The p75 neurotrophin receptor (p75NTR) was first identified about 20 years ago as the receptor for nerve growth factor (NGF) and was subsequently found to be the receptor for all other neurotrophins including brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/neurotrophin-5 (NT-4/NT-5) (Chao and Bothwell 2002; Barker 2004). p75NTR belongs to the tumor necrosis factor receptor superfamily which consists of ten different transmembrane glycoproteins (type I) (Gruss 1996). The role as the pan-receptor for neurotrophins enables p75NTR to play a diverse role in regulating cell survival. It can activate at least three signaling pathways including neuronal growth, apoptosis, and synapse plasticity, and most recently this receptor is also found to be involved in the neuronal cell cycle re-entry, which is considered a key pathological mechanism underlying the development of Alzheimer's disease and other neuronal degenerative diseases. This chapter focuses on the recent progress in understanding the physiological and pathological roles of p75NTR with particular interest in the role of p75NTR in development and intervention of Alzheimer's disease.

2 Biology of p75NTR

2.1 Molecular Biology, Structure, Distribution, and Expression Pattern

The structure of the human p75NTR gene was first described by Santee et al. in 1996 (Santee and Owen-Schaub 1996). It was identified as 19728 base pairs (bp) in size containing six exons and five introns. Sharing an analogous structure and function with the tumor necrosis factor (TNF) receptor, p75NTR is a transmembrane protein that consists of an extracellular domain, a transmembrane domain, and an intracellular domain. The extracellular domain consists of a stalk domain which links the transmembrane domain and four cysteine-rich repeat domains that facilitate neurotrophin binding. There is clear evidence that the third and fourth cysteine repeats are the binding sites for neurotrophins, as the mutant form of p75NTR that lacks these two domains cannot bind neurotrophins. The intracellular part of p75NTR contains an 80-amino acid "death domain" module. It connects the transmembrane domain through a flexible linker region N-terminal domain. The flexibility of the linker domain possibly plays an important role in multiple signal transduction. In addition, the intracellular, cytoplasmic region of p75NTR does not exhibit an intrinsic ligand-inducible enzymatic function, and this is distinctly different from tropomyosin receptor kinase (Trk) receptors. Although p75NTR is a member of the TNF receptor family, there are some differences between p75NTR and other TNF receptors. The death domain of p75NTR is a type-2 molecule, which is different from the type-1 molecules of other TNF receptors. Furthermore, unlike other TNF receptors, p75NTR does not self-associate in solution.

2.2 Expression Location of p75NTR

The p75NTR has a very wide tissue and cellular distribution in a wide range of species and its distribution varies during the different stages of the life. Its expression has been shown at the early developmental stages of the central nervous system (CNS) and peripheral nervous system (PNS). In the developing rat dorsal root ganglion (DRG), p75NTR expression can be found as early as E7 (Ernfors et al. 1988). The receptor was also found to be selectively expressed in the sympathetic ganglia (Buck et al. 1987). In the basal forebrain of the rat, the p75NTR immunoreactivity can be observed as early as E15 (Koh and Loy 1989) and throughout the whole of the adult life (Mufson and Kordower 1992; Hartig et al. 1998). In contrast to the other tissue organs, the expression of p75NTR in these basal forebrain neurons seems to be upregulated during aging while the Trk expression is downregulated (Ginsberg et al. 2006). Interestingly, p75NTR levels tend to be high and widely expressed during development but decrease dramatically in adulthood. In addition, p75NTR can be reexpressed or upregulated to a significant degree in pathological states related to neural cell death or after injury (Barrett and Bartlett 1994). In the adult mouse, p75NTR expression has also been shown to be present in a small subset of spinal cord ascending sensory axons, and in some retinal cells and subsets of dorsal root ganglia, but not the cortex and cerebellum. In addition to neurons, p75NTR is also expressed in a variety of glial tissues such as Schwann cells and oligodendrocytes during development and after injury (Cragnolini and Friedman 2008).

2.3 Physiological Roles of p75NTR and Its Metabolism

In contrast to the Trks receptors, the physiological roles of p75NTR are complicated and difficult to discern. Analysis of the p75NTR function has been complicated by the fact that the major physiological role of p75NTR may change dramatically depending on the cell context. p75NTR is a low-affinity pan-receptor which can functionally collaborate with Trk receptors to either enhance or reduce neurotrophin-mediated Trk receptor activation. The binding of p75NTR and Trks to neurotrophins can trigger several signal transduction pathways, which subsequently promote the survival, differentiation, and development of neuronal cells. In addition to promoting survival of neuronal tissues, another well-established and important functional role of p75NTR is to mediate the apoptosis in normal and pathological conditions. p75NTR has been shown to induce apoptosis in different cell types, including cultured neonatal sympathetic neurons (Bamji et al. 1998), motor neurons (Sedel et al. 1999), sensory neurons (Barrett and Bartlett 1994), oligodendrocytes (Casaccia-Bonnefil et al. 1996), and embryonic proprioceptive neurons when Trk activation is reduced or absent (Davey and Davies 1998). There is evidence indicating that p75NTR is involved in cholinergic neuronal death independent of TrkA expression during development and after injury (Van der Zee et al. 1996; Naumann et al. 2002).

p75NTR has more recently been shown to regulate neurite outgrowth through regulation of RhoA, in some contexts following activation by myelin proteins in conjunction with the Nogo66 receptor (Barker 2004). It can also promote neuronal differentiation and cell cycle. Adult dorsal root ganglion neurons or postnatal cerebellar neurons from mice carrying a mutation in the p75NTR gene are insensitive to MAG with regard to neurite collapse (Yamashita et al. 2002).

Some novel functional roles of p75NTR have been identified recently. NGF stimulates neurite outgrowth from embryonic rat hippocampal neurons and chick ciliary neurons which express p75NTR but not TrkA (Brann et al. 1999). The p75NTR receptor may also be involved in the inhibition of axonal elongation by myelin. In mice lacking p75NTR, aberrant axonal elongation is observed in the myelin-rich area where these axons would not grow (Walsh et al. 1999). These findings suggested that p75NTR may have bidirectional roles in regulating neurite outgrowth (Hasegawa et al. 2004).

In a recent study, a novel p75NTR-interacting protein named Sall2 has been found to link NGF signaling to cell cycle progression and neurite outgrowth (Pincheira et al. 2009).

p75NTR is physiologically cleaved by the enzyme known as TNF-alpha converting enzyme (TACE) in the juxtamembrane domain, to shed the extracellular domain (Weskamp et al. 2004). The exact significance of this process remains unknown. It is possible that the shedded extracellular domain can play an opposing role to negatively regulate the functions of the membrane counterpart, by competitively inhibiting the binding of ligands to membrane p75NTR.

2.4 Signal Pathway of p75NTR Action

p75NTR has a close collaboration with tyrosine kinases receptors. It regulates ligand specificity of Trk receptors and modulates binding affinity of TrkA to NGF (Huang and Reichardt 2003). Although other neurotrophins can interact with TrkB receptors, only BDNF provides a functional response upon co-expression of TrkB with p75NTR. Similarly, both NGF and NT-3 bind to TrkA, but p75NTR restricts TrkA-NGF signaling. In contrast, co-expression of p75NTR and TrkC decreases ligand specificity of TrkC to NT-3.

p75NTR interacts with a dozen of signaling molecules and mediates apoptosis, Schwann cell migration, myelination, axonal growth, and regeneration. The intracellular domain of p75NTR contains several potential motifs which modulates interactions of p75NTR with other proteins, subsequently activating different signaling pathways (Barker 2004; Bronfman and Fainzilber 2004; Dechant and Barde 2002; Roux and Barker 2002) such as NF-κB (Carter et al. 1996), c-jun kinase (JNK) (Friedman 2000; Yoon et al. 1998), and caspases (Troy et al. 2002). In addition, p75NTR activates a small GTPase Rho (Yamashita et al. 1999) involving different ligands derived from myelin, such as myelin-associated glycoprotein (MAG) and Nogo (Wang et al. 2002a; Wong et al. 2002; Yamashita et al. 2002) and two different co-receptors: a lipid-anchored ligand-binding subunit known as Nogo receptor (NgR) (Fournier et al. 2001) and Lingo-1 (Mi et al. 2004). For instance, BDNF binds to

p75NTR and induces apoptosis through activation of JNK pathway (Bhakar et al. 2003; Palmada et al. 2002). p75NTR and sortilin form a very-high-affinity receptor complex for the binding of proNGF and other proneurotrophins which promote apoptosis (Nykjaer et al. 2004). p75NTR also mediates biological activity of MAG and Nogo which inhibit axonal elongation and neurite growth via interacting with the Nogo receptor (Wang et al. 2002a, b).

3 Pathological Roles of p75NTR in the Nervous System

Although the expression of p75NTR is developmentally regulated in the nervous system, marked increase is observed under certain pathological conditions; however, the significance of the expression in these conditions is still not very clear.

In the dorsal root ganglia, the reduction of p75NTR levels by antisense oligonucleotides prevents the loss of axotomized neurons (Cheema et al. 1996). Similarly, the loss of motor neuron occurring after transection of the neonatal facial nerve is attenuated in mice carrying a mutation in the p75NTR gene (Ferri et al. 1998; Ferri and Bisby 1999). In contrast, the administration of NGF into the transected neonatal facial nerve of animals increases cell death (Sendtner et al. 1992). p75NTR is reexpressed in the transected neurons at levels comparable to those seen during the developmental stages. The upregulation of p75NTR is also observed in the cerebral cortex in Alzheimer's disease (Mufson and Kordower 1992). In a mouse model of amyotrophic lateral sclerosis, in which a mutant form of superoxide dismutase is overexpressed, p75NTR is reexpressed in lumbar motor neurons (Lowry et al. 2001) as the disease progresses. Consistently, the expression of p75NTR is also observed in motor neurons in the cervical spinal cords of patients with amyotrophic lateral sclerosis.

After axotomy, cortical spinal neurons strongly reexpress p75NTR three days after lesion, when neuronal death occurs. The activation of p75NTR by NT-3 causes the death of these neurons, as shown by experiments using blocking antibodies against p75NTR or NT-3 (Giehl et al. 2001). In spinal cord injury, p75NTR is essential for neuronal cell survival and functional recovery after injury (Chu et al. 2007). Activation of p75NTR contributes to NMDAR-mediated apoptosis in the neonatal brain (Griesmaier et al. 2010). These findings further suggest that p75NTR may be involved in neuronal death in neurological disorders. In a study using experimental autoimmune encephalomyelitis (EAE) animal models, in contrast to the clinical manifestation of EAE observed in wild-type C57/BL6 mice, mice deficient of p75NTR developed severe or lethal diseases and concomitant increased levels of inflammation in the CNS (Copray et al. 2004). This may suggest p75NTR is involved in the inflammation process but the detailed molecular mechanism is not clear. In retina degeneration, p75NTR is upregulated and exerts neurotoxic effect through paracrine mechanism (Bai et al. 2010). It appears that in pathologies involved in neuronal degeneration and death, p75NTR expression has a tendency to be upregulated in most experimental models used so far. However, the mechanism underlying the upregulation is not completely understood.

4 Roles of p75NTR in Pathogenesis of Alzheimer's Disease

4.1 p75NTR Expression in the Brain of Alzheimer's Disease

It is well known that cholinergic neurons in the basal forebrain especially in the nucleus basalis of Meynert (NBM) are most vulnerable and severely affected in Alzheimer's disease and they express p75NTR-positive, TrkA, TrkB, and TrkC (Salehi et al. 2000). Strikingly, very little or no p75NTR-positive neurons are normally observed in other brain regions. How the level of p75NTR expression changes in Alzheimer's disease patients and during the aging process remains controversial. Some researchers find that the expression of the nerve growth factor (NGF) receptor (including p75NTR) is increased in both cortical neurons and CA1 and CA2 subfields of the hippocampus in Alzheimer's disease patients compared with controls (Mufson and Kordower 1992; Hu et al. 2002). Some other studies show a significant reduction of p75NTR in Alzheimer's disease brains (Arendt et al. 1997; Salehi et al. 2000). Meanwhile, no significant differences in expression levels for p75NTR were observed across control, mild cognitive impairment (MCI, a pre-stage of Alzheimer's disease), nor Alzheimer's disease in other reports (Goedert et al. 1989; Treanor et al. 1991; Mufson et al. 2002; Ginsberg et al. 2006). The discrepancy on p75NTR expression in Alzheimer's disease may be due to the differences in investigated brain regions and measurements. The severity of Alzheimer's disease also influences the level of p75NTR, because it is certain that the greater the loss of cholinergic neurons occurring in Alzheimer's disease, the less that p75NTR is present in the basal forebrain. More work is required before a definite conclusion about this problem can be drawn regarding this issue. Studies on p75NTR expression in the Alzheimer's disease animal models and cell lines provide a clearer answer. In two different strains of transgenic Alzheimer's disease mice, the triple transgenic mice (3xTg-AD, harboring PS1M146V, APPswe, and tauP301L) and APPswe/PS1dE9 mice, the level of p75NTR is significantly increased and associated with the age-dependent rise of Aβ. Meanwhile, Aβ has promoted p75NTR expression in the membrane of SH-SY5Y human neuroblastoma cells (Chakravarthy et al. 2010). They further demonstrated that the microinjected Aβ oligomer can also increase p75NTR expression, which according to the results of in vitro study may be mediated through an insulin-like growth factor 1 receptor (IGF-1R) phosphorylation (Ito et al. 2012). Consistently, it was found that p75NTR expression increases in an age-dependent manner in wild-type mice and is higher in APPswe/PS1dE9 mice relative to their wild-type littermates at the same age (Wang et al. 2011). Although many of the human studies show a reduction of the p75NTR level in the brain, reflecting the loss of p75NTR-positive cholinergic neurons, these animal studies suggest that p75NTR expression increases with aging and is further activated by Aβ. The neurons of the transgenic animal models are more resistant to Aβ toxicity as reflected by the loss of very few neurons in the brain of the animal models, relative to humans (Gotz and Ittner 2008). Moreover, it was recently discovered that p75NTR would express in the cultured epithelial cells of choroid plexus, mainly in the cytoplasm and CSF side (Spuch and Carro 2011), which is an indication of its potential role to transport Aβ through BBB (Zhou and Wang 2011).

4.2 p75NTR Pathway Promotes Aβ Production

The level of p75NTR is significantly elevated in Alzheimer's disease brains, but little is known about the reason and meaning of this change. In our studies, the expression of p75NTR is much higher in the neurons of APPswe transgenic mice than that of the wild-type, suggesting Aβ is very likely to cause the high level of p75NTR in Alzheimer's disease. Our further studies showed that after the p75NTR gene knockout in APPswe transgenic mice, the production of Aβ was reduced in the cortex neurons, and the level of soluble Aβ also decreased (Wang, Wang et al. 2011). This indicates that p75NTR is able to promote Aβ production. Based on these results, it is speculated that Aβ upregulates the expression of p75NTR in Alzheimer's disease brains, and the activated p75NTR in turn stimulates Aβ production. Consequently they form a vicious cycle and finally result in Aβ overproduction. This hypothesis can explain the reason why Aβ production accelerates in Alzheimer's disease brains (Kawarabayashi et al. 2001) and why sporadic Alzheimer's disease patients have overproduction of Aβ when they do not have any known gene mutations with Aβ production (Selkoe 2001). It is demonstrated that beta-site APP-cleaving enzyme 1 (BACE1) protein increases in an annulus around amyloid plaques cores, and it occurs without any change in BACE1 mRNA level. Therefore, it can be concluded that amyloid plaques lead to the increased level of BACE1 surrounding neurons at an early stage before neuronal death occurs, and this may drive a positive-feedback loop in Aβ production (Zhao et al. 2007) (Fig. 1). Consistent with this conclusion, further research has described the same interactions between BACE1 and Aβ in the pathogenesis of Alzheimer's disease, no matter whether it is familial or sporadic (Tabaton et al. 2010). The positive-feedback loop in Aβ production is an important issue worthy of further investigations (Fig. 1).

Aging is the most important risk factor for Alzheimer's disease. Recently some researchers have identified the p75NTR system as a molecular link between normal aging and Alzheimer's disease. When p75NTR, which activates β cleavage of APP, is upregulated and TrkA, which reduces the cleavage, is downregulated during aging, the p75NTR-ceramide pathway is significantly activated, causing the increase of steady-state levels and activity of BACE1 downstream and eventually resulting in the acceleration of Aβ production (Costantini et al. 2005b). The caloric restriction and nSMase inhibitors could reduce Aβ production and the risks associated with aging, by interrupting this signaling pathway. Both the upregulation of p75NTR expression and the acceleration of Aβ production follow an age-dependent fashion. Further study of this research demonstrated that signaling through IGF1-R controls the level of TrkA and p75NTR in both human neuroblastoma cell lines and primary neurons from the mouse brain, and IGF1-R regulates Aβ production in the upstream of p75NTR-ceramide pathway (Costantini et al. 2006).

4.3 p75NTR Regulates Aβ Deposition and Clearance

Aβ mainly deposits in the cerebral neocortex, hippocampus, and vessel walls, which are coincident with the projection area of cholinergic neurons and

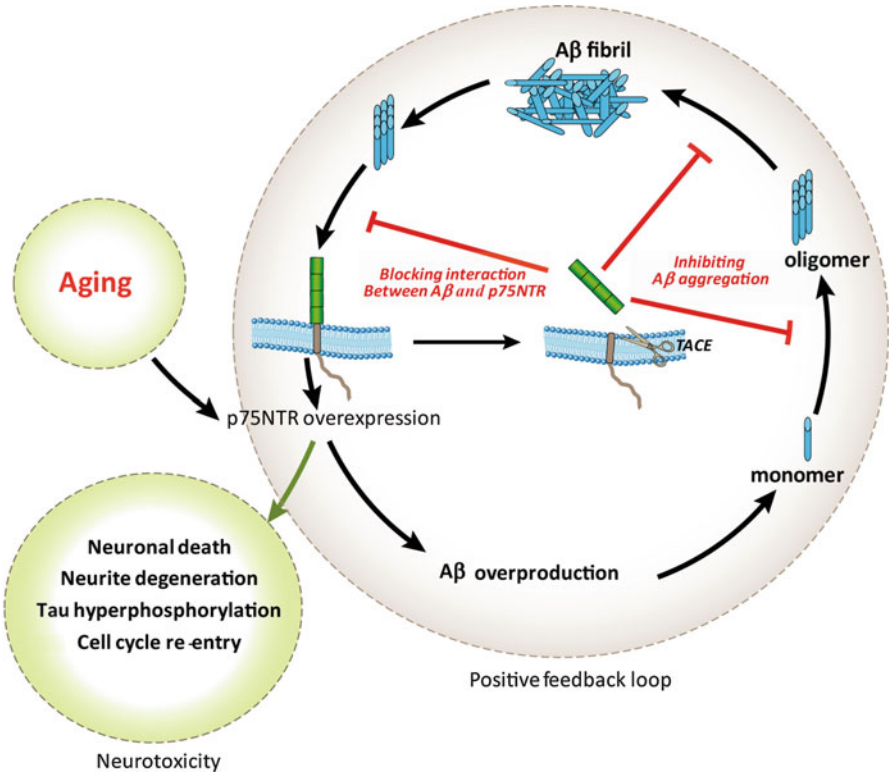

Fig. 1 Schematic diagram of p75NTR functions in Alzheimer's disease. In the brain of Alzheimer's disease, p75NTR expression is upregulated by aging and further activated by Aβ. p75NTR signaling increases Aβ production and thus enhances steady-state levels of Aβ in the interstitial space which may increase AD pathology. Aβ again promotes p75NTR expression. P75NTR/Aβ forms a positive-feedback loop. Besides Aβ production, p75NTR also mediates neurotoxicity of Aβ, such as neuron death, neurite degeneration, tau hyperphosphorylation, and cell cycle re-entry. p75NTR is to be cleaved by an enzyme named TACE to shed its extracellular domain. The extracellular domain of p75NTR after shedding from the membrane may bind to the 25–35 amino acid of Aβ, which is mainly responsible to Aβ aggregation and neurotoxicity, thus suppressing Aβ aggregation and reducing Aβ deposition in the brain. Meanwhile, the extracellular domain of p75NTR may also block the interaction between Aβ and membrane p75NTR by competitive binding Aβ, thus attenuating the p75NTR signaling which leads to both Aβ production and neurotoxicity. The shedded extracellular domain of p75NTR might be an endogenous protective molecule against Aβ production, deposition, and toxicity and would be an important and promising therapeutic target of Alzheimer's disease

sympathetic neurons expressing p75NTR. The underlying mechanism remains unclear. It was found that in the cerebral cortex and hippocampus of APPswe transgenic Alzheimer's disease mice, more than 90 % of the Aβ plaques contained p75NTR-positive fibers. More importantly, the p75NTR-positive fibers are mostly located in the cores of Aβ plaques, while the p75NTR-negative degenerated ones are located around the plaques. The appearance of p75NTR-positive neurites is

prior to Aβ plaques in the brain of Alzheimer's disease mice. These findings all indicate that p75NTR expressed on the fibers is probably an initiating or promoting factor for Aβ deposition. However, deletion of p75NTR can increase total Aβ level in the brain, with increased fibrillar Aβ levels but decreased soluble Aβ level. Therefore, how p75NTR influences Aβ deposition may be complicated.

As a member of the tumor necrosis factor receptor superfamily, p75NTR is cleaved by metalloproteases mainly TACE or ADAM17 in the normal metabolic process, and then the extracellular domain of p75NTR (p75NTR-ECD) is released (Weskamp et al. 2004). The physiological function of p75NTR-ECD has not been well studied. In our studies, after deleting the p75NTR gene of APPswe transgenic mice, insoluble Aβ deposition is significantly increased in the brain (Wang, Wang et al. 2011). Further study demonstrates that recombinant p75NTR-ECD inhibits Aβ oligomerization in a dose-dependent manner in vitro, and injection of p75NTR-ECD in the hippocampus of Alzheimer's disease mice can reduce local Aβ plaques. Based on these results, it can be concluded that p75NTR-ECD, which is released during the metabolic process of p75NTR, is a key regulatory factor of inhibiting Aβ aggregation and facilitating disaggregation of Aβ fibrils. It may act as an Aβ-sequestering molecule to clear Aβ in vivo. Seeking the Aβ binding sites on p75NTR-ECD is very valuable for revealing the mechanism about how p75NTR regulates Aβ deposition. After that, the effective control and interference with the deposition and clearance of Aβ can be achieved. It is worthy to note that since p75NTR is also expressed in endothelial cells of BBB, it may help transport Aβ from CSF to blood, thus facilitating Aβ clearance to some extent (Zhou and Wang 2011).

In the progression of Alzheimer's disease, the level of p75NTR is related to Aβ load and other factors in the brain. How is the extracellular shedding of p75NTR regulated in vivo? Is there any change of p75NTR-ECD level in the Alzheimer's disease brain, cerebral spinal fluid, blood, or urine? Are the function and metabolism of p75NTR-ECD impaired in Alzheimer's disease patients? Can Aβ influence p75NTR-ECD production? By what means does p75NTR transport Aβ through BBB? Are there any single nucleotide polymorphisms of the p75NTR gene associated with the risk of Alzheimer's disease? All these important questions need to be answered in future studies.

4.4 p75NTR and Neurite Degeneration

Neurite degeneration is a pivotal event of Alzheimer's disease and a main contributor of the memory loss. Aβ is an important factor which leads to neurite degeneration in Alzheimer's disease patients, but its receptor pathway and mechanism are still unknown (Petratos et al. 2008). It is demonstrated that intact p75NTR mediates or enables Aβ-induced neurite degeneration in vitro and in vivo via the c-Jun pathways, a known mediator of Aβ-induced deleterious signaling. After the removal of p75NTR extracellular domain, the Aβ-induced neuritic dystrophy in cultured hippocampus neurons and in the basal forebrain of chronic Alzheimer's

disease mice could be completely reversed, and the neuritic dystrophy in the hippocampus was also significantly diminished (Knowles et al. 2009). Besides, non-peptide small molecule p75NTR ligands which block the binding of Aβ to p75NTR are found to be capable of inhibiting Aβ-induced neurite degeneration, synapse impairment, and the activation of some molecules involved in Alzheimer's disease pathology including calpain/cdk5, GSK3β and c-Jun, and tau phosphorylation. They can also prevent Aβ-induced inactivation of AKT and CREB (Yang et al. 2008). In accordance with results above, it was observed that abundant degenerative fibers and neurites in the neocortex and hippocampus express p75NTR in APPswe/PS1dE9 mice (Wang et al. 2010b), suggesting that p75NTR is a key receptor modulating Aβ-induced neurite degeneration. At the same time, a recent study found that the sympathetic nervous system is severely impaired in p75NTR-deficient Alzheimer's disease model, which leads to critical dysfunction of sympathetic innervation to multiple organs and finally results in the death of the animal. The protective role of p75NTR against Aβ-induced neurite degeneration showed in this study could be the result of the combined effect of p75NTR and its co-receptors under in vivo condition, such as the enhanced NGF and TrkA signaling, and possibly the promoted glial cell line-derived neurotrophic factor (GDNF) signaling, especially in the sympathetic nervous system (Bengoechea et al. 2009).

The reduction of NGF has also been suggested to be involved in the pathogenesis of Alzheimer's disease, but the exact role of its precursor (proNGF) in Alzheimer's disease remains elusive. It is reported that proNGF is the predominant form of this neurotrophin in the human brain, and it binds to p75NTR more strongly than mature NGF (Fahnestock et al. 2001). ProNGF has been shown to induce apoptosis in neuronal cell cultures through its interaction with p75NTR and its co-receptor, sortilin (Niewiadomska et al. 2011). Besides, the binding of proNGF to p75NTR-SorCS2 (sortilin-related VPS10 domain-containing receptor 2) complex can disassociate the guanine nucleotide exchange factor Trio from the complex, which brings down the activity of the small GTPase Rac and finally leads to destabilization and collapse of actin filaments, as well as growth cone retraction and collapse in cultured hippocampus neurons (Deinhardt et al. 2011). Since the level of proNGF has been found to increase in the cerebral cortex in Alzheimer's disease, it may mediate neurite degeneration through this mechanism. Besides, blocking proNGF can inhibit neuronal loss (Friedman 2000; Podlesniy et al. 2006; Volosin et al. 2008). The effects of proNGF in vitro and in vivo were investigated, and the results showed that proNGF is localized to the Aβ plaques in the brain of Alzheimer's disease mice, which also induced the neuronal death and neurite degeneration of different neuronal cell lines and primary neurons in culture, likely dependent on the expression of p75NTR (Wang et al. 2010a) (Fig. 1).

4.5 p75NTR and Neuronal Death

Neuronal death is another important pathological character of Alzheimer's disease. As one ligand of p75NTR, Aβ is best known for mediating neuronal death and has

been consistently linked to the pathology of Alzheimer's disease. It is believed that the interactions of Aβ with p75NTR and other neuronal cell surface receptors can trigger the production of reactive oxygen species, expression of caspases and pro-apoptotic genes (such as p53, p35), and enhance mitochondrial permeability (Dias Bda et al. 2011). Evidence shows that p75NTR plays a critical role in the early and characteristic loss of cholinergic neurons in response to Aβ in the septohippocampal pathway in Alzheimer's disease (Sotthibundhu et al. 2008). A recent study demonstrated that overexpression of tumor necrosis factor receptor-associated factor 6 (TRAF6) and p62, which are essential in p75NTR polyubiquitination and NF-κB activation-mediated cell survival signaling downstream, can reduce Aβ-induced neuronal death (Geetha et al. 2012). It was found that in the presence of Aβ, more neurons survived in culture after the p75NTR gene was deleted. Besides, the application of the recombinant extracellular domain of p75NTR can decrease the Aβ-induced neuronal death. Thus, it is probable that Aβ toxicity can be antagonized by blocking the p75NTR-mediated pathway (Wang et al. 2010b). However, research shows that the role of p75NTR in neurotoxicity depends on the different forms of Aβ interacting with it. For fibrillar Aβ, p75NTR mediates neuronal death, whereas for soluble oligomeric Aβ, it exerts a protective role against the neurotoxicity (Costantini et al. 2005a). The protective effect may be mediated by phosphatidylinositide 3-kinase (PI3K) activity due to the function of the juxtamembrane sequence of the cytoplasmic region of p75NTR. Considering that the activation of p75NTR-mediated pathway may need the role of its specific co-receptors, and that most studies were confined to in vitro experiments, further investigation about how p75NTR mediates Aβ-induced neurotoxicity needs to be carried out in in vivo models (Coulson 2006).

proNGF participates in neuronal death in Alzheimer's disease as well. Some researchers demonstrate that proNGF from the injured spinal cord induces apoptosis in culture among p75NTR-positive, but not p75NTR-negative, oligodendrocytes, and its action can be blocked by proNGF-specific antibodies. ProNGF can eliminate damaged cells by activating the apoptotic machinery of p75NTR (Beattie et al. 2002). Other researchers also found that proNGF secreted by astrocytes under the stimulation of peroxynitrite can specifically cause motor neuron death via the engagement of p75NTR (Domeniconi et al. 2007). As for Alzheimer's disease, some studies showed that proNGF levels increased in glial cells and neurons of the cortex and hippocampus, which is closely related to the progression of Alzheimer's disease. The upregulation of proNGF may represent the dysfunction of maturation of NGF that enhances the vulnerability of cholinergic neurons in Alzheimer's disease (Cuello et al. 2007). Moreover, researchers found proNGF extracted from Alzheimer's disease brains can obviously induce apoptotic neuronal death through p75NTR (Pedraza et al. 2005). And p75NTR intracellular domain (p75NTR-ICD), the level of which was significantly increased and paralleled the increase of proNGF in the entorhinal cortex, should account for proNGF-induced apoptosis in Alzheimer's disease (Podlesniy et al. 2006). Nevertheless, some researchers speculated the possibility that the loss of proNGF-mediated signaling may reduce the TrkA receptors within the cholinergic basal forebrain (CBF) neurons, affecting

cell survival. Whether proNGF binds p75NTR in vivo leading to apoptosis remains unclear (Peng et al. 2004). A recent study indicated that cleavage-resistant mutated forms of proNGF can promote neurite outgrowth, increase cell survival, as well as cause apoptotic cell death through phosphorylation of TrkA and ERK1/2 or initiation of apoptotic pathway by cleavage of caspase 3. So the final result of cell viability or apoptotic effects will depend on the balance of proNGF:NGF and p75NTR:TrkA ratios in Alzheimer's disease brains (Clewes et al. 2008). This is further proved as deletion of p75NTR-ECD which consequently leads to the abrogating of proNGF signaling in AD12 mice, obtained by crossing AD10 mice which express anti-NGF antibodies with $p75NTR^{exonIII(-/-)}$ mice, can still exert a protective role to anti-NGF-induced amyloidogenesis as a result of dominant TrkA survival signaling (Capsoni et al. 2010).

4.6 p75NTR and Neuronal Cell Cycle Re-entry

Adult neurons in the brain are classically thought to be in terminal differentiation permanently, effectively precluding them from cell division. However, around a decade ago, it was shown that susceptible cortical and hippocampal neurons in Alzheimer's disease display an activated cell cycle, suggesting cell cycle re-entry of neurons. Accumulating evidence indicates that neuronal cell cycle re-entry represents an early and critical event in Alzheimer's disease, recapitulating known hallmarks of the disease including NFTs and deposition of Aβ plaques. The cell cycle re-entry hypothesis may be extensively applicable in many neurological diseases because the re-entry of cell cycle also occurs in other neurodegenerative diseases.

The mechanism and the role of p75NTR in cell cycle re-entry in Alzheimer's disease remain obscure. However, there is evidence that illustrates an important position of p75NTR in cell cycle re-entry. Firstly, it was demonstrated that during development of the nervous system, the activation of p75NTR by an endogenous source of NGF (possibly proNGF) can trigger cell cycle re-entry and tetraploidization of retinal ganglion cells (Jansen et al. 2007; Nakamura et al. 2007; Morillo et al. 2010). Secondly, many newly identified p75NTR intracellular interactors have been known to regulate cell cycle. Finally, as a known stress-response receptor, expression of p75NTR in affected neurons in Alzheimer's disease becomes upregulated in response to stress, which has a close relationship with cell cycle re-entry. The exact role of p75NTR in the cell cycle re-entry of neurons in Alzheimer's disease needs further investigation.

p75NTR can be activated by Aβ (Yaar et al. 1997) and promote neuritic dystrophy and apoptosis in vitro and in vivo (Sotthibundhu et al. 2008; Knowles et al. 2009). Binding of aggregated Aβ to p75NTR can also lead to Ras/ERK activation (Susen and Blochl 2005), suggesting that the previously described increase of Ras/ MAPK activity in the Alzheimer's disease brain could be induced by this particular p75NTR-dependent signaling pathway (Arendt et al. 1995; Gartner et al. 1995). Furthermore, p75NTR has also been shown to physically

and functionally interact with APP (Fombonne et al. 2009). p75NTR can interact with different neurotrophin precursors, including proNGF (Fombonne et al. 2009) which represents the predominant form of NGF in the brain. This interaction requires the presence of sortilin, known to bind to the "pro" domain. Interestingly, the expression of sortilin becomes increased in aging basal forebrain neurons (Al-Shawi et al. 2007; Al-Shawi et al. 2008), and this molecule is required for neuronal degeneration associated with aging (Jansen et al. 2007). ProNGF has been shown to trigger pro-apoptotic signals through the p75NTR/sortilin complex (Nykjaer et al. 2004) although proNGF-dependent trophic effects are also observed in vivo (Fahnestock et al. 2004; Al-Shawi et al. 2008). Importantly, proNGF becomes accumulated in the cortex and hippocampus (Fahnestock et al. 2001) of the Alzheimer's disease brain, as well as in the aged brain.

4.7 p75NTR and Cognition, Tau Phosphorylation

In Alzheimer's disease patients degenerated cholinergic neurons in the basal forebrain are closely related to the impaired learning and memory processes. Some researchers found that after deletion of exon III or IV of the p75NTR gene which leads to a partial or complete p75NTR knockout, the cholinergic neurons in the medial septal nucleus increase 13 % and 28 %, respectively, in Alzheimer's disease mice, which is sure to improve cognition to some degree (Naumann et al. 2002). The results also suggest that the cytoplasmic domain of p75NTR is responsible for the cell death effect, and complete deletion of the full-length p75NTR can decrease cholinergic neuronal death.

There is also some evidence to suggest that p75NTR may participate in the formation of NFTs, another pathological character of Alzheimer's disease. When studying the brain of postmortem Alzheimer's disease patients, the ratio of p75NTR-positive neurons to the total number of neurons was found to be significantly higher in the CA1 and CA2 subfields of the hippocampus. Besides, a large proportion of these p75NTR expressing neurons are co-localized with Alz-50, whose antibody can be regarded as an indirect indication of hyperphosphorylated tau in the same subfields of Alzheimer's disease patients, suggesting that p75NTR may be involved in the formation of NFTs (Hu et al. 2002).

Our recent research demonstrated that deletion of the p75NTR gene can also exacerbate other Alzheimer's disease-type pathologies in the brain of Alzheimer's disease mice, such as microgliosis and microhemorrhage but does not reduce the memory deficits of Alzheimer's disease mice until 9 months of age (Wang et al. 2011).

5 Potential Use of p75NTR as a Therapeutic Target for Alzheimer's Disease

The roles of p75NTR in the pathogenesis of Alzheimer's disease described above strongly suggest that p75NTR represents a valid therapeutic target for the

treatment of Alzheimer's disease (Dechant and Barde 2002; Coulson et al. 2009; Knowles et al. 2009). However, as p75NTR has double-faced roles in Aβ metabolism and neurotoxicity, it is cautioned that simply reducing expression of p75NTR may exacerbate Alzheimer's disease pathology, as knockout of the p75NTR gene results in increased Aβ deposition and Alzheimer's pathologies in an APPswe/PS1dE9 transgenic mouse model. However, the use of the extracellular domain not only may attenuate neurotoxic signals by blocking Aβ-p75NTR and proneurotrophin-p75NTR interactions on cell membranes but also may suppress Aβ aggregation and deposition and enhance Aβ clearance from the brain. In addition, it was found that the recombinant extracellular domain of p75NTR is also able to block the Aβ- and proNGF-induced neurotoxicity in vitro (Wang et al. 2010a). This data suggests that recombinant extracellular domain of p75NTR may be a desirable anti-Alzheimer's disease agent with multiple functions to facilitate Aβ clearance by inhibiting Aβ aggregation, and to protect cholinergic neurons from Aβ- and proneurotrophin-induced neurotoxicity by blocking their interaction with p75NTR, and to reduce Aβ production by interrupt feedback loop between Aβ and p75NTR (Fig. 1).

6 Conclusion

p75NTR is an important molecule which has diverse functions linked with neuron development, aging, stress, and neuropathological conditions. Recent studies suggest that p75NTR plays a critical role in the pathogenesis, almost all hallmarks of Alzheimer's disease, starting from the generation of Aβ and removal of Aβ deposition, to mediate Aβ-induced neuronal death, neurite degeneration, tau hyperphosphorylation, and cell cycle re-entry. The shedded p75NTR extracellular domain is regarded as an endogenous protective molecule to interrupt Aβ/p75NTR feedback loop, block Aβ neurotoxicity, and remove Aβ deposits. Thus, the extracellular domain of p75NTR is a promising therapeutic target for the development of therapeutics for Alzheimer's disease.

Seizures Tip the Balance of Neurotrophin Signaling Toward Neuronal Death

Wilma J. Friedman, Audrey P. Le, Soyoung Choi, and Marta Volosin

Contents

Abstract

Neurotrophins and proneurotrophins have opposing actions on neuronal survival, mediated by their respective receptors. Trk receptors are necessary for mature neurotrophins to support neuronal survival, while the p75 neurotrophin receptor ($p75^{NTR}$) mediates proneurotrophin-induced apoptosis. Therefore, the consequences of neurotrophin actions depend on expression of the different neurotrophin receptors; regulation of proneurotrophin cleavage, which can determine which receptor is bound; and activation of downstream signaling events supporting neuronal survival or apoptosis. Several types of brain injury, including seizures, lead to altered levels of neurotrophin receptors, with increased neuronal expression of $p75^{NTR}$ in the brain. Seizure-induced

injury also leads to increased secreted proNGF due to altered regulation of the extracellular proNGF-cleaving enzymes. Downstream signaling pathways triggered by proNGF activation of $p75^{NTR}$ include induction of the phosphatase PTEN, which antagonizes TrkB signaling triggered by BDNF and prevents the activation of Akt. Thus, the increase in extracellular proNGF and elevated levels of $p75^{NTR}$ that occur after injury create a milieu that leads to neuronal death.

1 Introduction

Neurotrophins have been well established as trophic factors in the peripheral and central nervous systems, supporting neuronal survival and promoting differentiation (Barde 1994; Huang and Reichardt 2001). The neurotrophin family, consisting of NGF, BDNF, NT3, and NT4, binds to two distinct types of receptors: a member of the Trk receptor tyrosine kinase family and the p75 neurotrophin receptor ($p75^{NTR}$). The role of Trk receptors in mediating neuronal survival, differentiation, and synaptic function has been well defined, and the major signaling pathways activated include the PI_3 kinase-Akt, ras-MAP kinase, and PLCγ signaling pathways, which have been extensively studied (Friedman and Greene 1999; Kaplan and Miller 2000; Patapoutian and Reichardt 2001). In contrast, the $p75^{NTR}$ has been more of an enigma, since it has been implicated in mediating many diverse cellular functions such as survival (Hamanoue et al. 1999; Chu et al. 2007), apoptosis (Casaccia-Bonnefil et al. 1996; Frade et al. 1996; Coulson et al. 1999), and axonal growth (Yamashita et al. 1999; Sun et al. 2012), depending upon the cellular context. Following numerous different types of injury, including seizures, traumatic brain injury, and axotomy, $p75^{NTR}$ has been shown to signal apoptosis (Friedman 2000; Beattie et al. 2002; Troy et al. 2002; Harrington et al. 2004). Although $p75^{NTR}$ can bind all the neurotrophins with low affinity, uncleaved proneurotrophins bind $p75^{NTR}$ with high affinity (Lee et al. 2001) due to the association with the co-receptor sortilin (Nykjaer et al. 2004) and potently induce neuronal death (Harrington et al. 2004; Volosin et al. 2008). Thus, neurotrophins can signal survival or apoptosis, depending on which form of the factor is secreted, which can determine which receptor and signaling pathways are activated. Therefore, determination of neuronal survival or death following injury depends on several events, such as altered expression of the different neurotrophin receptors, $p75^{NTR}$ and the Trk family. Moreover, regulation of proneurotrophin processing to determine whether the cleaved or uncleaved form is secreted and stabilized in the extracellular milieu can be a critical determinant of which receptor is engaged, leading to neuronal survival or death. Thus, a delicate balance of receptor expression and downstream signaling, as well as proneurotrophin processing, can critically determine the outcome for signaling neuronal survival or death.

2 $p75^{NTR}$ and Apoptotic Signaling

Many injury conditions, including seizures, lesions, and traumatic injuries, have been shown to induce the $p75^{NTR}$, suggesting an important role in mediating neuronal responses to injury (Ernfors et al. 1989; Roux et al. 1999). Moreover, in mice lacking this receptor, neuronal death is significantly reduced following injury (Beattie et al. 2002; Troy et al. 2002). Although $p75^{NTR}$ is a member of the TNF receptor family of death receptors, it does not signal through the same pathways as other members of this family, which generally recruit adapter proteins to the trimerized receptor to activate caspase-8 and the extrinsic apoptotic pathway (Green 2003). In contrast, activation of $p75^{NTR}$-mediated apoptosis requires phosphorylation of c-Jun N-terminal kinase (JNK) (Yoon et al. 1998; Friedman 2000) and phosphorylation of the pro-apoptotic proteins Bad (Bhakar et al. 2003) and BimEL (Becker et al. 2004), eliciting the release of cytochrome c from the mitochondria and the subsequent activation of caspase-9, caspase-6, and caspase-3 (Wang et al. 2001; Troy et al. 2002). Thus, apoptotic signaling via $p75^{NTR}$ is different from the classic members of the TNFR family of death receptors.

The $p75^{NTR}$ has no kinase activity and signals by recruiting intracellular binding proteins to activate downstream events. The receptor undergoes regulated intramembrane proteolysis (RIP), generating a C-terminal fragment (CTF) and ultimately the intracellular domain (ICD) that interacts with intracellular proteins such as NRIF, NRAGE, and NADE to promote cell death (Barker 2004), ultimately activating the intrinsic caspase cascade. Genetic mutation analysis of different domains of the $p75^{NTR}$ has demonstrated that specific amino acids distributed throughout the death domain are required for the activation of the caspase pathway, leading to cell death, while other domains are necessary for activation of RIP2 binding, leading to NF-κB activation and cell survival (Charalampopoulos et al. 2012). Activation of NF-κB by $p75^{NTR}$ has been observed in Schwann cells (Carter et al. 1996), but not in hippocampal neurons or astrocytes (Volosin et al. 2008). The activation of distinct cell-specific signaling pathways is likely regulated by the expression or recruitment of the specific adapter proteins that link the receptor to the different downstream pathways. The scattered amino acid residues that are required for caspase-3 activation suggest that multiple binding proteins are necessary for activation of this pathway, possibly forming a multi-molecular complex binding to the receptor.

Following damage in the brain, numerous cytokines and trophic factors are released that can impact upon the injured neurons. Mature neurotrophins, such as BDNF, are present in the hippocampus and can activate its TrkB receptor to promote signaling via the PI3K-Akt and ras-ERK pathways to support survival of these neurons. The ability of neurotrophins to support neuronal survival can be affected by changes in the neurotrophin receptor levels and signaling that occur following seizures. Seizures, as well as other types of injury, lead to an induction of $p75^{NTR}$ expression in the hippocampus (Roux et al. 1999; Troy et al. 2002). A previous study has shown that along with the increase in $p75^{NTR}$, there is a concomitant decrease in TrkB (Unsain et al. 2008), tilting the balance of signaling towards neuronal death. The induced $p75^{NTR}$ on hippocampal neurons can be activated by proNGF, which is

released following injury, leading to neuronal death. Neurons that may express both $p75^{NTR}$ and TrkB and may be exposed to BDNF and proNGF must integrate these signals to a decisive outcome, survival, or death. Interestingly, in contrast to sympathetic neurons where activation of Trk prevents $p75^{NTR}$-mediated apoptosis (Miller and Kaplan 2001), CNS neurons expressing both $p75^{NTR}$ and TrkB, and exposed to both proNGF and BDNF, were not protected from cell death by the BDNF. This was due to the induction of the PTEN phosphatase by $p75^{NTR}$ activation, which prevented the ability of TrkB to activate Akt, thereby inhibiting the ability of BDNF to promote survival and facilitating the apoptotic signaling of $p75^{NTR}$ (Song et al. 2010). When the induction of PTEN by proNGF was prevented, BDNF was able to rescue hippocampal neurons from death following seizures, indicating that the induction of PTEN is a critical checkpoint in the balance between survival and apoptotic signaling (Song et al. 2010). Thus, induction of neuronal apoptosis by proNGF in the presence of mature neurotrophins requires the suppression of Trk signaling as well as the activation of JNK and subsequent caspase cascade.

3 Seizure-Induced Changes in Connectivity

A major consequence of epileptic seizures is the dendritic sprouting and synaptic reorganization that leads to the formation of aberrant connections and the development of spontaneous recurrent seizures (Williams et al. 2009). Many studies have shown that BDNF is elevated in the hippocampus following different types of seizures (Ballarin et al. 1991). Levels of the TrkB receptor are particularly high in the mossy fibers, projections that undergo sprouting and circuit reorganization, which are thought to participate in the development of recurrent seizures, leading to increased seizure susceptibility (Koyama et al. 2004; McNamara and Scharfman 2012). In contrast to the stimulation of axonal and dendritic sprouting induced by BDNF, recent studies have demonstrated that $p75^{NTR}$ can induce axonal degeneration. In fact, the activation of caspase-6 by $p75^{NTR}$ has been implicated not only in cell death but also in axonal degeneration (Park et al. 2010), suggesting that activation of $p75^{NTR}$ may play a broader role following injury, not only inducing neuronal loss but also potentially triggering more subtle but widespread responses involving axonal loss and circuit remodeling. Thus, in addition to having opposing actions with respect to neuronal survival, TrkB and $p75^{NTR}$ have opposing actions in regulating axonal growth, with TrkB eliciting sprouting and $p75^{NTR}$ evoking degeneration, both of which may come into play following seizures with the consequent formation of aberrant circuits.

4 Regulation of $p75^{NTR}$ Following Injury

The $p75^{NTR}$ is not widely expressed in the adult brain but is induced following numerous different types of insults, including seizures, axotomy, and trauma. This receptor is also upregulated in neurodegenerative diseases such as Alzheimer's

disease. The induction of this receptor in all these pathological situations raises the question of whether there are common signals present in all these conditions that regulate expression of $p75^{NTR}$. One common feature of all these injury and disease conditions is hypo-osmolarity, which has been shown to regulate $p75^{NTR}$ expression via activation of Sp1 transcription factors (Ramos et al. 2007). Another common characteristic of these conditions is the presence of inflammation in the brain and high levels of inflammatory cytokines such as IL-1β and TNFα. These cytokines can induce expression of $p75^{NTR}$ in hippocampal neurons in vitro (Choi and Friedman 2009) and in vivo and may contribute to the mechanism by which $p75^{NTR}$ is induced on vulnerable neurons to promote neuron loss. IL-1β is known to enhance neuronal vulnerability to many types of damage, including traumatic brain injury and stroke. In culture, preexposure of hippocampal neurons to IL-1β enhances the apoptotic response to proNGF, suggesting that proNGF is part of the mechanisms by which IL-1β increases neuronal vulnerability.

5 Regulation of Extracellular Proneurotrophin Stability

Neurotrophins are synthesized as precursor proteins that undergo cleavage in the trans-Golgi network by enzymes such as furin and other proconvertases with the cleaved product being secreted as the mature neurotrophin (Seidah et al. 1996). As the precursors of neurotrophins, proneurotrophins are transiently present in neurons and glial cells in the brain; therefore, detection of intracellular proneurotrophins does not indicate which form of the proteins is secreted. The mechanisms by which proneurotrophins may be secreted without being processed are undefined; however, since neurotrophins and proneurotrophins can have opposing actions in mediating neuronal survival or death, and axonal sprouting and degeneration, it is clearly critical to maintain tight regulation of proneurotrophin cleavage. Therefore, in addition to the intracellular processing of this protein by furin, mechanisms also exist for promoting proneurotrophin processing in the extracellular environment. Extracellular enzymes that can cleave proneurotrophins include matrix metalloproteinases (MMPs) and the tissue plasminogen activator (tPA)-plasminogen cascade (Lee et al. 2001). In the pentylenetetrazole (PTZ) model, seizures increased levels of MMP-9, promoting the conversion of proBDNF to BDNF (Mizoguchi et al. 2011). In addition, electroconvulsive seizures (ECS) increased levels of proconvertase 1 and tPA (tissue plasminogen activator), which also promote processing of proBDNF to BDNF (Segawa et al. 2012). Thus, there is evidence that seizures promote cleavage of proBDNF to BDNF, which then increases the likelihood of recurrent seizures (McNamara and Scharfman 2012). However, in contrast to proBDNF, the unprocessed proNGF has been detected in cerebrospinal fluid under conditions of injury and neurodegenerative disease (Harrington et al. 2004; Le and Friedman 2012), indicating that the NGF precursor protein was secreted without being cleaved and is stable in the extracellular environment and not cleaved by extracellular proteases. This indicates that alterations in the levels and/or activity of these cleaving enzymes occur as

a consequence of the injury leading to stabilization of the proneurotrophin. Unlike proBDNF, proNGF is not cleaved by MMP9 but can undergo extracellular cleavage by MMP7. Seizure-induced injury leads to decreased levels of MMP7 protein and activity and increases in tissue inhibitor of metalloproteinase (TIMP)-1 (Rivera et al. 1997), resulting in inhibition of proNGF cleavage (Le and Friedman 2012). Moreover, infusion of exogenous MMP7 into the hippocampus following seizures resulted in cleavage of extracellular proNGF and provided neuroprotection (Le and Friedman 2012). Thus, the altered balance of these extracellular enzymes and their endogenous inhibitors regulates the stability of proNGF in the extracellular milieu, providing a specific ligand for binding the injury-induced $p75^{NTR}$ and promoting neuronal loss following seizures.

6 Conclusion

A tightly regulated balance exists between the ability of neurotrophins to promote neuronal survival and apoptosis. In the healthy brain, proneurotrophins are

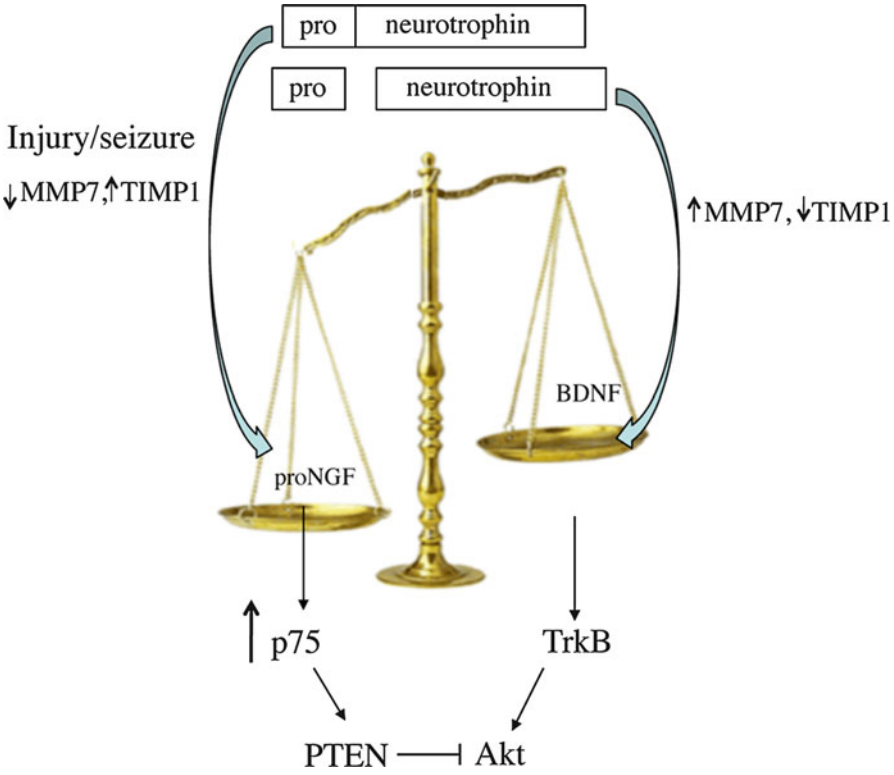

Fig. 1 Tilting the balance: seizure-induced alterations in the balance of proneurotrophin/neurotrophin signaling that lead to neuronal death

processed to generate the mature trophic factors, which signal via their Trk receptors to influence neuronal, survival differentiation and function. Following seizures and other types of injury, the induction of $p75^{NTR}$ expression on injured neurons and extracellular presence of proNGF shift the balance of neurotrophin actions towards inducing apoptosis of the injured cells (Fig. 1).

Contents

Abstract

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, plays an important role in neuronal survival, differentiation, neurite outgrowth, spine formation, synaptic plasticity, and memory. The regulation of its biological activity is well controlled by its gene expression, axonal transport, and release. It is well known that BDNF is synthesized and released in an activity-dependent manner. However, the molecular mechanism for its processing, axonal transport, and release is still not completely understood. In our recent studies we found that Huntingtin-associated protein (HAP1) and sortilin play important roles in BDNF trafficking and processing. HAP1 plays critical roles in BDNF intracellular trafficking, dendritic targeting, and metabolism by binding to the prodomain of

BDNF and forming a complex with sortilin. In this chapter, we focus on the recent progress made in understanding the molecular mechanism underlying the biosynthesis, transport, and release of BDNF, emphasizing the role of HAP1 and sortilin in the intracellular trafficking of BDNF.

List of Abbreviations

ARF	ADP-ribosylation factor
BDNF	Brain-derived neurotrophic factor
BDNF-GFP	Green fluorescent protein-tagged BDNF
CaRF	Calcium-responsive transcription factor
CREB	cAMP-responsive element-binding protein
HAP1	Huntingtin-associated protein 1
HFS	High-frequency stimulation
LFS	Low-frequency stimulation
LTD	Long-term depression
LTP	Long-term potentiation
MMPs	Matrix-metalloproteinases
MPR	Mannose 6-phosphate receptors
proBDNF	Precursor of brain-derived neurotrophic factor
RGCs	Retinal ganglion cells
SNP	Single nucleotide polymorphism
TGN	Trans-Golgi network
tPA	The tissue-plasminogen activator plasmin
trkB	Tyrosine kinase receptor B

1 Introduction

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, plays important roles in neuronal differentiation and survival, synaptic plasticity, and long-term potentiation during the entire life. BDNF mainly expresses in neural tissues and it is transported both anterogradely and retrogradely in neurons. It has an autocrine and paracrine effect on neuronal cells. BDNF mediates its biological action through binding to its high affinity receptor, tyrosine kinase receptor B (trkB), and p75, the pan receptor for other members of the neurotrophin family. However, the precursor of BDNF (proBDNF) has different binding characteristics and distinct biological activity in comparison with mature BDNF. It is well known that the biological action of BDNF is activity dependent and has been extensively explored. However, the molecular mechanism of its axonal transport and processing is not completely understood. Here in this chapter, we focus on BDNF axonal transport and describe the recent progress in BDNF trafficking, processing, and release.

2 The Expression of BDNF

The BDNF expression starts at an early embryonic stage. Its mRNA is expressed throughout development reaching the highest levels by postnatal day. In adult animals and humans, BDNF is expressed in the brain, with the highest levels in the hippocampus and cortex, suggesting an important role of this factor in the maintenance of the normal central nervous system. In humans, the BDNF gene is located in chromosome 11.

Like all neurotrophins, BDNF is expressed as a precursor encompassing two domains, the prodomain and the mature domain. The BDNF coding sequence has been determined in mice, pigs, rats, and humans. In all of these species, the mature BDNF shows complete identity in amino acid sequence. The expression of BDNF is well controlled in neurons by transcriptional regulation and differential targeting of BDNF transcripts at distinct cellular locations. In addition, neurotransmitters and membrane depolarization are also involved in the regulation of BDNF expression.

BDNF has at least 18 transcripts produced by alternative promoters, splicing, and polyadenylation sites, but each encodes an identical BDNF protein product. This complex transcriptional organization seems to provide multiple layers of regulation through alternative promoter usage, differential mRNA stability, and differential subcellular localization of either mRNA or protein. For example, it has been shown that the expression of the BDNF gene is regulated by neural activity through calcium-mediated pathways and that different BDNF mRNA transcripts driven by different promoters are differentially regulated. BDNF exon I and exon IV transcripts have previously been characterized as the most highly induced BDNF mRNAs, in response to excitatory treatment and KCl-mediated membrane depolarization in embryonic cortical neuron cultures. Several calcium-responsive elements and transcription factors binding to these elements in the promoter regions have been characterized. BDNF exon V, exon VII, exon VIII, and exon IXA transcripts have also been shown to be regulated by kainic acid and that the induction magnitude is comparable to that of BDNF exon I and IV transcripts. Importantly, differential regulation of BDNF mRNAs is found in mood disorder, exercise, and learning. Thus, it is suggested that the differential regulation of BDNF exon mRNAs might be involved in different neurodegenerative diseases in which BDNF levels are altered.

Regulation of the BDNF gene has been well studied. In addition to the transcriptional regulation, different BDNF messenger RNA (mRNA) transcripts are found at different subcellular locations in hippocampal and cortical neurons. BDNF expression was remarkably increased in the neocortex following experimentally induced seizures (Ernfors et al. 1991; Isackson et al. 1991). Several other studies also reported regulation of BDNF in vivo by sensory stimulation and in vitro by neuronal activity (Castren et al. 1992; Bozzi et al. 1995; Ghosh and Greenberg 1995; Lauterborn et al. 1996), suggesting that this is an important mechanism by which levels of BDNF are normally regulated. The transcription of BDNF can be regulated by neuron activity in hippocampal neurons (Tongiorgi et al. 1997). A recent study also showed that strong depolarizing stimuli, both in vitro and in vivo, cause accumulation of BDNF mRNA and protein in the distal dendrites,

through the activation of the *N*-methyl-D-aspartate and tyrosine kinase receptor B (TrkB) (Tongiorgi et al. 2006). Indeed, neuron activity can modulate the expression of many genes that affect the synaptic plasticity (Prakash et al. 2008). Therefore, knowledge regarding gene regulation of BDNF is important, in order for us to understand how altered BDNF expression and release can have an impact on the function of the neuronal circuit. Future characterization of the regulatory sequences and transcription factors mediating regulation of novel BDNF transcripts in different disease models is important for understanding BDNF gene regulation and its contribution to pathology.

3 BDNF Processing

BDNF, like other neuropeptide, is initially synthesized as a precursor containing a signal peptide in the endoplasmic reticulum. The signal peptide is cleaved off immediately, yielding so-called proproteins which undergo further posttranslational modifications in Golgi apparatus. Following the cleavage of the signal peptide, proBDNF is packaged in trans-Golgi network (TGN) for sorting into secretory vesicles. However, proBDNF may be converted into mature BDNF via both intracellular and extracellular enzymes. Studies show that the cleavage of proBDNF on the RVRR motif occurs in the trans-Golgi, by members of the subtilisin-kexin family of endoproteases such as furin, or in the immature secretory granules by proprotein convertases. It is also observed that tissue-plasminogen activator (tPA) converts proBDNF to the mature BDNF by activating the extracellular protease plasmin, which is critical for long-term potentiation (LTP) of the mouse hippocampus. Whether the conversion of proBDNF to mature BDNF is regulated by extracellular signals is not yet known. To understand the mechanisms that regulate the conversion of proBDNF to mBDNF, some experiments were undertaken to investigate how the physiologically relevant condition is associated with the secretion of specific isoforms of endogenous BDNF. It was demonstrated that under conditions that induce long-term depression (LTD), proBDNF is mainly secreted.

A stable status of endogenous proBDNF is important for its efficient axonal transport. It has been identified that sortilin binds to the prodomain of BDNF, which modulates its stabilization and regulates it into the secretory pathway. This regulation is dependent on the function of sortilin domains. Deletion of sortilin intracellular domain causes BDNF missorting to the constitutive secretory pathway, while overexpression of sortilin ectodomain impairs lysosomal targeting and leads to degradation of BDNF. Our recent data shows that co-expression of transfected proBDNF, HAP1, and sortilin in HEK293 cells can prevent proBDNF degradation, whereas the absence of sortilin significantly increased proBDNF degradation. The effect of sortilin on stabilization of proBDNF protein is dose dependent. These results suggest that normal BDNF trafficking and stabilization in neurons is dependent on the intact function of sortilin, in particular the complex of proBDNF/HAP1 and sortilin (Fig. 1).

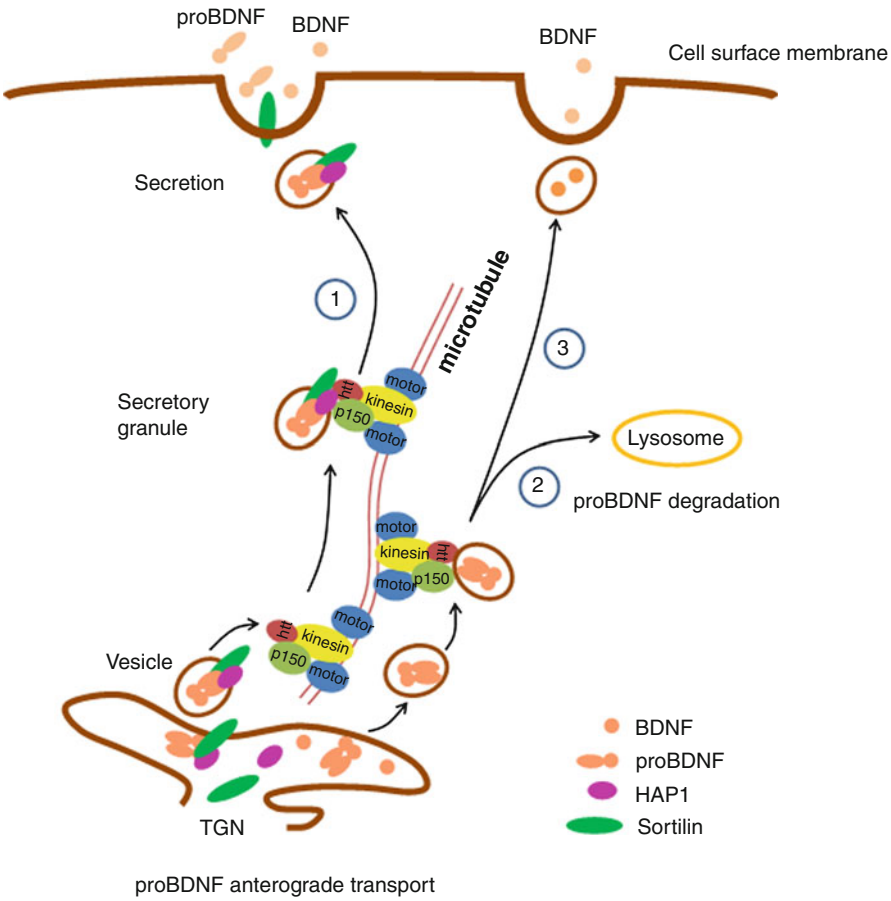

Fig. 1 proBDNF anterograde transport. New synthesized proBDNF proteins exist from endoplasmic reticulum (ER) and move to trans-Golgi network (*TGN*) for packaging and sorting. During the process, proBDNF can form a complex with HAP1 and sortilin and interacts with kinesin motor proteins through Htt and p150Glued. This proBDNF/kinesin complex is transported along with the microtubule to axonal terminal for secretion (*1*). When proBDNF is packaged itself in a vesicle without the participation of HAP1 and sortilin and is carried by the kinesin complex, some proBDNF proteins can be sent to lysosome for degradation (*2*), or a part of proBDNF can be converted to BDNF, which is sent to axonal terminal for secretion (*3*)

4 Transport of BDNF

The classic neurotrophic hypothesis is that neurotrophins are synthesized in peripheral target tissues, uptaken by the innervating nerve terminals, and retrogradely transported to the neuronal cell body, subsequently exerting their biological function by binding and activating their specific receptors. Like other neurotrophic factors,

BDNF was initially considered to be a retrogradely transported neurotrophic factor. ^{125}I-labelled BDNF injected into peripheral target tissues was found retrogradely transported into the subpopulation of peripheral and central neuronal cells. A study by intrastriatal infusion of BDNF revealed its retrograde transport in neurons in the brain. Furthermore, intraparenchymal injections of BDNF resulted in widespread retrograde transport throughout the central nervous system (CNS). However, the retrograde mode of BDNF transport cannot explain some of its functional roles. Moreover, it has been demonstrated that BDNF is produced in the sensory neurons because its mRNA and protein are both expressed in sensory neurons. Conversely, BDNF mRNA is not expressed in peripheral axonal terminals, whereas BDNF protein is detectable in terminals, suggesting that BDNF might be anterogradely transported in neurons.

We are among the first few groups that discovered the anterograde transport of BDNF in sensory neurons. We demonstrated that BDNF is transported anterogradely via both peripheral and central processes of spinal sensory neurons. Using specific antisera, we examined the distribution of BDNF immunoreactivity and found it to be present within a subpopulation of sensory neurons, primarily those with a small-to-medium diameter. The immunoreactivity was accumulated on both the distal and proximal sides of a ligature on the sciatic nerve (Fig. 2). The accumulation on the distal side, but not on the proximal side, was substantially reduced by pretreatment with BDNF antibodies in vivo. In contrast to the periphery, the immunoreactivity was only accumulated on the proximal side of a lesion of the dorsal root. In the spinal cord, most nerve terminals immunoreactive for BDNF were identified in lamina II. Lesion of the dorsal root led to a reduction of these nerve terminals. These studies have provided clear evidence that the factor is transported not only retrogradely, but also anterogradely from the spinal ganglia to terminals in the periphery and spinal cord. Consistently, studies from other research groups also confirmed anterograde transport of BDNF.

It was shown that BDNF is widely distributed in nerve terminals, even in brain areas such as the striatum that lack BDNF messenger RNA, suggesting this factor is anterogradely supplied to some areas of the brain. Interestingly, by using the same method, a study in our laboratory also showed that proBDNF is both anterogradely and retrogradely transported in sensory neurons. Similar to the mature BDNF, after ligation of the sciatic nerve, increased proBDNF expression can be detected both proximal and distal to the site of ligation. In CNS, analysis of distribution of BDNF and mRNA revealed more detailed transport patterns of BDNF in some neural structures. BDNF is also anterogradely transported in hippocampus mossy fibers and nerve terminals in other brain structures. Furthermore, BDNF is also found to be anterogradely transported in retina cells. Retinal ganglion cells (RGCs) also anterogradely transport exogenous neurotrophins including BDNF to the midbrain tectum/superior colliculus with significant downstream effects.

Consistent with in vivo studies, in vitro studies also showed BDNF is transported in an anterograde mode. Several neuronal types can internalize exogenous neurotrophic factors which then can be anterogradely transported to axonal

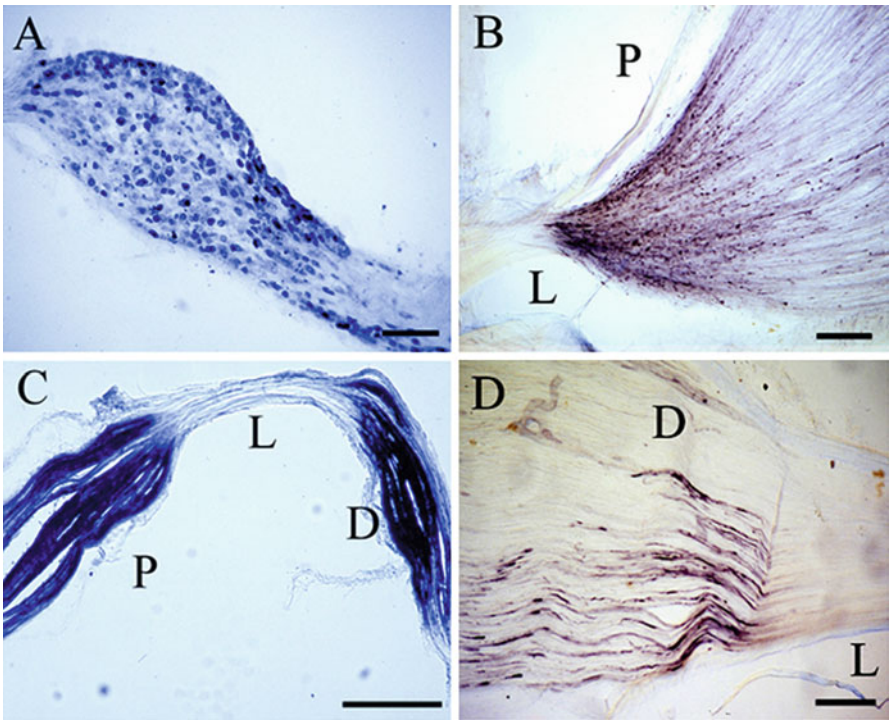

Fig. 2 Microphotographs showing the immunoactivity and transport of BDNF in the peripheral nervous system of adult rats. Panel (**a**): nodose ganglion; panel (**b**): proximal segments of ligated sciatic nerve; panel (**c**): ligated vagal nerve; (**d**): distal segment of ligated sciatic nerve. Abbreviations: *L* ligation site, *P* proximal to the ligation site, *D* distal to the ligation site. Scale bars in (**a**), (**b**), and (**d**) = 100 μm, in (**c**) = 1 mm

pathways. Neuronal bodies and dendrites possess receptors for the ligands, and a significant amount of internalized ligands are targeted for anterograde axonal transport, apparently with subsequent axonal release. While numerous studies demonstrate anterograde transport of trophic factors in axons, only few provide direct evidence of transcytosis of endogenous or exogenous trophic factors. Interestingly, a study comparing the trafficking pattern of BDNF in axons and dendrites demonstrated that axonal anterograde transport is the major form of BDNF transport. However, the axonal transport pattern is different from the dendritic transport pattern. The pattern and velocity of the trafficking of fluorescent protein-tagged BDNF is different between axons and dendrites. The movement of BDNF-GFP puncta in axons is faster than in dendrites, suggesting that the anterograde transport in axons may be the dominant site of BDNF release.

The anterograde transport of BDNF appears to be a universal phenomenon in the mammal nervous system. However, the real-time in vivo record of endogenous BDNF transport is lacking because of technique difficulties and a relatively small amount of detectable endogenous BDNF. The anterograde mode of BDNF

transport is critical for the neurotropism, which is not merely an alternative way for retrograde transport. Numerous studies have demonstrated that the bidirectional transfer and trafficking of BDNF through the neural network is a fundamental mechanism for its trophic regulation of neuronal survival, differentiation of phenotypes and dendritic morphology, synaptic plasticity, as well as excitatory neurotransmission. It is now clear that newly synthesized BDNF is packaged into vesicles and anterogradely transported to neuronal terminals for secretion, via interaction with kinesin motor protein complex along the microtubules. The molecular mechanism underlying BDNF intracellular trafficking still remains to be elucidated. Nevertheless, recent studies have provided some evidence of HAP1 and sortilin playing critical roles in BDNF trafficking and processing.

