamic control by NGF of innervation and neuropeptide synthesis, together with its direct effects on immune cell functions, indicate that NGF has a key role in the complex network of bidirectional signals between the nervous and immune systems. NGF receptors are expressed in immune organs and cell populations, allowing NGF to modulate cell differentiation and regulate immune response. NGF concentrations in tissues change during inflammation, and inflammatory mediators induce NGF

synthesis in a variety of cell types. As a growing number of studies have shown, an enhanced production of NGF characterizes inflamed tissues of patients with inflammatory and autoimmune diseases. Unfortunately, although the dynamic regulation of NGF synthesis seems to be a common feature of chronic inflammatory diseases, the reasons why NGF concentrations are enhanced and how this can affect inflammatory responses and the course of the diseases are far from being understood.

List of Abbreviations

BBB	Blood–brain barrier
CGRP	Calcitonin gene-related peptide
CHS	Contact hypersensitivity
CIPA	Congenital insensitivity to pain with anhidrosis
CNS	Central nervous system
COX2	Cyclooxygenase 2
CSF	Cerebrospinal fluid
DRG	Dorsal root ganglion
EAE	Experimental autoimmune encephalomyelitis
Gal	Galanin
GM-CSF	Granulocyte-macrophage colony-stimulating factor
IFN	Interferon
IL	Interleukin
LPS	Lipopolysaccharide
MAPK	Mitogen-activated protein kinase
MPB	Myelin basic protein
NGF	Nerve growth factor
NO	Nitric oxide
NPY	Neuropeptide Y
NT	Neurotrophin
NTR	Neurotrophin receptor
PI3K	Phosphatidylinositol 3-kinase
PNS	Peripheral nervous system
SP	Substance P
TH	Tyrosine hydroxylase
TNF	Tumor necrosis factor
TrkA	Tropomyosin kinase receptor A
UV	Ultraviolet
VIP	Vasoactive intestinal peptide

1 Introduction

The neurotrophin (NT) family of proteins is responsible for the growth and survival of neurons during development and for the maintenance and function of adult neurons (Rush et al. 1997; Ernfors 2001; McAllister 2001; Poo 2001). NTs also promote

regeneration of damaged axons after various peripheral and central nervous system injuries (Olson 1993; Connor and Dragunow 1998; Terenghi 1999; Chao et al. 2006).

Nerve growth factor (NGF) was the first NT to be discovered (Levi-Montalcini 1987). It is essential for the development and maintenance of neurons in the peripheral nervous system (PNS) and for the functional integrity of cholinergic neurons in the central nervous system (CNS) (Whittemore et al. 1987). For over 35 years, NGF has been considered a very powerful and selective growth factor for sympathetic and sensory neurons and for cells derived from the neuronal crest (Alleva et al. 1993; Rush et al. 1997; Cowan 2001). In the CNS, the phenotypic maintenance of cholinergic neurons is dependent on NGF, which is produced mainly in the cortex, the hippocampus, and the pituitary gland, although significant quantities of this NT are also produced in other brain areas, including the basal ganglia, thalamus, hypothalamus, and spinal cord, and in the retina (McAllister 2001).

NGF exerts its biological action by challenging the specific receptor tropomyosin kinase receptor A (TrkA), a typical tyrosine kinase receptor (Huang and Reichardt 2003). The major cytosolic/endosomal pathways activated by TrkA are Ras-mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase (ERK), phosphatidylinositol 3-kinase (PI3K)-Akt, and PLC-γ (Klesse and Parada 1999; Chao et al. 2006; Reichardt 2006). NGF also binds to and activates the nonselective p75 pan-neurotrophin receptor ($p75^{NTR}$). This receptor is a transmembrane glycoprotein that regulates signaling through TrkA (Friedman and Greene 1999; Schor 2005; Reichardt 2006); the binding of NGF to $p75^{NTR}$ activates additional signaling pathways that, in the absence of co-expressed TrkA, may signal cell death via apoptosis (Friedman and Greene 1999; Miller and Kaplan 2001; Schor 2005). Signaling pathways activated by $p75^{NTR}$ are the Jun kinase signaling cascade, NF-κB, and ceramide generation (Reichardt 2006).

The pioneering studies of Levi-Montalcini showed that, during development, limited amounts of NGF produced in target organs are responsible for the proliferation, differentiation, and survival of peripheral autonomic and sensory neurons (Levi-Montalcini 1987). Moreover, neutralizing endogenous NGF with anti-NGF antibodies during fetal life causes permanent damage to the sympathetic ganglia and a marked decrease in sensory neuron numbers (Levi-Montalcini 1987). In adult life, while sympathetic neurons continue to depend on NGF for their survival (Ruit et al. 1990), there is a change in the role of NGF in the sensory neurons. NGF is no longer essential for their survival but remains crucial for the maintenance of a differentiated phenotype (McMahon et al. 1995; Verge et al. 1995). In these mature sensory neurons, as well as in sympathetic neurons, NGF dynamically controls neurotransmitter and neuropeptide synthesis. In sympathetic neurons, the levels of norepinephrine are regulated by NGF through the selective induction of tyrosine hydroxylase (TH) (Otten et al. 1977). In dorsal root ganglia (DRG), the expression of neuropeptides such as substance P (SP) and calcitonin gene-related peptide (CGRP) in primary sensory neurons is under NGF control (Lindsay and Harmar 1989), and in vivo deprivation of NGF, following nerve transection or anti-NGF treatment, causes a marked decrease in SP and CGRP synthesis (Verge et al. 1995).

The NGF supplied from the innervation field influences the neuronal plasticity that allows the adult nervous system to modify its structure and functions in response to stimuli. Indeed, the constitutive synthesis of NGF in adult tissues correlates with the phenotypic features of PNS neurons, such as innervation density, cell body size, axonal terminal sprouting, dendritic arborization, and induction or inhibition of neuropeptides and neurotransmitters or transmitter-producing enzymes (Otten et al. 1977; Lindsay and Harmar 1989; Mearow and Kril 1995; Verge et al. 1995).

The spectrum of NGF action was once considered limited to functions related to specific CNS and PNS neuronal classes; however, more recent studies have revealed that the effects of NGF also extend to several kinds of nonneuronal cells. Indeed, NGF can influence the functioning of the immune-hematopoietic system (Aloe et al. 1997a; Bonini et al. 1999; Aloe 2001) and the neuro-endocrine system (Aloe et al. 1997a). Thus, the current view is that *NGF can affect the maintenance of a balanced interplay between the nervous*, *endocrine*, *and immune systems* (Alleva et al. 1993; Aloe et al. 1999, 2002) (Fig. 1).

2 NGF and the Immune System

2.1 NGF Influences Development and Differentiation of the Immune System

The release of neuropeptides from sensory nerve endings or of neurotransmitters from autonomic terminals represents a direct means for the nervous system to regulate immune response. Indeed, neurotransmitters and/or neuropeptide receptors are expressed by immune organs and cells, and their challenge has immune-modulatory value (Elenkov 2008; Tausk et al. 2008). NGF regulates neuropeptides and neurotransmitters in peripheral neurons by acting on their promoters or on neurotransmitter-producing enzymes (Otten et al. 1977; Lindsay and Harmar 1989; Verge et al. 1995). Thus, a possible mechanism by which NGF can affect the immune response is through the regulation of neurotransmitter and neuropeptide production. But NGF can also influence immune cell functions directly, as both NGF and NGF receptors are expressed in lymphoid organs and in purified immune cell populations. The expression of NGF receptors has been found in primary (thymus, bursa of Fabricius, bone marrow) and secondary (spleen, tonsils, lymph nodes) lymphoid organs (Laurenzi et al. 1994; Ciriaco et al. 1996; Garcia-Suarez et al. 2001), being raised during lymphocyte precursor migration but declining during postnatal life. NGF is produced in primary lymphoid organs (Laurenzi et al. 1994; Aloe et al. 1997b), and it is possible that localized synthesis of NGF may contribute to create the microenvironment for the differentiation of hematopoietic stem cells (Pezzati et al. 1992; Cattoretti et al. 1993). In vitro NGF stimulates the functional activity of thymic epithelial cells, inducing the expression of adhesion molecules important for thymocyte-thymic epithelia interaction, and upregulates the expression of thymopoietic factors such as IL-7, granulocyte-macrophage colony-stimulating factor (GM-CSF), and stromal cell-derived

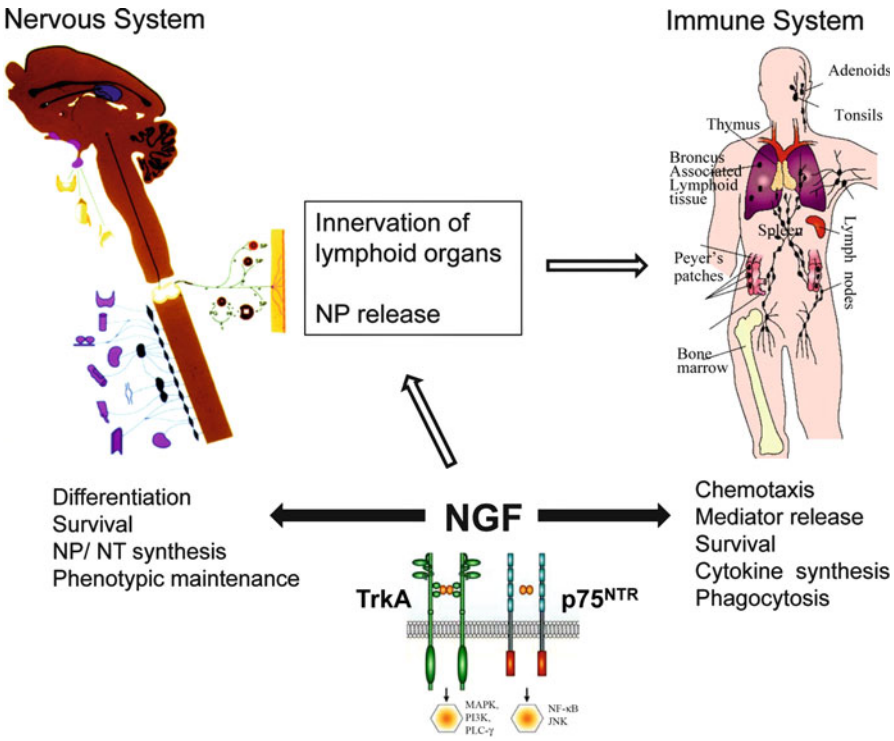

Fig. 1 *Nervous-immune systems interplay*. The NGF is at the interface of the nervous and immune system interactions. By activation of the specific TrkA receptor and/or the pan-neurotrophin p75 receptor, it acts on nervous system (*left side*) regulating survival, differentiation, and phenotypic features such as the synthesis of neurotransmitters and neuropeptides or the shape of cells and terminals. NGF influences immune system development and activity directly, by challenging NGF receptors expressed on the surface of immune cells. NGF also indirectly modulates immune system functions by regulation of the activity of nerve terminals innervating lymphoid organs and of the synthesis and release of neurotransmitters and neuropeptides that in turn activate specific receptors expressed by immune cells/organs. Abbreviations: *NP* neuropeptides, *NT* neurotransmitters, *TrkA* tyrosine kinase A receptor, $p75^{NTR}$ p75 neurotrophin receptor

factor-1 (Lee et al. 2008). TrkA expression has been described in hematopoietic precursors (Chevalier et al. 1994) and NGF functions as a survival factor (Bracci-Laudiero et al. 1993b; Auffray et al. 1996) and a colony-stimulating factor (Matsuda et al. 1988, 1991; Welker et al. 2000) for myeloid progenitors. Human CD34+ hematopoietic stem cells are characterized by the concomitant expression of TrkA and production of their own NGF, which is maintained during lineage differentiation but declines with the acquisition of a mature phenotype (Bracci-Laudiero et al. 2003). Moreover, the changes in TrkA expression observed in immature cord blood cells and mature immune cells may indicate a different requirement for NGF in these cells that depends on the state of maturity and functional activity of the immune cell (Bracci-Laudiero et al. 2003) (Fig. 2).

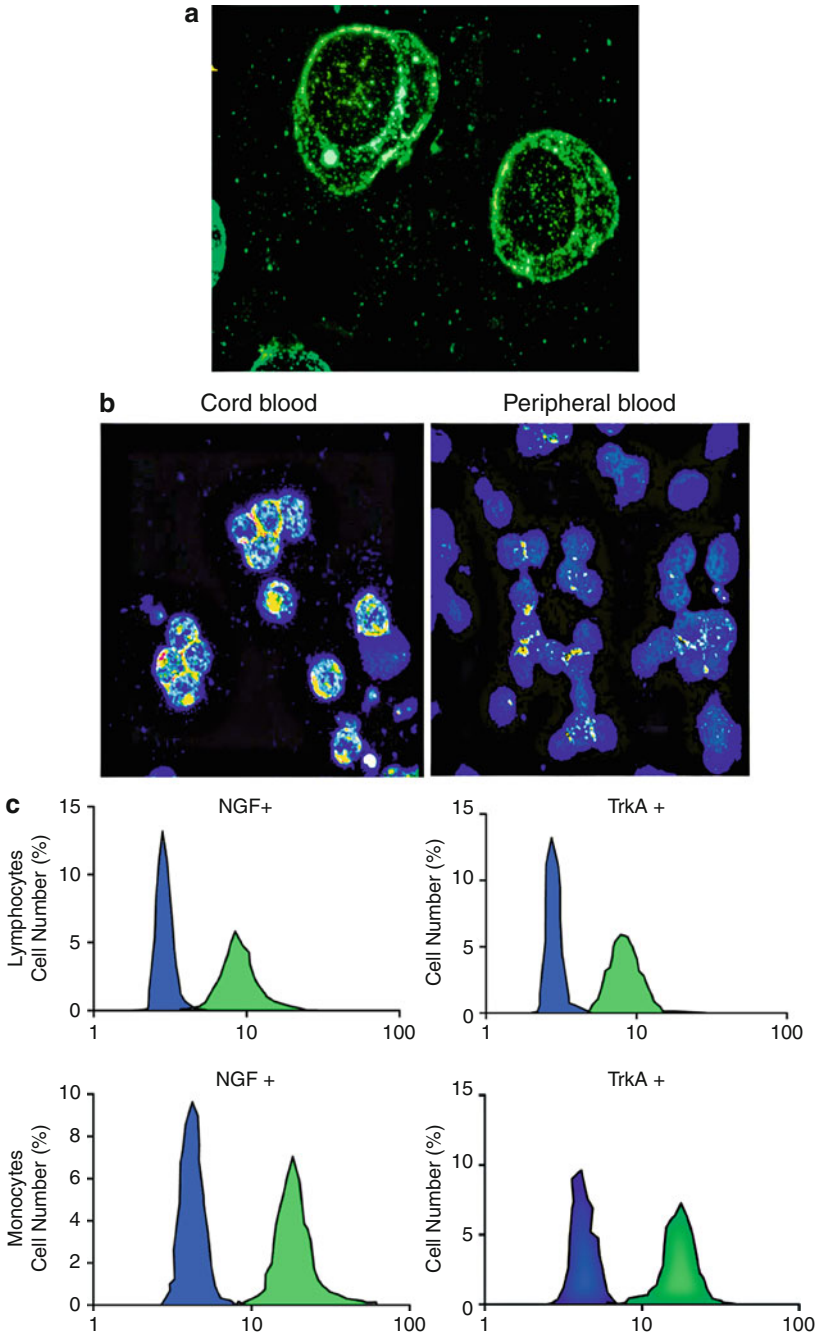

Fig. 2 (continued)

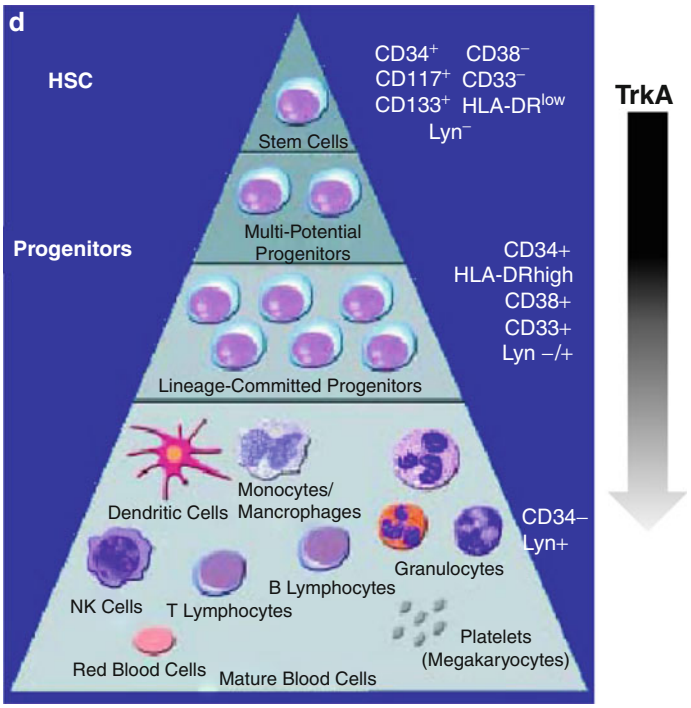

Fig. 2 *NGF influences the differentiation of hemopoietic stem cell*. TrkA (**a**) and NGF (**b**) expression is detected by immunofluorescence in CD34+ stem cells purified from human umbilical cord blood (HCB). Flow cytometry analysis (**c**) reveals that NGF and TrkA are co-expressed in the lymphocytic and monocytic components of HCB. As a clue of the importance of NGF in the development of immune cell lineage, the expression of TrkA is decreasing on immune cell surface as they become more differentiated (**d**)

2.2 NGF and Immune Cells

NGF receptor expression has been studied in purified immune cell populations. TrkA expression has been demonstrated in mononuclear cells (Thorpe et al. 1987a), thymocytes (Laurenzi et al. 1994), human B and T lymphocytes (Brodie and Gelfand 1992; Ehrhard et al. 1993; Torcia et al. 1996; Lambiase et al. 1997), monocytes (Ehrhard et al. 1993; Caroleo et al. 2001), mast cells (Nilsson et al. 1997), basophils (Burgi et al. 1996), and eosinophils (Noga et al. 2002). These cells have a basal expression of TrkA in the resting condition and upregulate it after antigenic or mitogenic stimulation, when functional activation is necessary (Ehrhard et al. 1993a, b; Torcia et al. 1996; Lambiase et al. 1997; Caroleo et al. 2001). The evidence that almost all immune cells express NGF receptors provided great impulse to studies on the influence of NGF on immune functions. The study demonstrating that the injection of NGF in newborn rats caused an increase in the number and size of mast cells (Aloe and Levi-Montalcini 1977) was the earliest

evidence of an effect of NGF on immune cells and outside the nervous system. After this, numerous studies have shown that NGF is able to exert a wide spectrum of effects on immune cells (Table 1). One of the effects of NGF that emerges as common to the greater part of cell populations analyzed is its dose-dependent influence on the survival of hematopoietic stem cells and mature, differentiated immune cells (Auffray et al. 1996; Bullock and Johnson 1996; Torcia et al. 1996; Bracci-Laudiero et al. 2003). The viability-sustaining activity of NGF has been attributed to its effect on the induction of anti-apoptotic proteins such as Bcl-2 (Bullock and Johnson 1996).