In search of the potential molecules involved in BDNF intracellular trafficking, we found that HAP1 and sortilin are ideal candidates. HAP1 is a cytoplasmic protein enriched in the brain and spinal cord. HAP1 was identified as a Huntingtin (Htt)-binding partner by yeast two-hybrid screens. It also associates with microtubules in addition to several vesicular organelles. Htt is a scaffold protein predominantly found in the cytoplasm, where it associates with various vesicular structures and molecular motors to form a cargo complex and play a role in intracellular trafficking. Despite the important role of HAP1 in neurons, the precise function of HAP1 in neurons remains to be seen. Some recent studies have shown that HAP1 is involved in endocytosis and vesicular trafficking. The expansion of polyglutamine (polyQ) repeats in Htt and the deletion of either HAP1 or p150Glued can reduce BDNF axonal transport and lead to the degeneration of striatal neurons. It is suggested that a molecular bridging of HAP1 with BDNF and kinesin motor complex may be involved in BDNF axonal transport. For example, HAP1 interacts with the p150Glued subunit of dynactin and regulates axonal trafficking. HAP1 also mediates the anterograde transport of the GABAA receptor to synapses and of neurotrophic factor receptors for neurite outgrowth.

Sortilin is a member of the Vps10p domain receptor family including SorLA and SorCS1, SorCS2, and SorCS3-3. Sortilin is highly expressed in the cortex and hippocampus. It can function as a cell surface receptor for proneurotrophins, neurotensin, and lipoprotein lipase. Sortilin is mainly distributed in intracellular compartments where it binds to diverse ligands including hydrolases. Sortilin is a sorting molecule which sorts lysosomal hydrolytic enzymes to lysosomes and BDNF into secretory pathways. Its short (53 aa) cytosolic tail contains a motif that is similar to that of the sorting receptor mannose 6-phosphate receptors (MPR) and low-density lipoprotein (LDL) receptors, which interact with the family of Golgi-localizing, γ-adaptin ear homologous ADP-ribosylation factor (ARF)-binding proteins (GGA) that shuttle between the Golgi and endosomes/lysosomes. The C-terminal acidic cluster-dileucine motif mediates endocytosis of the receptor. The cytosolic domain of sortilin also interacts with the retromer complex, which recycles sortilin back to Golgi for further trafficking and sorting of proteins. The retromer complex is composed of 3–4 VPS molecules VPS35, VPS29, and VPS26.

There are other factors which may directly or indirectly affect the BDNF trafficking. A Val66Met substitution of BDNF led to a significant decrease

of BDNF trafficking and secretion and was found to be associated with increased susceptibility to neuro-disorders including Alzheimer's disease, Parkinson's disease, depression, and bipolar disorder. Since sortilin interacts with the prodomain of BDNF in a discrete region containing the Met substitution, the altered BDNF trafficking and secretion is likely due to the disruption of the interaction between BDNF and sortilin. This concept is also supported by the evidence that sortilin is involved in anterograde transport of BDNF. These studies reveal a role of sortilin in mediating trkB receptors and BDNF anterograde transport, which is important for neurotrophin-induced neuronal survival. In addition, Jun NH (2)-terminal kinase-interacting protein 3 (JIP3) mediates trkB axonal anterograde transport and enhances BDNF signaling by directly interacting with trkB juxtamembrane region and linking trkB to kinesin-1. Given that both JIP3 and sortilin bind to trkB, their effect on enhancing BDNF signaling may rely on functions of both proteins. Nonetheless, these findings provide a novel mechanism of how the TrkB anterograde transport can be coupled to BDNF signaling in axons.

Our recent studies demonstrate that HAP1 and sortilin may play an important role in BDNF trafficking and processing. We investigated the HAP1 and BDNF interaction and the role of HAP1 in BDNF trafficking by using cell transfection and HAP1 knockout mice. Our mapping studies demonstrate that the region of HAP1 between amino acids 371 and 445 contains proBDNF-binding sites. Pull-down assays show that the region between amino acids 65 and 90 of the BDNF prodomain has a key structure for HAP1 binding. Our results also show that HAP1 regulates axonal transport and the activity-dependent release of BDNF, through HAP1 interaction with proBDNF but not mature BDNF. Reduced association of HAP1 with proBDNF by polyQ-expanded Huntingtin or Val66Met BDNF variant can negatively impact on proBDNF trafficking. We also observed a similar reduction in HAP1 and proBDNF interaction using the brain homogenate of Huntington's disease patients, suggesting that this reduced association of HAP1 with proBDNF can occur in vivo and may cause a deficiency of BDNF anterograde axonal transport. This hypothesis is supported by the evidence that ligation of the sciatic nerve did not show increased accumulation of BDNF in the proximal and distal segments of the ligation site and the deficit in proBDNF trafficking in HAP1−/− neurons was rescued by introduction of HAP1 cDNA in these neurons. Therefore, our data suggests that HAP1 may play a regulatory role in axonal transport of BDNF. Recently we also found that HAP1 can interact with proBDNF and form a complex with sortilin. This complex is found in most cellular organelles involved in protein sorting and trafficking such as ER, TGN, and Golgi complex. The complex can stabilize the proBDNF. In co-transfected HEK 293 cells, the complex helps to prevent proBDNF degradation. Furthermore, the complex facilitates furin cleavage to release mature BDNF.

5 BDNF Release and Secretion

There are two separate types of secretion pathways for BDNF: the regulated pathway and the constitutive pathway. The former employs Ca^{2+}-dependent exocytosis of

secretory granules, while the latter employs a distinct type of vesicles which releases the cargo by default when reaching the plasma membrane. It is suggested that the subcellular location of BDNF is important for understanding the function of BDNF and its role in synaptic plasticity. Since the level of endogenous BDNF is very low in most neuronal tissues, overexpression of BDNF-GFP has been used to study the transport and release of BDNF in neuronal culture. Although the expression of tagged protein may have altered binding to sorting partners, the distribution of BDNF-GFP is similar to that observed for endogenous BDNF. In dendrites, BDNF-GFP is packaged into secretory granules for the regulated secretion pathway, suggesting a dendritic secretion of BDNF. This finding is further supported by the evidence that local synthesis of dendritic BDNF and dendritic BDNF mRNA transcript has been detected in cultured hippocampal neurons. Also, alteration of dendritic BDNF mRNA can cause the change of the local BDNF level. However, a recent study, using specific monoclonal antibodies to label proBDNF and mature BDNF, has shown that proBDNF and mature BDNF exist in presynaptic dense core vesicles but not in dendrites. Hippocampal neurons from mutant mice with overexpressed BDNF also show that BDNF is only present in presynaptic dense core vesicles. The finding challenges the previous concept of activity-dependent dendritic synthesis and release of BDNF. However, the finding supports the conclusion that BDNF is transported in an anterograde mode, which is in contrast to the previous concept that BDNF is retrogradely transported in target cells. This in vivo study appears to provide convincing evidence that BDNF is located in presynaptic dense core vesicles.

There are controversial views about the neuronal release of proBDNF. Barde's group reported that proBDNF is only an intermediate metabolic product of precursor BDNF, which only presents transiently and does not have biological functions. In contrast, a similar study claims that proBDNF is present and is released from neurons exerting biological functions. In this study, different culture conditions were applied to avoid possible glial contamination, and alpha 2 antiplasmin was used to reduce the cleavage of secreted proBDNF. The secretion of proBDNF from cultured hippocampus neurons was convincingly demonstrated. The conclusion drawn from this study appears to be consistent with that from a previous study, reporting that the cleavage of proBDNF by tPA/plasma is essential for long-term hippocampus plasticity. tPA converts proBDNF to mature BDNF by activating the extracellular protease plasmin, and such conversion is critical for L-LTP expression in mouse hippocampus. Moreover, application of mBDNF is sufficient to rescue L-LTP when protein synthesis is inhibited, which suggests that mBDNF is a key protein synthesis product for L-LTP expression.

To reveal which isoform of BDNF is secreted under physiological stimulation, frequency stimulation of neuronal cells was performed. Studies have shown that proBDNF is mainly secreted from neuronal terminals during low-frequency stimulation (LFS). In contrast, mature BDNF is the major secreted isoform when neurons were stimulated with high-frequency stimulation (HFS, a condition that induces LTP). Thus, the secretion of either proBDNF or mature BDNF is dependent on low- or high-frequency neuronal activity. These findings suggest that high-frequency neuronal activity can enhance the function of mature BDNF.

In addition, the secretion of proBDNF or mature BDNF is also controlled by activity-dependent synaptic competition/elimination. ProBDNF can trigger synaptic depression and subsequent retraction of the axonal terminal through p75 receptors in Xenopus neuromuscular synapses. Active axonal terminals can cleave proBDNF to mature BDNF which protects the active terminal from depression and retraction.

BDNF release is a regulated response to its functional requirement. The dendritic BDNF synthesis and the release of BDNF-GFP under high-frequency electric stimulation provide evidence that BDNF release is in an activity-dependent manner from dendrites and axons. Although the importance of BDNF in synaptic plasticity has been clearly established, direct evidence for the activity-dependent dendritic secretion of BDNF has not been obtained. In the cerebellum, the depolarization-dependent release of BDNF from granule cells was reported to be regulated by the CAPS2 molecule, which leads to cell differentiation and survival during cerebellar development. Furthermore, exercise can increase the serum level of BDNF in human subjects. The molecular interaction has been determined to be responsible for BDNF-regulated release.

6 BDNF Transport and Release in Neurological Diseases and Neurotoxicity

BDNF is associated with the development of many neurological and psychiatric disease conditions because of its wide distribution and great functional diversities. Deficiencies in its synthesis, trafficking, and release play important roles in the pathogenesis of a wide range of neurodegenerative diseases and cognitive disorders. However, the molecular dissection of the trafficking and release of BDNF in diseased condition is limited, although the axonal transport in these disease conditions has been extensively studied. Axonal transport defects have been described as an early pathological feature in a variety of animal models of Alzheimer's disease (AD) and tauopathies. It is clear that BDNF axonal transport of BDNF is impaired in AD. In Huntington disease, there is reduced expression of BDNF and impaired axonal transport in the striatum. Huntingtin enhances retrograde transport of BDNF, which involves HAP1 and dynactin, but mutant Huntingtin is defective in this process (Gauthier et al. 2004). In Parkinson's disease, there is also reduced axonal transport of BDNF in dopaminergic neurons. The understanding of synthesis, transport, trafficking, and the release of BDNF in diseased conditions will provide useful knowledge for understanding the pathogenesis and underlying molecular mechanism and will help in developing novel therapeutic strategies.

BDNF, a powerful trophic factor with diverse functions, can act as a protector against some cellular damages caused by the neurotoxicity induced by physical and chemical insults. BDNF is a survival factor for cultured rat cerebellar granule neurons and protects them against glutamate-induced neurotoxicity. Restoring BDNF level CEP-1347 reduces mutant Huntingtin-associated neurotoxicity. Overexpression of BDNF is shown to firmly regulate cell survival and differentiation of neuron stem cells (NSC) and protects differentiated NSC against neurotoxicant trimethyltin

(TMT)-induced neurotoxicity through the PI3K/Akt and MAPK signaling pathways. BDNF can also protect against beta-amyloid-induced neurotoxicity both in vitro and in vivo in rats. How BDNF trafficking and release is affected in neurotoxicity would be an interesting area to explore.

7 Conclusion

BDNF is important for neuronal survival and synaptic plasticity. Its synthesis, transport, and release have been intensively investigated since its discovery. It is clear now that BDNF is both anterogradely and retrogradely transported in axonal terminals and it is released in an activity-dependent manner. Although controversies exist regarding the subcellular distribution of BDNF and its exact location of release, more convincing evidence shows that BDNF is stored in presynaptic dense core vesicles, suggesting that BDNF is predominantly transported in an anterograde mode. However, the molecular mechanism underlying intracellular trafficking has not been completely understood, particularly in diseased conditions. Our recent studies provide new evidence that HAP1 and sortilin play an important role in intracellular BDNF trafficking and processing. Future studies should focus on better understanding of more profound molecular mechanisms involved in the trafficking, release, and signaling of BDNF in diseased conditions. Insight into the molecular mechanism of BDNF would help in developing therapeutic treatment for different neurological disorders by targeting mature BDNF and proBDNF.

Trafficking of Neurotrophins and Their Receptors and Pathological Significance

Christopher S. von Bartheld

Contents

Abstract

To survive and function properly, innervating neurons need to communicate with their targets. This task is accomplished, in part, by trafficking of neurotrophic molecules, in particular the family of nerve growth factor-like molecules, the neurotrophins (NTs). This chapter reviews the intra- and intercellular trafficking of NTs and their receptors with a focus on axonal transport and synaptic transfer, methodology, current concepts, and the relevance for pathological neurological conditions. Neurotrophins are transported by retrograde axonal transport from the neuronal or non-neuronal target cells to the innervating neuronal cell body. The neurotrophic hypothesis postulates that targets produce limiting amounts of trophic substances, including NTs, for

which innervating neurons compete. NTs bind to NT receptors on axonal terminals and are internalized, presumably in vesicles or endosomes (signaling endosome hypothesis), and are transported by dynein-mediated retrograde axonal transport along microtubules to the cell body where the NT-specific receptors (trkA, B, and C) elicit signal transduction cascades that result in increased neuronal survival, differentiation, and/or plasticity. In addition to the retrograde route, NTs can also be transported anterogradely along axons and can be released at the axon terminal to influence postsynaptic cells. Thus, NTs can transfer in both directions across the synaptic cleft. NT receptors are expressed on the presynaptic as well as postsynaptic membrane, allowing for the activation of signal cascades at pre- as well as postsynaptic sites. NTs such as BDNF and NT-3 are particularly important messengers in synaptic plasticity. In addition to mature NTs, uncleaved precursors (pro-NTs) can also be trafficked and released, and their actions can oppose the functions of mature NTs by activating death signaling through the common NT receptor, p75. Several neurological disorders are currently being investigated for defects in NT trafficking, including Alzheimer's disease, Huntington's disease, Parkinson's disease, neurodevelopmental disorders, epilepsy, glaucoma, hyperalgesia, neuropathies, depression, and eating disorders. Progress in the understanding of physiological and pathological mechanisms of NT trafficking therefore may lead to improved therapies for neurological diseases.

Keywords

Axonal transport • Neurotrophin • Neurotrophin receptor • Neurotrophic hypothesis • Neurodegeneration • Synaptic plasticity

List of Abbreviations

BDNF	Brain-derived neurotrophic factor
CREB	cAMP response element-binding protein
DRG	Dorsal root ganglion
EM	Electron microscopy
ER	Endoplasmic reticulum
GFP	Green fluorescent protein
LDCV	Large dense-core vesicle
LTP	Long-term potentiation
MVB	Multivesicular body
NGF	Nerve growth factor
NT	Neurotrophin
NT-3	Neurotrophin-3
NT-4	Neurotrophin-4
P75	Common neurotrophin receptor
TrkA	Tropomyosin receptor kinase A
TrkB	Tropomyosin receptor kinase B
TrkC	Tropomyosin receptor kinase C

1 Introduction

Intra- and intercellular trafficking of neurotrophic factors is fundamentally important for the neurotrophic hypothesis. This wider framework includes the initial overproduction of neurons during development, followed by programmed (developmental) neuronal death, and the regulation of survival or death of neurons by neurotrophic factors, including the NTs. Besides survival functions, NTs have additional maintenance and plasticity functions in the adult nervous system. Nerve growth factor (NGF) served as the first, prototypical neurotrophic factor. NGF trafficking was closely linked to a paradigm shift in the later half of the 1900s that provided a plausible explanation of how the final number of neurons is matched to the size of their target (systems matching) and how neurons receive feedback from their target. This concept also involves competition for limited trophic supply in the target and trafficking of the NT from the target to deliver the trophic signal to the cell body of the innervating neuron. Early NGF research benefited from some remarkably favorable circumstances that have been reviewed on multiple occasions (Levi-Montalcini 1987; Purves 1988; Oppenheim 1996).

The discovery of the specific and saturable axonal transport of NGF has had a major impact in the field (Hendry et al. 1974; Stoeckel et al. 1975; reviewed from a historical perspective by Oppenheim 1996). Probing neurons with radiolabeled NGF in both in vivo and in vitro settings provided major insights due to high specificity and sensitivity of a quantifiable signal. These studies provided crucial experimental support for the neurotrophic hypothesis. NTs were studied in "Campenot chambers" (Campenot 1977), an experimental approach that allowed to examine NT trafficking in vitro combined with biochemical and molecular analyses (Bhattacharyya et al. 1997; Watson et al. 1999, 2001; MacInnis and Campenot 2002). The 1980s and 1990s saw further seminal progress in NT research with Yves Barde's identification, purification, and sequencing of the second NT, BDNF (Leibrock et al. 1989), and the subsequent expansion of the NT family (NT-3, NT-4). Not only was the entire family of NTs identified but also two types of NT receptors – first p75, then trkA, and other trks (Barbacid 1994; Huang and Reichardt 2003). At the same time, it was realized that signaling and endocytosis are intertwined in important ways (Di Fiore and de Camilli 2001; Sorkin and von Zastrow 2002), and progress was made in the identification of the molecular motors that move organelles and molecules along microtubules: dynein and kinesins and associated motor proteins (Hirokawa 1998; Goldstein and Yang 2000; Vallee et al. 2004). The early 2000s saw the distinction of the roles of mature NTs vs. pro-NTs and increased attention to pro-NT's death signaling capacities (Lee et al. 2001; Lu et al. 2005). The relevance of NTs – especially BDNF – for synaptic plasticity and LTP was realized; this added an entire new dimension in NT function and with that, also new questions and insights into NT trafficking (Poo 2001; Lu et al. 2005).

The scope and focus of this review is the intracellular and intercellular trafficking of NTs and their receptors; the review will consider primarily axonal but also dendritic, synaptic, and somal forms of trafficking. The chapter will also review current knowledge of how NTs are released from neurons and their target cells, how

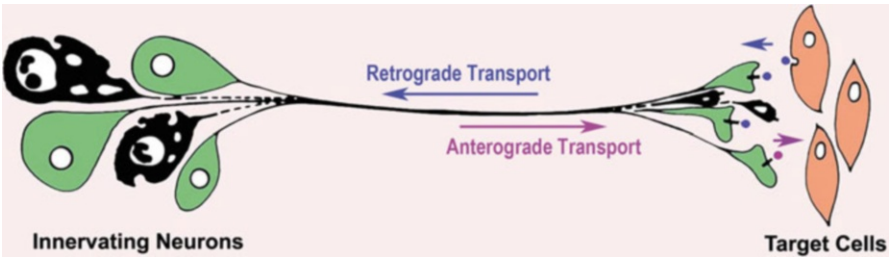

Fig. 1 Two major trafficking modes of neurotrophins: retrograde (*blue arrow*) and anterograde axonal transport (*purple arrow*). The neurotrophic hypothesis postulates that developing neurons survive (*green neurons*) only when they successfully compete for target-derived trophic molecules (*blue arrow*) that are internalized at the nerve terminal and are transported retrogradely along the axon (*long blue arrow*) to the cell body. Neurons that fail to obtain a sufficient flow of trophic molecules from the target die by programmed cell death (*black neurons* with condensed chromatin). Neurons also synthesize and send neurotrophins anterogradely along the axon (*long purple arrow*), from the cell body to the nerve terminal, where the neurotrophin is released (*purple*) (Modified and reproduced with permission from the publisher, Elsevier (Barde 1989, *Neuron* **2**, 1525–1534))

they are internalized and transported retrogradely and anterogradely (Fig. 1), and the type of methodology that is used with a discussion of technical challenges and limitations, and finally will examine the relevance of NT trafficking for neurological diseases. For other aspects of NT physiology and pathology, the reader is referred to previous reviews, e.g., on NT history (Oppenheim 1996), NT signaling (Huang and Reichardt 2001, 2003), synaptic plasticity/LTP and synaptic transfer of NTs (Poo 2001; Lessmann et al. 2003), functions of pro- vs. mature NTs (Lee et al. 2001; Lu et al. 2005), internalization of NT receptors in cell lines (Bronfman et al. 2007), retrograde transport of NTs (Reynolds et al. 2000), and retrograde NT signaling (Zweifel et al. 2005).

2 Release of Neurotrophins (NTs)

According to the neurotrophic hypothesis, NTs need to be released from target cells that can be neurons or other, non-neuronal cells, such as muscle. NTs can also be released from glial cells. NTs are extremely potent signaling molecules (Thoenen and Barde 1980), and therefore, cells release frustratingly low amounts of endogenous NTs (Gärtner et al. 2000; Dieni et al. 2012, but see Rush 2001, for an alternative view). Low amounts of released NTs are consistent with the neurotrophic hypothesis that postulates that trophic material be released in limiting amounts from target cells and must be competed for by innervating neurons. The apparent low abundance of NTs for release poses a considerable technical challenge, as will be further discussed in Sect. 5. Nevertheless, studies have shown that NTs can be released from different neuronal compartments, including dendrites (Hartmann et al. 2001; Kojima et al. 2001) and axon terminals (von Bartheld et al. 1996a; Fawcett et al. 1997; Kohara et al. 2001; Lever et al. 2001; Wang et al. 2002), while release from cell bodies is less

clear (Blöchl and Thoenen 1995; Balkowiec and Katz 2000). How are NTs or pro-NTs trafficked to sites of release? This is presumably accomplished by trafficking along routes previously established for other peptides, namely, through rough endoplasmic reticulum (ER), transport through the Golgi system, glycosylation, and cleavage of the pro-form in the Golgi system (Conner et al. 1998; Mowla et al. 1999, 2001; Farhadi et al. 2000; Lessmann et al. 2003), while the role of smooth endoplasmic reticulum is less clear (Gärtner et al. 2000). Distinct vesicles containing BDNF can be targeted to either dendritic or axonal compartments (Adachi et al. 2005; Dean et al. 2012).

Cells release peptides via two principal types of release, constitutive and regulated (activity-dependent) modes (Burgess and Kelly 1987). Release of NTs has been reported to be accomplished by both, constitutive and regulated pathways (Blöchl and Thoenen 1995; Goodman et al. 1996; Gärtner and Staiger 2002; Lessmann et al. 2003), although some investigators question the dichotomy and the existence of a true activity-independent baseline of release (Poo 2001). Several groups showed activity-dependent release (Ghosh et al. 1994; Blöchl and Thoenen 1995). Furthermore, the pattern of stimulation frequency is important (Balkowiec and Katz 2000), and release appears to depend on the status of internal calcium stores (Blöchl and Thoenen 1995; Gärtner and Staiger 2002; reviewed by Lessmann et al. 2003). Such release modes are highly relevant for mechanisms of LTP. In this context, properties of a val-met mutation of BDNF are of interest – this mutation does not affect constitutive release, but it impairs regulated BDNF release, apparently due to disruption of a trafficking signal in the BDNF prodomain region (Egan et al. 2003). The resulting defect in BDNF sorting to the regulated secretory pathway has consequences for several neurodegenerative and psychiatric disorders, including depression, eating, and bipolar disorders (Chao et al. 2006), as discussed in Sect. 6 of this review. Which compartments and organelles are involved in NT release? Ultrastructural studies designed to reveal the compartments and organelles involved in NT release from neurites have been inconclusive (Gärtner et al. 2000). Smooth ER membranes were labeled as well as microtubules, but there was no accumulation at synaptic vs. extrasynaptic sites, and large dense-core vesicles (LDCVs) were not labeled. The examination of the ultrastructural distribution in axon terminals has consistently shown NTs to be associated at least to some degree with LDCVs (Michael et al. 1997; Fawcett et al. 1997; Luo et al. 2001; Salio et al. 2007; Dieni et al. 2012). It has been proposed that the apparent lack or paucity of NT immunoreactivity in dendrites (Drake et al. 1999) is due to NTs being "obscured" by trks, so that NT antibodies fail to recognize NTs when they are bound by trk receptors (Rush 2001).

Release at synaptic/extrasynaptic sites – wiring or volume transmission? Being neuropeptides, NTs are supposed to be released primarily at extrasynaptic locations via "volume transmission" (Merighi 2002; Torrealba and Carrasco 2004; Feng et al. 2011), but not directly at the synaptic density. Consistent with such volume transmission, NTs appear to be released from neurites without preference for synaptic sites (Gärtner et al. 2000; Hartmann et al. 2001; Gärtner and Staiger 2002). On the other hand, NTs can be released from axon terminals,

as indicated by studies examining synaptosomes (Androutsellis-Theotokis et al. 1996; Fawcett et al. 1997), DRG terminals (Lever et al. 2001), cultured neuronal networks (Kohara et al. 2001), and retinal ganglion cell axon terminals (Wang et al. 2002). This suggests synaptic release after anterograde axonal transport, but primarily extra- (or iuxta-)synaptic release from postsynaptic sites in dendrites. Recent work indicates that synaptotagmin (Syt-IV) is involved in targeting BDNF-containing vesicles to either dendritic or axonal synaptic sites where they are released by activity-dependent mechanisms (Dean et al. 2012).

Are release mechanisms different between different NTs? Some studies have reported that BDNF release is regulated (or that regulated release occurs over a baseline constitutive component, Blöchl and Thoenen 1995; Lessmann et al. 2003), while NGF (and NT-3) release was reported to always be constitutive (Mowla et al. 1999; Farhadi et al. 2000). However, such differences may be ascribed to differences in experimental protocols rather than true differences between NTs (Griesbeck et al. 1999; Neet and Campenot 2001; Wu et al. 2004), and, as mentioned, some investigators question whether constitutive release truly exists for NTs (Poo 2001).

Initially, only release of mature NTs was envisioned, based on the assumption that all pro-NTs were cleaved intracellularly prior to release (Mowla et al. 1999, 2001; Farhadi et al. 2000). It is now thought that cells differ in the degree of such cleaving, resulting in release of both pro-NTs and mature NTs. If cleavage can occur both intra- and extracellularly, then this provides a novel level of complexity in the regulation of NT availability and function (Lee et al. 2001; Lu et al. 2005). However, because of the low abundance of released endogenous NTs, it is still controversial whether NTs and specifically BDNF are released by neurons in vivo as the pro-NT form or mostly as mature BDNF (Matsumoto et al. 2008; Yang et al. 2009; Greenberg et al. 2009; Dieni et al. 2012). This is an important question that has resulted in an ongoing controversy. Endogenous proBDNF can be transported anterogradely and retrogradely along axons (Wang et al. 2006), but this does not inform about the released form of BDNF. BDNF is easier to measure when overexpressed or tagged, and in vitro, but these conditions may change the release mode, the cleavage properties, and capacity of NT trafficking, and the in vitro condition may not reflect the in vivo situation (see Sect. 5).

Another question is whether the release of newly synthesized NTs is different from that of recycled (internalized) NTs. Based on evidence from other growth factors and examination of exogenous (radiolabeled) NTs, a substantial fraction of released and internalized trophic factors are not immediately degraded, but shuttled into a recycling pathway in neurons (von Bartheld et al. 2001; Rind et al. 2005). Depending on how much NT may be recycled rather than degraded, a major fraction of NTs in neurons may not comprise newly synthesized NT, but rather recycled NT after its initial release and internalization (von Bartheld et al. 2001; Lessmann et al. 2003). When recycled, what is the storage compartment? Multivesicular bodies (MVBs) are strong candidates for NT storage – NT-filled MVBs are often localized adjacent to synapses on the postsynaptic side (Rind et al. 2005; von Bartheld and Altick 2011). It has been shown that the recycled pool of BDNF indeed is relevant for LTP (Santi et al. 2006).

What is the role of NT receptors in release? NT receptors need to be targeted to pre- as well as postsynaptic membranes (Ascaño et al. 2009), indicating that NTs and/or pro-NTs can be released at synapses and may bind to pre- as well as postsynaptic NT receptors. Truncated trkB receptors have a role for BDNF release from glial cells (Alderson et al. 2000) and possibly neurons as well (Biffo et al. 1995).

3 Retrograde Axonal Transport

This section will follow the pathway of NTs when they are internalized by axon terminals and sent onto a trafficking route along the axon (a distance that may exceed 1–2 m) and that culminates with the delivery of the NT (and NT-induced signals) to the neuronal cell body. The evidence for receptors and organelles involved in this process will be reviewed, and the significance of the prevailing "endosome signaling hypothesis" and its alternatives discussed.

Internalization. It has been appreciated for a long time that the internalization of NTs is receptor mediated (Hendry et al. 1974; Stoeckel et al. 1975; Reynolds et al. 2000). The NT-receptor complex can be endocytosed by either clathrin-mediated or non-clathrin-mediated pathways (Howe and Mobley 2004; Bronfman et al. 2007). The so-called caveosomes may concentrate lipid-raft-derived NT signals (reviewed in Howe and Mobley 2004). Thus, in order to achieve internalization of NTs at the axon terminus, NT receptors need to be targeted first to, and incorporated into, the axon terminal plasma membrane. Which NT receptors mediate internalization and retrograde axonal transport of NTs? This has been examined extensively in the 1990s, and various lines of evidence indicate that NGF is internalized and transported in neurons primarily by trkA, while for other NTs (BDNF, NT-3 and NT-4) both trk receptors and p75 receptors contribute, and NT-4 appears to rely the most on p75 as a transporter (Curtis et al. 1995; von Bartheld et al. 1996b). p75 is believed to be expressed in vivo in a ratio of about five-to-tenfold higher than trk receptors (Chao 1994), and the relationship between p75 and trk receptors and the functional significance of co-expression of these two receptor types has been intensely studied (Bothwell 1995; Bronfman et al. 2007). Co-expression of p75 and trk receptors appears to create a higher-affinity binding site for NTs (Chao 1994; Bothwell 1995; Esposito et al. 2001). Initial models suggested a simultaneous binding of p75, trk, and the NT in a trimeric complex, but this is not consistent with more recent molecular modeling data (Wehrman et al. 2007; Barker 2007). It is possible that p75 receptors "present" the NT to the less common trk receptors (Biffo et al. 1995; Barker 2007). It has been suggested that the NT is initially captured by the more abundant p75 receptors and over time (during axonal transport) accumulates on trk receptors in the signaling endosome (Butowt and von Bartheld 2009; Chowdary et al. 2012). This proposed mechanism is consistent with the known differences in on-rates and off-rates (the p75 receptor has a faster off-rate than the trk receptors – Rodriguez-Tébar and Barde 1988; Bothwell 1995). NT-containing endosomes have been reported to co-localize p75 and trk receptors to varying degrees, and some studies suggest that p75-containing endosomes are routed differently than trk-containing endosomes (Hibbert et al. 2006; Bronfman et al. 2007). It has been known for a long time that

NTs injected directly into the cell body have no trophic effect, demonstrating that the binding of NTs to the cell surface NT receptor and the internalization of the ligand-receptor complex are essential for mediating the trophic signal (Claude et al. 1982; critically reviewed by Neet and Campenot 2001). Several molecules involved in the internalization and transport of NTs and NT receptors have been identified; these include pincher and Rabs (Rab5 and Rab7) (Heerssen et al. 2004; Saxena et al. 2005; Valdez et al. 2005; Deinhardt et al. 2006; Bronfman et al. 2007). The p75 receptor can be cleaved and the C-terminal p75 fragment may be trafficked; this fragment has been shown to retain signaling capacity (Kanning et al. 2003). In summary, there is abundant evidence for retrograde axonal transport of NTs (reviewed in Reynolds et al. 2000) as well as the NT receptors, p75 and trks (Johnson et al. 1987; Ross et al. 1994; Ehlers et al. 1995; Mufson et al. 1999; Moises et al. 2007).

The endosome signaling hypothesis and two alternatives. Evidence for the receptor-mediated internalization of NTs and emerging knowledge about endocytosis of growth factor receptors and their ligands prompted the so-called "endosome signaling" concept: Pinching off NT receptor containing plasma membrane results in vesicles with the NT bound on the inside and the tyrosine kinase domain of the NT receptor on the outside of the vesicle, available for docking of additional signaling molecules (Fig. 2). A large number of studies have accumulated supporting evidence for the validity of this model: Phosphorylated (activated) trkA is retrogradely transported (Ehlers et al. 1995; Bhattacharyya et al. 1997); signaling endosomes can be purified from nerves (Delcroix et al. 2003); they contain the relevant signaling molecules depicted in Fig. 2; some of the NT receptors possess moieties that directly attach to the molecular motor (dynein) that moves the endosome retrogradely along microtubules (Yano et al. 2001; Yano and Chao 2004); these vesicles retain signaling capacity, as reviewed by multiple groups (Zweifel et al. 2005; Wu et al. 2009; Oppenheim and von Bartheld 2008). Some of the signaling may occur already during transit, since sufficient signal transducers are attached to the NT- and NT-receptor-containing vesicle. However, most of the signaling is believed to occur once the signaling vesicle is delivered to the cell body. At the cell body, signaling cascades (via CREB and other pathways) regulate gene expression in the nucleus (Riccio et al. 1997); after delivery of the signal, the signaling endosome is believed to be dismantled, possibly by transition to a MVB and eventual to a lysosome (Mukherjee et al. 1997; von Bartheld and Altick 2011). Alternatively, the endosome or components of the signaling endosome are recycled by targeting to other cellular compartments (e.g., synapses on dendrites, von Bartheld et al. 2001; Rind et al. 2005). Currently, there is widespread support among investigators in the field for the signaling endosome hypothesis.

One alternative to the signaling endosome hypothesis is the concept that NTs may signal locally within the axon terminus and that this generates one or more second messengers in the axon terminal that is moved retrogradely along the axon. There is some evidence that second messengers other than axonally transported NTs or NT receptors contribute to the retrograde signal; these include G proteins as well as MEK kinase, MAP kinases, and PI3 kinases and/or their subunits

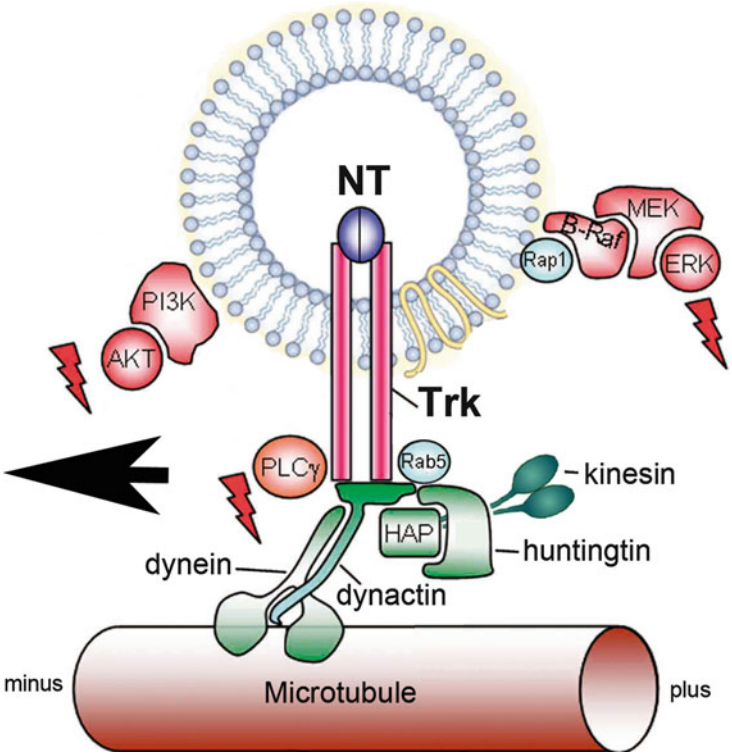

Fig. 2 The signaling endosome. The internalized neurotrophin (*NT*)-receptor (*Trk*) complex is transported retrogradely from the nerve terminal to the cell body. The internalized vesicle serves as a platform for docking of proteins that elicit signal transduction cascades (*red*): via the phospholipase C-gamma (*PLCγ*), Raf-MAPK-ERK, and PI3K/AKT signaling pathways (*red lightning symbol*); molecular motors and regulators (*green*) attach for transport along microtubules (*brown*). The *arrow* indicates the direction of transport toward the minus end of microtubules. For details and references, see Zweifel et al. 2005 (*Nature Reviews Neuroscience* **6**, 615–625) and Gauthier et al. 2004 (*Cell* **118**, 127–138) (Material adapted, with permission, from: Oppenheim and von Bartheld 2008 (Fundamental Neuroscience, 2nd edition, Academic Press))

(Johanson et al. 1996; Reynolds et al. 2000; Weible and Hendry 2004). It is unclear to what extent the transported NT-containing vesicle or endosome may contribute to the signaling beyond the initial signaling at the axon terminus; in the strongest form of the second messenger concept, the retrograde axonal transport of the NT may simply serve to remove the NT from the region of the axon terminus ("vacuum cleaner model", Bothwell 1995), so that the local NT signal can be terminated and does not continue to elicit signals.

A third possibility is the "wave model," which is based on the surprising observation that at least in some cases, a trophic signal arrives at the level of the cell body prior to the time needed for the NT-containing endosome to arrive there (Senger and Campenot 1997) and that consequently some signaling occurs that is independent of the retrograde axonal transport of the NT-containing vesicle that

initiated the signal (Miller and Kaplan 2001; Neet and Campenot 2001; MacInnis and Campenot 2002). The major weakness of this model is that there is no compelling physical mechanism of how the signal could spread as a lateral "wave" along the required distances (Ginty and Segal 2002; Howe and Mobley 2004; Wu et al. 2009). Furthermore, current evidence is based on a small set of in vitro experiments, and some assumptions are made about identical properties of radiolabeled vs. native NTs.

Transport organelle. Considering the long distance from the axon terminus to the cell body, it is surprising that there is very little direct evidence for the type of organelle that carries the NT signal retrogradely along the axon. Two major models can be distinguished: The signaling organelle is a multivesicular body (MVB, Parton et al. 1992; Valdez et al. 2005; Weible and Hendry 2004; Philippidou et al. 2011), or it is a small vesicle or endosome (Delcroix et al. 2003; Altick et al. 2009; Wu et al. 2009; von Bartheld and Altick 2011). The former notion is based primarily on in vitro experiments performed with large tags of the NT, which recent work has shown to generate abnormal organelles or quantities of organelles (von Bartheld and Altick 2011). The alternative view is that the endosome is a small vesicle and remains such a structure up to the level of the cell body. Purification experiments support this view (Delcroix et al. 2003), as do experiments with quantum dot-labeled NTs (Cui et al. 2007). MVBs were ruled out as the "normal" carrier based on their low frequency in normal nerves in vivo and lack of labeling when the ultrastructural distribution of radiolabeled NTs was determined within nerves (Altick et al. 2009). While there is no doubt that retrogradely transported NTs eventually accumulate in MVBs within the cell body (Claude et al. 1982; Rind et al. 2005; von Bartheld and Altick 2011), NTs do not appear to travel within this type of organelle while en route within the axon in vivo.

Arrival of the NT signal in cell body. The signal transduction pathways activated by NTs in the cell body have been reviewed elsewhere and will not be repeated here (Huang and Reichardt 2001, 2003). There has been one major aspect that has puzzled the investigators: How is it that the signal within the signaling endosome is so long-lived? When the same signaling cascades are activated by other ligands and other types of tyrosine kinase receptors, the MAP kinase activation is measured within minutes, not hours (Kao et al. 2001; Wu et al. 2001). Prolonged activation appears essential, since it can take hours to move a signaling endosome (or the NT) from the axon terminus to the cell body, e.g., in the motor neurons of the spinal cord. Several solutions have been offered why NT binding to trks in neurons may induce longer-lasting signal duration (Kao et al. 2001; Wu et al. 2001; Saxena et al. 2005). The concentration of trk receptors in the endosome is sufficiently high to dimerize and autophosphorylate (Miller and Kaplan 2001). Another mechanism in play could be that the NT comes off one NT receptor and binds another NT receptor within the same vesicle (Butowt and von Bartheld 2009; Chowdary et al. 2012). Does the cell body somehow know where the trophic signal was generated (axon target vs. dendritic afferents)? This question was examined by Segal and her colleagues,

and it appears that some signal transduction pathways (ERK) have certain specificity for where the NT signal was generated (Watson et al. 2001; Heerssen and Segal 2002). However, another study found that the same ERK was contained in signaling endosomes (Delcroix et al. 2003), indicating that the type of ERK activation may be variable between different cell types or other conditions (Bronfman et al. 2007).

Fate of NTs after arrival in the cell body. How is the NT signal "turned off"? One solution that has been proposed is that the NT endosome is incorporated into the internal vesicles of a MVB, essentially preventing access of the NT receptor to the cytosol (Sorkin and von Zastrow 2002; von Bartheld and Altick 2011). Initially, it was assumed that NTs are degraded immediately or within a few hours after signaling (Claude et al. 1982; Reynolds et al. 2000; Neet and Campenot 2001). Some neurotrophic factors such as cardiotrophin-1 indeed appear to be rapidly degraded in lysosomes (Rind et al. 2005). However, other trophic molecules are used multiple times prior to degradation, and NTs appear to belong to this group (von Bartheld et al. 2001; Rind et al. 2005; Sharma et al. 2010). Thus, there are two pools of NTs: newly synthesized NTs and internalized NTs that can be recycled. In fact, recycled, internalized NTs have been shown to serve important functions in LTP (Santi et al. 2006). One of the molecular mechanisms that decides between degradation and recycling of retrogradely transported NTs appears to involve phosphorylation of the p75 receptor (Butowt and von Bartheld 2009). While there has been progress in elucidating some of the mechanisms of retrograde neurotrophin signaling, major gaps in understanding of the transport and arrival of the signaling complex remain to be filled. The major steps of retrograde and anterograde trafficking of NTs are summarized in the schematic of Fig. 3.

4 Anterograde Axonal Transport

Based on the neurotrophic hypothesis and the early discovery of retrograde axonal transport of NGF and other NTs (Hendry et al. 1974; DiStefano et al. 1992), trafficking of NTs was for several decades thought to occur primarily if not exclusively in the direction toward the cell body. Despite abundant evidence for trophic effects of afferents on neurons (Linden 1994), it came as a surprise when it was discovered in 1996 that both exogenous and endogenous NTs can move anterogradely along axons (von Bartheld et al. 1996a; Zhou and Rush 1996) and that NTs can be transferred from presynaptic to postsynaptic sites (von Bartheld et al. 1996a). These first reports were rapidly confirmed (Altar et al. 1997; Johnson et al. 1997; Altar and DiStefano 1998; Conner et al. 1998). The discovery of anterograde axonal transport of NTs opened a new venue of NT research: Can NTs behave like neurotransmitters? Are they released at the axon terminus by activity-dependent mechanisms? In which organelles are they stored there, and how are they released? What are the functions of this new trophic pathway?

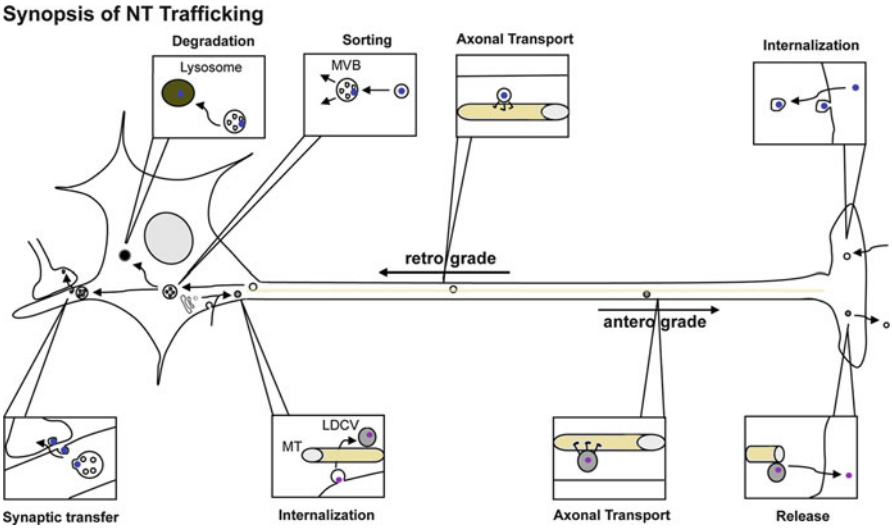

Fig. 3 Synopsis of retrograde and anterograde trafficking of neurotrophins (*NTs*). The upper half of the schematic illustrates the major steps of retrograde traffic, from internalization at the axon terminus, via microtubule-mediated axonal transport along the axon, sorting in the cell body and eventual degradation in lysosomes. The lower half of the schematic shows the major steps of synthesis or internalization of NTs in the cell body, microtubule-mediated anterograde axonal transport, and release at the axon terminus. In addition, synaptic transfer of NTs via MVBs is indicated. Abbreviations: *LDCV* large dense-core vesicle, *MT* microtubule, *MVB* multivesicular body

Some investigators now believe that anterograde axonal transport of NTs is quantitatively more significant than the "conventional" retrograde axonal transport (Conner et al. 1998; Adachi et al. 2005). Despite its moment of fame in the late 1990s, anterograde axonal transport of NTs has been studied much less than retrograde transport, and therefore, less is known about its mechanism. Anterogradely transported NTs are now believed to be mostly stored within LDCVs in axon terminals (Michael et al. 1997; Fawcett et al. 1997; Luo et al. 2001; Salio et al. 2007; Dieni et al. 2012), although some controversy remains. The amounts of both endogenous and exogenous NTs that are transported anterogradely appear to be lower, on a per neuron basis, than those that can be transported retrogradely (von Bartheld et al. 1996b). Anterogradely transported neurotrophins have been shown to have multiple effects on their afferents, not only with regard to neuronal survival but also synaptic transmission and dendritic morphology (Caleo et al. 2003; Caleo and Cenni 2004; von Bartheld 2004).

It should be noted that anterograde axonal transport of NTs and NT receptors serves two very different functions: NT anterograde transport appears to mediate trophic signals that arise from afferents (Linden 1994), as opposed to the well-established roles of efferent targets, while anterograde transport of NT receptors primarily delivers the NT receptors that are needed in the axon terminus for

internalization and retrograde transport of target-derived trophic signals (Ascaño et al. 2009). While it is known that the anterograde axonal transport of NTs in adults does not require p75 receptors, the role of trk receptors is less clear, although they seem to contribute to anterograde axonal transport of BDNF (Butowt and von Bartheld 2005). Anterograde axonal transport of NTs is mediated by conventional kinesins (Butowt and von Bartheld 2007), while anterograde axonal transport of trk receptors is facilitated by sortilin (Vaegter et al. 2011), and the association between trkB receptors and kinesin-1 is accomplished by the protein JIP3 (Huang et al. 2011).

Release mechanisms of anterogradely transported NTs have to be studied specifically at the axon terminus, which is not an easy task. Such release was first examined in synaptosomal preparations (Androutsellis-Theotokis et al. 1996; Fawcett et al. 1997), and subsequently by utilizing advantageous model systems such as the DRG central projection into the spinal cord (Lever et al. 2001), retinal ganglion cell axons in the optic tectum (Wang et al. 2002). In addition, one can culture neurons and let them form synaptic connections, engineered to express BDNF-GFP in the presynaptic neuron and observe labeled puncta to transfer from presynaptic to postsynaptic sites (Kohara et al. 2001). These studies showed that such pre- to postsynaptic transfer of NTs was activity dependent and modulated by numerous compounds, including intracellular calcium, cAMP, NMDA receptors, and stimulation pattern (Kohara et al. 2001; Lever et al. 2001; Wang et al. 2002).

Anterograde axonal transport of internalized NTs. While much of the anterograde axonal transport of NTs presumably involves newly synthesized NTs, exogenous NTs can also be targeted to an anterograde axonal pathway (Butowt and von Bartheld 2001). Such exogenous NTs are internalized by retinal ganglion cells, traverse the Golgi system, and thereby join what is presumably the "normal" anterograde axonal route. Some of the NTs in this pathway are packaged in LDCVs (Wang et al. 2002), and they are released from axon terminals in the optic tectum in an activity-dependent fashion (Wang et al. 2002). One exogenous NT, NGF, was shown to be immunoprecipitated by p75 receptor antibodies in this pathway to the optic tectum where the same NGF subsequently (after release) binds primarily to trkA receptors and embarks on a new route to the locus ceruleus (Feng et al. 2011). Thus, NT itineraries can be linked in neural networks in different anterograde and retrograde trafficking combinations (Figs. 1 and 3).

5 Methodology

This section reviews the types of techniques that researchers use to investigate trafficking of NTs. It will examine limitations and pitfalls, as well as strategies to overcome challenges, and discuss some current controversies in the field.

When endogenous NTs are examined, they can be visualized with NT-specific antibodies (Conner 2001). Another approach is to express a specific tag (such as GFP or a myc tag) with the NT of interest. Obviously, all NTs recognized by the antibody or the tag signal itself will be visualized (as in a snap shot), and therefore,

this approach alone does not reveal the trafficking itself (either qualitative or quantitative). For example, the presence of the NT in the axon suggests axonal transport, but it does not indicate the direction (anterograde or retrograde) or the velocity and capacity. Some hints may be given by the lack of synthesis (by in situ hybridization) of the NT in the cell body or the target cells (Conner et al. 1997), but if expression levels are very low, no firm conclusions can be made about trafficking. A useful and common technique is to apply a ligature to a nerve and to determine whether the NT accumulates distally or proximally to the ligature or both (Johnson et al. 1987; Ross et al. 1994; Ehlers et al. 1995; Mufson et al. 1999). This gives information about the direction of axonal transport and a rough estimate of the relative amount. Caveats are that glial cells surrounding the site of ligature may be induced to express NTs, and they may thus accumulate in response to such nerve injury, resulting in false-positives.

A major problem with the study of endogenous NTs is the extremely low abundance of the endogenous NTs in vivo. This is a challenge, because the methods used to visualize the NT may not have sufficient sensitivity. In addition, NTs may simply be present in concentrations too low to be detected, yet high enough to have significant trophic effects. Therefore, lack of label cannot be interpreted as evidence for a lack of NTs. Furthermore, based on the localization of NTs, antibodies may fail to reveal the NT, for example, if the antibody does not recognize the NT when it is bound to certain receptors (Rush 2001). One solution to the problem of low abundance is to overexpress the NT of interest. However, this approach may saturate normal trafficking capacities and thus lead to false conclusions about trafficking. Another approach is to transfect tissues or cells with a molecular tag on the NT – this, however, may change NT trafficking, receptor binding, sorting and degradation, as well as kinetics. This is especially important to consider when the tag is large relative to the size of the NT protein (Möller et al. 1998; Parak et al. 2005; Chowdary et al. 2012).

When exogenous NTs are examined, some of the abovementioned problems (such as not knowing the direction and quantity of trafficking) are minimized when the NT is introduced into a well-defined compartment. However, the exogenous NT has to be different or tagged so that it can be distinguished from the endogenous NT already present in the system. There are several different options of how NTs can be tagged (Fig. 4). Particularly important, historically, has been the tagging of NTs with the isotope 125I (radioiodination). This procedure only minimally modifies the NT, so the radiolabeled NT's binding properties are unaffected and the NT maintains bioactivity (Johnson et al. 1978; Vale and Shooter 1985; Rosenfeld et al. 1993; von Bartheld 2001). The probe is highly sensitive and quantifiable and can be localized at the ultrastructural level without compromising tissue quality, since probe penetration through tissue is not an issue as it is with antibody visualization. Drawbacks are that the probe cannot be tracked in real time and that the resolution at the EM level is poor, allowing only localization of the NT (silver grain) with major organelles and large enough structures such as synapses (Claude et al. 1982; von Bartheld 2001; Rind et al. 2005). Other options for tagging NTs include biotinylation (Rosenberg et al. 1986), conjugation with GFP (Gerdes and

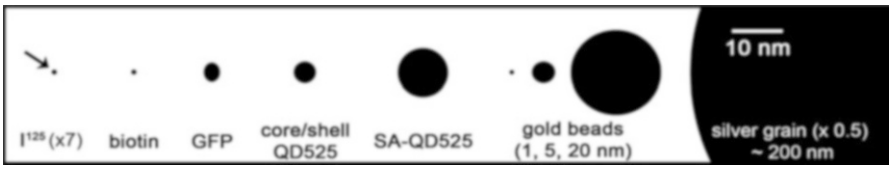

Fig. 4 Comparison of the sizes of commonly used protein tags. I125 is the smallest tag (seven times smaller than indicated). The core/shell of quantum dots (*QDs*) is similar in size to green fluorescent protein (*GFP*). Gold particles come in various sizes, as indicated. After autoradiographic development of radiolabel in monolayer emulsion, silver grains are the largest with diameters of 100–200 nm, thereby relinquishing the small size of the radiolabeled tag. Abbreviation: *SA* streptavidin

Kaether 1996; Haubensak et al. 1998; Watson et al. 1999; Kohara et al. 2001; Adachi et al. 2005; Guillemot et al. 2007), myc tagging (Möller et al. 1998), gold particle tagging (Sandow et al. 2000; Salio et al. 2007), and conjugation with quantum dots (Giepmans et al. 2005; Vu et al. 2005; Cui et al. 2007; Rajan et al. 2008; Altick et al. 2009; Chowdary et al. 2012; Xie et al. 2012). With the exception of biotinylation and myc tagging, these procedures result in a NT-tag complex that is considerably larger than the original, native NT, and the obvious concern is that such a protein modification may change trafficking properties of NTs. Typical controls include verification that the tagged NT still binds to its receptors, has bioactivity, and that it is internalized (Vu et al. 2005; Cui et al. 2007; Rajan et al. 2008; Xie et al. 2012). However, investigators rarely test tagged NTs for any trafficking changes, including capacity, speed, sorting, intracellular aggregation, organelle transition, and degradation kinetics (Neet and Campenot 2001). Indeed, it is not known how such tags affect the NT itineraries, sorting, recycling, and degradation and whether and at what point the tag may dissociate from its target protein (Tekle et al. 2008; Wiggins et al. 2012).

Another problem with expression of either tagged NTs or overexpression of tagged or native NTs is that this may result in much higher levels of the NT than normal, and this may saturate the normal capacity of NT processing, cleavage, trafficking, sorting, and release and accordingly may lead to false-positives, because the tagged and/or overexpressed NT may partially or entirely be directed to abnormal trafficking routes and sites of accumulation (Hartmann et al. 2012; Wiggins et al. 2012). Some of these issues may explain discrepant findings and current controversies, for example, the question whether neurons release BDNF mostly as a mature BDNF form or whether also the uncleaved proBDNF is released by neurons in vivo (Matsumoto et al. 2008; Yang et al. 2009; Greenberg et al. 2009; Dieni et al. 2012). In this context, it is important to remind the reader that caution is also advised when experiments are performed in vitro as opposed to in vivo. For example, extracellular BDNF is rapidly cleaved in vivo by glial cells; when neurons are maintained in an artificial environment lacking glial cells, extracellular proBDNF can persist for a longer time (Yang et al. 2009). Also, neurites (neuronal processes) grown in vitro tend to express many more MVBs than they would in vivo, and application of exogenous NTs conjugated to particles such as gold

can induce formation of multivesicular bodies and incorporation of NTs into such organelles, when this would not normally happen (von Bartheld and Altick 2011). Nevertheless, trafficking studies in Campenot chambers and microfluidic chambers have considerably extended knowledge and concepts of NT trafficking (MacInnis and Campenot 2002; Cohen et al. 2011). Examination of NT receptors rather than NT ligands is technically more robust, since receptors are expressed at higher levels than NTs and therefore are easier to visualize, both by immunological and GFP-expression methods. Furthermore, NT receptors stay confined to the producing cells and typically are not released from cells and do not transfer from one cell to another cell (with the possible exception of transfer via exosomes, von Bartheld and Altick 2011). Taken together, results obtained from in vitro studies, and results obtained by observing trafficking of grossly-modified NTs, need to be interpreted with considerable caution.

6 Diseases and Disorders Related to NT Trafficking

With the emergence of the neurotrophic hypothesis, it was suggested that the neurotrophic concept may not only apply to the development and differentiation of neurons but also to their maintenance. Accordingly, neurodegeneration may be the result of a failed supply of neurotrophic signals (Appel 1981; Saper et al. 1987). Based on this concept, neurodegenerative diseases may result from a reduced production, reduced axonal transport, or reduced efficacy of neurotrophic signaling. Many neurodegenerative diseases manifest with axonal transport problems (Krüttgen et al. 2003; Bronfman et al. 2007; Perlson et al. 2010; de Vos et al. 2008), and some neurological disorders have been associated with specific NTs (Shu and Mendell 1999; Bender 2004; Chao et al. 2006; Perlson et al. 2010; Hartmann et al. 2012). Abnormalities in neurotrophin signaling during formation of neural circuits may lead to disorganization of those circuits and predispose to neuropsychiatric disease during later life (Angelucci et al. 2005; Autry and Monteggia 2012). This section reviews current evidence for defects or abnormalities in NT or NT receptor trafficking for several key neurological disorders, including Alzheimer's disease, Huntington's disease, Parkinson's disease, Rett and fragile X syndromes, epilepsy, glaucoma, hyperalgesia, neuropathies, as well as psychiatric disorders such as schizophrenia and eating disorders.

6.1 Neurodegenerative Diseases

Alzheimer's disease. The hallmark of Alzheimer's disease is the degeneration of cholinergic basal forebrain neurons, among other cell types. These neurons are NGF dependent, and mouse models of Alzheimer's disease suggest that abnormalities in the retrograde axonal transport of NGF play a pathophysiological role (Cooper et al. 2001; Salehi et al. 2009). Increased levels of amyloid precursor protein (APP) appear to cause a specific NGF trafficking defect in cholinergic

basal forebrains in a mouse model (Salehi et al. 2006). Enhancing levels of NGF has been tested as a therapeutic approach in patients with early stage Alzheimer's and showed potential effectiveness (Tuszynski et al. 2005), but this phase 1 clinical trial also revealed some of the challenges in NT delivery to the brain (Tuszynski 2007).

Huntington's disease. In the heritable Huntington's disease, neurons degenerate in the basal ganglia, primarily the caudate/putamen. The key mutation of this disease is huntingtin, a protein that attaches to the molecular motor that moves cargo along microtubules, among other functions (Gauthier et al. 2004; Ross and Tabrizi 2011). Cortical neurons produce BDNF and transport it and other cargo molecules by anterograde axonal transport to the striatum (Charrin et al. 2005), but when huntingtin is mutated, the anterograde trafficking of BDNF to striatal synapses is abnormally reduced. Indeed, supply of exogenous BDNF can improve symptoms of Huntington's in animal models of the disease (Zuccato and Cattaneo 2007). Accordingly, this is a prime example of the physiological significance of a trafficked NT for disease progression and therapeutic improvement using targeted NTs. In other motor degenerative disease such as amyotrophic lateral sclerosis, trafficking of neurotrophic factors does not appear to be central to disease pathology (Marinkovic et al. 2012; Redler and Dokholyan 2012).

Parkinson's disease. The cause of Parkinson's disease is the degeneration of dopaminergic neurons in the substantia nigra, pars compacta. It is suspected that neurotrophic factors are involved, including NTs, but the precise cause and problem (expression, transport, receptors), susceptibility to toxic factors and cytokines, reduced levels of neurotrophins, and thus potential therapeutic strategies are not yet clear (Siegel and Chauhan 2000; Rangasamy et al. 2010).

6.2 Neurodevelopmental Disorders

Rett syndrome is a severe neurodevelopmental disorder with regressive cognitive and language skills, caused by a mutation in the MeCP gene. Brains of patients with Rett syndrome have reduced dendritic growth and spine densities in cortical neurons. Not only BDNF expression, but possibly also BDNF trafficking and secretion are affected (Zeev et al. 2009). Fragile X syndrome is another neurodevelopmental disorder, with impairment of BDNF vesicle docking and fusion (dense-core vesicle docking). Thus in both syndromes, BDNF expression, trafficking, and/or release are suspected to play key roles in the disease process (reviewed in Hartmann et al. 2012).

6.3 Other Disorders

Glaucoma. Glaucoma is characterized by progressive optic nerve degeneration and retinal ganglion cell death due to increased intraocular pressure. It has been shown that a major factor causing retinal ganglion cell death is the reduction in BDNF

retrograde axonal transport along the optic nerve fibers from central targets (Quigley et al. 2000; Almasieh et al. 2012). Thus, the sustained retrograde axonal trafficking of an NT is a major determinant of neuronal survival in the adult nervous system.

Epilepsy. Seizures induce BDNF mRNA upregulation that leads to increased BDNF production by the dentate granule cells, enhanced anterograde transport and release of BDNF from mossy fiber axons, and activation of either pre- or postsynaptic trkB receptors in the hilus and CA3 stratum lucidum (reviewed in Bender 2004).

Hyperalgesia and Charcot-Marie-Tooth neuropathy. The anterograde axonal transport of BDNF in DRG neurons affects pain thresholds (Shu and Mendell 1999). Several proteins controlling endosomal traffic have recently been shown to be affected in peripheral neuropathies. The small GTPase Rab7 regulates trkA trafficking (Saxena et al. 2005). Dynamin and Rabs affect the traffic of several different types of endosomes, but do not appear to be specific for endosomes containing NTs (Bronfman et al. 2007). Therefore, these traffic regulatory proteins likely affect multiple signaling systems.

Psychiatric diseases. Bipolar disorder, schizophrenia, eating disorders, and depression have been associated with BDNF (Angelucci et al. 2005). The BDNF hypothesis of neuropsychiatric diseases postulates that BDNF is required developmentally for normal circuit formation and also in the mature CNS to maintain plasticity and function. Diseases specifically linked to BDNF included eating disorder, depression, bipolar disorder, and schizophrenia (reviewed in Chao et al. 2006). A mouse model with a BDNF mutant (Egan et al. 2003) suggested that a relatively common BDNF mutation in humans causes anxiety and depression-like behavior (Chen et al. 2006). However, this simple hypothesis that a traffic-impaired BDNF mutant caused depression or anxiety did not hold up with further scrutiny and meta-analyses (Groves 2007; Frustaci et al. 2008; Verhagen et al. 2010). This does not call into question a fundamentally important role of BDNF in the pathophysiology and/or treatment of these diseases. BDNF's role appears well supported for eating disorders and bipolar disorder/schizophrenia, but the precise roles of BDNF need further clarification.

7 Conclusion

Trafficking of NTs is important in neuronal development, for neuronal plasticity, and in the adult nervous system. Ideal tagging of NTs is still hypothetical, and limitations of current tagging methods need to be taken into account. It has major consequences that NT trafficking can be altered by impairments of the molecular motors that move NTs along axons and in endosome traffic. Although the details of the pathophysiological mechanisms are still to be worked out, there is hope that therapeutic interventions can be designed to remove the toxic insult, halt the degenerative process, and preserve the remaining neurons in neurodegenerative disorders.

Diseases and Disorders Relevant to Neurotoxins

Drug Abuse Neurotoxicity: Alcohol and Nicotine as Developmental Stressors

Trevor Archer, Serafino Ricci, and Max Rapp-Ricciardi

Contents

Abstract

Drugs of abuse have the property of inducing adverse health complications, not least neurotoxicity under conditions where both the environmental conditions and activity states associated with their intake may strongly enhance drug toxicity, thereby causing life-threatening health complications and tragedy for relations and caregivers. While both chronic alcohol and/or nicotine abuse induce a variety of neuropathological effects, including damage to the brain, the extent of damage and disruption observed in the developing brain and CNS is a considerable affliction for the affected individuals. On the basis of laboratory and clinical studies, the potential of chemicals, including therapeutic and abused agents, to induce neurotoxic effects has been assessed, with considerations of abuse drugs neurotoxicity encompassing several factors that may accelerate and complicate prevailing conditions: the type and influence of environmental

conditions, the presence of daily habits such as coffee breaks/smoking breaks, nutritional status, and neuroimmune system mobilization. Abuse neurotoxicity at several stages of early development, alcohol neurotoxicity, nicotine neurotoxicity, and combinations of alcohol-nicotine neurotoxicity present a threatening scenario of two compounds, benefitting from legality and availability that nevertheless have such potential for destruction over multiple domains, particularly in the undeveloped brain.

Abuse drugs • Alcohol • Apoptosis • Development • Nicotine • Oxidative stress • Smoking

1 Introduction

The potential of chemicals, including therapeutic and abused agents, to induce neurotoxic effects may be assessed at (i) early developmental, (ii) adolescent/preadolescent, and (iii) adult stages of individuals' life cycle. In each case, the level of neurotoxicity or neurotoxic propensity remains a singularly important regulatory drug issue and a uniquely significant area of public concern, not least due to the preponderance of agents that have been characterized or are still to be characterized (Judson et al. 2009) due to logistical constraints (OECD 2007). Normal brain development follows a preprogrammed pathway, whether at neuronal, circuitry, or regional levels, that differentiates specific and distinctive regional structural characteristics, phenotypes, and functions in the infant, adolescent, and adult (Bayer et al. 1993; Herschkowitz et al. 1997). The influence of epigenetic factors (e.g., mutant strains), of evermore critical importance (Dufault et al. 2012; Marti et al. 2007), reflects the sensitivity and responsiveness of human and animal brains in constantly changing circumstances regulating gene expression profiles (Archer et al. 2011). The course of brain development may be altered by a wide range of exogenous agents thereby threatening the integrity of affected brains with permanent consequences (Stanwood and Levitt 2004) that culminate in dire neurodevelopmental (Llop et al. 2012) and neuropathophysiological (Miller et al. 2012) outcomes. The enormous range of exogenous agents capable of disrupting the integrity of the affected brain, within defined parameters and conditions, may wreak damage that is all too often permanent and irreversible (Archer 2011). In order to confront the neurotoxic propensities of abused drugs, alcohol and nicotine (smoking), and their combination, are chosen as "drug cases" for several reasons, not least the situation that both are "legal drugs" judicially in most countries. Alcohol presents the greatest social and monetary chemical risk to individuals' well-being and health, and alcoholism is a multifactorial, genetically associated disorder with major negative issues, highly frequent and a strong cause of premature death.

Considerations of abuse drugs neurotoxicity must take into account several factors that may accelerate and complicate prevailing conditions: the type and influence of environmental conditions, the presence of daily habits such as coffee

breaks/smoking breaks, nutritional status, and neuroimmune system mobilization. It ought to be borne in mind that the environmental conditions and activity states associated with their intake are likely to enhance markedly drug toxicity levels, thereby developing a situation wherein continued abuse leads not only to adverse health complications, including neurotoxicity, but also to life-threatening health complications. For example, animal experiments indicate that even moderate increases in environmental temperatures and physiological activation, the conditions typical of the so-called "rave parties," dramatically potentiate brain hyperthermic effects of psychomotor stimulants, particularly methamphetamine (METH) and 3,4-methylenedioxymethamphetamine (MDMA). Kiyatkin and Sharma (2012) have demonstrated that methamphetamine also induces breakdown of the blood–brain barrier, acute glial activation, brain edema, and structural abnormalities of various subtypes of brain cells. These effects are also strongly enhanced when the drug is used at moderately warm environmental conditions. They implied that the mechanisms underlying environmental modulation of acute drug neurotoxicity focus on the role of brain temperature, a critical homeostatic parameter that could be affected by metabolism-enhancing drugs and environmental conditions and affect neural activity and functions.

Another important consideration is the concomitant consumption of caffeine, i.e., daily coffee intake and habitual behavior, with recreational psychostimulant drugs of abuse, may provoke varyingly severe acute adverse reactions in addition to longer-term consequences since the mechanisms by which caffeine increases the toxicity of psychostimulants include changes to body temperature regulation, cardiotoxicity, and lowering of the seizure threshold. Vanattou-Saïfoudine et al. (2012) have reviewed current notions of such caffeine-related drug interactions, placing a particular emphasis on an adverse interaction between caffeine and the substituted amphetamine MDMA which has been most recently described and characterized. The coadministration of caffeine and MDMA profoundly enhances the acute toxicity of MDMA in rats, as manifested by high core body temperature, tachycardia, and increased mortality. In addition, coadministration of caffeine enhances the long-term serotonergic neurotoxicity induced by MDMA. Their studies coincide with reports of caffeine-related drug interactions with cocaine, d-amphetamine, and ephedrine where similar mechanisms are implicated. Finally, it is an unpleasant reality that neurotoxic actions of chemical agents on humans and animals are usually studied with little consideration of the subject's nutritional status. The status of protein-calorie, vitamin, and/or mineral undernutrition levels and contingencies are linked with a range of neurodevelopmental, neurological, and psychiatric disorders, commonly with involvement of both the central and the peripheral nervous system. Undernutrition can modify risk for certain chemical-induced neurologic diseases, and in some cases, undernutrition may be a prerequisite for neurotoxicity to surface. Spencer and Palmer (2012) have observed that combined effects of undernutrition and chemical neurotoxicity are most relevant to people in disaster areas or those with low incomes who experience, and continue to experience, chronic hunger, parasitism, and infectious disease; monotonous diets of plants with neurotoxic potential (notably cassava);

environmental pollution from rapid industrial development; chronic alcohol abuse; or prolonged treatment with certain therapeutic drugs. Finally, it is increasingly clear that drug-induced activation of central immune signaling contributes markedly to the pharmacodynamic actions of the drugs of abuse, e.g., by enhancing the engagement of classical mesolimbic dopamine reward pathways and withdrawal centers. Coller and Hutchinson (2012) have reviewed critical in vivo animal, human, biological, and molecular evidence of these central immune signaling actions of opioids, alcohol, cocaine, METH, and MDMA. These emerging notions of the central immune function signaling property of drugs of abuse present unlimited possibilities for novel therapeutic strategies and eventual interventions with opportunities to identify "at-risk" individuals through the use of immunogenetics.

2 Abuse Neurotoxicity at Early Developmental Stages

Brain and CNS development encompass several critical periods of vulnerability during which the developing individual is particularly sensitive to environmental neurotoxic insult, such as alcohol or nicotine (Berger et al. 1998; Rice and Barone 2000; Taranukhin et al. 2010). The effects of these drugs have been shown at both prenatal and postnatal stages of early development with regard to disruptions of both structure and function. For instance, the prenatal effects of alcohol exposure for the developing brain and CNS have been described (Goodlett et al. 2005; Riley et al. 2001; Savage et al. 2010). Purkinje cell vulnerability, for instance, occurs during postnatal days 4–6 in rodents when peak blood ethanol concentration (BEC) determines the extent of cell loss (Pierce et al. 2010). Oxidative stress is one of several mechanisms through which drugs instigate a neurotoxic action (Crews and Nixon 2009; Haorah et al. 2008). Alcohol induces lipid peroxidation in the developing brain (Kumral et al. 2005; Wang et al. 2012). Ramezani et al. (2011) observed that ethanol, administered 6 g/kg on postnatal days 4 and 5, induced lipid peroxidation, increased thiobarbituric acid reactive substance (TBARS), and decreased glutathione peroxidase levels in the cerebellum of rat pups, as well as impairing rotarod performance and locomotor activity at adolescent age of test. They observed also the neuroprotective action of 17β-estradiol, injected 30 min before ethanol, which attenuated the motor impairments and lipid peroxidation and restored antioxidant levels. Alcohol is now generally acknowledged as the leading human teratogen and, if the estimates of prevalence of fetal alcohol spectrum disorders (FASD) are correct, is one of the leading known causes of neurodevelopmental disorders in Western society (Goodlett 2010).

3 Alcohol Neurotoxicity

Ethanol crosses the blood–brain barrier readily and is metabolized in the brain by several enzymes in processes rendering reactive oxygen species. Excessive reactive oxygen species (ROS) that disturb the normal cellular redox state induce oxidative

stress leading to cellular damage (Hampton and Orrenius 1998). Alcohol is a neuroteratogen which induces loss of neurons in the CNS that from a neurodevelopmental aspect account for several of the symptoms expressed in fetal alcohol syndrome (Chen et al. 2008; Riley and McGee 2005). Certain regions of the developing brain are selectively vulnerable to alcohol and there are peak periods of sensitivity within these regions (Rice and Barone 2000; Stoltenburg-Didinger 1994). A single ethanol exposure in rats during the first several postnatal days (P4-5) that correspond to the human third trimester induces a huge loss of neurons in brain (Bonthius and West 1991; Hamre and West 1993); slightly later periods show greater resistance to similar exposure (Goodlett and Eilers 1997; Light et al. 2002). The window of vulnerability (also termed peak sensitivity, although the latter is more reliably linked to vision) coincides with the developmental period of synaptogenesis, also known as the brain growth-spurt period, which in rodents is a postnatal event, but in humans extends from the 6th month of gestation to several years after birth. It appears likely that the alcohol-induced disruption of neurodevelopment involves apoptotic processes implicating the Bcl-2 family of survival-regulatory proteins (Ge et al. 2004; Lee et al. 2008; Ullah et al. 2012). The proapoptotic Bax protein, within the Bcl-2 gene family, is implicated in alcohol-induced cell death in developing organisms. After neonatal ethanol administration during ages of peak sensitivity, Bax migrates to the mitochondrial membrane where it participates in initiating apoptosis (Siler-Marsiglio et al. 2005; Heaton et al. 2012a). Heaton et al. (2012b) studied the interactions between Bax and proteins of the permeability transition pore (PTP), voltage-dependent anion channel (VDAC), and adenine nucleotide translocator (ANT) of the outer and inner mitochondrial membranes. They found that after alcohol treatment, Bax proapoptotic associations with VDAC and ANT were increased, especially at peak sensitivity, and sustained at least 2 h posttreatment. Ethanol neurotoxicity in cultured neuronal preparations was abolished by pharmacological inhibition of VDAC and ANT interactions but not by a Bax channel blocker. They concluded that, following ethanol treatment, BAX initiated the apoptosis cascade through interactions with proteins of the PTP complex but not channel formation independent of PTP constituents.

Generally, chronic alcohol intake is more harmful than acute intake (Eysseric et al. 1997; Lamarche et al. 2003). The brain and CNS, and not least neurons, are major targets for the uptake and pharmacological action of alcohol, and chronic consumption of ethanol is associated with several neurodegenerative disorders (Brooks 1997, 2000; Dlugos 2009) and conditions of neurodegeneration (Qin and Crews 2012). The brain damage is characterized by cerebral and cerebellar atrophy and widespread neuronal deficits in several regions in adult chronic alcohol abusers (Bleich et al. 2003; Harper 1998; Harper and Matsumoto 2008). Alcohol-related neuropathology is associated with both excitotoxic (Krystal et al. 2003) and oxidative stress (Sakaguchi et al. 2011; Tiwari et al. 2012). Ethanol exposure produces ROS which cause oxidative stress in the brain. The excessive production of ROS during ethanol catabolism or from damaged mitochondria following ethanol exposure exacerbates the neurotoxicity, particularly during brain development. Kruman et al. (2012) have outlined mechanisms involving the accumulation of DNA

damage in the absence of cellular repair that unfolds in the expression of genomic instability and neuronal death. Genomic instability involves structural alterations that modify the standard chromosomal complement; this process may lead to a situation of aneuploidy, an abnormal number of chromosomes, through which the cells present a chromosomic number that is either higher or lower than the normal complement for the species. For example, alcohol is capable of contributing toward the initiation of cancer through the induction of genomic (chromosomal) instability and aneuploidy, which may be a result of multiple indirect mechanisms (Benassi-Evans and Fenech 2011). Alcohol interacts also with different metabolic pathways. The one-carbon metabolism (OCM) is critical for the synthesis of DNA precursors. It is also a methyl donor for methylation events. Maintenance of genomic stability is dependent upon the processes of DNA repair and methylation such that the interaction of ethanol with OCM poses the threat of DNA damage and DNA repair dysfunction (Kruman et al. 2012).

Autophagy is a carefully regulated pathway that involves the lysosomal degradation of cytoplasmic organelles or cytosolic components, a cell biological process providing a central component of the integrated stress response. Since eukaryotic cells, defined by their membrane complexity, are under constant need to adapt to changing environments (or "stressors" of varying magnitude), it is the response of such cells to these fluctuating stressors that determines whether functionality and survival or cell death occurs. Incorporated in the response to stress (assumed sublethal) is the capacity for rapid changes adapting metabolism and promoting protection. Autophagy is a major pathway mediating stress-induced metabolic adaptation and protective measures that promote species survival against neurodegenerative, neuroinflammatory, and neoplastic stressors, involving abnormal cell proliferation (Levine and Kroemer 2008; Mizushima et al. 2008). A close integration between regulatory processes in response to stress, including nutrient uptake, metabolism, cell cycle and growth control, cell fate and lineage decisions, and cellular survival and death programs, and processes regulating autophagy is maintained, thereby promoting the fundamental adaptation to environmental stressors. Impairments in autophagy lead to accumulation of damaged proteins and organelles thereby eliciting increased cellular stress. Autophagy, through the elimination of potential proapoptotic sources such as damaged mitochondria, provides a cytoprotective pathway which sets a higher threshold against global apoptosis induction (Kroemer et al. 2010). The survival function of autophagy in nutrient- or growth factor-deprived cells (Klionsky 2007) is linked to cellular repair and antipathogen defense (Melendez and Neufeld 2008). The generation of oxidative stress and mitochondrial-related changes by alcohol is an important aspect of the damaging influence of the drug (McVicker et al. 2009). Nonetheless, since autophagy exerts either a pro-survival or pro-death effect, its influence by exposure to the drug is of some importance. Von Haefen et al. (2011) have shown that ethanol downregulated the autophagy proteins, Beclin-1 and LC3-II, with enhanced apoptosis through breakdown of mitochondrial potential, upregulation of cleaved caspase-3 and PARP-1, and downregulation of antiapoptotic protein Bcl-2. They concluded that ethanol inhibited autophagy thereby enhancing vulnerability for cell death.

4 Nicotine Neurotoxicity

The disrupting influences of developmental neurotoxicity by drugs of abuse presents an important regulatory issue as well as a necessary area for significant public concern (Archer and Kostrzewa 2012). Despite the plethora of evidence, the developmental neurotoxicity of a huge number of compounds has yet to be determined (Judson et al. 2009). This type of neurotoxicity involves several manners of expression, including cell proliferation (Breier et al. 2008), synaptogenesis (Harrill et al. 2011), gene expression (Hill et al. 2008), neurite formation (Radio and Mundy 2008), network formation (Robinette et al. 2011), and function and regional integrity (Lai et al. 2011). Applying methods for detecting chemical-induced alterations in proliferation, apoptosis, and viability, Culbreth et al. (2012) have described viability (status of a cell to survive, grow, and multiply) changes in human neuroprogenitor cells following nicotine exposure. Despite evidence that cigarette smoking during pregnancy is associated with fetal, obstetrical, and developmental outcomes, 15–20 % of all women smoke throughout the duration of pregnancy (Andres and Day 2000; Srisukhumbowornchai et al. 2012). Maternal smoking results in myriad physical, cognitive, and behavioral effects in offspring due to prenatal exposure to nicotine. A great proportion of the adverse physiological symptoms attributed to smoking termination (craving, irritability, restlessness, anxiety, and appetite) are related to nicotine withdrawal (Glynn et al. 2009). Through its capacity to bind with cholinergic nicotinic receptors (nAChRs), nicotine dysregulates several essential biological processes such as angiogenesis, apoptosis, and cell-mediated immunity (Zeidler et al. 2007), with proapoptotic effects, in vivo and in vitro, particularly in the developing brain (Abreu-Villaca et al. 2004; Qiao et al. 2003; Roy et al. 1998, 2002). Finally, the effects of nicotine upon permeability of the blood–brain barrier may expose brain regions to potentially serious neurotoxicity (Manda et al. 2010).

Nicotine taken in by pregnant women crosses the placenta, concentrates in fetal blood and amniotic fluid, and is detectable in breast milk during lactation (Lambers and Clark 1996). The effects of nicotine replacement therapy for offspring are linked to fetotoxicity and neuroteratogenicity (Ginzel et al. 2007), as well as adverse cardiovascular, respiratory, endocrine, and metabolic outcomes (Laitinen et al. 2012; Oken et al. 2008; Syme et al. 2010). In order to model the human maternal smoking situation in the animal laboratory, a gestational nicotine exposure has been devised (Coleman 2008; Dwyer et al. 2008, 2009; Franke et al. 2007; Prins et al. 2012). Similar to prenatal smoking exposure in humans, the gestational exposure in animals dose-dependently induces low birth weight, cognitive performance deficits, and enhanced locomotor activity (Eppolito and Smith 2006). Nicotine, a major neurotoxin in cigarette smoke, crosses the placental barrier and fetal, poorly-developed, blood–brain barrier and binds to nAChRs, thereby contributing to the pathogenesis of abnormal brainstem neurochemistry. The gestational nicotine model presented also extensive neurochemical deficits that were manifested during adolescence (Franke et al. 2008; Slotkin 2008). Nevertheless, not all the prenatal nicotine alterations seem to imply permanent deficits. Santiago and

Huffman (2012) have observed that although mouse mother nutrition, dam weight gain, and litter size were not significantly affected by nicotine treatment, prenatal nicotine exposure resulted in lower newborn birth weight and brain weight and length. Remarkably however, the reduction of body weight, brain weight, and brain length observed in newborn prenatal smoking exposure mice, compared to control mice, was no longer present at the 10th postnatal day. Wei et al. (2011) used a pathway-focused oligonucleotide microarray to analyze molecular mechanisms underlying how gestational exposure to nicotine alters brain development in five regions: amygdala, prefrontal cortex, nucleus accumbens, periventricular nucleus of the hypothalamus, and caudate putamen. They identified 24 cell death/survival-related pathways modulated significantly by gestational nicotine that were classified into three categories: (i) growth factor, (ii) death receptor, and (iii) kinase cascade, on the basis of their biological functions. Kinase cascades present a series of several protein kinases that phosphorylate and activate each other: Kinase-1 phosphorylates and activates kinase-2, in turn then phosphorylating and activating kinase 3. This cascade serves to amplify greatly a signal since each protein kinase can phosphorylate multiple substrates. Quantitative real-time PCR (polymerase chain reaction) array was applied to verify their findings through measures of 29 genes involved in cell death/survival-related pathways and indicated that gestational nicotine exposure exerted significant effects on these pathways in the brains of adolescent offspring. These effects were brain region specific and actualized through the expression of growth factors and receptors, caspases, kinases, and transcription factors. They have presented the notion that gestational nicotine exposure affects cell death and survival in adolescent offspring brains by regulating the balance between growth-factor and death-receptor pathways (Wei et al. 2011).

The apoptotic propensity of fetal and neonatal nicotine exposure and its accompanying health hazards have been described both neurodevelopmentally and pathophysiologically (Bruin et al. 2008; 2012). In this vein, it ought to be noted that, whereas there is no information on the long-term effects of developmental nicotine exposure in humans, the consensus from laboratory studies indicates that nicotine alone is the key factor underlying pathophysiology, including Type 2 diabetes, neurobehavioral defects, obesity, hypertension, impaired fertility, and respiratory dysfunction (Bruin et al. 2010). The neurotoxic agency of nicotine is not straightforward but rather complex and enigmatic. It would appear that nicotine exerts, concurrently, both positive, neuroprotective, and apoptosis-inhibiting effects (Hejmadi et al. 2003; Tizabi et al. 2005; Zhang et al. 2006) and conversely negative, neurotoxic, and apoptosis-promoting effects (Barr et al. 2007; Crowley-Weber et al. 2003; Zhao and Reece 2005) with regard to the integrity of the developing and the mature brain. Nicotine, with its specific binding to nAChR, functions as a dysregulator of essential developmental biological processes, such as cell proliferation, apoptosis, migration, invasion, angiogenesis, inflammation, and cell-mediated immunity in a wide variety of cells including fetal (regulation of development), embryonic, and adult stem cells, adult tissues, as well as invading cancer cells (Cardinale et al. 2012). In cardiomyocytes, which may offer a model cell type for examining neurotoxicity, nicotine promoted apoptosis by inducing

oxidative stress and disrupting apoptosis-related gene expression (Zhou et al. 2010). The neurodevelopmental toxicity of nicotine has been described to some extent and in comparison with other real and potential neurotoxicants using zebrafish development as the laboratory model (Muth-Köhne et al. 2012). From these propensities, it seems clear that the action of the drug is multifaceted, possibly involving different neuronal circuits influencing each other through complicated interactions. Ferrea and Winterer (2009) have summarized the most important results of experiments about nicotinic neuroprotection and neurotoxicity propensities in humans and animals. In the first place, well-known modifications of cholinergic transmission during physiological (normal aging) and pathological neurodegeneration have been outlined, and in the second place, neuroprotective and neurotoxic effects of nicotine, also mentioning the underlying molecular mechanisms, have been described.

Maternal smoking exerts critically health hazards that may through indirect means induce neurotoxic actions in brain regions leading to functional deficits. Multiple pathophysiological mechanisms, e.g., respiratory control abnormalities, contribute to these defects. Smoking/nicotine during pregnancy pressurizes the maternal metabolic system and contributes to adverse pregnancy outcomes, predicting future risks for respiratory dysfunction, neurobehavioral deficits in cognitive-emotional domains, cardiovascular disease, obesity, and Type-2 diabetes (Ellis et al. 2012; Langley et al. 2012; Mamun et al. 2012; Zhu et al. 2012). "Catch-up" growth is observed normally in children exposed to intrauterine smoke which was linked to subsequent childhood obesity (Chen et al. 2012). The abnormal hypothalamic gene expression of appetite regulators, e.g., downregulation of pro-opiomelanocortin and neuropeptide Y in the arcuate nucleus of the hypothalamus may be one expression of health hazard. Human studies indicate that maternal smoking causes changes in ventilator control, and respiratory and arousal patterns in newborn infants, decreasing ventilator drive and blunted hypoxic ventilator response (Ueda et al. 1999). There exists a dose-dependent increase in the frequency and duration of obstructive respiratory events in term infants born to mothers who smoked (Kahn et al. 1994). Prenatal exposure to cigarette smoke is associated with decreases in arousal responses after obstructive events (Tirosh et al. 1996). Preterm infants born to smoking mothers showed increased apneic events and decreased respiratory arousal (Sawnani et al. 2004). Nicotine, despite the presence of other chemicals in cigarette smoking, provides the major factor underlying alterations in respiratory control. Nicotine-exposed neonatal rats showed lower minute ventilation on room air thereby evidencing nicotine effects on eupneic, normal, good breathing, ventilation (St. John and Leiter 1999), showing lower tidal volume and higher respiratory frequency (Hafstrom et al. 2002a). Prenatal nicotine attenuates the hypoxic ventilator response (Bamford and Carroll 1999; Hafstrom et al. 2002b; Milerad et al. 1995). Prenatal nicotine exposure is accompanied by a decrease in the magnitude of hypoxic ventilator depression, the component of hypoxic ventilator response that activates the PDGF-β receptor (platelet-derived growth factor-β receptor) and its downstream antiapoptotic cascade in the caudal brainstem of developing rats (Gozal et al. 2000).

Simakajornboon et al. (2010) examined the effect of prenatal nicotine exposure on PDGF-β receptor activation and the subsequent activation of downstream antiapoptotic processes through the Akt/BAD pathway (Akt promotes cell survival through phosphorylation of BAD) which in itself is inhibited by stress (Zundel and Giacco 1998). They concluded that prenatal nicotine exposure attenuated the phosphorylation of PDGF-β receptor, Akt, and BAD-136 during hypoxia in the caudal brainstem of developing rats, suggesting the elevated apoptosis in this region and increased vulnerability of neural cells in the respiratory control area.

5 Alcohol-Nicotine Combinations

Adolescence, characterized as a period of vulnerability (Grant 1998), is a critical period with likely debut for both smoking and alcohol (National Institute on Drug Abuse 1998; Spear 2000), and adolescent "drinkers" are more likely to be "smokers" than "non-drinkers," and vice versa (Chen and Kandel 1995; Van Zundert et al. 2012; Zhang et al. 2012); the consequences are much more serious with pregnant mothers (McDonnell-Naughton et al. 2012). Nicotine, by itself, is damaging to the adolescent brain (Abreu-Villaca et al. 2003). Adolescents appear to be consuming larger quantities of cigarettes and alcohol earlier in life (Perkonnig et al. 2006) with a strong relationship between onset of tobacco use at an early age and alcohol addiction (Burns and Proctor 2012; Muñoz et al. 2012). Smoking prevalence among individuals under treatment for alcoholism is 3–4-fold that of the general population (Batel et al. 1995). It has been shown that nicotine and ethanol interact during adolescence among mice to affect cognitive performance (Abreu-Villaca et al. 2007) and affective status (Abreu-Villaca et al. 2008), during both exposure and withdrawal. Hippocampal cell death and reduced densities of neuronal and glial cells were observed during adolescent nicotine or ethanol exposure whereas the drug combination caused less significant effects (Oliveira-da-Silva et al. 2009). The effects of nicotine and/or ethanol upon several regions of the hippocampus were investigated (Oliveira-da-Silva et al. 2010); these included the granular layer of the dentate gyrus, molecular layer, CA1, CA2, and CA3 of C57/Bl6 mice, using TUNEL assay. There were increases in the numbers of TUNEL + cells in both the nicotine and ethanol groups, with less severe effects in the nicotine-ethanol combination group. Their results point toward the deleterious effects of nicotine and/or ethanol that were reversed during prolonged withdrawal.

Both animal and human studies have described tolerance, consumption, relapse, and behavioral interactions between ethanol and nicotine administration. Nevertheless, the interactions of these drugs with particular reference to developmental and adolescent neurotoxicity, ethanol withdrawal in adulthood for subjects who have an adolescent history of using these drugs, and their combined effects on neuroimmune signaling and mobilization remain neglected although attention emerges (Durazzo et al. 2007). For example, Riley et al. (2012) have investigated nicotine's influence on ethanol withdrawal seizures in two different age groups of

male C3H mice. Adolescent and adult male C3H mice, beginning at postnatal day 28 or 70, respectively, were subjected to a 7-day chronic exposure to ethanol only, ethanol plus nicotine, nicotine only, or vehicle treatment. Six weeks later, all the groups were subjected to chronic exposure to ethanol vapors and the severity of their ethanol withdrawal seizures was assessed by handling-induced convulsions. An adolescent exposure to chronic nicotine resulted in an exacerbation of ethanol withdrawal seizures in adulthood. Given this, adolescence may contain a neurophysiological critical period that is sensitive to nicotine and which may result in an altered response to ethanol dependency in adulthood. These findings have serious implications for the long-term consequences following co-abuse of these drugs during adolescence. The synergistically detrimental effects of combined alcohol and nicotine exposure upon neurodevelopment and brain and CNS integrity ought not to be underestimated (Ramlochansingh et al. 2011).

The effects of nicotine on neural mechanisms modulating respiratory and cardiovascular functioning outlined above become rather more noteworthy with the neurophysiological interactions that arise in combination with alcohol. The prenatal exposure to high levels of nicotine or alcohol separately, e.g., in tribal groups of the North American Plains Indians, has been considered to constitute a major factor contributing to sudden infant death (Gunn et al. 2000; Isayu et al. 2002). In an autopsy study of the Aberden Area Infant Mortality Study, Duncan et al. (2010) investigated the effects of cigarette smoke and alcohol upon the distribution and binding of nAChRs in the brainstem of sudden death cases (SIDs). The expression of nAChRs in the brain is widespread, primarily presynaptic. These receptors, contributing to neurotransmitter release, neurite outgrowth and differentiation, and neuronal survival (Gotti and Clementi 2004; Torrao and Britto 2002), are ligand-gated ion channels, pentameric in structure, and comprised of homomeric or heteromeric combinations of 12 genes [α2-10, β2-4] (Landgren et al. 2011). The ^{3}H-nicotine radioligand was chosen since it binds, with varying affinity, to all subunits of nAChRs but preferentially to the $\alpha_4\beta_2$ subunit to which nicotine in cigarette smoke binds (Benwell et al. 1988). ^{3}H-nicotine binding in five nuclei related to cardiorespiratory control decreased with increasing number of drinks (Duncan et al. 2008). In three mesopontine nuclei critical for arousal, there were reductions in binding for controls exposed to cigarette smoke compared with controls not exposed (ibid). The authors indicate that maternal smoking and alcohol affected ^{3}H-nicotine binding in the infant brainstem, irrespective of cause of death. Durazzo et al. (2004) used human in vivo proton magnetic resonance spectroscopic imaging to observe that chronic cigarette smoking exacerbated chronic alcohol-induced neuronal injury and cell membrane damage in the frontal lobes of recovering alcoholics (14 smokers and 10 nonsmokers) in treatment compared with 26 light-drinking controls (7 smokers and 19 nonsmokers). They found independent adverse effects on neuronal viability and cell membranes in the midbrain and on cell membranes of the cerebellar vermis, with higher smoking levels being associated with metabolite concentrations in the selected subcortical structures.

6 Conclusion

Substance abuse, as above with ethanol, nicotine, or both, is associated with levels of neurotoxicity encompassing most systems of the brain and CNS. The transition from occasional-recreational use to chronic abuse and addiction presents serious psychiatric obstacles that allow few avenues for effective and definitive treatment since most individuals relapse, even after long periods of abstinence. The elucidation of mechanisms through which these substances exert neurotoxicity and mediate addiction remains an essential requirement and mostly involves altered gene function (Kovatsi et al. 2011). Thus, the increasing evidence derived from epigenetics implicating the epigenome in situations of altered gene function may guide through to an understanding of etiopathogenesis. Nevertheless, despite the identification of several genes linked to alcoholism, the genetic basis remains a mystery; advances pursued through the development of transcriptomics, epigenomics, and proteomics may eventually explain genetic susceptibility to alcohol (Buscemi and Turchi 2011). It is expected that the eventual understanding of fetal alcohol syndrome disorders requires (1) the identification of genetic and epigenetic modifications that may be predictive of the neurobehavioral and neurobiological dysfunctions in offspring induced by gestational alcohol exposure and (2) the determination of the relationship structural brain alterations induced by gestational alcohol exposure and the functional-epigenetic outcomes in the offspring (Reynolds et al. 2011). Both the major problem of adverse drug reactions and related neurotoxicity (Kacevska et al. 2011) and the influence of chronic nicotine administration prior to cocaine abuse that exacerbates the epigenetic, gene expression, and electrophysiological and neurobehavioral effects during the transition from acute to chronic responses to cocaine (Volkow 2011) may be linked to the addictive process (Archer et al. 2011, 2012; Archer and Kostrzewa 2013; Blum et al. 2011).

Experimental Approach to Alzheimer Disease

M. Salkovic-Petrisic, S. Hoyer, and Peter Riederer

Contents

Abstract

This review on current experimental models of Alzheimer disease is based on human postmortem findings showing keystone markers for a pathology within the ß-amyloid transduction cascade as well as pathology in the mechanism of phosphorylation of τau protein. Evidence for risk factors triggering this devastating disease focuses on type II diabetes. Therefore, modelling Alzheimer disease tries to get profound knowledge of these underlying mechanisms by studying experimental animal models. Here will be discussed in detail two

pharmacological models, the one mirroring type II diabetes-induced AD pathology by streptozotocin and its influences on the insulin/insulin receptor cascade as well as ß-amyloid and τau pathologies. Behavioral studies give evidence that this model is currently the most detailed described AD model. While transgenic mouse models, like the APP Tg2576 model, demonstrate ß-amyloid plaque formation and impaired memory rather in old age, streptozotocin is able to aggravate the process of pathology so that AD pathology is seen months earlier. This indicates a profound interaction of AD pathology with the insulin/insulin receptor cascade and pathobiochemistry.

Modelling cholinergic deficits has been done by using the cholinotoxin AF64A. This model reflects changes in the acetylcholine metabolism as well as in monoaminergic transmitter systems, and behavioral studies are in line with AD-based impairment of learning and memory. However, ß-amyloid and τau pathologies as well as insulin-resistant brain state have not been studied in detail.

Keywords
AF64A model • Alzheimer disease • Dementia model • Streptozotocin • Transgenic dementia models • Type II diabetes

1 Introduction

Any model of a disease should reflect the core abnormalities of that disease in morphobiological and clinical terms. In case of Alzheimer disease (AD), it has to be taken into account that AD is not a single disorder from a nosological point of view. A very small proportion of 513 families worldwide (by August 2011) are suffering from AD caused by missense mutations: in the amyloid precursor protein (APP) gene on chromosome 21 (89 families ∼ 17.3 %), in the presenilin gene 1 on chromosome 14 (402 families ∼ 78.4 %), and in the presenilin gene 2 on chromosome 1 (22 families ∼ 4.3 %) (http://www.molgen.ua.ac.be/admutations). These currently known three mutations are involved in both the overexpression and the abnormal cleavage of APP and the increased formation of the APP derivative ß-amyloid (Aß1–40, Aß1–42/43), a keystone for the amyloid hypothesis of AD (Sandbrink et al. 1996; Hardy and Selkoe 2002; Selkoe 2003). Clinically, the dementia symptoms may become evident as early as in the third decade of life.

In contrast, in sporadic AD (sAD), which approximately more than 15 million people worldwide suffer from (Blennow et al. 2006), no such mutations were found as yet, i.e., the mutation-related stimulus is lacking, and its role in the causation of sAD remains enigmatic (Hoyer 1993; Joseph et al. 2001). Also, in longitudinal studies on aged nondemented, cognitively normal subjects, abundant neuritic plaques and neurofibrillary tangles were found in the brain (Crystal et al. 1988; Davis et al. 1999; Snowdon 1997). Moreover, the decline of the mental status starting in later life and followed over several years was demonstrated not to be

accompanied by changes in the numerical density of plaques and tangles (Bennett et al. 1993; Davies et al. 1987; Mann et al. 1985). Finally, it was the neuronal loss rather than neuritic plaques and neurofibrillary tangles that directly contributed to cognitive damage (Gomez-Isla et al. 1997). Also, in postmortem sAD brain, Aß42 immunization over 84 weeks induced a marked reduction of amyloid plaques. However, this clearance did not prevent both the progression of dementia and severe end-stage dementia before death (Holmes et al. 2008). Overall, the above findings clearly indicate that sAD is due to risk factors other than mutations in the APP gene or other genes.

Among the risk factors under discussion are, first, age as a leading one (Evans et al. 1989; Ott et al. 1995); second, a single nucleotide polymorphism found in the gene coding for 11ß-hydroxysteroid dehydrogenase I, which is associated with a sixfold increased risk for sAD (de Quervain et al. 2004); and, third, allelic abnormalities of the APO-E 4 gene on chromosome 19 (Mahley and Rall 2000; Tanzi and Bertram 2001). People carrying one copy of this allelic abnormality (around 24 % of the population) or carrying two copies (around 2–3 % of the population) were found to show drastic abnormalities in the cerebral metabolic rate of glucose (Corder et al. 1993), i.e., the nutritional state of the brain may be severely perturbed under these conditions.

The latter data may indicate that the cerebral glucose metabolism may be of pivotal significance. In the normal mature mammalian brain, oxidative glucose/energy metabolism is largely under the control of the neuronal insulin signal transduction cascade (Hoyer 2004a; Maurer and Hoyer 2006). This metabolic pathway is the source of acetyl-CoA necessary for the formation of the neurotransmitter acetylcholine and of ATP which drives nearly all cellular and molecular processes (for a review, see Salkovic-Petrisic et al. 2009). In patients suffering from very early sAD, the cerebral glucose metabolism was found to be reduced in the posterior cingulate cortex (Minoshima et al. 1997) whereby the impairment of cerebral glucose metabolism was found to be of predictive significance (Mosconi 2005). As sAD progresses, the abnormalities in cerebral glucose utilization grow more severe, whereas cerebral blood flow and oxygen consumption of the brain were found to be much less perturbed (Foster et al. 1984; Hoyer et al. 1991; Mielke et al. 1994), i.e., the abnormal glucose metabolism in the brain may be in the center of metabolic abnormalities in sAD, although the glucose concentration in arterial blood was found to be unchanged (Fig. 1).

2 Relevant Animal Models

Based on the latter, cerebral glucose metabolism may be experimentally damaged via the insulin receptor in the brain by two different ways: first, by chronic elevation of the circulating corticosterone (cort) concentration and, second, by direct functional damage by the diabetogenic substance streptozotocin (STZ) applied to the brain only.

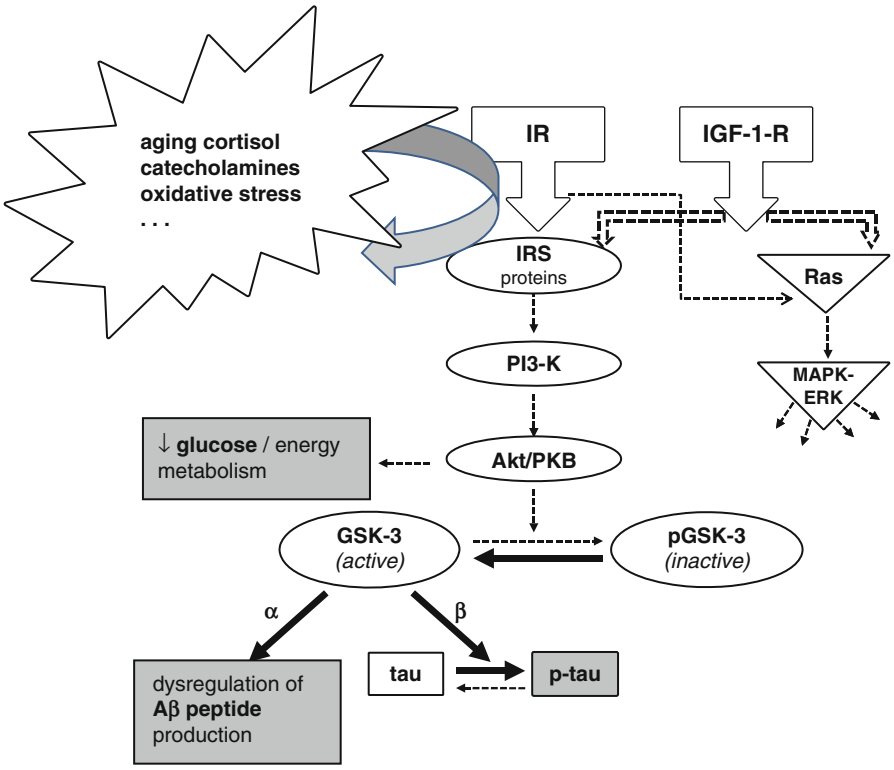

Fig. 1 *Insulin receptor signalling in the insulin-resistant brain state*. Insulin receptor (IR) signalling in the brain may be affected by various factors: physiological and pathophysiological conditions like aging, cortisol, catecholamines, and oxidative stress (as reviewed elsewhere, Hoyer 2004, Salkovic-Petrisic and Hoyer 2007). They may act at the level of the IR and its tyrosine kinase activity and/or at any other element downstream the IR signalling cascade (insulin receptor substrate/IRS) leading to its dysfunction which is finally expressed as the insulin-resistant brain state (IRBS), found in both sAD humans and respective animal models (Hoyer 2004; Salkovic-Petrisic and Hoyer 2007). Namely, the target elements downstream the IR signalling pathways, in particular the PI3K pathway parameters presented at the figure, behave like they are resistant to the influence of insulin due to the reduction/loss of physiological insulin functioning. Low activity of AKT/PKB protein kinase, induced by upstream IR signalling malfunctioning, leads to (i) a decrease in glucose/energy metabolism via glucose transporters and (ii) less phosphorylation and by that activation of glycogen synthase kinase-3 (GSK-3) isoforms α and β. Activated GSK-3α is involved in the dysregulation of β-amyloid peptide (Aβ) production, while activated GSK-3β favors hyperphosphorylation of tau protein, all being a hallmark of sAD pathology. In the STZ-icv rat model, IRBS is induced by the icv administration of low doses of STZ, a drug selectively toxic to glucose transporter-2 and IR expressing cells (Szkudelsky 2001). *Solid arrows*, function stimulated; *dashed arrows*, function inhibited

2.1 Corticosterone Model

It has been well documented that chronic elevation of cort in circulating blood induced a strong increase of cort in both cerebral cortex and hippocampus associated with both learning and memory deficits (Wüppen et al. 2010;

Hoyer and Lannert 2008; Feldmann et al. 2008). This state can be achieved by prenatal stress of (rat) dams during the last week of pregnancy and postnatal daily handling of the pups during the first 3 weeks of life. However, cognitive alterations in Y maze and radial maze were observed only in later life (Steen et al. 2005). Chronic glucocorticoid administration (as a stress model) reduced insulin-degrading enzyme (IDE) protein levels and IDE mRNA in different regions of aged macaque brain associated with increased Aß42 levels relative to Aß40 levels (Rivera et al. 2005).

Exposure of 3 T3-L1 cells to dexamethasone resulted in decreased insulin stimulation of glucose uptake (Moloney et al. 2010). This generation of an insulin-resistant brain state was found to be characterized by reduced gene expression of insulin and insulin receptor density and associated by increased tau protein gene expression (Vallee et al. 1999). Additionally, cerebral glucose metabolism was shown to be markedly reduced by corticosterone (Hoyer and Lannert 2008; Kulstad et al. 2005).

As related to human beings, a disinhibition of the HPA axis causes hypercortisolemia in sAD (Grünfeld et al. 1981), and hypercortisolemia may be supplemented by 11ß-hydroxysteroid dehydrogenase to amplify glucocorticoid action in sporadic AD (Grünfeld et al. 1981) to increase its risk.

2.2 Streptozotocin Model

With respect to insulin/insulin receptor (IR) in sAD brain, a decrease was found in both insulin concentration and tyrosine kinase activity along with an increase in IR density (Frölich et al. 1998). More recent studies demonstrated a drastic reduction of both the expression of insulin and IGF-1 and the respective receptors in different areas of the AD brain accompanied by a reduced insulin signal transduction capacity (Plaschke et al. 1996), whereby the expression of insulin, IGF-1 and IGF-2, and their receptors decreased with advancing AD (Pascualy et al. 2000). Intraneuronally, alterations were found in a predominance at internal and nuclear sites and in a diminution at cytoplasmic and dendritic sites (Frölich et al. 1998). These above findings may point to the neuronal insulin/insulin receptor system as the site of the predominant and early abnormality in sAD, i.e., an insulin-resistant brain state may be assumed.

It is difficult to establish an experimental animal model that would faithfully mimic the developmental pathology of AD in humans, in particular the pathology of the prevailing sporadic form, the causation of which is still unclear. The streptozotocin (STZ) model that will be described here has actually been reported in literature more than 20 years ago (Mayer et al. 1990), but the proposal that it could be considered as a model for the sAD came some 8 years afterwards (Lannert and Hoyer 1998).

STZ (2-deoxy-2-(3-(methyl-3-nitrosoureido)-D-glucopyranose)) is a betacytotoxic drug which, following peripheral (parenteral) administration at high doses, selectively destroys insulin-producing/insulin-secreting β cells in the pancreas and causes type I diabetes mellitus in adult animals (Szkudelski 2001). Treatment with

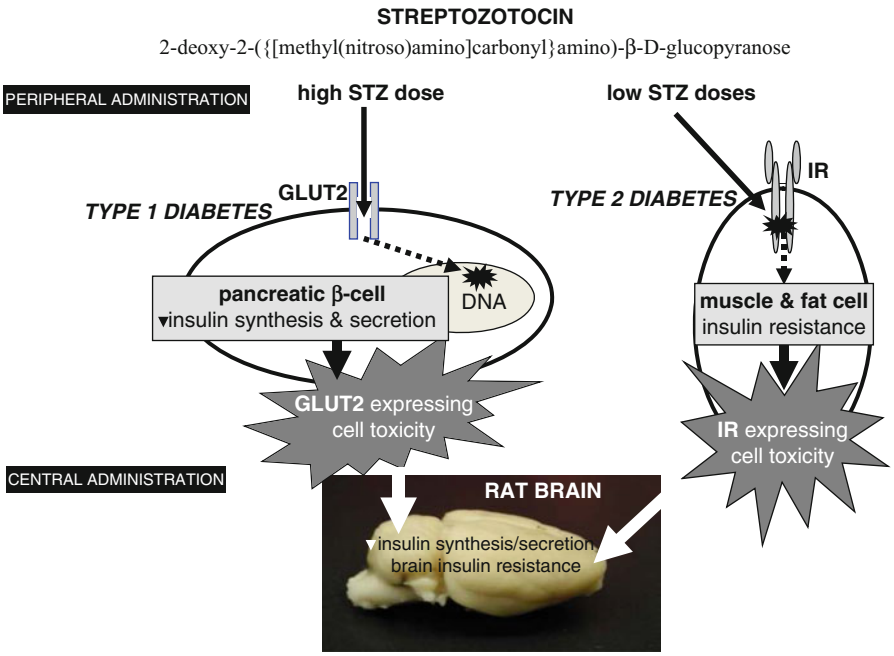

Fig. 2 *Mechanism of action of streptozotocin*. Due to its chemical structure (2-deoxy-2-(3-(methyl-3-nitrosoureido)-D-glucopyranose)), streptozotocin (STZ) is a selective substrate of the glucose transporter-2 (GLUT2) which at the periphery enables entry of this compound into the insulin-producing/insulin-secreting cells, the highest expression of which is on the membrane of pancreatic β cells (Szkudelsky 2001). Following peripheral (parenteral) administration at high doses, STZ selectively destroys insulin-producing/insulin-secreting β cells in the pancreas and causes type I diabetes mellitus in adult animals (Szkudelsky 2001). Treatment with low to moderate doses of STZ causes insulin resistance (Blondel and Portha 1989) via a decrease in autophosphorylation (Kadowaki et al. 1984) and an increase in total number of insulin receptor (IR), but with little change in phosphorylated IR-β subunit (Giorgino et al. 1992). The mechanism of central STZ action and its target cells/molecules in the brain have not been identified yet, but given the presence and the regionally specific distribution of GLUT2 and IR in the mammalian brain, similar mechanism may have been speculated to induce the insulin-resistant brain state following the STZ-icv administration

low to moderate doses of STZ has been demonstrated to cause insulin resistance (Blondel and Portha 1989) via a decrease in autophosphorylation (Kadowaki et al. 1984) and an increase in the total number of IRs, but with little change in phosphorylated IR-β subunit (Giorgino et al. 1992) (Fig. 2). Considering this selectivity to insulin system-related cells and a presence of insulin and IRs in the brain, the idea of the first experiments performed in the 1990s was that the central application of low STZ doses (up to 100x lower than peripheral ones) into the lateral ventricles (icv) might be associated with a kind of local, cerebral diabetes which might be reflected on behavior and brain neurochemistry. Among all changes, cognitive deficits were demonstrated first in STZ-icv-treated

rats (Mayer et al. 1990) and were followed by reports of changes in brain glucose metabolism (Nitsch and Hoyer 1991; Duelli et al. 1994). In spite of that, it has been repeatedly demonstrated that central STZ administration causes neither systemic metabolic changes nor diabetes mellitus (as reviewed by Salkovic-Petrisic and Hoyer 2007). Generally, in the research published so far, STZ has been administrated icv into one or both ventricles of adult rats, mostly in a 1–3 mg/kg dose. There are only a few reports of intracortical administration of low STZ doses (40 μg/kg) to 3-day-old rat pups (Lester-Coll et al. 2006; de la Monte et al. 2006) and recent reports of STZ-icv administration to mice in doses similar to those in rats (Plaschke et al. 2010a; Kumar et al. 2010; Pinton et al. 2011). Variation in the susceptibility of individual animals as a characteristic feature of STZ-icv treatment has been reported by some authors (Blokland and Jolles 1993, 1994; Prickaerts et al. 2000). STZ-icv-induced effects have not been related to the direct nonspecific toxic effect of STZ at the site of drug administration because identical biochemical changes were found in the left and right striatum after unilateral administration of STZ to the right lateral cerebral ventricle (Salkovic-Petrisic et al. 1995). Further support to the specific effect of STZ within the brain has come from a number of experiments which have shown that changes in neurochemistry and morphology are not generalized all over the brain but regionally specific and pronounced at most in the hippocampus (as reviewed by Salkovic-Petrisic and Hoyer 2007).

Due to its chemical structure, STZ is a selective substrate of the glucose transporter GLUT2 which at the periphery enables entry of this compound into the insulin-producing/insulin-secreting cells, the highest expression of which is on the membrane of pancreatic β cells (Szkudelsky 2001). The mechanism of central STZ action and its target cells/molecules in the brain have not been identified yet, but given the presence and the regionally specific distribution of GLUT2 in the mammalian brain as well as its expression in glucose-sensing brain neurons (Brant et al. 1993; Leloup et al. 1994; Ngarmukos et al. 2001; Arluison et al. 2004a, b), similarity to the peripheral mechanism and/or cellular targets seems likely. STZ is a cytotoxic compound, and in vitro experiments on β cells show that within the cell it causes alkylation of β-cell DNA which triggers activation of poly ADP-ribosylation, leading to depletion of cellular NAD^+ and ATP (Szkudelski 2001). Decreased levels of ATP have indeed been reported in the particular brain regions following STZ-icv treatment (Nitsch and Hoyer 1991; Lannert and Hoyer 1998), further supporting the similarity between the peripheral and the central STZ mechanisms of action.

The 20-year-long research of STZ-icv rat model has extensively documented several behavioral, neurochemical, and structural features which resemble those found in human sAD patient brain post-mortem. However, knowledge about glucose metabolism and cholinergic deficit induced by STZ-icv administration and behavioral changes has not made much progress over the years. Nevertheless a significant contribution to the characterization of this model has been provided by revealing of the alterations in the brain insulin system and tau and β-amyloid (Aβ) pathologies, which will be elaborated further on in this text.

The main clinical feature in sAD patients is progressive memory loss, and the representative experimental model of this disease should manifest similar cognitive changes. Deficits in learning and memory functions, usually recorded in the Morris water maze swimming and passive avoidance tests, have been consistently reported and observed as early as 2 weeks after the STZ-icv administration, persisting up to 12 weeks posttreatment (the longest observational period reported until now) (Lannert and Hoyer 1998; Salkovic-Petrisic et al. 2006; Shoham et al. 2007; Grünblatt et al. 2007). The former test is measuring the spatial learning and memory function, while the latter is testing the memory acquisition of the painful stimulus which should be avoided. By means of these tests, cognitive deficits have been found regardless of age in both 1–2-year- and 3-month-old rats (as reviewed by Salkovic-Petrisic and Hoyer 2007). Some correlation between the spatial discrimination performance in the Morris water maze task and the decrease in hippocampal choline acetyltransferase (ChAT) activity has been found in STZ-icv-treated rats (Blokland and Jolles 1993, 1994), although no signs of reduction in specific cholinergic markers were detected in the cortex or hippocampus prior to cognitive deficit appearance (Shoham et al. 2007). The exact mechanism by which STZ-icv treatment impairs cognitive functions has still not been elucidated, but factors like direct neurotoxicity, brain glucose/energy and cholinergic deficits, oxidative stress, and insulin-resistant brain state, all found in the STZ-icv rat model, may form the biological basis for the marked reduction in learning and memory capacities found in this model.

At the neurotransmission level, similarity between the human sAD and the STZ-icv rat model has been demonstrated in altered cholinergic neurotransmission in the brain. Significant increase in the activity of acetylcholinesterase (AChE), the enzyme responsible for a rapid acetylcholine degradation, has been found from 1 to 3 weeks following the STZ-icv treatment in adult rats (Sonkusare et al. 2005; Ishrat et al. 2006; Tota et al. 2011), rat pups (Lester-Coll et al. 2006; de la Monte et al. 2006), and mice (Kumar et al. 2010), generally associated with a decrease in the activity of ChAT, the enzyme involved in acetylcholine synthesis (Hellweg et al. 1992; Blokland and Jolles 1993, 1994; Prickaerts et al. 1999; Terwel et al. 1995).

Glucose represents the primary energy source for the brain, and brain neurons are unable to synthesize or store glucose but depend on glucose transport across the blood–brain barrier and then into the neurons. Three weeks following the STZ-icv administration, concentrations of glucose and ADP, as well as glycogen levels, were increased in the cerebral cortex (Nitsch and Hoyer 1991), and glucose metabolism was significantly decreased (44 %) (Pathan et al. 2006). Six weeks following STZ-icv treatment, reduced glucose utilization (up to 30 %) was found in 17 of 35 brain areas, particularly the frontal, parietal, sensory motor, auditory, and entorhinal cortices and in all hippocampal subfields (Duelli et al. 1994). Additionally, significant decreases in activities of glycolytic key enzymes were found in the brain cortex and hippocampus (Plaschke and Hoyer 1993). Recent data has demonstrated in vivo spatial distribution of glucose hypometabolism induced by STZ-icv administration (2 mg/kg) in cynomolgus monkeys similar to that at early

stages of sAD patients, which in the monkeys persists both 6 and 12 weeks following the STZ-icv treatment (Heo et al. 2011).

STZ generates intracellular free radicals: nitric oxide (NO) and hydrogen peroxide (Szkudelski 2001). Estimations of oxidative stress induced by STZ-icv treatment commonly utilize the measurement of malondialdehyde levels (MDA), a product of lipid peroxidation used as an indicator of free radical generation, and glutathione levels, an endogenous antioxidant that scavenges free radicals and protects against oxidative stress. Significant elevations of MDA levels and decreased glutathione levels have been found in the brain up to 8 weeks following the STZ-icv treatment (Sharma and Gupta 2001, 2002; Ishrat et al. 2006; Pathan et al. 2006; Shoham et al. 2007; Kumar et al. 2010; Saxena et al. 2011) demonstrating resemblance to the oxidative stress condition in the human sAD patients post-mortem (Götz et al. 1992; Gsell et al. 1995).

Morphological changes in the brain of the STZ-icv rat model have been investigated in much lesser extent than the behavioral and neurochemical ones. The earliest study published on that suggested that a single STZ-icv dose (1.5 mg/kg) might cause neuronal damage indicated by a reduction of 30–50 % in the weight of the septum (Terwel et al. 1995). The first more direct evidence of specific neuronal damage after the STZ-icv injection has been provided by the group of Weinstock and co-workers. Using silver impregnation staining, they found that three consecutive STZ-icv injections (in total 3 mg/kg dose) caused degeneration in the fornix, a loss of white matter, and occasional clusters of myelinated axons with distorted morphology, 40 days after the first injection (Weinstock and Shoham 2004). At that posttreatment time point, selective injury to myelin and axons in the fornix and hippocampus was found in association with the activation of microglia, as demonstrated by the increased expression of the glial fibrillary acidic protein (GFAP), a marker of astrogliosis (Prieckaerts et al. 2000). The 3rd ventricle was found enlarged by 100–150 % because of a loss of ependymal cells and damage to hypothalamic periventricular myelin (Shoham et al. 2003). Their work published afterwards indicated that activated microglia and astrocytes found in the cortex, around the cannula penetration area, in the hippocampal CA1 region, corpus callosum, and medial and lateral septum, could be found already 1 week after a single STZ-icv injection (1.5 mg/kg), while 8 weeks after the injection, the whole area of the cannula penetration site contained scar tissue that was filled with tightly packed nonreactive astrocytes and no reactive microglia around (Shoham et al. 2007). Inflammatory processes, reduced neuronal density, and axonal neurotoxicity following the STZ-icv treatment have also been confirmed by recent reports (Dhull et al. 2012; Diwu et al. 2011) in addition to the report of decreased hippocampal neurogenesis found 1 month following the treatment (Qu et al. 2012). Reduced expression of neuronal- and oligodendroglia-specific genes and increased expression of genes encoding GFAP and microglia-specific proteins were also found in rat pups administered with STZ intracortically (STZ-ic) (Lester-Coll et al. 2006).

With regard to the ultrastructural changes induced by the STZ-icv treatment, a significant enlargement of the Golgi apparatus in the frontoparietal cortical neuronal cells caused by 2x-fold expansion of the trans-Golgi segment of the

cellular protein secretory pathway was found 3 weeks after STZ-icv injection (Grieb et al. 2004). Considering that proamyloidogenic processing of β-amyloid precursor protein may occur preferentially in the trans-Golgi segment, the observed early response of neuronal ultrastructure might be of importance for predisposing cells to form β-amyloid deposits.

Demonstration of structural changes in the brain of the STZ-icv-treated rats manifested as Aβ pathology has been a great step in the process of the characterization and validation of this non-transgenic sAD model. Pathological Aβ aggregation in the form of cerebral amyloid angiopathy was visualized by Congo red staining in meningeal capillaries but not earlier than 3 months after the STZ-icv injection (Salkovic-Petrisic et al. 2006) and was further supported by positive Aβ1–42 immunolabelling found in the blood vessel wall at that time point (Salkovic-Petrisic et al. 2011). In the recently published paper, thioflavine-S and Congo red staining revealed diffuse congophilic deposits in the wall of meningeal and cortical blood vessels both 6 and 9 months after the STZ-icv treatment (Salkovic-Petrisic et al. 2011), suggesting a process of progression of the cerebral amyloid angiopathy. However, no diffuse or compact amyloid plaques and neurofibrillary tangles could be detected in the rat brain up to 3 months after icv STZ treatment (Salkovic-Petrisic et al. 2006), while some preliminary work of the same authors suggests a possibility of development of the primitive plaque-like formations appearing from 6 month post-STZ-icv treatment onward (unpublished data). A positive Aβ42 immunosignal has been found in the brain of the STZ-intracerebrocortically treated rat pups (Lester-Coll et al. 2006). These results provide further evidence of the resemblance of the STZ-icv rat model to the human sAD patient pathophysiology and strongly suggest that there is a need to characterize the post-STZ-icv time dependency of the development of amyloid pathology in the brain of this non-transgenic model in which clear differences in comparison to the APP transgenic mice models become obvious.

None of the previously explored alterations were able to provide a missing link to the primary event which could initiate the pathological hallmarks of sAD, hyperphosphorylated tau protein in neurofibrillary tangles, and aggregated Aβ peptide in amyloid plaques. Evidence has gathered indicating that central STZ administration induces region-specific and, for some parameters, time-progressive dysfunction in the rat brain insulin signalling, i.e., an insulin-resistant brain state (IRBS) which highly resembles those found in sAD patients post-mortem (Hoyer 2004; Cole and Frautschy 2007; Qiu and Folstein 2006; Watson and Craft 2006; Wada et al. 2005), suggesting the IRBS might be the missing link. Insulin in the brain binds to IRs which have been found functionally linked to improved cognition, in particular general and spatial memory (Zhao et al. 1999; for review Park 2001; Zhao et al. 2004). Activated IR tyrosine kinase, in addition to the protein kinase (MAPK) mitogen pathway, activates also the phosphatidylinositol-3 kinase (PI3K) pathway and its downstream elements (Johnston et al. 2003), protein kinase B (Akt/PKB) which phosphorylates and consequently inactivates both α and β cytosolic forms of glycogen synthase kinase-3 (GSK-3) (Cross et al. 1995), involved in regulation of APP metabolism and Aß peptides production

(Phiel et al. 2003) and in tau protein phosphorylation (Ishiguro et al. 1993), respectively. IRBS in the STZ-icv rat model is manifested as decreased expression of the insulin genes 1 and 2, as well as the IR gene mostly pronounced in hippocampus but present also in the cerebral cortex, 2 and 12 weeks following the drug administration (Agrawal et al. 2011; Grünblatt et al. 2007). This is followed by decrement in IR-β protein level and unchanged Akt/PKB protein expression at 4 weeks but decreased by 12 weeks posttreatment (Salkovic-Petrisic et al. 2006). Recent data demonstrates significant decrease in IR protein expression, phosphorylation of its downstream substrate (IRS-1), and Akt/PKB in hippocampal CA3 region of STZ-icv-treated rats already 2 weeks following the treatment compared to the control rats subjected to cognitive training (Agrawal et al. 2011). Decreased phosphorylation of PI3K has been also demonstrated in cerebral cortex 3 weeks following the STZ-icv treatment in rats (Deng et al. 2009). Downstream the IR–PI3K pathway, IRBS is manifested by unchanged total GSK-3β levels and decreased p-GSK-3β levels with consequently decreased p-GSK-3/GSK-3 ratio in the hippocampus and cerebral cortex, found 2, 3, and 12 weeks following STZ-icv treatments, indirectly suggesting increased GSK-3β activity (Salkovic-Petrisic et al. 2006; Deng et al. 2009; Ponce-Lopez et al. 2011). In line with dysfunction in the upper part of IR–PI3K signalling pathway manifested already 2 weeks after the STZ-icv treatment, IRBS seems to eventually progress to its lower parts with increased hippocampal expression of tau protein and the p-tau/tau ratio being manifested 4 and 12 weeks following STZ-icv treatment (Salkovic-Petrisic et al. 2006; Grünblatt et al. 2007). Similar IRBS condition with altered IR–PI3K signalling pathway has been also found in STZ-intracortically treated rat pups (Lester-Coll et al. 2006). Recent data demonstrated that the STZ-icv treatment effects on the IR–MAPK pathway might be also time and region dependent as decreased levels of phospho-ERK were found in the cerebrum 3 weeks after the treatment (Deng et al. 2009) while phospho-ERK and its upstream element, phospho-Shc, were found unchanged 2 weeks after the treatment in the hippocampus (Agrawal et al. 2011). Disturbances in insulin action, IR function, and downstream signalling pathways have been found post-mortem in the brain of sAD patients (Hoyer 2004; Cole and Frautschy 2007; Qiu and Folstein 2006; Watson and Craft 2006; Wada et al. 2005; Frölich et al. 1998), but it was only the STZ-icv rat model which has provided evidence that IRBS forms the core of the sAD pathophysiology by preceding and eventually triggering the sAD-like pathology. This hypothesis seems to gain more and more attention in the sAD research field, in particular now when the "amyloid cascade" hypothesis has been argued and the idea of causally different sAD forms is starting to be considered (Correia et al. 2011).

To conclude, a growing body of evidence indicates similarities in cognitive deficits, brain neurochemical and structural pathology between the sAD patients and STZ-icv rats which have been proposed as a non-transgenic model of sAD. Considering the recognition of the IRBS condition in the sAD patients post-mortem, the development of IRBS following the STZ-icv treatment suggests that the STZ-icv rat model might be a promising experimental tool in both the sAD etiopathogenesis research and novel drug testing. Preliminary data on IRBS being

the primary event in this non-transgenic model which could eventually progress and initiate the pathological hallmarks of sAD might provide a new perspective in the research of early diagnosis of this disease in humans. Considering the literature data on environmental and food contaminant exposures to compounds structurally related to STZ, the hypothesis that environmental toxins might play a significant role in the sAD etiopathogenesis should not be neglected (Landrigan et al. 2005; Tong et al. 2009; de la Monte and Tong 2009; de la Monte et al. 2009). In line with that, the STZ-icv rat model provides a wide range of application in the translational neuroscience, and hopefully its further characterization and validation, in particular regarding the long-term follow-up, will bring about the change in elucidating of the sAD enigma.

2.3 Streptozotocin-icv + Transgenic Mice

Considering the STZ-icv rat as a model for the sporadic form and the transgenic (Tg) mice overexpressing beta-amyloid protein precursor (APP Tg2576) as a model for the familial (hereditary) form of AD (Hsiao et al. 1996), the question has arisen on how the STZ-icv treatment would affect the Alzheimer-like pathology in the latter model. Generally, in APP Tg2576 mice, a significant increase in soluble Aβ1–40 and Aβ1–42/43 peptides is found from 3 to 9–10 months of age, and the senile amyloid plaques are formed at the age of 1 year and older (Hsiao et al. 1996), while the impaired spatial memory is found at the age of 9–10 months and later (Ashe 2001). STZ-icv treatment of 3-month-old APP Tg2576 mice induced increased mortality, and measurements done at the age of 9 months (6 months after the STZ-icv treatment) demonstrated reduced spatial cognition and increased cerebral aggregated Aβ fragments, total tau protein, and congophilic amyloid deposits in comparison to the untreated APP Tg2576 mice (Plaschke et al. 2010b). These changes were associated with decreased GSK-3α/GSK-3β ratio (phosphorylated/total) and additionally with a linear negative correlation between Aβ1–42 and cognition and between GSK-3α/GSK-3β ratio and aggregated Aβ1–40 + 1–42, indicating that the STZ-icv treatment induced significant aggravation of the Alzheimer-like pathology in this transgenic mice model of familial AD.

2.4 Cholinotoxin Model

One of the oldest theories of the AD etiopathogenesis proposed the cholinergic deficits, demonstrated as a dramatic decrease of ChAT in the hippocampus and frontal cortex and the marked reduction in cholinergic neuron counts in the nucleus basalis in AD patient brains post-mortem, to be the core in the AD pathophysiology (Greenwald and Davis 1983). Importantly, ChAT deficit has been shown to correlate with histopathologic changes in the brain and psychologic test scores in AD patients (Greenwald and Davis 1983). In line with that, the putative cholinergic

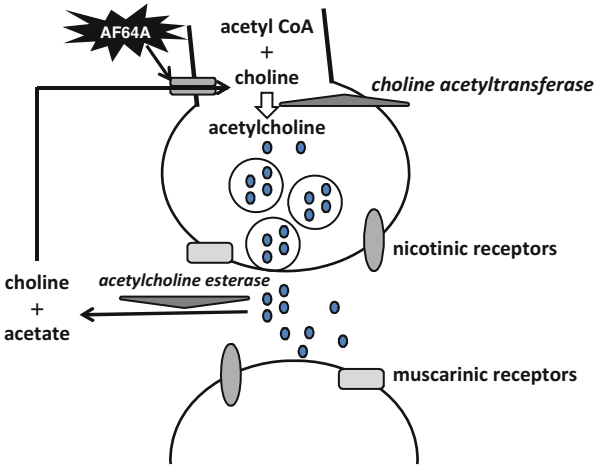

Fig. 3 *Mechanism of action of cholinotoxin AF64A in the cholinergic synapse*. Acetylcholine is synthesized in the presynaptic cholinergic neuron from acetyl coenzyme A (acetyl-CoA) and the precursor choline by means of the choline acetyltransferase. Degradation of acetylcholine in the synaptic cleft is mediated by the acetylcholine esterase, generating acetate and choline. The uptake of choline back into the presynaptic nerve ending is mediated by the high-affinity choline membrane transporter, and this process provides the only source of choline necessary for the acetylcholine synthesis. AF64A is an ethylcholine mustard aziridinium ion, a neurotoxic choline analogue, which is taken up by the high-affinity choline transport system into cholinergic neurons (Fisher et al. 1982)

neurotoxin AF64A was injected intracerebroventricularly in order to determine whether it would produce specific damage to the cholinergic cell bodies and thus be useful in developing animal models of AD (Fig. 3). AF64A is an ethylcholine mustard aziridinium ion, a neurotoxic choline analogue, which is taken up by the high-affinity choline transport system into cholinergic neurons (Fisher et al. 1982). Intracerebroventricular administration of 65 nmol of AF64A to mice was not acutely lethal, but produced delayed behavioral effects similar to those found after parenteral administration of AF64A (ataxia, hypokinesia, weight loss) (Fisher et al. 1982). Seven days following the icv treatment, there was a significant decrease in acetylcholine content in the cortex, striatum, and hippocampus, but no change in choline levels. Acetylcholine content was still significantly reduced in the hippocampus at 3 weeks after this treatment (Fisher et al. 1982). The reduction in activity of choline acetyltransferase and high-affinity choline transport paralleled the reduction in acetylcholine measured at 7 days post AF64A treatment, whereas muscarinic receptors in all three brain areas were unchanged (Fisher et al. 1982). Data has indicated that AF64A is a presynaptic chemical neurotoxin, capable of inducing a persistent deficiency in central cholinergic transmission. The work that followed has demonstrated that AF64A-icv injections in addition to causing cholinergic damage in the septum cause also glial lesions in the lateral septal nucleus and in the lateral zones of the hippocampus (Dudas et al. 2004). Small amounts of

AF64A (0.01 nmol/μL) injected in each ventricle had little effect on the appearance of the nucleus basalis of Meynert (nbM) or on the ChAT levels in the cortex (Kozlowski and Arbogast 1986). Larger amounts of AF64A (0.02 and 0.05 nmol/μL and 0.02 nmol/10 μL, respectively) produced a loss of diffuse acetylcholinesterase (AChE) staining in the nbM and a loss of large positively staining neurons as well as a significant reduction of ChAT activity in the central portion of the cortex without affecting non-cholinergic neurons (Kozlowski and Arbogast 1986). ChAT activity in the AF64A rat model was preferentially reduced in tissue samples of the dorsal compared to the ventral hippocampus (Ayala-Grosso and Urbina-Paez 1999). At the gene level, AF64A-icv injection (2 nmol) was accompanied by a tenfold increase in the AChE mRNA and a twofold decrease in the butyrylcholinesterase (BChE) and AChE mRNA expression in the hippocampus by day 7 with the latter remaining decreased until day 60 posttreatment (Lev-Lehman et al. 1994). AF64A treatment affects also monoaminergic transmission in the brain, as demonstrated by a dose-dependent decrease in noradrenaline level and increased level of its metabolite in the hippocampus 2 days after the treatment (Hörtnagl et al. 1989) and increased serotoninergic neuronal activity and decreased densities of 5-HT uptake sites in different brain regions (Park and Lim 2010).

AF64A-treated rats exhibit learning and memory deficits which have been recorded in different cognitive tests (Nakahara et al. 1988; Lim et al. 2001; Mukhina et al. 2004). In the Morris water maze, these rats showed the delayed latencies to find the platform from the 6th day after the infusion, while in pretrained rats, AF64A treatment caused the significant delay of latency at the 7th day, but not the 8th day (Lim et al. 2001). In the passive avoidance test, AF64A-treated rats shortened the latency 1.5 h but not 24 h after the electroshock, suggesting that AF64A impairs the learning and memory but also that the disturbed memory might rapidly recover after the first retrain (Lim et al. 2001). No literature data are available regarding the amyloid and tau protein pathologies as well as the IRBS in the cholinotoxin AF64A animal model of AD which has not been frequently used in the contemporary AD research.

Fusion Models and "Fusioning" in Parkinsonism: Protection and Restoration by Exercise

Trevor Archer and Anders Fredriksson

Contents

Abstract

Fusion models, or the "fusioning" of models, of Parkinson's disease (PD) to attain the sufficiency of disorder etiopathogenesis have spurred the development of laboratory models incorporating neurotoxin treatments in combination with genetic manipulations of animals studied. The present review describes fusion from two directions: (i) through the fusioning of neurotoxin and genetic models, and, It was observed that wheel-running exercise (four 30-min sessions/week) attenuated the motor deficits, both assessed as distance run in the running wheels and as locomotor, rearing and total activity counts in the motor activity test chambers, and the dopamine (DA) loss induced by the DA neurotoxin, MPTP compared with the no exercise MPTP group (one 30-min session/week).

Keywords

DA • Exercise • Mice • Motor activity • MPTP • PD

1 Introduction

Parkinson's disease (PD) is second only to Alzheimer's disease as a neurodegenerative disorder afflicting humankind with four to five million individuals, diagnosed or undiagnosed in the USA alone (Korell and Tanner 2005). PD most commonly affects individuals in their sixth decade or later and involves several risk factors including pesticides, head trauma, and aging (Allam et al. 2005). Pathways mediated through mitochondrial actions are implicated heavily in the neurodegenerative cascades that result in dopaminergic cell death (Jordan et al. 2003, 2011), with mitochondrial outer membrane permeabilization intimately associated with the apoptotic process (Galluzzi et al. 2009; Gomez-Lazaro et al. 2008). PD is a relatively common, idiopathic neurodegenerative movement disorder with the cardinal features of impaired motor function, resting tremor, rigidity, akinesia/bradykinesia, and postural instability (Gaggelli et al. 2006; Jankovic 2008; Lees et al. 2009). It is a progressive neurodegenerative disorder with late onset and, compared with familial forms, is associated most often with advanced age (>55 years of age). PD symptoms are manifested following 50–75 % loss of striatal dopamine (DA, Riederer and Wuketich 1976; Scherman et al. 1989) and 30–60 % destruction of nigrostriatal DA neurons (Cheng et al. 2010; Fearnley and Lees 1991). Axonal pathology in PD is supported by various sources, not least genetic mutational models (Li et al. 2009; Mortiboys et al. 2008; Saha et al. 2004). For example, Mortiboys et al. (2010) obtained impaired mitochondrial function and morphology in LRRK2 (G2019S)-mutant PD patient tissue, i.e., shared features in early-onset and late-onset PD. The consensus of these and other studies indicating alterations of axonal transport (Meissner et al. 2011; Weihofen et al. 2009) reinforces the notion that neurons in the substantia nigra degenerate through "retrogradely perishing" axonopathy whereby deterioration originates in the distal axon and proceeds to the cell body temporally (Antenor-Dorsey and O'Malley 2012). Converging pathogenic mechanisms imply a restricted number of mechanisms that include oxidative stress, mitochondrial defects and dysfunctionality, proteolytic stress, and neuroinflammation (Braak et al. 2006).

The pathophysiology of PD involves dopaminergic neuron death and accumulation of Lewy bodies associated with mutations in α-synuclein, a 14-kDa protein predominantly expressed in the brain and CNS (Rasia et al. 2005). PD patients show decreased levels of presynaptic DA neuron terminal markers in the basal ganglia (Felicio et al. 2009), consistent with loss of dopaminergic terminals due to degeneration of neuronal cell bodies in the substantia nigra pars compacta (Hattori et al. 2006). They also exhibit decreased levels of DA transporters (DATs) and vesicular monoamine transporter type 2 (VMAT2) as well as reduced activity of dopa decarboxylase, assessed by striatal conversion of L-Dopa to DA, according to PET and SPECT analyses. Wu et al. (2012) using MRI showed that the substantia nigra pars compacta expressed a decreased connectivity with several regions, including the striatum, globus pallidus, subthalamic nucleus, thalamus, supplementary motor area, dorsolateral prefrontal cortex, insula, default mode network, temporal lobe, cerebellum, and pons in patients compared

to controls. They found that L-Dopa administration partially normalized the pattern of connectivity to a similarity such as that expressed by the healthy volunteers involving causal connectivity of basal ganglia networks from the substantia nigra pars compacta. Postsynaptic D_2 DA receptors (D_2Rs) are either unaffected or increased in the striatum of untreated PD patients (Antonini et al. 1994). Oxidative injury appears to be one effect of α-synuclein (α-Syn) aggregates and could ultimately produce neuronal cell death. α-Syn, a 140 residue, intrinsically disordered protein is localized in presynaptic terminals of DA neurons (Yang et al. 2010). Autonomic nervous system involvement occurs at early stages in both PD and incidental Lewy body disease and affects the sympathetic, parasympathetic, and enteric nervous systems. It has been proposed that α-Syn pathology in PD has a distal to proximal progression along autonomic pathways. According to Braakian notions, the enteric nervous systems is affected before the dorsal motor nucleus of the vagus, and distal axons of cardiac sympathetic nerves degenerate before there is loss of paravertebral sympathetic ganglion neurons. Cersosimo and Benarroch (2012a) have shown that consistent with neuropathological findings, some autonomic manifestations such as constipation or impaired cardiac uptake of norepinephrine precursors occur at early stages of the disease even before the onset of motor symptoms (cf. Braak et al. 2006; Cersosimo and Benarroch 2012b; Hawkes et al. 2007).

2 Fusion in PD

The notion concerning the "fusion of models" of PD, the current and latest phase of Parkinsonian model development, has provided a major basis for studying the etiopathogenesis of the disorder through the presentation of a whole new set of animal models and clinical scenarios whereby gene x environment interactions may be analyzed (Manning-Bog and Langston 2007). Several models of PD induced by systemic treatment with neurotoxins included 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), the pesticide rotenone, the herbicide paraquat, and liposaccharide (LPS) occurring in outer membrane of gram-negative bacteria, which combine to provide dopaminergic vulnerability for PD that endows the "multiple-hit" aspect to establish PD symptom profiles, if not a complete pathophysiology. Other models of PD are based upon some form of genetic mutation of α-synuclein or Parkin deficiency, DJ-1 deficiency, and *PINK-1* and *LRRK2* genes that are employed in transgenic models (Manning-Bog and Langston 2007). Remarkably, Westerlund et al. (2010) advocated genetic factors as the major causative factor in PD due to the multiplicity of genes now implicated in the etiopathogenesis that involve several molecular pathways and downstream effectors affecting the trophic support and/or the survival of DA neurons. Nevertheless, much evidence suggests that multiple factors combining environmental agents and genetic predispositions orchestrate the fate of DA neurons (de Lau and Breteler 2006; Gupta et al. 2008; Schapiro et al. 2009). Manning-Bog and Langston (2007), as well as others (Nieto et al. 2006; Song et al. 2004), have presented the notion of

"fusion" between transgenic mouse lines, which indicate subtle alterations with risk factor relevance but generally fail to show overt damage to the nigrostriatal DA system, and laboratory models of neurotoxin-induced DA depletion and altered neurotransmission. Several instances of genetic and neurotoxin model have been reported: Liu et al. (2012) have found that SIRT2 (a sirtuin) deacetylates Foxo3a, increases RNA and protein levels of Bim, and, as a result, enhances apoptosis following MPTP treatment and that chronic MPTP- induced neurodegeneration was prevented by the genetic deletion of SIRT2 in mice. The deletion of SIRT2 led to the reduction of apoptosis due to an increase in acetylation of Foxo3a and a decrease in Bim levels. Peroxisome proliferator-activated receptor-gamma coactivator-1α (PGC-1α), a transcriptional coactivator regulating cell metabolism, mitochondrial biogenesis, oxidative stress, and gene expression, modulates the sensitivity of neurons in the brain to insults; PGC-1α knockout mice were shown to be supersensitive to MPTP (St-Pierre et al. 2006). Several recent studies have shown that PGC-1α is necessary for the integrity of DA neurons through its actions against oxidative stress and enhancing neuronal viability (Breidert et al. 2002; Zheng et al. 2010). Mudo et al. (2012) applied resveratrol to modulate/activate PGC-1α in dopaminergic SN4741 cells in vitro via the deacetylase SIRT1, thereby enhancing PGC-1α gene transcription with elevated SOD2 and Trx2.

The necessity for a model fusion approach has been spurred by several avenues of discontent stemming from what has been described as a "myopic" predilection for neurotoxin-based assaults of the dopaminergic nigrostriatal system (Langston 2006); all viable notions pertaining to the etiopathogenesis of the disorder must accommodate the circumstance that PD presents not a single entity that is the cumulative effect of a dopaminergic structural and functional defect accompanied by several related deficits but expresses rather a concatenation of destructive regional, cellular, and molecular events brought together by a combination of genetic and environmental factors (Litvan et al. 2007a, b). The existence of familial (i.e., genetic) forms of the disorder that appears to account for about 10–18 % of PD diagnoses has been considered (Wirdefeldt et al. 2011). Gao et al. (2012) showed that a family history of Parkinsonism was associated with PD risk (odds ratio = 2.71, 95 % confidence interval, 1.97–3.74), but at the same time was affected marginally, or not at all, by further adjustment for these SNPs and environmental exposures; they obtained a significant interaction with rs2896905 at SLC2A13, near LRRK2, with 32–35 % higher risk levels. Blandini and Armentero (2012) have classified animal models of PD on the basis of systemic/intracerebral administration of neurotoxins that replicated pathological and phenotypic characteristics of the disorder yet describe the proliferation of mammalian and nonmammalian transgenic models presenting disease-inducing mutations identified for monogenic forms of familial PD. Nevertheless, the current trend towards "fusioning" of animal models in this respect holds both specific characteristics that may not be commensurate with essential aspects of the disorders, such as "staging" (Archer et al. 2011c), or limitations requiring much careful consideration prior to selection and application. Soreq et al. (2012) carried out a meta-analysis on 131 brain region transcriptomes from mice overexpressing

native or mutated α-synuclein (SNCA) with or without the protective HSP70 chaperone or exposed MPTP, with or without the protective acetylcholinesterase variant, AChE-R, all of which presented risk-inducible and protection-suppressible transcript modifications. Their conclusions imply that metal ions mediated the "cross talk" between nuclear and mitochondrial pathways by both environmental and genetic risk and those protective factors which eventually culminate in neuroinflammation in the PD cascade. In nonhuman primate studies of PD, both the motor and cognitive capacities of nonhuman primates (NHPs) provide levels of structural and functional complexity that permits laboratory observations to attain insights for applications in the clinical realities (Capitanio and Emborg 2007).