2.2.1 Granulocytes and Mast Cells

In general, in vitro studies of granulocytes and mast cells have shown that *NGF can potentiate their responses to inflammatory stimuli*, but its effects differ depending on the cell type analyzed. In activated basophils, NGF enhances the synthesis of lipid mediators (leukotrienes) in response to inflammatory stimuli (Bischoff and Dahinden 1992; Takafuji et al. 1992) and, together with IL-3 and IL-33, acts as cofactor to induce the release of histamine and enhance the response to IgE in both basophils and mast cells (Mazurek et al. 1986; Horigome et al. 1993; Sin et al. 2001; Gibbs et al. 2005). In contrast to its effect on basophils, NGF tends to suppress leukotriene formation in eosinophils (Takafuji et al. 1992). However, NGF seems to stimulate the production of IL-4 (Noga et al. 2002); it influences the release of peroxidase in eosinophils and enhances cytotoxic activity (Hamada et al. 1996). It also enhances, in a dose-dependent way, the survival of eosinophils (Hamada et al. 1996) and neutrophils (Kannan et al. 1991) by suppressing apoptosis, an effect abolished by anti-NGF antibody treatment. In neutrophils, in addition to its survival effect, NGF enhances superoxide production after cell activation with zymosan and stimulates phagocytosis (Kannan et al. 1991).

As for granulocytes, a pro-survival effect of NGF has also been demonstrated in mast cells (Kawamoto et al. 1995; Bullock and Johnson 1996). NGF also influences mast cell activation in various stages of cell differentiation: it causes a dose-dependent upregulation of tryptase and IgE receptors in immature mast cells (Welker et al. 1998), while the addition of NGF after stimulation of mature mast cells with lysophosphatidylserine induces and enhances cyclooxygenase2 (COX2) expression and the generation of prostaglandin D2 (Murakami et al. 1997).

Several studies have shown that NGF is a chemoattractant factor for both granulocytes (Gee et al. 1983; Boyle et al. 1985) and mast cells (Sawada et al. 2000). The migration of eosinophils towards the site of inflammation in the airways is influenced by the presence of NGF, and this effect seems to be regulated by neuropeptides (Quarcoo et al. 2004). Circulating neutrophils also seem to be involved in NGF-induced hyperalgesia in the skin of rat paw (Bennett et al. 1998). Indeed, local administration of NGF in rat skin induced hyperalgesia and neutrophil accumulation, an effect that appears to be mediated by the induction by NGF of adhesion molecules (i.e., ICAM-1) in endothelial cells (Foster et al. 2003). The use of anti-ICAM-1 antibodies blocked neutrophil accumulation in

Table 1 Summary of main effects of NGF on immune cells

	Cell type	NGF-/TrkA-regulated functions	References
	Hematopoietic stem cell	Survival, differentiation	Matsuda et al. (1991), Bischoff and Dahinden (1992), Takafuji et al. (1992), Cattoretti et al. (1993), Chevalier et al. (1994), Auffray et al. (1996), Bracci-Laudiero et al. (2003), Sato et al. (2004)
	Eosinophils	Differentiation, mediator release	Takafuji et al. (1992), Hamada et al. (1996), Noga et al. (2002), Quarcoo et al. (2004)
	Basophils	Differentiation, mediator release	Bischoff and Dahinden (1992), Takafuji et al. (1992), Burgi et al. (1996), Sin et al. (2001), Gibbs et al. (2005)
	Neutrophils	Chemotaxis, phagocytosis, mediator release, survival	Gee et al. (1983), Boyle et al. (1985), Kannan et al. (1991), Bennett et al. (1998), Beigelman et al. (2009)
	Mast cells	Degranulation, mediator release, survival	Mazurek et al. (1986), Matsuda et al. (1991), Kawamoto et al. (1995), Lambiase et al. (1995), Bullock and Johnson (1996), Lowe et al. (1997), Murakami et al. (1997), Nilsson et al. (1997), Welker et al. (1998), di Mola et al. (2000), Sawada et al. (2000), Welker et al. (2000), Xiang and Nilsson (2000), Stanzel et al. (2008)
	B lymphocytes	Proliferation, differentiation, IgG synthesis, survival, CGRP synthesis	Otten et al. (1989), Kimata et al. (1991), Brodie and Gelfand (1992), Franklin et al. (1995), Brodie et al. (1996), Melamed et al. (1996), Torcia et al. (1996), Bracci-Laudiero et al. (2002), Coppola et al. (2004), Sato et al. (2004), Abram et al. (2009)
	T lymphocytes	Proliferation, NPY synthesis	Thorpe et al. (1987b), Ehrhard et al. (1993), Bracci-Laudiero et al. (1996a), Lambiase et al. (1997)
	Monocytes	Oxidative burst, cytokine release, survival, CGRP release	Ehrhard et al. (1993), Susaki et al. (1996), la Sala et al. (2000), Barouch et al. (2001), Caroleo et al. (2001), Bracci-Laudiero et al. (2002), Bracci-Laudiero et al. (2005), Noga et al. (2007), Samah et al. (2009), Ma et al. (2010)

NGF-treated skin, suggesting that NGF has primarily an activating effect on endothelial cells, resulting in the accumulation of neutrophils (Foster et al. 2003). Abnormally decreased migration of neutrophils has been reported in patients with congenital insensitivity to pain with anhidrosis (CIPA), a rare genetic disease characterized by mutation of the TrkA gene (Beigelman et al. 2009). All these data suggest that the presence of *NGF is pivotal to cell recruitment at the inflammation site*, though the mechanisms and mediators involved still remain to be clarified.

2.2.2 B and T Lymphocytes

Experimental evidence produced in the 1980s indicated that NGF receptors are expressed on lymphocytes and that NGF is able to potentiate the proliferative response of B- and T-cells to mitogens (Thorpe and Perez-Polo 1987; Thorpe et al. 1987a, b). The addition of NGF to culture media induces interleukin-2 receptors in mature lymphoid cells, and the proliferative response is augmented in B-cells when NGF is added together with IL-2 (Brodie and Gelfand 1992). Although CD4+ lymphocytes also express TrkA receptors (Ehrhard et al. 1993a), few data on these cells are available, while more numerous studies have focused on B lymphocytes. B-cells express TrkA (Torcia et al. 1996), and the binding of NGF to this receptor activates intracellular pathways and nuclear factors in a manner similar to that described in neurons (Franklin et al. 1995; Melamed et al. 1996). Abolition of TrkA function in knockout mice models (Coppola et al. 2004) or in CIPA patients (Sato et al. 2004) results in altered differentiation and survival of B lymphocytes. Moreover, NGF can influence the production of IgM and IgG (especially IgG4) (Otten et al. 1989; Kimata et al. 1991). Overall these results support the conclusion that *NGF stimulates B-cell immune responses*.

However, other reports describe evident contradictions to those cited above, with findings showing that NGF is a survival factor for memory B-cells (Torcia et al. 1996), promotes the differentiation of B-cells into immunoglobulin-secreting plasma cells (Otten et al. 1989), and influences plasma cell survival (Abram et al. 2009). Activation of B-cells with anti-CD40 plus NGF decreases instead of increasing immunoglobulin secretion in a dose-dependent manner (Brodie and Gelfand 1994; Brodie et al. 1996). Moreover, the finding that TrkA knockout mice have increased IgM, IgG1, and IgG2 levels (Coppola et al. 2004) suggests that a clear understanding of the physiological effects of NGF on B-cells is still lacking.

2.2.3 Monocytes/Macrophages and Dendritic Cells

Monocytes and macrophages express TrkA and $p75^{NTR}$, while differentiated dendritic cells lose TrkA and maintain $p75^{NTR}$ expression only (Ehrhard et al. 1993b; la Sala et al. 2000; Caroleo et al. 2001). Inflammatory stimuli enhance (Ehrhard et al. 1993b; Caroleo et al. 2001) or induce a reexpression (Noga et al. 2007) of TrkA in all these cells. NGF protects monocytes from apoptosis

induced by UVB radiation or gliotoxin, regulating the expression of anti-apoptotic proteins Bcl-2, Bcl-xl, and Bfl-1 (la Sala et al. 2000). In vitro migratory properties are also affected by NGF, which increases CXCR4 expression and chemotactic response to suboptimal CXCL-12 concentrations in macrophages (Samah et al. 2009). Inflammatory macrophages isolated from the peritoneum after stimulation and then treated with NGF show increased phagocytosis, enhanced parasite-killing activity, and increased production of IL-1beta (Susaki et al. 1996). NGF can also induce TNF-alpha secretion and increase nitric oxide (NO) production in macrophages, this latter effect being strongly amplified by pretreatment with interferon-gamma (Barouch et al. 2001). NGF promotes LPS-induced maturation and secretion of inflammatory cytokines in dendritic cells (Noga et al. 2007). Dendritic cells derived from allergic donors and stimulated with LPS and CD40 ligand increase IL-6 production when challenged with NGF, while the effect of NGF on dendritic cells generated from healthy donors is to induce more IL-10 production (Noga et al. 2007). Consistent with this finding is the fact that NGF deprivation in LPS-treated monocytes results in a significant decrease in IL-10 synthesis (Bracci-Laudiero et al. 2005).

2.3 NGF Induces Neuropeptide Production in Immune Cells

Besides its ability to induce inflammatory mediators and cytokines, NGF can also modulate immune response by regulating the synthesis of neuropeptides in immune cells. Similarly to its effect on neuronal cells, NGF induces NPY expression in T lymphocytes (Bracci-Laudiero et al. 1996a) and regulates the expression and release of CGRP in human B lymphocytes (Bracci-Laudiero et al. 2002) and monocytes (Bracci-Laudiero et al. 2005; Ma et al. 2010) and macrophages. By inducing CGRP and IL-10 production, NGF can reduce the antigen-presenting capacity and co-stimulatory function of monocytes and may contribute to the downregulation of T-cell responses. Indeed, using CGRP receptor antagonists in LPS-treated monocytes, the expression of membrane molecules involved in antigen presentation, such as HLA-DR and CD86, is increased (Bracci-Laudiero et al. 2005). These data suggest that at least some of the NGF effects described to date are not directly dependent on NGF itself but rather are regulated by intermediate mediators whose synthesis is under NGF control. Neuropeptides, such as SP, CGRP, NPY, and VIP, have all been indicated as possible mediators of NGF effects on immune system response, in regulating inflammatory and anti-inflammatory responses and in maintaining homeostasis (Brain 1997; Delgado et al. 2004; O'Connor et al. 2004; Prod'homme et al. 2006). The point that deserves underlining is that *NGF can act on immune cells*, *stimulating neuropeptide synthesis in both the neuronal and immune systems* (Fig. 3).

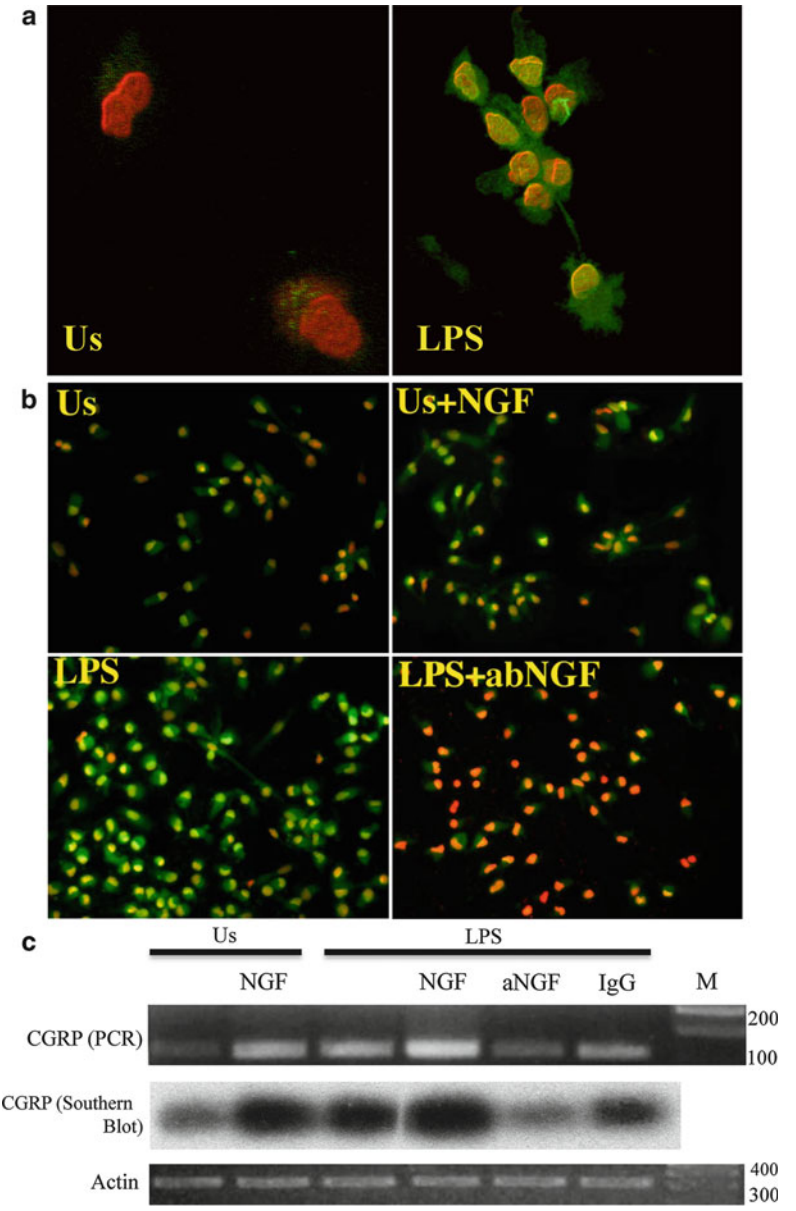

Fig. 3 *NGF induces CGRP in cultured macrophages*. Purified macrophages express calcitonin gene-related peptide (CGRP), as revealed by green fluorescence, if challenged with lipopolysaccharide (LPS) (**a**). Neutralizing NGF by specific anti-NGF antibody counteracted the CGRP expression in macrophages activated by exposure to LPS (**b**). Gene expression analysis (**c**) by PCR and Southern blot reveals that both unstimulated (Us) and LPS-challenged macrophages increase CGRP gene expression when exposed to NGF in culture, while anti-NGF decreases CGRP mRNA in stimulated cells