Applying a different point of departure to the investigation of Parkinsonism in the laboratory, fusion dynamics (mitochondrial biogenesis, bioenergetics, dynamics, transport, quality control, and the genes involved) are critical for the life cycle and maintenance of dopaminergic neuron mitochondria. Mitochondrial integrity, dependent upon specific morphological, biochemical, and physiological features, is of critical importance for the maintenance and survival of neurons (Exner et al. 2012) with dysfunctions linked to severe cellular consequences that result in neurodegenerative diseases and aging. Thus, Arduino et al. (2011) have proposed that the cellular demise and neurodegenerative propensity in PD pathophysiology may be modulated by an interaction between mitochondrial dysfunction, mitochondrial trafficking disruption, and impaired autophagic clearance. Sporadic PD case studies, neurotoxin-mediated animal models, and genetically based (familial PD) PD etiology imply that mitochondrial dysfunction/dysregulation constitutes an earl feature of the disorder (Burman et al. 2012; Cooper et al. 2012; Moran et al. 2012). Increased mitochondrial damage due to complex I inhibition, derangement of Ca^{++}, oxidant stress, or impaired clearance of mitochondrial debris leads to the accumulation of nonfunctional organelles contributing to neuronal disrepair (McCoy and Cookson 2012). Several gene mutations regulate the responses to cellular stress with enhanced sensitivity to mitochondrial neurotoxins and oxidative stress (Alberio et al. 2012; Heo et al. 2012; Rochet et al. 2012). Macroautophagy is associated with prevention and limitation of mitochondrial damage and debris through degradation of superfluous or severely damaged mitochondria (Lynch-Day et al. 2012; Wang and Klionsky 2011). Mitochondrial fusion processes, distinguished from membrane fusion mechanisms in secretory pathway or membrane-bound organelles, are divided into three events: "docking," outer membrane fusion, and inner membrane fusion. Injuries to mitochondria impair fusion activate fission-dependent fragmentation and trigger mitophagy (Kim et al. 2007). For instance, mitochondria-derived reactive oxygen species (ROS) at low concentrations may act as signaling molecules and induce mitophagy (Scherz-Shouval et al. 2007). Mitochondrial quantity and quality are regulated to prevent excess energy and harmful ROS. Mitophagy limits the mitochondria to a basal level to fulfill cellular energy requirements and preventing excess ROS production (Kurihara et al. 2012). Arduino et al. (2011) have proposed that cellular demise and neurodegeneration in PD stem from the interactions between mitochondrial

dysfunction and trafficking disruption and autophagic clearance. In this context, fusion-fission models of the disorder pertain to conditions wherein mitochondrial structural-functional integrity through the effective working of cellular autophagy and mitophagy has been compromised (Santos and Cardoso 2012; Youle and van der Bliek 2012).

From a PD perspective, axonal integrity and function are disrupted also by a variety of environmental and laboratory neurotoxins, including 6-hydroxydopamine (Segura Aguilar and Kostrzewa 2004; Kostrzewa et al. 2006), MPTP (see below, Annese et al. 2012; Villalba and Smith 2011), rotenone (Norazit et al. 2010; Press and Milbrandt 2008), and paraquat (Brooks et al. 1999; Peng et al. 2004). Both MPP^+ and rotenone disrupt axonal integrity and function by inhibiting mitochondrial complex I activity (Sterky et al. 2012) and depolymerizing microtubules leading to axon fragmentation and decreased synaptic function (Cabeza-Arvelaiz and Schiestl 2012; Cartelli et al. 2010; Hongo et al. 2012; Qureshi and Paudel 2011); the neurotoxic insults of these agents linked to inhibition of axon transport directly (Behrouz et al. 2007; Kim-Han et al. 2011; Morfini et al. 2007). Axon degeneration, characteristic to neurodegeneration, shares many morphological features with events expressed in acute injuries; the expression of the Wallerian degeneration slow (Wld^S) transgene delays nerve degeneration in both types of insult (Wang et al. 2012). Wallerian degeneration occurs through crushing/cutting nerve fibers whereby the section of the axon separated from the cell body degenerates distal to the injury; Wallerian-type degeneration occurs in PD through compromise of axonal transport. The Wallerian degeneration slow fusion protein, Wld^S, delays axonal degeneration about 10-fold (Avery et al. 2012; Chitnis et al. 2007; Coleman and Freeman 2010; Samsam et al. 2003; Takada et al. 2011) and blocks axon degeneration in several models, such as animal models of PD (Mi et al. 2005; Sajadi et al. 2004) that include the MPTP model (Antenor-Dorsey and O'Malley 2012; Hasbani and O'Malley 2006). Using mutant mice and lentiviral transduction of DA neurons, Antenor-Dorsey and O'Malley (2012) showed that Wld^S, but not Nmnat1, Nmnat3, or cytoplasmically targeted Nmnat1, protected DA axons from MPTP treatment that resulted in MPP^+. Lentiviral transduction refers to a form of "gene therapy" used to designate a process through which viruses are exploited to carry specific genetic information into a cell, thereby transducing the cells' function (cf. Tolu et al. 2010). NAD^+ synthesis was not required but was, by itself, sufficiently axonally protective and was additive in effect together with Wld^S. It appears that Wld^S and NAD^+ act through separate pathways to protect DA neurons through preserving mitochondrial health and/or maintaining cellular metabolism.

The regulation of processes incorporating mitochondrial dynamics encompasses essential mechanisms that control the eventual fate of cells, such as dopaminergic neurons (Liesa et al. 2009); these processes include fission, fusion, and mitophagy, with fusion and fission acting antagonistically, and imbalances in mitochondrial dynamics contributing to PD (Cho et al. 2010; Lees et al. 2009; Su et al. 2010). Mitophagy eliminates damaged or aged mitochondria, thereby maintaining mitochondrial quality, an autophagy-dependent degradation of mitochondria that

contributes to the removal of dysfunctional, aged, or excess mitochondria (Hirota et al. 2012). Galindo et al. (2012) have shown that the regulation of dynamic mitochondrial processes such as fusion, fission, and mitophagy has been unfolded as cascades contributing to important mechanism controlling neuronal fate.

3 MPTP Model of PD

Repeated administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to C57/BL6 mice produces selective lesions of dopaminergic neurons in substantia nigra pars compacta and long-lasting depletion of dopamine (DA) in basal ganglia (Jackson-Lewis et al. 1995; Jones-Humble et al. 1994; Langston 1985; Langston et al. 1984). The susceptibility of mice to the neurotoxic actions of MPTP can be quite variable, depending on gender and strain differences, expressed in functional, neurochemical, and histochemical analyses (Schwarting et al. 1999; Sedelis et al. 2000a, b, 2001, 2003). C57/BL6 and Swiss Webster strains were shown to differ in c-Jun N-terminal kinases (JNKs) and c-JUN activation in response to MPTP. JNKs, of the mitogen-activated protein kinase family, are responsive to stress stimuli, such as cytokines, ultraviolet irradiation, heat shock, and osmotic shock; c-Jun is the name of a gene and protein that, in combination with c-Fos, forms the AP-1 early-response transcription factor. MPTP induced COX-2, an enzyme responsible for inflammation and pain, responding exclusively in C57/BL6 mice (Boyd et al. 2007). MPTP, administered systemically, induces Parkinsonism in human and nonhuman primates (Langston 1985) that results in the loss of *substantia nigra* cells in the *pars compacta* of adult animals (Chiueh et al. 1985). MPTP selectively destroys nigrostriatal neurons, thereby inducing acute, subacute, long-lasting, and even permanent effects that resemble certain features of PD, particularly the hypokinesia effects (Schultz et al. 1989). Systemic administration of MPTP (2×40 mg/kg, s.c.) caused L-Dopa reversible hypoactivity (Fredriksson et al. 1990; Sundström et al. 1990). A less rigorous dose regime, e.g., 2×20 or 25 or 30 mg/kg, of MPTP has been found not to reduce motility in the C57 black mice, although DA brain concentrations may indicate up to 50–80 % reductions (Heikkila et al. 1989; Sonsalla and Heikkila 1986), unless given much more repeatedly (cf. Kurz et al. 2007). The parameters of MPTP treatment neurotoxicity in mice are long-lasting (up to and beyond 52 weeks after treatment), with strong correlations between the functional deficits, particularly hypokinesia, the main biomarker, severe DA depletions, and a dose- and time-dependent recovery of several parameters of motor behavior following treatment with the DA precursor, L-Dopa (Archer and Fredriksson 2003; Fredriksson and Archer 1994; Fredriksson et al. 1999).

4 Exercise Intervention in PD

In the unilateral 6-hydroxydopamine rat model of PD, Tillerson et al. (2001) abolished the lesion-induced motor asymmetry by forcing rats to use the affected (contralateral)

limb, whereas forced nonuse exacerbated the injury (Tillerson et al. 2002). Both DA and 3,4-dihydroxyphenylacetic acid (Dopac) were elevated markedly in "casted" 6-OHDA-treated rats (forced to use the contralateral limb) compared with "non-casted" rats (Cohen et al. 2003). More recently, Choe et al. (2012) showed that exercise recovers PD-induced dopaminergic neuron loss and contralateral soleus muscle atrophy. Using the DA neurotoxin, MPTP as their model of PD, Sung et al. (2012) observed that treadmill exercise prevented dopaminergic neuronal loss by inhibiting brain inflammation through suppression of microglial activation in the PD mice. Archer and Fredriksson (2010) found that daily running-wheel activity attenuated the hypokinesia effects of MPTP in both a concentrated (2 × 40 mg/kg, 24-h interval) and progressive (1 × 40 mg/kg, weekly doses over 4 weeks) schedule with regard to spontaneous motor behavior and activity following a subthreshold dose of L-Dopa. The loss of DA in each case was attenuated by exercise also (experiment I, 61 % of control vs. 17 %; experiment II, 24 % vs. 11 %). Using the progressive schedule of MPTP treatment and extending the exercise intervention from 7 to 14 weeks, it was shown that spontaneous motor activity after MPTP was close to restoration, whereas activity after subthreshold L-Dopa was completely recovered (Fredriksson et al. 2011); DA levels were restored from 17 % (non-exercised) to 64 % in the 14-week exercise intervention, and levels of brain-derived neurotrophic factor were increased significantly. Also, both the functional and DA deficits by MPTP were attenuated even by delayed introduction of exercise (Archer and Fredriksson 2012).

Zigmond et al. (e.g., Cohen et al. 2003; Tillerson et al. 2001, 2002) have utilized the unilateral 6-hydroxydopamine (6-OHDA) rat model of PD whereby they increased the use of the normally denervated contralateral by constraining the other forelimb with a cast, thereby reducing the function and neurochemical effects of the DA neurotoxin evidenced by marked elevations of DA and metabolites. Using MPTP to deplete DA, Klaissle et al. (2012) analyzed newborn cells in the substantia nigra at different stages of maturation and time points as a function of voluntary physical activity, environmental enrichment, and L-Dopa treatment. They observed a motor activity-induced, running-wheel increase in neuroglial antigen-2-positive cells and mature oligodendrocytes in the substantia nigra of healthy mice. In MPTP-treated mice, the stimulation of neuroglial antigen-2-positive cell generation and oligodendrogenesis was dependent upon L-Dopa administration. The authors have suggested that DA is the key regulator for generation of neuroglial antigen-2-positive cells and oligodendrocytes in the substantia nigra that ought to be taken into account as an important contributor to endogenous nigral cellular plasticity. The integrity of the nigrostriatal system under MPTP insult is linked further with dynamics of glial cell activation: CD11b expression, a surface marker on the plasma membrane of microglia and the α-component of several integrins, is increased in the striatum and substantia nigra following MPTP (Kang et al. 2008; Singh et al. 2011). Integrins, transmembrane receptors that mediate the attachment between neurons and surrounding tissues, pass information about the chemical composition and mechanical status of the extracellular matrix. Sung et al. (2012) have shown that treadmill

running exercise prevented the loss of dopaminergic neurons and ameliorated coordination dysfunction in MPTP mice by inhibiting brain inflammation through microglial activation. The effects of physical exercise upon functional and biomaker integrity have been amply shown (Archer 2011, 2012; Archer et al. 2011a, b, 2012; Archer and Kostrzewa 2012; Archer and Fredriksson 2013).

5 Conclusion

The fusion modeling of PD, whether viewed as neurotoxin-genetic model fusions or fusioning within mitochondria, offers an abundance of structural, epigenetic, bio-, and even neurophysiologic markers (Baziyan 2012) as evidence for essential neurodegenerative processes involved in the disorder, if not a complete etiopathogenesis. There is an emerging consensus that genetic- and toxin-induced animal together with cellular models and postmortem human brain tissue provide evidence that mitochondrial dysfunction/dysregulation forms the basis disorder pathophysiology (Chaturvedi and Beal 2012; Van Laar and Berman 2012). From the distinguishing perspective of neuroprotection and/or neurorestoration, Ohshima-Hosoyama et al. (2012) have combined the human insulin receptor (HIR) with glial-derived neurotrophic factor (GDNF) in the fusion protein, HIRMAb-GDNF, in order to induce neuroprotection in Parkinsonian monkeys. However, their results demonstrated that HIRmAb-GDNF dosing in a monkey model of PD was not an effective neuroprotective strategy. Physical exercise has proven effective even using other laboratory models of PD: using the chronic haloperidol administration model of PD, Baptista et al. (2013) showed that exercise alleviated haloperidol-induced akinesia (see also Abrantes et al. 2012). Finally, taking into account noninvasive, non-pharmacological strategies to prevent/restore against brain degeneration in PD, physical exercise has been shown to offer a remarkably effective strategy, alleviating and even restituting brain tissue and mitochondrial dysfunction. Marquis-Aleixo et al. (2012) have described the role of physical exercise in the modulation of the mechanisms involved in neuroprotection including the activation of signaling pathways underlying brain protection.

Iron-Induced Dopaminergic Cell Death In Vivo as a Model of Parkinson's Disease

Manfred Gerlach, Kay L. Double, and Peter Riederer

Contents

Abstract

Histopathological, biochemical, and in vivo brain imaging techniques have revealed a consistent increase of total iron in the substantia nigra pars compacta (SNc) of Parkinson's disease (PD) patients. Interestingly, the increased iron was shown to be restricted to the SNc and occurs in the ferric (Fe^{3+}), rather than ferrous (Fe^{2+}), form of the metal.

The objective of this chapter is to discuss the evidence for dopaminergic cell death in the rat following unilateral ferric iron injections into the SN. In addition, this chapter will briefly review findings showing that NM-bound ferric iron represents a pool of iron that, under certain circumstances, can be released to interact with free radical-producing pathways and the ubiquitin proteasome system, ultimately leading to dopaminergic nerve cell death in the rat. Special attention will be paid to summarize evidence that iron-induced dopaminergic cell death reproduces key features of PD and mimics molecular mechanisms underlying dopaminergic cell death in PD.

Keywords
Animal models • Iron • Neuromelanin • Oxidative stress • Parkinson's disease • Progression

1 Introduction

Parkinson's disease (PD) is the most common neurodegenerative movement disorder. The most striking neuropathological characteristic of PD is the relatively specific loss of the pigmented dopaminergic neurons of the substantia nigra (SN) pars compacta (SNc) and the resulting pallor of the midbrain, as well as the development of abnormal α-synuclein-immunopositive inclusion bodies within the boundaries of the pigment (Jellinger 2012). While the full clinical syndrome of PD is a complex multi-transmitter disorder, the characteristic motor symptoms associated with the sporadic, and all genetic, forms of this disorder result from the degeneration of the dopamine-producing neurons of the SNc. While the trigger for this relatively selective neuronal vulnerability remains unknown, the cascade of degenerative events leading to cell death is beginning to be understood. The major hypotheses believed to contribute to the eventual demise of nigral dopamine-producing cells include altered protein handling, disturbed iron homeostasis, oxidative stress, mitochondrial dysfunction, and neuroinflammation (Gerlach et al. 1994, 2006a; Sian-Hulsmann et al. 2011; Schapira and Jenner 2011). Age is the single most important risk factor for PD, and the biochemical changes that are consequences of aging amplify these abnormalities in the PD brain (Schapira and Jenner 2011).

Histopathological, biochemical, and in vivo brain imaging techniques have revealed a consistent increase in total SNc iron in PD (Gerlach et al. 1994, 2006a; Sian-Hulsmann et al. 2011). Interestingly, the increased iron was shown to be restricted to the SNc and occurs in the ferric (Fe^{3+}), rather than ferrous (Fe^{2+}), form of the metal (Sofic et al. 1988).

Iron increases have also been observed in the brain of nonhuman primates and rodents after exposure to dopaminergic neurotoxins such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; Mochizuki et al. 1994), 6-hydroxydopamine (6-OHDA; Oestreicher et al. 1994), methamphetamine (Melega et al. 2007), and lipopolysaccharide (Zhang et al. 2012). For a detailed treatment of MPTP,

6-OHDA, and methamphetamine, the interested reader is referred to corresponding chapters in this handbook.

Increased iron deposits in the SNc in PD may result from several sources, including a damaged or "leaky" blood-brain barrier in the SN and disturbances of iron uptake, storage, and transport as neurodegeneration progresses (Gerlach et al. 2006b; Sian-Hulsmann et al. 2011). Major iron stores are ferritin and hemosiderin in glial cells, and neuromelanin (NM) in neurons. Age- and disease-dependent overload of iron storage molecules may result in iron release upon reduction. Consequently, the low molecular weight chelatable iron complexes may trigger redox reactions (e.g., oxidative stress), leading to damage of biomolecules, ultimately leading to dopaminergic nerve cell death. This damage includes a defect in complex I in mitochondria, DNA fragmentation, lipid peroxidation of cell membranes, protein misfolding, and disturbance of calcium homeostasis. Additionally, upon neurodegeneration, there is strong microglial activation that can be another source of high iron concentrations in the brain. Although the current evidence suggests that increased brain iron may be a secondary result of neuronal degeneration and reactive gliosis in several neurological disorders affecting the basal ganglia including PD, progressive supranuclear palsy, and multisystem atrophy, the question of whether iron-associated degenerative pathways are a significant factor driving progressive neuronal death in these disorders is yet to be definitively answered.

The objective of this chapter is to discuss the evidence for dopaminergic cell death in the rat following unilateral ferric iron injections into the SN. In addition, this chapter will briefly review findings showing that NM-bound ferric iron represents a pool of iron that, under certain circumstances, can be released to interact with free radical-producing pathways and the ubiquitin proteasome system, ultimately leading to dopaminergic nerve cell death in the rat. Special attention will be paid to summarize evidence that iron-induced dopaminergic cell death reproduces key features of PD and mimics molecular mechanisms underlying dopaminergic cell death in PD.

2 Effects of Unilateral Intranigral Injections of Ferric Iron

The unilateral injection of 50 μg of ferric iron into the right SN of the rat produced a strongly altered motor behavior in the animals, which even 3 weeks after application is expressed by a reduction in spontaneous locomotor activity in a strange environment, by a lower frequency of getting up onto the hind-legs, by a transient appearance of "freezing" phenomena and by spontaneous ipsilateral rotations that are accentuated by amphetamine (Ben-Shachar et al. 1991). This altered motor behavior was accompanied by an average 95 % reduction of the dopamine concentration in the ipsilateral striatum, as well as smaller reductions in the dopamine metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) (85 % or 45 % respectively) measured *post mortem*. Similar changes were also observed at lower iron concentrations (70–350 ng; Sengstock et al. 1992, 1993). In contrast, other neurochemical striatal markers,

such as noradrenaline, serotonin, and 5-hydroxyindoleacetic acid, were unchanged (Ben-Shachar et al. 1991; Arendash et al. 1993).

Histopathological investigations predominantly showed damage of the SNc (Sengstock et al. 1992; Arendash et al. 1993). As early as 24 h after intranigral application of 70 ng of ferric iron, iron-stained astrocytes and microglia were demonstrated. Immediately adjacent to these iron-stained cells, there was a severe loss of neurons and a reactive gliosis, still demonstrable after at least 6 months, as well as a decreased number of neurons stained immunohistochemically of tyrosine hydroxylase (TH).

This damage to the dopaminergic system produced by intranigral ferric iron injection was also demonstrated in vivo by voltammetric procedures measuring dopamine release (Junxia et al. 2003) and extracellular DOPAC concentrations (Wesemann et al. 1993, 1994). In the striatum of rats that have been lesioned with 50-μg ferric iron, the DOPAC signal was diminished. It is interesting to note the time course of this signal: During the 1st week following the lesion, there has been a 79 % reduction on the side of the injection compared to the opposite side, while 3–6 weeks later, the signals were diminished by 86 % or 97 % (Wesemann et al. 1994). This was the first time that a toxic insult has been shown to result in a chronic and progressive course in an animal model of PD. This chronic and progressive course provoked by the nigral iron injection was confirmed by other parameters (Sengstock et al. 1994): First, there was a similarly progressive course on dopamine and HVA changes in the striatum, determined at *post mortem*; second, a progressive atrophy of the SN has been found; and third, there was progressive alteration in apomorphine-elicited rotational behavior.

Interestingly, the unilateral injection of low amounts of ferric iron (1.5 μg) into the left ventral striatum of the rat induced also a long-lasting disturbance of the dopaminergic function (Kolasiewicz et al. 1995). Ten weeks following injection, there was a decrease of the spontaneous night locomotor activity; 14 weeks post-injection, there was a decrease of spontaneous locomotor activity during the adaptation phase in a new environment and an induction of contralateral rotation behavior following subcutaneous administration of 2 mg/kg apomorphine.

The mechanism of the neurotoxic effect of injected ferric iron has not been extensively investigated and is only partly understood. It is assumed that ferric iron is taken up into the neurons and glia by transferrin-receptors (Arendash et al. 1993). Indeed, it was demonstrated in SH-SY5Y neuroblastoma cells that exposure to ferric iron (1–80 μM) leads to a concentration-dependent accumulation of intracellular ferric iron (Nunez et al. 2004). Ferric iron is probably reduced to ferrous iron in the cytosol of these cells. Ferrous iron showed a cytotoxic action in primary cultures of neurons derived from the mesencephalon of rat embryos (Michel et al. 1992). In a reaction similar to the Fenton reaction, excess ferrous iron could catalyze the formation of hydroxyl free radicals from hydrogen peroxide which is an endogenous product of enzymatic dopamine metabolism. This proposed mechanism for the neurotoxic effect was indirectly confirmed by the demonstration of increased amounts of thiobarbituric acid-reactive compounds (a measure of lipid peroxidation) in the SN of ferric iron-infused rats (Arendash et al. 1993;

Wesemann et al. 1993; Sengstock et al. 1997) and the inhibitory effect of desferrioxamine, an iron chelator (Wesemann et al. 1993; Lan and Jiang, 1997). In addition, cell culture studies have demonstrated that exposure of ferric iron (40–150 μM) leads to oxidative stress, assessed by reduction of reduced glutathione (GSH) and total glutathione (GSH and GSSG) concentrations (Nunez et al. 2004) as well as activation of redox-sensitive signals (Salvador and Oteiza 2011), and apoptotic cell death (Salvador and Oteiza 2011).

It has also been shown that ferrous iron led to the formation of large perinuclear inclusion bodies in SH-SY5Y cells that overexpress α-synuclein (Hasegawa et al. 2004). However, the presence of Lewy body-like nigral inclusions has not been established in animals injected with ferric iron into the SN. This is probably the result of the acute administration of iron. It has been observed that inclusions form only in MPTP-treated mice when the neurotoxin is administered continuously at low doses (Fornai et al. 2005).

Extracellular iron has also been shown to increase activated microglia, the principal immune cells in the CNS, and subsequent neurodegeneration in animal models of PD (Shoham and Youdim 2000). Interestingly, an increased SN iron content and increased amounts of activated microglia are associated with SN hyperechogenicity in postmortem brains, whereas increased SN neuromelanin content is related to reduced SN echogenicity (Berg et al. 2010).

3 Effects of Unilateral Injections of Human Neuromelanin-Bound Ferric Iron into the Substantia Nigra

NM is considered as an endogenous iron-binding molecule in pigmented neurons as ferritin is primarily located in glia, rather than neurons, and is believed to play a physiological role in intraneuronal iron homeostasis (Double et al. 2000; Gerlach et al. 2006a). Isolated human NM consists of 2.8 % iron as estimated by Mössbauer spectroscopy (Gerlach et al. 1995), while the concentration of ferric iron in the SN has been determined using electron paramagnetic resonance at 11.3-μg iron/mg isolated NM (Shima et al. 1997). Our Mössbauer spectroscopy data demonstrated also that the iron bound to NM is purely ferric iron that is bound to ferritin-like oxyhydroxide clusters (Gerlach et al. 1995). In PD, where nigral iron levels are increased, saturation of high affinity iron-binding sites on NM may overwhelm the protective capacity of this molecule, leading instead to an increase in redox-active iron, and subsequent cellular damage (Gerlach et al. 2008). Support for this theory comes from changes in NM in the PD brain where significantly less iron is bound to NM than that seen in the normal brain (Lopiano et al. 1999). This suggests that changes in iron-binding to NM may result in increased levels of intraneuronal free iron and subsequent cell damage.

Indeed, it has been demonstrated in adult male Sprague-Dawley rats that injection of 1 μl of a NM/ferric iron (2.5 nmol or 0.139 μg iron) suspension into the ventrolateral region of the left SNc leads to a 50 % reduction of the dopamine neuron number (counted as TH-immunopositive neurons) 8 weeks after injection

compared to that in vehicle-injected animals (Double et al. 2003). The absence of motoric disturbances or a striatal dopamine deficit in these animals suggests a subclinical dopaminergic lesion. This is in contrast to many of the commonly used animal models of PD including the unilateral injection of 50 μg of ferric iron, where nigral TH-immunopositive neurons' cell number is dramatically reduced (up to 95 % cell loss; Gerlach and Riederer 1996).

In humans, at least 70 % of dopaminergic neurons in the SN and 70 % of striatal dopamine must be lost before the symptoms of PD develop (Riederer and Wuketich 1976; Halliday et al. 1996). Progressive neurodegeneration thus occurs several years prior to the onset of the characteristic motor symptoms. The current lesion mimics that which occurs in the parkinsonian brain, where nigral cell loss exhibits a distinct pattern, beginning with the loss of the ventrolateral neurons and progressing to loss of dorsolateral and medial nigral cell groups (Halliday et al. 1996). A localized loss of 50 % of ventrolateral dopaminergic neurons thus represents the pattern of cell loss occurring in preclinical PD. The success of this approach is demonstrated by the absence of behavioral changes following apomorphine challenge or a striatal dopamine deficit in these animals (Double et al. 2003).

A nearly 50 % reduction of TH-positive neuronal cells was also found in the SN of adult male Wistar rats 1 week following unilateral intranigral injection of 2-μl human NM (0.5 mg/ml; Zecca et al. 2008). This injection also induced a strong inflammatory response assessed by immunostaining with glial fibrillary acidic protein and Iba-1 in close vicinity to the NM granules. It has been recently shown that human NM in vitro induces microglial proliferation, chemotaxis and activates proinflammatory microglial properties by stimulating the release of tumor necrosis factor, interleukine-6, and nitric oxide (Wilms et al. 2003).

4 Conclusion

In summary, studies using unilateral intranigral administration of ferric iron and NM-bound ferric iron have been shown to result in dopaminergic neurodegeneration with characteristic features of the human disease in the rat (Table 1). Further, these studies provided insights into the pathophysiological mechanisms of redox-active iron underlying dopaminergic neuronal cell death in PD.

The ideal model of PD (Duty and Jenner 2011) would exhibit a high degree of construct validity (that is similar pathogenesis to the disease), of face validity (that is, similarity in symptoms, neurochemistry, and neuropathology to the human condition) as well as predictive validity (that is, the ability to positively identify agents that are clinically effective). Unilateral administration of ferric iron and NM-bound ferric iron into the SN is therefore a valid experimental model of mechanisms, leading to dopaminergic neurodegeneration in PD, and for the development of neuroprotective agents for PD that stop or slow disease progression (Table 1).

Table 1 Similarities of ferric iron-induced characteristic features to the human condition

	Unilateral intranigral ferric iron injection	Unilateral intranigral human NM-bound ferric iron injection
Construct validity	High (increased SNc ferric iron, oxidative stress, inflammation)	High (increased SNc ferric iron, oxidative stress, inflammation, proteasome inhibition)
Face validity		
Symptoms	Reduction of spontaneous locomotor activity	Absence of motoric disturbances: subclinical model
Neurochemistry	Severe striatal dopamine depletion (up to 95 %)	Moderate striatal dopamine depletion (50 %)
Neuropathology	Nearly complete dopaminergic SNc cell loss	Dopaminergic SNc cell loss
		Moderate dopaminergic SNc cell loss (50 %)
Progression	Intracellular proteinaceous aggregates: No	Not investigated
	Yes	Not investigated
Predictive validity	Yes (development of iron chelators for protection of dopaminergic neurons)	Not investigated

NM neuromelanin, *SNc* substantia nigra pars compacta

homeostasis. The effects observed long after perinatal asphyxia have been explained by overexpression of sentinel proteins, such as poly(ADP-ribose) polymerase 1 (PARP-1), competing for NAD^+ during reoxygenation, leading to the idea that sentinel protein inhibition constitutes a suitable therapeutic strategy. Asphyxia also induces transcriptional activation of proinflammatory factors, including NFκB, and its subunit p65, whose translocation to the nucleus was found here, is significantly increased in brain tissue from asphyxia-exposed animals, in tandem with PARP-1 overactivation, suggesting that PARP-1 inhibition downregulates the expression of proinflammatory cytokines. Indeed, TNF-α and IL-1β were found to be increased 8 and 24 h after perinatal asphyxia in mesencephalon and hippocampus of rat neonates.

The possible neuroprotection effect of nicotinamide has been studied in an experimental model of global perinatal asphyxia in rats, inducing the insult by immersing rat fetuses into a water bath for various periods of time. Following asphyxia, the pups are delivered, immediately treated, or given to surrogate dams for nursing, pending further experiments. Systemic administration of nicotinamide was found to rapidly distribute into the brain reaching a steady-state concentration sufficient to inhibit PARP-1 activity for several hours. Nicotinamide prevented several of the long-term consequences elicited by perinatal asphyxia, supporting the idea that it constitutes a lead for exploring compounds with similar or better pharmacological profiles.

List of Abbreviations

AIF	Apoptosis-inducing factor
AN	Nicotinamide-treated, asphyxia-exposed rats
AS	Asphyxia exposed, saline treated
ATP	Adenosine triphosphate
BAD	Bcl-2-associated death factor
BAX	Bcl-2-associated X factor
BBB	Blood–brain barrier
bFGF	Basic fibroblast growth factor
CNS	Central nervous system
COX-2	Cyclooxygenase-2
CREB	cAMP-response element-binding protein
CS	Caesarean delivered, saline treated
DG	Dentate gyros
DNMT1	DNA(cytosine-5-)-methyl transferase 1

DPQ	3,4-dihydro-5-[4-(1-piperidinyl)butoxy]-1(2H)-isoquinolinone
DR2313	2-methyl-3,5,7,8-tetrahydrothiopyranol[4,3-d]pyrimidine-4-one
E2F	Family of DNA-binding transcription factors
EPO	Erythropoietin
ERCC2	Excision repair cross-complementing rodent repair group 2
ERK	Extracellular signal-regulated kinases
FOXO	Subclass of forkhead O family of transcription factors
FR247304	5-Chloro-2-[3-(4-phenyl-3,6-dihydro-1(2H)-pyridinyl) propyl]-4(3H)-quinazoline
GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
HDAC	Histone deacetylases
HIF	Hypoxia-inducible factor
HRE	Hypoxia-responsive elements
ICAM-1	Intercellular adhesion molecule-1
IGF-1	Insulin-like growth factor-1
IL-1β	Interleukin-1β
iNOS	Inducible nitric oxide synthase
IQ	Intelligence quotient
IκB	Inhibitor of kappa B protein
Ku70	Protein encoded by the XRCC1 gene, required for the nonhomologous end joining pathway of DNA repair
LIG3	DNA ligase 3
LPS	Lipopolysaccharides
NAD^+	Nicotinamide adenine dinucleotide
NADH	Reduced nicotinamide adenine dinucleotide
NFκB	Nuclear factor-κB
ONO-1924H	*N*-3-(4-oxo-3,4-dihydrophthalazin-1-yl)phenyl-4-(morpholin-4-yl) butanamide methane sulfonate monohydrate
P	Postnatal day
p300	Histone acetyltransferase p300
p65	Transcription factor p65
PAR	Poly(ADP-ribose) polymers
PARG	Poly(ADP-ribose) glycohydrolase
PARPs	Poly(ADP-ribose) polymerases
PARylated PARP	Poly-ADP-ribosylated PARP
PBS	Phosphate-buffered saline
PCAF	P300/CBP-associated factor
PCr	Phosphocreatine
PHD	Prolyl hydroxylase domain
PJ34	[*N*-(6-oxo-5,6-dihydrophenanthridin-2-yL)-*N*,*N*-dimethylacetamide.HCl]

POLB, DNA	Polymerase-β
ROS	Reactive oxygen species
SIRT	Sirtuin
SRY	Sex-determining region Y
Strep-HRP	Streptavidin-horseradish peroxidase
SVZ	Subventricular zone
TH	Tyrosine hydroxylase
TNF	Tumor necrosis factor
TUNEL	Terminal deoxynucleotidyl transferase dUTP nick end labelling
VEGF	Vascular endothelial factor
XRCC1	X-ray cross-complementing factor 1

1 Introduction

Obstetric complications are important risk factors for several psychiatric and neurological disorders characterized by a delayed clinical onset. Hypoxia is a common factor of obstetric complications, priming brain development by mechanisms not yet established (Basovich 2010).

Delay in starting pulmonary ventilation at birth implies decreased oxygen saturation in blood and decreased oxygen supply to the brain, which depends upon aerobic metabolism for generating energy and for maintaining the respiratory chain and mitochondrial ATPase activity. Hypoxia implies a switch to glycolysis, which for neurons is a poor metabolic alternative, because of low stores of glucose in brain tissue and deficient ATP output by the glycolysis pathway. Furthermore, glycolysis implies production of lactate, which is accumulated in extracellular compartments, causing acidosis, although there is evidence indicating that lactate can provide a significant source of energy to neurons (Wyss et al. 2011). Prolonged hypoxia further involves suppression of gene expression and translation, favoring the activation of genes for sustained survival, such as hypoxia-inducible factor (HIF) and its target genes (Iyer et al. 1998).

The incidence of perinatal asphyxia is still high, despite improvements of perinatal care (2–6/1,000 term births; De Hann et al. 2006), occurring with higher prevalence in developing countries (Lawn et al. 2010). After asphyxia, infants can develop long-term neurological sequelae, their severity depending upon the extent of the insult. Severe asphyxia has been linked to cerebral palsy, mental retardation, and epilepsy, while mild to severe asphyxia has been associated with attention deficits, hyperactivity, and schizophrenia. No strict correlation has yet been demonstrated between the clinical outcome and the severity and/or the extent of the insult, but the outcome and how the infants recover from the insult are related. In a cohort study monitoring approximately 6,000 children for 8 years, it was demonstrated that resuscitated infants, even if asymptomatic for encephalopathy,

showed an increased risk for low IQ score (Odd et al. 2009). At present, there is no therapeutic strategy to significantly prevent the long-term effects produced by perinatal asphyxia, apart from hypothermia, which still is a controversial issue (Robertson et al. 2012).

2 Reoxygenation

While the average pO_2 in tissue is approximately 65 mmHg, it can decline below 5 mmHg following severe hypoxia. Reoxygenation is mandatory for restoration of function and survival. However, functional constraints of the cells affected by reduced oxygen may be exacerbated during reoxygenation, implying oxidative stress and production of proinflammatory cytokines, delaying the onset of proper homeostasis and complete recovery (Hagberg et al. 1996; Shalak et al. 2002; Girard et al. 2009). Reoxygenation can even enhance protein synthesis over normal levels (see Fähling 2009), including ribosomal biogenesis, leading to defects in protein synthesis fidelity, a mechanism associated to several neurodegenerative diseases (Lee et al. 2006). A number of proteins has to be increased upon reoxygenation, triggering (i) cell death, (ii) cell repairing (e.g., basic fibroblast growth factor, bFGF; VEGF, CREB-binding protein; ribosomal protein S_{19}; casein kinase 1), and (iii) *neuritogenesis* and *synaptogenesis*, required for maturation of neurocircuitries, also implying neurogenesis. Increased postnatal neurogenesis has been observed in subventricular zones (SVZ) and dentate gyrus (DG) of hippocampus in response to hypoxia/ischemia (Scheepens et al. 2003; Bartley et al. 2005).

The leading role in these early events following hypoxia is taken over by HIF-1α that is both an oxygen sensor and a transcription factor. After heterodimerization with HIF-1β, it binds to hypoxia-responsive elements (HRE) on promoters of genes like VEGF, iNOS, hemoxigenase-1, and EPO or to the oxygen sensors prolyl hydroxylase domain (PHD) proteins 2 and 3. HIF-1 also binds to other transcription factors, such as X-ray cross-complementing factor 1 (XRCC1) (Green et al. 1992), excision repair cross-complementing rodent repair group 2 (ERCC2) (Sung et al. 1993; Chiappe-Gutierrez et al. 1998; Lubec et al. 2002), and poly(ADP-ribose) polymerases (PARPs), mainly PARP-1 (Amé et al. 2004). The coordinated action of the products of these genes is believed to minimize and compensate for the damage induced by hypoxic conditions, acting on genes involved in glycolysis, oxygen transport, cell survival, and apoptosis (see Correia and Moreira 2010).

3 Sentinel Proteins

Most of the adaptive changes elicited by hypoxia begin at the level of the DNA. Indeed, within minutes of cerebral hypoxia/ischemia, oxidative damage of DNA is observed in brain parenchyma, including oxidation of guanosine to 8-oxo-guanine and deamination of cytosine to uracil. A major repair mechanism to reconstitute

damaged DNA is base excision repair, shown to be elevated following hypoxia/ischemia, implying activation of PARP-1, XRCC1, ERCC2, DNA polymerase-β (POLB), and DNA ligase (LIG3) (see Ellenberger and Tomkinson 2008; Herrera-Marschitz et al. 2011).

PARPs, XRCC1, ERCC2, POLB, and LIG3 are rapidly activated whenever there is a risk of genome damage. These proteins play a pivotal role not only in repairing mechanisms but also in other environmentally induced DNA modifications. They can act as both cell survival- and cell death-inducing factors by regulation of DNA repair, chromatin remodelling, and regulation of transcription. PARP-1 overactivation may be elicited by P300/CBP-associated factor (PCAF), resulting in caspase-independent translocation of apoptosis-inducing factor (AIF) from mitochondria to the nucleus and subsequent cell death by *chromatinolysis*. Indeed, PARP-1 activation is essential for AIF truncation and release from mitochondria (Kolthur-Seetharam et al. 2006). PARP-1 can be acetylated for enhancing nuclear factor-κB (NFκB)-, FOXO- and Ku70-mediated transcription and for that of tumor suppressor protein p53 (Zampieri et al. 2009). Otherwise, PARP-1 can be deacetylated by proteins of the sirtuin (SIRT) family, histone deacetylases (HDAC) type III, resulting in its inactivation. Activated SIRT also blocks release of truncated AIF from mitochondria (Kolthur-Seetharam et al. 2006; Rajamohan et al. 2009).

PARP-1 activity is strictly controlled to maintain the balance between cell survival and cell death. The equilibrium between the antagonistic actions of SIRT and PARP-1 is maintained through their strict dependency from and competition for NAD^+ (Berger 1985). Increased demand for NAD^+ by PARP-1 inhibits SIRT and vice versa. If both are overactive simultaneously, NAD^+ depletion generates large quantities of nicotinamide that has been shown to inhibit both SIRT and PARP activities (Rajamohan et al. 2009), probably by an end-product inhibitory mechanism. Thus, PARP and SIRT are at the core of epigenetic actions encompassing DNA and histone modifications.

4 Apoptosis

Apoptosis is the prevalent type of delayed cell death in the perinatal brain, mediated by caspase-dependent and caspase-independent mechanisms (Northington et al. 2001; see Morales et al. 2008). Indeed, pro-apoptotic proteins have been observed to be increased following perinatal asphyxia, including Bcl-2-associated X (BAX), and Bcl-2-associated death (BAD) factors, and also anti-apoptotic proteins, including Bcl-2, ERK2, and bFGF, suggesting the activation of neuroprotective and repair pathways (Morales et al. 2008). Extensive and regionally selective nuclear fragmentation has been observed in control and asphyctic rat pups, depending upon the stage of development and the analyzed brain region (Dell'Anna et al. 1997). Signs of apoptosis were observed in para- and presubiculum of both control and asphyxia-exposed animals, independently upon the severity of the insult, with the highest number of cells showing nuclear fragmentation observed

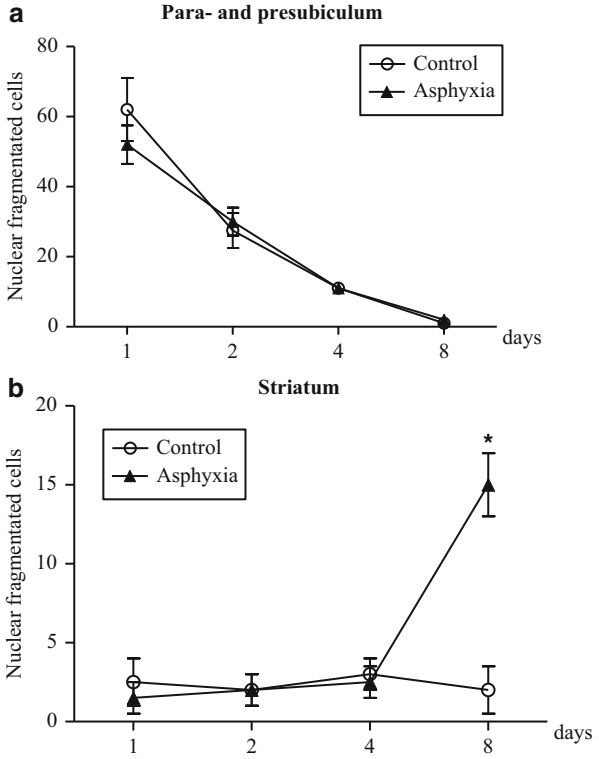

Fig. 1 *Number of neurons showing nuclear fragmentation in para- and presubiculum* (**a**) *and neostriatum* (**b**) *of asphyxia-exposed and control rat pups 1–8 days after birth***.** Brain sections (sagittal 20 μm serial formalin-fixed sections) were obtained from asphyxia-exposed (20–21 min of asphyxia) ($n = 5$–7 animals per group) (*filled triangles*) and the corresponding control ($n = 9$–16) (*open circles*) animals, 1–8 days after delivery. The sections were stained for hematoxylin-eosin and in situ DNA double-strand breaks and analyzed under light microscopy at 40× magnification to detect cellular alterations, using Foster atlas (1998) for proper brain region identification (see Dell'Anna et al. 1997). Values are expressed as means ± SEM (*$p < 0.05$; Student's *t*-test)

at P1-2, decreasing thereafter, with no cells showing nuclear fragmentation at P8 (Fig. 1a). In contrast, no significant nuclear fragmentation was observed in neostriatum of control pups, but a progressive increase in the number of cells showing chromatin fragmentation was observed in asphyxia-exposed animals, with a maximum observed at P8 (Fig. 1b). Similar results were also observed in frontal cortex and cerebellum, increasing with the length of perinatal asphyxia (Dell'Anna et al. 1997).

The effect of perinatal asphyxia on apoptosis is heterogeneous even on a particular region. Indeed, when assayed with an *Apop Tag*^{R} TUNEL kit (Millipore, Temecula, CA), the number of apoptotic cells was particularly

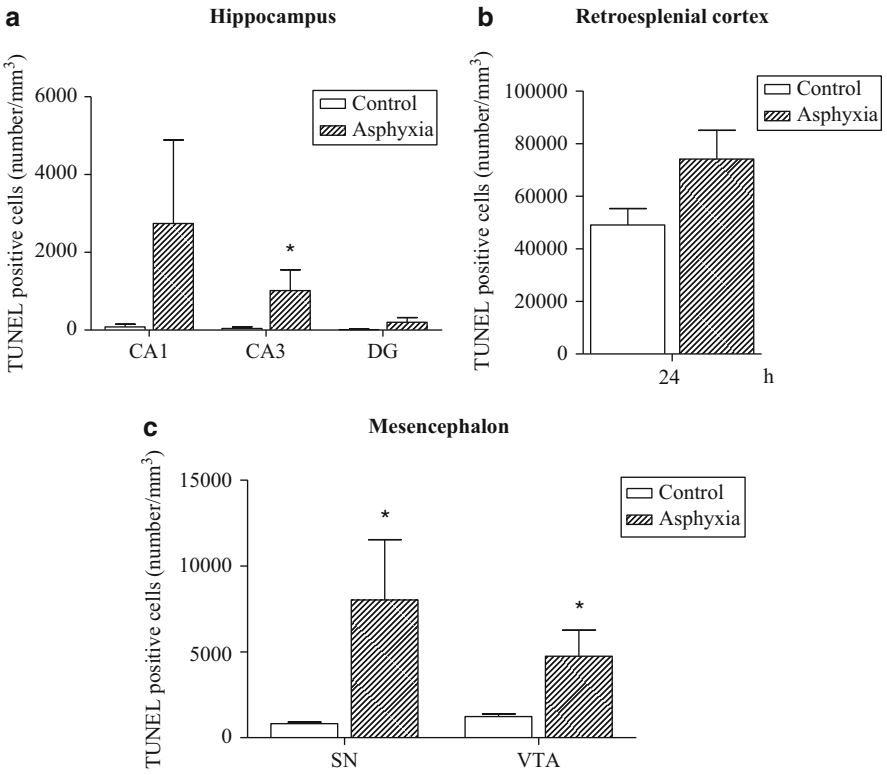

Fig. 2 *Delayed cell death following perinatal asphyxia*. Twenty-four hours after delivery, asphyxia-exposed and control animals were sacrificed, the brains rapidly removed and fixed in 0.1 M pH 7.4 phosphate-buffered saline (PBS) containing 4 % paraformaldehyde, kept in 20 % sucrose, embedded in cryomatrix (Thermo Electron Corp, Pittsburgh, PA, USA), and stored at −80° C. DNA fragmentation was evaluated in coronal brain sections (20 μm thick) with the TUNEL assay (*ApopTag*®; Millipore, Temecula, CA). TUNEL-positive cells (brown) were manually counted in a Nikon TS100 microscope (magnification 100×). The number of TUNEL-positive cells per mm^3 was determined in sections showing hippocampus (**a**), retrosplenial granular zone (**b**), and mesencephalon (**c**) (Foster atlas 1998) from the asphyxia exposed (*dashed bars*) and the corresponding controls (*open bars*). Comparisons were tested with a Student's *t*-test (*$p < 0.05$)

increased in CA1 and CA3 regions of the hippocampus of asphyxia-exposed pups, compared to that from controls (Fig. 2a). A large increase was also observed in the retrosplenial granular cortex (Fig. 2b) (Neira-Peña et al. unpublished), a region connecting the hippocampus with the entorhinal cortex (Wyss and Van Groen 1992). This is an exciting observation, because entorhinal cortex is a brain area consistently observed to be abnormal in psychiatric disorders associated to metabolic insults occurring at birth (Bachus et al. 1997). Indeed, entorhinal cortex (Akil et al. 2000) receives dopamine nerve terminals from mesencephalon

(Hökfelt et al. 1974). In agreement, as shown in Fig. 2c, apoptosis was also increased in mesencephalon following perinatal asphyxia, both in substantia nigra and VTA (Neira-Peña et al. unpublished).

5 Neuroinflammation

Asphyxia can induce transcriptional activation of proinflammatory factors, including NFκB that is normally located in the cytoplasm as a heterodimer, composed of p65 and p50 subunits, coupled to IκB. IκB dissociates from the complex when phosphorylated, liberating p65/p50, which are translocated to the nucleus for inducing the transcription of TNF-α, IL-1β intercellular adhesion molecule-1 (ICAM-1), cyclooxygenase-2 (COX-2), iNOS, and IL-6, all genes involved in inflammation (see Girard et al. 2009).

The immature CNS is capable of mounting innate and adaptive immune responses, through microglial and astrocytes, although it has been argued that the immune responses of the developing CNS differ from that of the adult, in part due to immaturity of blood–brain barrier (BBB). Tight junctions are, however, present early during embryonic development (Kniesel et al. 1996), controlling the interchange of proteins, including leukocytes (Engelhardt 2003; Vexler and Yenari 2009). The developing brain is, however, vulnerable to increases of inflammatory cytokines, leading to a substantial cross talk between peripheral and local brain immune components (see Ransohoff et al. 2003; Vexler and Yenari 2009). Indeed, Qiao et al. (2001) have demonstrated that in neonatal brain, disruption of the BBB to proteins occurs earlier after hypoxic-ischemic insult than in the mature brain.

Microglia provide immunosurveillance to the brain by stimulus-dependent activation (see Vexler and Yenari 2009). Microglia populate the developing brain at birth, and activated microglia can release a number of cytokines, including IL-1β, IGF-1, and TNF-α. It is not clear yet whether microglia activation contributes or protects against the long-term deficits induced by perinatal asphyxia, but it has been reported that minocycline, a tetracycline derivative with anti-inflammatory properties, protects the neonatal brain against ischemia, partly by inhibiting microglia activation and monocyte infiltration (Arvin et al. 2002; Dommergues et al. 2003; Denker et al. 2007). Nevertheless, to investigate the involvement of different cytokines is complex, depending upon the type of the insult, upon the timing along the development axis, and also upon specific brain regions.

The translocation of NFκB was investigated in tissue samples from mesencephalon, hippocampus, and telencephalon from asphyxia-exposed and control rat pups, 1–24 h after birth, with an antibody specific to p65. It was found (Neira-Peña et al. unpublished) that translocation of p65 to the nucleus was significantly increased ($>10\times$) in mesencephalon of both control and asphyxia-exposed pups 24 h after birth, but that increase was already remarkable 8 h after birth in asphyxia-exposed animals (Fig. 3b). In hippocampus, translocation of p65 was enhanced 1 h after birth in control animals, decreasing thereafter at 8–24 h (Fig. 3a). In contrast, in asphyxia-exposed animals, translocation of p65 was remarkably enhanced in

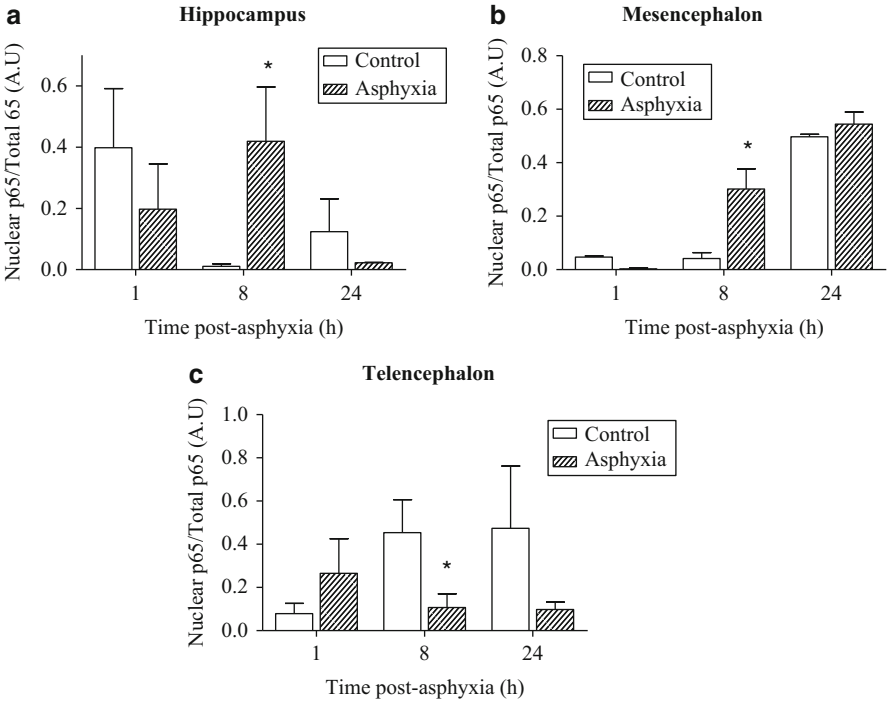

Fig. 3 *Effect of reoxygenation on p65 activation.* Asphyxia and control rats were sacrificed 1, 8, and 24 h post-birth; the brain was rapidly removed, taking up tissue samples from hippocampus (**a**), mesencephalon (**b**), and telencephalon (**c**), placed in Eppendorf tubes, frozen in liquid nitrogen, and stored at −80 °C, pending further analysis. Cytosolic and nuclear protein was extracted with a ProteoJet™ kit (Fermentas). P65 levels were determined in cytosolic and nuclear protein fractions of tissue samples from asphyxia-exposed (*dashed bars*) and controls (*open bars*) rat pups. Western blot was performed using an anti-NFκB p65 antibody (65 KDa) (Santa Cruz Biotechnology, Inc, Santa Cruz, CA). Tubulin and histone H4 were used as controls for the respective fractions. A density-graphic analysis of the bands was performed. Data are represented as nuclear p65/total p65 ratio of Arbitrary Units (AU) (comparisons were analyzed with a Student's *t*-test; $*p < 0.05$)

hippocampus 8 h after birth, decreasing thereafter to almost negligible levels at 24 h (Fig. 3a). In telencephalon, translocation of p65 increased (>10×) from 1 to 8–24 h after birth in the controls, but in asphyxia-exposed animals, translocation of p65 was increased compared to the controls at 1 h, decreasing thereafter (Fig. 3c). Furthermore, TNF-α mRNA levels were increased in hippocampus 8 h after perinatal asphyxia (Fig. 4a), while IL-1β mRNA levels were only increased in mesencephalon, 24 h after the insult (Fig. 4b).

DNA damage and cell death elicited by perinatal asphyxia has the potential of activating PARP-1, promoting NFκB activation (see Skaper 2003; Gagne et al. 2008). In agreement, Ullrich et al. (2001) showed that the microglial migration towards the site of neuronal injury is controlled by PARP-1 overactivation, correlating with NFκB translocation. To evaluate the role of

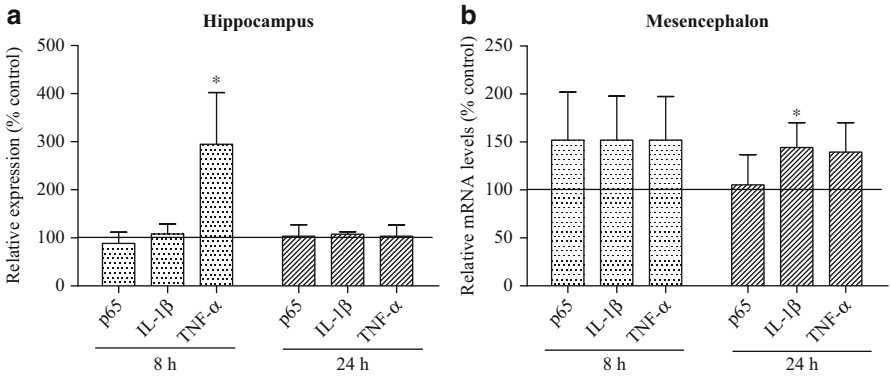

Fig. 4 *mRNA expression of inflammatory-related genes*. Total RNA was extracted with DNAzol, treated with DNAse, and subsequently verified for optical density 260/280 absorption ratios. The integrity of RNA was analyzed by denaturing gel electrophoresis. Reverse transcription was performed with oligo-dT primers from total RNA to obtain cDNA. Relative mRNA levels to GAPDH of p65, IL-1β, and TNF-α were measured by RT-qPCR in tissue samples from hippocampus (**a**) and mesencephalon (**b**). Figure shows the ratio asphyxia-exposed/control rats, at 8 (*stippled bars*) and 24 h (*dashed bars*) after birth. Results, in triplicates, were analyzed with a MxPro software (comparisons tested by a Student's *t*-test; $*p < 0.05$)

PARP-1 in inflammatory processes, PARP-1 $^{-/-}$ mice were challenged with lipopolysaccharides (LPS), finding that the knockout mice were resistant to the endotoxin shock compared with wild-type animals. The knockout mice also showed low levels of TNF-α, due to reduced transcriptional activity of NFκB (Petrilli et al. 2004).

Inhibition of PARP-1 downregulates the expression of proinflammatory cytokines and suppresses NFκB-dependent gene transcription in microglia. Kauppinen et al. (2006, 2009) demonstrated in a model of bilateral carotid occlusion-reperfusion in rats that treatment with the PARP-1 inhibitor PJ34 ([*N*-(6-oxo-5, 6-dihydrophenanthridin-2-yl)-*N*, *N*-dimethylacetamide.HCl]), 48 h later, rapidly suppressed the ischemia-induced microglial activation, enhancing long-term neuronal survival, neurogenesis, and spatial memory. Also, in a model of forebrain ischemia, PJ34 produced a near-complete inhibition of microglia activation and a significant reduction of neuronal death in the hippocampus (Hamby et al. 2007). Furthermore, it was reported that minocycline protects cortical neuron cultures against genotoxic agents causing DNA damage. Interestingly, minocycline also inhibits PARP-1 activity (Alano et al. 2006).

6 Epigenetics

PARP-1 activity is under control of and controls in a reciprocal way the activity of H1-histone, resulting in exclusion of H1 from a subset of PARP-regulated promoters and subsequent regulation of chromatin structure.

PARP itself can be poly-ADP-ribosylated (PARylated PARP), which is reversed by poly-ADP-ribose glycohydrolase (PARG). There is a link between poly-ADP-ribosylation and DNA methylation implying DNA silencing (Cohen-Armon et al. 2007). Specifically, it has been shown that PARG overexpression, or reduction of PARylated PARP, results in methylation of CpG islands in the DNA (cytosine-5-)-methyltransferase 1 (DNMT1) promoter (Zampieri et al. 2009). Gene silencing leads to widespread DNA hypomethylation, resulting in increased gene expression. Conversely, when PARylated PARP occupies the DNMT1 promoter, it protects its unmethylated state and DNMT transcription. Additionally, other transcription factors, such as p300, SRY, or E2F, are associated with PARP at the DNMT1 promoter (Rajamohan et al. 2009).

Thus, epigenetics is a factor to be considered when studying plastic changes elicited by metabolic insults occurring at birth. There is evidence that the molecular machinery that regulates histone acetylation and DNA methylation might be intimately involved in synaptic plasticity, including learning and memory. Importantly, dysfunction of epigenetic gene expression in the brain may result in neurodegenerative and psychiatric diseases (Sananbenesi and Fischer 2009). Conversely, drugs that increase histone acetylation (such as HDAC inhibitors) exhibit neuroprotective and neuro-regenerative properties in animal models of neurodegenerative diseases, enhancing cognitive functions (MacDonald and Roskams 2009).

7 A Therapeutic Target

The adverse consequences of long-term effects of overactive PARP-1 in response to asphyxia (Martin et al. 2005) have led to the notion that PARP-1 is a suitable target for therapeutic interventions preventing the long-term effects of perinatal asphyxia (see Herrera-Marschitz et al. 2011). Nicotinamide has been proposed as a prototype for counteracting PARP-1 overactivation (see Virag and Szabo 2002), replacing NADH/NAD^+ (Zhang et al. 1995), and protecting against oxidative stress (Yan et al. 1999; Wan et al. 1999; Sakakibara et al. 2000) and inflammation (Ducrocq et al. 2000).

It has been reported (Bustamante et al. 2003, 2007) that nicotinamide prevents several of the changes induced by perinatal asphyxia on monoamine contents and dopamine release monitored with in vivo microdialysis 3 months after birth, even if the treatment was delayed for 24 h, suggesting a clinically relevant therapeutic window, supporting the idea that nicotinamide can constitute a therapeutic strategy against the long-term deleterious consequences of perinatal asphyxia, as already proposed for several other pathophysiological conditions (see Virag and Szabo 2002). Nicotinamide has also been proposed as a treatment of Alzheimer's disease (Green et al. 2008).

The therapeutic doses of nicotinamide (0.8 mmol/kg, i.p.) used in the above-reported studies produce a long-lasting inhibition of PARP-1 activity measured in

brain and heart from asphyxia-exposed and control animals (Allende-Castro et al. 2012) and also a decrease of the number of apoptotic nuclei in hippocampus, increased by perinatal asphyxia (Morales et al. 2010).

The use of nicotinamide has, however, been challenged because of its low potency, limited cell uptake, and short cell viability, stimulating the search for more specific compounds, such as 3-aminobenzamide (Ducrocq et al. 2000; Hortobagyi et al. 2003; Koh et al. 2004); 3,4-dihydro-5-[4-(1-piperidinyl)butoxy]-1(2H)-isoquinolinone (DPQ) (Takahashi et al. 1999); PJ34 (Abdelkarim et al. 2001); *N*-3-(4-oxo-3,4-dihydrophthalazin-1-yl)phenyl-4-(morpholin-4-yl) butanamide methane sulfonate monohydrate (ONO-1924H) (Kamanaka et al. 2004); 5-chloro-2-[3-(4-phenyl-3,6-dihydro-1(2H)-pyridinyl) propyl]-4(3H)-quinazoline (FR247304) (Iwashita et al. 2004); and 2-methyl-3,5,7,8-tetrahydrothiopyranol[4,3-d]pyrimidine-4-one (DR2313) (Nakajima et al. 2005). Ultrapotent novel PARP inhibitors are in clinical trials for reducing parenchymal cell necrosis following stroke and/or myocardial infarction, downregulating multiple pathways of inflammation and tissue injury following circulatory shock, colitis, or diabetic complications (Jagtap and Szabo 2005).

There is, however, concern about applying ultrapotent PARP inhibitors during development, since it has been shown that PARP is required for efficient repair of damaged DNA (Trucco et al. 1998; Schultz et al. 2003), suggesting that moderate PARP-1 inhibitors should be chosen for neuronal protection, whenever used for pediatric patients (Moonen et al. 2005; Geraets et al. 2006).

Nicotinamide is therefore an interesting molecule because of its low potency, which can be an advantage when used for developing animals, antagonizing the effects elicited by PARP-1 overactivation without impairing DNA repair or cell proliferation. Nicotinamide has already been tested in human clinical trials without showing any significant toxicity, although its therapeutic efficacy is still controversial (Macleod et al. 2004). Nicotinamide can constitute a lead for exploring compounds with similar or better pharmacological profiles.

8 An Experimental Model for Perinatal Asphyxia

A model for investigating the short- and long-term outcome of perinatal asphyxia was proposed at the Karolinska Institutet, Stockholm, Sweden, in the nineties (Bjelke et al. 1991; Andersson et al. 1992; Herrera-Marschitz et al. 1993). Asphyxia is induced at the time when the rats are delivered providing some features with clinical relevance: (i) it occurs at term, (ii) it is largely noninvasive, (iii) it allows studying peripheral and brain tissue in the same animal, (iv) it allows studying short- and long-term consequences of the insult in the same preparation, and (v) it is highly reproducible among laboratories. Lubec and coworkers in Vienna (Austria) (Lubec et al. 1997a, b; Seidl et al. 2000) have stressed the issue that the model allows to study the early phase of perinatal asphyxia, as observed in the clinical setup.

The model starts by evaluating the estral cycle of young female Wistar rats (~2 months of age), in order to plan for a programmed mating. A vaginal frottis is taken for evaluating the cycle, identifying proestrus, estrus, metaestrus, or diestrus. The female is then exposed to a male at the time of the proestrus for one night, evaluating thereafter for the presence of a vaginal clot. Thus, the time of delivery is calculated, supported by ethological and clinical observations, to predict the exact time of delivery (22 days). At the time of delivery, a first spontaneous birth can be observed before the dams are neck dislocated, and subjected to a caesarean section and hysterectomy. The uterine horns containing the fetuses are immediately immersed into a water bath at 37° C for various periods of time (0–22 min). Following asphyxia, the pups are removed from the uterine horns and resuscitated by cleaning from fluid and amniotic tissue, freeing the mouth and the nose. Pups exposed to caesarean delivery only (CS, 0 asphyxia) or to mild asphyxia (2–10 min) are rapidly resuscitated, without requiring anything else but removing fluid and amniotic tissue from the mouth. For pups exposed to longer periods of asphyxia (19–21 min), resuscitation implies expert and skilful handling, and it takes a long time (4–6 min) for a first gasping and even longer time for establishing a more or less regular breathing, always supported by gasping. After 60 min of caretaking, the pups are given to surrogate dams for nursing, pending further experiments. An Apgar scale is applied during the recovery period, similar to that observed in neonatal units, including parameters such as weight, sex, color of the skin, respiratory frequency, gasping, vocalization, muscular rigidity, and spontaneous movements (Dell'Anna et al. 1997; Morales et al. 2010; see Herrera-Marschitz et al. 2011). The Apgar evaluation is a critical parameter, because it assesses whether the pups are subjected to mild or to severe asphyxia, which is directly determined by the percentage of survival and recovery (Herrera-Marschitz et al. 1993, 1994). The Apgar evaluation also provides information about the condition shown by the caesarean-delivered control pups, which has to be similar to that shown by vaginally delivered pups. Thus, the Apgar evaluation is a requirement when using the present model of perinatal asphyxia, because it permits to compare results obtained by different laboratories and/or different treatments. The quality of the handling of the pups and the experience of the surrogate dam are important factors for the acceptance and nursing of both asphyxia-exposed and control pups.

The model has been useful for describing early molecular, metabolic, and physiological effects. Tissue sampling can be collected immediately after delivery, the time when the pups are removed from the uterine horns (0 min, with or without previous immersion into a water bath), or soon after reoxygenation (Lubec et al. 1997a, b; Seidl et al. 2000; Engidawork et al. 2001). Thus, energy-rich phosphates have been measured in brain and peripheral tissue immediately after delivery following short or long periods of perinatal asphyxia, demonstrating that adenosine triphosphate (ATP)/phosphocreatine (PCr) levels were first significantly decreased in kidneys (after 2 min of asphyxia), then in brain tissue (after 10 min), but in heart ATP dropped down after 20 min of asphyxia (Lubec et al. 1997a; Seidl et al. 2000; see Herrera-Marschitz et al. 2011).

9 Effect of Nicotinamide on the Long-Term Functional Consequences Elicited by Perinatal Asphyxia

Motor and cognitive alterations of variable severity, including cerebral palsy, seizures, spasticity, attention deficit, hyperactivity, mental retardation, and/or neuropsychiatric syndromes with delayed clinical onset have been associated to perinatal asphyxia (du Plessis and Volpe 2002; Van Erp et al. 2002; Kaufman et al. 2003; Vannuci and Hagberg 2004; Odd et al. 2009). With the proposed experimental model, several labs have investigated the behavioral effects associated to perinatal asphyxia, addressing motor function (Bjelke et al. 1991; Chen et al. 1995), emotion (Dell'Anna et al. 1991; Hoeger et al. 2000; Venerosi et al. 2004, 2006; Simola et al. 2008; Morales et al. 2010), and spatial memory (Boksa et al. 1995; Iuvone et al. 1996; Hoeger et al. 2000, 2006; Loidl et al. 2000; Van de Berg et al. 2003; Venerosi et al. 2004).

The issue whether perinatal asphyxia produces long-term effects on cognition has also been investigated. Novel object recognition was studied with a test applied under ethological-like conditions, devoid of any stressful cues or primary reinforcers, such as swimming, food deprivation, or electric shocks (Ennaceur and Delacour 1988). The animal is tested to discriminate between objects differing in shape and color, without any genuine significance to the rat or being previously associated to any rewarding or aversive stimuli. During a first session, two copies of the same object are presented to the rat for 4 min and then again, during a second session, when one of the previously presented objects is replaced by a novel one, similar in size, but different in shape and/or color. The rat has to recognize the novel object, spending longer time exploring the novel than that previously presented. The first and the second sessions are separated by different time intervals, for evaluating learning consolidation. A good memory would be able to recognize a previously presented object after a long time elapsing between a first and a second session, meaning that the animal would concentrate on exploring the novel object. Novel object recognition was studied using a 15 or 60 min interval, when the animals were 3 months old (Simola et al. 2008). No differences were observed between asphyxia-exposed (20 min asphyxia) and control animals when a 15 min interval elapsed between the first and the second session. Both asphyxia-exposed and control rats recognized the novel stimulus similarly well, spending longer time exploring the novel object. However, when 60 min elapsed between the first and second session, asphyxia-exposed animals spent less time exploring the novel object, indicating that asphyxia-exposed rats could not recognize its novelty. Conversely, asphyxia-exposed rats could not remember that one of the objects was already presented during the first session (Simola et al. 2008). This was a straightforward experiment showing a subtle consequence of hypoxia occurring at birth, impairing a cognitive function that shows up only after a proper challenge. It is very much reminiscent to the clinical experience revealing effects only when the child starts the primary school (see Odd et al. 2009; Strackx et al. 2010).

In a parallel study, the same condition was repeated, but a cohort of asphyxia-exposed and of control rats received 0.8 mmol/kg, i.p. of nicotinamide 1, 24, and 48 h after birth and evaluated 2–3 month later for the novel object recognition

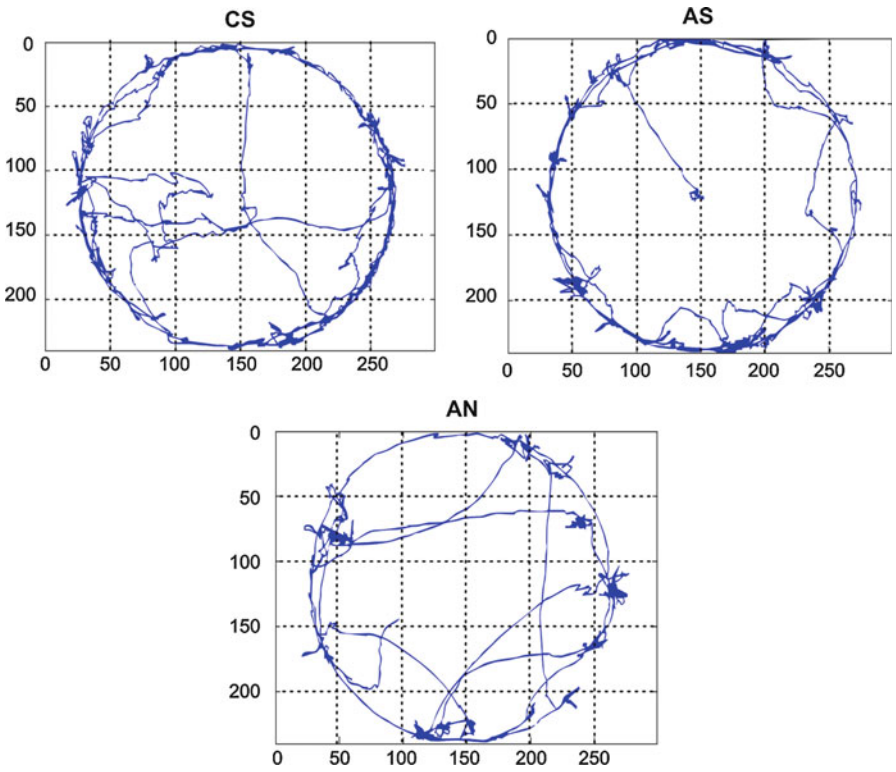

Fig. 5 *Reversal of the effect of perinatal asphyxia on exploratory behavior by neonatal nicotinamide treatment***.** Exploratory behavior was examined in a circular arena placed in a noise-free room. Arena was 140 cm in diameter painted in black, with a continuous wall of 15 cm high and placed 50 cm above the floor. A camera placed 250 cm over the arena was used for recording the rat performance. The camera was connected to a computerized processing unit (*CPU*) placed in the next room where the examiner stayed during the experiment. At 2–3 months of age, control (CS) and asphyxia-exposed (AS) rats treated with saline (3 × 0.1 ml/kg, i.p) or with nicotinamide (AN) (0.8 mmol/kg, i.p.; 1, 24 and 48 h after birth) were placed in the center of the arena free to explore for 5 min (Individual experiments taken from cohorts reported by Allende-Castro et al. 2012)

task. Nicotinamide did not affect the performance of the control animals, but prevented the effect of perinatal asphyxia, since the animals receiving nicotinamide performed identically as the controls on novel object recognition (Morales et al. 2010).

Asphyxia-exposed, treated, and control animals were tested in the first 2–3 months after birth for exploratory behavior, monitored with a video camera when animals were placed in a circular arena in a noise-free room. Each animal was left to explore the new environment for 5 min, monitoring the time expended in the center of the arena, exploiting the natural aversion of rodents for open spaces devoid of thigmotactic cues. A decreased time in the center of the arena was considered as a measure of anxiety (Perez de la Mora et al. 2012). Figure 5 shows the tracking of

a caesarean-delivered saline-treated (CS), a saline-treated asphyxia-exposed (AS), and a nicotine-treated asphyxia-exposed (AN) rat. As previously reported (Allende-Castro et al. 2012), the AS, but not CS or AN, rats avoided areas devoid of thigmotactic cues, indicating unconditioned fear and anxiety, also observed when analyzing the behavioral profile on an elevated plus maze of parallel experimental cohorts (Morales et al. 2010). Nicotinamide prevented the anxiety-related behavior in both experimental paradigms.

10 Pharmacodynamics and Pharmacokinetics of Nicotinamide

It was further investigated whether the effect of nicotinamide was related to PARP-1 inhibition using an enzymatic assay of PARP-1 activity, based on the accumulation of PAR polymers. It was found that a single dose of 0.8 mmol/kg, i.p. of nicotinamide decreased PARP-1 activity by ~70 % in brain (mesencephalon, telencephalon) and peripheral (heart) tissue of asphyxia-exposed and caesarean-delivered control pups, compared with the corresponding saline controls, 1–24 h after birth. A remarkable PARP-1 inhibition was still observed 24 h after the treatment. In vivo microdialysis experiments in ~8h-old pups allowed to monitor the distribution of a single dose of nicotinamide (0.8 mmol/kg, i.p.), in peripheral (subcutaneous) and brain (neostriatum) tissue (Allende-Castro et al. 2012), finding a rapid distribution of nicotinamide into the brain, detectable for longer than 6 h at a steady-state concentration of 20 μM. In the same study, theophylline was also investigated, only finding PARP-1 inhibition in peripheral tissue, in agreement with a poor distribution of a single dose of theophylline (0.14 nmol/kg, i.p.) into the brain compartment.

11 Conclusion

Perinatal asphyxia is still a health concern worldwide, a risk factor for several mental and neurological disorders with a delayed clinical onset. Hypoxia implies a severe energetic crisis, leading to death if reoxygenation is not promptly restored. The functional constraints produced by the lack of oxygen can be exacerbated by and during the reoxygenation period, implying oxidative stress, synthesis, and release of metabolic by-products delaying the onset of proper homeostasis and recovery. A leading role is played by HIF-1α, promoting the synthesis of proteins thought to minimize or compensate the damage induced by the hypoxic condition, but also to promote proinflammatory cytokines leading to cell death. A number of sentinel proteins are rapidly activated whenever there is a risk of genome damage, stimulating base excision repair. PARP-1 has been shown to play a pivotal role for repairing damaged DNA, but also for eliciting caspase-independent cell death when repairing is not viable, modulating pro- and anti-inflammatory signalling.

Furthermore, there is equilibrium between PARP-1 and SIRT proteins, regulating histone acetylation and DNA methylation, the core of epigenetic modification.

PARP-1 overactivation can lead to NAD^+ exhaustion, worsening the energy crisis, leading to the hypothesis that PARP-1 is a suitable target for therapeutic interventions preventing the long-term effects of perinatal asphyxia, nicotinamide being a prototype for counteracting PARP-1 overactivation.

The neuroprotection effect of nicotinamide has been studied in an experimental model of global perinatal asphyxia in rats. In this model, asphyxia is induced by immersing rat fetuses into a water bath for various periods of time. Following asphyxia, the pups are delivered, immediately treated, or given to surrogate dams for nursing, pending further experiments.

Following systemic administration, nicotinamide rapidly distributes into the brain and peripheral compartments reaching a steady-state concentration sufficient to inhibit PARP-1 activity for several hours. Nicotinamide prevents several of the long-term consequences elicited by perinatal asphyxia, supporting the idea that it can constitute a lead for exploring compounds with similar or better pharmacological profiles.

Abstract

Since its discovery in 1976, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) models in rodents and nonhuman primates have continuously renewed to keep up with progresses of Parkinson's disease (PD) research. MPTP is able to reproduce almost all the clinical and neuropathological features of PD when administered to monkeys. In contrast, up to date no rodent model has been able to reproduce all PD features in one. Nevertheless, MPTP is a very versatile neurotoxin that can reproduce different aspects of PD pathology, depending upon the dose and regimen of administration. At the present time, a number of different MPTP models have been developed, allowing researchers to investigate either the classical PD neuropathology and neuroprotective mechanisms or known pathological processes underlining more recently discovered aspects of the disease, such as nonmotor symptoms. In this chapter primate and rodent MPTP models are reviewed, focusing mainly on the contribution that different MPTP protocols can offer to reproduce the multifaceted aspects of the disease.

Keywords

Model • MPTP • Parkinson • Primate • Rodent

1 Introduction

Preclinical investigation of Parkinson's disease (PD) neuropathology and testing of the neuroprotective strategies depends on the availability of reliable experimental animal models. However, modeling PD represents a sorely intricate task. Although several neurotoxin-based and genetic models of PD have been developed, most of them display limitations. Optimally, experimental models of PD should display face validity, reproducing the highest number of features of human PD; predictive validity is also sought, where the neuropathology should evolve progressively as in PD, and therapy responses should be comparable to the human disease; lastly, on a neuropathological view, a PD model should display construct validity, reproducing the complex interaction between neurons and surrounding cells. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is able to reproduce almost all the clinical and neuropathological features of PD when administered to monkeys (Wichmann and DeLong 2003). However, up to date no rodent model has been able to reproduce all of these features together. Depending on the

MPTP model, important limits may include lack of neurodegeneration, absence of motor symptoms despite a nigrostriatal degeneration, failure to reproduce the progressive, and slow nature of human pathology. Moreover, PD involves multiple brainstem nuclei and systemic pathologies, which is difficult to reproduce in a single animal model. On the other hand, MPTP has conveyed to be a very versatile neurotoxin, reproducing different aspects of PD pathology, depending upon the dose and regimen of administration adopted. Keeping this concept in mind and carefully pre-considering dosing regimens, MPTP models provide an incredible contribution to the understanding of the neuropathological mechanisms of PD and to the investigation of neuroprotective and disease-modifying strategies.

2 PD Symptoms and Neuropathology

Parkinson's disease is the most frequent neurodegenerative disorder after Alzheimer disease, affecting nearly 1 % of the population over 60s. Symptoms are mainly motor, including akinesia, rigidity, bradykinesia, postural abnormalities, and tremor. Furthermore, over the past decades substantial evidence has documented a plethora of nonmotor aspects of the disease. These may have either a central or an autonomic basis and include olfactory dysfunction, REM behavior disorders, chronic constipation, orthostatic intolerance, sweating, swallowing difficulties, and chronic fatigue. In addition, neuropsychiatric components such as depression, anxiety, cognitive decline, and dementia may often complicate the clinical picture. Most motor symptoms of PD are caused by the degeneration of nigrostriatal dopamine neurons. In addition, the involvement of brain areas other than the dopaminergic has been described since many years and is now gaining increasing attention for the understanding of biochemical mechanisms of nonmotor symptoms. Hence, PD is now recognized as a complex multisystem pathology, where neurodegeneration extends to brain areas such as the locus coeruleus, raphe nuclei, and dorsal motor nucleus of the vagus as well as to parts of the autonomic nervous system (Hawkes et al. 2009; Braak and Del Tredici 2008).

The appearance of motor symptoms reflects the nigrostriatal degeneration, rising when striatal DA drops to 20–30 % of physiological levels and when over 60 % of nigral neurons are lost. Most nonmotor symptoms also correlate with the advancing disease; however, some of them such as sleep behavior disorder and olfactory deficits precede the onset of motor symptoms by a number of years, being currently investigated as markers for early clinical diagnosis (Chaudhuri and Naidu 2008).

Alongside the degeneration of neurons of the substantia nigra *pars compacta* (SNc), cellular hallmarks of PD are the Lewy bodies and dystrophic neurites. Moreover, a number of malfunctioning cellular processes have been described, including oxidative stress, mitochondrial dysfunction, and impaired protein disposal system (Olanow 2007). In the past decade, several evidences have pointed to neuroinflammation as a key pathological feature and likely a hallmark of PD (Long-Smith et al. 2009). Postmortem studies have described reactive microglia around degenerating neurons in the SN, while inflammatory cytokines levels are elevated in the brain, cerebrospinal fluid, and serum of PD patients

(Blum-Degen et al. 1995; Dobbs et al. 1999; McGeer and McGeer 2008; Mogi et al. 1994). In PD, activated microglia are engaged in a vicious cycle called reactive gliosis, in which constant inflammation contributes to neuronal damage (Carta et al. 2011; Hirsch and Hunot 2009; Ransohoff and Cardona 2010; Schwartz et al. 2006).

3 MPTP Neurotoxicity

The use of MPTP to model PD is one of the few cases where the effect of a neurotoxin was discovered in humans first and then translated to an animal model. In 1982 a cluster of drug addicts in California were inadvertently intoxicated by MPTP, found as a by-product in a street preparation of an analog of the opioid meperidine. The parkinsonian syndrome shown was almost indistinguishable from PD, characterized by severe bradykinesia and rigidity, which were relieved by traditional antiparkinsonian therapies (Langston et al. 1983).

MPTP does not exert the neurotoxic effect by itself, but, after crossing the blood–brain barrier by virtue of its lipophilic nature, is rapidly oxidized to 1-methyl-4-phenyl-2,3-dihydropyridinium (MPDP+) by monoamine oxidase B (MAO-B) in glia and serotonergic neurons (Fig. 1). It is then converted by spontaneous oxidation to the neurotoxic compound 1-methyl-4-phenylpyridinium (MPP+), which is a high-affinity substrate for the dopamine transporter (DAT). MPP+ can now effortlessly be taken up into dopaminergic cells and concentrated within mitochondria, following the mitochondrial transmembrane potential (Javitch et al. 1985; Mayer et al. 1986; Ramsay and Singer 1986; Ransom et al. 1987) (Fig. 1). At this level, MPP+ exerts its toxic effect by inhibiting the complex I of the electron transport chain and impairing oxidative phosphorylation (Nicklas et al. 1985). This event induces a decrease in ATP (Chan et al. 1991; Fabre et al. 1999) content and increase in ROS production that rapidly leads to cell damage and cell death (Hasegawa et al. 1990). Besides these direct effects on dopaminergic neurons, an important contribution to MPP+ toxicity is given by glial cells, which not only are responsible of MPP+ production but also are activated by MPP+ itself or by injury factors released by degenerating neurons, to upregulate inflammatory cytokines and the inducible nitric oxide synthase (iNOS) (Teismann et al. 2003; Youdim et al. 2002). Nitric oxide (NO) easily crosses cell membranes and diffuses toward surrounding dopaminergic neurons, thus contributing to oxidative stress, since peroxynitrite (ONOO-) derived from the reaction of NO with superoxide is highly reactive and induces nitration of proteins (Ischiropoulos and al-Mehdi 1995; Przedborski et al. 1996, Przedborski and Vila 2003).

4 Animal Species and Strand Sensitivity to MPTP Neurotoxicity

4.1 Rodents

In general, rodents are less susceptible than primates to MPTP toxicity. Among rodents, mice are mostly used, while rats are not recommended for

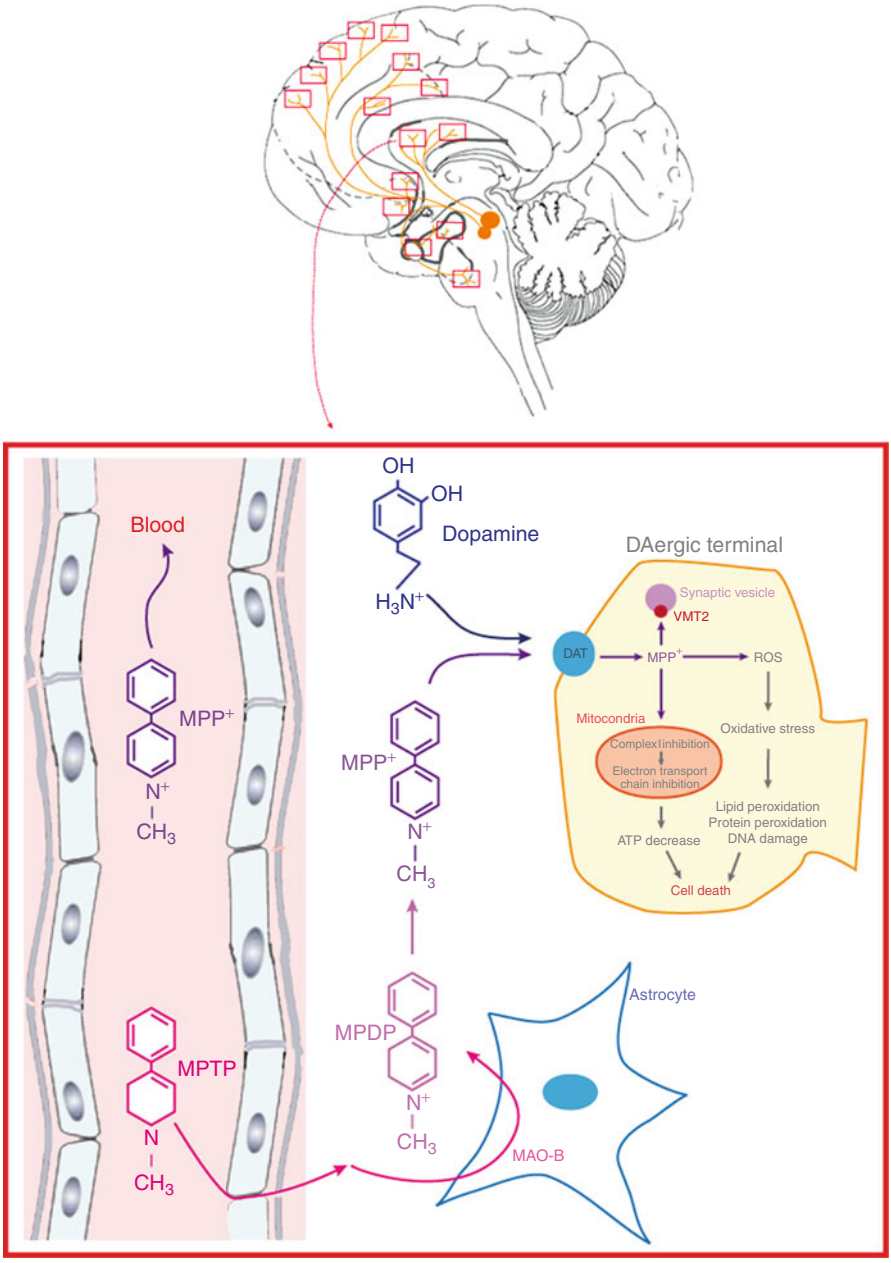

Fig. 1 Once MPTP has crossed the BBB, it is transformed to MPP+ inside the astrocytes through the action of MAO-B. Then, MPP+ enters DA neurons through the DAT and either inhibits the complex I of the mitochondria, inducing cell death, or enters into the synaptic vesicles through the VMAT-2. The levels of astrocytic MAO-B and the expression of DAT and VMAT-2 in DA neurons are important factors in the susceptibility to MPTP

MPTP models, as they display an elevated resistance to the neurotoxin (Giovanni et al. 1994; Heikkila et al. 1984; Sahgal et al. 1984). Variable susceptibility among mouse strains has also been found, the C57black/6 strain being the most sensitive to systemic MPTP injection and currently the most popular for PD research (Giovanni et al. 1994; Schmidt and Ferger 2001; Sedelis et al. 2000). Such differences among animal species and strains may be partially related to the metabolic processes that convert MPTP to toxic metabolites in the brain and periphery. MPTP clearance in the brain, and liver metabolism to nontoxic species, is slower in black mice as opposed to white mice and rats (Riachi et al. 1988). Furthermore, MAO activity in brain microvessels is lower in mice, leading to a reduced conversion of MPTP to MPP+ before entering the brain and to an enhanced capacity of MPTP to reach its sites of toxicity (Riachi et al. 1989). A higher VMAT2 density in DA neurons of rats with respect to mice has been also found (Staal and Sonsalla 2000). Based on that, a more efficient sequestration into synaptic vesicles has been suggested as a further mechanism of protection and reduced vulnerability of rats against MPP+ neurotoxicity. More recently, it has been suggested that variances in immunological backgrounds, or differences in glial and microglial cell number and ratio, might be major contributing factors in susceptibility differences to MPTP (Smeyne et al. 2005; Yasuda et al. 2008).

4.2 Primates

Apparently, all species of primates seem to be susceptible to the neurotoxin MPTP; however, species and primate families display some differences. For instance, old-world primates (those evolved in Africa, Asia, and small areas in Europe) such as baboons and macaques show a higher degree of susceptibility as compared to new-world primates (those evolved in America), such as capuchins monkeys, squirrel monkeys, or marmosets (Emborg 2007).

In order to achieve a stable parkinsonism in old-world primates such as baboons, macaques, green monkeys, and vervet monkeys, doses of MPTP range from 0.2–0.3 mg/kg to 0.6–1 mg/kg. However, 1.2 mg/kg, 2 mg/kg, or even higher doses should be used for new-world primates (Barcia et al. 2004a; Elsworth et al. 2000; Emborg 2007; Hantraye et al. 1996; Herrero et al. 1993b; Pearce et al. 1995; Perez-Otano et al. 1991; Varastet et al. 1994). These differences have led to believe that the higher degree in the phylogenetic scale, the more susceptibility to MPTP is shown. Hence, humans are highly susceptible to MPTP according to the small doses extrapolated from accidentally intoxicated individuals (Langston et al. 1983). We do not have data from great apes, such as gorillas, orangutans, or chimpanzees to compare with, but specific characteristics, described below, suggest that they may also present high susceptibility.

Different factors may contribute to the different susceptibility among primate species. Specifically, the levels of MAO-B and neuromelanin seem to play a main role. According to its higher susceptibility, primate brain contains high proportions of MAO-B (about 70–80 %) as compared with rodent brain that contains

predominantly MAO-A (Zesiewicz and Hauser 2002). On the other hand, neuromelanin, a pigment present in dopaminergic neurons, is contained in higher levels in the mesencephalic dopaminergic areas most susceptible to MPTP (Herrero et al. 1993b). In addition, elegant experiments have shown that chloroquine, a drug that blocks MPP+ binding to neuromelanin, protects monkeys from MPTP-induced dopaminergic degeneration (D'Amato et al. 1987). It is well known that MPTP susceptibility increases with age. Besides the aging effect on DA neurons itself, neuromelanin accumulation with age may also increase neuronal vulnerability to MPTP (Herrero et al. 1993a). It is noteworthy that within primates, there is a progressive increase of neuromelanin pigmentation as the phylogenetic relationship to man becomes closer (Marsden 1961; Scherer 1939), in line with an increased susceptibility to MPTP of phylogenetically higher primate species.

5 Currently Available In Vivo MPTP Models

Although a number of MPTP paradigms involving variable routes of administration have been developed to date, a main limit for all of these models is the failure of reproducing the complete and multifaceted PD pathology, particularly when working with rodents. For this reason, none of them are eligible as the best preclinical PD model, but each one should be regarded and carefully chosen for the specific purpose of the study, e.g., investigating motor or nonmotor disturbances, neurodegenerative and neuroprotective mechanisms, and neuroplastic changes.

5.1 Rodents

A variety of models are currently available, mostly in mice, since their higher sensitivity to systemic MPTP, including systemic administration (i.e., subcutaneous, intraperitoneal, or intranasal), or local injection (i.e., intraventricular or intranigral). Subcutaneous or intraperitoneal MPTP administration is used in mice only, while intracerebral injection or intranasal administration, allowing MPTP to bypass the BBB, is used in both mice and rats (Prediger et al. 2010; Yazdani et al. 2006). With regard to the protocol of administration, rodent models can be referred to as acute, subacute, or chronic. Acute models include single day-treatment paradigms. MPTP hydrochloride is administered via peripheral route and may involve a single dose of 20–40 mg/kg or a series of four doses (10–30 mg/kg) usually injected in 2 h intervals (Bezard et al. 1997a; Jackson-Lewis et al. 1995; Kohutnicka et al. 1998). A recent acute MPTP model involves the intranasal neurotoxin administration, where mice or rats receive small amounts (10–15 μl) of a MPTP solution directly in each nasal cavity (Prediger et al. 2006, 2010; Rojo et al. 2006). Subacute paradigms generally last about a week, with a daily administration protocol of doses ranging from 20 to 30 mg/kg (Carta et al. 2009; Tatton and Kish 1997; Vila et al. 2000). Chronic MPTP paradigms might be more reliable PD models, since they are able to mimic a higher number of PD features, including

the slow progressive pattern of neurodegeneration seen in human PD. Chronic protocols can last 3–5 weeks, with continuous or intermittent MPTP treatment. Intermittent treatment involves either daily or twice/week neurotoxin peripheral injection at doses 4–20 mg/kg (Bezard et al. 1997a; Lau et al. 1990; Petroske et al. 2001; Schintu et al. 2009). Concomitant administration of the clearance inhibitor probenecid (MPTPp model), by reducing brain and kidney excretion of MPTP, helps in keeping higher and more stable levels of the neurotoxin during treatment, resulting in a slowly progressing but persistent neurodegeneration (Lau et al. 1990; Petroske et al. 2001; Schintu et al. 2009). An alternative route of chronic neurotoxin administration consists in the continuous MPTP delivery via osmotic minipumps providing a daily dose of 30 mg/kg (Fornai et al. 2005).

5.2 Primates

The most common model used in primates to induce a parkinsonian syndrome is the intravenous administration of MPTP through the saphenous vein (Emborg 2007; Guridi et al. 1996). With this type of administration, a bilateral and stable parkinsonism can be achieved. Another commonly used protocol is the intracarotid administration, consisting of MPTP infusion through the carotid artery, leading to a hemi-parkinsonism, where animals only show symptoms of PD in one side of the body (contralateral to the injection side) (Emborg 2007; Kordower et al. 2000). The majority of animals display symptoms after 3–4 doses of MPTP, but some individuals may present a clear parkinsonian syndrome with even one dose (highly susceptible animals), while others may not show signs even after several doses (not susceptible animals) (Fig. 2). For this reason, it is important to evaluate and monitor each animal individually.

Both intrasaphenous and intracarotideal models show advantages as well as disadvantages. Parkinson's symptoms may be better measured in hemi-parkinsonian monkeys since the evaluation can be compared with the contralateral side of the same animal. On the other hand, the bilateral model, although trickier to detect small changes, mimics closer the clinical scenario observed in humans. However, in the bilateral model, one side is generally slightly more affected than the other, making it difficult to assess regular motor scores for parkinsonian monkeys. As a main advantage, the bilateral model with intrasaphenous infusion does not involve any surgery, being therefore a less complex and safer procedure for the animal.

The protocols of MPTP administration can be considered acute, subacute, subchronic, and chronic. Acute treatment is usually referred to a single dose of MPTP, with animals being sacrificed within 24 h, although some variations can be found in the literature. Subacute models may be more variable, being described as a short-term MPTP administration, with animals being sacrificed after few weeks (Garrido-Gil et al. 2009; Vazquez-Claverie et al. 2009a). A subchronic protocol is commonly referred to a MPTP treatment lasting few weeks to a month and sacrificing the animals within 3 months (Barcia et al. 2004a; Goldstein et al. 2003). The chronic protocol, also called remote, is usually referred to

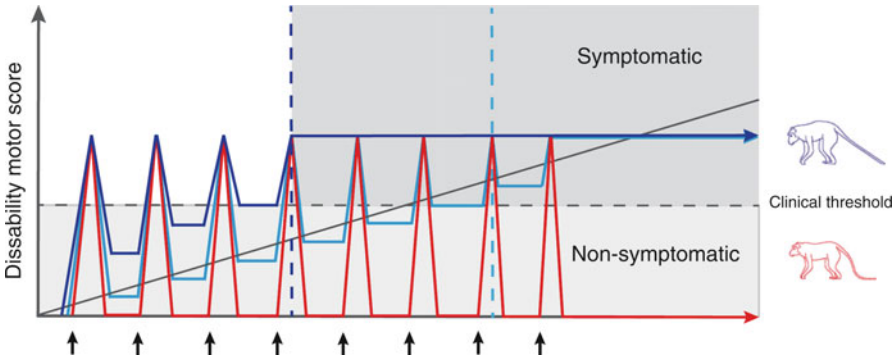

Fig. 2 The panel on the right shows the typical posture of a control longtail macaque (Macaca fascicularis) compared with a parkinsonian macaque. Note that the parkinsonian monkey shows a particular curvature of the limbs and trunk as well as rigidity of the tail. The panel on the left shows a chart with the typical curve of the motor score of a susceptible monkey compared with an asymptomatic one. After the systemic effects, the susceptible monkeys maintain stable parkinsonian symptoms, while asymptomatic animals recover completely after the systemic effects

a MPTP treatment lasting 3 months or more and sacrificing the monkeys within 6–35 months or even years after MPTP administration (Barcia et al. 2004b; Colosimo et al. 1992; Goldstein et al. 2003; Halliday et al. 2009; McGeer et al. 2003).

6 Motor and Nonmotor Symptoms

MPTP administration induces a short-term and transient systemic effect both in monkeys and in rodents, which is independent from its ability to alter locomotor activity but may be a confusing factor for the detection of PD symptoms. Systemic effect may include piloerection, hypersalivation, hypokinesia and seizures, tachycardia, hyperventilation, and hypothermia that may require the use of a heater and recover within 24–48 h. Hours after MPTP administration, primates may also show some episode of vomiting and lack of appetite that may result in loss of body weight. When working with MPTP, it is essential to respect the time of quarantine to reach a full elimination of any residual MPP+ by the urine and feces.

6.1 Rodents

The induction and detection of motor impairments in mice are profoundly affected by the schedule of MPTP delivery and behavioral tests applied, for which reason results have been variable and sometimes ambiguous (Table 1). Acute MPTP paradigms convey a reduction, no changes, or even an increase in locomotor activity (Colotla et al. 1990; Fredriksson and Archer 1994; Luchtman et al. 2009;

Table 1 Effect of acute, subacute, and chronic MPTP protocols (see text for details) on mice motor activity or on nonmotor symptoms typical of PD. Motor activity was measured as spontaneous activity or via more specific tests such as the rotarod or the beam-walking test. ↑ and ↓ indicate, respectively, an increase and a decrease with respect to the motor performance of drug-naive mice; = indicates no differences

	Schintu et al. 2009	↓	

Quinn et al. 2007; Rousselet et al. 2003; Sedelis et al. 2000; Tillerson et al. 2002). In any case, the motor impairment induced by acute MPTP recovers nearly completely after 3–7 days postinjection (Schmidt and Ferger 2001). Subacute MPTP treatments have also given contradictory results. When mice are treated for a period ranging from 5 days to few weeks, no changes (Petroske et al. 2001; Willis and Donnan 1987), decrease (Arai et al. 1990), or increase (Chia et al. 1996; Luchtman et al. 2009) in locomotor activity has been reported.

After a series of improvements and protocol adjustments, chronic MPTP models are now able to provide more consistent results. In a first attempt of reproducing the disease in chronic nature, MPTP was given daily at a very low dose for 20 days (Bezard et al. 1997a). Unfortunately, despite a progressive decline of TH immunoreactivity, the MPTP-treated mice did not display parkinsonian motor abnormalities after this dosing regimen (Bezard et al. 1997b). In the last decade, the chronic MPTPp protocol, firstly proposed by Lau in 1990 and widely characterized by several studies thereafter, brought a significant improvement to PD models (Lau et al. 1990). First, the MPTPp administration schedule (twice/week) allows to perform motor tests between injections, offering the useful advantage of monitoring motor symptoms in the presence of an ongoing neurodegeneration. When tested along the treatment, mice display an increasing impairment in motor performance, suggesting the development of progressive nigrostriatal degeneration (Schintu et al. 2009). Moreover, MPTPp-treated mice display a reduced motor performance when tested 3 weeks to 6 months after treatment, suggesting persistent neurodegeneration (Petroske et al. 2001; Schintu et al. 2009). Confirming dopaminergic degeneration, amphetamine-induced locomotor activity is reduced after 4 weeks from neurotoxin treatment (Al-Jarrah et al. 2007). As an alternative model, the continuous MPTP

delivery through minipumps was reported to dramatically depress spontaneous activity in the open field test (Fornai et al. 2005). However, constant brain levels of MPTP obtained by this route may induce some nonspecific systemic effects, including depressed motor behavior that may confound the assessment of PD symptoms.

A further burst to the use of MPTP models in PD research comes from recent studies, highlighting that specific protocols may be suitable for studying nonmotor aspects of the disease (Table 1). The possibility of mimicking symptoms associated with the early premotor phases of PD has been deeply explored in the intranasal MPTP infusion model (Prediger et al. 2006, 2010). In this model, animals develop selective symptoms such as olfactory dysfunction and cognitive deficits, while not displaying a clear motor impairment, suggesting that this MPTP protocol may provide a useful model of premotor symptoms of PD. Interestingly, in the MPTPp model, olfactory deficits appear after the first neurotoxin administration, preceding motor symptoms, accordingly with the graded progression of PD neuropathology (Hawkes et al. 2009; Haehner et al. 2011; Schintu et al. 2009). Cognitive impairment was reported after an acute intraperitoneal MPTP administration as well (Monaghan et al. 2010). Among other nonmotor symptoms, sleep alterations have been reported after a subacute MPTP treatment (Laloux et al. 2008). Peripheral pathologies associated with PD have been sparely investigated. Interestingly, behavioral and electrophysiological defects in the enteric nervous system, associated with a significant reduction of TH-positive neurons in the same site, were reported after acute MPTP intoxication in mice (Anderson et al. 2007; Tian et al. 2008). Certainly more efforts are sought to evaluate the possible contribution of MPTP models to the understanding of peripheral aspects of PD pathology; nevertheless, these few studies support the interesting possibility that MPTP may provide a useful tool to investigate on the graded neuropathology hypothesis of the disease (Hawkes et al. 2009).

6.2 Primates

The evidence of major motor symptoms of PD after MPTP intoxication of young drug addicts prompted researchers to test the neurotoxin in nonhuman primates. Since then, the MPTP model has been used both as a pathogenic and as a clinical symptomatic model in monkeys for its peculiarity of mimicking almost all of the clinical hallmarks of the disease (Bezard and Przedborski 2011), including the side effects induced by dopamine replacement with levodopa and/or dopaminergic agonists (Blanchet et al. 2004; Herrero et al. 1995; Jenner 2003). After MPTP intoxication, monkeys develop akinesia/bradykinesia, rigidity, and freezing phenomena. They also may show tremor in the arms and hands and occasionally in the head. Differently from humans, who show resting tremor, MPTP-intoxicated monkeys show a tremor that appears with action. Eventually, monkeys may display occasional falls and vertical saccadic eye movements. After MPTP exposure, a stable parkinsonism may be observable through the years (Halliday et al. 2009). Although some animal may improve slightly during the observation, parkinsonism

is usually irreversible. However, as described above, it is important to consider that some individuals are not susceptible to MPTP, and after the recovery of systemic symptoms (24–48 h), no apparent motor alterations may be seen. MPTP-treated monkeys also show a postural alteration that is characterized by the curvature of the limbs and trunk and a peculiar rigidity of the tail (Fig. 2).

MPTP-treated monkeys also show similarities with PD patients with regard to nonmotor symptoms. Similarly to the patients, MPTP-treated monkeys present alterations in the heart sympathetic innervation (Goldstein et al. 2003; Li et al. 2002; Yuste et al. 2012), enteric nervous system (Chaumette et al. 2009), retina (Cuenca et al. 2005), as well as sleep disorders (Almirall et al. 1999) and modifications in the circadian rhythm of secretion of hormones such as prolactin and melatonin (Barcia et al. 2003). Moreover, when the schedule of MPTP intoxication is chronic and slow, fronto-executive cognitive impairments are evident even before and independent of the motor symptoms (Schneider and Pope-Coleman 1995). The first cognitive symptoms include significant impairment in performing short- and medium-duration delay trials, suggesting attentional deficits that disrupt the encoding of behaviorally relevant information to be kept in short-term memory. These symptoms have been also reported in asymptomatic MPTP-treated monkeys. Moreover, after repeated administration of low doses of MPTP for long periods, parkinsonian monkeys develop significant impairment in planning, cognitive flexibility, and attention set shifting (Decamp and Schneider 2004). Altogether, these evidences point to the MPTP primate model as a useful tool for studying the progression of parkinsonian symptoms (Storvik et al. 2010) as well as for the understanding of the broad range of systems that are affected in PD (Olanow et al. 2011).

Importantly, the MPTP primate model faithfully reproduces L-DOPA-induced dyskinesia. Similarly to humans, L-DOPA administration in parkinsonian primates brings about recovery of motor symptoms, while the prolonged L-DOPA treatment causes the appearance of dyskinesia. The MPTP primate model gives the unique opportunity to replicate a dyskinesia nearly identical to parkinsonian patients (Ahmed et al. 2010; Clarke et al. 1987; Herrero et al. 1995).

7 Neuropathological Markers of PD in MPTP Models

While nigrostriatal degeneration can be achieved by different protocols of MPTP administration, the dosing regimen and schedule of administration are the main determinants for modeling histological features of PD, such as α-synuclein-positive inclusion bodies, chronic neuroinflammation, and neuronal death by apoptotic mechanisms.

7.1 Neurodegeneration in Rodents

Classically, MPTP leads to the selective degeneration of nigrostriatal dopamine neurons. Striatal dopamine terminals are extremely sensitive to MPTP toxicity, and

Table 2 Effect of different MPTP protocols on striatal dopamine levels (DA), TH immunoreactivity (TH-IR), histological staining, and the appearance of apoptotic cells in the substantia nigra pars compacta (SNc). ↓ indicates a decrease in the measured parameter, = indicates no changes with respect to drug-naïve mice, - means not analyzed

	Schintu et al. 2009	↓	↓	↓	–

even a single dose leads to a rapid decrease of striatal dopamine and DOPAC levels (Hallman et al. 1985; Jackson-Lewis et al. 1995; Schintu et al. 2009) (Table 2). Moreover, an important aspect that has been revaluated in recent years is the MPTP-induced depletion of catecholamines in areas other than the striatum. MPTP-induced decrease of dopamine and/or noradrenaline in the olfactory bulb and prefrontal cortex, associated with the appearance of typical PD nonmotor symptoms, supports the interesting perspectives of using MPTP to model nonmotor aspects of the disease (Dluzen 1992; Dluzen and Kefalas 1996; Hallman et al. 1985; Luchtman et al. 2009; Prediger et al. 2010; Tanila et al. 1998).

As compared to striatal terminals, degeneration of cell bodies in the SNc is a more challenging task. MPTP toxicity toward dopaminergic cell bodies is age dependent, particularly after acute protocols (Ricaurte et al. 1987). Moreover, contradictory results have been reported on nigral lesion after acute (Hallman et al. 1985; Heikkila et al. 1984; Jackson-Lewis et al. 1995; Ricaurte et al. 1986), subacute (Carta et al. 2009; Petroske et al. 2001; Vila et al. 2000; Willis and Donnan 1987), and chronic (Alvarez-Fischer et al. 2008; Bezard et al. 1997a; Fornai et al. 2005; Petroske et al. 2001; Rousselet et al. 2003; Schintu et al. 2009) MPTP regimens (Table 2). To this regard, the possible lack of correlation between the loss of TH-positive immunoreactivity and loss of Nissl-stained cells is a pivotal

factor to be considered (Bian et al. 2007; Jackson –Lewis et al. 1995; Seniuk et al. 1990). For instance, after acute MPTP treatment, the number of TH-positive neurons decreases rapidly, while the effective loss of Nissl-stained cells only begins at 12 h postinjection and continues up to 4 days (Jackson-Lewis et al. 1995). Therefore, neurodegeneration is best shown through histological direct evidence. Accordingly, a lack of correlation between motor impairment and loss of nigral TH-positive neurons has been often reported. Importantly, the rate and mechanism of cell death is also strictly dependent on the MPTP schedule and dosing (Table 2). After acute and subacute protocols, cell death occurs rapidly. In contrast, chronic MPTP, particularly when associated with a clearance inhibitor, induces a slower and progressive loss of DA neurons (Alvarez-Fischer et al. 2008; Petroske et al. 2001; Schintu et al. 2009). Furthermore, neuronal loss is a transient phenomenon after short-term regimens, while on the other hand, it is long lasting after chronic regimens, being stable up to 6 months after the last MPTP administration (Petroske et al. 2001; Schintu et al. 2009). Finally, acute MPTP protocols result in a rapid non-apoptotic, likely necrotic cell death, while subacute and chronic regimens, where lower MPTP doses are delivered over days or weeks, lead to preferential cell death by apoptotic mechanisms (Jackson-Lewis et al. 1995; Novikova et al. 2006; Tatton and Kish 1997; Vila et al. 2000).

7.2 Neurodegeneration in Primates

The degeneration of the SNc in MPTP-treated monkeys presents a region-dependent vulnerability, similarly to humans. The ventrolateral part is the most susceptible, displaying the highest degree of dopaminergic degeneration (80–90 %). This area is equivalent to the α + β area defined in humans, presenting very similar features, and it is equally vulnerable in humans and in all families of primates. Other mesencephalic areas are less susceptible and appear to be partially protected against degeneration. The ventral tegmental area (VTA), the dorsal and lateral part of the SNc, presents a 50 % of dopaminergic loss upon MPTP intoxication, while the periaqueductal gray matter (PAG) and periretrorubral area A8 shows 10 % or less dopaminergic degeneration (Herrero et al. 1993b). These differences in regional susceptibility may be due to several factors such as the level of neuromelanin, as described above, as well as the levels of calbindin, DAT, and vesicular monoamine transporter-2 (VMAT-2) that also show regional differences within dopaminergic areas. Accordingly, dopamine neurons of most susceptible mesencephalic areas display high levels of DAT and low levels of VMAT-2, showing the highest cytoplasmic accumulation of MPP+ (Dauer and Przedborski 2003).

The loss of DA neurons of the SNc in MPTP-treated monkeys mimics and matches with the scenario observed in human PD. Usually, there is a fine correlation between the level of dopaminergic cell loss caused by MPTP and motor alterations (Barcia et al. 2011; Mounayar et al. 2007). However, this correlation may have a range of variation depending on the adaptation, recovery, and compensatory mechanisms that the animal may develop in response to MPTP.

In contrast with DA neurons, the degeneration of dopaminergic fibers in the striatum seems to differ between humans and nonhuman primates. In PD patients, the putamen is the most affected striatal area. However, MPTP seems to affect to a higher extent the caudate rather than the putamen in primates (Moratalla et al. 1992; Snow et al. 2000). Moreover, other brain regions may be affected by MPTP in primates as, for instance, the locus coeruleus (Forno et al. 1986; Herrero et al. 1993a) or the dorsal raphe nucleus (Perez-Otaño et al. 1991). It has also been reported that the damage and alteration of Purkinje cells of the cerebellum may correlate with nigral degeneration (Heman et al. 2012; Necchi et al. 2004). Although the cerebellar activity is altered in PD patients, histological evidences in this nucleus are elusive.

7.3 Alpha-Synuclein/Lewy Body Deposits in Rodents

Ubiquitin- and α-synuclein-positive Lewy bodies have not been observed with any MPTP treatment in mice, despite the evidence that α-synuclein is involved in MPTP neurotoxicity in this species (Dauer et al. 2002; Shimoji et al. 2005). Nevertheless, an increase of α-synuclein-positive neurons in the SNc of mice treated with a subacute MPTP regimen has been reported (Vila et al. 2000). Moreover, in mice chronically treated with MPTP either i.p. or through minipumps, alpha-synuclein-immunoreactive inclusions have been reported in a few neurons of the SNc by two studies (Fornai et al. 2005; Meredith et al. 2002) but not by other studies (Alvarez-Fischer et al. 2008; Shimoji et al. 2005), leaving this issue controversial.

7.4 Alpha-Synuclein/Lewy Body Deposits in Primates

α-Synuclein aggregation after the administration of MPTP occurs in both old-world (Kowall et al. 2000) and new-world primates (Purisai et al. 2005). This phenomenon has been related with the dopaminergic cell death, although the mechanism linking α-synuclein aggregation with neuronal damage is unclear (Sulzer 2010). Despite α-synuclein accumulation, studies performed in acute MPTP-treated primates have revealed that this does not result in the formation of Lewy bodies (Kowall et al. 2000; Purisai et al. 2005). Since these experiments have been performed in acute protocols of MPTP administration, it has been postulated that a longer period of years may be required for Lewy body formation. However, studies performed in monkeys bearing parkinsonism from over a decade failed to reveal any Lewy body formation (Halliday et al. 2009), which suggests that this phenomenon may be an exclusive feature of the human disease.

7.5 Neuroinflammation in Rodents

A number of studies have reported a neuroinflammatory response in mice treated either acutely (Kurkowska-Jastrzebska et al. 1999), subacutely (Carta et al. 2009),

or chronically (Schintu et al. 2009) with MPTP. However, the mouse MPTP model presents some limitations in reproducing the inflammatory scenario that characterize PD. In vivo and ex vivo observations in parkinsonian patients, as well as in MPTP-treated primates, have shown a chronic and persistent inflammatory response, where activated microglia is engaged in the auto-fueling and detrimental cycle named reactive gliosis (Hirsch and Hunot 2009). In contrast, the neuroinflammatory response in mice is transient and tightly related to the neurotoxin administration (Schintu et al. 2009).

Nevertheless, MPTP studies in mice have contributed to highlight the involvement of neuroinflammation in dopaminergic degeneration. Upon MPTP administration, neuroinflammation has been mainly described as microglia activation associated with the overproduction of inflammatory cytokines. Acute and subacute MPTP intoxication causes a rapid and transient microglial activation in the striatum and in the SNc that returns to basal levels within 14 days post-intoxication (Carta et al. 2009; Kurkowska-Jastrzebska et al. 1999). Moreover, a transient increase in either protein or mRNA for inflammatory cytokines in both areas was reported shortly after MPTP injection (Ciesielska et al. 2003; Kurkowska-Jastrzebska et al. 1999; Lofrumento et al. 2011; Pattarini et al. 2007). The chronic administration of MPTP in association with probenecid induces a gradual increase of microglial activation and density (Meredith et al. 2005; Novikova et al. 2006; Schintu et al. 2009). Interestingly, activated microglia persist longer after chronic MPTP intoxication as compared to shorter protocols, being still detectable up to 6 months posttreatment (Meredith et al. 2005; Schintu et al. 2009). In addition, microglia undergoe changes in morphology and phenotype upon this protocol of MPTP administration, gradually switching to more activated states, associated with altered cytokines production (Pisanu et al. in preparation).

7.6 Neuroinflammation in Primates

Different from mice, the inflammatory response caused by MPTP in primates is persistent and may be perpetuated over the years (Barcia et al. 2004b; McGeer et al. 2003). This inflammatory response is characterized by an increase of proinflammatory cytokines in the blood and brain, similar to PD patients, and can be clearly detected at the cellular level (Barcia et al. 2005, 2011; Hunot and Hirsch 2003). From a histological point of view, the inflammatory response is characterized by microglia and astroglia activation specifically in the SNc, appearing particularly higher in the $\alpha + \beta$ area where DA cell loss is higher (Barcia et al. 2004b). After MPTP intoxication, microglial cells display a bigger cell body and a higher number of processes and ramifications and overexpress human leukocyte antigen-DR (HLA-DR) in their membrane (Barcia et al. 2009; McGeer et al. 2003). These features are very similar or even identical to the scenario observed in humans intoxicated with MPTP and in PD patients (Langston et al. 1999; McGeer et al. 1988). Importantly, the level of activation appears very similar in acute and chronic protocols of MPTP administration (Vazquez-Claverie et al. 2009b). On the other

hand, astrocytes also appear over-reactive in MPTP-treated primates similarly to humans, showing a bigger cell body and increased number of ramifications (Barcia et al. 2009; Forno et al. 1992). Particularly, the glial fibrillary acidic protein (GFAP) is overexpressed in reactive astrocytes over the dopaminergic pathway, and again, it is particularly increased in the α + β area of the SNc, where DA loss is highest. Importantly, the levels of cytokines in the blood and brain seem to contribute to the inflammatory response (Barcia et al. 2011; De Lella Ezcurra et al. 2010; Pott Godoy et al. 2008). Particularly, IFN-γ and TNF-α are thought to be involved in the mechanisms of microglial and astroglial activation and may be key cytokines in the neuroinflammatory response occurring in dopaminergic degeneration (Barcia et al. 2011; De Lella Ezcurra et al. 2010; Mount et al. 2007).

8 Conclusion

MPTP administration to primates reproduces almost all of the clinical hallmarks of PD, being used as a pathogenic as well as clinical symptomatic model of the disease. Importantly, MPTP-induced parkinsonism in monkeys is usually irreversible, and the neurodegeneration progresses even after withdrawal of neurotoxin. On the other hand, to reproduce PD by MPTP administration in rodents represents a more intricate task. Up to date, no MPTP rodent model has been able to reproduce all PD features in one. Nevertheless, a number of protocols have been developed that can reproduce different aspects of PD pathology, depending upon the dose and regimen of MPTP administration. Therefore, while rodent models allow to investigate on motor and nonmotor symptoms and on PD neuropathology, a careful evaluation of the most appropriate protocol for the study purpose has to be made in advance. Keeping this concept in mind, MPTP models of PD have provided and continue to give a great contribution to the understanding of disease neuropathology and to the development of new symptomatic and disease-modifying compounds.

Abstract

The need for the development of nanomedicines for the treatment of degenerative and inflammatory diseases of the nervous system is of immediate importance. Nanoparticles are drug carriers that can specifically target diseased brain subregions and thus enhance therapeutic efficacy. Multifunctional nanoparticles delivering pharmaceutical agents serve a dual purpose: While they facilitate drug delivery they also provide imaging of cell dynamics and pharmacokinetic assessments. Polymer science and nanotechnology could be used to improve diagnostic and therapeutic outcomes. Despite their promise in combating disease, nanomedicines have yet to make their mark as broadly viable pharmaceuticals. The translation of nanoformulation technology for clinical therapeutic and diagnostic applications shows both real potential and inherent obstacles. However, safety concerns remain operative for their potential broad clinical implications, tempering any translational potential.

Keywords

Cell-based drug delivery • Nanomedicines • Nanoparticles • Neuroimmunology • Neuroinflammatory disease

1 Introduction

A range of insults can affect the nervous system that include infection, trauma, vascular insufficiency, misfolded aggregated protein-induced degeneration, toxins and metabolic dysregulations (de Vries et al. 1997, 2012; Frank-Cannon et al. 2009; Graves and Vernino 2012; Kanwar et al. 2012a; Rosenberg 1997). All lead to activation of the immune system that serves as a key factor in both the etiology and progressive nature of a number of neurological diseases (de Vries et al. 1997, 2012; Frank-Cannon et al. 2009; Rosenberg 1997). Such immune responses can serve as disease propagators and healers. The former leads to sustained phenotype switches for glia (microglia and astrocytes) with the secretion of a broad range of inflammatory mediators that include excitotoxins, pro- and anti-inflammatory cytokines, and chemokines (Ransohoff and Engelhardt 2012). These result in alterations in phagocytosis, intracellular killing, clearance, and antigen presentation. Ultimately compromise of the blood-brain barrier (BBB) ensues with extravasation of toxic proteins, altered glial secretions, and neurotoxicity (de Vries et al. 1997; Kanwar et al. 2012a; O'Callaghan et al. 2008; Rosenberg 1997). While complex in nature, each component step for disease provides opportunities for therapeutic intervention (Kanwar et al. 2012b). In all, the targeting of such interventional strategies with facilitation of drug penetrance across the BBB could lead to improved therapeutic outcomes in central nervous system (CNS) disease (Kanwar et al. 2012a).

1.1 Current Treatment Strategies

Treatment of Alzheimer's and Parkinson's diseases (AD and PD, respectively), amyotrophic lateral sclerosis (ALS), a range of microbial infections and multiple sclerosis (MS) is limited to ameliorating symptoms and as such poses continuous challenges to clinicians and clinical investigators (de Vries et al. 1997, 2012; Kanwar et al. 2012a). Simply stated, conventional treatments are palliative. Curative therapies are available, for the most part, only for infectious diseases (Elman et al. 2007; Nowacek et al. 2009a). Even with the potential of disease cure, microbial resistance remains an ever significant concern. Furthermore, accurate diagnosis often precludes early therapeutic intervention. Complicating treatment for neurodegenerative, neuroinfectious, and neuroinflammatory diseases is poor penetration of many drugs across the BBB. To this end, considerable efforts are being placed on developing novel strategies for improving drug penetrance and delivery to sites within the brain parenchyma that are disease targets as well as developing improved methods for early disease diagnosis (Alam et al. 2010).

1.2 Urgent Need for Nanomedicines

Considerable emphasis is being placed on the future development of therapeutic drug formulations that target the CNS and halt ongoing toxic, metabolic, and inflammatory events that affect the tempo and progression of neurodegenerative diseases (Graves and Vernino 2012; Ulbrich and Lamprecht 2010). Nanotechnology offers one important means toward such a goal. The ability of nanoparticles to traverse the BBB can be exploited to enhance drug entry into the CNS (Fernandes et al. 2010; Kanwar et al. 2012b). Nanoparticles targeted to the CNS can be efficient delivery strategies to improve the efficacy of commonly used medicines along with developing new therapeutics intended to reach the site of disease action (Kanwar et al. 2012b; Metcalfe and Fahmy 2012; Silva 2005; Ulbrich and Lamprecht 2010). In addition, nanoparticle-based imaging systems can provide earlier and more effective diagnosis of subtle brain dysfunctions (Kanwar et al. 2012b; Stoll and Bendszus 2010).

2 Nanoparticle Compositions

Disorders of the CNS that include AD, PD, ALS, and stroke are rapidly increasing in disease prevalence and incidence (Brown et al. 2005; Checkoway et al. 2011; Mayeux 2003). Therapies that can change the course of disease would have substantial impact as AD alone costs more than $100 billion/year in the United States for medical and institutional care. Such numbers will certainly double in the next decades (ADI 2012). Currently, disease diagnosis is made, for the most part, by clinical observation as it has for more than 100 years (de Carvalho et al. 2008;

Jack et al. 2011; Li et al. 1991; Rao et al. 2006; Yew and Cheng 2009). Drugs, vaccines, or regenerative proteins present "real" possibilities to positively alter disease outcomes.

Delivery of drugs to treat CNS diseases poses particular challenges. Barriers to CNS drug delivery include CNS structure, function, and physiology. To enter into the brain parenchyma, drugs must cross the endothelial cell lining of the microvasculature (Nowacek et al. 2009a). Under physiologic conditions, this barrier selectively regulates intracellular and paracellular exchange of nutrients, macromolecules, and cells between the blood and the CNS. Permeability of many drugs through the BBB is very low even though the capillary surface area is large. Thus, the BBB plays an indispensable role in regulating drug CNS concentrations (Alam et al. 2010).

Development of ways to overcome the barriers to CNS drug delivery is of clinical relevance. Delivery of drugs by nanocarrier systems is a strategy that could overcome barriers to CNS drug delivery, including poor BBB penetration, extensive binding to plasma proteins, and the presence of drug efflux pumps that diminish drug levels crossing the BBB into the CNS parenchyma (Bhaskar et al. 2010; Kanwar et al. 2012b; Nowacek et al. 2009a). Various nanotechnology-based systems are being developed to overcome barriers to drug delivery for improving CNS treatments. These systems are discussed in relation to their potential use in neuroinflammatory and neurodegenerative disorders.

2.1 Liposomes

Liposomes are spherical vesicles composed of a lipid bilayer membrane surrounding an aqueous inner core (Fernandes et al. 2010; McMillan et al. 2011). Their high biocompatibility, low immunogenicity, and extended circulation time contribute to their use as drug-delivery systems. Hydrophilic drugs can be loaded into the aqueous core, while hydrophobic molecules can be carried in the lipid membrane for delivery to the target site. However, low loading capacity, relatively quick release profiles of hydrophobic drugs, and lesser physical stability than polymeric formulations limit their applications for specific drugs (Liu et al. 2010). Inclusion of cholesterol into the liposomal membranes can improve stability of the bilayer, coating with polyethylene glycol (PEG) chains can enhance the circulation time of liposomal formulations in vivo by reducing uptake by the reticuloendothelial system, and adding targeting moieties on the liposome surface can improve delivery to the target site (Fernandes et al. 2010; McMillan et al. 2011; Micheli et al. 2012). The mechanism by which liposomes transverse the BBB is still not understood but is proposed to be achieved by passive diffusion through the brain capillary endothelial cells, by endothelial cell endocytosis, or by fusion with the endothelial cell membrane (Fernandes et al. 2010). Improved CNS drug delivery and reduced toxicity have been observed in animal models using liposomal systems for antifungals, antiretrovirals, antiepileptics, anti-ischemia drugs, and chemotherapeutics (Wong et al. 2012). Cationic liposomes are being explored to improve delivery of nucleic acids to target cells for gene therapy (Fernandes et al. 2010).

2.2 Solid Lipid Nanoparticles and Nanocapsules

Other lipid-based systems that show potential for enhanced drug delivery across the BBB include solid lipid nanoparticles and lipid nanocapsules (Fernandes et al. 2010; Wong et al. 2012). These systems usually use triglycerides and phospholipids to encase the drug and are stabilized using surfactants. Solid lipid nanoparticles containing nitrendipine or 5-fluoro-2-deoxyuridine improved penetration of the drugs into the brain up to twofold (Fernandes et al. 2010; Manjunath and Venkateswarlu 2006; Wang et al. 2002). Indomethacin-loaded nanocapsules reduced tumor size and decreased morbidity and mortality in rats implanted with C6 glioma (Bernardi et al. 2009).

2.3 Polymeric Micelles

Polymeric micelles can be used to deliver poorly soluble drugs with high bioavailability (Gaucher et al. 2010; Kanwar et al. 2012a; Kedar et al. 2010). Polymeric micelles have an anisotropic water distribution with a hydrophilic corona and hydrophobic core. Amphiphilic block polymers containing poly (ethylene) oxide-polypropylene oxide are most commonly used in assembly of polymeric micelles for targeted drug delivery. Kabanov et al. demonstrated CNS delivery of micelles formed by polymeric block polymers surrounding a non-covalently bound drug core (Manickam et al. 2012; Sharma et al. 2008). One of the major important advantages of this system is the ability of the micellar formulations to be used in applications involving drug delivery across the BBB, since the micellar formulations are able to transport the active agents into body compartments where the free drug alone cannot penetrate (Manickam et al. 2012; Sharma et al. 2008). They also have a low critical micelle concentration and slow rate of dissociation that allows the loaded drugs to remain in the system for a longer period of time and provides greater drug delivery to the target site (Batrakova et al. 2011; Fernandes et al. 2010; McMillan et al. 2011).

2.4 Polymeric Nanoparticles

Polymeric nanoparticles are prepared using a variety of polymers. Intended drugs can be dissolved or encapsulated to obtain nanospheres or nanocapsules by attaching the drug to the surface of the nanoparticle (Gupta and Jain 2010; Mallipeddi and Rohan 2010). Nanocapsules are fabricated by confining the drug to a cavity surrounded by a polymer membrane, and nanospheres are matrix systems formed by a uniform dispersion of the drug (Gupta and Jain 2010). The development of biodegradable polymers and their use for various drug-delivery applications have been described recently. The most widely used nontoxic polymeric materials include polyvinyl alcohol (PVA), polyacrylic acid (PAA), polyacrylamide, PEG, and polycaprolactone (Gupta and Jain 2010). These polymers

could break down easily into biologically acceptable molecules. Polymeric nanoparticles may cross the BBB by passing through tight junctions; enhanced binding, endocytosis, and transcytosis by endothelial cells; or inhibition of endothelial cell efflux transporters (Fernandes et al. 2010; Kanwar et al. 2012a; Khalil et al. 2011; Wong et al. 2012).

2.5 Dendrimers

Dendrimers are macromolecules with a defined branched architecture. They are assembled in layers, or generations, and are composed of a series of repeated branched chains around a central core with many identical functional groups on the exterior (Boas and Heegaard 2004). Drugs or other molecules can be carried within the void spaces in the interior of the structures, while attachment of functional groups on the exterior can provide targeting to specific cells and tissues (Fernandes et al. 2010; McMillan et al. 2011). The ability to pass through the BBB is greatly influenced by the molecular architecture (Fernandes et al. 2010).

2.6 Fullerenes, Carbon Nanotubes, and Carbon Nanofibers

Biomedical application of fullerenes and carbon nanotubes has been limited due to their poor water solubility. Functionalization has increased their water solubility and utility for use in nanomedicine. Use of functional moieties such as dendrimers, amino acids, peptides, proteins and growth factors, liposomes, polyamines, polymers, carboxyl groups, and gadolinium has expanded their application for drug delivery, reactive oxygen species quenching, promotion of neurite outgrowth, and imaging. Carbon nanofibers have potential for design of neural prosthetics (Kanwar et al. 2012b; McMillan et al. 2011).

3 Nanoparticles for Imaging and Diagnostics

Nanoparticles are used for neuroimaging and are increasingly being used as tools to help identify biomarkers of disease and monitor the success of stem cell treatment (Kanwar et al. 2012b; McMillan et al. 2011; Stoll and Bendszus 2010). Liposomes, dendrimers, magnetic nanoparticles, and quantum dots are being developed for single photon emission computed tomography, positron emission tomography, magnetic resonance imaging (MRI), fluorescence microscopy, computed tomography, and ultrasound. Of importance, these nanoparticles can be targeted to specific cell types and proteins to enhance sensitivity and improve detection of early markers of disease including BBB integrity and secretion of pro-inflammatory markers (Kanwar et al. 2012b). Incorporating multiple contrast agents into a single particle can provide for multiple imaging modalities, while incorporating drug and contrast agents into one particle can enable in vivo tracking of the drug distribution (Bhaskar et al. 2010; McMillan et al. 2011). Iron particles are commonly used as contrast agents in the

form of superparamagnetic iron oxide (SPIO) or ultrasmall superparamagnetic iron oxide (USPIO) (Bhaskar et al. 2010) and provide a means to track the cells and determine CNS infiltration by MRI (Stoll and Bendszus 2010). SPIO have been used successfully in experimental models of MS, stroke, and other CNS disorders to track the migration of circulating monocytes/macrophages over the course of inflammation (Bhaskar et al. 2010; Stoll and Bendszus 2010).

4 Neuroimmunology and Nanomedicine

4.1 Innate and Adaptive Immune Responses

Neuroinflammation is centered on microglial activation (de Vries et al. 1997, 2012). In the presence of an activating stimulus, microglial surface receptor expression and production and secretion of immunomodulatory factors is altered (reviewed by de Vries et al. (2012) and Frank-Cannon et al. (2009)). Glial production of specific pro-inflammatory mediators such as tumor necrosis factor (TNF) and interleukins-1 (IL-1), -2, -4, -5, -8, -10, and -12 alter brain capillary endothelial cell function and promote leukocyte infiltration into the CNS (Benoit et al. 2008; de Vries et al. 1997; Persidsky et al. 2006; Ransohoff and Engelhardt 2012). Secretion of interleukins, such as IL-6 and -8, can promote both leukocyte infiltration and neuroinflammation (Benoit et al. 2008; de Vries et al. 1997; Persidsky et al. 2006). Glial production of interferon gamma (IFN-γ) and macrophage colony–stimulating factor (MCSF) stimulates release of eicosanoids, reactive oxygen and reactive nitrogen species, and chemokines, such as RANTES and macrophage inhibitory proteins-1 alpha and -1 beta (MIP-1α and MIP-1β) (de Vries et al. 1997; Persidsky et al. 2006). Infiltration of neutrophils, monocytes, and antigen-specific B and T cells into the CNS is accelerated by the expression of intercellular adhesion molecule-1 (ICAM-1), ICAM-2, and vascular cell adhesion molecule-1 (VCAM-1) on brain capillary endothelial cells (de Vries et al. 1997; Persidsky et al. 2006) and their interactions with lymphocyte functional antigen-1 (LFA-1) and very late antigen-4 (VLA-4) (de Vries et al. 1997; Kanwar et al. 2012a; Lyck and Engelhardt 2012). IL-1 beta (IL-1β) is one example of the range of inflammatory factors that affects endothelial cell expression of adhesion molecules, enhances chemoattractant secretions by astrocytes, and promotes inflammatory cell migration (Brabers and Nottet 2006). Chronic activation of this system designed to fight CNS inflammation in disease or injury is believed to underlie the pathobiology of neurodegenerative diseases (de Vries et al. 1997, 2012).

4.2 Cell-Based Drug Delivery

The application of cells as targeted carriers for nanomedicines is a developing concept. Because of their ability to migrate to sites of disease and inflammation, immunocytes, mononuclear phagocytes (MP; monocytes, macrophages, dendritic

cells), lymphocytes, neutrophils, and stem cells are attractive as drug carriers (Batrakova et al. 2011; McMillan et al. 2011). They can also act as Trojan horses for delivery of drug cargo across biologic barriers such as the BBB. For cells to be effective drug carriers, however, a number of criteria must be fulfilled. First, the cells must migrate to the site of injury or disease in sufficient numbers. For CNS disorders, this means that the cells must be able to cross the BBB. Second, the cells must release their drug cargo intact at the disease site. Thus, the drug must be carried in non-degrading compartments within the cell and be released from the cell continuously at the site of action. Finally, carriage of the drug cargo should not adversely affect the cell's normal function. The potential for cell-based drug delivery has been demonstrated by our own studies. Macrophages loaded with indinavir nanoparticles and injected intravenously into severe combined immunodeficient (SCID) mice migrated to a site of HIV-encephalitis (HIVE) in the brain, reduced the level of infection, and provided enhanced drug levels at the site of infection (Dou et al. 2009). As a second example, in an experimental model of Parkinson's disease, macrophages loaded with catalase nanozymes were injected into 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine (MPTP)-treated mice and provided enhanced catalase levels in the brains of these mice (Batrakova et al. 2007; Brynskikh et al. 2010). Drug loading of neural stem cells and their use as drug-delivery vehicles to areas of CNS disease is also being explored (Martinez-Serrano and Bjorklund 1998; Martinez-Serrano et al. 1996; McMillan et al. 2011; Muller et al. 2006). The success of a nanocarrier for use in a cell-based delivery system is determined by a number of factors. Drug nanocarriers are commonly composed of a polymeric outer shell with an inner core for drug carriage. The charge state of the outer polymeric shell can directly influence the uptake of the nanoparticles by immunocytes and stem cells through cell surface receptor interactions and stability of the nanoparticles inside the cells (Batrakova et al. 2011; McMillan et al. 2011). As an example, nanozymes containing superoxide dismutase were protected inside macrophages when the nanoparticles were made using positively charged block copolymers but not negatively charged block copolymers (Batrakova et al. 2011; Zhao et al. 2011). The composition of the outer polymeric coating can also influence the toxicity of the nanoparticles to the cells (Batrakova et al. 2011; McMillan et al. 2011). We have demonstrated that nanoformulations of the antiretroviral drug ritonavir, which enter cells through clathrin-mediated endocytosis, are trafficked to and stored in recycling endosomes and can be released intact (Fig. 1) (Kadiu et al. 2011). Of particular interest these compartments are the same compartments where the human immunodeficiency virus-1 (HIV-1) replicates (Kadiu and Gendelman 2011).

While these experiments demonstrate the potential for cell-based drug delivery, they require pre-loading of cells with nanoparticles and injection into donors. A more practical, clinically useful system would provide for administration of drug nanoparticles to the diseased patient; uptake of the nanoparticles by host MPs, immunocytes, or lymphocytes; and storage within these cells to provide (a) sustained drug release and (b) delivery of the drug nanoparticles to sites of CNS disease. We have recently demonstrated this possibility using polymeric crystalline

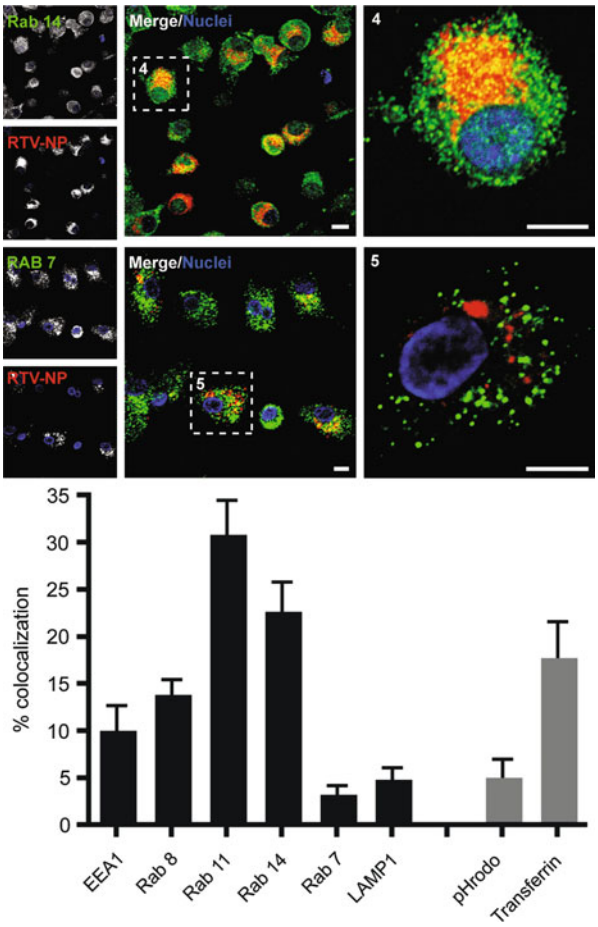

Fig. 1 Immunohistological identification of nanoparticle subcellular localization. Confocal microscopy confirmed distribution of RTV-NP within recycling endosomal (Rab 14) rather than late endosomal (Rab 7) compartments. Note that RTV-NPs are *red* and compartments are *green*, and *yellow* signifies compartment marker-particle overlap in all panels. Pearson's co-localization coefficients indicate RTV-NPs are preferentially distributed to Rab11 and Rab14 recycling endosomes compared with early endosomes, Rab8 or Rab7 endosomes, and lysosomes. Analysis of distribution of RTV-NP within acidified (degrading) compartments, identified by pHrodo-dextran beads, revealed minimal overlap, indicating RTV-NPs likely bypass degradation within the cell and are primarily recycled for release. High RTV-NP co-localization with transferrin also indicates that particles are most likely recycled. Measure bars equal 1 μm. Graphical data represent the mean ± standard error of the mean for n = 3. *NP* Nanoparticle, *RTV* Ritonavir (Figure reprinted with permission from Kadiu et al. (2011))

nanoparticles of the antiretroviral drugs atazanavir (ATV) and ritonavir (RTV) (Fig. 2). Polymer-coated crystalline nanoparticles of antiretroviral drugs (nanoART) are taken up by macrophages in culture, retained inside the cells for up to 15 days, and demonstrate antiretroviral efficacy over this time period

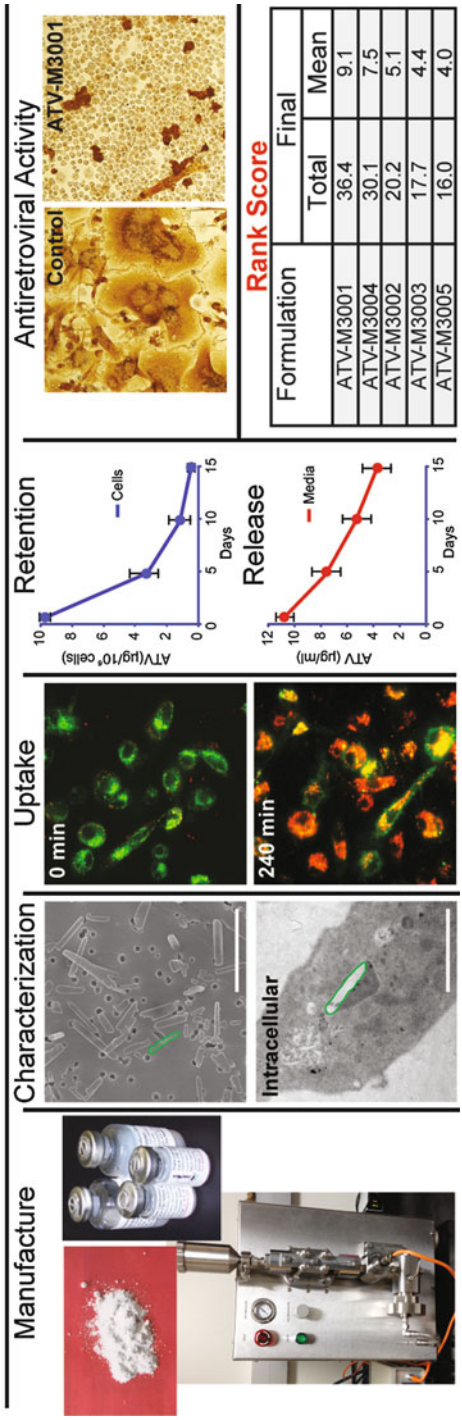

Fig. 2 Schematic for manufacture, characterization, cell-based screening, and scoring of nanoformulated antiretrovirals (nanoART). Crystalline antiretroviral drug is coated with polymer surfactant by high-pressure homogenization and characterized by size, polydispersity, zeta potential, and shape. NanoART is screened in cell-based assays for macrophage uptake, retention, release, and antiretroviral efficacy. The formulations are rank-scored for selection of those suitable for animal testing, as described by Nowacek et al. (2011)

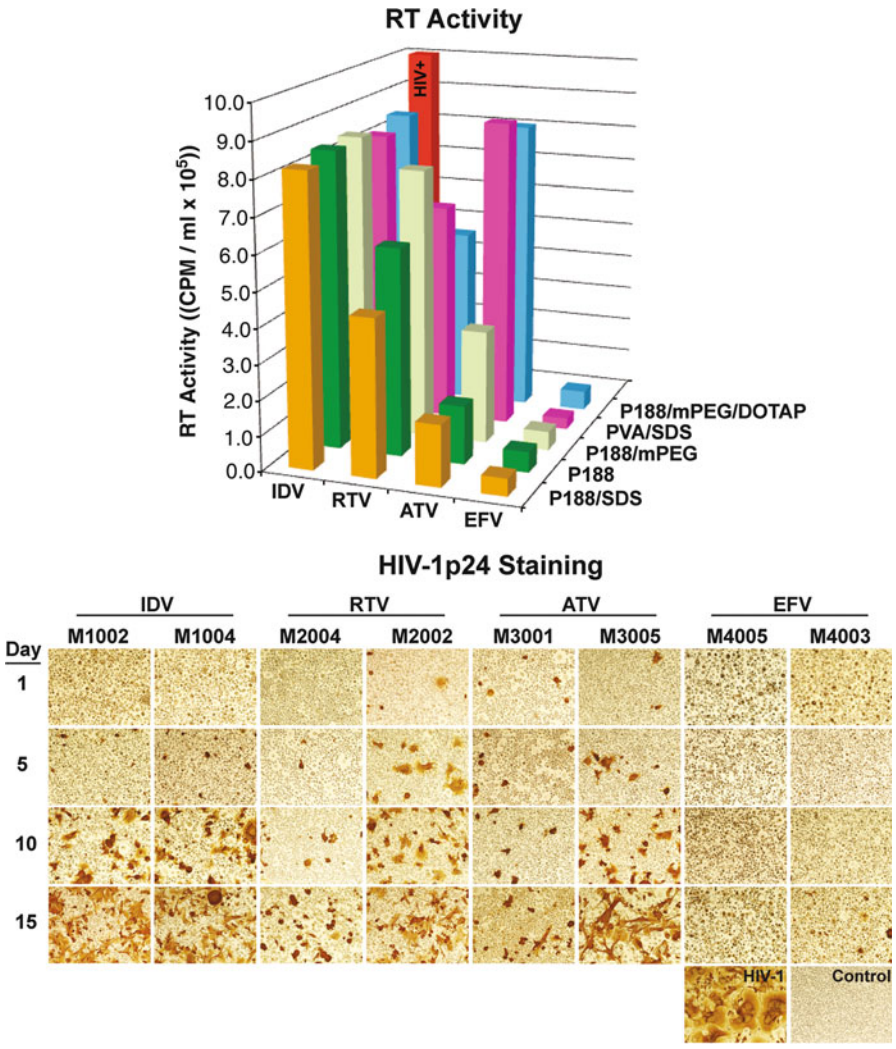

Fig. 3 **Antiretroviral efficacy of nanoART**. Comparison of antiretroviral effects in monocyte-derived macrophages challenged with HIV-1_{ADA} 15 days after pretreatment with nanoART, as measured by reverse transcriptase (RT) activity and HIV-1p24 antigen staining 10 days after viral challenge. RT activities were measured by ^{3}H-TTP incorporation. Data represent mean for n = 8 determinations/treatment (Figure reprinted with permission from Nowacek et al. (2011))

(Fig. 3) (Balkundi et al. 2011; Nowacek et al. 2009b, 2010, 2011). When administered subcutaneously to mice, nanoART (250 mg/kg, ATV/RTV) provided sustained plasma ATV concentrations (>100 ng/ml) and liver and spleen levels exceeding 1,000 ng/g (Roy et al. 2012) for up to 2 weeks. Predominant sequestration of nanoART inside liver Kupffer cells was demonstrated in mice

treated with dye-labeled nanoART followed by isolation and selection of Kupffer cells by in situ collagenase digestion and CD11b + cell sorting (Gautam et al. 2013). Of significance, weekly administration of nanoART reduced HIV-1 viral load to nearly undetectable levels in a humanized mouse model of chronic HIV infection (Dash et al. 2012). Targeting the folate receptor on macrophages using a folate-modified polymer coating improved by up to twofold in vitro macrophage uptake and antiretroviral efficacy of nanoART and enhanced mouse plasma and tissue drug levels up to fivefold compared to non-targeted nanoART (Puligujja et al. 2013).