3 NGF and Inflammation

3.1 In Vivo Evidence and Experimental Models

An increase in NGF in tissues at the site of inflammation is a characteristic of several inflammatory diseases. Increased NGF concentrations, which closely follow the course of the disease, were initially found in the cerebrospinal fluid of multiple sclerosis patients (Bracci-Laudiero et al. 1992), in the synovial fluids of rheumatoid arthritis patients (Aloe et al. 1992), and in the sera of systemic lupus erythematosus (SLE) patients (Bracci-Laudiero et al. 1993a; Aalto et al. 2002). NGF mRNA expression and protein levels increase in animal models of inflammation such as Freund's adjuvant-induced and carrageenan-induced arthritis (Safieh-Garabedian et al. 1995; Manni and Aloe 1998), in a model of human SLE (Bracci-Laudiero et al. 1996b), and in experimental autoimmune encephalomyelitis (EAE) (De Simone et al. 1996). Many other inflammatory diseases, such as interstitial cystitis (Lowe et al. 1997; Jacobs et al. 2010), allergic asthma (Bonini et al. 1996; Braun et al. 1998), vernal keratoconjunctivitis (Lambiase et al. 1995), Crohn's disease and colitis (di Mola et al. 2000; Stanzel et al. 2008), psoriasis (Fantini et al. 1995; Raychaudhuri et al. 1998), and atopic dermatitis (Toyoda et al. 2002), are characterized by increased tissue and/or circulating NGF. Taken together, these data suggested that inflammation and tissue damage generate mediators that control the local concentration of NGF. Inflammatory cytokines such as IL-1beta, TNF-alpha, and IL-6 are able to modify the basal production of NGF in the organism and induce the synthesis of NGF in a variety of cell types and tissues (Lindholm et al. 1987; Friedman et al. 1990; Gadient et al. 1990; Steiner et al. 1991; Hattori et al. 1994; Kossmann et al. 1996; Marz et al. 1999; Olgart and Frossard 2001; Manni et al. 2003; Moser et al. 2004; Ryan et al. 2008; Seidel et al. 2010). Other inflammatory mediators such as prostaglandins and histamine have also been shown to induce NGF production in certain cell types (Lipnik-Stangelj and Carman-Krzan 2004a, b; Toyomoto et al. 2004; Bullo et al. 2005). In addition, stimulation with specific antigens and cytokines of immune cells involved in innate and acquired immunity modulates their basal expression of NGF (Torcia et al. 1996; Lambiase et al. 1997; Xiang and Nilsson 2000; Caroleo et al. 2001; Kobayashi et al. 2002). Activation of the NF-κB pathway seems to be essential in regulating NGF expression in B lymphocytes (Heese et al. 2006). The endogenous levels of NGF are substantially increased in inflamed tissues, dynamically regulating innervations and neural activities during the inflammatory process (Carr and Undem 2001). During inflammation, the neuronal phenotype can be modified, altering the amount or type of neurotransmitters produced and stored in nerve terminals. As a result, pain sensitivity is increased during inflammation: the properties of the somatosensory neurons change so that the pain threshold decreases, noxious stimuli evoke more acute and prolonged pain (hyperalgesia), and normally innocuous stimuli became painful (allodynia) (Woolf and Salter 2000). This peripheral sensitization increases the firing of nociceptors, and the intense stimulation induces

the release from nerve endings of neuropeptides that can influence a variety of immune cell functions. One of the best-known neuroimmune mechanisms involving sensory neuropeptides is neurogenic inflammation: this is characterized by a release of neuropeptides by sensory nerves that in turn induces vasodilatation and plasma extravasation, promotes leukocyte chemotaxis and phagocytosis (Zegarska et al. 2006), and directly affects the release of inflammatory mediators from mast cells and macrophages (Tore and Tuncel 2009). In the mucosae and in lymphoid organs, sensory fibers are in close contact with the cell membranes of mast cells, macrophages, Langerhans cells, and endothelial cells in what has been defined a "neuroimmune junction" (Straub 2004). Neuropeptides released from nerve terminals induce synthesis of inflammatory mediators and cytokines in these cells and affect their functions. While SP has a demonstrated pro-inflammatory role (O'Connor et al. 2004), CGRP, which is often co-localized with SP in nerve endings, can also have an inhibitory action. CGRP is a potent inhibitor of mitogen- and antigen-stimulated proliferation of T-cells (Carucci et al. 2000), antigen presentation by antigen-presenting cells (Hosoi et al. 1993), and cytokine synthesis (Gomes et al. 2005). The localized increased production of NGF in inflammatory conditions induces modification of gene expression in dorsal root ganglia that can be prevented using anti-NGF antibodies (Donnerer et al. 1992). The neuronal phenotypic changes driven by NGF during inflammation include elevation of neuropeptides, which amplify sensory input signals in the spinal cord and augment neurogenic inflammation in the peripheral tissues.

3.2 In Vivo Anti-inflammatory Action

The previously cited evidence indicates that *NGF maintains immune cells in a* "*state of alert*" to potential danger signals. NGF by itself does not seem to induce inflammatory and immune responses efficiently, but, in the presence of specific stimuli, it enhances mediator release and cytokine production and activates the functions of innate immune cells. In other words, *NGF helps to mount a faster and stronger inflammatory response*. However, at present, some of the data obtained in vivo are not consistent with this conclusion. The reasons why NGF production is increased during inflammation and how this enhanced concentration affects the immune and inflammatory responses are still far from being understood. The notion that NGF plays a much more complex role in the scenario of immune response has emerged from studies on experimental models of EAE. In marmoset EAE, intracerebroventricular administration of NGF delays the onset of clinical signs and prevents the full development of histological lesions in the CNS (Villoslada et al. 2000). NGF reduces the number and size of inflammatory infiltrates, and demyelination is minimal in the brain of NGF-treated animals (Villoslada et al. 2000). Moreover, the production of interferon-gamma by the T-cells infiltrating the brain is reduced, while production of IL-10 is enhanced in NGF-treated animals (Villoslada et al. 2000). In a murine model of EAE, intraperitoneal injections of NGF starting one day after immunization with myelin basic

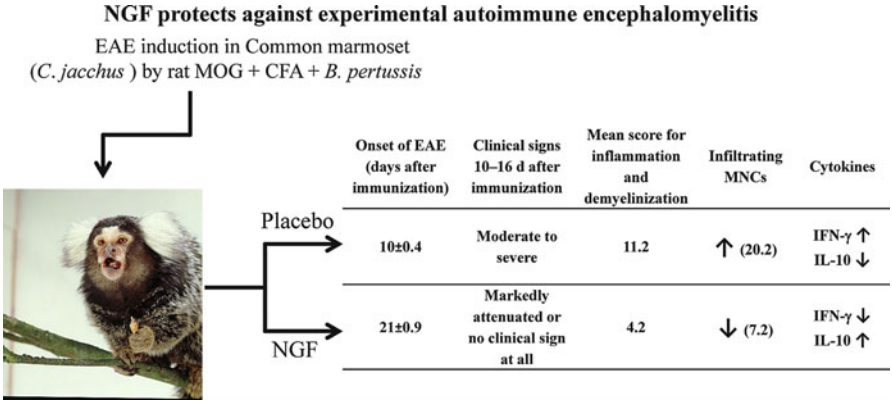

Fig. 4 *NGF protects common marmosets against autoimmune encephalomyelitis*. The figure is a summary of results published by Villoslada and collaborators (Villoslada et al. 2000). In this paper, the authors demonstrated that intracerebroventricular (icv) NGF was able to revert clinical manifestations of the experimental autoimmune encephalomyelitis (EAE), an animal model for human multiple sclerosis. In such a model, the immunization with myelin oligodendrocyte glycoprotein (MOG) induces a massive autoimmune response in the central nervous system, characterized by infiltration of activated T-cells and activation of glial cells. Brain-delivered NGF was able to delay the onset of clinical signs and prevent the full development of histological lesions, reducing the number and size of inflammatory infiltrates and the demyelination. Moreover, the production of interferon-gamma by the T-cells infiltrating the brain was reduced, while production of IL-10 by glial cells was enhanced in NGF-treated animals

protein (MBP) or after adoptive transfer of encephalitogenic T-cells led to a delayed onset, decreased clinical signs of the disease, and enhanced survival of the animals (Arredondo et al. 2001). In a T-cell transfer model of EAE, myelin basic protein-specific CD4+ T-cell clones were transfected with recombinant retrovirus encoding for NGF and used to induce EAE in rats (Flugel et al. 2001). The clones producing NGF did not induce EAE, while the pathogenic wild-type clones injected together with the NGF-transfected clones induced a very mild disease with no or only minor clinical signs (Flugel et al. 2001). A reduction in inflammatory cells crossing the endothelial blood–brain barrier (BBB), with the number of activated macrophages being especially decreased, was also found (Flugel et al. 2001). Complementary effects are observed in another EAE rat model, in which NGF deprivation results in exacerbated brain inflammation and more severe clinical signs (Micera et al. 2000). Thus, the overall data obtained from EAE models point to an anti-inflammatory role of NGF in CNS immune-mediated inflammation. NGF seems to exert its effects directly on immune cell activity: inhibition of monocyte migration and antigen presentation, altered T-helper balance, downregulation of IFN-gamma synthesis, and upregulation of the anti-inflammatory cytokine IL-10 (Fig. 4). Similarly, in experimental models of colitis, it has been shown that NGF production remains elevated in the tissue until colon inflammation subsides (Barada et al. 2007), while neutralizing NGF by anti-NGF antibodies causes a significant increase in the severity of clinical signs with more

extended lesions and ulcers, together with an increase in the number of infiltrating neutrophils and macrophages (Reinshagen et al. 2000). Also in this experimental model, the increase in NGF correlates with the enhancement of IL-10 (Barada et al. 2007), possibly because NGF and IL-10 are able to regulate each other's expression in intestinal epithelial cells (Ma et al. 2003). In addition, functional sensory neurons and their neuropeptides (i.e., CGRP) are probably involved in the in vivo action of NGF. In the colitis model, enhanced tissue inflammation caused by NGF neutralization is associated with a marked reduction in CGRP content in the gut (Reinshagen et al. 1994). Moreover, the ablation of sensory fibers results in a marked severity of inflammation in acute and chronic models of experimental colitis, and in both cases the decrease in CGRP content or its inhibition in the colon using CGRP receptor antagonist aggravates experimental colitis (Reinshagen et al. 1998).

The NGF produced in vivo *at the site of inflammation thus represents a critical link between nervous and immune cells*. This hypothesis is supported by studies on a mouse model in which the animal's skin received ultraviolet B (UVB) irradiation. UVB induces systemic suppression of contact hypersensitivity (CHS) responses, and NGF, together with nerves and neuropeptides, seems to play a relevant role in this phenomenon. In mouse epidermis, UVB irradiation upregulates NGF expression, which peaks after 12 h (Gillardon et al. 1995). Anti-NGF antibodies administered prior to UVB irradiation abrogate the systemic suppression of CHS in mice (Townley et al. 2002). The CHS response in healthy mice was also inhibited by NGF treatment of the skin prior to trinitrochlorobenzene sensitization (Townley et al. 2002). Moreover, when mice were treated with capsaicin, which depletes nerve endings of sensory neuropeptides, preincubation with NGF was not effective in suppressing CHS response (Townley et al. 2002). Also in this model, *NGF-induced synthesis of CGRP seems to represent a key mediator for the control of immune cell activity and for balancing pro- and anti-inflammatory responses*. In UV-induced tolerance, the induction of CGRP synthesis in skin after UV radiation (Legat et al. 2004) is regulated by keratinocyte-derived NGF (Townley et al. 2002). In vivo CGRP administration dampens the immune response essentially by affecting antigen presentation in a variety of antigen-presenting cells (Raud et al. 1991; Hosoi et al. 1993; Asahina et al. 1995; Carucci et al. 2000), through inhibition of the NF-kappaB pathway (Millet et al. 2000) and a rapid upregulation of inducible cAMP early repressor (Harzenetter et al. 2007), which causes premature repression of inflammation-induced transcriptional activity. Thus, the ability of NGF in vivo to regulate production and release of sensory neuropeptides seems to be a key factor not only in *keeping the defense system active* (i.e., through SP) but also in *activating inhibitory pathways that limit inflammation*.

Data from in vivo models of inflammation show that integrity of the peripheral nervous system is essential for the activation of an anti-inflammatory feedback circuit (Rook et al. 2002; Holzer 2007; Dirmeier et al. 2008; Boisse et al. 2009; Kroeger et al. 2009). Cutaneous infections and altered immune responses in diabetes represent a characteristic example of nerve damage leading to uncontrolled

tissue inflammation. Impaired production of NGF is responsible for the reduction in skin innervations in diabetes (Hellweg and Hartung 1990; Anand 1996). In animal models, the exogenous administration of NGF, while improving nerve functions and restoring innervation in the skin (Christianson et al. 2003), normalizes the diabetes-impaired response to wound healing by decreasing neutrophil accumulation and increasing reepithelialization and matrix density (Matsuda et al. 1998).

4 Conclusion

Since its discovery in the 1950s, NGF has been extensively studied for its trophic, pro-survival, and differentiative effects in both neuronal and nonneuronal cell populations. Several studies have shown that the neurotrophin can display contradictory behavior, acting either as a survival or as an apoptotic factor in neuronal cells (Lee et al. 2001). In the last decade, the apparently controversial effects of NGF on neuronal cells have been better elucidated, in light of the discovery and characterization of the precursor form of NGF, named proNGF. ProNGF can be released by cells and cleaved to form mature NGF (Bruno and Cuello 2006) or can act as an active molecule, being a specific and selective ligand for a receptor complex made by $p75^{NTR}$ and sortilin (Fahnestock et al. 2004), a protein that shuttles other proteins within cells and acts as a receptor for neurotensin (Mazella 2001). In several injury models in the central nervous system, proNGF expression is detectable for several days to weeks following injury. Surprisingly, little conversion of proNGF to mature NGF is observed in these in vivo settings (Beattie et al. 2002; Harrington et al. 2004; Jansen et al. 2007). This finding suggests that the mature and pro-forms of NGF may perform opposing actions. Expression of the $p75^{NTR}$ receptor has emerged as a key regulatory element in proNGF-induced cell death. In most adult tissues, $p75^{NTR}$ is expressed at low levels, in contrast to its stronger and more widespread distribution in development (Yang et al. 2009; Roux and Barker 2002). However, in pathologic states, including seizure, brain injury, ischemia, and excitotoxicity, $p75^{NTR}$ expression is induced. The significant reduction in injury-induced apoptosis observed in $p75^{NTR}$-deficient mice (Troy et al. 2002; Harrington et al. 2004) clearly indicates the importance of $p75^{NTR}$ induction in determining cell loss following injury.

Until now, very few studies have addressed the function of proNGF in the immune system, but this promises to be an exciting field of research for the near future. Only very recently was the action of proNGF on immune cells addressed in a work investigating the effects of $p75^{NTR}$/sortilin activation in NK cells in vitro (Rogers et al. 2010). Freshly isolated NK and B-cells, but not T lymphocytes, expressed significant amounts of sortilin but did not express significant amounts of $p75^{NTR}$ in unstimulated conditions. The expression of $p75^{NTR}$ is induced in NK cells by IL-12. Addition of proNGF in the presence of IL-12 induced NK cell death (Rogers et al. 2010). Immune cells, such as mast cells, have been indicated as a possible source of proNGF. Indeed, proNGF

immunoreactivity was increased in skin-homed mast cells in an in vivo model of neuropathic pain (Peleshok and Ribeiro-da-Silva 2012). Mast cells may also have a role as key players in the extracellular maturation of NGF from its precursor. Tryptase-secreting mast cells have been detected in close proximity to NGF-secreting cells in the testis of infertile patients, and it is likely that they are able to alter the ratios of proNGF/NGF by increasing tryptase enzymatic cleavage of proNGF (Spinnler et al. 2011). There is also evidence that neuroimmune modulators may be involved in regulating the proNGF/NGF balance. In an in vitro model of inflamed skin, the addition of neuropeptides such as SP, CGRP, VIP, and GAL to normal human keratinocytes results in an increased expression of IL-1β, IL-8, and TNF-α; release of proNGF; and its increased conversion into mature NGF in the culture medium (Dallos et al. 2006).

In view of the apparent discrepancies in the effects of NGF on immune functions, it is to be hoped that future studies of NGF and proNGF will help to clarify the role of this neurotrophin in regulating immune response and inflammation. A better understanding of proNGF/NGF actions could be of immense value, with translational implications for human diseases.

NGF/P75 in Cell Cycle and Tetraploidy

Noelia López-Sánchez, María Carmen Ovejero-Benito, Claudia Rodríguez-Ruiz, and José María Frade

Contents

Abstract

Neurotoxicity, neurodegeneration, and other disorders affecting neuron survival are often related to cell cycle reentry in neurons. Traditionally, cell cycle reentry of these postmitotic cells has been thought to be associated with apoptosis. Nevertheless, cell cycle reentry and DNA synthesis in neurons could also lead to tetraploidy which may explain long-lasting neurodegenerative processes. During development, a subpopulation of newborn neurons reactivates the cell cycle and becomes tetraploid in response to $p75^{NTR}$ activation. These neurons enlarge their cell bodies and increase their dendritic trees, thus generating specific neuronal populations that innervate particular areas. Pathological states in the nervous system could also lead to $p75^{NTR}$-dependent neuronal tetraploidy.

DOI 10.1007/978-1-4614-5836-4_27,

De novo tetraploid neurons might become structurally and functionally altered, thus leading to neurodegeneration at late stages of the disease. This chapter describes what is currently known about the interplay between $p75^{NTR}$ and the cell cycle, stressing the role played by different $p75^{NTR}$ interactors, including the MAGE and Bex1/NADE adaptor proteins and the transcription factors SC1, NRIF, and Sall2, in cell cycle regulation. The chapter also discusses on the effects of $p75^{NTR}$, as a cell cycle regulator, in neural stem cell proliferation, neurogenesis, and neuronal tetraploidization, as well as on the connection of $p75^{NTR}$ in pathology, including its putative effects in neurodegeneration.

List of Abbreviations

Aβ	Amyloid-β
BDNF	Brain-derived neurotrophic factor
Bex-1	Brain-expressed X-linked 1
BrdU	Bromodeoxyuridine
cdk	Cyclin-dependent kinase
CMAGE	Chicken MAGE
CNS	Central nervous system
Dlxin-1	Dlx/Msx-interacting MAGE/Necdin family protein
E2F1	E2 promoter-binding factor-1
EGFP	Enhanced green fluorescent protein
ERK	Extracellular signal-regulated kinase
JNK	c-Jun N-terminal kinase
MAGE	Melanoma antigen
MAPK	Mitogen-activated protein kinase
NADE	$p75^{NTR}$-associated cell death executor
NGF	Nerve growth factor
NRAGE	Neurotrophin receptor-interacting MAGE homolog
NRIF	Neurotrophin receptor-interacting factor
NT3	Neurotrophin-3
$p75^{ICD}$	$p75^{NTR}$ intracellular domain
$p75^{NTR}$	p75 neurotrophin receptor
PCNA	Proliferating cell nuclear marker
PNS	Peripheral nervous system
PR/SET	Positive regulatory/suppressor of variegation, enhancer of zeste, trithorax
Rb	Retinoblastoma
RGCs	Retinal ganglion cells
Sall2	Sal-like protein 2
SC1	Schwann cell factor 1
SGZ	Subgranular zone
SVZ	Subventricular zone
TNF	Tumor necrosis factor
Trk	Tropomyosin-related kinase

1 Introduction

Neurotrophins are best known as neuronal survival factors with multiple effects in the structure and function of the adult vertebrate nervous system (Huang and Reichardt 2001). The first neurotrophin to be described was NGF in the early 1950s (Levi-Montalcini and Hamburger 1951), being initially purified from sarcoma tumor cells (Cohen et al. 1954). Several decades later, other members of the neurotrophin family were characterized, including BDNF (Barde et al. 1982), NT3 (Hohn et al. 1990; Maisonpierre et al. 1990; Rosenthal et al. 1990; Jones and Reichardt 1990), and NT4/5 (Hallböök et al. 1991; Berkemeier et al. 1991). In the brain, mature neurotrophins coexist with their precursor pro-forms, namely, proNGF, proBDNF, and proNT3 (Fahnestock et al. 2001; Michalski and Fahnestock 2003). The neurotrophin pro-forms fulfill specific functions, usually opposed to that of the mature neurotrophins, including induction of cell death (Lee et al. 2001; Teng et al. 2005; Yano et al. 2009) and, in the case of proBDNF, synapse modulation (Lu 2003; Woo et al. 2005; Greenberg et al. 2009). These opposed effects can be explained due to the capacity of neurotrophins to interact with two different types of receptors, $p75^{NTR}$ and the members of the Trk tyrosine kinase receptor family. $p75^{NTR}$ was the first member of the TNF receptor family to be described (Chao et al. 1986; Johnson et al. 1986; Radeke et al. 1987). Unlike the Trk receptors, known to interact with specific neurotrophins (Kaplan et al. 1991; Klein et al. 1991a, b, 1992; Lamballe et al. 1991), $p75^{NTR}$ can bind to, and be activated by, all neurotrophins (Rodríguez-Tébar et al. 1990, 1992). Although $p75^{NTR}$ was initially thought to be a mere Trk co-receptor, it is now clear that this receptor is at the core of at least two other signaling networks, including the $p75^{NTR}$/sortilin platform that induces apoptosis in response to the pro-forms of the neurotrophins (Nykjaer et al. 2004; Teng et al. 2005; Yano et al. 2009) and the $p75^{NTR}$/NgR/LINGO-1 complex that regulates axonal outgrowth (Wang et al. 2002; Mi et al. 2004). In some cases, signaling through $p75^{NTR}$ requires the release of its intracellular domain ($p75^{ICD}$), which can be translocated to the nucleus (Frade 2005; Parkhurst et al. 2010). This mechanism has been shown to lead to apoptosis (Majdan et al. 1997; Kenchappa et al. 2006, 2010; Podlesniy et al. 2006), and it can also participate in Trk signaling (Skeldal et al. 2011).

Mounting evidence indicates that neurotrophins can regulate cell cycle progression through both $p75^{NTR}$ and the Trk receptors (López-Sánchez and Frade 2002). This chapter will firstly describe what is known about the interplay between $p75^{NTR}$ and the cell cycle machinery. Then, the chapter will be focused on the role played by this receptor in the normal nervous system in terms of cell cycle regulation (proliferation of neural stem cells, embryonic and adult neurogenesis, and neuronal tetraploidization). Finally, a discussion on the possible involvement of $p75^{NTR}$ as a cell cycle regulator in neurodegeneration will be presented.

2 Interplay Between $p75^{NTR}$ and the Cell Cycle

$p75^{NTR}$ is the founder member of the tumor necrosis factor receptor family. This receptor, characterized by the presence of one transmembrane domain and a type II death domain within its intracellular domain, is expressed by a variety of neuronal and non-neuronal cell types, frequently showing proliferative capacity. In this regard, $p75^{NTR}$ was initially described in proliferating cells derived from pheochromocytoma, neuroblastoma, and melanoma tumors (Yankner and Shooter 1982). More recently, this receptor is often used as a marker of neural progenitor cells in the adult brain (Giuliani et al. 2004; Young et al. 2007; Bernabeu and Longo 2010) and as a tumor suppressor gene in a number of tumor cells (Krygier and Djakiew 2001; Yuanlong et al. 2008; Jin et al. 2007; Khwaja and Djakiew 2003; Khwaja et al. 2006). $p75^{NTR}$ has opposing effects on the cell cycle, inducing cell cycle arrest in some instances and cell cycle progression in other circumstances. For instance, $p75^{NTR}$-dependent cell cycle arrest, associated with reduced expression of cyclin D1, cyclin E, cdk2, E2F1, PCNA, and the cdk inhibitor $p16^{INK4a}$, decreased cdk2 activity, and hyper-phosphorylation of Rb protein, has been shown to occur in bladder tumor epithelial cells (Khwaja and Djakiew 2003). In human gastric cancer cells, $p75^{NTR}$ expression suppresses proliferation by downregulation of cyclin A, cyclin D1, cyclin E, cdk2, and phospho-Rb and upregulation of the cell cycle inhibitors Rb and $p27^{KIP1}$. This antiproliferative activity in human gastric cancer cells is dependent on the presence of the death domain of $p75^{NTR}$ (Jin et al. 2007). $p75^{NTR}$ expression in hepatocellular carcinoma cells has also been shown to downregulate the expression of cyclin A, cyclin D1, cyclin E, cdk2, p-Rb, and PCNA and upregulate the expression of the cell cycle inhibitor Rb (Yuanlong et al. 2008). Examples of $p75^{NTR}$-dependent cell cycle progression are also available in the literature. For instance, $p75^{NTR}$ has been shown to be expressed by human oral keratinocyte stem cells showing high in vitro proliferative capacity and clonal growth potential (Nakamura et al. 2007) as well as by human esophageal keratinocyte stem cells able to undergo self-renewal and self-amplification (Okumura et al. 2003). Moreover, $p75^{NTR}$ can be detected in cycling cells from the subventricular zone of adult male rats (Giuliani et al. 2004), and the addition of NGF has been shown to revert $p75^{NTR}$-dependent cell cycle arrest in bladder tumor epithelial cells (Khwaja and Djakiew 2003).

The mechanisms used by $p75^{NTR}$ to regulate cell cycle progression are beginning to be elucidated. In this regard, $p75^{NTR}$ is known to activate different members of the MAPK family able to regulate the cell cycle (Ambrosino and Nebreda 2001; Zhang and Liu 2002), including JNK, $p38^{MAPK}$, and ERK (Casaccia-Bonnefil et al. 1996; Susen et al. 1999; Costantini et al. 2005; Jiang et al. 2007). Moreover, the opposing effects of $p75^{NTR}$ on cell cycle regulation can be explained by the different molecules with which this receptor interacts (see Fig. 1). $p75^{NTR}$ can modulate the cell cycle through the interaction of its intracellular domain with a number of proteins known to regulate the cell cycle, some of which are transcription factors. In some instances, $p75^{NTR}$ has been shown to sequester these molecules at the plasma membrane.

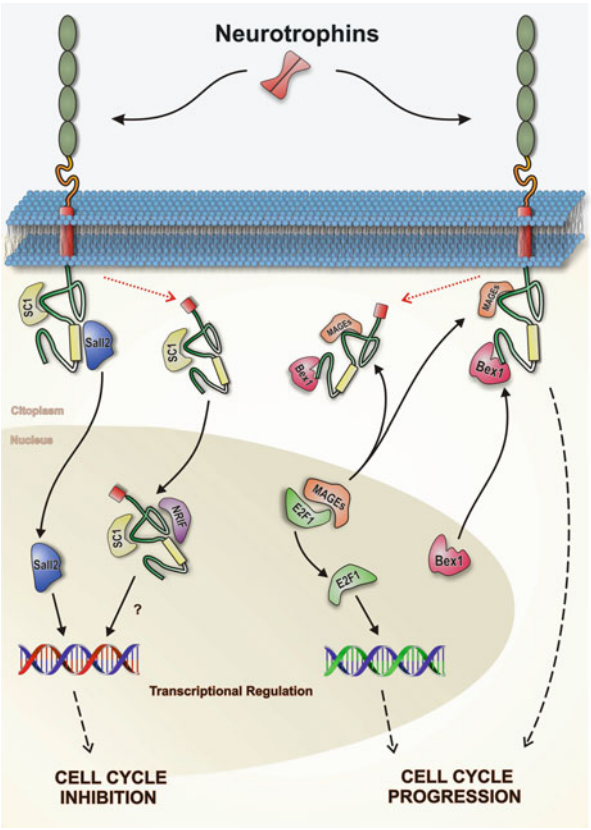

Fig. 1 Scheme of the signaling pathways used by $p75^{NTR}$ to regulate the cell cycle. *Dotted arrows* represent the release of $p75^{ICD}$ as a consequence of regulated γ-secretase-dependent cleavage of $p75^{NTR}$. *Solid arrows* describe the dynamics of the different proteins involved in the $p75^{NTR}$ signaling. *Dashed arrows* represent the final biological output of the corresponding pathways. The *question mark* represents the putative transcriptional activity of $p75^{ICD}$ complexed with NRIF and/or SC1. See main text for further details

In addition, $p75^{NTR}$ is susceptible to undergo γ-secretase-dependent cleavage and release its intracellular domain ($p75^{ICD}$) which may subsequently translocate to the nucleus (Kanning et al. 2003; Frade 2005). The interaction of $p75^{ICD}$ with transcription factors led to the suggestion that it can regulate gene expression when located in the nucleus. This notion has recently been confirmed as $p75^{ICD}$ has been shown to translocate to the nucleus and activate a green fluorescent protein reporter (Parkhurst et al. 2010). Furthermore, NGF can induce the interaction of $p75^{ICD}$ with the *cyclin E* promoter, thus inhibiting its activity in HeLa cells (Parkhurst et al. 2010), a result consistent with the observation that NGF-dependent nuclear translocation of $p75^{ICD}$ in schwannoma cells (Frade 2005) correlates with cell cycle repression in these cells (Morillo and Frade 2008). The expression of $p75^{ICD}$ in $p75^{NTR}$-negative PC12 cells downregulates cyclin D2 expression as well (Fritz et al. 2006). $p75^{NTR}$ can regulate the cell cycle by means of recruitment of adaptor proteins such as different MAGE proteins or Bex1, known to be involved in the cell cycle regulation, and also by regulating the expression of cell cycle-regulating genes through transcription factors such as SC1, NRIF, and Sall2, all of them able to interact with $p75^{ICD}$.

2.1 MAGE Proteins

The MAGE protein family comprises more than 60 adaptor proteins in mammals, containing a conserved MAGE homology domain. Originally, MAGE proteins were discovered because peptides derived from MAGE gene products are presented on the cell surface of human melanoma cells by the major histocompatibility complex (Barker and Salehi 2002). MAGE proteins can be divided into two major groups: type I and type II MAGE proteins. The former are only expressed in tumors, male germinal cells, and placenta. In contrast, the latter group, defined by a phylogenetically distinct MAGE homology domain, comprises around ten different proteins expressed in both differentiating and adult cells (Barker and Salehi 2002). Most of the MAGE proteins are encoded by genes containing a single exon, suggesting that the whole MAGE protein family evolved from a retrotransposition event that occurred in an ancestral gene orthologue of the gene encoding NRAGE/Dlxin-1/MAGE-D1, the only MAGE gene containing exons in its sequence, followed by extensive gene duplication. This hypothesis is consistent with the existence of a single MAGE gene in all nonmammalian species including unicellular, plants, fungi, invertebrates, and nonmammalian vertebrates (López-Sánchez et al. 2007).

The mammalian MAGE II proteins Necdin, NRAGE/Dlxin-1/MAGE-D1, MAGE-H1, and MAGE-G1 as well as CMAGE are known to interact with $p75^{NTR}$ through its intracellular domain (Salehi et al. 2000; Tcherpakov et al. 2002; Kuwako et al. 2004; López-Sánchez et al. 2007), and they have effects on cell cycle regulation. Therefore, these proteins are candidates for the effects of $p75^{NTR}$ on the cell cycle. Necdin can bind to the transcription factor E2F1, thus blocking its capacity to trigger G1/S transition (Taniura et al. 1998; Kuwako et al. 2004). The activation of $p75^{NTR}$ by NGF can recruit Necdin to the cell membrane, thus favoring E2F1-dependent cell cycle progression and subsequent death of differentiated neurons (Kuwako et al. 2004) (see Fig. 1). Alternatively, the presence of the $p75^{ICD}$ fragment can displace both Necdin and CMAGE from their interaction with E2F1 in differentiating neurons, thus leading to cell E2F1-dependent cycle reentry and apoptosis (López-Sánchez et al. 2007) (see Fig. 1). NRAGE/Dlxin-1/MAGE-D1 can also block cell cycle progression (Salehi et al. 2000), likely by inducing the expression of the cell cycle-inhibiting protein $p21^{Waf1}$ in a p53-dependent manner (Wen et al. 2004). NRAGE/Dlxin-1/MAGE-D1 associates with the plasma membrane when NGF is bound to $p75^{NTR}$ (Salehi et al. 2000), as it occurs with Necdin (see above). Therefore, sequestering of MAGE proteins by $p75^{NTR}$ seems to be a general mechanism for enhancement of cell cycle progression in different cellular systems.

2.2 Bex/NADE

$p75^{NTR}$ is also known to interact through its death domain with the small adaptor-like proteins from the Bex/NADE family (Mukai et al. 2000; Vilar et al. 2006), including Bex1 and Bex3/NADE. Among them, Bex1 can constitutively

interact with $p75^{NTR}$ (see Fig. 1) and favor cell cycle progression when overexpressed in differentiating PC12 cells (Vilar et al. 2006). This is consistent with the increase of Bex1 during S phase in PC12 cells, as it occurs with the presence of $p75^{NTR}$ on the surface of these same cells (Urdiales et al. 1998). Upon NGF treatment, Bex1 translocates from the nucleus to the cytoplasm (see Fig. 1), suggesting that this mechanism is required for the effect of this protein on cell cycle regulation. Interestingly, in other cell systems Bex1/2 seems to act as a putative tumor suppressor gene in malignant glioma (Foltz et al. 2006), although in this case the participation of $p75^{NTR}$ is currently unknown.

2.3 SC1

The $p75^{NTR}$-interacting protein SC1 is a member of the PR/SET domain-containing zinc finger protein family, which can be detected in both the nucleus and cytoplasm when overexpressed (Chittka and Chao 1999). SC1 is redistributed from the cytoplasm to the nucleus after NGF treatment in a $p75^{NTR}$-dependent manner, acting as a transcriptional repressor (see Fig. 1). Nuclear SC1 correlates with the loss of BrdU incorporation, likely due to its ability to repress cyclin E expression (Chittka et al. 2004). Interestingly, NGF has been shown to induce the association of endogenous $p75^{ICD}$ with the cyclin E promoter (Parkhurst et al. 2010), suggesting that a complex formed by $p75^{ICD}$ and SC1 can be formed in the promoter of different genes encoding cell cycle-regulating proteins (see Fig. 1).

2.4 Sall2

Sall2 is another transcription factor able to regulate cell cycle progression which can interact with $p75^{NTR}$ through its intracellular domain (see Fig. 1). This protein is a tumor suppressor that becomes dissociated from its binding to $p75^{NTR}$ upon interaction of the latter with NGF (Pincheira et al. 2009). Sall2 is known to activate $p21^{Waf1}$ and promote growth arrest in neurons. This observation is consistent with the $p75^{NTR}$-dependent increase of $p21^{Waf1}$ expression and decrease of Rb phosphorylation in breast cancer cells (Verbeke et al. 2010).

2.5 NRIF

The zinc finger proteins of the Krüppel family NRIF1 and NRIF2 are able to interact with the intracellular domain of $p75^{NTR}$ through its juxtamembrane and death domains (Casademunt et al. 1999; Benzel et al. 2001) (see Fig. 1). These proteins have been suggested to be transcription factors based on structural characteristics and their ability to translocate to the nucleus (Gentry et al. 2004), and they prevent cell cycle progression when expressed in 293T cells. Interestingly, the release of $p75^{ICD}$ correlates with the translocation of NRIF to the nucleus

(Kenchappa et al. 2006; Volosin et al. 2008), suggesting the complex NRIF/$p75^{ICD}$ may participate in the regulation of the cell cycle, as it occurs with $p75^{ICD}$ and SC1 (see above).