5 Degenerative, Inflammatory, and Infectious Diseases of the Nervous System

5.1 AD, PD, and ALS

5.1.1 Pathobiology of Diseases

AD, PD, and ALS are progressive neurodegenerative disorders that usually develop later in life. The etiologies of these diseases are different but have in common deposition of mutated proteins and chronic neuroinflammation (Kanwar et al. 2012b; Nowacek et al. 2009a; Re et al. 2012b). AD is characterized by losses in memory and cognitive function and pathologically by neurofibrillary tangles formed by hyperphosphorylated tau protein and extracellular β-amyloid protein (Aβ) plaques, considered the cause of neuronal loss. PD is marked by degeneration of dopaminergic neurons in the substantia nigra and characterized pathologically by cytoplasmic inclusions called Lewy bodies composed of mutated α-synuclein. ALS is marked by the selective loss of motor neurons in the brain and spinal cord leading to paralysis. The majority of ALS cases are sporadic; however, the familial form has been linked to missense mutations in superoxide dismutase 1 (SOD1), which forms intracellular deposits that inhibit chaperone and proteasome activity.

5.1.2 Nanoparticle-Based Therapies and Diagnostics

Approved therapies for these diseases are mainly symptomatic. AD treatments include acetylcholinesterase inhibitors to prevent breakdown of acetylcholine and the use of antioxidants and anti-inflammatory drugs (Kanwar et al. 2012a). Treatments for PD include dopamine mimetics and monoamine oxidase inhibitors to reduce dopamine degradation (Kanwar et al. 2012a). The only currently approved treatment for ALS is riluzole, a sodium channel blocker that inhibits stimulation of glutamate receptors and is used to slow the progression of the disease. None of these treatments are curative, and there is a grave need for novel therapeutic and early diagnostic approaches.

Development of nanotherapeutic-based treatments for each of these diseases is ongoing (Kanwar et al. 2012b; Nowacek et al. 2009a). However, while some are promising, none have reached clinical trials. Again, many, but not all, of the nanoparticle-based systems are designed to enhance the effectiveness and reduce the toxicity of traditional treatments. Use of nanoparticles for treating AD has

focused on three strategies: prevention of Aβ aggregation in the CNS and blood; reducing transition-metal-induced production of reactive oxygen species; and improved delivery of acetylcholinesterase inhibitors to the CNS (Nowacek et al. 2009a; Re et al. 2012a). Polyamidoamine (PAMAM) dendrimers, and nanoliposomes decorated with phosphatidic acid, cardiolipin, anti-Aβ antibody or a curcumin derivative can inhibit in vitro aggregation of Aβ, and C_{60} fullerenes were reported to prevent cognitive impairments induced by Aβ aggregation in rats (Nowacek et al. 2009a; Re et al. 2012a). Aberrant homeostasis of transition metals in the CNS has been associated with oxidative insult to neurons and promotion of Aβ aggregation. The use of metal chelators has been proposed, but is complicated by their systemic toxicity and inability to cross the BBB. To improve the therapeutic efficacy and CNS delivery of chelators and reduce their unwanted systemic toxicity, nanoparticle systems are being developed (Cui et al. 2005; Liu et al. 2009a,b). Nanoparticle systems to improve delivery of anticholinesterase inhibitors to the brain, such as polysorbate 80-coated poly(*n*-butylcyanoacrylate) nanoparticles to deliver tacrine and poly(DL-lactide-co-glycolic acid) (PLGA) microspheres to deliver huperzine-A, are also under development (Chu et al. 2007; Nowacek et al. 2009a; Re et al. 2012a; Wang et al. 2007; Wilson et al. 2008).

Nanoparticles for treatment of PD are being developed to treat loss of dopamine and dopaminergic neurons and reduce microglia-activated reactive oxygen species production (Nowacek et al. 2009a; Re et al. 2012a). To deliver dopamine to the CNS, chitosan nanoparticles containing dopamine adsorbed to the surface were developed and provided reduced toxicity and increased dopamine levels in the striatum (Trapani et al. 2011). Solid lipid nanoparticles containing bromocriptine, a dopamine agonist, improved performance in behavioral tests when administered to rats (Esposito et al. 2008). Lactoferrin-modified nanoparticles containing human neurotrophic factor were used for gene therapy in a rat model of PD and provided improved locomotor activity, reduced neuronal loss, and increased brain dopamine levels.

Fewer nanoparticle treatments are under development for ALS than for AD and PD; however, the approaches being used are similar (Nowacek et al. 2009a; Re et al. 2012b). Solid lipid nanoparticles containing riluzole exhibit high drug loading, a greater ability to deliver drug to the brain, and a higher efficacy compared to free drug (Bondi et al. 2010). In addition, PLGA nanoparticles containing SOD1 and carboxyfullerene SOD mimetics show protection from hydrogen-peroxide-induced damage in neuronal cultures, (Ali et al. 2008; Reddy et al. 2008) which opens the way for these systems to be tested in animal models of ALS.

A cell-based Trojan horse approach for treatment of neurodegenerative disease has been developed by Batrakova and coworkers (2007, 2011; Brynskikh et al. 2010). Catalase was packaged into nanoparticles composed of a block copolymer complex with polyethyleneimine-PEG (termed nanozymes) and loaded into mouse bone marrow macrophages in vitro. The macrophages loaded with nanozymes were adoptively transferred into isologous mice treated with MPTP as a model of acute PD. Nanozyme-loaded macrophages were able to cross the BBB and deliver active

catalase to sites of damage to a greater extent that free catalase (Batrakova et al. 2007), providing proof that this concept is feasible and could be applied to other neurodegenerative disorders.

Nanotechnology also offers tools for early disease diagnosis. Ultrasensitive assay systems for detecting low concentrations of AD pathogenic proteins using gold nanoparticles have been developed by Georganopoulou et al. (2005) and Neely et al. (2009). Amyloid plaques in brains of AD transgenic mice were detected using Aβ-coupled iron oxide particles and MRI (Yang et al. 2011). For early diagnosis of PD, sensitive in vitro nanoparticle-based systems are being developed for detection of α-synuclein (An et al. 2010; Yu and Lyubchenko 2009). MRI has also been used to track CD4+ lymphocytes loaded with SPIO nanoparticles and injected into a rat model of ALS to detect regions of pathology in the CNS (Bataveljic et al. 2011; Machtoub et al. 2011).

5.2 Multiple Sclerosis

5.2.1 Pathobiology of Disease

MS is a progressive inflammatory autoimmune disorder of the CNS characterized by demyelination and degeneration of neuronal axons (Goldenberg 2012; Lassmann and van Horssen 2011). Destruction of oligodendrocytes occurs upon infiltration of lymphocytes into the CNS and initiation of inflammation and autoimmune reactions (Kanwar et al. 2012a). The disease can be manifest as a relapsing remitting MS, characterized by recurring attacks of acute focal neurological deficits or exacerbation of existing deficits followed gradually by partial or full recovery, or a progressive steady decline without remission (Goldenberg 2012). The disease course includes distinct exacerbations with no symptom-free remissions; instead, patients will experience progressive acceleration of disability, accumulating irreversible neurologic deficits.

The pathology of MS was originally defined by the presence of focal white matter lesions, characterized by primary demyelination with partial preservation of axons and reactive astrocytic scar formation (Bo et al. 2003; Nylander and Hafler 2012). The disease pathology changes with time. For patients in the early stages of disease experiencing clinical relapses and remissions, inflammatory demyelination leads to the formation of focal plaques predominantly located in the white matter (Rovira and Leon 2008). In latter stages of the disease, widespread demyelination in the cerebral and cerebellar cortex is seen as well as diffuse degenerative changes throughout the entire white and gray matter. Long-standing severe disease results in profound brain and spinal cord atrophy, with extreme tissue loss and dilatation of cerebral ventricles (Androdias et al. 2010; Kutzelnigg et al. 2005; Popescu et al. 2011). In a substantial number of patients, the disease eventually subsides and inflammation as well as neurodegeneration decline to levels seen in age-matched controls. During stages of active disease, both in the relapsing as well as in the progressive stages, profound oxidative tissue injury is seen. In early stages, oxidative damage is mainly driven by inflammation, resulting in an oxidative burst in microglia and macrophages. In the progressive stage, active neurodegeneration occurs against a background of mild-to-moderate inflammation, and oxidative

damage appears to be augmented by release of iron from intracellular stores. In the latter stages, the presence of iron in the brain in the absence of additional oxidative bursts from microglia does not lead to further neurodegeneration; however, patients may be affected by concomitant diseases such as stroke or AD.

5.2.2 Current Treatments

Traditional treatment for MS is aimed at shortening the duration and frequency of acute exacerbations and providing symptomatic relief. Most currently approved MS therapeutics are immunosuppressants with the exception of beta interferons and glatiramer acetate as disease-modifying drugs for relapsing remitting MS (Gasperini and Ruggieri 2012; Silva 2005; Tubaro et al. 2012). The mechanism by which these drugs act involves downregulation of T-cell proliferation and migration, reduction in antigen presentation, and shifting the immune response to T-helper 2 (Th2) cells (Devonshire and Verdun di Cantogno 2011). The necessity for repeated subcutaneous or intramuscular injections of these drugs can lead to suboptimal long-term adherence in some patients and can negatively affect clinical outcomes. Other treatments target immune suppression by inducing apoptosis in lymphocytes (mitoxantrone) or T and B cells (cyclophosphamide) or using corticosteroids to suppress the immune response. While these are commonly used for treatment of relapsing remitting MS, they have limited application in the treatment of other forms of MS because of undesirable side effects.

5.2.3 Nanoparticle-Based Experimental Systems

Nanoparticle-based treatments for MS are being developed that seek to not only modulate the immune response, but also promote neuroprotection and myelin regeneration (Amedei et al. 2012; Dharamkar 2008; Ellis-Behnke 2007; Silva 2005; Ulbrich and Lamprecht 2010). PEG-coated liposomal formulations of the traditional MS therapeutics, prednisolone and minocycline, are being developed for enhanced delivery of drug to inflammatory lesions in the CNS and to minimize serious systemic side effects (Hu et al. 2009; Linker et al. 2008; Schmidt et al. 2003a, b). PEG-coated liposomal prednisolone administered intravenously to rats with experimental autoimmune encephalomyelitis (EAE), an animal model of MS, provided a 4.5-fold higher concentration of drug in the spinal cord in comparison to rats without disease (Schmidt et al. 2003a, b). High levels of prednisolone in the CNS were observed only in EAE rats and were accompanied by low levels of free drug in the serum. In other studies Linker et al. (2008) observed that liposomal methylprednisolone and PEG-liposomal prednisolone had superior efficacy to methylprednisolone pulse therapy in EAE rats through second or third relapses. Studies by Hu et al. (2009) demonstrated that PEG-liposomal minocycline, administered every 5 days, was as effective as daily injections of non-formulated minocycline at reducing CNS manifestations in EAE rats. These results suggest that long-acting nanoformulations of glucocorticoids and minocycline can improve pharmacokinetics and drug dosing while reducing unwanted side effects in MS treatment.

Nanoparticle systems that deliver non-traditional therapeutics for MS are also being developed. Therapeutics that aid neuroprotection and neuroregeneration are of

particular interest. A water-soluble fullerene derivative ABS-75 attached to an *N*-methyl-D-aspartate (NMDA) receptor antagonist was designed to contain both antioxidant (fullerene) and anti-excitotoxic (NMDA receptor antagonism) properties (Basso et al. 2008). Fullerene ABS-75 reduced the clinical progression of EAE in a mouse model immunized with myelin oligodendrocyte glycoprotein (MOG). This was accompanied by reduced axonal loss and demyelination and inhibition of oxidative injury, CD11b+ cell infiltration, and CCL2 expression in the spinal cord. Nanoparticles have also been proposed as a way to deliver myelin to demyelinated cells (Dharamkar 2008) and as scaffolds for neuroregeneration (Ellis-Behnke 2007; Silva 2005).

In addition to drug delivery, nanoparticles are being used to aid in the development of stem cell therapies for inducing local neurogenesis or myelogenesis in CNS lesions. Mesenchymal stem cells (MSCs), which can give rise to neural-, glial-, and astrocytic-like cells in vitro, were labeled with the SPIO MRI contrast agent ferumoxides (Feridex) and injected intrathecally and intravenously into MS patients (Karussis et al. 2010). MRI revealed the presence of MSCs in the occipital horns of the ventricles, indicating the possible migration of cells into the meninges, subarachnoid space, and spinal cord. In addition, an increase in CD4+ CD25+ T cells and a decrease in lymphocyte proliferation and expression of CD40+, CD83+, CD86+ and HLA-DR on myeloid dendritic cells indicated immunomodulatory effects of MSC transplantation. Further studies by Cohen et al. (2010) demonstrated that uptake of ferumoxides by neural precursor cells (NPCs) produced no adverse effects on in vitro cell survival or differentiation or in vivo functional response, suggesting that tracking of ferumoxides-labeled NPCs by MRI is a viable noninvasive method for monitoring transplantation.

A hallmark of the immune response in disorders such as MS is a deficit in the numbers of T regulatory (Treg) cells (Buckner 2010; Wing and Sakaguchi 2010). In an effort to enhance Treg numbers, PEG-coated gold nanoparticles were used to co-administer the aryl hydrocarbon receptor activator, 2-(1′H-indole-3′-carbonyl)-thiazole-4-carboxylic acid methyl ester (ITE), and a T-cell epitope from MOG (MOG_{35-55}) to promote the generation of Tregs by dendritic cells (Yeste et al. 2012). When administered to EAE mice, the ITE-$MOG_{35–55}$ nanoparticles expanded the $FoxP3^+$ Treg population and suppressed the development of disease.

5.3 Microbial Infections

5.3.1 Bacterial Meningitis

Pathobiology of Disease

Meningitis is an inflammation of the brain and spinal cord caused by chemical irritation, drug allergies, tumors, fungal infections, and infectious agents (Yogev and Tan 2011). Viral meningitis, most commonly caused by a number of enteroviruses, but also by herpes viruses and West Nile virus, occurs frequently but usually resolves without treatment. Treatment with antivirals is required for herpes virus infections (Stahl et al. 2011a, b).

Bacterial meningitis is more severe and can result in brain damage or even death if not treated. The most frequent causative agents are *Hemophilus influenzae, Neisseria meningitidis* and *Streptococcus pneumoniae*. The only clinically available vaccine is against *H. influenzae* (McIntyre et al. 2012; Schuchat et al. 1997; Yogev and Tan 2011) and has been very effective in eliminating this disease when introduced into a population (Schuchat et al. 1997; Yogev and Tan 2011). Effective antibiotics are available, although the mortality rate in the very young and the elderly remains high. However, the increasing development of antibiotic-resistant organisms is of great concern. The pathogenesis of bacterial meningitis involves the infiltration of bacteria into the subarachnoid space. Bacterial degradation products stimulate the release of pro-inflammatory cytokines, such as TNFα and IL-1β, and prostaglandins by leukocytes, microglial cells, astrocytes, and endothelial cells, leading to increased BBB permeability. Infiltration of neutrophils and leakage of plasma proteins produces further damage (de Vries et al. 1997). Antibiotics can halt bacterial replication but are not effective alone in reducing the inflammatory events that contribute to brain damage and long-term disability (Borchorst and Moller 2012; de Vries et al. 1997; van de Beek et al. 2012). Adjunctive therapy with corticosteroids to reduce inflammation is recommended, but the incidence of detrimental side effects is high (Borchorst and Moller 2012). Thus, there is a need for new therapeutics that can penetrate the BBB and deliver traditional and novel antibiotics and adjuncts to the site of infection and inflammation while reducing the incidence and severity of side effects.

Complicating effective treatment of the disease are the time-consuming methods used for diagnosis, which can delay initiation of therapy and contribute to morbidity and mortality. Current diagnostic methods use conventional microscopy and bacterial culture of blood and cerebrospinal fluid followed by confirmation and serotype identification by polymerase chain reaction (PCR) (Bronska et al. 2006; Reddy et al. 2012; Rosenstein et al. 2001; Tunkel et al. 2004). New methods to speed diagnosis and expedite drug therapy are sorely needed.

Nanoparticle-Based Therapies

A number of experimental nanoparticle-based systems for diagnosis and treatment of infectious meningitis have been described. A recent study by Reddy et al. (2012) described the development of an acoustic wave immunosensor for meningococcal antigen that is enhanced using gold nanoparticles. Cell surface outer membrane protein 85 (OMP85) of *N. meningitidis* was bound to gold nanoparticles and quantitated by interaction with antibody immobilized on the surface of a polyvinylidene fluoride–coated quartz crystal microbalance. Binding of OMP85 to the gold nanoparticles allowed detection of as little as 312 ng/ml OMP85 and would provide detection of antigen in blood or CSF with minimal sample preparation.

Development and efficacy of self-assembled cationic antimicrobial peptide nanoparticles has been described (Liu et al. 2009c; Wang et al. 2010) for treatment of *Staphylococcus aureus* and *Cryptococcus neoformans* meningitis in rabbits. Cholesterol-conjugated G_3R_6TAT (CG_3R_6TAT) self-assembled in deionized

water into cationic core/shell nanoparticles with TAT-anchored shells. The nanoparticles crossed the BBB and were equally as effective as vancomycin and amphotericin B in treating *S. aureus* and *C. neoformans* meningitis, respectively (Liu et al. 2009c; Wang et al. 2010). In addition, they did not impair liver and kidney functions or induce blood electrolyte imbalances. Of critical importance antimicrobial peptide nanoparticles show promise for treating drug-resistant bacterial, yeast, and fungal meningitis infections. Recently, a different nanoparticle-based approach to combat development of drug-resistant *S. aureus* was described by Chakraborty et al. (2012). Folic acid–tagged chitosan nanoparticles were used to effectively deliver vancomycin into a drug-resistant strain of *S. aureus* in an in vitro study and promote bacterial lysis. Using the folic acid–conjugated chitosan nanocarrier provided an effective way of delivering vancomycin across the thicker cell wall in vancomycin-resistant bacterial strains (Chakraborty et al. 2012).

Adjunctive nanoparticle-based therapies have also been described. Tsao et al. (1999) demonstrated that *Escherichia coli*–induced meningitis could be inhibited by carboxyfullerene (C60). Treatment of *E. coli*-infected mice with a water-soluble malonic acid derivative of C60 reduced mortality, decreased levels of TNFα and IL-1β in the brain, and inhibited increases in BBB permeability and neutrophil infiltration (Tsao et al. 1999).

5.3.2 Human Immunodeficiency Virus

Pathobiology of Disease

HIV-associated neurocognitive disorders (HAND) comprise a spectrum of disease states from clinically asymptomatic to overt cognitive and behavioral impairments to full-blown dementia (HIVE). HIVE is fueled by immune activation of CNS cells and virotoxins, including viral proteins, cytokines, and chemokines that are secreted by infected brain macrophages and microglia (Kaul 2009; Shapshak et al. 2011). Following HIV infection, the resulting early inflammation and secreted viral proteins induce a breach in the BBB integrity, allowing HIV and infected mononuclear phagocytes to invade the CNS. Virus and toxic products secreted by infected brain mononuclear phagocytes and glial cells induce neuroinflammation, neurodegeneration, and encephalopathy. The neuropathology of HIVE is characterized by neuronal loss, glial activation, presence of multinucleated giant cells, perivascular mononuclear infiltration, myelopathy, and myelin pallor. In addition to neuronal loss, aberrant sprouting, and dystrophic synaptodendritic connections, HIVE is also characterized by extensive damage to microvessels of the blood-brain barrier caused by infiltration of HIV-infected cells and inflammatory cells into the brain (Gelman et al. 2006, 2012).

The mechanism by which HIV infection leads to neuroinflammation and encephalitis is multifactorial and has been shown to involve direct viral infection of brain mononuclear phagocytes and dysfunction and injury of brain endothelial cells, astrocytes, oligodendrocytes, and neurons, induced by HIV itself and secreted

viral factors (Byrd et al. 2012; Noorbakhsh et al. 2005; Pacifici et al. 2013; Silva et al. 2012). HIVE generally occurs in the late stages of HIV infection and is associated with low levels of CD4+ T cells and high plasma viral loads. It involves continued CNS inflammation and neuronal and astrocyte injury induced by the virus, secreted viral proteins, and secreted cytokines and chemokines (Pacifici et al. 2013).

Current Treatments

With the advent of effective combination antiretroviral therapy (cART) (Table 1) and the longer survival of infected patients, the pathogenesis of HIVE has been transformed from a subacute, neuroinflammatory disorder with florid neurological alterations, to a chronic and protracted condition. Advances in ART drugs and treatment regimens have improved virological control and greatly increased the life expectancy of infected individuals. However, cART has not eradicated virus from protected sites, such as the brain and lymphoid tissue, nor has it eliminated the incidence of milder forms of HAND (Valcour et al. 2011). With the need for continued life-long daily doses of cART, occurrence of adverse side effects, and lack of adherence to treatment regimens, the development of resistant strains has become a cause for concern (Chen et al. 2002; Chulamokha et al. 2005; Fellay et al. 2001; Hawkins 2006; Shehu-Xhilaga et al. 2005). Thus, there is need for novel adjunctive treatments that address HIV-associated neurological deficits and improved antiretroviral therapies to reduce the incidence of side effects and simplify dosing regimens (Mahajan et al. 2012; Nowacek and Gendelman 2009).

Nanoparticle-Based Experimental Systems

Various nanoparticle-based systems have been explored for improving antiretroviral therapy. Efavirenz (EFV)-poloxamine/poloxamer polymeric micelles were synthesized as nanocarriers via oral administration, and displayed promising physical stability and pharmacokinetics (Seremeta et al. 2013). Intranasal administration of poly(ethylene oxide)-poly(propylene oxide) polymeric micelles loaded with EFV enhanced bioavailability of the drug in the CNS fourfold and increased the relative exposure index (ratio between the area under the curve in the CNS and plasma) fivefold with respect to the same system administered intravenously (Chiappetta et al. 2013). Polybutylcyanoacrylate and methylmethacrylate-sulfopropymethacrylate nanoparticles have been reported to increase delivery of ART drugs to the CNS (Mulik et al. 2012). The disadvantages of polymeric nanoparticles include residual contamination, polymer initiation, toxic monomers, and stability issues. Shibata et al. (2013) produced biodegradable combination antiretroviral PLGA nanoparticles containing EFV and lopinavir by high-pressure homogenization. These nanoparticles also efficiently inhibited in vitro HIV-1 infection and transduction. Tenofovir, a nucleotide analog reverse transcriptase inhibitor, was embedded in PLGA and chitosan nanocarriers and demonstrated sustained in vitro release, suggesting that these particles could be effective and attractive drug carriers (Belletti et al. 2012).

Table 1 FDA-approved antiretroviral (ARV) drugs for HIV-1 treatment

ARV class	ARV agent	Abbreviation	Recommended as initial therapy
Non-nucleoside reverse transcriptase inhibitors			
	Efavirenz	EFV	Yes
	Nevirapine	NVP	Yes
	Rilpivirine	RPV	Yes
	Delavirdine	DLV	No
	Etravirine	ETR	No
Nucleoside analog reverse transcriptase inhibitors			
	Emtricitabine	FTC	Yes
	Lamivudine	3TC	Yes
	Abacavir	ABC	Yes
	Zidovudine	ZDV	Yes
	Didanosine	ddI	No
	Stavudine	d4T	No
	Apricitabine	ATC	Phase III trials
Nucleotide analog reverse transcriptase inhibitor			
	Tenofovir disoproxil fumarate	TDF	Yes
Protease inhibitors			
	Atazanavir	ATV	Yes
	Darunavir	DRV	Yes
	Fosamprenavir	FPV	Yes
	Lopinavir	LPV	Yes
	Saquinavir	SQV	Yes
	Ritonavir	RTV	Yes (as boost)
	Indinavir	IDV	No
	Nelfinavir	NFV	No
	Tipranavir	TPV	No
Integrase strand transfer inhibitors			
	Elvitegravir	EVG	Yes
	Raltegravir	RAL	Yes
CCR5 antagonist			
	Maraviroc	MRV	Yes
Fusion inhibitor			
	Enfuvirtide	T20	No
CYP3A4 inhibitor			
	Cobicistat	COBI	Yes (as boost)

Cell-Based Nanoparticle Delivery for HIV-1 Treatment

Use of macrophages as Trojan horses to improve ART dosing by acting as drug reservoirs and providing delivery to sites of residual viral infection is being developed in our own laboratories (Balkundi et al. 2011; Nowacek et al. 2009b, 2010, 2011). We have developed polymer-coated crystalline nanoformulations of antiretrovirals (nanoART) that can be taken up by macrophages and remain inside the cells for an extended period of time (Dou et al. 2009; Nowacek et al. 2011). These formulations were manufactured by high-pressure homogenization or wet milling of crystalline drug using various surfactants including poloxamer 188 (P188), poloxamer 407 (P407), 1, 2-distearoyl-sn-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethyleneglycol)-2000] (DSPE-mPEG), PVA, and PLGA. NanoART was efficiently and rapidly taken up by human monocyte–derived macrophages (MDM) in culture. Drug (atazanavir (ATV), ritonavir (RTV), or EFV) was retained inside the cells for up to 14 days and inhibited HIV-1 replication in macrophages in a dose-dependent manner (Balkundi et al. 2011; Nowacek et al. 2009b, 2010, 2011). NanoART-loaded macrophages could deliver drug to sites of HIV-1 infection in the brain in an animal model of HIVE. Importantly, nanoART (P188-ATV/RTV) administered subcutaneously at weekly doses (250 mg/kg each drug) provided sustained plasma and tissue ATV levels above the minimal effective concentration, suppressed viral replication in spleen and brain, and maintained CD4+ T-cell numbers in a humanized mouse model of chronic HIV-1 infection (Dash et al. 2012). These studies are an important step in the development of a cell-based delivery system for ART drugs (Balkundi et al. 2010; Nowacek et al. 2009b).

Our group has also developed nanoART targeted to macrophage receptors. Decorating nanoART with folic acid (to target macrophage folate receptors) elicited a >2-fold concentration-dependent enhancement of macrophage uptake and retention in vitro when compared to replicate non-decorated nanoART (Puligujja et al. 2013). Antiretroviral activity, measured by inhibition of HIV reverse transcriptase activity and HIV-1p24 staining, was also enhanced twofold. These activities paralleled greater nanoART retention in recycling endosomes, providing a stable cell-based drug depot. We also observed that by actively targeting the nanoART to macrophages through folate modification, plasma and tissue ATV levels could be maintained at levels above the minimum effective concentration after a single intramuscular injection (50 mg/kg) in mice (Puligujja et al. 2013).

We are also developing a novel nanoparticle system to provide a noninvasive assessment of ART tissue distribution by MRI. Small magnetite ART (SMART) particles were manufactured by encasing ATV and SPIO (magnetite) in PLGA, 1,2-distearoyl-*sn*-glycero-3-phosphocholine, and DSPE-mPEG. SMART particles were efficiently taken up by MDM in culture and retained in the cells for up to 15 days. The levels of drug and magnetite in the cells mirrored the drug/magnetite ratio of the SMART particles (Guo et al. 2013). As shown in Fig. 4, parenteral administration of SMART particles to mice demonstrated that

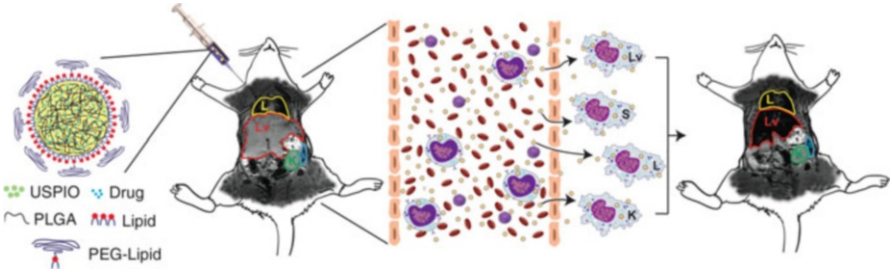

Fig. 4 Small magnetitie-containing antiretroviral (SMART) nanoparticles can be used to assess drug biodistribution. SMART particles, parentally administered to mice, are taken up by circulating monocytes/macrophages and accumulate in tissues, including liver (Lv), spleen (S), lungs (L), and kidneys (K). Magnetic resonance imaging (MRI) is used to monitor biodistribution of the magnetite-/drug-containing SMART particles (Figure reprinted with permission from Guo et al. (2013))

magnetite and drug biodistribution paralleled one another. SMART nanoparticles could facilitate the evaluation of drug biodistribution and provide rapid in vivo assessment of nanoparticles that target cell and tissue viral reservoirs. These findings can serve to improve and speed pharmacokinetic parameters in nanoparticle-based systems and to bring nanotechnology closer to human clinical application.

6 Nanotoxicology

Most neuroinflammatory nanomedicine studies have focused on drug delivery of nanoparticles, but the consequent adverse effects or toxicity issues of the nanocarriers cannot be ignored. Toxicity depends on various parameters of nanoparticles including morphology, size, charge, surface area, material solubility, dose, route, and duration of administration (Kanwar et al. 2012b; Liu et al. 2012). Smaller nanoparticles exhibit superior translocation kinetics; however, their smaller size could result in toxicological effects caused by the trade-off between drug potency and immunologic surveillance (Beyerle et al. 2010; Bhaskar et al. 2010; Chen and Schluesener 2008; Tian et al. 2006). The physicochemical properties of nanosized materials differ with respect to their larger counterparts, increasing the potential for toxic interactions (Nel et al. 2006, 2009). Nonbiological nanoparticulate carriers larger than 200 nm can cause cell membrane ruffling, cytoskeletal rearrangement and stimulate endocytic machinery, promoting uptake by phagocytic cells (Harding and Song 1994; Paulo et al. 2011; Pichai and Ferguson 2012). Furthermore, some studies show that nanoparticles can be pro-oxidant and pro-inflammatory (Stoeger et al. 2006, 2009). Certain types of nanoparticles may stimulate the release of cytokines and chemokines such as IL-6, IL-1β, TNFα, reactive oxygen species, and C-reactive

protein with subsequent activation of mitogen-activated protein kinase (MAPK), redox-activated transcription factors, the transcription factor nuclear factor kappa B (NFkB), and activating protein-1 (AP-1). Long-term exposure to nanoparticles may thus result in chronic inflammation that could accelerate atherosclerosis (Fernandes et al. 2010). Data are limited, however, on the potential toxicities of long-term nanoparticle exposure and possible neurological consequences of these drug-delivery systems (Bhaskar et al. 2010; Kanwar et al. 2012b).

Although nanomedicines for treatment of neuroinflammation have shown promise, further studies on the safety of these systems are needed. To reduce the potential for adverse effects, a couple of different strategies are being used in the development of nanoparticle drug carrier systems. Novel biodegradable or biocompatible polymers are being used in the preparation of nanoparticles to reduce their toxicity and allow them to escape the reticuloendothelial system, as well as to aid drug release. Biocompatible polymers such as polylactic acid, polybutylcyanoacrylate, and polycaprolactone are being used in the preparation of nanomedicines to decrease toxicity (Kanwar et al. 2012b; Nel et al. 2006). In addition, surface functional modification of nanomedicines to actively target nanoparticles to sites of disease is being increasingly used to decrease nonspecific interactions and toxicities (Koo et al. 2005; McMillan et al. 2011).

7 Conclusion

Treatments of neurodegenerative and neuroinflammatory disorders require drugs acting on the CNS. Thus, development of novel nanoparticle systems for drug delivery across the BBB is a promising and urgent industry aimed at improving disease outcomes (Bhaskar et al. 2010; Fernandes et al. 2010; Kanwar et al. 2012a, b; Re et al. 2012b). Nanoparticles may be employed as drug carrier systems that assist in therapeutic targeting to the CNS. Multifunctional nanoparticles allow delivery of pharmaceutical agents into the brain and provide for neuroimaging of cell dynamics and tracking of nanoparticle delivery. Such nanocarriers and/or their combination with other drugs will drive the search for targeting specific areas in the brain and thus enhance therapies. Nanomedicine has yet to make its mark in clinical studies; however, nanoparticle-based drugs are gaining considerable interest in the pharmaceutical industry. The translation of nanoparticles for clinical use in therapeutic and diagnostic applications is promising amid recent developments. However, even though nanoparticle-based diagnostic and therapeutic agents for neuroinflammatory diseases have shown great potential, there continues to be concerns about the safety of these particles. Thus, it is also necessary to gain a better understanding of the potential neurotoxicity associated with nanoparticle-based therapies.

Neurodegenerative Aspects of Multiple System Atrophy

Rowan Radford, Mathew Wong, and Dean L. Pountney

Contents

Abstract

Multiple system atrophy (MSA) closely resembles Parkinson's disease clinically but with a range of autonomic signs in addition to motor symptoms, resulting in its designation as a Parkinson's-plus disease/atypical parkinsonism. However,

unlike Parkinson's disease that displays primarily neuronal pathology, the neurodegenerative aspects of MSA reflect widespread glial cell dysfunction and the occurrence of intracytoplasmic inclusion bodies predominantly in oligodendrocytes. Alpha-synuclein, a key protein component of the glial cytoplasmic inclusions, is thought to mediate cytotoxicity via a range of abnormal modified and aggregated soluble molecular species that may even propagate from cell to cell as cargo in exosomes. Moreover, cellular model studies suggest that the sequestration of abnormal alpha-synuclein within microscopically visible intracellular inclusion bodies occurs as a defensive response that utilizes the aggresome machinery. Although aggregation of alpha-synuclein plays a central role in the disease pathology, it is becoming clear that there is a complex interplay of factors, including heat shock proteins, inflammation, calcium homeostasis, the ubiquitin proteasome system, autophagy, and oxidative stress. Recent studies have highlighted the involvement of metallothioneins, small ubiquitin-like modifier (SUMO), and p25α, thus providing several new potential targets for therapeutic intervention. Inflammatory pathways may also be exploited in new treatment approaches, although it remains to be determined whether the astrocyte and microglial activation present is secondary to alpha-synuclein aggregation or primary to the disease pathogenesis, and may even have some beneficial consequences.

1 Introduction

Multiple system atrophy (MSA) is a sporadic neurodegenerative disorder clinically characterized by autonomic failure with motor syndrome presenting as atypical parkinsonism and/or ataxia. The prevalence of MSA is estimated to be 4.6 cases per 100,000 people (Marpillat 2013; Schrag et al. 1999). The prognosis of MSA is poor with death occurring within 8 years after onset (Wenning and Stefanova 2009). MSA is a heterogeneous group of neurological diseases, often misdiagnosed clinically as Parkinson's disease, which have as a common neuropathological hallmark the occurrence of filamentous, intracytoplasmic inclusion bodies in oligodendrocytes throughout the brain (Graham and Oppenheimer 1969; Papp et al. 1989; Gilman et al. 2008). Previously known as three separate clinical conditions, namely, olivopontocerebellar atrophy, striatonigral degeneration, and Shy-Drager syndrome, the signs and symptoms of MSA include autonomic malfunction, highlighted by postural hypotension, urinary complications (e.g., inability to drain bladder, urge incontinence), and persistent constipation and motor complications, such as parkinsonism, cerebellar ataxia (lack of muscle coordination), and pyramidal symptoms (Wenning et al. 2004, 2008; Wenning and Jellinger 2005; Stefanova et al. 2009). There are two subtypes of MSA as determined by the motor complication: MSA-P refers to parkinsonism, and MSA-C refers to cerebellar ataxia.

In the western world, MSA-P has been shown to be the more common of the two at around 80 % prevalence (Wenning et al. 2008), although autonomic failure is seen in both subtypes (Wenning and Stefanova 2009). The macroscopic changes in brain anatomy associated with MSA have been reviewed recently (Ahmed et al. 2012). To summarize, the clinical signs, including ataxia and bradykinesia, correspond to the loss of neurons in multiple brain regions, including the striatum, substantia nigra pars compacta, locus coeruleus, cerebellum, pontine nuclei, inferior olives, and intermediolateral columns (Wenning et al. 1997; Jellinger 2003; Ozawa et al. 2004; Stefanova et al. 2009), and the severity of disease symptoms correlates well with the frequency of inclusion body-bearing cells (Papp and Lantos 1994; Jellinger and Lantos 2010). Another important aspect of the pathology of MSA is widespread gliosis associated with neuronal loss (Ishizawa et al. 2004; Stefanova et al. 2007; Song et al. 2009; Fellner et al. 2011) and the accompanying upregulation of neurotrophic factors, such as BDNF, GDNF, and IGF-I (Kawamoto et al. 1999, 2000; Pellecchia et al. 2010). The focus of this chapter is the molecular pathology of MSA, with the aim of highlighting key molecular components and their potential roles in the progression of the disease.

1.1 Glial Cytoplasmic Inclusions and the Aggresome Model

Many neurodegenerative diseases are characterized by microscopically visible intranuclear or intracytoplasmic protein inclusion bodies (IB), within various disease-specific neural cell populations. In MSA, the pathological inclusion bodies occur predominantly in the oligodendrocyte cells leading to MSA being referred to as a glial α-synucleinopathy, with the characteristic glial cytoplasmic inclusions (GCIs) composed largely of aggregated filamentous α-synuclein (Gai et al. 1998; Wenning et al. 2008), although a subpopulation of GCIs were also immunopositive for the tau protein associated with Alzheimer's disease (Cairns et al. 1997). Figure 1a represents a typical α-synuclein-positive GCI in an oligodendrocyte in MSA tissue (visual cortex). Although the inclusion bodies are seen mostly in oligodendrocytes, cytoplasmic and intranuclear neuronal inclusions and astrocyte inclusions are also seen on occasion (Nishie et al. 2004). The GCIs are often sickle shaped and found in the cytoplasm adjacent to the nucleus (Arima et al. 1992), with the inclusion body adjacent to and/or wrapped around the nucleus, and recent studies have shown that GCIs occur in mature oligodendrocytes and not in oligodendrocyte precursor cells (Ahmed et al. 2013).

In general, pathological inclusion bodies, and by extension GCIs, are believed to be formed actively in a defensive response to soluble cytotoxic protein aggregates, resembling aggresomes (Kopito 2000; Olzmann et al. 2008; Chin et al. 2010). An aggresome is formed when misfolded proteins are either not refolded with the aid of chaperones or not degraded by the normal proteolytic mechanisms (such as lysosomal autophagy and the ubiquitin-proteosome system (UPS)) (Wong and Cuervo 2010; Johnston et al. 1998). Protein misfolding can be caused by genetic or environmental factors, such as oxidative stress and metal binding (reviewed in Jomova et al. 2010). Perinuclear aggresomes are rich in aggregation-prone protein, such as α-synuclein and

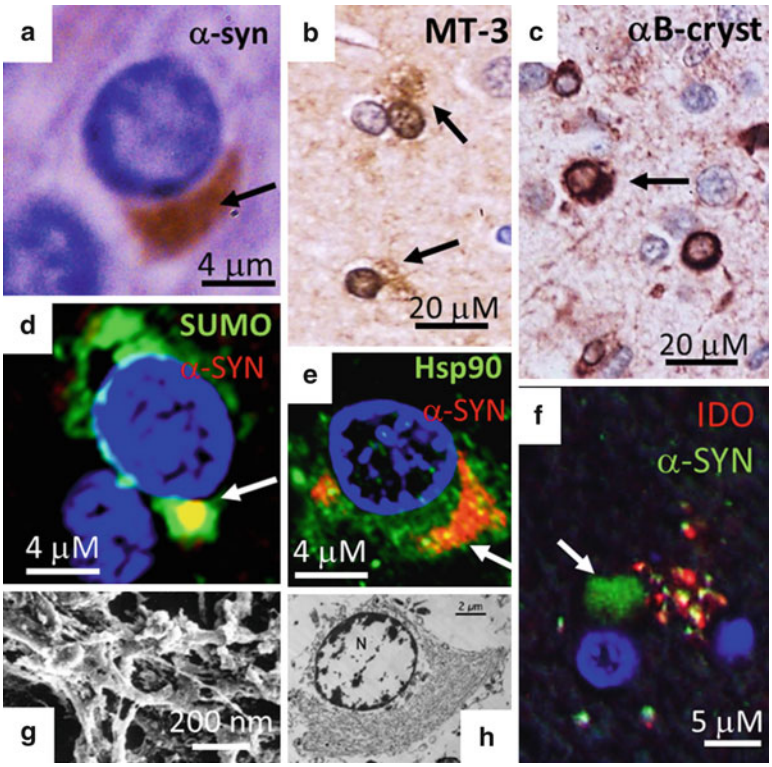

Fig. 1 *Glial cytoplasmic inclusion bodies (GCIs) and gliosis are the primary pathological hallmarks of MSA.* Although composed largely of filamentous α-synuclein aggregates, GCIs are immunopositive for ubiquitin and a diverse range of other components linked to cellular systems, such as autophagy, the proteasome pathway, inflammation, and the cytoskeleton. Illustrative micrographs of MSA brain tissue sections are presented showing (**a**) α-synuclein, (**b**) metallothionein-III, and (**c**) αB-crystallin immunostaining (visual cortex). Confocal immunofluorescence (**d–f**) shows the relationships between α-synuclein and (**d**) SUMO-1, (**e**) Hsp90, and (**f**) indoleamine-2,3-dioxygenase (IDO). Panels (**g–h**) represent the ultrastructural features of GCIs. (**g**) Example scanning electron micrograph of isolated GCI surface showing ~10 nm single filaments and ~30–50 nm bundles of filaments. (**h**) Transmission electron micrograph of typical perinuclear GCI, showing the partial alignment of filaments towards the poles of the crescent-shaped inclusion body

ubiquitin, and cytoskeletal proteins, such as vimentin, that form a "cage" around the developing aggresome. Protein aggregates are actively transported to the microtubule-organizing center (MTOC) along microtubules by the dynein motor proteins, along with other components to form a microscopically visible aggregate, or aggresome (Iwata et al. 2005; Olzmann et al. 2007). p97/VCP protein escorts ubiquitinated proteins to the aggresome via interactions with other ubiquitin-binding proteins, such as rad23 or HDAC6, respectively (Ju et al. 2008). This process can also be mediated by Hsp90-dependent trafficking and is inhibited by the overexpression of dynamitin that dissociates dynein from its cargo and by inhibition of tubulin re-polymerization by

nocodazole (Taylor et al. 2003; Thomas et al. 2006). Recent studies have found that the parkin ubiquitin-protein isopeptide ligase (or E3) and lysine residue 63 (K63)-linked polyubiquitination are vital for dynein transport and therefore aggresome formation (Olzmann et al. 2007; Chin and Olzmann 2010). Under proteasomal impairment, parkin cooperates with the E2 enzyme Ubc13/Uev1a and PACRG to mediate Lys63-linked polyubiquitination of misfolded proteins (Taylor et al. 2012). Lys63-linked polyubiquitin chains promote binding to HDAC6 adaptor protein and thereby link the misfolded proteins to the dynein motor complex for retrograde transport towards the MTOC to form the aggresome. Binding is strengthened by editing of the K63-linked ubiquitin chains by ataxin-3 that creates free ubiquitin C-termini with increased affinity for HDAC6 (Ouyang et al. 2012). Recruitment of polyubiquitinated proteins to the aggresome is promoted by the TRIM50 protein. Lys63-linked polyubiquitination may also promote binding to the p62 protein and thereby facilitate the recruitment of autophagic membrane to the aggresome via interaction with LC3 to form an autophagosome (Fusco et al. 2012). Fusion of the autophagosome with the lysosome may allow degradation of aggregated proteins by lysosomal proteases, a process that may be overwhelmed in protein misfolding disease.

GCIs, in common with other IBs, often contain chaperone proteins, including Hsp90, and ubiquitin, which has been shown to be intimately linked to aggresome biogenesis (Olzmann et al. 2007). The GCIs are comprised largely of 9–10 nm filaments of the α-synuclein protein, which is also found in the neuronal inclusion bodies (Lewy bodies) associated with Parkinson's disease and Lewy body dementia (Gai et al. 1998; Spillantini and Goedert 2000; Pountney et al. 2005a), leading to the grouping together of these diseases as α-synucleinopathies. Some studies implicate the dysregulation of metals, such as copper, iron, calcium, and zinc, which are able to interact with α-synuclein, inducing aggregation, oligomerization, and conformational changes in the protein (Breydo et al. 2012). Other IB components that have been identified besides α-synuclein aggregates are microtubule proteins, αB-crystallin, neurofilament proteins, lipids, organelles (lysosomes and mitochondria), microtubule-associated protein 1B, and parts of the UPS (Gai et al. 1999; Ruipérez et al. 2010). Figure 1b–e illustrates the typical pattern of immunoreactivity of several GCI components in MSA tissue. Isolated GCIs can be resolved to reveal many distinct protein species (Fig. 2). An extensive list of GCI components that have been identified has been reported in the recent review by Jellinger and Lantos (2010). In the remainder of this chapter, several key factors linked to cellular systems will be highlighted that may be important to disease pathogenesis.

2 α-Synuclein

The main component of GCIs in MSA is aggregated filamentous α-synuclein, leading to the classification of the disease as an α-synucleinopathy (Gai et al. 1998; Spillantini and Goedert 2000). Indeed, GCIs containing α-synuclein are required to be present upon autopsy in order for the diagnosis of MSA to be confirmed (Gilman et al. 2008). Although the origin of α-synuclein in oligodendrocytes in MSA is unclear, the

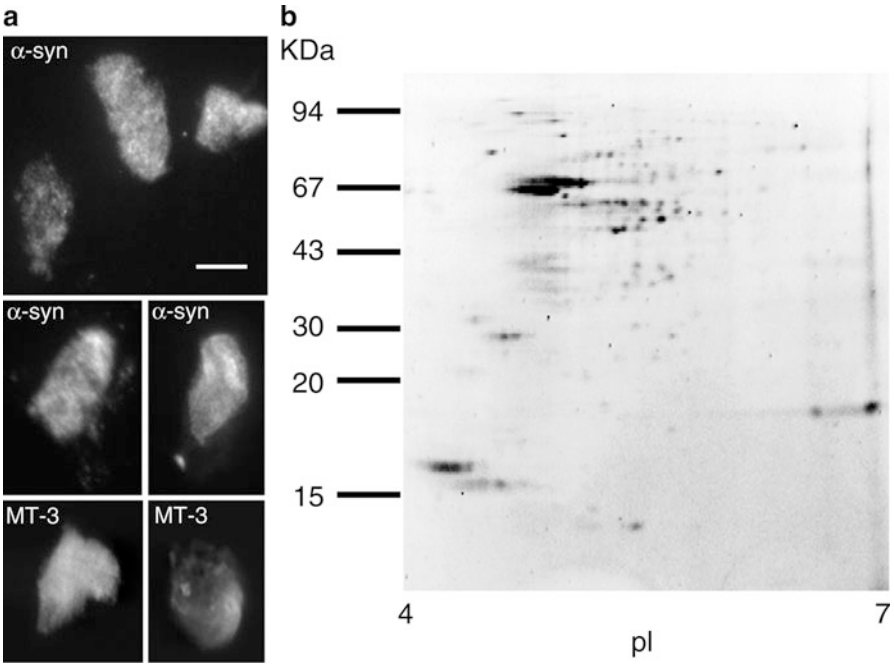

Fig. 2 *Isolated GCIs show differential distributions of inclusion body components and resolve by electrophoresis to reveal abundant distinct protein species*. (**a**) Immunofluorescence of GCIs immunoisolated from fresh, frozen MSA brain tissue using magnetic beads (Pountney et al. 2011). α-Synuclein and metallothionein-III show different patterns of immunoreactivity. Scale bar, 2 μm. (**b**) Two-dimensional gel electrophoresis of purified GCIs (SYPRO Ruby stain, inverted) illustrates the huge diversity of distinct protein species present in the inclusion bodies (for conditions, see Pountney et al. 2005b)

accumulation of α-synuclein-positive GCIs in white matter in MSA brain tissue has been shown to correlate well with the severity of tissue injury (Ishizawa et al. 2008). The α-synuclein protein is encoded by the SNCA gene and comes from a family of synuclein proteins. This group encompasses three other proteins: β-syn, γ-syn, and synoretin, all of which are expressed in neuronal cells (Lavedan 1998). A wide range of in vitro and in vivo data strongly suggests a central role of α-synuclein molecular interactions in the pathogenesis of α-synucleinopathies (Polymeropoulos et al. 1997; Lesage and Brice 2009). A53T, G51D, E46K, and A30P mutations linked to familial PD promote the formation of soluble α-synuclein protofibrils, although only the A53T and E46K mutants accelerate filament formation (Conway et al. 2000; Fredenburg et al. 2007; Kiely et al. 2013). Unlike other α-synucleinopathies, such as Parkinson's disease and dementia with Lewy bodies, there have been no familial forms of MSA reported that are linked to α-synuclein gene mutations, although GCI pathology has recently been found in Parkinson's disease with the G51D mutation (Kiely et al. 2013). Indeed, no clear genetic links to MSA have so far been elucidated (as reviewed by Stemberger et al. 2011; Ahmed et al. 2012), with the exception of recent studies

associating MSA cases with the H1 haplotype of MAPT, commonly associated with tauopathies, such as progressive supranuclear palsy (Vilariño-Güell et al. 2011) and *COQ2* mutations linked to coenzyme Q_{10} deficiency (Tsuji et al. 2013).

α-Synuclein is a protein composed of 140 amino acids, with three distinct domains: a hydrophobic central domain, a negatively charged carboxyl terminus capable of calcium binding, and an amino terminal lipid-binding domain (Ruipérez et al. 2010; Pountney et al. 2005a; Nielsen et al. 2001). Currently, the role of α-syn is unknown. It is expressed in copious amounts in neurons of the central nervous system and is concentrated at presynaptic terminals near synaptic vesicles (Cookson 2009; Leong et al. 2009). In animal models, overexpression of α-synuclein has been attributed to the formation of aggregates and cytotoxicity (Fernagut and Chesselet 2004; Feany and Bender 2000), and cells overexpressing α-synuclein (wild-type or mutants) form α-synuclein-positive cytoplasmic aggregates (Bodner et al. 2006). Indeed, oligodendrocyte expression of α-synuclein in transgenic mice in conjunction with oxidative stress could replicate MSA pathology (Stefanova et al. 2005). Although, the normal cellular function of α-synuclein is still not fully understood, it has been implicated in neurotransmitter vesicle binding and recycling (Nemani et al. 2010). While the free α-synuclein monomer is a natively unfolded protein in dilute solution (Uversky 2009), interaction with lipid vesicles results in folding, yielding a more ordered structure (Uversky and Eliezer 2009; Perlmutter et al. 2009; Drescher et al. 2010). Many different exogenous factors, including oxidation, metal ions, and lipids, have been shown to induce the formation of potentially cytotoxic soluble α-synuclein oligomers (Breydo et al. 2012).

There is no endogenous expression of α-synuclein in oligodendrocytes in either MSA or normal human brain (Miller et al. 2005). Moreover, the expression of α-synuclein in oligodendrocytes in rat has been found to be developmentally regulated, with no expression in mature cells (Richter-Landsberg et al. 2000). Thus, the origin of α-synuclein in GCIs is likely ectopic and may result from uptake of extracellular protein. Indeed, extracellular α-synuclein has recently been identified as a potential therapeutic target in α-synucleinopathies (Vekrellis and Stefanis 2012). Neuronal secretion of α-synuclein can occur via exosomes (Marques and Outeiro 2012), and oligodendrocyte uptake of extracellular α-synuclein is mediated by endocytosis (Konno et al. 2012). There has also been much recent interest in blood and CSF α-synuclein and the possibility that circulating forms of the protein could be analyzed to provide diagnostic information for α-synucleinopathy diseases, including MSA (Eller and Williams 2011).

2.1 Alpha-Synuclein Aggregation and p25α

The native structure of α-synuclein is a soluble unfolded or disordered conformation that can form insoluble fibrils (Vilar et al. 2008). However, the N-terminus can bind to lipid membranes where it becomes α-helical in its secondary structure (Perlmutter et al. 2009; Sulzer et al. 2010). This has led to the implication that the protein may function in controlling synaptic transmission, through binding to

synaptic vesicles and controlling neurotransmitter release and vesicle salvage (Nemani et al. 2010). However, studies with knockout α-synuclein mice showed no detrimental signs, suggesting there are alternate methods in the control of synaptic transmission available and that α-synuclein is not critical to neural development (Fernagut and Tison 2012). In vitro studies have shown that α-synuclein readily forms aggregates, including both filamentous/fibrillar and oligomeric forms. Soluble oligomers of α-synuclein have been shown to have a number of toxic effects, such as inhibiting the UPS, forming pores in lipid membranes, and disturbing intracellular transport (Pountney et al. 2005a; Schmidt et al. 2011). The protein C-terminus has also been shown to have a low affinity for and is required for interaction with calcium ions (Lowe et al. 2004; Nath et al. 2011), and calcium (II) binding to α-synuclein has recently been shown to induce the formation of annular oligomers (Lowe et al. 2004; Nath et al. 2011).

In GCIs, ultrastructural studies have found that α-synuclein is predominantly fibrillar, comprising single ~10 nm amyloid-like filaments as well as ~30 nm bundles of filaments (Gai et al. 2003), although there is also some interstitial, amorphous α-synuclein aggregate. Figure 1g shows a scanning electron micrograph of the surface features of a typical GCI isolated from MSA brain tissue homogenate (Pountney et al. 2003). Furthermore, transmission electron microscopy has revealed that α-synuclein filaments often align within GCIs, especially near the poles of the most common type of crescent-shaped inclusion bodies (Fig. 1h), and has also provided evidence of entrapped vesicular structures, such as mitochondria (Gai et al. 2003; Arima et al. 1992). By treating isolated GCIs with mild detergents, it was possible to release stable annular α-synuclein oligomeric species (Pountney et al. 2004) that closely resemble annular α-synuclein species formed in vitro (Lowe et al. 2004; Nath et al. 2011) and bacterial pore-forming toxins, such as hemolysin.

Various factors, including calcium and other metal ions (Lowe et al. 2004; Nath et al. 2011; Uversky 2009; Uversky and Eliezer 2009; Follett et al. 2012), lipids (Riedel et al. 2011), and oxidative stress (Riedel et al. 2010; Goodwin et al. 2012), have been implicated in promoting α-synuclein aggregation, and recent studies have also implicated the p25α protein (also known as tubulin polymerization-promoting protein, TPPP) that is differentially expressed in MSA brain tissue and itself a GCI component, in promoting the formation of cytotoxic α-synuclein aggregates (Lindersson et al. 2005; Song et al. 2007; Hasegawa et al. 2010; Kragh et al. 2013).

2.2 Posttranslational Modifications of Alpha-Synuclein

Several modified forms of α-synuclein have been reported in MSA and α-synucleinopathy pathology, including Ser129-phosphorylation (Fujiwara et al. 2002; Braithwaite et al. 2012; Anderson et al. 2006; Kragh et al. 2009), glycosylation (Shimura et al. 2001), nitrotyrosine (Beyer and Ariza 2013), and various truncated and cross-linked forms of the protein (Anderson et al. 2006; Pountney et al. 2004). Recently, SUMOylation of α-synuclein has been shown to inhibit filament formation and reduce neuronal toxicity in animal models (Krumova et al. 2011).

The relative importance of these different species in relation to the disease progression cannot currently be estimated; however, many recent studies have focussed on the abundant phosphorylated (phospho-Ser129) α-synuclein species that can be produced by leucine-rich repeat kinase 2 (LRRK2; Qing et al. 2009), also a GCI component (Huang et al. 2008). Earlier studies have linked the glycosylated 22KDa α-synuclein form to targeting of the protein to the ubiquitin proteasome pathway (Shimura et al. 2001). The nitrotyrosine modification in α-synuclein has been proposed as a specific molecular marker indicating oxidative stress (Schildknecht et al. 2013). Oxidative dityrosine cross-linking has also been implicated in stabilizing α-synuclein oligomers (Pountney et al. 2004). The various low-molecular weight truncated forms of α-synuclein, especially the C-terminal truncations that are more prone to aggregation, have received considerable recent attention in proteomics analyses (Anderson et al. 2006), whereas the nature of the wide array of high-molecular weight, stable and cross-linked oligomeric α-synuclein species is still relatively unclear (Deleersnijder et al. 2013).

3 Heat Shock Proteins

3.1 αB-Crystallin and Small Heat Shock Proteins

Heat shock proteins (Hsp), including members of the small heat shock family, have been linked to the formation of aggresomes, cytoplasmic accumulations of aggregated proteins at the microtubule-organizing center (MTOC), in response to unfolded protein stress (Berke and Paulson 2003; Bolhuis and Richter-Landsberg 2010). The chaperone activity of αB-crystallin and several other small chaperone proteins, such as HSP27, is influenced by a wide range of posttranslational modifications, including phosphorylation (Aquilina et al. 2004; Kostenko and Moens 2009). αB-Crystallin is upregulated in neurodegenerative diseases (Muchowski and Wacker 2005) and αB-crystallin has been shown to be present in GCIs (Gai et al. 1999). The interaction between αB-crystallin and α-synuclein can result in inhibition of chaperone activity (Rekas et al. 2004), and recent studies have shown that αB-crystallin can influence the α-synuclein fibrillation pathway (Waudby et al. 2010) and have implicated hyperphosphorylated αB-crystallin forms in MSA (Pountney et al. 2005b).

3.2 Heat Shock Protein 90

Hsp90 is a multifunctional protective chaperone protein, often working in concert with Hsp70 that is involved in the folding, refolding, and disaggregation of a diverse range of proteins. Other important functions of Hsp90 include the maintenance of tertiary structure and ATPase activity of proteasomes, activation of protein kinases, and activation of heat shock factor-1 (HSF-1). This functional diversity and specificity of Hsp90 is made possible by its conformational flexibility and dynamic association with various co-chaperone complexes. The association of Hsp70 and Hsc70 with

GCIs has been reported by Kawamoto and co-workers (2007), and the association of Hsp90 with GCIs has been reported by Trojanowksi and co-workers (Uryu et al. 2006), showing granular cytoplasmic Hsp90 staining of GCI-bearing cells. Recent studies indicate that pharmacological inhibition of Hsp90 can induce Hsp70 and promote clearance and detoxification of α-synuclein aggregates (Putcha et al. 2010). Hsp90 has also been linked to one form of chaperone-mediated autophagy (Kaushik et al. 2011), and the endoplasmic reticulum analogue of Hsp90 participates in the sorting of cargo proteins in autophagic clearance (Suntharalingam et al. 2012). Other recent studies have shown that Hsp90 associates with lysosomes and SUMO-1 in GCI-bearing cells in MSA (Wong et al. 2013).

4 Inflammation and Inflammatory Markers

Severe neuronal loss in MSA is seen in the substantia nigra, cerebellum, putamen, and locus coeruleus (Wenning et al. 1997), with neuronal loss in the brainstem and hypothalamus correlated with the autonomic dysfunction typical of MSA cases (Ozawa 2006). Considerable neuronal loss is also apparent in cortical areas, especially the motor cortex (Spargo et al. 1996; Su et al. 2001). Accompanying the neuronal loss, there is also commonly widespread demyelination observed in the white matter tracts (Papp et al. 1989). Astrogliosis and activated microglia are also found in those brain regions affected by neuronal loss and where there is a high GCI burden (Ozawa et al. 2004; Ishizawa et al. 2008), suggesting that inflammatory pathways are of major importance in MSA pathogenesis.

4.1 Microglia and Astroglia

The appearance of highly stellate, swollen, strongly GFAP-positive astrocytes is one of the most striking pathological features of MSA brain tissue, with this type of activated astrocyte morphology most often occurring in affected brain regions in cells neighboring GCI-positive oligodendrocytes. Figure 3 illustrates the juxtaposition of factors influencing oligodendrocyte GCI formation and astrocyte activation in MSA, with inset the typical morphology of an activated, GFAP-stained astrocyte and nearby GCI-positive oligodendrocyte observed in MSA brain tissue. The rounded morphology of activated microglia is also seen to accompany the more obvious astrocytic changes. Microglia have also been found to be more abundant in degraded regions of white matter in MSA (Ishizawa et al. 2008). The morphological indications of glial involvement in MSA is also reflected in the expression of markers for activated glia, such as increased astrocytic expression of metallothionein-III (Pountney et al. 2011) and indoleamine-2,3-dioxygenase (IDO; Radford et al. (unpublished data); Fig. 1f). Mouse models of MSA have also consistently implicated gliosis, especially microgliosis (Stefanova et al. 2005, 2007), and the interaction between α-synuclein and glial cell activation has recently been linked to the TLR4 receptor (Fellner et al. 2013).

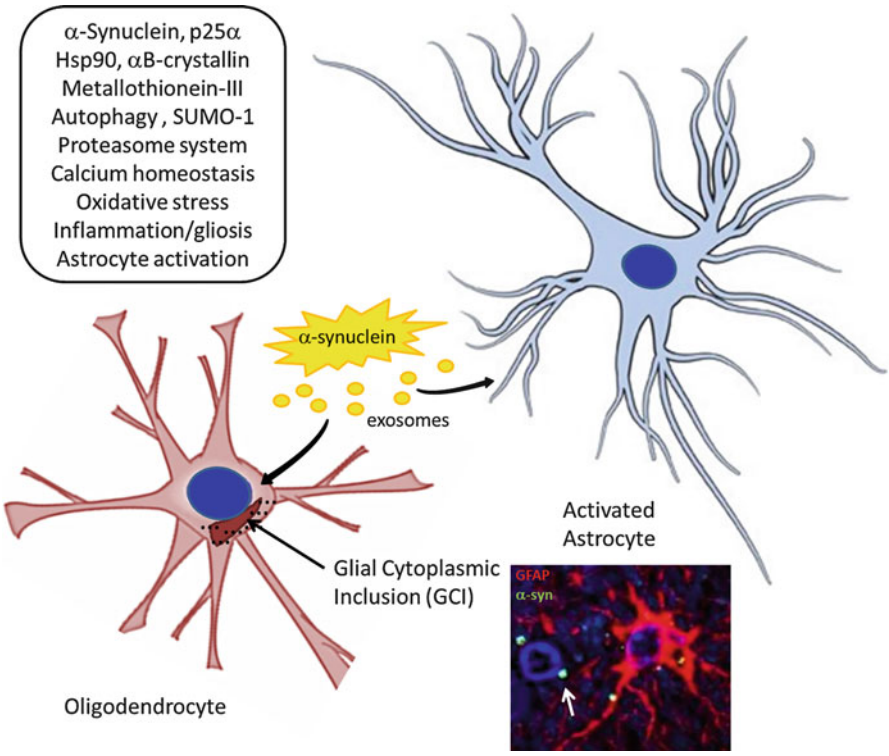

Fig. 3 *Diverse factors implicated in MSA pathogenesis result in oligodendroglial cytoplasmic inclusion body (GCI) formation and astrocyte and microglial activation*. GCI formation and oligodendrocyte dysfunction together with the activation of neighboring astrocytes and microglia are the primary features characterizing MSA, leading to the secondary neuronal degeneration. α-Synuclein secreted via the exosome pathway is taken up by oligodendrocytes and may act on astrocytes; however, the relationship between GCI formation and astrocyte activation remains unclear. Inset shows immunofluorescence of MSA tissue (visual cortex) stained for the astrocyte marker, GFAP, and α-synuclein, illustrating a GCI-bearing oligodendrocyte (*arrow*) and the characteristic morphology of a nearby activated astrocyte

4.2 Metallothionein

The metallothioneins (MTs) are small (6–7 KDa) proteins, the expression of which is induced by a wide range of factors, including heavy metals, glucocorticoids, cytokines, and oxidative stress, that current evidence suggest may have a number of specific functions in the brain (Chung et al. 2008; West et al. 2008; Vasák 2005). MTs bind zinc and copper, as well as toxic heavy metals, and have also been shown to efficiently scavenge reactive oxygen species, such as nitric oxide, thereby playing a protective role against oxidative cell damage. Mammalian MT isoforms are grouped according to their charge. MT-I/II isoforms are expressed in all mammalian tissues, whereas MT-III is expressed primarily in brain and MT-IV in

squamous endothelial tissues. Recently, a significant increase was found in the number of MT-III-positive cells, especially astrocytes, in MSA brain, compared to normal brain tissue (Pountney et al. 2011). MT-III immunoreactivity was also detected in GCIs, whereas the MT-I/II isoforms were not detected, indicating a specific association between MT-III and MSA. Recent evidence shows that MT-I/II is released from astrocytes during brain injury and interacts with a neuronal cell-surface receptor to promote neuronal survival, although much less is known about the function of other isoforms. MT-III (or neuronal growth inhibitory factor, GIF) can inhibit neuritic sprouting of cultured neurons and has been reported to be downregulated in Alzheimer's disease neurons (Uchida et al. 1991; Su et al. 2001) yet is unchanged in Alzheimer's mouse models (Carrasco et al. 2006). MT-III may be linked to the cellular response to mild CNS insult, such as neurotrauma, kainic acid-induced seizures, and autoimmune responses, being coordinated with the action of various neurotrophic factors. The origin of metallothionein-III in MSA may relate to the known association of these proteins with neuroinflammation and oxidative stress (Manso et al. 2011) or may indicate a disturbance of metal ion homeostasis. MT-III has also been linked to lysosome function in astrocytes (Lee and Koh 2010). Interestingly, recent studies have shown that astrocyte expression of MT-III can promote actin polymerization (Lee et al. 2011), and so it may be that increased expression of this protein occurs as a consequence of the cytoskeletal changes during astrocyte activation.

5 Calcium Homeostasis

It has been speculated that calcium may play a crucial role in the pathogenesis of neurodegenerative diseases, such as α-synucleinopathies (Mattson 2007). In PD pathology, it has been noted previously that neurons with higher levels of the calcium buffer, calbindin/D28K, are relatively spared (Yamada et al. 1990) and there may be an interplay between calcium homoeostasis and dopamine in mediating neuronal cell death (Mosharov et al. 2009). Indeed, α-synuclein has been found to perturb cellular calcium homoeostasis (Hettiarachchi et al. 2009; Danzer et al. 2007). Recently, it was demonstrated that increased intracellular free calcium causes the formation of microscopically visible α-synuclein aggregates in the cytoplasm of α-syn-eGFP-transfected human glioma cells (Nath et al. 2011) and more recently that oxidative stress and raised calcium can act synergistically to cause α-synuclein aggregation (Goodwin et al. 2012).

6 Ubiquitin and Ubiquitin Homologues

Ubiquitin, a small protein that attaches covalently to other proteins to target them to cellular pathways, such as proteasomal degradation, has long been known as

a major component of GCIs, and its presence has been linked both to the ubiquitin proteasome system, autophagy, and aggresome biogenesis. Recent studies indicate that polyubiquitin chains can be linked one ubiquitin to the next via many different ubiquitin functional groups, with each different type of ubiquitin chain conferring a different function on the modified protein carrying it, with the lysine-63-linked polyubiquitin targeting proteins to the aggresome and K48-linked ubiquitin chains targeting the proteasome (Kulathu and Komander 2012; Trempe 2011). Deubiquitinated α-synuclein is targeted for autophagic degradation, while monoubiquitination preferentially targets α-synuclein to the proteasome (Rott et al. 2011). In MSA, ubiquitin modifications of various proteins have been reported, including parkin and α-synuclein, and compromise of the ubiquitin proteasome system has also been inferred based on reduced 20S proteasome subunit expression (Bukhatwa et al. 2010). Soluble aggregated forms of α-synuclein have been shown to bind to the 19S cap of the 26S proteasome and inhibit proteasome-mediated protein degradation (Snyder et al. 2003; Lindersson et al. 2004). In a recent study using a transgenic mouse model of MSA expressing α-synuclein under an oligodendrocyte-specific promoter, Stefanova and co-workers (2012) have shown that proteasome inhibition caused by administration of a chemical inhibitor led to an MSA phenotype with pathological features, including fibrillar glial α-synuclein aggregates, demyelination, and axonal disturbances, that closely mirror those of MSA.

6.1 SUMO-1

In 2005, it was reported that minute subdomains exist in GCIs that are marked by small ubiquitin-like modifier, SUMO-1 (Pountney et al. 2005c). SUMO (small ubiquitin-like modifier) is similar to ubiquitin in structure but with more diverse physiological functions. SUMOylation requires the coordinated actions of E1 (SUMO activating), E2 (SUMO-specific conjugating, Ubc9) and, in most cases, E3 (SUMO ligase, e.g., PIAS3) enzymes, and despite being a covalent protein modification, SUMOylation is readily reversed by SUMO-specific deSUMOylation enzymes, SENPs. Thus, the balance between Ubc9-mediated conjugation and SENP-mediated deconjugation determines the SUMOylation state (Martin et al. 2007). SUMOylation can inhibit protein binding or, alternatively, SUMOylation of target proteins can promote interactions with other proteins via SUMO interaction motifs (SIMs). SUMOylation functions to regulate nucleocytoplasmic transport by modification of RanGAP1 and subsequent association with the nuclear pore complex and also has roles in mitochondrial fission. SUMOylation modifies the mitotic spindle and, by mediating non-covalent interactions with dynamin, influences endocytosis. SUMO-1 has also been linked to a range of neuropathological protein species; indeed, both α-synuclein and tau have been shown to be capable of SUMO-1 modification (Krumova and Weishaupt 2012). SUMO-1 was first identified in pathological inclusion bodies in neuronal intranuclear inclusions in neuronal

intranuclear inclusion disease, spinocerebellar ataxia type III, and Huntington's disease (Pountney et al. 2003). Recent studies have shown that neuron-specific expression of the SUMO-2 isoform can result in some SUMOylation of α-synuclein and that the SUMOylated protein is less prone to aggregation (Krumova et al. 2011). However, the significance of this finding to glial cells is unclear. Several target proteins of SUMO-1 have been determined in intranuclear inclusions that could be associated with lysosomal or secretory pathways (Hsp90, Munc18, NSF, and dynamin-1) (Pountney et al. 2008), and it has been shown that SUMO-1 marks a subset of lysosomes in MSA and in glial cell culture models of proteolytic stress and protein aggregation. This tagging of lysosomes by SUMO-1 is correlated with the presence of cytoplasmic inclusion bodies and associated with Hsp90, suggesting SUMO-dependent modulation of the autophagy pathway in MSA (Wong et al. 2013).