3 The Role of $p75^{NTR}$ as a Cell Cycle Regulator in Nervous System Physiology

A critical feature of the nervous system is the requirement of neurons to be postmitotic. The avoidance of cell division in these cells is likely derived from their complex morphology, required for their function, which is incompatible with the reorganization of the cytoskeleton necessary for the mitotic process. Therefore, at certain point of neural development, proliferating neuronal precursors stop dividing and differentiate as neurons in a process referred to as neurogenesis. During development, $p75^{NTR}$ can be detected in the proliferating epithelium of the retina (Frade and Barde 1999; Morillo et al. 2010; López-Sánchez et al. 2011), spinal cord (Frade and Barde 1999; López-Sánchez et al. 2011), and other structures of the CNS including the dorsal telencephalon in the chick (Fig. 2), suggesting that it can participate in the neurogenic process. Furthermore, $p75^{NTR}$ is expressed by neural crest cells (Bannerman and Pleasure 1993), a proliferating cell population giving rise to the PNS, among other structures. Some evidence exists for the participation of $p75^{NTR}$ in cell cycle withdrawal of precursor cells and neuronal differentiation during embryonic development (Hapner et al. 1998; Hosomi et al. 2003; Zhang et al. 2009). Much more evidence exists for the participation of $p75^{NTR}$ in adult neurogenesis and neuronal tetraploidization during embryonic development. These two processes are further described below.

3.1 Adult Neurogenesis

For many decades it was assumed that the generation of functional neurons from precursors (i.e., neurogenesis) only occurs during embryonic and perinatal stages of development in mammals. This view has been ruled out, and nowadays it is widely accepted that neural stem cells can be present in the adult nervous system, being able to proliferate in vitro giving rise to neurospheres (Reynolds and Weiss 1992). Neurons are known to be produced during adulthood in two main brain regions, in the SVZ of the lateral ventricle (giving rise to the rostral migratory stream that colonizes the olfactory bulb) and the SGZ from the dentate gyrus of the hippocampus (producing dentate granule neurons).

Interestingly, $p75^{NTR}$ is expressed by cycling cells in the SVZ of adult male rats (Giuliani et al. 2004). This $p75^{NTR}$-positive cell population integrates all of the neurosphere-producing SVZ precursors, which are known to enhance neuronal production in response to NGF or BDNF (Young et al. 2007). The importance of $p75^{NTR}$ in SVZ adult neurogenesis is further supported by the observation that the neurogenic potential is reduced in neurospheres derived from $p75^{NTR}$ knockout

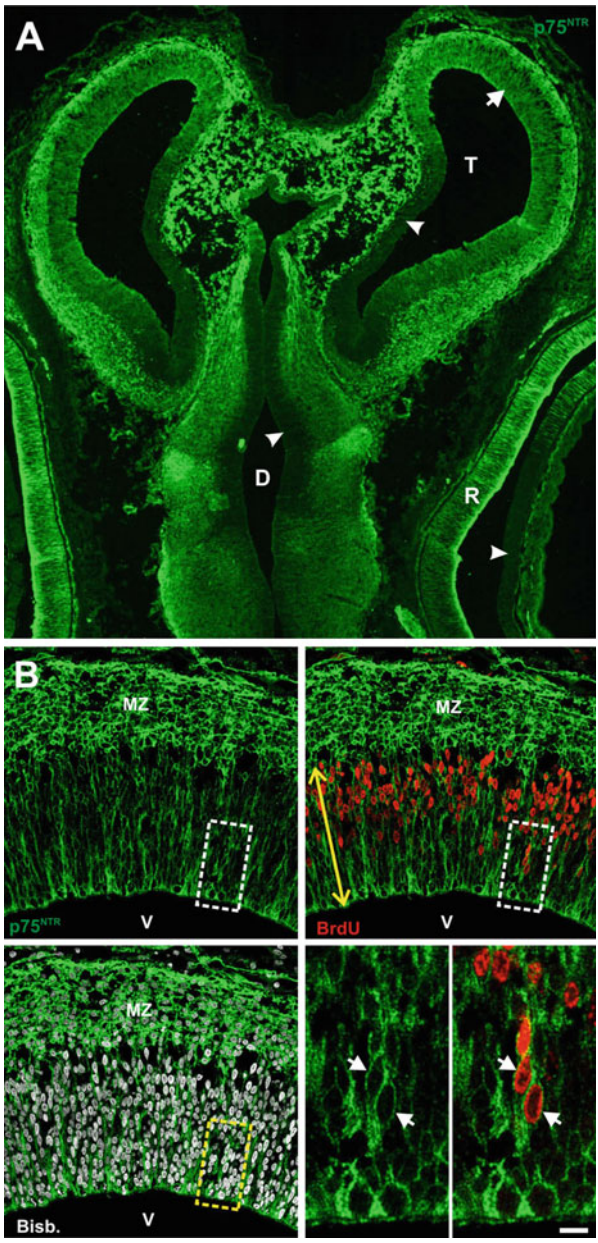

Fig. 2 $p75^{NTR}$ expression in the chick brain at developmental day 6 (E6). (**A**) Horizontal section through the E6 chick brain, immunostained with the ChEX anti-$p75^{NTR}$ antibody (kindly provided by L. F. Reichardt, University of California San Francisco). $p75^{NTR}$ is expressed in specific regions of the neuroepithelium (*arrow*), while this protein cannot be detected in other areas of the neuroepithelium (arrowheads). *T* telencephalic derivatives, *D* diencephalic derivatives, *R* retina. (**B**) A high magnification from the telencephalic wall (dorsal hyperpallium) from E6 chick embryos treated with BrdU for 20 min. BrdU is incorporated by nuclei of progenitors undergoing S phase (*red*) which, due to the interkinetic nuclear movement, are mostly located far from the ventricle (*V*). Nevertheless, some nuclei from $p75^{NTR}$-expressing precursors incorporate BrdU when located close to the ventricle (*dashed box* and *arrows* in the magnification of the *dashed box* shown in the *bottom right panels*). Nuclei were labeled with bisbenzimide (*Bisb.*). Abbreviation: *MZ* mantle zone. Bar – 65 μm (**A**), 25 μm (**B**)

mice (Young et al. 2007). $p75^{NTR}$ might also regulate proliferation of SVZ precursors in pathological states. For instance, $p75^{NTR}$ activation with $A\beta_{1\text{-}42}$, the pathological form of Aβ in Alzheimer's disease, has been shown to favor proliferation and neuronal differentiation in neurosphere-forming adult progenitors,

an effect that is not observed in $p75^{NTR}$ knockout mice (Sotthibundhu et al. 2009). Moreover, an increase in the proliferation activity of $p75^{NTR}$-positive SVZ precursors has been described in rats subjected to experimental allergic encephalomyelitis, a demyelinating disease widely used as an experimental model for human multiple sclerosis (Calzà et al. 1998). In the SGZ, $p75^{NTR}$ is expressed in dividing SGZ cells (Okano et al. 1996; Bernabeu and Longo 2010), and it seems to participate in adult hippocampal neurogenesis as neurogenic potential is reduced in the SGZ of $p75^{NTR}$ knockout mice (Bernabeu and Longo 2010; Colditz et al. 2010), maybe due to reduced survival of neuroblasts (Catts et al. 2008). Neurogenesis can also take place in different regions of the nervous system in response to injury. This is the case of the adult dorsal root ganglia, in which a subpopulation of glia may play a role in neurogenesis after peripheral nerve injury. These cells express $p75^{NTR}$, and in vitro they have been reported to form neurospheres (Li et al. 2007). Neurogenesis in the striatum in response to focal cerebral ischemia can be also potentiated by $p75^{NTR}$ since the proportion of neurons incorporating BrdU was increased in this paradigm (Zhu et al. 2011).

3.2 Neuronal Tetraploidy

The acquisition of multicellularity in evolution has allowed the emergence of the somatic lineage, in which genomic modifications may occur without transmission to the descendants. These genomic alterations, including somatic polyploidy, may participate in the differentiation of specific tissues. This is the case, for instance, of the liver and heart in vertebrates, which have both been shown to contain polyploid cells (Anatskaya and Vinogradov 2007).

Examples of somatic polyploidy in neurons have been described in some invertebrates (Coggeshall et al. 1970: Manfredi Romanini et al. 1973). In contrast, the presence of polyploid neurons in the vertebrate nervous system has been under controversy for decades (see Swartz and Bhatnagar 1981). It was not until the advent of modern techniques such as fluorescent in situ hybridization, flow cytometry, slide-based cytometry, and quantitative PCR analysis of nuclear DNA that the classical belief that all vertebrate neurons contain a diploid DNA amount (Swift 1953) was challenged. Recent analyses, for instance, have proved that 10 % of cortical neurons display a more than diploid DNA content in humans (Mosch et al. 2007). In this regard, tetraploid neurons have been shown to exist in different neural structures (López-Sánchez et al. 2011) including the normal vertebrate retina. In this latter tissue, tetraploid neurons constitute a subpopulation of RGCs that, in the chick, innervate lamina F in the stratum-griseum-et-fibrosum-superficiale of the tectal cortex (Morillo et al. 2010). In the retina, tetraploid RGCs are generated as they migrate to the ganglion cell layer, soon after they undergo their final mitosis and acquire neuronal markers (Morillo et al. 2010). During this stage differentiating RGCs express $p75^{NTR}$ and a subpopulation of these neurons incorporates BrdU, thus becoming tetraploid

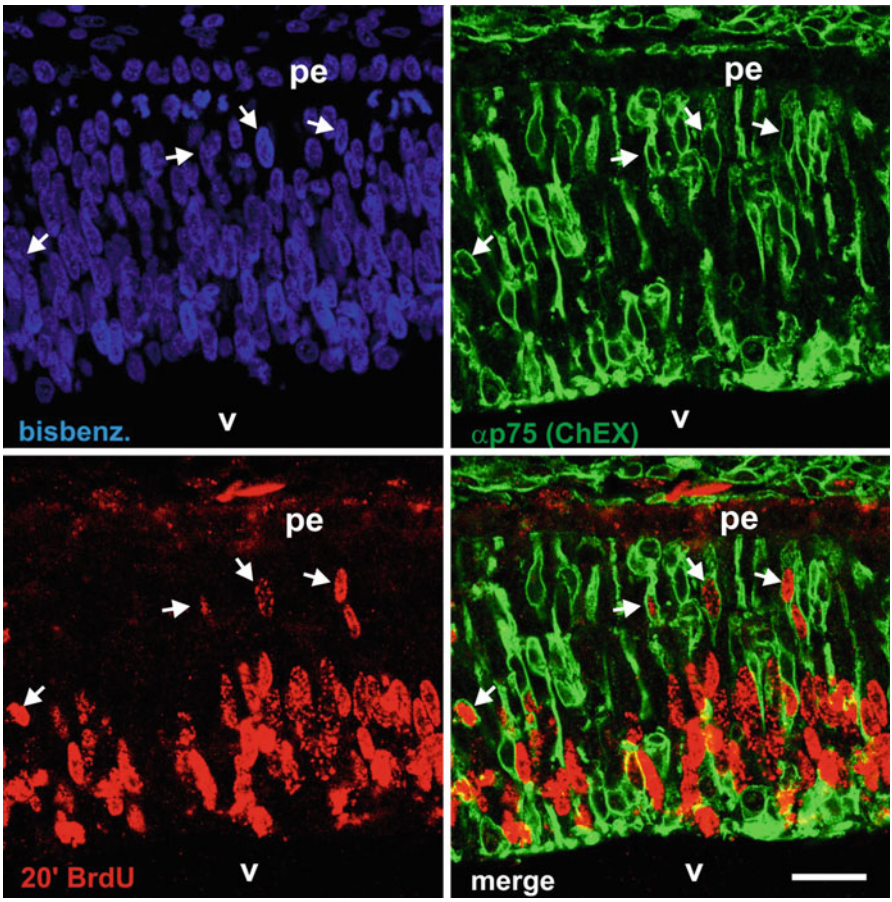

Fig. 3 Colocalization of $p75^{NTR}$ and BrdU in apically located cells from the E6 chick retina. Embryos were treated for 15 min with 40 μl of a solution containing 10 μg/ml BrdU and then fixed. Sagittal sections through the E6 chick retina were obtained, and they were subsequently immunostained with the ChEX anti-$p75^{NTR}$ antibody (*green*) and an anti-BrdU antibody (*red*) as previously described (López-Sánchez et al. 2011). $p75^{NTR}$ is expressed by BrdU-positive cells with nuclei located at the apical portion of the neuroepithelium (*arrows*). Nuclei were labeled with bisbenzimide (*Bisb.*). Abbreviations: *pe* pigment epithelium, *v* vitreous body. Bar, 18 μm

throughout an endoreduplicative mechanism (Morillo et al. 2010; see also Fig. 3). Our work has demonstrated that DNA duplication in differentiating RGCs is triggered by NGF through $p75^{NTR}$, since blocking antibodies against these molecules were able to prevent cell cycle reentry (Morillo et al. 2010). BrdU incorporation in neural progenitor cells expressing $p75^{NTR}$ can also be observed in other neural structures of the chick embryo such as the spinal cord (López-Sánchez et al. 2011) or the telencephalon (Fig. 2b). Although further analyses are still needed to demonstrate that these $p75^{NTR}$-positive cells are equivalent to those neurons

becoming tetraploid in the retina (Morillo et al. 2010), these results suggest that the participation of $p75^{NTR}$ in neuronal tetraploidization is a general feature of the developing vertebrate nervous system.

Somatic polyploidy can be generated by different mechanisms usually linked to alterations of the mitotic cycle, including endoreduplication (i.e., a modified version of the cell cycle characterized by S phase without mitosis) and endomitosis (i.e., a mitotic cycle in the absence of anaphase/cytokinesis thus resulting in genomic DNA duplication) (Edgar and Orr-Weaver 2001; Ullah et al. 2009). Tetraploid RGCs are originated in the developing retina through an endoreduplicative cycle since they remain in a G2-like state after replicating their nuclear DNA (Morillo et al. 2010). Evidence exists that the neurotrophin BDNF, through its receptor TrkB, fulfills a critical role in preventing G2/M transition in retinal tetraploid neurons. Indeed, blockade of endogenous BDNF resulted in an increase of differentiating RGCs undergoing mitosis (Morillo et al. 2010). Therefore, neurotrophins, including NGF and BDNF, seem to play a critical role in neuronal tetraploidization in vertebrates. Tetraploid neurons that undergo mitosis finally die (Frade 2000; Morillo et al. 2010; López-Sánchez et al. 2011), and the regulation of the G2/M transition in these cells is likely crucial for removal of specific neuronal types during development (Frade et al. 1997), thus adjusting the ratio between tetraploid and diploid neurons in specific areas. Importantly, this process may be involved in neuronal death associated to neurodegenerative diseases (see below).

Polyploidy is usually linked to enlarged cell size (Edgar and Orr-Weaver 2001; Ullah et al. 2009), a concept that can be extrapolated to the vertebrate nervous system. For instance, neuronal hypertrophy has been shown to occur in tetraploid strains of Xenopus laevis, whose neurons contain significantly enlarged cell somas and dendrites (Szaro and Tompkins 1987). As expected, our studies have revealed that tetraploid RGCs show enlarged cell somas and dendritic arbors (Morillo et al. 2010), suggesting that somatic tetraploidy is associated with morphological and functional diversity in the nervous system.

4 $p75^{NTR}$ in Neurodegeneration: The Tetraploid Connection

Cell cycle reentry in neurons represents a critical feature of both acute neuronal damage and chronic neurodegenerative diseases (Wang et al. 2009). In this regard, cell cycle regulators have been proposed as therapeutic targets for stroke (Osuga et al. 2000), excitotoxicity (Verdaguer et al. 2004), trauma (Di Giovanni et al. 2005), and Alzheimer's disease (Woods et al. 2007).

In cases of acute injury to the CNS such as kainic acid excitotoxicity and trauma, cell cycle reentry is usually stopped at the G1/S phase and it leads to rapid apoptosis (Kuan et al. 2004; Byrnes et al. 2007). In contrast, chronic neurodegenerative diseases are normally associated with DNA synthesis in particular neuronal populations, which can be arrested at the G2/M transition and survive for some time before dying by apoptosis. This is the case, for instance, of neurons subjected to ischemia-hypoxia (Byrnes et al. 2007; Burns et al. 2007).

These neurons incorporate BrdU and remain alive for days, before they die. Examples of cell cycle reentry and hyperploidization have also been shown to occur in Alzheimer's disease (Yang et al. 2001; Mosch et al. 2007; Arendt et al. 2010). Furthermore, increased expression in neurons of cell cycle regulators involved in G1/S transition has been described in patients suffering amyotrophic lateral sclerosis (Ranganathan and Bowser 2003, 2010; Ferraiuolo et al. 2007), Parkinson's disease (Höglinger et al. 2007), Huntington's disease (Pelegrí et al. 2008; Fernandez-Fernandez et al. 2011), and different tauopathies (Stone et al. 2011). Furthermore, the Parkin2 gene, known to be a frequent cause of early-onset Parkinson's disease, is a tumor suppressor gene whose inactivation results in an increase in cyclin E levels (Veeriah et al. 2010). Neuronal cell cycle reentry in pathological states has often been interpreted as de novo adult neurogenesis (Fallon et al. 2000; Arvidsson et al. 2002; Curtis et al. 2003; Becker et al. 2007). Nevertheless, this conclusion has been proved to be erroneous in some cases. For instance, the use of conditional transgenic mice expressing EGFP under the control of the nestin promoter allowed Burns et al. (2007) to demonstrate that ischemia-hypoxia-dependent BrdU incorporation mostly occurs in differentiated neurons.

In the adult nervous system, $p75^{NTR}$ is reexpressed in various neuropathological conditions, including Alzheimer's disease (Hu et al. 2002), amyotrophic lateral sclerosis (Lowry et al. 2001), Parkinson's disease (Chen et al. 2008), and Huntington's disease (Zuccato et al. 2008), likely participating in the etiology of neurodegeneration (Dechant and Barde 2002). $p75^{NTR}$ is therefore a candidate for the induction of cell cycle reentry leading to tetraploidy in the affected neurons (Frade and López-Sánchez 2010). Since developmentally regulated tetraploidy in neurons correlates with cell body and dendritic tree enlargement (see above), it is conceivable that a similar effect may occur in adult neurons undergoing de novo tetraploidization, thus explaining, at least partially, the pathological signs of the disease. Structural alterations in neurons becoming tetraploid may correlate with functional changes, including alterations of metabolic activity, higher rate of membrane biosynthesis, changes in neuronal circuits, and alterations in electrical signal propagation (see Frade and López-Sánchez 2010). Furthermore, genome duplication may result in changes of gene expression in particular loci, as those observed in liver and heart cells (Anatskaya and Vinogradov 2007) and tetraploid mouse embryos (Kawaguchi et al. 2009). It is likely that all these alterations associated with tetraploidy in neurons could functionally compromise the affected neurons. Further insights on the molecular mechanisms triggering tetraploidy in neurons will probably be crucial for the design of appropriate therapeutic tools for patients that suffer from neurodegenerative diseases.

5 Conclusion

$p75^{NTR}$ is a pleiotropic receptor that fulfills several critical functions in the nervous system, including the regulation of the cell cycle in both embryonic and adult nervous system. Indeed, $p75^{NTR}$ seems to be involved in stem cell

maintenance, neurogenesis, and neuronal tetraploidization. The molecular mechanisms used by $p75^{NTR}$ to regulate the cell cycle are far from being fully understood, but they are likely based on its capacity to interact with a number of cell cycle regulators, as well as its ability to translocate its intracellular domain to the nucleus to act as a transcriptional regulator. The capacity of $p75^{NTR}$ to regulate the cell cycle has opened new research avenues not only focused on the normal development of the vertebrate nervous system but also related with neuropathological conditions, since deregulation of this receptor in the adult brain could participate in neurodegenerative diseases. It is likely that future research in this field will yield hints of possible therapeutic approaches for these devastating diseases.

p75NTR Processing and Signaling: Functional Role

Ramiro D. Almeida and Carlos B. Duarte

Contents

Abstract

The p75 neurotrophin receptor ($p75^{NTR}$) was the first neurotrophin receptor to be identified and, more than two decades after, significant advances have been made in understanding its biological actions. $p75^{NTR}$ belongs to the tumor necrosis factor receptor superfamily (TNFRS) and is particularly important during developmental neural cell death and under injury conditions in the adulthood. However, recent studies shed new light into the functions of $p75^{NTR}$ in the nervous system. $p75^{NTR}$ either acting autonomously or as part of a complex with other co-receptors regulates neuronal survival and differentiation, cell cycle and proliferation, axonal outgrowth, and synaptic

Axonal growth • Cell cycle • Neuronal death • Neurotrophins • p75NTR • Synaptic plasticity

1 Introduction

The p75 neurotrophin receptor ($p75^{NTR}$) belongs to the tumor necrosis factor receptor superfamily (TNFRS) and was first identified by Shooter and colleagues (reviewed in Herrup and Shooter 1973). $p75^{NTR}$ has an important role in the development of the nervous system and accordingly is mainly expressed during development, decreasing in the adulthood, except in a few selected populations of neurons and under pathological conditions, when it is re-expressed (reviewed in Dechant and Barde 2002). It should also be emphasized that $p75^{NTR}$ has critical roles in glial biology and outside the nervous system, namely, in the immune and vascular systems.

All known mammalian neurotrophins, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin 4/5 (NT-4/5), bind to $p75^{NTR}$ with similar affinities. However, they bind their cognate tropomyosin-related kinase (Trk) receptor with different specificities. Generally, NGF binds TrkA, BDNF and NT-4/5 activate TrkB, and NT-3 recognizes TrkC, and this selectivity is believed to promote neuronal survival and differentiation in distinct populations of neurons (reviewed in Lu et al. 2005). Neurotrophins can also induce cell death by activating $p75^{NTR}$ and this causes an apparent contradiction. The latter effects are mediated by proneurotrophins, the immature uncleaved form, which bind $p75^{NTR}$ with relatively higher affinity than to Trk receptors, thereby promoting cell death. Accordingly, the mature forms of neurotrophins preferentially bind Trk receptors (Lee et al. 2001; Teng et al. 2005). This specificity is achieved through the formation of molecular complexes with different co-receptors. While mature neurotrophins bind to a complex of $p75^{NTR}$ and Trk, the proforms preferentially bind to a complex of $p75^{NTR}$ and Sortilin, another type I transmembrane protein, but structurally unrelated to $p75^{NTR}$ (reviewed in Nykjaer et al. 2005). This feature reveals a distinctive characteristic of $p75^{NTR}$: signaling independently and in conjunction with its co-receptors. The best studied $p75^{NTR}$ partner is the Trk receptor, and the molecular basis of their interaction has been extensively studied. $p75^{NTR}$ is able to form complexes with TrkA, TrkB, and TrkC, altering its affinity and signaling properties (reviewed in Chao 2003). Recent studies revealed new roles for $p75^{NTR}$ in the nervous system and along with it new co-receptors and cytosolic interactors were described. In fact, $p75^{NTR}$ was described to regulate additional aspects of neuronal development like axonal growth, cell cycle, and synaptic plasticity (reviewed in Ibanez and Simi 2012). Although exciting, these novel observations raise the question of how $p75^{NTR}$ signaling specificity is achieved

with a relatively high number of signaling partners. It is believed that such specificity of $p75^{NTR}$ actions is likely to be dependent on the developmental and cellular context in which the receptor is integrated.

2 Expression: Isoforms and Co-receptors

The $p75^{NTR}$ is widely expressed in the nervous system during development. In the developing CNS, the $p75^{NTR}$ is present in spinal motor neurons and brain stem motor nuclei, lateral geniculate nucleus, medial terminal nucleus of the accessory optic tract, ventral and dorsal cochlear nucleus, thalamic nucleus, nucleus of the lateral lemniscus, amygdala, cortical subplate neurons, olivary pretectal nucleus, cuneate nucleus, and gracile nucleus, in addition to Purkinje neurons and the external granule layer and deep nuclei of the cerebellum (Buck et al. 1988; Ernfors et al. 1988; Heuer et al. 1990; Schatteman et al. 1988). In the adult nervous system, the $p75^{NTR}$ is found mainly within the basal forebrain (Hefti et al. 1986; Schatteman et al. 1988; Springer et al. 1987; Yan and Johnson 1988), and lower expression levels are observed in the caudate/putamen neurons (Henry et al. 1994), cerebellar Purkinje neurons (Cohen-Cory et al. 1991; Koh et al. 1989; Mufson et al. 1991; Shelton and Reichardt 1986), motor neurons (Armstrong et al. 1991; Ernfors et al. 1989), and within several central nuclei (Cohen-Cory et al. 1991; Koh et al. 1989; Schatteman et al. 1988; Shelton and Reichardt 1986; Sofroniew et al. 1989). $p75^{NTR}$ is expressed in neurons and glia (Cragnolini and Friedman 2008), and their expression is induced by many types of injury, including transient forebrain or global cerebral ischemia (Junier et al. 1994; Lee et al. 1995; Oderfeld-Nowak et al. 2003), in ischemia induced by cortical devascularization (Angelo et al. 2009), and in the brain of rats subjected to pilocarpine-induced seizures (Roux et al. 1999; Unsain et al. 2008) [for a detailed review see Ibanez and Simi (2012)]. In the peripheral nervous system, the $p75^{NTR}$ is expressed in dorsal root ganglia sensory neurons as well as in a subpopulation of enteric and parasympathetic neurons (Carroll et al. 1992; Schatteman et al. 1993; Verge et al. 1992; Yan and Johnson 1988). Axotomy of peripheral motor neurons, resembling the lesions resulting from severe traumatic injuries of the limbs, was also shown to upregulate $p75^{NTR}$ expression in adult animals (Ferri et al. 2002). Furthermore, $p75^{NTR}$ is present outside the nervous system, where the highest expression of the receptor is found (reviewed in Barker 1998).

The $p75^{NTR}$ belongs to the tumor necrosis factor family of receptors (TNFR), comprising an extracellular region with four cysteine-rich domains, each with six cysteine residues, a single transmembrane domain, and the intracellular region. The latter region contains two domains that are able to mediate intracellular signaling, the Chopper domain and the death domain homologous to that present in the TNFR family (reviewed in Skeldal et al. 2011). The Chopper domain is a juxtamembrane region with the ability to induce cell death when bound to the membrane (Coulson et al. 2000; Underwood et al. 2008) (Fig. 1). The $p75^{NTR}$ can bind all four neurotrophins (NGF, BDNF, NT3, and NT4/NT5) (Rodriguez-Tebar et al. 1992;

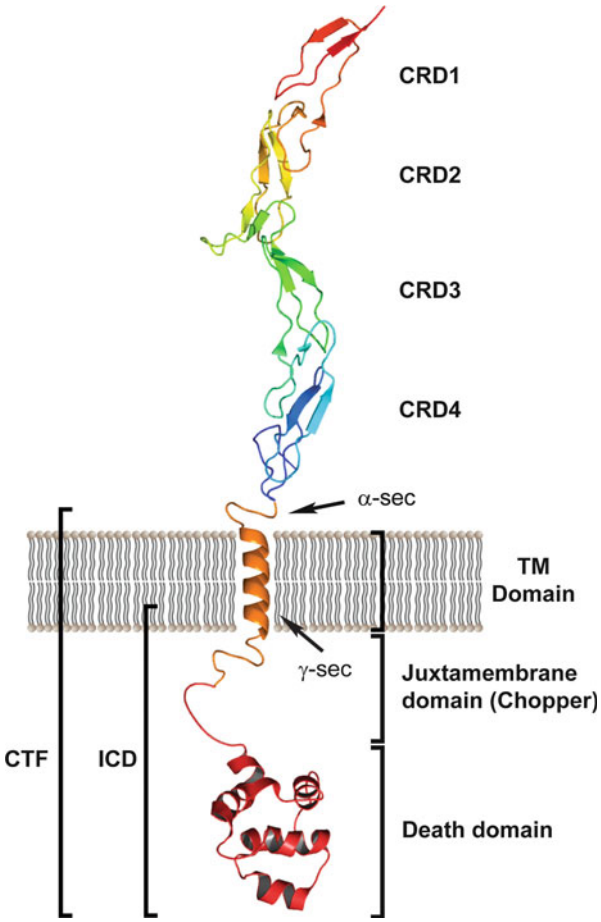

Fig. 1 $p75^{NTR}$ protein structure. $p75^{NTR}$ has an extracellular domain with four cysteine-rich repeats, characteristic of TNFR superfamily members, a transmembrane domain, and an intracellular death domain. Neurotrophins bind to cysteine-rich domains 2–4, which are coded in Exon III, leading to a conformational change that ultimately results in the recruitment and activation of downstream signaling pathways. The *black arrows* indicate the sites of α- and γ-secretase cleavage (regulated intramembrane proteolysis). Abbreviations: *CRD* cysteine-rich domain, *TM domain* transmembrane domain, *CTF* C-terminal fragment, *ICD* intracellular domain

Ryden et al. 1995; Urfer et al. 1994), as well as to proNGF and proBDNF (Lee et al. 2001; Teng et al. 2005). The crystal structure of the extracellular domain of $p75^{NTR}$ complexed with NGF (Aurikko et al. 2005) or NT3 (Gong et al. 2008) showed a symmetrical 2:2 receptor-ligand complex. However, a different study reported that $p75^{NTR}$ binds NGF in a 1:2 stoichiometry (He and Garcia 2004), which may correspond to an intermediate step before a symmetrical 2:2 receptor-ligand complex is formed. The $p75^{NTR}$ forms dimers even in the absence of neurotrophins through cysteinyl residues within the transmembrane domain, and it was proposed that the interaction of the neurotrophins with the receptor complex induces a conformational change in the $p75^{NTR}$ intracellular domain which may allow the recruitment of the effector molecules NRIF and TRAF6 (Vilar et al. 2009a, b). The activation of $p75^{NTR}$ by all neurotrophins contrasts with the more stringent specificity of the Trk family of receptors for neurotrophins.

The biological effects of proNGF and proBDNF mediated by activation of $p75^{NTR}$ require the co-receptor sortilin which interacts with the prodomain of the

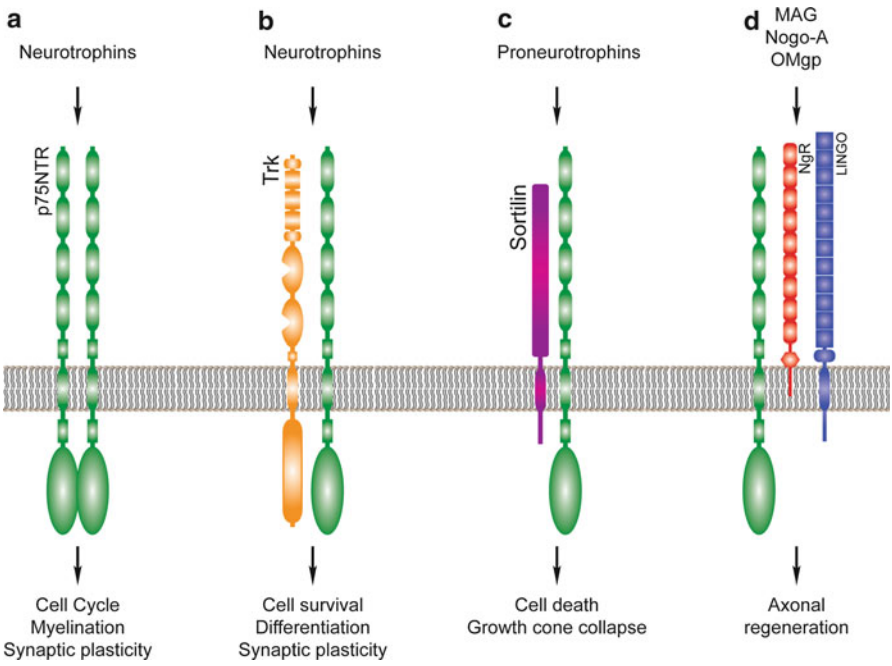

Fig. 2 $p75^{NTR}$ co-receptor complexes and their biological function. To date, $p75^{NTR}$ was shown to interact with a diversity of receptors, namely, Sortilin, LINGO-1, NgR, and Trk receptors. The outcome of these interactions is a variety of cellular responses including cell death, synaptic plasticity, neurite outgrowth and cell cycle regulation. The C-terminal fragment of $p75^{NTR}$ can also bind other cytosolic interactors (not depicted here), increasing the diversity and complexity of signaling mechanisms that are regulated by this receptor. Abbreviations: *MAG* myelin-associated glycoprotein, *OMGP* oligodendrocyte myelin glycoprotein

neurotrophins (Nykjaer et al. 2004; Teng et al. 2005) (Fig. 2c). However, it is still not yet clear whether each prodomain of the dimeric neurotrophin molecules binds to a different sortilin molecule or whether two prodomains bind to the same sortilin protein (Feng et al. 2010). During development, sortilin is expressed in the brain cortex, hippocampus, and neural retina, and this pattern is preserved in the adulthood, when the protein is particularly abundant in pyramidal cells of the hippocampus (Hermans-Borgmeyer et al. 1999; Sarret et al. 2003). Activation of the $p75^{NTR}$/sortilin complex by proNGF or proBFNF was shown to induce apoptotic cell death in cultured sympathetic neurons, but this effect was not observed in cells derived from mice lacking $p75^{NTR}$ or in the presence of the sortilin antagonist neurotensin (Nykjaer et al. 2004; Teng et al. 2005).

A truncated isoform of $p75^{NTR}$ has been described, resulting from alternative splicing and lacking the cysteine-rich repeats 2, 3 and 4 (s-$p75^{NTR}$) (Paul et al. 2004; von Schack et al. 2001), which are required for neurotrophin binding (Aurikko et al. 2005; Feng et al. 2010; Gong et al. 2008; He and Garcia 2004). Although these variants are unable to bind neurotrophins, they may regulate cellular activity by

interacting with some of the intracellular signaling proteins regulated by the full-length $p75^{NTR}$. Furthermore, a neurotrophin receptor homologue-2 (NRH2, also termed PLAIDD or NRADD) was described, which lacks the ligand-binding domain present in the $p75^{NTR}$ but has some similarity with its transmembrane, juxtamembrane and the death domain regions (Kanning et al. 2003; Murray et al. 2004). The expression of NRH2 receptors is developmentally regulated, decreasing in adult tissues (Frankowski et al. 2002; Wang et al. 2003). Although the homology between $p75^{NTR}$ and NRH2 suggests that it may act as a functional analogue of the s-$p75^{NTR}$, the differences between the intracellular domains of the two receptor proteins may provide some specificity in the biological activity of NRH2 receptors (Kim and Hempstead 2009). NRH2 facilitates the formation of a complex between $p75^{NTR}$ and sortilin, and was proposed to act by impairing the degradation of sortilin in the lysosomes and by redistributing sortilin to the surface (Kim and Hempstead 2009). However, additional studies are required to determine the stoichiometry of the interactions between $p75^{NTR}$, sortilin, and NRH2.