7 Autophagy

Autophagy is an evolutionarily conserved bulk degradation process that involves lysosomes. There are three types of autophagy: microautophagy which is the direct uptake of cytosolic proteins or organelles into the lysosome, chaperone-mediated autophagy which involves the chaperone conjugate Hsc70 directing protein substrates to the lysosome, and also macroautophagy (autophagy) which involves the formation of autophagosomes that then fuse with endosomes or lysosomes (Klionsky et al. 2011). Significant progress has been made in delineating the molecular mechanisms of chaperone-mediated autophagy that includes targeting of proteins via EF1α and interaction with GFAP at the lysosomal membrane (Kaushik et al. 2011). Recent studies have linked hsc70 also to a selective variant of autophagy that involves translocation of proteins via the multivesicular body (Sahu et al. 2011). Experiments have shown that autophagy is highly important in neural cells and disruption of the process can lead to aggregate formation and neurodegeneration, further highlighting its importance in neural tissue. The autophagy pathway has been implicated in neurodegenerative disease, and evidence of the pathways' involvement in MSA is seen in the presence of LC3 and lysosome components in glial inclusion bodies (Schwarz et al. 2012). Autophagy has been shown to contribute to aggresome clearance in neurodegenerative models and is believed to be an important cellular response to increased aggregating protein stress. Mouse knockouts of autophagy genes show progressive neurodegeneration, and disease-linked α-synuclein forms have been shown to inhibit chaperone-mediated autophagy (Rami 2009). Macroautophagy can enable the clearance of α-synuclein aggregates, and disruption of the process can lead to aggregate formation and neurodegeneration, further highlighting its importance in neural tissue (Crews et al. 2010). All of these studies indicate a neuroprotective role for the autophagy pathway in neurodegenerative disease and raise the possibility of modulating this pathway as a therapeutic treatment.

8 Oxidative Stress

Oxidative stress arises from an imbalance between the cellular processes that can generate powerful oxidants, such as superoxide and peroxynitrite, and the cellular defenses, such as glutathione, that normally combat them. Oxidative stress of neural cells has been implicated in the pathology of many neurodegenerative diseases, including MSA, and may play an important role in the development of MSA pathology, with the occurrence in GCIs of oxidized components, such as nitrated α-synuclein and protein-bound 4-hydroxy-2-nonenal (Gómez-Tortosa et al. 2002; Norris and Giasson 2005; Shibata et al. 2010). Oxidative nucleic acid damage has also been reported in MSA (Kikuchi et al. 2002). Furthermore, oxidation is among the many different exogenous factors, including metal ions and lipids, that have been shown to induce the formation of potentially cytotoxic soluble α-synuclein oligomers in cell culture and animal models of MSA (Breydo et al. 2012; Stefanova et al. 2005, 2007; Riedel et al. 2007; Ubhi et al. 2009). Recently, the interaction between oxidation/oxidative stress and raised calcium was investigated, and it was found that these two factors act synergistically to induce α-synuclein aggregates in vitro and in glial cells (Goodwin et al. 2012).

9 Conclusion

In conclusion, there is a strong burden of evidence pointing to a pivotal role of α-synuclein aggregation in MSA development. Although it is likely that aggregated α-synuclein forms occur at an early stage in the disease progression, there are many factors that have been identified, including oxidative stress and calcium dysregulation, that may participate in triggering the production of the pathogenic forms of the protein. The role of α-synuclein posttranslational modifications, such as Ser-129 phosphorylation, is also unclear, especially with respect to the timing of the modifications either as a precursor to or a consequence of aggregate formation. Accumulation in GCIs of α-synuclein and another small, acidic protein, metallothionein-III, even though mature oligodendrocytes do not normally express either protein, suggests that abnormal uptake of proteins by oligodendrocytes may be a feature of the etiology of MSA. Indeed, extracellular roles for both α-synuclein and MT-III have recently been reported. Future studies will need to address the causes of (and potential remedies for) α-synuclein aggregation in MSA as well as the origin of the protein in glial cells.

Another important aspect of MSA pathogenesis that will need to be probed further is the relationship between the formation of GCIs primarily in oligodendrocyte cells and the activation of neighboring astrocytes and microglia. Although it is clear that neuronal degeneration in the disease occurs as a downstream consequence of the glial cell disturbances, the relative importance of oligodendroglial dysfunction and demyelination compared to the influence of the inflammatory cytokines and astrocyte and microglial activation is unknown. Indeed, recent studies by Sofroniew and

co-workers suggest that reactive astrogliosis may even have some neuroprotective as well as deleterious effects on neuronal survival in injured brain tissue (Sofroniew 2009; Verkhratsky et al. 2012).

Neurotoxic Vulnerability Underlying Schizophrenia Spectrum Disorders

Trevor Archer, Ulla Karilampi, Serafino Ricci, and Max Rapp-Ricciardi

Contents

Abstract

Neurotoxic vulnerability that putatively contributes to the etiopathogenesis of schizophrenia spectrum disorders encompasses perinatal adversity, genetic linkage, epigenetic disadvantage, and neurodegenerative propensities that affect both symptom domains, positive, negative, and cognitive, and biomarkers of the disorder. Molecular and cellular apoptosis/excitotoxicity that culminates in regional brain loss, reductions in reelin expression, trophic disruption, perinatal adversity, glycogen synthase kinase-3 dysregulation, and various instances of

oxidative stress all influence the final end point disorder. The existence of prodromal psychotic phases, structural–functional aspects of regional neuroimaging, dopamine signal overexpression, and psychosis propensity provide substance for neurodegenerative influences. The pathophysiology of schizophrenia spectrum disorder encompasses the destruction of normal functioning of the neurotrophins, in particular brain-derived neurotrophic factor (BDNF), dyskinesia of necessary movements, and metabolic–metabolomic and proteomic markers. Neurotoxic accidents combined with genetic susceptibility appear to play a role in interfering with normal neurodevelopment or in tissue-destructive neurodegeneration or both, thereby elevating the eventual risk for disorder tendencies and eventual expression.

1 Introduction

The contributions of neurotoxic circumstances to the development, predisposition, precipitation, and eventual expression of schizophrenia spectrum disorders may be sought at different levels of etiopathophysiogenesis. Several lines of evidence imply that these disorders originate from the abnormal development of the central nervous system (CNS) peculiar to the human condition, as exemplified by the entorhinal cortex that is involved in widespread cognitive networks (Akil and Lewis 1997; Arnold et al. 1991, 1997; Falkai et al. 2003). These may be illustrated in several respects. Both structural and functional abnormalities are associated with development of schizophrenia spectrum disorders: for example, lateral ventricular and third and fourth ventricular enlargements accompanied by reduced prefrontal, thalamic, and hippocampal volume have been observed consistently in the brain of patients afflicted by the disorder (Welch et al. 2011). These deficiencies include smaller-sized hippocampus and entorhinal cortex both associated with reduced neuronal body sizes (Baiano et al. 2008; Jonsson et al. 1999; Turetsky et al. 2003; Zaidel et al. 1997). Alexander-Bloch et al. (2010) have observed disrupted modularity and local connectivity of brain functional networks in childhood-onset schizophrenia. It has been shown too that both neuropsychologically near normal and neuropsychologically impaired patients had markedly smaller gray matter and larger third ventricle volumes than healthy comparison subjects. However, only neuropsychologically impaired patients had significantly less white matter and larger lateral ventricle volumes than healthy comparison subjects (Wexler et al. 2009). Thoma et al. (2009) showed that neuropsychological-functioning schizophrenic patients were impaired overall, and anterior hippocampus volume was smaller in the patient group. In healthy controls, the hippocampus–memory relationships involved the anterior and posterior hippocampus wherein correlations were significant for verbal memory measures. Among the schizophrenia patients,

positive correlations were constrained to the posterior hippocampus. Negative correlations emerged between anterior hippocampus and verbal and visual memory measures. For both groups, cortical volume negatively correlated with age, but a negative correlation between age and hippocampus volume was found only among the schizophrenia patients. In their sample of adults with schizophrenia, atypical relationships between regional hippocampus volumes and episodic memory ability were found, as was an atypical negative association between hippocampus volume and age. Taken together, these diverse observations on the abnormal structural–functional relationships in schizophrenia spectrum disorders prompt notions of neurodegenerative disruptions during the early and later life cycles of brain development.

Imaging studies (positron emission tomography [PET]) or single photon emission tomography (SPET) and magnetic resonance imaging (MRI) attest to regional glutamatergic abnormalities in psychosis and are beginning to describe both the neurodevelopment of these abnormalities over the course of the illness and their response to therapeutic intervention (Egerton and Stone 2012). Fitzgerald (2012) discussed an N-methyl-D-aspartate Receptor (NMDAR) "suppression" hypothesis that focuses upon several aspects of evidence for NMDA influence in disorder: (1) epilepsy studies, (2) neurotoxicity studies, (3) mouse knockout studies of particular receptor subunits, (4) electrophysiological studies, (5) 2-deoxyglucose studies, and (6) functional brain imaging studies. Further, the activation of glycogen synthase kinase-3 (GSK-3) has been implicated in the cellular neurotoxicity of NMDAR antagonists (Large et al. 2011), with GSK-3 also implicated in schizophrenia (Brambrink et al. 2012; Pollard et al. 2012). Chan et al. (2012) have shown the critical role of glycogen synthase kinase-3 (GSK-3) in the expression of neurobehavioral aberrations associated with NMDAR hypofunction. They have suggested that GSK-3 inhibitors may ameliorate certain behavioral and cognitive dysfunctions in patients presenting schizophrenia. Neurotoxicity may be initiated by inflammatory agents: as described by Burd et al. (2012), infection-induced maternal immune activation leads to a fetal inflammatory response mediated through cytokines and are implicated in the pathophysiology of not only periventricular leukomalacia and cerebral palsy but also a spectrum of neurodevelopmental disorders, including attention-deficit hyperactivity disorder (ADHD), autism, and schizophrenia. Alternatively, Marona-Lewicka et al. (2011) have proposed an LSD model of schizophrenia whereby the chronic treatment of rats with low doses of LSD can serve as a new animal model of psychosis that may mimic the development and progression of the disorder.

Neurotoxic influences in schizophrenia spectrum disorders, to a large extent, would appear to be based upon circumstantial evidence rather than hard neurodegenerative loss of essential tissue, thereby rendering the associations somewhat tenuous. Notwithstanding these obvious constraints, there exists a sufficiency of observations from laboratory animal model studies, neuroimaging studies, and postmortem assays together with a neurodevelopmental viewpoint of disorder etiopathogenesis, suggesting that neurodegenerative processes contribute to heightened predisposition and susceptibility to the precipitation of symptom domains through a staging notion (Archer et al. 2010a, b). Genetic risk factors may impact

upon or disrupt developmental trajectories (Dauvermann et al. 2012; Sullivan et al. 2003). Indeed, genetic predispositions for neurodegenerative influences may be quite likely, since despite the absence of astrogliosis, impaired expression of astrocyte- and oligodendrocyte-related genes was observed in patients with major psychiatric disorders, including schizophrenia and mood disorders (Steiner et al. 2011). There is much support for the notion that schizophrenia spectrum disorders have their origin during gestation and/or in early infancy (Graff et al. 2011; Sawa and Snyder 2002). Insults during the early infancy or perinatal period, or even during the course of early-to-late childhood and adolescence, are implicated in the etiopathogenesis of the marked structural and functional abnormalities that distinguish the symptoms of disorder (Cannon et al. 2002a, b; Fontes et al. 2011; Geddes et al. 1999). The eventual contribution of neurodegenerative processes affecting the disorder must take into account the plethora of interactive factors and agents that include inherited and acquired attributes (Elia et al. 2011; Jablonka and Raz 2009). The disorder pathophysiology may involve the influences of several contributory processes, including cellular apoptosis/excitotoxicity, viral and bacterial infections, anoxic birth injury, maternal starvation, and other conditions exerting detrimental effects on neurogenesis. Both neurogenetic and epigenetic forces arising from gene-environment interactions affecting developmental trajectories impart levels of predisposing vulnerability that may or may not lead to the manifestation of schizophrenic symptoms (Gratacos et al. 2007; Hoenicka et al. 2010) or those of related conditions (Bergman et al. 2011; Jacob et al. 2010). Whether or not the neurodegenerative aspect of the disorder may be neurogenetic or epigenetic, there does exist compelling evidence for expressions of the disruptive influence affecting normal development.

2 Regional Loss

At first sight, the accumulated evidence for progressive volumetric loss, e.g., in cortical volume/thickness (Honea et al. 2008; Goldman et al. 2009) and loss of functional connectivity (Meyer-Lindenberg et al. 2005; Yu et al. 2011), argues for the aspect of neurodegeneration in schizophrenia. Yet the possible impact of peristaltic and environmental agents must be understood prior to deriving a reliable conclusion (Meyer-Lindenberg 2011). For example, Goto et al. (2010) compared 18 patients (9 males, 9 females; age range: 13–52 years) with 18 healthy volunteers (9 males, 9 females; age range: 15–49 years) with no current or past psychiatric history, using magnetic resonance spectroscopy (MRS). They found that levels of *N*-acetylaspartate/Cr in the left basal ganglia and parieto-occipital lobe, but not in the frontal lobe, were significantly lower in patients with first-episode schizophrenia psychosis than in control subjects. No differences were observed between the serum brain-derived neurotrophic factor levels of patients with first-episode schizophrenia psychosis and the healthy control subjects. The plasma levels of catecholamine metabolites, plasma 3-methoxy-4-hydroxyphenylglycol (MHPG), but not homovanillic acid (HVA), were

significantly lower in the patients with first-episode psychosis than in control subjects. In addition, a significantly positive correlation was observed between the levels of *N*-acetylaspartate/Cr of the left basal ganglia and plasma MHPG in all subjects. The authors concluded that brain *N*-acetylaspartate levels in the left basal ganglia and plasma MHPG levels were significantly reduced at the first episode of schizophrenia psychosis, indicating that neurodegeneration via noradrenergic neurons might be associated with the initial progression of the disease.

Regional loss of glutamate and glutamine in schizophrenic patients (Tayoshi et al. 2009) may offer evidence of an excitotoxic process in the disorder pathophysiology. The loss of parvalbumin-containing cells, an observation that has been reported consistently in postmortem analysis of the brains of schizophrenic patients following NMDAR blockade, offers support for this notion (Adell et al. 2012; Dean et al. 2011). Aoyama et al. (2011) have demonstrated that the loss of thalamic glutamate in the brain of schizophrenia patients correlated significantly with loss of gray matter in the middle and inferior frontal gyrus and temporal pole. Thalamic gray matter and glutamate losses were observed in individuals at risk for developing schizophrenia (Stone et al. 2009). Glutamate-glutamine ratios in the frontal cortices of adolescents at risk for the disorder are correlated, as well as performance scores on the Global Assessment of Functioning Scale (Tibbo et al. 2004). It has been suggested that the elevated glutamine levels in never-treated patients followed by the decreased level of thalamic glutamine and gray matter loss in connected regions may be indicative of either neurodegeneration or a plastic response to reduced subcortical activity (Theberge et al. 2007). There appears to be a consensus of sorts for an excitotoxic contribution primarily in early stage schizophrenia (Bustillo et al. 2010). Glutamatergic alterations and loss of cortical gray matter originating from basal ganglia-corticothalamic circuits may be the expressions of excitotoxicity through these regions. First-episode schizophrenic patients have exhibited increased membrane breakdown in magnetic resonance spectroscopy applying labeled phosphorous (Miller et al. 2009).

3 Perinatal Adversity

Several perinatal insults have been shown to induce schizophrenia-like symptoms in a laboratory setting (Archer 2010). Bilateral excitotoxin-induced lesions, administering ibotenic acid to the ventral hippocampus typically to 7-day-old rat pups, induces disruptions of prepulse inhibition (PPI) to the acoustic startle response, a model of sensory gating in rodents, hyper-responsiveness to stressful stimuli, supersensitivity to dopamine (DA) agonists, and NMDAR antagonists (Lipska et al. 1992, 1995, 2001; Tseng et al. 2007, 2009). Additionally, persistent deficits in working memory and spatial navigational learning (O'Donnell et al. 2002), together with hyper-responsiveness to stimulation of the ventral tegmental area (Lillrank et al. 1999; Lipska and Weinberger 1994), have all been observed in neonatal ventral hippocampus-lesioned rats. Prenatal administration of methylazoxymethanol (MAM) disrupts early brain development with structural and functional

abnormalities in the cortex and hippocampus, many of which bear similarities to schizophrenia, expressed in the adult rats (Flagstad et al. 2005; Lodge and Grace 2008; Mohammed et al. 1986a, b; Moore et al. 2006). MAM induces programmed cell death in neuroepithelial-proliferating cells (Cattabeni and Di Luca 1997), without causing any teratogenic effects in any other organs (Balduini et al. 1991). It is generally administered on embryonic, gestation, day 17 (E17) as this is when neurogenesis peaks in the hippocampal formation (Bayer and Altman 2004), and the time when projections between the hippocampus and entorhinal cortex are established (Ceranik et al. 1999). Hippocampal formation disruption is central to schizophrenia pathophysiology (Harrison 2004). The utility of prenatal MAM as an animal model of the disorder highlights the neurodegenerative aspect (Chen and Hillman 1986; Ferguson and Holson 1997; Ferguson et al. 1996; Virgili et al. 1997), particularly with regard to the neurocognitive deficits (Fiore et al. 2002; Gourevitch et al. 2004; Lee and Rabe 1992; Leng et al. 2005). The model has been validated by several studies (cf. Gill et al. 2011; Hradetzky et al. 2011; Lodge and Grace 2012; Valenti et al. 2011). Neurophysiological studies confirm that MAM-treated rats show an augmented DA system function consistent with enhanced DA signaling underlying positive symptoms of disorder and defective hippocampal interneurons (Konradi et al. 2011; Lahti et al. 2006). Similar to patients presenting cognitive deficit profiles in schizophrenia spectrum disorder (Karilampi et al. 2007, 2011), MAM induces marked deficits on an attentional-shift task (analogous to the Wisconsin Card Sorting Task) and on a differential reinforcement of low rate of responding (DRL-20 performance, analogous to continuous performance) task (Featherstone et al. 2007). Prenatal MAM administration disrupts early cortical development causing deficits in medial prefrontal functions at adult ages (Goto and Grace 2006). Sanderson et al. (2012) obtained a reduction in synaptic innervation and synaptic transmission in the dorsal hippocampus of MAM (E17)-treated rats, accompanied by a pronounced increase in CA1 pyramidal neuron excitability. These effects of the prenatally administered neurotoxin interrupt normal neuronal development, stress and immune response systems, and signal transduction mechanisms (Ciani et al. 2003; Ferrer et al. 1997; Lafarga et al. 1997; Rice and Barone 2000), thereby reinforcing its utility as a model of schizophrenia (Gill et al. 2011; Le Pen et al. 2011) and implying the neurotoxic aspect of the disorder.

Traumatic/adverse experiences during infancy and early childhood compromise healthy brain development in several domains, including cognitive, emotional, and motor. Traumatic environmental confrontation during early neurodevelopment, such as parental loss (maternal separation), that induces a marked provocation of the hypothalamic–pituitary–adrenal (HPA) axis was found to cause schizophrenia-like deficits, e.g., impairments of sensory gating, symptoms in the rats as adults (Ellenbroek et al. 1998), as well as other expression of the disorder (Furukawa et al. 1998). Rosenberg et al. (2007) surveyed 569 adults presenting schizophrenia with regard to adverse childhood events (including physical abuse, sexual abuse, parental mental illnesses, loss of a parent, parental separation or divorce, witnessing domestic violence, and foster or kinship care), evaluating the relationships between cumulative exposure to these events and psychiatric, physical, and functional

outcomes. They found that increased exposure to adverse childhood events was strongly related to psychiatric problems in both cognitive and emotional domains (suicidal thinking, hospitalizations, distress, and posttraumatic stress disorder), substance abuse, physical health problems (HIV infection), medical service utilization (physician visits), and poor social and daily care functioning (homelessness or criminal justice involvement). Similarly, Morgan et al. (2007) observed that separation from, and/or the death of, one parent prior to the age of 16 years was strongly associated with a twofold to threefold increases in the risk of psychosis. It was shown that the strength of these associations was similar for White British and Black Caribbean (but not Black African) subjects, although separation from (but not death of) a parent was more common among Black Caribbean controls than White British controls. Finally, a 10-year cohort of high security hospital patients who had either a personality disorder or schizophrenia found a rate of child–parent separation of 178/289 (62 %) in the schizophrenia group compared with a rate of 119/147 (81 %) in the personality disorder group of patients that had been separated from one or both parents before the age of 16 (Pert et al. 2004). Several studies have described the extreme adverse effects of perinatal starvation/malnutrition involving severe deficits of necessary nutrients, including folate, essential fatty acids, retinoids, vitamin D, and iron, the "nutritional hypothesis of schizophrenia" (Brown and Susser 2008). Additionally, elevated prenatal homocysteine level provides a plausible risk factor for schizophrenia because of its partial antagonism of *N*-methyl-D-aspartate receptors under physiologic glycine concentrations and its association with abnormal placental function and pregnancy complications (Bleich et al. 2007; Brown and Susser 2005; Brown et al. 2007).

An abundance of clinical and preclinical (animal modeling) findings posit the notion that immune system dysfunction(s) – related to genetic, environmental, and neurobiological influences – may play a role in the etiology of schizophrenia in a subset of patients (Richard and Brahm 2012). Exposure to prenatal immune challenge induces early pre- and postnatal alterations in peripheral and central inflammatory response systems. Consequentially, these alterations may disrupt the normal development and maturation of neuronal systems from juvenile to adult stages of life, thereby affecting brain structure and function. Developmental neuroinflammatory processes of this type may adversely affect processes that are pivotal for normal brain maturation, including myelination, synaptic pruning, and neuronal remodeling, all of which occur to a great extent during postnatal brain maturation (Meyer 2011). Brown and co-workers (Brown and Derkits 2010; Brown and Patterson 2011; Brown et al. 2009, 2011) and others (Arias et al. 2012; Nielsen et al. 2011; Tedla et al. 2011) have conducted birth cohort studies to address whether in utero exposure to infectious agents, prospectively documented by biomarker assays of archived maternal sera and by detailed obstetric records, confers an increased risk of schizophrenia in adult offspring. Prenatal exposure to influenza, elevated toxoplasma antibody, rubella, genital/reproductive infections, and other infections have been associated with an increased risk of schizophrenia among offspring. Animal models have supported these epidemiologic findings by revealing that maternal immune activation causes phenotypes analogous to those

found in patients with schizophrenia (Brown 2011). In a population-based study, Benros et al. (2011) have shown that autoimmune disease conditions and the number of infections requiring hospitalization pose risk factors for schizophrenia. Increased risk for the disorder was compatible with an immunological hypothesis in subgroups of schizophrenia patients.

4 Reelin Reduction

Reelin, present throughout the brain, spinal cord, blood, and other organs and tissues, is a large secreted extracellular matrix glycoprotein that facilitates regulation of processes involving neuronal migration and positioning in the developing brain by controlling cell–cell interactions and maintains its role in the adult brain. Reelin modulates synaptic plasticity and stimulates dendrite and dendritic spine development and regulates the continuing migration of neuroblasts generated at sites of adult neurogenesis (Niu et al. 2008). Expression of the protein is found to be significantly lower in schizophrenia and psychotic bipolar disorder (Maloku et al. 2010; Pisanté et al. 2009; Suzuki et al. 2008). Several studies have shown that in schizophrenia spectrum disorders, reelin expression in several brain regions, such as the cerebral cortex and hippocampus, is reduced (Eastwood and Harrison 2006; Fatemi et al. 2000; Impagnatiello et al. 1998). Reelin expression is reduced in the prefrontal cortex (PFC), hippocampus, caudate nucleus, and cerebellum of patients presenting psychotic illness (Guidotti et al. 2000; Tueting et al. 2006); GABAergic interneurons express reelin in several brain regions (Miyata et al. 2010; Pascual et al. 2004; Pesold et al. 1998). In order to induce prenatal infection (gestation days 15 and 16) in rat offspring, Nouel et al. (2012) exposed them to lipopolysaccharide, a bacterial endotoxin, and then assessed the number of reelin-immunoreactive (reelin+) cells and glutamic acid decarboxylase 67 (GAD67) immunoreactive (GAD67+) cells that were present in the hippocampus at postnatal days 14 and 28. They observed decreases in both reelin+ and GAD67+ expression in the dentate gyrus of infected animals at postnatal day 14 and concluded that prenatal infection caused postnatal reductions in postnatal reelin and GAD67. Prenatal exposure to influenza, elevated toxoplasma antibody, genital/reproductive infections, rubella, and other pathogens have been shown to be associated with schizophrenia (Brown 2012; Ducharme et al. 2012; Kneeland and Fatemi 2012; Macêdo et al. 2012).

Reelin regulates radial neuronal migration in the embryonic brain, promotes dendrite outgrowth in the developing postnatal forebrain, and strengthens synaptic transmission in the adult brain. In contrast, reelin deficiency induces specific defects in the molecular composition of the synapses in the adult brain (Ventruti et al. 2011). The MAM E17 model of schizophrenia was observed to cause whole neuronal density changes from the PFC and parvalbumin-positive-cell density changes from the hippocampus, and similar deficits were seen in the PFC of schizophrenic patients (Lodge et al. 2009; Moore et al. 2006). Matricon et al. (2010) exposed rat fetuses to MAM during E17 and then studied behavioral parameters and biomarkers in the adult animal. They found that behavioral

characteristics and neuropathology pertaining to the PFC similar to clinical features of the disorder were in evidence. In comparison with untreated offspring, MAM-exposed offspring showed a reduction in the volume of entorhinal cortex, hippocampus, and mediodorsal thalamus that was associated with reduced neuronal soma. The entorhinal cortex also showed laminar disorganization and neuronal clusters. Reelin methylation in the hippocampus formation was decreased although reelin + neurons and reelin expression were unchanged. They concluded that MAM-treated animals have a diminished neuropil possibly arising from abnormal neurite formation. The deterioration of the neuropil in cortical regions is implicated in the neuropathology of schizophrenia (Somenarain and Jones 2010). Protein loss in the disorder induces dendrites and spines to deteriorate in the dorsolateral PFC that is involved in several key cognitive domains.

5 Trophic Disruption

Brain-derived neurotrophic factor (BDNF) is essential for the maintenance of functional neurons, regulating growth, differentiation, synaptic connectivity, neurorepair, and longevity (Altar et al. 1997; Niu and Yip 2011). BDNF, central for the survival and differentiation of midbrain dopaminergic neurons (Hyman et al. 1991) and phenotypic differentiation of locus coeruleus noradrenergic neurons (Traver et al. 2006), has emerged as an important biomarker for schizophrenia spectrum disorder (Pae et al. 2012; Favalli et al. 2012; Zhang et al. 2012b). Sixty-three patients presenting schizophrenia symptoms were compared with 52 age- and sex-matched healthy controls for performance on a battery of neuropsychological tests by Niitsu et al. (2011). They found that although there were no significant differences in serum BDNF levels between normal controls and schizophrenic patients, serum BDNF levels for normal controls, but not schizophrenic patients, showed negative correlations with verbal working memory. On the other hand, serum BDNF levels of schizophrenic patients indicated positive correlations with the scores of the Scale for the Assessment of Negative Symptoms (SANS) and the Information subtest scores of Wechsler Adult Intelligence Scale Revised (WAIS-R). Serum BDNF levels were related with the impairment of verbal working memory and negative symptoms in patients with schizophrenia. In 22 acute schizophrenic patients and 22 age-matched healthy volunteers, Lee et al. (2011) observed significantly reduced serum levels in the unmedicated schizophrenic patients ($n = 22$; 4.38 ± 2.1 ng/mL) compared to the age-matched healthy volunteers. The percentage change of BDNF (increase, 173 % $\pm$ 110) correlated negatively with the percentage change of PANSS score with BDNF increase during psychotic treatment, as shown by several others (e.g., Pedrini et al. 2011; Yoshimura et al. 2007, 2010). Reduced BDNF concentrations have been reported in chronic antipsychotic-treated patients (Grillo et al. 2007; Ikeda et al. 2008; Rizos et al. 2010), neuroleptic-free (Palomino et al. 2006) and neuroleptic-naïve (Chen and Huang 2011; Rizos et al. 2008) patients. Finally, the levels of peripheral BDNF seem to be altered in first-episode patients presenting psychosis as well as in chronic schizophrenic patients. Although a paucity

of studies have reported changes in peripheral BDNF levels following antipsychotic treatment, the role of Val66Met polymorphism in BDNF has been found to contribute to structural and functional plasticity in schizophrenia (Buckley et al. 2007, 2011).

Long-term administration of antipsychotic agents induces tardive dyskinesias (TDs), a syndrome composed of involuntary, hyperkinetic, and abnormal movements often expressed through excessive chewing or dancing/foot shuffling behaviors (Jafari et al. 2012; Correll and Schenk 2008). Lower serum concentrations of BDNF, inversely correlated with Abnormal Involuntary Movement Scale (AIMS) scores, have been observed in patients presenting TDs (Tan et al. 2005). Additionally, associations between TD and BDNF polymorphisms have accumulated (Park et al. 2009; Zai et al. 2009). Yang et al. (2011) compared serum BDNF levels in schizophrenic patients with ($n = 129$) and without ($n = 235$) TDs with healthy controls ($n = 323$), with concurrent assessment of AIMS and the Positive and Negative Symptoms Scale (PANSS). Schizophrenic patients presenting TDs showed lower BDNF concentrations, while schizophrenic patients lacking TDs had BDNF levels similar to that of healthy controls. Lower BDNF serum concentrations correlated with higher PANSS negative subscores, but not with AIMS scores. The authors concluded that reduced BDNF concentrations may be associated with greater TD pathophysiology and negative symptoms in schizophrenia. Zhang et al. (2010) have indicated that schizophrenic patients with TD presented higher serum levels of S100B, a calcium-binding protein, than normal, healthy controls and those patients without TD. The serum S100B levels were positively correlated with AIMS scores in patients with TD. The authors concluded from these results that increased S100B levels may be related to the neurodegenerative aspect of disorder, associated with TD pathophysiology. TDs are generally indicative of neurodegenerative pathologies (e.g., Miller and Chouinard 1993).

6 GSK Regulation

The glycogen synthase kinase-3 s (GSK, α, and β), involved in glycogen metabolism, are expressed ubiquitously over various tissues and are abundant in brain tissue (Jaworski et al. 2011; Perez-Costas et al. 2010). Kaidanovich-Beilin and Woodgett (2011) have discussed the fundamental roles for these protein kinases in memory, behavior, and neuronal fate determination. It has been argued that Schizophrenia-1 (DISC1) represents a candidate gene for neuropsychiatric disorders and an influential involvement during brain structural and functional development. Singh et al. (2011) have observed that DISC1 variants are implicated in the loss of function in Wnt/GSK-3β signaling and thereby interrupt the course of brain development. Common DISC1 polymorphisms (variants) are associated with neuropsychiatric phenotypes including altered cognition, brain structure, and function. The contribution of the DISC1 gene to neural development and the eventual neurodevelopment of schizophrenia risk has been studied (Wexler and Geschwind 2011). GSK-3, a regulator of a wide range of cellular processes, plays a key dual role in apoptosis with putative contribution to schizophrenia neuropathology

(Emamian et al. 2004) and other neurodegenerative disorders (Avila et al. 2004; Berger et al. 2005; Onishi et al. 2011). Its role in the apoptotic signaling underlying excessive cell death may imply a neurodegenerative involvement in schizophrenia spectrum disorders, at least during the early stages of development (Gomez-Sintes et al. 2011). Astrocytic glycogenolysis and glycogen mobilization are implicated in normal brain function (Brown and Ransom 2007; Brown et al. 2003; Swanson 1992) and neuronal energy requirements (Brown et al. 2004; Wender et al. 2000), and not least in the necessities of cognitive function (Gibbs et al. 2006; Hertz et al. 2003; Suzuki et al. 2011). The links between glycogen metabolism and the glutathione (GSH) system have been studied (Dringen and Hirrlinger 2003): Shinohara et al. (2010) have shown that activation of GSK-3β is a key mediator of the initial phase of acetaminophen-induced liver injury through modulating glutamate cysteine ligase (GCL) and myeloid cell leukemia sequence-1 degradation. GSH deficits occur both in neurodegenerative conditions and in schizophrenia (Ballatori et al. 2009; Do et al. 2009; Dringen et al. 1997), and a GCL gene polymorphism, affecting GSH synthesis, is associated with the disorder (Tosic et al. 2006). In this regard, Lavoie et al. (2011) have found that glucose metabolism and glycogen utilization are dysregulated in astrocytes showing chronic deficit in GSH, implying dysfunctional brain energy metabolism in schizophrenia.

7 Oxidative Stress

Dysregulation in reactive oxygen species (ROS) and reactive nitrogen species (RNS) evidenced by lipid peroxidation in plasma, red blood cells, blood platelets, and cerebrospinal fluid have been observed in schizophrenic patients (Dietrich-Muszalska et al. 2005; Li et al. 2006; Yao et al. 1998, 2001). For example, Dietrich-Muszalska et al. (2005) found that oxidative stress occurred as reflected by superoxide dismutase (SOD) in platelets from schizophrenic patients; suppressed SOD activity was associated with enhanced ROS generation and lipid peroxidation as compared with healthy volunteers. In the acute phase of psychosis in schizophrenic patients, levels of isoprostanes were remarkably high compared with the healthy control group (Dietrich-Muszalska and Olas 2007). The isoprostanes are prostaglandin-like compounds formed in vivo from the free radical-catalyzed peroxidation of essential fatty acids (primarily arachidonic acid) without the direct action of cyclooxygenase (COX) enzyme, and increased levels are associated with oxidative stress and oxidative damage of lipids. During the same acute phase of psychosis, biomarker concentrations of oxidation/nitration proteins in plasma were markedly higher in patients, as too was the homocysteine (Hcys) level (Dietrich-Muszalska et al. 2009): Hcys may function as an oxidant both in vitro and in vivo (Carluccio et al. 2007; Olas et al. 2008) since there is a reduced plasma status of antioxidants in schizophrenic patients (Dietrich-Muszalska and Kontek 2010). Significant positive relationships between brain atrophy and plasma Hcys levels have been obtained (Bleich et al. 2002; Sachdev et al. 2002), with Hcys metabolism implicated in schizophrenia pathophysiology (Song et al. 2007).

Furthermore, increased third trimester Hcys concentrations could well enhance the risk for development of the disorder through structural and functional alterations (Brown and Ransom 2007). In this regard, Dietrich-Muszalska et al. (2012) investigated, in schizophrenic patients, the effect of elevated Hcys on parameters of oxidative stress, including thiobarbituric acid reactive substances (TBARS), levels of carbonyl groups in plasma proteins, and levels of 3-nitrotyrosine in plasma proteins. They observed that in these patients, plasma Hcys was greater than in controls. Also, the biomarkers of oxidative/nitrative stress, carbonyl groups and 3-nitrotyrosine, were enhanced significantly.

The pathophysiology of schizophrenia spectrum disorders may be the result of deregulation of synaptic plasticity, with downstream alterations of inflammatory immune processes regulated by cytokines, impaired antioxidant defense, and increased lipid peroxidation. Pedrini et al. (2012) examined serum oxidative stress markers and inflammatory cytokines in early and late phases of chronic SZ. They studied patients at early stage (within first 10 years of a psychotic episode), 39 at late stage (minimum 10 years after diagnosis of SZ), and their respective matched controls. From each patient/subject 5 mL blood samples were collected (venipuncture) for assay of TBARS, total reactive antioxidant potential (TRAP), protein carbonyl content (PCC), Interleukins 6 and 10 (IL-6, IL-10), and tumor necrosis factor alpha (TNF-alpha). TBARS, IL-6, and PCC levels were significantly higher in schizophrenic patients at early and late stages than in healthy controls. No differences for TRAP and TNF-alpha levels in patients with SZ at early and late stages than in controls were obtained. IL-10 levels were decreased in patients at late stage and a decrease trend in early stage was found. Their findings offer evidence consistent with comparable biological markers across the chronic disorder. Other results suggest that oxidative stress may be involved in the pathophysiology of the disorder and associated functioning, e.g., cognitive impairment: Zhang et al. (2012a) found that in schizophrenic patients' plasma, total antioxidant status was inversely associated with some domains of cognitive deficits in schizophrenia, such as attention and immediate memory. It is known too that adult neurogenesis transiently generates oxidative stress which may further contribute to the pathophysiology (Walton et al. 2012). Finally, Sullivan and O'Donnell (2012) have advanced the notion of an *excitation–inhibition imbalance* hypothesis of the neurodevelopment of symptom profiles in schizophrenia spectrum disorders; they have examined ongoing efforts that investigate the determination of whether or not cortical inhibitory interneurons are affected by oxidative stress during brain development.

8 Saitohin Gene Expression

Finally, Saitohin, an intronless gene nested within the human tau gene that contains a single nucleotide polymorphism (A/G), may be involved in the pathophysiology of neurodegenerative disorders (Combarros et al. 2003). The Saitohin gene is unique to humans and their closest relatives although function is not currently understood. It contains a single polymorphism (Q7R); the Q allele is human specific

and confers susceptibility to several neurodegenerative diseases (Gao et al. 2005; Wang et al. 2011). Certain neurodegenerative disorders, particularly Alzheimer's disease and progressive nuclear palsy, have been found to be associated with the presence of the Q allele of the Saitohin gene (Janković et al. 2008; Lorenzi et al. 2010; Schutte et al. 2011). In a sample of 48 schizophrenic patients and 47 healthy controls, Bosia et al. (2011) tested the role of saitohin polymorphism as a concurring factor of cognitive decline among these patients using the Wisconsin Card Sorting Test for executive functioning. They observed a significantly greater frequency of G allele among patients with frontotemporal dementia and schizophrenic patients presenting impaired Wisconsin Card Sorting Test performance. They concluded that the products expressed by the Saitohin gene affected core frontal executive function deterioration likely through mechanisms occurring through neurodevelopment with neurodegenerative outcome.

9 Conclusion

The myelin-centered model of the human brain's extensive and effective myelination implies the availability of higher metabolic resources underlying evolutionary adaptations resulting in the quadratic (inverted U) myelination trajectory that is peaking during the sixth decade of life (Bartzokis 2011). The notion proposes further that optimal brain function depends on exquisite action potential synchronization that myelin makes possible and that myelin's exceptional vulnerability to subtle metabolic/oxidative abnormalities may promote both developmental and degenerative diseases. It remains a possibility that in the interventions for schizophrenia spectrum disorders, the widespread use of psychotropic treatments may induce underappreciated CNS metabolic and neurotransmitter effects on myelination, its plasticity, and neuronal repair (Bartzokis 2011).

Neurotoxicity of Methamphetamine

Rosario Moratalla, Sara Ares-Santos, and Noelia Granado

Contents

Abstract

Recreational consumption of the highly addictive psychostimulant methamphetamine is becoming a serious public health problem worldwide. Recent estimates indicate that methamphetamine abuse has increased in the last decade and that only cannabis is used by a greater number of consumers. Despite its popularity, methamphetamine is a known neurotoxin that damages dopaminergic terminals

in the striatum, as indicated by reductions in striatal levels of dopamine and its metabolites and a sustained decrease in the expression of markers for dopaminergic terminals such as TH and DAT. In addition, methamphetamine affects the cell bodies of these same dopaminergic neurons in the substantia nigra, resulting in cell loss. The mechanisms underlying dopaminergic neurotoxicity are the focus of intense research, and knowledge in this area has expanded in recent decades. Evidence from previous studies points to dysregulation of dopamine, oxidative stress, DNA damage, and mitochondrial dysfunction as the main causes of methamphetamine neurotoxicity. The dopamine receptors D1 and D2 also play an important role in methamphetamine-induced neurotoxicity since inactivation of either receptor is neuroprotective against methamphetamine. Recent results from clinical research indicate that methamphetamine abusers have a higher risk of developing Parkinson's disease; this is in keeping with results in laboratory animals and confirms the persistence of methamphetamine-induced dopaminergic injury. These findings suggest that neuroprotective strategies that are effective against methamphetamine-induced toxicity are also promising candidates for preventive therapy for Parkinson's disease and other persistent dopaminergic injuries.

Keywords

Amphetamine derivatives • Designer drugs • Dopamine • Drug addiction • Methamphetamine • Neurotoxicity • Parkinson's disease • Psychomotor stimulants

List of Abbreviations

ATS	Amphetamine-type stimulants
$D1R^{-/-}$	D1R knockout mice
D1R	Dopamine D1 receptor
$D2R^{-/-}$	D2R knockout mice
D2R	Dopamine D2 receptor
DAT	Dopamine transporter
DOPAC	3,4-Dihydroxyphenylacetic acid
Gclm	γ-Cysteine ligase modulatory subunit
Gclc	γ-Cysteine ligase catalytic subunit
GPx	Glutathione peroxidase
HVA	Homovanillic acid
MDMA	3,4-Methylendioxymethamphetamine also called "ecstasy"
Nrf2	Nuclear factor-erythroid 2-related factor 2
PD	Parkinson's disease
ROS	Reactive oxygen species
SNpc	Substantia nigra pars compacta
TH	Tyrosine hydroxylase
VMAT2	Vesicular monoamine transporter

1 Introduction

1.1 Background, Medical Use, and Epidemiology

Methamphetamine (*N*-methyl-1-phenylpropan-2-amine) is a synthetic drug first used clinically at the beginning of the twentieth century. Therapeutic use of methamphetamine was based on its sympathicomimetic properties, but its current illicit use as a recreational drug in several countries around the world is due to its psychostimulant effects. It is also used for weight loss and for enhancing alertness, focus, motivation, and mental clarity for extended periods of time. Methamphetamine is structurally related to the neurotransmitters dopamine and phenylethylamine, and to other psychostimulant drugs like amphetamines (Fig. 1).

Methamphetamine has proven to be highly addictive and its abuse can result in severe psychological and physical dependence. It is therefore classified as a Schedule II drug under the Convention on Psychotropic Substances. Methamphetamine abuse is increasingly recognized as a major global health problem (Degenhardt et al. 2008). The 2012 World Drug Report (UNODC 2012) suggests that the global use of amphetamine-type stimulants (ATS; methamphetamine,

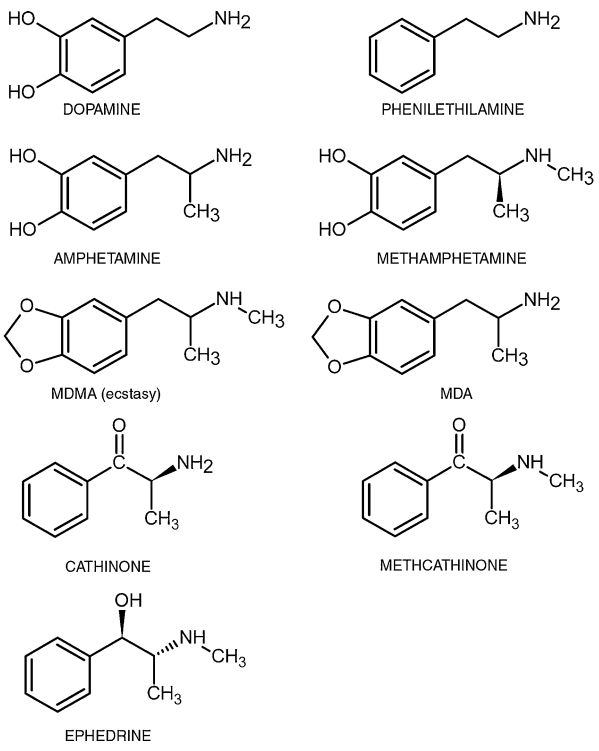

Fig. 1 Chemical structures of methamphetamine and related amphetamine compounds. All compounds share chemical structure with dopamine and therefore have strong effects on the dopamine system

amphetamine, and methcathionine) (excluding "ecstasy") is second only to cannabis. They were used by 14–53 million people in 2010 equivalent to 0.3–1.2 % of the global population aged 15–64 years.

1.2 Administration Routes and Patterns of Methamphetamine Use

Methamphetamine comes in several forms. The hydrochloride salt of methamphetamine is a white, crystalline, bitter, odorless powder. It is water-soluble and strongly hygroscopic (absorbs water quickly). The common street names "speed," "Meth," or "chalk" refer to the salt, while "crystal," "crystal Meth," and "ice" refer to crystalline methamphetamine, a form purer than the powder. Methamphetamine is also known by a variety of other names, including shabu, batu, D-meth, tina, and glass. Methamphetamine freebase is oily and is uncommon on the street.

Methamphetamine can be taken orally (in pill form), by intravenous injection, smoking, snorting (in powder form), or by anal or vaginal insertion of a suppository. The effects experienced by the user last 6–8 h, depending on the rate at which methamphetamine reaches the blood, which depends on the route of administration. The faster the drug reaches the blood, the greater the "high" and other effects experienced by the user.

Following administration by any route, methamphetamine is distributed through most organs, including the lungs, liver, and stomach. Moderate levels reach the brain by crossing the blood–brain barrier. It also crosses the placenta and is secreted into breast milk. Methamphetamine is metabolized in the liver, with the main metabolites including the active compounds amphetamine, 4-hydrooxyamphetamine, and norephedrine. The concentration of amphetamine metabolite peaks at 10–24 h post-administration.

Methamphetamine abuse has two distinct use patterns. The first, characterized by low intensity use, does not confer psychological dependence. The second, known as "binge" use, consists of repeated redosing, usually by inhalation or injection, for several days in a row; generally, withdrawal symptoms occur when drug delivery is stopped abruptly.

1.3 Methamphetamine: Mechanism of Action and Effects

Methamphetamine's effects on the body are due to its structural resemblance to the neurotransmitter dopamine (Fig. 1). It easily crosses the blood–brain barrier, reaches the brain, and enters the axons of dopaminergic neurons through the dopamine transporter DAT and by passive diffusion (Granado et al. 2011a; Krasnova and Cadet 2009). Once inside the axon, methamphetamine triggers the release of dopamine from synaptic storage vesicles, resulting in an unusually high concentration of dopamine in the cytoplasm (Krasnova and Cadet 2009). Methamphetamine cannot directly activate dopamine receptors; rather, it acts as an indirect

dopamine agonist that increases dopamine concentration in the synapse by increasing dopamine release and blocking dopamine uptake. Methamphetamine also releases norepinephrine and serotonin by a similar mechanism; however, in the brain, methamphetamine is selectively concentrated in norepinephrine and dopamine nerve terminals because it is a substrate for the molecular transporters present in these terminals.

As a consequence of this increased release of dopamine in several areas of the brain, methamphetamine produces a number of acute psychological effects including euphoria (also known as "flash" or "rush", and lasting only several minutes). After this first short period, other feelings and behaviors may appear, including a false sense of self-confidence and power (delusions of grandeur), loquacity, moodiness, irritability, anxiousness, nervousness, aggressiveness, and violent behavior. Methamphetamine consumption has many acute adverse physical effects, including hyperthermia, increase in blood pressure and heart rate, mydriasis (pupil dilatation), logorrhoea, grinding teeth (trismus and bruxia), gastrointestinal irritation, appetite loss, itching, welts on skin, hyperactivity, involuntary body movements, irreversible damage to blood vessels in the brain resulting in cerebrovascular accidents, arrhythmia, tachycardia, cardiovascular collapse, and death. The most common symptoms of chronic methamphetamine abuse include temporomandibular joint syndrome, tooth erosion, and myofacial pain, all manifestations of acute trismus and bruxia. Other long-term symptoms are loss of appetite, weight loss, accelerated aging, nose bleeding, and "Meth mouth," an oral disease characterized by tooth erosion, extensive caries, decayed surfaces, missing teeth, tooth wear, plaque, and calculus (Fig. 2). Methamphetamine is highly addictive, and its use can result in tolerance: The effects decrease gradually with chronic use; thus, increased dosages are required to achieve the desired effects.

2 Methamphetamine Induces Neurotoxicity

Repeated methamphetamine administration results in neurotoxicity, primarily affecting dopaminergic neurons in the nigrostriatal system as reflected by long-lasting reductions in levels of dopamine and its metabolites (DOPAC and HVA), dopaminergic markers such as tyrosine hydroxylase (TH) (the rate-limiting enzyme for dopamine synthesis), and DAT (Krasnova and Cadet 2009) (Fig. 3).

Several studies have demonstrated dopaminergic axon loss in the striatum after repeated methamphetamine use, indicated by loss of TH and DAT immunoreactivity. Although there is partial recovery of axonal TH and DAT immunoreactivity, some loss persists for long periods. Other amphetamine compounds such as ecstasy (MDMA) also produce this persistent axonal loss, which correlates with dopaminergic cell body loss in the substantia nigra pars compacta (SNpc), as demonstrated by rigorous stereology/cell counts with TH and Nissl staining and by use of cell death markers such as Fluorojade (Granado et al. 2008a). Apoptotic cell bodies, an irrefutable marker of cell death, have also been observed in the SNpc of methamphetamine-treated mice (Ares-Santos et al. 2012, 2013; Granado et al. 2011a).

Fig. 2 Methamphetamine abuse can produce accelerated aging, "METH mouth," and "METH mites." (**a**). Physical aspect of a woman at several time points during 4 years of methamphetamine abuse. (**b**). Case of "Meth Mouth". (**c**). Sores on the skin known as "meth mites," which result from scratching to relieve the feeling of having small bugs under the skin that methamphetamine abusers may experience (Taken from drug enforcement administration www.dea.gov)

Interestingly, the compartments of the mouse striatum – the striosomes and matrix – differ in their vulnerabilities to methamphetamine, (Granado et al. 2010) (see Fig. 4). Striosomes, which are connected to the limbic system and are functionally associated with reward-related behaviors and emotional events (White and Hiroi 1998), are more vulnerable to methamphetamine-induced dopaminergic terminal loss than the matrix, which is connected to sensorimotor regions of the brain and is more closely associated with normal motor functions.

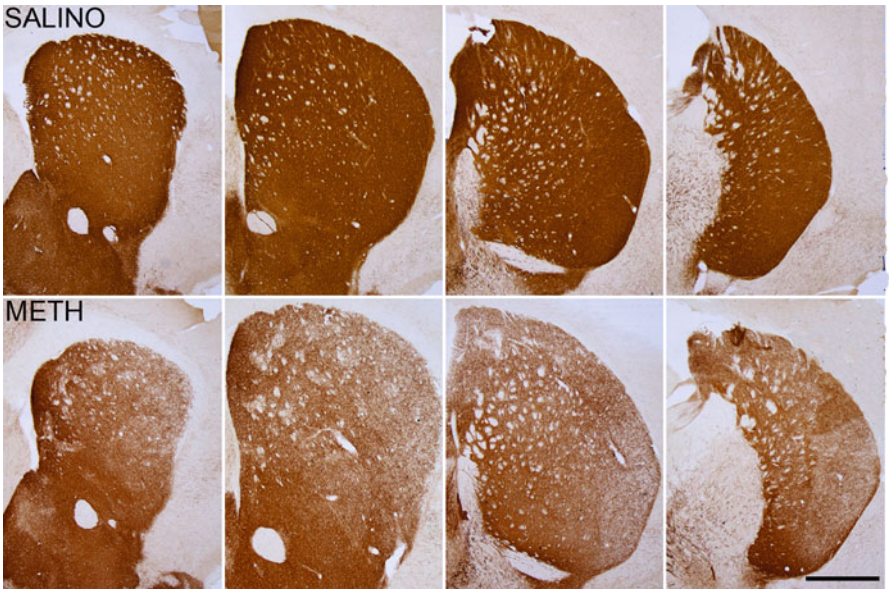

Fig. 3 Methamphetamine induces a loss of striatal TH-ir, indicative of dopamine fiber loss. Photomicrographs of striatal sections from mice treated with saline or methamphetamine stained for TH. METH produced a marked loss in striatal TH-ir that persists 7 days after treatment. Scale bar indicates 500 μm

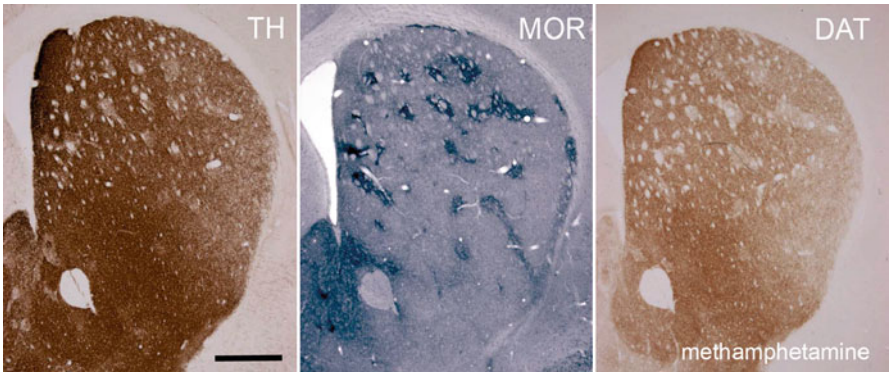

Fig. 4 Striatal vulnerability to methamphetamine. Methamphetamine toxicity occurs primarily in the striatum. Methamphetamine produces a preferential loss of TH and DAT in the striosomal compartment compared to the matrix. Photomicrographs of mouse brain sections 7 days after saline or methamphetamine treatment were stained for TH, MOR-1, and DAT. MOR-1 is a marker for striosomes. Scale bar indicates 500 μm (Modified from Granado et al. (2010))

The pattern of dopamine degeneration in the striatum is similar to that observed in the early stages of other neurodegenerative diseases such as Huntington's disease, hypoxic ischemic injury, and treatment with MPTP, a selective neurotoxin for dopaminergic neurons that is frequently used as a model of Parkinson's disease.

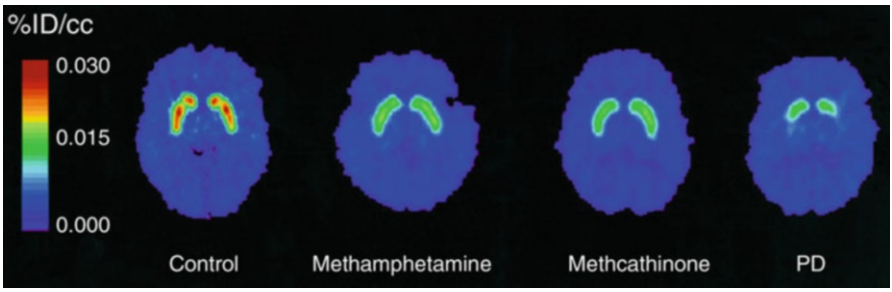

Fig. 5 Reduced DAT function in methamphetamine users. PET images showing accumulation of [11C] WIN-35,428 in the striatum of a control subject, an abstinent methamphetamine subject, an abstinent methcathinone subject, and a PD patient 70–90 min after injection of [11C] WIN-35,428 (Taken from McCann et al. (1998))

The nucleus accumbens is resistant to methamphetamine-induced dopaminergic axon loss (Granado et al. 2010), paralleling the effects of Parkinson's disease (Hurtig et al. 2000).

Methamphetamine neurotoxicity has also been demonstrated in humans (Fig. 5). PET studies in methamphetamine abusers found a reduction in DAT density in the caudate nucleus (26 % loss) and the putamen (21 % loss) after a short period of abstinence (Volkow et al. 2001a). Other authors reported similar DAT loss even 3 years after methamphetamine withdrawal (McCann et al. 1998). Studies in postmortem striatal tissue from chronic methamphetamine abusers showed a significant dopamine reduction concomitant with loss of DAT and TH immunoreactivity, indicative of dopamine nerve fiber loss. These effects have been related to loss of neurological function, including memory loss and motor and verbal learning impairments (Volkow et al. 2001b). Methamphetamine also causes neurotoxicity in other brain areas including somatosensory parietal, frontal, and piriform cortex, olfactory bulb, and hippocampus, where apoptotic neurons have been found following exposure to the drug.

These studies in animals and in human abusers suggest that methamphetamine consumers may be more susceptible to neurodegenerative diseases like Parkinson's disease (PD), raising important concerns about the use and abuse of amphetamines clinically and recreationally. A very recent clinical study shows that methamphetamine users have a 76 % greater risk of developing PD than normal subjects. Although these studies have not yet confirmed neuronal damage in the substantia nigra of human methamphetamine abusers, results in animals support this loss and are consistent with the idea that repeated methamphetamine abuse predisposes the abuser to PD. Methamphetamine also causes neuronal loss in other brain areas such as the olfactory bulb, cortex, hippocampus, and striatum, as indicated by increased apoptosis, increased numbers of TUNEL-positive cells, and decreased numbers of neurons in the brains of methamphetamine-treated laboratory animals (Krasnova and Cadet 2009).

3 Mechanisms of Methamphetamine-Induced Neurotoxicity

3.1 Role of Dopamine

Methamphetamine consumption greatly increases the dopamine concentration in brain synapses. Excessive dopamine in the synaptic cleft is responsible for most of the physical and psychological effects of the drug, including addiction and psychomotor stimulant effects. An imbalance in the distribution of dopamine in the brain also seems to give rise to neurotoxicity, a fact that explains the localization of drug-induced degeneration to dopaminergic terminals (Fig. 6).

Following synthesis in dopaminergic neurons, dopamine is first released to the cytosol before being stored in vesicles where it is protected from metabolism and auto-oxidation. Methamphetamine induces a redistribution of dopamine inside the terminal, releasing dopamine from the vesicles into the cytosol where it is a substrate for metabolic and oxidative reactions, resulting in the production of dopamine quinones, superoxide anions, and hydrogen peroxide and hydroxyl radical species. This can further promote the oxidation of cytosolic dopamine, generating oxidative stress and leading to mitochondrial dysfunction and damage in the dopaminergic terminal (Cadet and Krasnova 2009; Thomas et al. 2008). The detrimental role of excessive cytosolic dopamine and its implication in the neurotoxic effects of methamphetamine is supported by the fact that when dopamine synthesis is inhibited by αMPT, protection against methamphetamine toxicity is observed (Albers and Sonsalla 1995; Ares-Santos et al. 2012). Moreover, pretreatment with L-DOPA, a precursor of dopamine, and treatment with reserpine, which releases dopamine from vesicles to the cytoplasm, both potentiate methamphetamine toxicity (Albers and Sonsalla 1995; Granado et al. 2011a).

3.2 Implications of Oxidative Stress

Reactive nitrogen species and reactive oxygen species (ROS) are by-products of normal physiological metabolism in the brain, but excessive production of these reactive species can damage cell components, including lipids by lipid peroxidation, proteins by formation of protein carbonyls, and mitochondrial and nuclear DNA by peroxidation of these macromolecules. These reactive species impair mitochondrial respiratory chain enzymes and inhibit sodium-potassium ATPase, generating oxidative and nitrosative stress that leads to metabolic collapse and necrotic or apoptotic cell death. These oxidative stress cascades occur in several neurodegenerative disorders including Parkinson's disease.

Methamphetamine administration increases levels of extra-vesicular dopamine in the cytosol, where it can be metabolized by MAO or auto-oxidized in a process that generates toxic dopamine quinones. These dopamine quinones can damage cell proteins by binding to cysteine residues or by generating hydrogen peroxide (H_2O_2) and superoxide anions ($O_2\bullet-$), considered a major culprit in methamphetamine toxicity. The methamphetamine-induced increase in

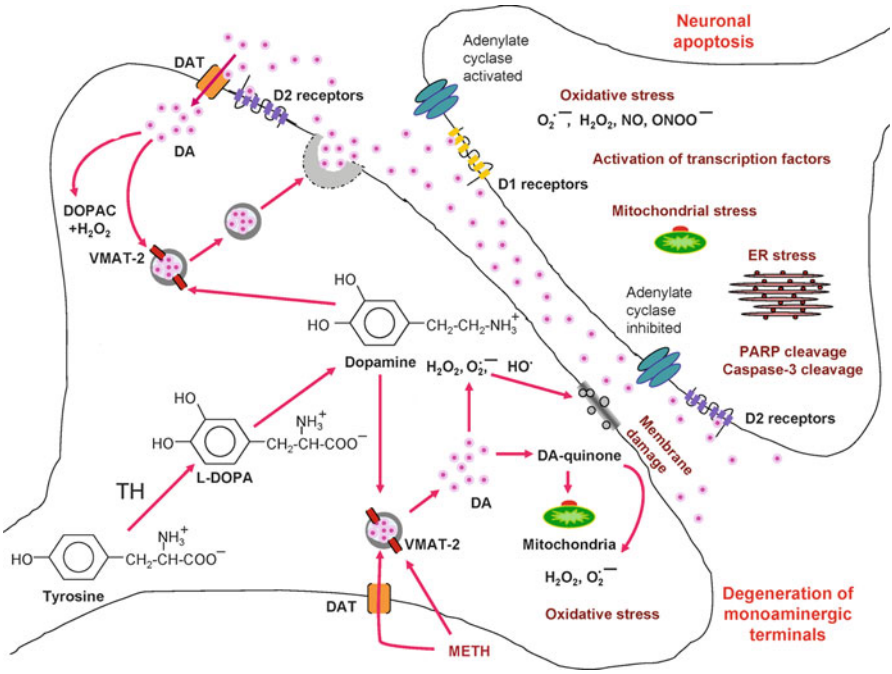

Fig. 6 Schematic representation of cellular and molecular events involved in methamphetamine-induced dopamine terminal degeneration and neuronal apoptosis within the striatum. The figure summarizes findings of various studies that have addressed the role of dopamine, oxidative stress, and other mechanisms in methamphetamine toxicity. Methamphetamine enters dopaminergic neurons via DAT and passive diffusion. Within these neurons, methamphetamine enters synaptic vesicles through VMAT2 and causes dopamine release into the cytoplasm via changes in pH balance. In the cytoplasm, dopamine auto-oxidizes to form toxic dopamine quinones, generating superoxide radicals and hydrogen peroxides via quinone cycling. Subsequent formation of hydroxyl radicals through interactions of superoxides and hydrogen peroxide with transition metals leads to oxidative stress, mitochondrial dysfunctions, and peroxidative damage to presynaptic membranes. The toxic effects of released dopamine might occur through activation of dopamine receptors, as dopamine receptor antagonists block degeneration of dopamine terminals (Modified from Krasnova and Cadet (2009))

interaction of superoxides and hydrogen peroxide with transition metals like iron can lead to the formation of hydroxyl radicals (•OH) that cause oxidative stress, mitochondrial dysfunction, and peroxidative damage to dopaminergic terminal membranes (Krasnova and Cadet 2009).

The methamphetamine-induced increase in oxidative stress likely results from an imbalance between ROS production and the capacity of antioxidant enzyme systems to scavenge ROS: Methamphetamine both increases ROS production and reduces levels of the ROS scavengers CuZnSOD, catalase, glutathionine, and peroxiredoxins in the brain (Jayanthi et al. 1998; Li et al. 2008). Oxidative stress increases the susceptibility of the striosomal compartment to methamphetamine-induced dopaminergic toxicity (Granado et al. 2010). SOD is less abundant in

striosomes than in the matrix (Medina et al. 1996), which may explain the greater vulnerability of the striosomes to methamphetamine neurotoxicity. This is supported by the finding that transgenic mice overexpressing CuZnSOD are resistant to methamphetamine-induced striatal neuronal damage (Hirata et al. 1996). Furthermore, antioxidants like ascorbic acid (vitamin C), vitamin E, bromocriptine (a hydroxyl radical scavenger), and coenzyme Q10 (antioxidant and mitochondrial energy enhancer) attenuate methamphetamine toxicity (Wagner et al. 1986). Free radical scavengers like PBN (α-phenyl-*N*-terbutil nitrone) also reduce neurotoxic damage (Yamamoto and Zhu 1998), without altering the hyperthermic response that follows methamphetamine administration and that contributes to methamphetamine neurotoxicity (see Sect. 3.3 below).

3.3 Role of Hyperthermia

Methamphetamine usually produces a hyperthermic response in experimental animals and human meth abusers directly proportional to the dosage of the drug and to the ambient temperature in the place of treatment. This hyperthermia can be lethal (it is the first cause of methamphetamine-induced deaths) and can promote long-term neurotoxicity, as a relationship has been observed between the hyperthermic response and the neurotoxicity induced by the drug (Ares-Santos et al. 2012; Bowyer et al. 1994; Granado et al. 2010, 2011a). Strategies that reduce or avoid this hyperthermic response after methamphetamine treatment, like administering the drug at low ambient temperatures (4 °C) or pretreatment with pharmacologic agents like diclocipine or haloperidol, prevent or attenuate drug-induced neurotoxicity (Albers and Sonsalla 1995; O'Callaghan and Miller 1994). Furthermore, methamphetamine administration at high ambient temperatures promotes the hyperthermic response and increases neurotoxicity (Ares-Santos et al. 2012; Bowyer et al. 1994; Granado et al. 2011a; Miller and O'Callaghan 2003).

The correlation between hyperthermia and neurotoxicity is believed to be due to the fact that hyperthermia can potentiate DAT function (Xie et al. 2000), increasing free radicals and dopamine oxidation in the brain (Krasnova and Cadet 2009; LaVoie and Hastings 1999). Conversely, hypothermia has inhibitory effects on oxidative stress, as it reduces dopamine oxidation (LaVoie and Hastings 1999) and the formation of hydroxyl radicals (Fleckenstein et al. 1997; Krasnova and Cadet 2009). Moreover, neurons in animals maintained at low body temperature have reduced energetic demand, which may be protective since administration of methamphetamine produces striatal loss of ATP, possibly as a consequence of metabolic stress in dopaminergic neurons (Chan et al. 1994).

In contrast to these results, other pharmacological and genetic studies indicate that while hyperthermia contributes to methamphetamine-induced dopaminergic neurotoxicity, it is not required. For example, reserpine, a pharmacologic agent that dramatically lowers body temperature, strongly potentiates methamphetamine-induced neurotoxicity while blocking the hyperthermic response (Albers and Sonsalla 1995; Ares-Santos et al. 2012; Granado et al. 2011a). These results

indicate that blocking the hyperthermic response is not sufficient to protect against neuronal damage. Moreover, total or partial inactivation of DAT, nNOS, IL-6, or c-jun protects against methamphetamine-induced toxicity without altering the hyperthermic response. Thus, methamphetamine-induced hyperthermia contributes to, but is not required for, the neurotoxic effects of the drug.

3.4 Role of Dopamine Receptors and Dopaminergic System

As evidence points to dysregulation of dopamine as the primary cause of methamphetamine-induced neurotoxicity, the role of the dopaminergic system in this process has also been evaluated. In particular, as methamphetamine acts as an indirect dopamine agonist, several studies have focused on elucidating the role of dopamine receptors. There are five different dopamine receptors (D1–D5), which fall into two families based on pharmacologic classification: the D1-like receptors (D1 and D5) and the D2-like receptors (D2, D3, and D4). Both families are involved in behavior and cognition, voluntary movement, motivation, punishment and reward, attention, working memory and learning, and in several neurodegenerative diseases like PD (Darmopil et al. 2009; Granado et al. 2008b; Ortiz et al. 2010).

Pharmacologic studies with the D2 receptor antagonists sulpiride, eticlopride, and raclopride have shown a dose-dependent prevention of methamphetamine toxicity in mice (Albers and Sonsalla 1995; Eisch and Marshall 1998). However, these compounds do not differentiate between members of the D2 receptor family, so it was not clear which receptor(s) mediate the protective effect. Recent studies using genetically modified mice lacking dopamine receptor D2 demonstrated that it is specifically the D2 receptor that is involved in methamphetamine toxicity as its genetic inactivation prevented the loss of dopaminergic striatal markers and inhibited the loss of dopaminergic neurons in the substantia nigra (Granado et al. 2011a).

D2 receptors are localized pre- and postsynaptically. At presynaptic locations, D2 receptors control dopamine release and thereby regulate extra-synaptic dopamine levels, which are involved in non-dopaminergic toxicity, such as in striatal medium spiny neurons, cortical and hippocampal neurons and neuropil. In addition, D2 receptors form heteromeric protein-protein complexes with DAT localized in the dopaminergic terminals that potentiate DAT activity. Blockade or inactivation of the D2R decreases striatal DAT activity. Since DAT knockout mice exhibit full protection against methamphetamine-induced dopaminergic toxicity (Fumagalli et al. 1998), indicating that active DAT is required for this neurotoxicity, the decrease in DAT is likely a major factor in the reduction of methamphetamine-induced dopaminergic toxicity induced by blockade or inactivation of the D2R. Moreover, fast scan cyclic voltammetry indicates that dopamine D2R$^{-/-}$ mice have lower vesicular dopamine content, resulting in lower cytosolic dopamine levels. This also contributes to the reduction in methamphetamine-induced toxicity because cytosolic dopamine levels determine the severity of the toxicity (Granado et al. 2011a).

Receptors from the D1 family are also involved in methamphetamine-induced neurotoxicity as their pharmacologic inactivation with antagonists like SCH23390 also confers protection (Sonsalla et al. 1986). Genetic inactivation of the dopamine D1 receptor (D1R) also protected against reductions in striatal TH and DAT expression and against loss of dopaminergic neurons in the substantia nigra following methamphetamine administration, indicating that the D1R in particular is involved in methamphetamine neurotoxicity (Ares-Santos et al. 2012). Neuroprotection afforded by D1R inactivation is due in part to inhibition of hyperthermia, but also to the redistribution of dopamine inside the terminal. Animals lacking the D1R store more dopamine in vesicles and therefore have a reduced cytosolic dopamine pool compared to WT mice (Ares-Santos et al. 2012). Blockade of D1/D5R also suppresses activation of caspases 3 and 8, mediators of the calcineurin/NFAT/FasL-dependent apoptotic cell death pathway (Jayanthi et al. 2005; Krasnova and Cadet 2009); this may also contribute to the neuroprotective effects of D1/D5 blockade or inactivation. Finally, SCH23390 decreases dopamine-induced oxidation and cytotoxicity mediated by ERK and JNK activation (Chen et al. 2004).

Other components of the dopaminergic system are also involved in methamphetamine-induced toxicity. Vesicular monoamine transporter (VMAT2) takes up dopamine from the cytosol to store it in synaptic vesicles, decreasing dopamine oxidation. Methamphetamine interacts with VMAT2 to cause a possible association of vesicles inside the dopaminergic terminal, increasing the release of dopamine to the cytosol and thereby increasing oxidative stress (Sulzer et al. 2005). VMAT2 knockout mice, with higher levels of cytosolic dopamine, are more sensitive to methamphetamine dopaminergic toxicity and show greater expression of oxidative stress markers than WT animals (Larsen et al. 2002). Other results are in line with these findings, showing that VMAT2 becomes nitrated 1 h after methamphetamine administration, which may reduce its activity (Eyerman and Yamamoto 2005), and that methamphetamine also reduces VMAT2 expression in the striatum (Krasnova and Cadet 2009).

3.5 Role of Glutamate and Nitric Oxide

Methamphetamine produces excitotoxicity by increasing glutamate release in the striatum (Nash and Yamamoto 1992), activating *N*-methyl-D-aspartate (NMDA) and alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. Stimulation of these receptors increases intracellular levels of Ca^{2+}, causing activation of kinases, lipases, and proteases that damage the cytoskeleton, generating free radicals and DNA damage (Sattler and Tymianski 2000). Pharmacological studies using MK801, a noncompetitive NMDA receptor antagonist, prevented the long-term dopamine loss induced by methamphetamine (Sonsalla et al. 1989).