In addition to its signaling activity, the $p75^{NTR}$ may also interact with the TrkA (Huber and Chao 1995), TrkB, and TrkC receptors (Bibel et al. 1999), thereby modulating their activity. In particular, the $p75^{NTR}$/TrkA complexes show an increased affinity for NGF when compared with each one of the receptors expressed independently (Hempstead et al. 1991), and the co-expression of the two classes of receptors allows TrkA-mediated responses at lower concentrations of NGF (Horton et al. 1997; Lee et al. 1994). The TrkA and $p75^{NTR}$ were shown to interact through their intracellular domains even before NGF stimulation, and this association may contribute to the observed high-affinity NGF-binding sites (Iacaruso et al. 2011).

3 $p75^{NTR}$ Proteolysis and Signaling in Cell Death and Survival

The absence of catalytic activity in the $p75^{NTR}$ intracellular region suggests that the intracellular signaling activity is mediated by binding partners that may be recruited upon receptor activation and/or constitutively bound. In fact, more than 20 different intracellular binding partners of $p75^{NTR}$ were identified up to now (Barker 2004; Bronfman and Fainzilber 2004; Dechant and Barde 2002; Roux and Barker 2002; Schecterson and Bothwell 2010).

Initial studies showed a role for $p75^{NTR}$ in the facilitation of survival signals induced by Trk receptors, activated by the mature form of neurotrophins, and this effect has been attributed to an increase in the affinity of the Trk receptor for the ligand (Roux and Barker 2002) (Fig. 2b). Furthermore, $p75^{NTR}$ increases the specificity of Trk receptors for particular ligands, which may change the pattern of signaling response to stimulation by each neurotrophin (Clary and Reichardt 1994). The mechanism whereby $p75^{NTR}$ increases Trk receptor activity has not been elucidated, but should involve the intracellular region of the receptor since extracellular domain mutations of $p75^{NTR}$ proteins also allow the formation of

high-affinity Trk binding sites (Esposito et al. 2001). This is supported by results obtained with Förster resonance energy transfer showing that $p75^{NTR}$ and TrkA receptors physically interact through their intracellular domains, even before stimulation with NGF (Iacaruso et al. 2011). A model was proposed according to which Trk receptor activation leads to activation of the transmembrane cysteine protease α-secretase tumor necrosis factor-α converting enzyme/a disintegrin and metallopeptidase domain (TACE/ADAM) 17 by MEK-dependent phosphorylation, which is followed by $p75^{NTR}$ cleavage. TACE/ADAM17 displays α-secretase activity, cleaving $p75^{NTR}$ in the extracellular juxtamembrane domain, releasing the extracellular domain and giving rise to a product that remains anchored at the membrane. According to this model, the $p75^{NTR}$ cleavage product feeds back to enhance Trk-induced neurotrophin signaling, thereby increasing ERK and Akt activity which enhance cell survival (Ceni et al. 2010; Kommaddi et al. 2011). Whether the $p75^{NTR}$ cleavage products directly interact with Trk receptors to increase the affinity for ligands remains to be elucidated.

The $p75^{NTR}$ may also be coupled to cell death when activated by proneurotrophins, and in this case, sortilin has been shown to act as a co-receptor, increasing the affinity of $p75^{NTR}$ for the ligand (Nykjaer et al. 2004). Sortilin interacts with the prodomain of neurotrophins, and the signaling that leads to cell death may occur in the absence or in the presence of Trk receptors. The role of $p75^{NTR}$ and sortilin in proneurotrophin-induced cell death is supported by studies showing that antibodies against sortilin, $p75^{NTR}$, or proNGF protect cells from apoptotic death (Beattie et al. 2002; Nykjaer et al. 2004; Volosin et al. 2006, 2008). Furthermore, an excess of the prodomain of proNGF or neurotensin, which also binds sortilin (Quistgaard et al. 2009), inhibits proNGF-induced cell death (Jansen et al. 2007; Nykjaer et al. 2004; Rogers et al. 2010; Volosin et al. 2006).

An interesting feature of $p75^{NTR}$ function is its ability to undergo proteolysis with the generation of fragments with signaling capability. $p75^{NTR}$ proteolysis was described to be required for cell survival (addressed below), cell migration, neurite growth inhibition, and cell cycle. In fact, several intracellular domain interactors that regulate cell cycle, like Schwann cell factor-1 (Sc-1), brain-expressed X-linked 1 (Bex1), and melanoma antigen gene (MAGE), have been found in the nucleus after $p75^{NTR}$ activation (reviewed in Skeldal et al. 2011), but $p75^{NTR}$ regulated intramembrane proteolysis (RIP) has been best studied in neuronal death. The process of $p75^{NTR}$ proteolytic cleavage occurs through the sequential action of two distinct proteins. First, the extracellular domain (ECD) of $p75^{NTR}$ is cleaved by TACE/ADAM17, generating a membrane-bound C-terminal fragment (CTF). The CTF undergoes a second cleavage by the presenilin-dependent γ-secretase, releasing the intracellular domain (ICD) into the cytoplasm (Jung et al. 2003; Kanning et al. 2003) (Fig. 3). NRH2 can also undergo proteolytic cleavage, releasing its cytoplasmic domain, which unlike the ICD has higher stability (Kanning et al. 2003).

The $p75^{NTR}$ ICD regulates neuronal cell death in vitro and in vivo. Neurotrophin binding to $p75^{NTR}$ was shown to promote γ-secretase-dependent

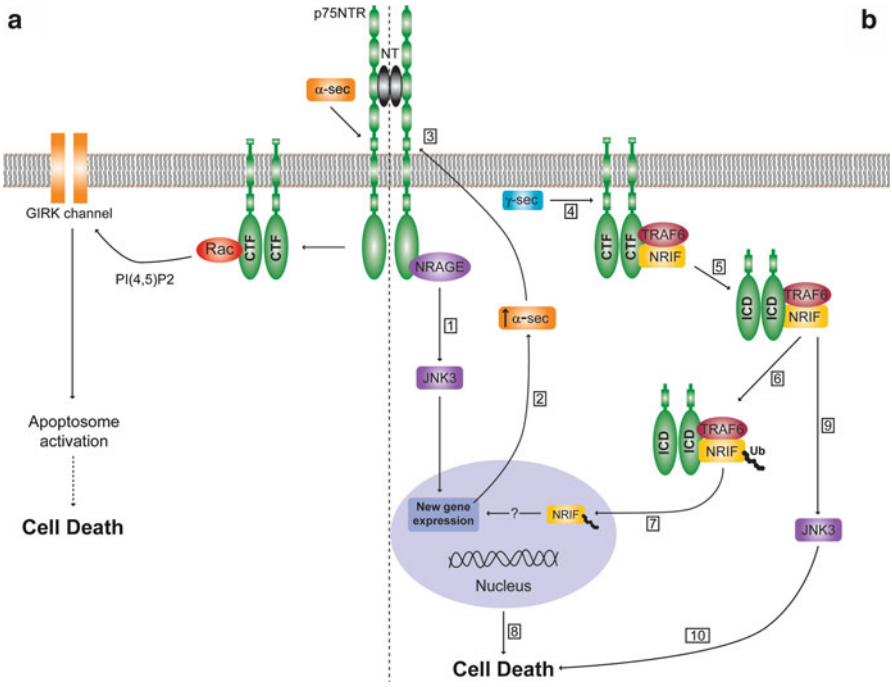

Fig. 3 $p75^{NTR}$ proteolysis and cell death signaling pathways. Regulated intracellular proteolysis of $p75^{NTR}$ leading to neuronal cell death can act through two distinct pathways. (**a**) In one model, the 29 amino acid intracellular juxtamembrane region of $p75^{NTR}$ named "chopper" induces cell death through activation of G-protein-coupled inwardly rectifying potassium (GIRK/Kir3) channels. The corresponding potassium efflux supposedly leads to apoptosome activation and by consequence neuronal cell death. (**b**) In another model $p75^{NTR}$ activates JNK 3 (*1*), which leads to the transcription-dependent upregulation of α-secretase (*2*) that cleaves $p75^{NTR}$ extracellular domain (*3*). γ-secretase releases the ICD into the cytoplasm (*4*) which associates with the DNA-binding protein NRIF and the E3 ubiquitin ligase TRAF6 (*5*). The formation of this ternary complex leads to TRAF6-dependent ubiquitination of NRIF (*6*) and nuclear translocation (*7*), a process required for $p75^{NTR}$-dependent cell death (*8*). In parallel, this ternary complex further activates JNK3 (*9*), amplifying the apoptotic signal (*10*). Abbreviations: *JNK3* c-Jun N-terminal kinase 3, *NRAGE* neurotrophin-receptor-interacting MAGE (melanoma-associated antigen) homologue

cleavage, with the cytosolic release of ICD and subsequent nuclear translocation (Frade 2005; Kenchappa et al. 2006). The complete picture is however considerably more complicated and involves a dual-phase signaling mechanism. Stimulation of the receptor with BDNF induces the activation of JNK3, leading to the upregulation of TACE/ADAM17 by a transcription-dependent mechanism (Kenchappa et al. 2010). The $p75^{NTR}$ is first cleaved by TACE/ADAM17 and then by the γ-secretase complex, releasing the intracellular domain (ICD) of the receptor and allowing the translocation of neurotrophin-receptor-interacting factor (NRIF) to the nucleus. The $p75^{NTR}$ ICD can also translocate to the nucleus

where it regulates gene expression (Parkhurst et al. 2010). The nuclear translocation of NRIF depends on its polyubiquitination mediated by the E3 ubiquitin ligase TRAF6, and is necessary for $p75^{NTR}$-mediated apoptosis (Geetha et al. 2005; Kenchappa et al. 2006). In addition, the ICD/TRAF6/NRIF complex can activate JNK3 directly further amplifying the cell death cascade (Fig. 3b). NRIF nuclear translocation seems to be of particular importance in the period of naturally occurring superior cervical ganglion (SCG) neuron death since this protein is observed in the nucleus of SCG neurons at postnatal day 4 but not at postnatal day 24, a developmental time point when neuron elimination has diminished (Kenchappa et al. 2010). How the nuclear translocation of NRIF induces apoptosis has not yet been elucidated, but considering that NRIF is a zinc finger DNA-binding protein, it may act through altering the expression of proapoptotic genes (Kenchappa et al. 2006). NRIF was also shown to mediate the apoptotic signaling initiated by $p75^{NTR}$ in hippocampal neurons after pilocarpine-induced seizures (Volosin et al. 2008). The protein NRAGE (neurotrophin-receptor-interacting MAGE homolog), a member of the MAGE (melanoma antigen) family, also interacts with the $p75^{NTR}$ intracellular region, facilitating the receptor-induced apoptotic death (Salehi et al. 2000). The effects of NRAGE are mediated by stimulation of JNK and c-Jun, which is followed by the cytochrome C release from the mitochondria, and activation of caspases–9, –3, and –7 to induce cell death (Salehi et al. 2002).

Under certain conditions, the C-terminal fragment of $p75^{NTR}$ resulting from metalloprotease cleavage may induce cell death without additional cleavage by γ-secretase to generate the ICD (Coulson et al. 2000, 2008; Underwood et al. 2008). The $p75^{NTR}$ CTF contains a cytoplasmic juxtamembrane sequence of 29 amino acids that is both necessary and sufficient to trigger cell death (Coulson et al. 2000). According to the model proposed, the cleavage of $p75^{NTR}$ followed by palmitoylation of the CTF causes its translocation to cholesterol-rich domains of the plasma membrane (Underwood et al. 2008). The $p75^{NTR}$ CTF upregulates the production of phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) through activation of Rac, and the locally generated PtdIns(4,5)P_2 activate G-protein-coupled inwardly rectifying potassium (GIRK/Kir3) channels (Coulson et al. 2008) (Fig. 3a). The resulting increase in K^+ permeability with consequent reduction in the $[K^+]_i$ may contribute to induce the apoptotic pathway. However, additional studies are required to determine under which conditions this pathway is active in vivo and how the CTF- and the ICD-mediated pathways are differentially regulated.

In addition to the activation of apoptotic signaling pathways, $p75^{NTR}$ may also be coupled to the induction of cellular alterations that prevent the trophic effects of Trk neurotrophin receptors, thereby contributing to cell death. Such a mechanism was described in basal forebrain neurons, one of the few CNS populations that express $p75^{NTR}$ throughout life. Stimulation of $p75^{NTR}$ with proNGF upregulates PTEN (phosphatase and tensin homolog deleted on chromosome 10) in basal forebrain neurons, a protein known to antagonize the activation of Akt by PI3-K. When the cells are stimulated simultaneously with proNGF and BDNF, to activate

$p75^{NTR}$ and TrkB receptors, respectively, the inhibition of the TrkB-induced PI3-K signaling by PTEN is sufficient to abrogate the trophic effects of TrkB signaling (Song et al. 2010). Accordingly, inhibition of PTEN was shown to prevent neuronal loss in the hippocampus following pilocarpine-induced seizures, a model of $p75^{NTR}$-mediated neuronal death (Song et al. 2010).

4 Axonal Growth

The antagonistic functions of neurotrophins and their receptors are well depicted in sympathetic neuron growth and target innervations. NGF acting through TrkA induces axonal growth, while BDNF acting on $p75^{NTR}$ inhibits it (Kohn et al. 1999). These evidences are supported in vivo where the pineal gland, a sympathetic target organ, of BDNF −/− mice is hyperinnervated (Kohn et al. 1999). This axonal pruning depends on activity-dependent release of BDNF by the wining axons that in turn acts on $p75^{NTR}$ present in the losing axons, antagonizing NGF/TrkA (Singh and Miller 2005; Singh et al. 2008). This model provides an elegant explanation of how competing axons can promote growth inhibition and axonal degeneration on less favored neighboring axons.

Currently, it is widely accepted that central nervous system (CNS) neurons do not have the ability to regenerate upon injury. Several factors account for this phenomenon such as the scar generation at the injury site, reduced regrowth capability of mature neurons, and myelin-associated inhibitory factors (MAIFs) (Chen et al. 2009). Myelin-derived molecules such as myelin-associated glycoprotein (MAG), oligodendrocyte myelin glycoprotein (oMgp), and Nogo exert their action through a common receptor, the Nogo receptor (NgR) (Fournier et al. 2001), and this effect is mediated by activation of a small G protein, the Ras homologue member A (RhoA) (Niederost et al. 2002; Yamashita et al. 2002). However, NgR is a glycosyl-phosphatidylinositol (GPI)-linked membrane protein, with no cytoplasmic domain and therefore, it is not capable of transducing an appropriate signal upon ligand binding. Subsequently, it was demonstrated that $p75^{NTR}$ is a co-receptor for NgR (Wang et al. 2002; Wong et al. 2002). Neurons from $p75^{NTR}$ knockout mice are no longer responsive to myelin, and blocking NgR-$p75^{NTR}$ interaction has a similar effect (Wang et al. 2002). However, in a reconstituted nonneuronal system, NgR and $p75^{NTR}$ alone are not able to activate RhoA, indicating that an additional molecule or molecules are required. Exogenous expression of a dominant negative LINGO-1 in cerebellar granular neurons reduced myelin inhibition (Mi et al. 2004) (Fig. 2d), indicating LINGO-1 forms a signaling complex with NgR and $p75^{NTR}$.

$p75^{NTR}$ directly regulates RhoA activation. Barde and colleagues demonstrated that neurotrophin binding to $p75^{NTR}$ inhibits RhoA activation, increasing the rate of neurite outgrowth (Yamashita et al. 1999). A similar effect is observed on filopodial dynamics where neurotrophin treatment of retinal or dorsal root ganglion (DRG) neurons leads to a decrease in RhoA activity, which in turns increases filopodial length. On the other hand, when MAIFs bind to $p75^{NTR}$, RhoA is activated and

neurite outgrowth reduced. This effect is mediated by the Rho-GDP dissociation inhibitor (Rho-GDI) which interacts with the cytoplasmic domain of $p75^{NTR}$. Usually, RhoA is bound to Rho-GDI, but the MAG or Nogo proteins facilitate the interaction between $p75^{NTR}$ and Rho-GDI, releasing RhoA (Yamashita and Tohyama 2003), which then leads to actin depolymerization. Additionally, MAG induces α- and then γ-secretase-mediated proteolysis of $p75^{NTR}$ and this cleavage is required for the activation of RhoA and neurite outgrowth inhibition (Domeniconi et al. 2005). However, $p75^{NTR}$ is only expressed in selected populations of mature neurons, raising the question of how myelin inhibitory signals are transduced in $p75^{NTR}$-lacking cells. TROY/TAJ, another TNFR homologue, broadly expressed in postnatal and adult neurons, can also bind NgR and LINGO-1, to form a functional complex and activate RhoA in the presence of myelin inhibitors (Park et al. 2005; Shao et al. 2005). Together, these studies established that $p75^{NTR}$ has a crucial role in axonal regeneration.

It is puzzling why the nervous system would increase the expression of $p75^{NTR}$ when its effects are so deleterious to neurons. Currently, there is no clear answer to this question, but we can speculate that the detrimental effects of $p75^{NTR}$ in neuronal injury could be due to a deregulation of a homeostatic mechanism (reviewed in Ibanez and Simi 2012). In line with this, a recent study in the uninjured adult mice brain showed that myelin acting through $p75^{NTR}$ is responsible for the axonal degeneration of aberrant septal cholinergic axons projecting to the cerebral cortex and hippocampus through the supra-callosal pathway (Park et al. 2010). Interestingly, this effect required BDNF binding to $p75^{NTR}$ since an antibody against BDNF rescued myelin-induced inhibition of axonal growth and axonal degeneration (Park et al. 2010). These results provide an explanation to the intrinsic inability of CNS neurons to regrow on myelin inhibitory substrates.

$p75^{NTR}$ also regulates growth cone collapse. Recently, it was shown that proNGF induces growth cone collapse in cultured hippocampal neurons. Binding of proNGF to a $p75^{NTR}$ and sortilin-related VPS10 domain-containing receptor 2 (SorCS2) complex decreases Rac activity and inactivates fascin, an actin-bundling protein, regulating actin dynamics (Deinhardt et al. 2011). A single nucleotide polymorphism (SNP) is present on the 5′ proBDNF sequence at codon 66, producing an amino acid substitution (Val66Met). In humans, the Met66BDNF was associated with abnormal hippocampal activation and poorer episodic memory (Egan et al. 2003). Interestingly, preliminary studies suggest that recombinant Met66 but not Val66 BDNF prodomain induces growth cone collapse in cultured hippocampal neurons and this effect is dependent on $p75^{NTR}$ and SorCS2 (Anastasia et al. 2013). The authors claim Met66 prodomain is intrinsically disordered with some transient secondary structure. However, it is not clear how proNGF and proBDNF(Val66), which share a high degree of homology in their prodomain, elicit different results.

Recently, $p75^{NTR}$ has been involved in two other systems of axonal guidance, Sema3A and ephrin-A. Eph/ephrins are membrane proteins that regulate neuronal migration, synapse formation, and axon guidance. The eph/ephrin system is divided into class A and B, and they can signal bidirectionally; eph signaling is considered

forward while ephrin signaling is considered reverse (reviewed in Xu and Henkemeyer 2012). Similarly to the Nogo receptor, class A ephrins are GPI-linked proteins and require a co-receptor as a transducing unit. Using retinal ganglion cells (RGCs), a widely used axon guidance model system, O'Leary and colleagues reported that ephrin-As colocalize with $p75^{NTR}$ in retinal axons and this association is required for Fyn phosphorylation upon ephA binding (Lim et al. 2008). Moreover, this requirement is specific to ephrin reverse signaling since eph forward signaling is not affected (Lim et al. 2008). Sema3A is a secreted protein that regulates growth cone collapse and repulsion, and signals through plexins and neuropilins (Pasterkamp 2012). Sema3A was found to increase the co-localization of $p75^{NTR}$ and neuropilin-1 in DRG growth cones, and inhibits the direct association of plexinA4 with neuropilin-1, presumably by sequestering the latter receptor. Less plexinA4/neuropilin-1 complex leads to increased sensitivity of DRG neurons from $p75^{NTR}$ (ExonIII−/−) mice to Sema3A (Ben-Zvi et al. 2007).

5 Regulation of Cell Cycle

The $p75^{NTR}$ is expressed very early during development of the nervous system (Yan and Johnson 1987, 1988), when many precursor cells are still not differentiated and before targeting specific neuronal populations for programmed cell death. The role of $p75^{NTR}$ signaling in the modulation of cell cycle progression has been investigated in vitro and in vivo. Thus, the pheochromocytoma PC12 cells differentiate in response to NGF when stimulated in the G1 phase (but not during the other phases of the cell cycle) (Rudkin et al. 1989), and this effect correlates with the transient surface expression of $p75^{NTR}$ (Ito et al. 2002, 2003; Urdiales et al. 1998). Furthermore, stimulation of $p75^{NTR}$ with NGF was shown to prevent the progression through the G1 phase of the cell cycle in astrocytes (Cragnolini et al. 2009; Cragnolini et al. 2012). Activation of $p75^{NTR}$ was also shown to play a role in BDNF-induced differentiation of neural precursor cells in culture (Hosomi et al. 2003) and may be involved in the development of dendrites by purified subventricular cells cultured in the presence of neurotrophins (Gascon et al. 2005).

In contrast with the differentiating effects described above, $p75^{NTR}$ receptors were shown to mediate the NGF-induced proliferation of mouse embryonic stem cells in culture (Moscatelli et al. 2009). $p75^{NTR}$ is also expressed in adult dentate gyrus progenitor cells, playing a role in the proliferation and/or early maturation of neuronal and glial cells, as well as other cell types (Bernabeu and Longo 2010). Furthermore, in vitro and in vivo studies identified a population of highly proliferative subventricular zone cells in the adult rat, characterized by the expression of $p75^{NTR}$ and showing an increased rate of neuroblast generation in response to BDNF (Giuliani et al. 2004; Young et al. 2007). However, under disease or injury conditions, the potential of these $p75^{NTR}$-expressing cells present in the subventricular zone may be altered, to yield glial progenitors in addition to their neurogenic potential. In patients and in animal models of multiple sclerosis,

the $p75^{NTR}$-positive cells in the subventricular zone may give rise to oligodendrocyte progenitors (Petratos et al. 2004). The amyloid-beta peptide (Aβ), which is accumulated in amyloid plaques and generally recognized as a key feature of Alzheimer's disease, was also shown to stimulate adult SVZ neurogenesis, by a mechanism dependent on the expression of $p75^{NTR}$ by the precursor cells and activation of the receptors through cleavage by metalloproteases (Sotthibundhu et al. 2009). This correlates with the results showing an interaction of Aβ with $p75^{NTR}$ (Yaar et al. 1997, 2002), but was observed mainly in younger animals. Based on these observations, it was suggested that overstimulation of $p75^{NTR}$-positive progenitor cells early in life may lead to the depletion of a pool of stem cells with a consequent downregulation in basal neurogenesis (Sotthibundhu et al. 2009). Excitotoxic stimulation of the adult striatum also induces the expression of the $p75^{NTR}$ protein in astrocytic progenitor cells (Hanbury et al. 2002), and pilocarpine-induced seizures upregulated $p75^{NTR}$ protein levels in neurons and astrocytes (Cragnolini et al. 2009; Cragnolini et al. 2012). Since $p75^{NTR}$ controls the astrocytic proliferation (see above) and its ligand (NGF) is produced by astrocytes under inflammatory conditions (Friedman et al. 1996; Oderfeld-Nowak and Bacia 1994), NGF may have an autocrine or paracrine effect in the regulation of reactive gliosis in vivo after injury.

The diversity of mechanisms contributing to the differential effects of $p75^{NTR}$ and NGF on cell cycle is not fully understood, but these responses are likely to be mediated by the interaction of the receptor with different intracellular proteins under distinct cellular contexts. Several of the $p75^{NTR}$ binding partners are regulators of the cell cycle, and their interaction with the receptors is controlled by ligand binding. The zinc finger protein SC1 interacts with the intracellular region of the $p75^{NTR}$, being translocated to the nucleus following stimulation of COS cells with NGF (Chittka and Chao 1999). SC1 acts as a transcriptional repressor and may interact with histone deacetylases to repress the promitotic genes cyclin E and B, thereby inducing growth arrest (Chittka et al. 2004). The NRAGE (neurotrophin-receptor-interacting MAGE homolog) protein also interacts with the $p75^{NTR}$, and it is thought to compete with TrkA receptors for binding to a juxtamembrane domain of the receptor (Salehi et al. 2000). Interaction of NRAGE with the $p75^{NTR}$ is mediated by a conserved sequence called MAGE homology domain, which also determines the interaction of necdin and MAGE-H1 (two MAGE proteins) with $p75^{NTR}$. The interaction of these two MAGE proteins with the $p75^{NTR}$ is enhanced by ligand stimulation, which may contribute to the recruitment of a signaling complex to induce differentiation (Tcherpakov et al. 2002). Similarly, the $p75^{NTR}$ binding partner NRAGE was shown to facilitate cell cycle exit in HEK293 cells (Salehi et al. 2000). Sall2 also interacts and sequesters $p75^{NTR}$, and activation of TrkA receptors is required to induce the nuclear translocation of the protein with consequent activation of target genes. The induction of $p21^{WAF1/CIP1}$ may mediate the effects of Sall2 on NGF-dependent cell cycle arrest and growth inhibition (Pincheira et al. 2009). In contrast with SC1, MAGE proteins, and Sall2, which induce cell cycle arrest, Bex1 (brain-expressed X-linked 1) competes with the receptor interacting protein 2 (RIP2) for binding to the $p75^{NTR}$, thereby maintaining

proliferation and preventing differentiation. Studies performed in astrocytes, which express $p75^{NTR}$ but not TrkA receptors, showed that NGF attenuates the EGF-induced upregulation of cyclins D1 and E, inhibits the interaction between cyclin D1 and Cdk4, which is required for progression from G1 into S phase, and upregulates cyclin kinase inhibitory proteins (Cragnolini et al. 2012). These evidences indicate that $p75^{NTR}$ receptors may act at different levels to induce cell cycle arrest in a given cell.

6 Synaptic Plasticity

Neurotrophins were found to modulate synaptic transmission and plasticity. Valuable insight came from observing the peripheral nervous system, particularly the heart sympathetic innervation. This system can be reproduced in vitro by co-culturing SGCs neurons with cardiac myocytes where acute application of norepinephrine increases the contraction frequency of myocytes while acetylcholine has the opposite effect (Furshpan et al. 1976). Neurotrophins regulate sympathetic neuron cotransmission by modulating the activity-dependent release of norepinephrine and acetylcholine (Lockhart et al. 1997; Yang et al. 2002). Similarly to other neuronal functions described throughout this chapter, Trk receptors and $p75^{NTR}$ function antagonistically. NGF induces potentiation of excitatory noradrenergic transmission that is mediated by the TrkA receptor (Lockhart et al. 1997), while BDNF induces a shift from excitatory to inhibitory (cholinergic) transmission acting through the $p75^{NTR}$ (Yang et al. 2002). CaMKII acts downstream of $p75^{NTR}$ to control the shift from excitatory to inhibitory transmission since presynaptic inhibition of CaMKII activity or expression of constitutively active CaMKII blocks or mimics BDNF-induced inhibitory transmission respectively (Slonimsky et al. 2006).

Synaptic plasticity in the CNS induced by BDNF has been particularly well studied (Carvalho et al. 2008; Santos et al. 2010). Application of BDNF or NT-3 induced an enhancement of synaptic strength at the Schaffer collateral-CA1 synapses (Kang and Schuman 1995). Accordingly, BDNF regulates long-term potentiation (LTP) in the hippocampus (Figurov et al. 1996; Korte et al. 1996; Patterson et al. 1996) and in the visual cortex (Akaneya et al. 1997; Huber et al. 1998). Application of exogenous BDNF is able to induce LTP in hippocampal slices, and this effect is blocked by BDNF scavengers like BDNF antibodies or TrkB-IgG fusion proteins (Chen et al. 1999; Figurov et al. 1996; Pozzo-Miller et al. 1999). In line with these evidences, BDNF knockout animals show impaired LTP in the CA1 region of the hippocampus, and exogenous BDNF or re-expression of BDNF using a virus-based strategy restored LTP in BDNF-deficient mice (Korte et al. 1996; Patterson et al. 1996). An additional layer of complexity was added when Pang et al. showed tPA is responsible for plasmin-dependent conversion of proBDNF into mature BDNF and this is required for late-phase long-term potentiation (L-LTP) (Pang et al. 2004). However, another study reports proBDNF is rapidly converted intracellularly to mature BDNF and the mature but not the precursor form

is secreted upon stimulation. Moreover, the authors show hippocampal long-term depression (LTD) is unaffected in slices prepared from conditional BDNF KO animals (Matsumoto et al. 2008). The reasons for these conflicting results are still elusive and additional studies are required to clarify these divergent observations.

The opposing roles of $p75^{NTR}$ and Trk receptors in the nervous system led the investigators to ask if the $p75^{NTR}$ could negatively regulate structural and functional plasticity. As hypothesized, $p75^{NTR-/-}$ mice have higher spine density and greater dendritic complexity than wild-type mice. Accordingly, overexpression of $p75^{NTR}$ decreased dendritic complexity and the number of spines (Zagrebelsky et al. 2005). Interestingly the phenotype of p75 (ExonIV−/−) animals, which lack both the FL-p75 and s-p75 isoforms, is more dramatic than the one observed in p75 (EXONIII −/−) animals. The authors claim this could be due to a compensatory effect by the s-p75 isoform (Zagrebelsky et al. 2005). Additionally, Korte and colleagues showed that $p75^{NTR}$-null animals have impaired hippocampal LTD while LTP is unchanged, with the expression levels of GluA2 and GluA3 subunits of the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor in the hippocampus being altered in the $p75^{NTR}$ null animals (Rosch et al. 2005). In line with these studies, proBNDF was shown to induce NMDA-dependent LTD in the hippocampus which is mediated by $p75^{NTR}$ and the GluN2B subunit. Blocking the function of $p75^{NTR}$ or GluN2B abolishes proBDNF enhancement of LTD (Woo et al. 2005). Furthermore, GluN2B-mediated synaptic currents and expression are reduced in the hippocampus of $p75^{NTR-/-}$ mice (Woo et al. 2005). However, at the moment, there is no direct link between $p75^{NTR}$ and NMDA receptors and it remains to be determined if $p75^{NTR}$ regulates the trafficking or endocytosis of GluN2B and/or of GluA2/3. In Xenopus neuromuscular synapses, exogenous proBDNF induces synaptic depression. Moreover, stimulation-induced release of proBDNF from myocytes leads to synaptic depression and retraction and this effect is mediated by presynaptic $p75^{NTR}$ (Yang et al. 2009).

Paralleling the effects attributed to $p75^{NTR}$ in synaptic plasticity has proven more difficult in behavioral animal models. Some studies claim $p75^{NTR}$ null animals have behavioral impairments, particularly deficits in memory task acquisition (Peterson et al. 1999; Wright et al. 2004), while others presented evidences for better spatial learning performance in $p75^{NTR}$ knockout mice when compared to control animals (Barrett et al. 2010; Greferath et al. 2000). The different genetic background of the animals used in these studies could account for the conflicting results, but further investigation is required to reconcile this discrepancies. Taken together, these results show that $p75^{NTR}$ has a role in activity-dependent synaptic plasticity.

7 Conclusion

Although $p75^{NTR}$ was the first neurotrophin receptor to be identified, for many years, it stood in the shadow of the Trk receptor with a mere supporting role. We now know that $p75^{NTR}$ plays a major role in the nervous system, especially during development and in injury scenarios, but with the latest developments, we face the

risk of this vision also becoming outdated. Recent studies provided a fresh new look into $p75^{NTR}$ function, for example, the diversity of mechanisms induced to promote cell cycle arrest in a given cell, its role in axonal pruning, and the specificity of neural connectivity in the adult brain (Park et al. 2010; Singh et al. 2008). Also, unforeseen $p75^{NTR}$ partners and consequently new functions were identified, adding new layers of complexity to $p75^{NTR}$ function. It will be of the outmost importance to design experiments to understand how these different ligands, co-receptors, and cytosolic interactors, acting through the same receptor, activate the specific signaling pathways that are responsible for the variety of physiological functions attributed to the $p75^{NTR}$. It is tempting to speculate that the different microdomains within a neuronal cell could provide the most needed functional specificity but this is unlikely to be the sole answer to this question. A major challenge will be to understand the spatial and temporal expression patterns of $p75^{NTR}$, its co-receptors, homologues, and intracellular partners, to have an integrative view of $p75^{NTR}$ function in the nervous system.

Abstract

The p75 neurotrophin receptor (p75NTR) is a pan-receptor for neurotrophins including nerve growth factor, brain-derived neurotrophic factor, neurotrophin-3, and neurotrophin 4/5. P75NTR plays a diverse role from regulating cell survival to modulating neurite outgrowth. Under some pathological conditions, p75NTR expression is activated and plays detrimental roles in disease progression. Alzheimer's disease (AD), the most common form of dementia, is characterized by the deposition of amyloid plaques, accumulation of fibrillary tangles in neurons, neurite degeneration, loss of neurons, and a progressive loss of cognitive function. Recent studies suggest that p75NTR, also a receptor for amyloid-beta (Aβ), is a critical factor involved in the pathogenesis of AD. This chapter is to discuss the roles of p75NTR in the production of amyloid-beta (Aβ), neuronal death, neurite degeneration, tau hyperphosphorylation, cell cycle re-entry, and cognition decline, to propose that p75NTR is a potential target for the development of therapeutic drugs for AD, and to provide perspectives in developing various therapeutic strategies targeting different aspects of AD hallmarks which relate to p75NTR functions, and breaking the p75NTR-mediated positive-feedback loop which promotes the cascades in the pathogenesis of AD.

Keywords

Alzheimer's disease • Amyloid-beta • Cell cycle • Cognition • Extracellular domain • Neurodegeneration • Neuronal death • p75NTR • tau

List of Abbreviations

AD	Alzheimer's disease
APP	Amyloid precursor protein
Aβ	Amyloid-beta
BACE	Beta-site APP-cleaving enzyme
BDNF	Brain-derived neurotrophic factor
CNS	Central nervous system
DRG	Dorsal root ganglion
ECD	Extracellular domain
MAG	Myelin-associated glycoprotein
NBM	Nucleus basalis of Meynert
NGF	Nerve growth factor
NT	Neurotrophin
p75NTR	p75NTR neurotrophin receptor
PNS	Peripheral nervous system
TACE	TNF-alpha converting enzyme
TNF	Tumor necrosis factor
Trk	Tropomyosin receptor kinase

1 Introduction