Moreover, NMDA receptor overactivation results in the production of superoxide radicals (O_2•−) and nitric oxide (NO). When these two species react with each other, peroxynitrite ($ONOO^-$), a more potent oxidative species, is formed, further

potentiating neurotoxicity. To examine the contribution of this strong oxidizing agent to methamphetamine toxicity, a previous study measured the formation of neural 3-nitrotyrosine (3-NT), a product of tyrosine nitration that indicates irreversible structural modification of proteins (Butterfield et al. 2011) that can lead to loss of physiological cell functions, appearance of abnormal functions, and eventually cell death. A single injection of methamphetamine produced a significant rise in 3-NT concentrations in the striatum, signifying the involvement of $ONOO^-$ in the destructive effects methamphetamine abuse. Genetic or pharmacological inactivation of nNOS, the enzyme that produces nitric oxide in the brain, considerably reduced methamphetamine neurotoxicity without affecting the hyperthermic response (Itzhak et al. 1998, 2002), likely due to loss of peroxynitrite production.

3.6 Role of Astroglial and Microglial Activation

The central nervous system (CNS), consisting of the brain and the spinal cord, is an "immune privileged" area with an immune system distinct from that in the rest of the body. Microglia, a type of glial cell, are the resident macrophages of the central nervous system, and so act as its first and main form of active immune defense. These cells are normally in a resting state, but become activated after certain types of CNS damage, as a part of the innate immune response. Activated microglia migrate rapidly to the damage sites and secrete reactive species including proinflammatory cytokines (IL-1β, IL-6, TNF-α) chemokines, prostaglandins, reactive oxygen species (ROS), nitric oxide, and superoxide to protect the brain. However, overactivation can be detrimental, producing cell death and astroglial dysfunction.

Amphetamines increase microglia activation in the striatum, hippocampus, cortex, and SN, with populations peaking 1 day after administration. Following administration of methamphetamine or other amphetamine derivatives, activated microglia are found in the areas in which dopaminergic neurotoxicity occurs, and the intensity of activation seems to be correlated with the level of dopaminergic damage. The highest levels of microglial activation occur in the dorsal striatum, an area highly affected by methamphetamine treatment, while the nucleus accumbens, more resistant than the striatum to methamphetamine-induced dopaminergic toxicity, has relatively few reactive microglia. Methamphetamine administration also results in increased levels of the three principal proinflammatory cytokines: IL-1β, IL-6, TNF-α, that in large part result from microglial activation (Clark et al. 2013). Thus, microglial activation represents a direct response to damage by amphetamines and is part of the cascade leading to neuronal damage (Thomas et al. 2008). Although many of the molecules secreted by activated microglia have been implicated in methamphetamine-induced neurotoxicity, and some anti-inflammatory drugs like ketoprofen, indometacin, tetracycline, and minocycline can protect against methamphetamine-induced microglial activation and neurotoxicity, attenuating microglial activation is not sufficient to protect against methamphetamine neurotoxicity (Sriram et al. 2006).

CNS damage is also accompanied by reactive gliosis, the injury-induced activation of astrocytes. The most abundant cells in the human brain, astrocytes, provide nutrients to nervous tissue, maintain extracellular ion balance, support other brain cells, and play an important role in repair and scar formation in the CNS after injury.

Recently, the immunomodulatory role of astrocytes has begun to emerge. Astrocytes can be protective, increasing levels of glutathionine (an antioxidant), facilitating sprouting, and providing growth factors, guidance molecules, and scaffolding for axonal regeneration, but they can also initiate several neuroinflammatory pathways and release inflammatory cytokines, some of which are neurotoxic. However, it seems likely that astrocytes play a positive role in limiting neuroinflammation and the balance between the activation of microglia and astrocytes leads to a detrimental or beneficial outcome (Clark et al. 2013).

Reactive gliosis is considered a universal reaction to CNS damage and is used as a sensitive marker of neuronal damage. Methamphetamine increases astrocyte activation in the striatum, as seen by increased expression of the marker glial fibrillary acidic protein (GFAP), which reaches maximal levels between 3 and 7 days after drug administration (Fig. 7). However, there are much earlier indications of reactive gliosis: Within a few minutes of methamphetamine delivery, there is already a 20 % increase in the magnitude of the Ca^{2+} fluorescence signal in striatal astrocytes, and a 50–60 % increase in the number of responding astrocytes, indicating a primary astrocytic response (Granado et al. 2011b). As with microglia, activation of astrocytes takes place in the areas the most affected by methamphetamine, while the astrocyte population does not increase in the nucleus accumbens, where dopaminergic damage is normally not significant. Briefly, neuroinflammatory mechanism could in part contribute to the gradually escalating deleterious effects of methamphetamine.

3.7 Nrf2 and Inflammation Play a Role in Methamphetamine-Induced Neurotoxicity

The transcription factor Nrf2 (nuclear factor-erythroid 2-related factor 2) has been recently shown to have a protective role against methamphetamine-induced dopaminergic neurotoxicity (Granado et al. 2011b). Nrf2 is considered a master regulator of redox homeostasis, as it regulates the expression of a group of genes that encode the phase 2 detoxification enzymes, including heme oxygenase-1 (HO-1), NADPH quinone oxidoreductase (NQO1), and the catalytic and modulatory subunits of γ-glutamyl synthase (GCLM, GCLC) (Clark and Simon 2009; Johnson et al. 2008). In normal conditions, Nrf2 has a very short half-life because of its interaction with the BTB-Kelch protein Keap1, which promotes Nrf2 degradation by the proteasome (Lo et al. 2006). However, oxidant molecules are able to disrupt the Keap1/Nrf2 complex, rescuing Nrf2 from proteasomal degradation and allowing its entry into the nucleus and transcriptional activity.

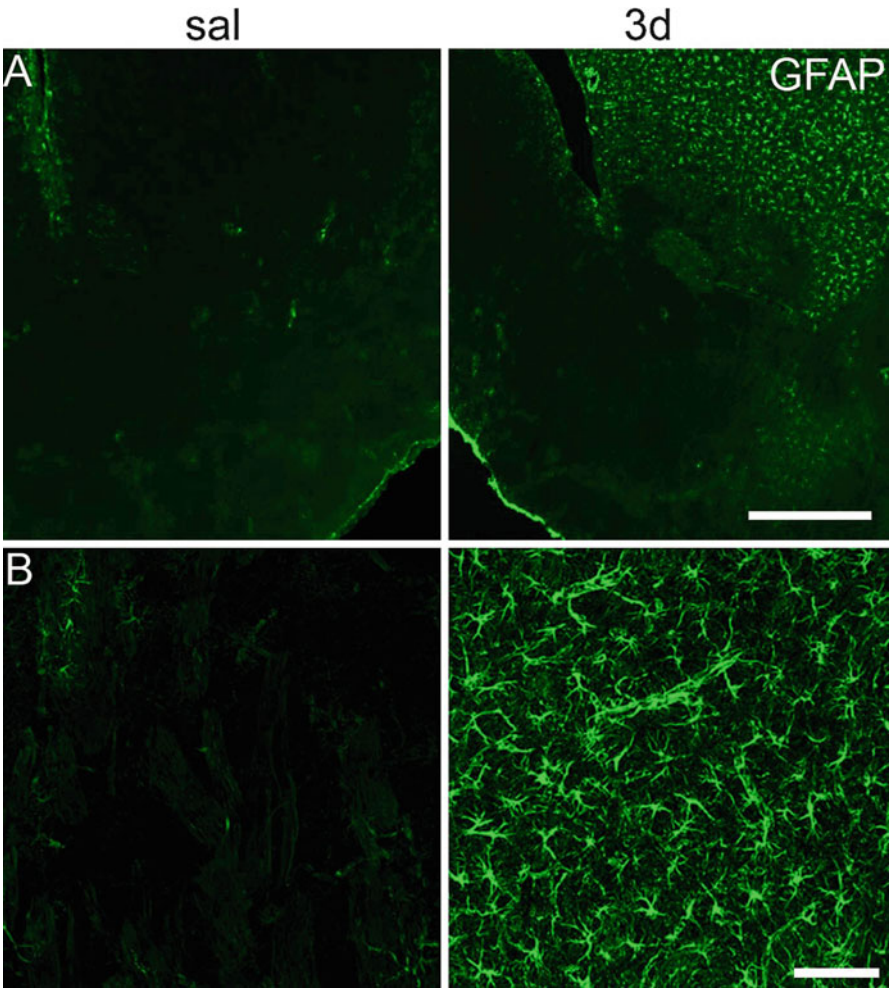

Fig. 7 Methamphetamine induces astrogliosis in mouse striatum but not in nucleus accumbens. (**a**) Photomicrographs of striatal sections from methamphetamine-treated mice stained for GFAP. (**b**) Enlargements of striatum sections shown in (**a**). Animals were killed 3 days after methamphetamine treatment. Methamphetamine increased GFAP staining in the striatum but not in nucleus accumbens. Bar indicates 500 μm for (**a**) and 100 μm for (**b**) (Modified from Granado et al. (2010))

Recent studies have shown that Nrf2 is activated by methamphetamine administration (Jayanthi et al. 2009) and that it plays a crucial role in the protection of dopaminergic neurons against oxidative stress by detoxifying mitochondrial complex I inhibitors and downregulating genes involved in the brain innate immune response. Mice lacking Nrf2 are more susceptible than WT mice to methamphetamine toxicity (Granado et al. 2011b), showing exacerbated hyperthermia, enhanced striatal TH and DAT-fiber loss, and greater decrease in dopamine levels,

and increased dopamine and nigrostriatal dopaminergic alterations and gliosis following administration of methamphetamine (Granado et al. 2011b). This is due to the fact that in the absence of Nrf2, ARE-regulated genes in the striatum, including HO-1 and other antioxidant genes, are not induced by methamphetamine as they are in WT mice, leading to increased oxidative stress, accumulation of ROS (Chen et al. 2009), and ultimately to dopamine fiber loss. In addition, cytokine mRNA levels (TNF-α, IL-1β), gliosis, and astrocytosis in the striatum were elevated to a greater extent in methamphetamine-treated $Nrf2^{-/-}$ mice than WT mice, indicating that the proinflammatory effects of methamphetamine treatment are potentiated in the absence of Nrf2.

Moreover, $Nrf2^{-/-}$ mice treated with methamphetamine presented significantly lower levels of modulatory subunits of γ-cysteine ligase (Gclm) and glutathione peroxidase (GPx) than WT animals, meaning that the detoxificating response is reduced in absence of Nrf2, a fact that could contribute to the increased detrimental effects induced by the drug.

Our finding that Nrf2-deficient mice were more sensitive than WT mice to methamphetamine-induced striatal damage further demonstrates that Nrf2 activation is part of a defensive response to methamphetamine neurotoxicity that involves modulation of methamphetamine-induced inflammation and oxidative stress (Granado et al. 2011b). This defensive modulation of inflammation and oxidative stress by Nrf2 is also seen following administration of other ROS-generating toxins like MPTP (Chen et al. 2009) and lipopolysaccharide (Rangasamy et al. 2004). Intriguingly, Nrf2 deficiency potentiates methamphetamine-induced neurotoxicity in the striatum but not in the SN. It is possible that methamphetamine differentially activates Nrf2-ARE transcription pathways in the striatum and the SN. Thus, differential regulation of Nrf2 by methamphetamine in SN and striatum might explain the lack of effect of $Nrf2^{-/-}$ on neurotoxicity in the SN in our study. These results strongly support the hypothesis that methamphetamine produces dopaminergic neurotoxicity through a process involving inflammation and oxidative stress (Granado et al. 2011b).

3.8 Role of Mitochondrial Dysfunction and DNA Damage

Methamphetamine-induced neurotoxicity also causes mitochondrial dysfunction and DNA damage. Mitochondria are the main source of cellular energy through activation of the ATP-producing mitochondrial respiratory chain, or electron transport chain, composed of a series of four complexes (I–IV). Methamphetamine is a cationic and lipophilic molecule that can diffuse into the mitochondria, where it is able to inhibit ATP synthesis (Asanuma et al. 2000; Krasnova and Cadet 2009). Administration of high doses of methamphetamine in rats decreases the activity of complexes II and IV of the respiratory chain in the striatum and prefrontal cortex, even in the absence of hyperthermia (Brown et al. 2005). Moreover, methamphetamine reduces ATP accumulation, resulting

in mitochondrial dysfunction. The increase in reactive oxygen and nitrogen species may also contribute to the observed mitochondrial dysfunction.

Elevated production of oxygen- and nitrogen-based radicals and related non-radical products leads to the oxidation of essential macromolecules, including DNA. DNA damage plays a role in the pathogenic mechanism of methamphetamine, as the drug increases DNA oxidation in the striatum, hippocampus, substantia nigra, and olfactory bulb (Jeng et al. 2006), causing apoptotic cell death in experimental animals (Deng and Cadet 2000). In particular, the 8-oxoguanine (8-oxoG) produced in DNA lesion may mispair with adenine, causing transversions or mutations, altering the DNA binding of nuclear transcription factors or blocking RNA polymerase, resulting in altered or delayed transcription of proteins. DNA repair genes, including members of the BER pathway, are upregulated in adult mice after methamphetamine administration, suggesting that increased repair activity is induced to counteract the oxidative DNA damage induced by the drug.

4 Neuroprotective Strategies Against Methamphetamine-Induced Neurotoxicity

As basic and clinical research findings begin to elucidate mechanisms of methamphetamine-induced neurotoxicity, potential neuroprotective strategies are being proposed. Since oxidative stress and mitochondrial dysfunction are important factors in methamphetamine-induced neurodegeneration, pretreatment with antioxidants like *N*-acetyl-L-cysteine, ascorbic acid, vitamin E, or coenzyme Q_{10} was evaluated and shown to have protective effects against depletion of monoaminergic axons (Krasnova and Cadet 2009). Melatonin, another antioxidant compound that also has antiapoptotic effects, also reduces methamphetamine-induced depletion of dopaminergic markers in the striatum (Hirata et al. 1998).

Other strategies for avoiding an increase in oxidative stress, such as preventing methamphetamine-induced hyperthermia by pharmacologic treatment or by maintaining animals at cool ambient temperatures during drug administration, also reduce mortality and neurotoxicity.

Controlling the amount of dopamine in the cytosol, where it is susceptible to oxidation, causing oxidative stress, is another neuroprotective strategy. Increasing VMAT2, the vesicular monoamine transporter that sequesters dopamine into vesicles, and administering dopamine uptake inhibitors or dopamine receptor antagonist, all provide protection against methamphetamine -induced degeneration of striatal dopamine terminals. In addition, some trophic factors provide protection against the toxic effects of methamphetamine. Administration of glial cell line-derived neurotrophic factor (GDNF) or brain-derived neurotrophic factor (BDNF) can prevent methamphetamine-mediated reduction in dopamine in the striatum and caspase activation (Dluzen 2004; Matsuzaki et al. 2004; Melega et al. 2000).

Since neuroinflammation may contribute to methamphetamine neurotoxicity, some cytokines, such as interferon gamma, TNF-alpha among others, have been

evaluated and were shown to protect against methamphetamine toxicity. Estrogen can also protect against methamphetamine-induced damage to the nigrostriatal dopamine system (D'Astous et al. 2005). Pretreatment with tamoxifen, a selective estrogen receptor modulator, showed neuroprotective effect against methamphetamine-induced toxicity and attenuated inflammatory response in the striatum when used alone but abolishes estrogen's positive effects when combined with this hormone. While both treatments prevented dopamine decrease, estrogen protected more efficiently other dopaminergic parameters, suggesting that overall estrogen is more effective than tamoxifen as a neuroprotectant of the nigrostriatal dopaminergic system (Bourque et al. 2007; D'Astous et al. 2005).

5 Conclusion

Methamphetamine is a synthetic drug used worldwide, mostly for recreational purposes, due to its powerful psychostimulant effects. It has addictive effects due to its structural analogy with dopamine, but also has neurotoxic effects on the dopaminergic system. The drug causes a reduction in dopamine markers in the striatum similar to that seen in the early stages of neurodegenerative diseases like PD, Huntington's disease, and hypoxic/ischemic injury. In experimental animals, methamphetamine also causes neuron loss in the substantia nigra. This may explain why patients who abuse methamphetamine have a predisposition to future development of PD. Among the mechanisms responsible for methamphetamine's neurotoxic effects are oxidative stress, hyperthermia, microglia and astroglia activation, mitochondrial dysfunction, DNA damage, and elevated levels of glutamate and nitric oxide. The recent implication of the D1 and D2 receptors in methamphetamine-induced neurotoxicity suggests that targeting these receptors may be a promising strategy for development of new approaches to prevention and treatment of methamphetamine addiction and its neurotoxic effects. In addition, the neuropathological similarities between methamphetamine neurotoxicity and PD and the demonstrated predisposition of methamphetamine abusers to developing PD indicate that similar therapeutic approaches may be useful in the early stages of PD and related neurodegenerative diseases.

Pathophysiology of Obsessive-Compulsive Disorder: Insights from Normal Function and Neurotoxic Effects of Drugs, Infection, and Brain Injury

Henry Szechtman, Sohel Shivji, and Erik Z. Woody

Contents

Abstract

The clinical presentation of obsessive–compulsive disorder (OCD) is summarized and a theoretical model of the disorder and its neurobiology are described. The model is used as a framework to account for the observed pattern of clinical symptoms, for the pathophysiology of OCD, and for medical reports of OCD-like symptoms from neurotoxic effects of drugs, brain injury, and infection. The essential clinical feature of OCD is preoccupation with ideas and behaviors called "obsessions" and "compulsions," respectively. The characteristic content of obsessions and compulsions is concern about dangers that might happen in the

future – as opposed to actual threats that are direct and immediate. Hence, OCD is a clinical preoccupation with *potential* threats. A model is considered where normal concerns regarding potential danger and security are handled by a biologically ancient hard-wired motivational system, called security motivation system (SMS), which has as its output the same repertoire of precautionary behaviors that characterize OCD compulsions. In the model, OCD symptoms emerge because security motivation is normally deactivated by a negative feedback signal generated by performance of precautionary behaviors, but in patients with OCD, this signal is inoperative, resulting in continued motivation to perform security-related behaviors. The neurobiology of SMS consists of functional loops involving a cascade of cortico-striato-pallido-thalamo-cortical connections, with inhibitory connections from the brainstem. Accordingly, OCD pathophysiology is overly persistent and uncontrolled neural activity in SMS, possibly due to a dopamine–serotonin imbalance. Evidence of OCD symptoms from drugs, brain injury, and infection is consistent with disturbed basal ganglia regulation as the pathophysiology of OCD.

1 Introduction

A comprehensive understanding of the pathophysiology of obsessive–compulsive disorder (OCD) is lacking because the cause of this disease is unknown. In general, if the cause of a disease is known then the course of pathogenesis can be traced forward from a well-defined starting point. In this way, even when the pathophysiology and presentation of symptoms are varied, it is nevertheless certain that they all belong to the same disease (stem from the same cause). However, if the disease cause is unknown, and one observes variations in pathophysiology and symptoms, it is not certain whether those variations belong to one disease with several presentations or in fact reflect several different diseases with different causes.

Criteria for disease causality were laid down by Robert Koch in 1882 when he proved the causation of tuberculosis, a devastating disease then believed to result from societal woes (Barnes 2000). Koch established that a bacterium (which he called "tubercle bacillus") is the causal agent of tuberculosis and he proved this through experiments demonstrating:

> (1) The parasite occurs in every case of the disease. (2) The parasite does not occur in other diseases or nonpathogenically. (3) After being fully isolated and repeatedly grown in pure culture the parasite can induce the disease by being introduced into a healthy animal. (Barnes 2000, p. 433)

As noted, when it comes to OCD, its cause – its agent of origin – is unknown. In fact, whether there are multiple sufficient causes that result in OCD is also unknown. However, information exists regarding the nature of the behavioral systems affected by OCD, and this information can be integrated into a theoretical model that provides a useful framework for considering the pathophysiology of OCD and how the function of these systems can be affected by neurotoxicity.

Below, the clinical presentation of OCD is summarized and a theoretical model is described that provides a framework to explain the symptoms of OCD and their neurobiological underpinnings. This framework is followed by a review of case reports to illustrate the neurotoxic effects of drugs, brain injury, and infection as causal agents producing OCD-like behavior.

2 Description of OCD

Given that the cause and pathophysiology of OCD are unknown, there are no biological tests for OCD, and, hence, a diagnosis of OCD is made solely from evidence of a particular behavioral profile (American Psychiatric Association. Task Force on DSM-IV 2000). The essential features of this behavioral profile are preoccupation by the individual with certain types of ideas and behaviors. The preoccupation is clinically significant because it is (a) *excessive* (it consumes more than 1 h in a day and interferes with normal daily function), (b) *ego-dystonic* (it gives no pleasure to the individual but the subject feels driven to be so engaged), and (c) *unreasonable* (the person acknowledges the preoccupation may appear to others as disconnected from objective reality). The ideas and behaviors that preoccupy the individual are called "obsessions" and "compulsions," respectively. According to Reed (Reed 1985), the content of obsessions may include thoughts involving (a) self-depreciation, self-denigration, and unworthiness either with reference to perceived social norms or the individual's own standards; (b) undue concern with one's bodily functions; (c) fears, doubts, and preoccupations about dirt and the spread of disease to self; and (d) fears of harm to a friend or relative and being responsible for the imagined event. The range of compulsive behaviors includes (Reed 1985) (a) excessive *checking* activities, characterized by repeated re-doings of actions supposedly related to security, orderliness, or accuracy; (b) *avoidance behaviors*, which are "activities engaged in to avoid feared objects, places, or situations" (p. 37); and (c) *washing and cleaning*, generally of hands but sometimes also compulsive washing of clothes, teeth cleaning, or the cleaning of possessions or parts of the home. Individuals may be preoccupied with more than one obsession and/or compulsion. The two most common characteristics of obsessions are doubts and indecision, and the two compulsive behaviors performed most often are checking and washing (Rasmussen and Eisen 1992).

It is remarkable that despite being aware that their preoccupation is exaggerated, afflicted individuals feel unable for any extended period of time to control their obsessions and compulsions; indeed, powerlessness over time spent engaged in obsessions and compulsions is very often the immediate reason for seeking help. But OCD does not reflect weaknesses of the will (Huoranszki 2011) or intellect. Most revealingly, there are individuals with OCD who despite the distresses of their illness manage very prolific and intellectually exceptional careers, one famous example being Samuel Johnson, the eighteenth century English writer and literary critic who counts among his major works the sole authorship of "A Dictionary of the English Language." There are many such

examples of highly successful individuals with OCD where clearly neither weak will nor poor intellect are the reasons for OCD symptoms (the interested reader may view video testimonials and descriptions of OCD on YouTube, e.g., http://www.youtube.com/watch?v=Rn1OYlYzgm8 or http://www.youtube.com/watch?v=dSZNnz9SM4g). Rather, the striking disconnection in OCD between knowing rationally that some actions are unreasonable, but nevertheless feeling that they must be performed, demonstrates the presence of a powerful "feeling" system as a determinant of behavior (Kahneman 2011), a notion which is elaborated upon in the next section.

It is should be noted that the DSM-IV manual indicates criteria for the differential diagnosis of OCD. Specifically, it states that OCD "must be distinguished from Anxiety Disorder Due to a General Condition" or from a "Substance-Induced Anxiety Disorder." Those diagnoses apply, respectively, "when the obsessions or compulsions are judged to be a direct physiological consequence of a specific general medical condition" or "when a substance (i.e., a drug of abuse, a medication, or exposure to a toxin) is judged to be etiologically related to the obsessions or compulsions" (American Psychiatric Association. Task Force on DSM-IV 2000). At first glance, the differential diagnosis suggests the presence of another disease, with a pathophysiology distinctly different from the pathophysiology of OCD diagnosed solely from behavioral evidence. However, the utility of the differential diagnosis probably applies to the clinical management of the symptoms rather than indicating that the differently labeled disorders have their own distinct pathophysiology. Indeed, as argued later, the medical conditions producing compulsions and obsessions reveal a plausible pathophysiology of OCD.

3 Security Motivation System as the Framework to Explain OCD

Disease in an organism was seen for a long time as due to invasion by unseen spirits, and it is relatively recently that the unseen forces have been given a physical reality, as demonstrated by Robert Koch above. The history of psychiatric disorders is no different, and even today mental illness is often viewed as a creation of outside forces, such as possession by various spirits or demons, environmental evils, abnormal learning, or mutation of genes. Nevertheless, it is crucial to appreciate that whatever the actual agent may turn out to be, and regardless of how bizarre the psychiatric symptoms may seem, the psychiatric condition is not a de novo creation but a phenomenon already in the repertoire of the organism. After all, the agent must act on the body and consequently the observed behavioral output, regardless of how bizarre, is a reflection of the functions the brain is built to perform. Accordingly, psychiatric disorders, including OCD, reflect the exaggerated operation of normal brain system(s) present in the population. This perspective raises the following two defining and related questions regarding OCD:

(i) Is there a common theme to the symptoms of OCD, or are the symptoms merely a collection of unrelated acts?

(ii) What are the normal constitutive processes that can lead an individual to feel driven to engage in irrational acts (obsessions and compulsion) but without showing a disconnection from objective reality?

With regard to a possible relationship among OCD symptoms, a perusal of the various obsessions and compulsions (Reed 1985) suggests that they can be conceptualized as belonging to a specific domain. In particular, the content of most OCD thoughts and behaviors seems to revolve around concerns related to security or safety, either of the self or of others. Hence, following an expression used by Paul MacLean (MacLean 1973), the core theme of OCD obsessions and compulsions may be described as concerns regarding "self-preservation or preservation of the species" (Szechtman and Woody 2004). Importantly, because the concerns in obsessions and compulsions are about dangers that *might* happen in the future – as opposed to actual threats that are direct and immediate – it is ***potential* threats** that are proposed to constitute the domain of OCD concerns (Szechtman and Woody 2004; Woody and Szechtman 2011).

The domain of potential threats belongs to the normal concerns of everyone and is not unique to OCD (Muris et al. 1997; Rachman and De Silva 1978; Rassin and Muris 2007; Reed 1985; Salkovskis and Harrison 1984). Within this normal domain several classes of potential threats are present, but of most salience to OCD are the security concerns engendered by predation (attack by others) and contamination–contagion. Interestingly, these security concerns are among the key normal fears of children, with a clear developmental time-course (Boyer and Bergstrom 2011). The two classes of potential dangers normally evoke appropriate and specific precautionary responses, namely, checking and washing, respectively. As noted, the exaggerated performance of checking and washing are the two most common OCD compulsions (Rasmussen and Eisen 1992). Conceivably, OCD subtypes of checkers and washers map onto the predation and the contamination–contagion classes of security concerns, respectively.

There are crucial distinctions between threats that are potential and those that are direct and immediate, with profound implications for the design of systems that process them (Boyer and Lienard 2006; Szechtman and Woody 2004; Woody and Boyer 2011; Woody and Szechtman 2011). One important distinction is that the two types of threat necessitate different types of responses. Already-present threats require fast responses to confront the danger, the faster the better – whereas potential ones require behavioral adjustments that can take more time to develop and perform. Furthermore, behaviors evoked by immediate threats are directed and constrained by moment-to-moment interaction with the source of danger. In contrast, potential threats are countered by indirect precautionary measures, such as avoidance or probing, and are free of constraint by an actual confrontation.

Another important distinction between potential and immediate threats relates to feedback from external environment regarding elimination of the threat. With actual threats, cues of danger confront the senses and thus there is no ambiguity about the presence of the threat or its successful elimination. In contrast, for potential threats there is an information asymmetry regarding presence versus elimination of threat. Potential dangers such as contagion or predator presence

are detected on the basis of particular partial cues, such as rotting smells or predator spoor. However, once the organism has engaged in precautionary behaviors, there is no positive evidence that these did actually eliminate or sufficiently reduce the danger. For example, the absence of a predator smell is no positive evidence for the predator's absence. Thus, taking precautions does not create clear signals that the danger is removed. Hence, with potential threats, the external environment provides no actual feedback either that the danger is eliminated or that the precautionary behavior was appropriate and effective.

This peculiar property inherent to potential threat – no feedback from external information that performance of precautionary behaviors achieved security – creates an obvious design challenge for a system handling potential threats: (1) what ensures that precautionary behaviors are initiated and performed and (2) what decides that a satisfactory level of security has been achieved? As explained below, it is hypothesized that this challenge is met through a biologically "hard-wired" special motivation – the security motivation system (SMS) (Szechtman and Woody 2004, 2006; Woody and Szechtman 2005, 2011).

The challenge of ensuring that precautionary behaviors are initiated and performed is answered by employing a dedicated motivational system. A defining design property of motivation is the urge to engage in species-typical preprogrammed responses when the motivation is activated. Accordingly, a mechanism to process potential threats through a dedicated security motivation system has a built-in urge to perform security-related precautionary behaviors in response to potential threats.

The next challenge – how to satisfy security without external feedback – is answered by utilizing signals generated internally. Most motivations are deactivated through contact with the appropriate goal object; for example, hunger motivation is deactivated by eating food, which generates a negative feedback satiety signal that terminates the motivation to attain food (Toates 1986). Because no external goal objects exist to satisfy an activated security motivation, then it must be that motivation gets deactivated through the very act of performance of security-related precautionary behaviors. In other words, self-generated signals from engagement in precautionary behaviors serve as the negative feedback satiety signal that terminates security motivation. Such an arrangement is functionally plausible because species-typical motor activity per se is rewarding (Glickman and Schiff 1967). Clearly, the built-in reward for security-related engagement contributes also to maintenance of precautionary responses to potential threats.

The model of SMS shown in Fig. 1 makes comprehensible how OCD can represent the exaggerated activity of a normal system and how normal constitutive processes can indeed compel performance of seemingly irrational acts (obsessions and compulsion) despite awareness of a seemingly inconsistent objective reality. The design in Fig. 1 of SMS follows the generic blueprint for a special motivation and consists of four modules shown in the middle row: a specialized module for detection of potential threats (*green* circle labeled "appraisal of potential danger") that turns on a "security motivation" module, which generates a coordinated set of processes to energize and focus brain resources on attaining a specified goal.

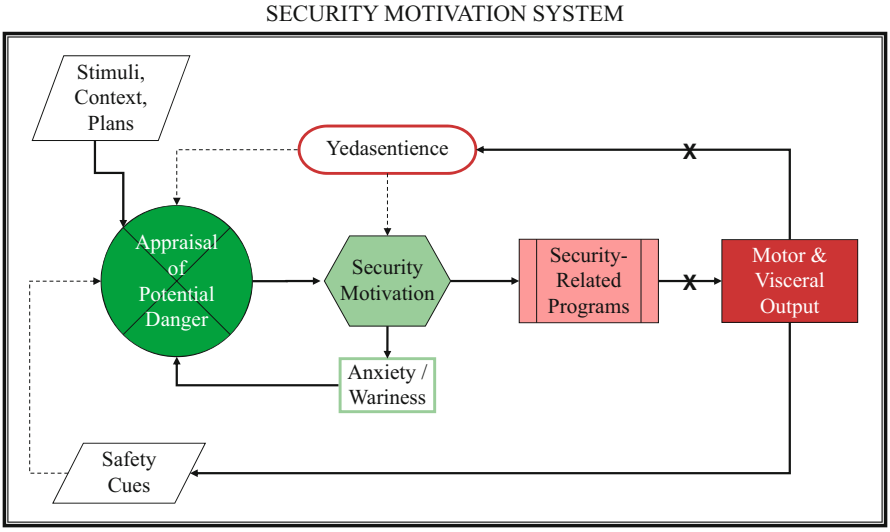

Fig. 1 A conceptual model of the security motivation system and sites of dysfunction producing OCD. Solid arrows indicate excitatory and dashed arrows inhibitory stimulation, respectively. Yedasentience output does not act on environmental input but rather on the appraisal of potential danger and the security motivation processors to inhibit their activity. Exposure through motor output to "safety" stimuli provides inhibitory stimulation to appraisal of potential danger [Modified from (Szechtman and Woody 2004)]

The signal from "security motivation" selects from the "security-related programs" module the plan of programs appropriate for the particular class of potential threat (e.g., washing and cleaning behaviors for the contamination–contagion class, probing and checking for the predation class). The "security-related programs" module in turn activates the "motor and visceral output" module, which executes and implements the actual performance of the species-typical motor actions. Execution of precautionary responses generates also internal feedback signals, including the signal labeled "yedasentience" shown in red in the top row [*yedasentience* = "feeling of knowing" (Szechtman et al. 2002; Szechtman and Woody 2004; Woody and Szechtman 2000)]. This yedasentience signal inhibits the "security motivation" and "appraisal of potential danger" modules, thereby stopping SMS activity.

Termination of security motivation activity by the self-generated yedasentience negative feedback signal provides an explanatory mechanism for OCD compulsions and obsessions. Specifically, failure to generate yedasentience (or respond to this signal) leaves SMS activity on for a prolonged period of time, driving persistent performance of precautionary behaviors – this continued performance constitutes OCD obsessions and compulsions. Two potential sites where damage may lead to a failure to generate yedasentience and yield obsessions and compulsions are shown by X in Fig. 1.

Lack of yedasentience feedback also explains how seemingly unreasonable obsessions and compulsions can exist alongside a normal sense of reality. Two particular characteristics of SMS contribute to the explanation. The first relevant property is the hierarchical dominance of an activated SMS. Specifically, when SMS is activated, it functions at the top of the hierarchy among competing systems controlling brain resources and actions. This is a design feature of special motivations which are engaged to perform functions vital for survival of the organism (Hebb 1966). Hence, it follows that when security motivation is stimulated, the individual becomes preoccupied with security, at the expense of other cues in the environment, and in this respect such preoccupation is normal and does not reflect any loss of a sense of reality.

The second relevant property is peculiar to SMS: an inherent disconnection of SMS deactivation from objective reality. As noted above, the external environment provides no reliable feedback either that potential threat was eliminated or that precautionary behaviors were appropriate and effective in achieving security. Consequently, as shown in the model in Fig. 1, information from the external environment has no access to security motivation to shut it down – only the self-generated yedasentience feedback can turn off security motivation. Hence, the drive to engage in obsessions and compulsions can coexist with a logically conflicting sense of reality.

4 Neurobiology of SMS and Substrate of OCD Pathophysiology

Framing OCD as a disturbance of security motivation simplifies the task of identifying OCD pathophysiology because it reduces the pathophysiology of OCD to a dysfunction in the neurobiology of SMS, and a fairly good model of a functional SMS neurobiology exists (Szechtman and Woody 2004, 2006; Woody and Szechtman 2011). The model follows the generic plan of motivational systems derived from behavioral neuroscience studies on motivation. Accordingly, the proposed schematics of SMS neurocircuitry and physiology are shown in Figs. 2 and 3.

Like other neuroanatomical models of motivation [e.g., (Brown and Pluck 2000; Everitt and Wolf 2002)], the SMS diagram in Fig. 2 consists of functional loops involving cortico-striato-pallido-thalamo-cortical connections, as advanced by Alexander et al. (1986) and others (Groenewegen et al. 1999; Haber et al. 2000; Joel and Weiner 2000; Penney and Young 1983). Importance of the yedasentience signal is highlighted by inhibitory connections from the brainstem. There are four cascading neural loops in Fig. 2, each mediating one of the four functional components in Fig. 1 – the color codes of the loops correspond to the functional modules in Fig. 1. Accordingly, the circuits in Fig. 2 are labeled: appraisal of potential danger loop (*green*), security motivation and affect loop (*light green*), security-related programs loop (*light red*), and brainstem output network (*red*), where each loop contains specific brain structures that are interconnected to form a specialized neurocircuit mediating a distinct motivational task.

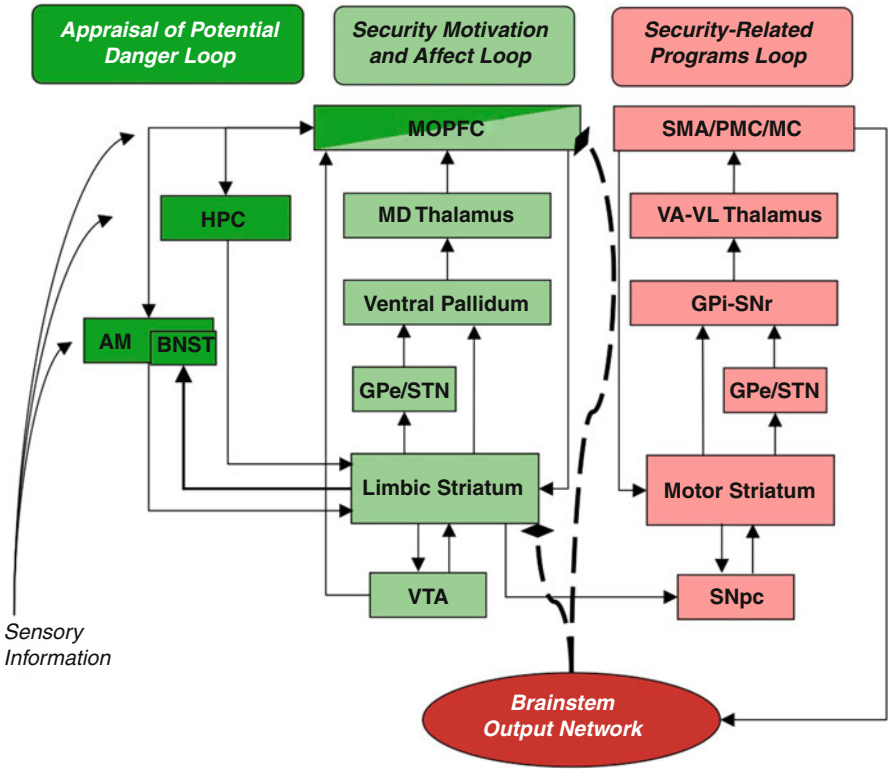

Fig. 2 A neural circuit model of the security motivation system. Each of the four distinct subcircuits (*loops*) subserves one of the functional components in Fig. 1 and is identified by corresponding colors. The dashed line indicates possible sites of yedasentience feedback inhibition. Abbreviations: *AM* amygdala, *BNST* bed nucleus of the stria terminalis, *GPe* external segment of the globus pallidus, *GPi* internal segment of the globus pallidus, *HPC* hippocampus, *MC* motor cortex, *MD* Thalamus, mediodorsal thalamic nucleus, *MOPFC* medial prefrontal cortex and orbital prefrontal cortex, *PMC* premotor cortex, SMA, supplementary motor area, *SNpc* substantia nigra pars compacta, *SNr* substantia nigra pars reticulata, *STN* subthalamic nucleus, *VA* ventroanterior thalamic nucleus, *VL* ventrolateral thalamic nucleus, *VTA* ventral tegmental area [Reprinted by permission from (Szechtman and Woody 2004)]

The first motivational task – detection of potential danger – is handled by the appraisal of potential danger loop composed of the interconnected green-coded brain regions in Fig. 2. The indicated interconnected limbic regions – the hippocampus, the amygdala, and the bed nucleus of the stria terminalis (BNST), as well as the medial and orbital prefrontal cortex (MOPFC) – process motivation-related input, including security-related information (Bechara et al. 2000; Fiddick 2011; LeDoux 2000; Woody and Szechtman 2011). Thus, this detection circuit has the computational functions to quickly process signalling cues (e.g., rotting smells, predator spoor, novelty) and more complex information ("context," "plans") and determine whether a change of present circumstance could result in a future harm.

If computational outcome is indeed potential danger, the appraisal of potential danger loop has neuroanatomical links needed for activation of the next motivational task, handled by the security motivation and affect loop (*light green*-colored boxes). Specifically, the hippocampus and the amygdala have projections to the ventral striatum, a key area in the security motivation and affect loop; moreover, the MOPFC (denoted by the box with *green* and *light green* colors) is a component of both the appraisal of potential danger loop and the security motivation and affect loop, providing an interface between the two circuits.

The next motivational task is the engagement of motivational drive and affect and is handled by the security motivation and affect loop (light green-coded brain regions in Fig. 2). The neuroanatomical sites of this loop are linked as a prototypical basal ganglia–thalamocortical circuit (Alexander et al. 1986) and form, specifically, the "limbic striatum loop" (Brown and Pluck 2000; Joel and Weiner 2000). Three attributes of this neurocircuit seem especially relevant for the designated job of the security motivation and affect loop. First, it contains dopamine innervation from the VTA onto the limbic striatum and the prefrontal cortex. Dopamine input can supply the tonic ignition of the loop and this dopamine stimulation is likely the implementation of a salient characteristic of motivations, namely, the urge to engage in goal-directed behaviors. Indeed, stimulation of the mesolimbic dopamine system yields approach and investigatory behaviors (Ikemoto and Panksepp 1999), and such motor activity is part of the repertoire of many motivations, including security motivation, where it manifests itself as probing the environment for potential danger. Second, the loop involves connections with limbic regions implicated with processing of affect accompanying motivation. In the case of security motivation, it has been suggested that the connection from the limbic striatum to BNST (Davis and Shi 1999; Davis et al. 1997; Lang et al. 2000; Woody and Szechtman 2011) is especially important in mediating the feelings of anxiety and wariness, the phenomenological cues of potential danger (Masterson and Crawford 1982; Woody and Szechtman 2011). Finally, the neural arrangement of the regions within the loop is such as to prolong and sustain reverberatory activity (Alexander et al. 1986; Penney and Young 1983) needed to maintain motivational drive and also activate the next motivational task.

The next motivational task is the selection and engagement of an appropriate security-related response. This job is executed by the security-related programs loop (light-red-coded brain regions in Fig. 2); this loop is also a prototypical basal ganglia neurocircuit but interconnected with the dorsal (or "motor" striatum) and innervated by dopamine from the substantia nigra. The circuit has design features especially useful for "selection" of appropriate responses (Mink 1996; Penney and Young 1983; Wolgin 2012). Every motivation has its own set of species-typical behavioral actions; typically, the neural instructions of how to implement the organization of a species-typical pattern of behavior are held in the striatum in the form of a precoded "program" (Aldridge et al. 2004; MacLean 1978; Penney and Young 1983; Wise and Rapoport 1989). Accordingly, depending on the domain of potential danger, the security-related programs loop engages the appropriate program (e.g., for probing or checking the environment in case of potential threat of

attack and for washing or grooming in case of contamination–contagion), and at the same time it inhibits and prevents competing behavioral programs from access to motor output. Dopamine activity from the nigrostriatal system probably helps to maintain the neural operation of the selected program and intensity of its execution, reflected in the vigor of motor performance (Dvorkin et al. 2010).

Finally, the program selected by the security-related programs loop implements those instructions by activating the brainstem output network (*red*-coded area in Fig. 2), and stimulating brainstem output neurons that convey neural signals for the actual contraction of muscles that move the body and viscera in performance of the species-typical actions. In addition to patterned movements, the brainstem output network generates the yedasentience negative feedback signal, which shuts down security motivation via inhibitory input possibly to the ventral striatum and MOPFC (heavy dashed line in Fig. 2). This negative feedback pathway is probably serotonergic, given that the serotonin neurotransmitter serves widely as a "stop" or "satiety" signal in many functions (e.g., Blundell 1991; Lorrain et al. 1999; Soubrie 1986) and serotonin reuptake inhibitors have therapeutic effects in OCD (DeVeaugh-Geiss 1994).

Every motivation which has a characteristic neural network possesses also a characteristic physiology that facilitates network operation at its optimum. The model in Fig. 3 shows that physiological mechanisms that support an activated security motivation operate through stimulation of the hypothalamic–pituitary–adrenocortical (HPA) axis and regulation of the parasympathetic nervous system (PNS). These systems contribute peripherally and centrally to enhance security motivation, which is turned on by potential threat and thus geared for action – for doing *something* that will relax the psychological tension of uncertain danger. To support those SMS prerequisites, HPA and PNS engage peripheral mechanisms to mobilize energy for physical work and also exert central effects on the *appraisal of potential danger* and *security motivation and affect* loops to potentiate threat detection and motivation [Fig. 3; for details, see (Woody and Szechtman 2011)].

5 Pathophysiology of OCD

Using the above framework of a fully functional SMS (Figs. 2 and 3), the pathophysiology of OCD is relatively clear cut – OCD pathophysiology is normal neural activity in SMS loops that becomes overly persistent and uncontrolled (Saxena et al. 1998; Wise and Rapoport 1989). While there are many possible neuroanatomical spots where a malfunction (regardless of cause) can produce this pathophysiology, two salient malfunctions likely to yield prolonged and uncontrolled SMS neural activity are excessive dopaminergic stimulation, insufficient serotonergic negative feedback, or possibly both. Indeed, there is evidence for each possibility in OCD (Denys et al. 2004; Westenberg et al. 2007), including dysfunction in both dopamine and serotonin (Nikolaus et al. 2010) attested by current clinical practice of combining dopamine blockers with serotonin reuptake inhibitors for treatment of OCD (Bloch et al. 2006; Dougherty et al. 2004).

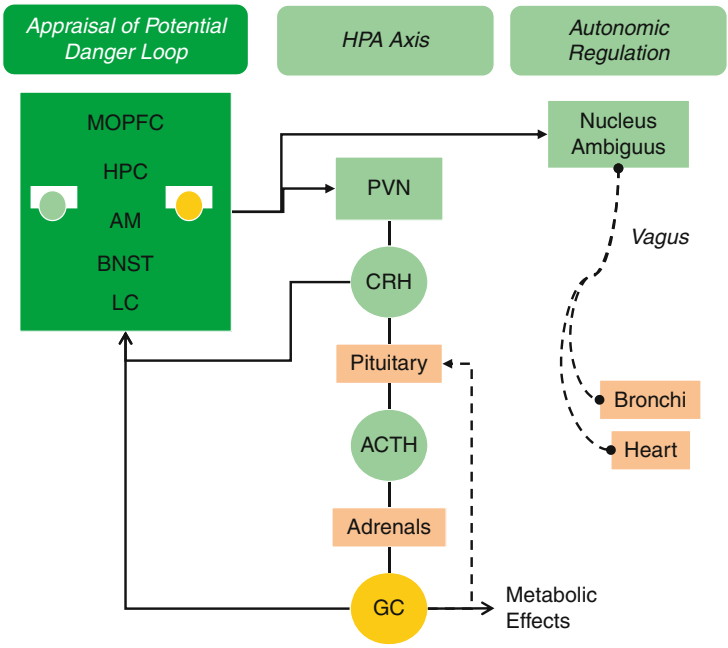

Fig. 3 The physiological network associated with security motivation. The appraisal of potential danger loop of Fig. 2 connects with the HPA Axis, which has both input from and output to the Appraisal Loop. Within the Appraisal Loop there are receptors for CRH and GC, denoted by the respective circles in white rectangles, by which HPA can modulate it; CHR also acts as a neurotransmitter within the Appraisal Loop. Finally, the Appraisal Loop affects Autonomic Regulation, by which the myelinated vagus modulates the bronchi and heart. Abbreviations: *AM* amygdala, *BNST*, bed nucleus of the stria terminalis, *CRH* corticotropin-releasing hormone, *GC* glucocorticoids, *HPC* hippocampus, *LC* locus coeruleus, *MOPFC* medial prefrontal cortex and orbital prefrontal cortex, *PVN* paraventricular nucleus [Reprinted by permission from (Woody and Szechtman 2011)]

One manner by which dopamine–serotonin imbalance can yield excessive SMS activity and thus OCD pathophysiology is as follows. OCD concerns are the normal security-related concerns of everyone and indeed their incidence does not differ between OCD and non-patient populations (Muris et al. 1997; Rachman and De Silva 1978; Rassin and Muris 2007; Reed 1985; Salkovskis and Harrison 1984). Consequently, individuals are often presented with some potential threat that activates the dopaminergic motivational drive of the security motivation circuit. However, in individuals with a constitutively hyperfunctional dopamine system, activation of security-related dopaminergic motivational drive produces excessive stimulation of dopamine receptors thereby driving the SMS circuit continually and overpowering any negative feedback to shutdown SMS activity. Similarly, in individuals with a constitutively ineffective serotonergic negative feedback,

activation of security motivation also yields OCD pathophysiology but here SMS activity stays prolonged not because of an intrinsic or pathologic dopamine hyperfunction. Instead, SMS activity is prolonged because serotonergic negative feedback is the normal mechanism to deactivate the dopaminergic motivational drive, and consequently, without a serotonergic "stop" signal, SMS activity continues unabated.

6 Evidence for Overactive SMS Circuit in OCD

The foundational line of evidence for overactive functional loops involving cortico-striato-pallido-thalamo-cortical connections came from early positron emission tomography (PET) studies measuring the brain distribution of glucose metabolism in patients with OCD. Such PET studies showed metabolic hyperactivity in orbitofrontal cortex and caudate nucleus in patients with OCD, a hyperactivity that resolved upon disappearance of OCD symptoms with therapy (Baxter 1992; Baxter et al. 1992; Benkelfat et al. 1990; Swedo et al. 1992). Subsequent brain imaging studies have also implicated hyperfunction of the orbitofrontal cortex, basal ganglia, and the limbic system in OCD (Adler et al. 2000; Friedlander and Desrocher 2006; Kim et al. 2001; Mataix-Cols et al. 2004; McGuire et al. 1994; Menzies et al. 2008; Phillips and Mataix-Cols 2004; Rauch et al. 1994; Rotge et al. 2008; Saxena et al. 1998; van den Heuvel et al. 2004).

Deep brain stimulation (DBS) has been found effective for some patients with symptoms of OCD (Alegret et al. 2001; Anderson and Ahmed 2003; Fontaine et al. 2004; Mallet et al. 2002; Nuttin et al. 1999, 2003; Piasecki and Jefferson 2004), with the three sites targeted being the subthalamic nucleus (Fontaine et al. 2004; Mallet et al. 2002), the anterior limbs of the internal capsules (Anderson and Ahmed 2003; Nuttin et al. 2003), and the nucleus accumbens (Denys et al. 2010; Huff et al. 2010; Sturm et al. 2003). Although it is not well understood how DBS yields therapeutic effects, it may involve disruption of reverberatory activity in basal ganglia loops (Aouizerate et al. 2004; Bourne et al. 2012; Haynes and Mallet 2010; Tass et al. 2003), consistent with OCD pathophysiology. A similar disruption of overactivity may be expected from strategically placed lesions, and indeed severe cases of OCD may be improved with psychosurgery, in particular with anterior capsulotomy or cingulotomy (Baer et al. 1995; Chiocca and Martuza 1990; Dougherty et al. 2002; Jenike et al. 1991; Kettl and Marks 1986).

7 Neurotoxic Effects Producing OCD Pathophysiology

The pathophysiology of OCD – persistence of activity in SMS functional loops – could result from many types of insults and probably at several neuroanatomical locations in the neurocircuit. This section consults the clinical literature for medical conditions with a presentation of OCD phenomenology and asks whether those

medical perturbations could have yielded unregulated activity in basal ganglia functional loops. Three types of perturbations are considered: by drugs, brain injury, and infection.

7.1 Drugs

Given the prominent role of dopamine systems in SMS circuit (Fig. 2), it is expected that dopamine-activating drugs should provoke OCD phenomenology, at least with prolonged use. The clinical literature does indeed support this expectation with case reports of OCD symptoms from chronic exposure to amphetamines (Marchesi et al. 2009; Semple et al. 2011; Woolley and Heyman 2003), cocaine (Crum and Anthony 1993), and other direct dopamine receptor agonists (Ahlskog 2011). In animals, too, dopamine agonists produce compulsive behaviors considered to model OCD (De Carolis et al. 2011; Szechtman et al. 1999, 1998).

At first blush, a contradictory literature seemingly exists as well, because drugs used in treatment of OCD, dopamine receptors blockers (Bloch et al. 2006; Dougherty et al. 2004), may themselves induce OCD symptoms. There are clinical reports that atypical antipsychotics, such as aripiprazole (Desarkar et al. 2007), clozapine, risperidone, and olanzapine (Lykouras 2003), can produce or exacerbate OCD symptoms, as evidenced by the appearance and disappearance of symptoms with the introduction and removal of the drug. Clearly, those drug effects may involve an action on other than dopamine receptors. However, a possible mechanism via dopamine receptors should not be ignored, given that dopamine receptor supersensitivity may develop with exposure to dopamine blockers (Kostrzewa 1995) and given that dopamine D2 receptors play a role not only in the initiation of behavior but also in arresting ongoing activity (Ghahremani et al. 2012; Hoffman and Rueda Morales 2012). Indeed, the intricate circuitry of basal ganglia loops contains many inhibitory and excitatory connection points, not just dopaminergic or serotonergic (Bourdy and Barrot 2012; Pittenger et al. 2011; Rotge et al. 2010), and a disruption at any such point can yield overly sustained reverberatory activity.

7.2 Brain Injury

Symptoms of OCD often appear associated with neurologic disorders. These include postencephalitis Parkinsonian syndrome (Schilder 1938), Parkinson's disease (Kurlan 2004), striatal (Ercan et al. 2008) or globus pallidus necrosis (Laplane et al. 1989), Huntington's chorea (Cummings and Cunningham 1992), and Gilles de la Tourette's syndrome (TS) (Pauls et al. 1986). All of these conditions involve a disturbance of the basal ganglia, suggesting that upon activation of security motivation those neurologic disturbances may also yield the characteristic pathophysiology of OCD, namely, prolonged overactivity in the SMS neurocircuit. A similar inference of SMS circuit perturbation may relate to cases of OCD following acquired brain injury (Coetzer 2004).

7.3 Infection

Some instances of infection may result in OCD symptoms that resolve upon disappearance of the infection. For instance, there are such reported cases for cerebral malaria (Idro et al. 2005), *Mycoplasma pneumoniae* infection (Ercan et al. 2008), *Borna disease virus* (BDV) infection (Rotge et al. 2010), as well as streptococcal infection, the latter infection having a designation on its own for the ensuing OCD – PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) (Swedo et al. 1998, 1989). Some autoimmune disorders, including Sydenham's chorea (Swedo et al. 1989) and systemic lupus erythematosus (Yu et al. 2008), may also present with OCD symptoms. More generally, various immune markers may be altered in patients with OCD (da Rocha et al. 2008). Such findings suggest three types of mechanisms whereby infection and immune activation could yield OCD pathophysiology.

One type of mechanism follows the disease model of tuberculosis, namely, that a specific pathogen causes OCD, just like *tubercle bacillus* is the causal agent of tuberculosis. In tuberculosis, the symptoms and the pathophysiology of the disease are the outcomes of the bacterium lodging preferentially in certain body organs (e.g., lungs) and its interaction with immune processes to contain it. This battle yields "collateral damage" in the afflicted organs and physiology, and such particular perturbations are manifested as disease-specific symptoms. Similarly, for OCD, Rotge and colleagues (Rotge et al. 2010) elaborated a plausible scenario for "the process by which infection becomes disease" (Barnes 2000, p. 439). Following up on reports (Bode et al. 1995) that BDV infection may play a role in psychiatric disorders, Rotge and colleagues (Rotge et al. 2010) noted that the virus' preferential neurotropism for brain regions of relevance to OCD would mount an immune response there, leading possibly to a region-specific malfunction as a by-product of the immune response. While there are many plausible mechanisms by which immune reactions can perturb neuronal function (for a recent review, see Kapadia and Sakic (2011)), the authors highlight a mechanism which involves glutamate neuroexcitotoxicity, in light of genetic findings of a glutamate transporter gene SLC1A1 association with OCD (Arnold et al. 2006; Wu et al. 2012) and recognition that glutamate is both a neurotransmitter and an immunomodulator. According to the authors, genetic alterations of the glutamatergic system in some individuals would facilitate BDV-induced immunopathological reactions in the OCD-relevant brain regions (Rotge et al. 2010), with consequent hyperactivity of basal ganglia loops (Wu et al. 2012) that constitute the SMS neurocircuit.

Another type of mechanism is closely related to the above in that it also invokes immune activation as the agent producing neural dysfunction. However, this mechanism is related to autoimmune processes rather than stemming from local reactions to neurotropic pathogens. An example of such an autoimmune-induced OCD-related neural dysfunction is PANDAS. The mechanism underlying the OCD of PANDAS is considered to involve an autoimmune response triggered by Group A beta-hemolytic streptococcal infection. In individuals

positive for the D8/17 antigen on the surface of peripheral blood mononuclear cells, the antistreptococcal antibodies are thought to cross-react with neuronal basal ganglia antigens (Eisen et al. 2001; Swedo et al. 1997). This autoantibodies basal ganglia cross-reactivity can produce various forms of altered cellular function, including perturbation of neuronal signal transduction (Kapadia and Sakic 2011). Accordingly, OCD will ensue when humoral immunity targets neuronal elements of the SMS neurocircuit, and the resultant malfunction consists of overly persistent and uncontrolled circuit activity characteristic of OCD pathophysiology.

The last mechanism that can produce OCD pathophysiology is different: while still related to immune function, it does not involve an immunopathogenic effect on neuronal function. Rather, the OCD pathophysiology is produced by a sensitization-related mechanism that renders the SMS neurocircuit hyperfunctional. This may occur in the course of normal physiological function and not necessarily due to some immunopathogenic process. An example of such a phenomenon is "compensatory behavioral prophylaxis" (Fessler 2001). At times of relatively high progesterone levels, women are more susceptible to illness from infection because the immune system is suppressed, and a behavioral compensation at such times is enhanced precaution about contamination. Through a process of sensitization (Woolf 2011), this behavioral compensation mechanism can lead to SMS hyperactivity, producing OCD symptoms.

8 Conclusion

Because the cause or causes of OCD are unknown, it is uncertain whether variations in pathophysiology and symptoms constitute different manifestations of one disease or different diseases with distinct causes. However, whatever the causal agent may turn out to be, OCD is not a de novo creation but instead must reflect an exaggeration of the operation of a normal brain system. As argued here, information about the nature of the behavioral system affected by OCD can be integrated into a theoretical model of this normal system, called the security motivation system.

Recognizing both the similarities and differences between this system and other hard-wired motivational systems, a neurobiological model of the SMS may be derived from behavioral neuroscience studies of motivation. It consists of functional loops involving a cascade of cortico-striato-pallido-thalamo-cortical connections, with inhibitory connections from the brainstem. The pathophysiology of OCD can then be understood as normal neural activity in this system that becomes overly persistent and uncontrolled, e.g., due to a dopamine–serotonin imbalance. Three types of medical perturbations have been reported to produce OCD symptoms: drugs, brain injuries, and infections. The available evidence on these effects is broadly consistent with disturbances of regulation in the activity of the hypothesized basal ganglia functional loops. Thus, the SMS model provides a unifying framework for understanding the likely mechanisms of these neurotoxic effects.

Physical Exercise as Intervention in Parkinsonism

Trevor Archer and Anders Fredriksson

Contents

Abstract

Physical exercise, particularly for individuals with sedentary occupations and independent of activity type, offers probably the most effective health-ensuring policy available. The associations between physical exercise and symptoms/biomarkers of idiopathic Parkinsonism and animal models of Parkinson's disease (PD), quality of life and self-reliance, disorder progression, and risk factors all support the contention that activity provides for an improved prognosis. In the present treatise, mice treated with the selective dopamine neurotoxin (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, 3 × 30 mg/kg once each week over three weeks), or Vehicle, were given access to running-wheel exercise from the week

following the first injection of MPTP onwards: the MPTP-Exercise group received four 30-min sessions in the running wheels (Mondays to Thursdays), whereas the MPTP No-exercise and Vehicle groups received a single session each week (Wednesdays). It was observed that the MPTP+Exercise group increased the distance run on each Wednesday 30-min session incrementally, whereas the MPTP No-exercise and Vehicle groups remained at the same distance throughout; similarly, during the 10-min test session on Fridays, prior to the tests of motor activity, the MPTP+Exercise group increased the distance run on each successive occasion but the MPTP No-exercise and Vehicle groups did not. In the tests of spontaneous motor activity, running-wheel exercise over 4 days/week (30 min, Mon.–Thurs.) improved all three parameters of motor activity, locomotion, rearing, and total activity, in the activity test chamber during test weeks 2–7, compared to the MPTP group following the MPTP administration. In the L-Dopa-induced activity test, running-wheel exercise over 4 days/week enhanced locomotor and rearing but not total activity following the subthreshold dose of L-Dopa for the MPTP+Exercise group but not the MPTP No-exercise group. Running-wheel exercise over 4 days/week increased the DA concentrations in the striatum of MPTP+Exercise mice.

1 Introduction

Physical exercise has been described as any and all activity that generates force through muscular activity that disrupts a homeostatic state (McArdle et al. 1971; Scheuer and Tipton 1977). Although daily physical activity holds benefits for general measures of function, quality of life, and physical strength, as well as increasing endurance (Dechamps et al. 2010a, b; Marks et al. 2009), much evidence presents the manifest advantages for cerebral integrity during aging (Kramer et al. 1999; Lustig et al. 2009; Marks et al. 2010). Any bodily activity that enhances or maintains physical fitness implies the involvement of regular and frequent exercise. Morris and Schoo (2004) have defined exercise as a planned, structured physical activity with the purpose of improving one or more aspects of physical fitness and functional capacity. Regular physical exercise/exertion promotes neuroimmune functioning and facilitates prevention of heart conditions, cardiovascular diseases, type II diabetes and obesity, and mental health improvements, e.g., depressiveness, all of which may exacerbate the PD condition (Nicolucci et al. 2012; Stampfer et al. 2000). Physical exercise offers a nonpharmacologic, noninvasive intervention that enhances brain health and plasticity (Cotman and Berchtold 2002). It has been characterized on the basis of type, intensity, frequency, and duration, with

either endurance or resistance as the training endpoint (Mougios 2010). Long-term exercise benefits brain functioning by increasing cerebral blood flow and oxygenation (Linkis et al. 1995), mobilizing growth factors and synaptic plasticity (Hunsberger et al. 2007) and facilitating performance through neurotransmitter release (Morishima et al. 2006; Hsu et al. 2011). Regular physical exercise holds particular benefits for older individuals, whether under conditions of normal aging or affected by neurodegenerative disorders (Archer 2011; Archer et al. 2011a, b).

Parkinson's disease (PD), a progressive brain disorder that impairs motor function, presents the cardinal symptoms of akinesia/hypokinesia, rigidity, and tremors as a result of the marked degeneration of the nigrostriatal dopamine (DA) pathway (Bernheimer et al. 1973; Goetz et al. 2001). This loss of DA in the basal ganglia is associated with deterioration in balance and postural control together with progressive reductions in the speed and amplitude of everyday movements (Morris et al. 2001; Smithson et al. 1998). The postural instability and disturbances in gait, which are major PD symptoms, are extremely disabling and lead to accidents, freezing, and involuntary movements, all of which worsen prognosis and elevate mortality risk (Adkin et al. 2003; Bloem et al. 2004; Wielinski et al. 2005). The progression of the disorder leads to reduced physical fitness and muscular capability (Canning et al. 1997) with psychosocial and economic implications for patients and caregivers (Schenkman et al. 2001). Fatigue presents a recurring symptom, described subjectively as "an overwhelming sense of tiredness, lack of energy, or feeling of exhaustion" (Krupp and Pollina 1996), that is linked to depressive symptoms and sleep disturbances with consequential loss of quality of life (Friedman and Friedman 2001; De Boer et al. 1996; Karlsen et al. 2000). Although there has been much advance in pharmacological and surgical interventions, postural instability, problems of gait, and instability of balance persist, thereby causing disablement (Grimbergen et al. 2004) and restriction of functional independence and quality of life (Martinez-Martin 1998; Schrag et al. 2000). Patients with PD may develop also a range of nonmotor conditions, including depression, apathy, sleep disturbances, constipation, and cognitive dysfunction, all of which together with the motor deficits may lead to adoption of a sedentary lifestyle (Fertl et al. 1993; van Nimwegen et al. 2011). Unsurprisingly, the prevalence of osteoporosis is high in patients with PD (63 % of PD women and 20 % of PD men compared with healthy age-matched control (29 % in women and 12 % in men) individuals (Invernizzi et al. 2009; Lorefält et al. 2007; Schuit et al. 2004), thereby increasing risk of falls (Sato et al. 2001).

It has been shown that physical exercise improves motor performance in PD patients (Bergen et al. 2002; Comella et al. 1994; Schenkman et al. 2008). In several controlled clinical studies, the implementation of continuous exercise for early-stage PD patients has provided improved daily activity, motor performance, ambulation, and overall functional independence (Baatile et al. 2000; Miyai et al. 2000; Reuter et al. 1999). In the laboratory, studies in healthy older rodents have shown that regular aerobic physical exercise promotes plasticity-related changes in the brain and CNS that include synaptogenesis neuronal arborization, enhanced

glucose utilization, angiogenesis, and neurogenesis (Hirsch and Farley 2009). It promotes also a healthy brain by reducing inflammation, suppressing oxidative stress, and stabilizing calcium homeostasis (Cotman et al. 2007). Several beneficial cerebral features of exercise have been observed from imaging studies: the volume and preservation of gray and white matters of sedentary individuals was enhanced through aerobic activity (Colcombe et al. 2006; Parker et al. 2011; Szabo et al. 2011). It has been suggested that in PD patients adaptive neuroplasticity may occur spontaneously at the level of both the basal ganglia and the cortex (Buhmann et al. 2005); these compensatory processes may be even initiated during the prodromal stage of disorder (van Nuenen et al. 2009). There is evidence that increased homocysteine (Hcy) levels might accelerate dopaminergic cell death in Parkinson's disease (PD) through neurotoxic effects (Gorgone et al. 2012; Lee et al. 2011; Zoccolella et al. 2010). Hyperhomocysteinemia presents a major risk factor for cerebral and peripheral vascular diseases as well as cortical and hippocampal injury, including an increased risk of dementia and cognitive impairment, and in PD patients treated with levodopa, elevated serum homocysteine (Hcy) concentrations are common. Nascimento et al. (2011) have found that even with regular levodopa therapy, Hcy concentrations in PD patients who had exercised regularly were significantly lower than in PD patients who had not exercised and were similar to the Hcy concentrations in the healthy controls. Taken together, evidence suggests that there is a strong tendency for PD patients toward sedentary lifestyle, whereas it is highly evident that a regime of regular physical exercise offers manifest benefits (Speelman et al. 2011; van Nimwegen et al. 2010).

Physical exercise is known to ameliorate both the symptoms and disability caused by PD (Bilowit 1956; Hurwitz 1989; Palmer et al. 1986). For example, the immediate effects of structured speed-dependent treadmill training, limited progressive treadmill training, conventional gait training, or a control intervention were compared in 17 early-stage PD patients. It was found that speed and stride length, the main gait disturbances, were improved markedly by speed-dependent training (Pohl et al. 2003). In another study, the effects of high-intensity training on the treadmill was compared with low- or no-intensity training with marked postexercise increases in gait speed, step, and stride by the former compared with the latter two conditions (Fisher et al. 2008). Treadmill physical activity has provided a variety of improvements for PD patients including motor performance (Schenkman et al. 2008), capacity for daily activities (Miyai et al. 2000, 2002), reduced incidence and lethality of disorder (Kuroda et al. 1992), strength, balance and gait speed (Toole et al. 2005), motor and postural flexibility (Kurtais et al. 2008), and neurocognitive performance (Ahlskog 2011; Gomez-Pinilla 2011). In addition to the cardinal symptoms, hypokinesia, gait and posture disturbance, tremors, and rigidity, several factors contribute negatively to reduced quality of life in PD patients: pain and fatigue, depressive symptoms and cognitive deficits, sleep problems, and detrimental social functioning with accompanying economical impact (Chrischilles et al. 2002; Whetten-Goldstein et al. 1997). Both functional mobility and quality-of-life variables have been improved by exercise programs of various different types (Herman et al. 2007; Kadivar et al. 2011; Rodrigues de Paula et al. 2006).

Despite being slower compared to age-matched healthy controls, PD patients show motor learning with repetitive practice (Jessop et al. 2006; Michel et al. 2009; Onla-or and Winstein 2008; Smiley-Oyen et al. 2006). Both short-term and extensive practices of movement gave benefits against the bradykinesia of PD patients (Smiley-Oyen et al. 2012).

Repeated administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to C57/BL6 mice induces selective and long-lasting lesions of DA in nigrostriatal regions of the brain (Jackson-Lewis et al. 1995; Jones-Humble et al. 1994). The neurotoxin, administered systemically, induces Parkinsonism in human and nonhuman primates (Langston 1985) that results in the loss of *substantia nigra* cells in the *pars compacta* of adult animals (Chiueh et al. 1985). It destroys selectively nigrostriatal neurons, thereby inducing acute, subacute, long-lasting, and even permanent effects that resemble certain features of PD, particularly the hypokinesic effects (Schultz et al. 1989). Systemic administration of MPTP (2 × 40 mg/kg, s.c.) caused L-Dopa reversible hypoactivity (Fredriksson et al. 1990; CR0105146 et al. 1990). A less rigorous dose regime, e.g., 2 × 20, or 25 or 30 mg/kg, of MPTP has been found not to reduce motility in the C57 black mice, although DA brain concentrations may indicate up to 50–80 % reductions (Heikkila et al. 1989; Sonsalla and Heikkila 1986), unless given much more repeatedly (cf. Kurz et al. 2007). The parameters of MPTP treatment neurotoxicity in mice are extremely long-lasting (up to and beyond 52 weeks after treatment) with strong correlations between the functional deficits, particularly hypokinesia, the main biomarker, severe DA depletions, and a dose- and time-dependent recovery of several parameters of motor behavior following treatment with the DA precursor, L-Dopa (Archer and Fredriksson 2003; Fredriksson and Archer 1994; Fredriksson et al. 1999).

In the unilateral 6-hydroxydopamine rat model of Parkinson's disease (PD), Tillerson et al. (2003) abolished the lesion-induced motor asymmetry by forcing the rats to use affected (contralateral) limb, whereas as forced nonuse exacerbated the injury (Tillerson et al. 2002a, b). Both dopamine (DA) and 3,4-dihydroxyphenylacetic acid (DOPAC) were elevated markedly in "casted" 6-OHDA-treated rats (forced to use the contralateral limb) compared with "noncasted" rats (Cohen et al. 2003). Archer and Fredriksson (2010) found that daily running-wheel activity attenuated the hypokinesic effects of MPTP in both a concentrated (2 × 40 mg/kg, 24-h interval) and progressive (1 × 40 mg/kg, weekly doses over 4 weeks) schedule with regard to spontaneous motor behavior and activity following a subthreshold dose of L-Dopa. The loss of DA in each case was attenuated by exercise also (Experiment I, 61 % of control rather than 17 %, Experiment II, 24 % rather than 11 %). Using the progressive schedule of MPTP treatment and extending the exercise intervention from 7 to 14 weeks, it was shown that spontaneous motor activity after MPTP was close to restoration, whereas activity after subthreshold L-Dopa was completely recovered (Fredriksson et al. 2011); DA levels were restored from 17 % (non-exercised) to 64 % in the 14-week exercise intervention and levels of brain-derived neurotrophic factor were increased significantly. It was shown also that both the functional and DA deficits

by MPTP were attenuated even by delayed- introduction of exercise (Archer and Fredriksson 2012).

Brain-derived neurotrophic factor (BDNF) is a neurotrophin with widespread expression in the brain and is connected intimately with brain metabolism and homeostasis (Chaldakov 2011). It is associated with neurogenesis, neuronal survival, and neuroreparation in the brain and CNS (Cui 2006; Numakawa et al. 2010). Treatment interventions that enhance BDNF-related signaling have the potential to restore neural connectivity (Kaplan et al. 2010). Physical exercise induces improvements in motor ability and enhances BDNF expression (Macias et al. 2009). It is linked to elevated BDNF levels in the hippocampus (Neeper et al. 1996; Oliff et al. 1998). Voluntary running, as physical activity, amplifies the BDNF signal that augments neurogenesis through diverse molecular pathways (Stranahan et al. 2009). BDNF mediates several essential morphological changes at neuronal levels that include dendritic arborization (Imamura and Greer 2009; Zhou et al. 2008), axonal and dendritic remodeling (Menna et al. 2005), synaptogenesis (Liu et al. 2009; Tchantchou et al. 2009), and synaptic efficacy (Boulanger and Poo 1999; Sallert et al. 2009). Faherty et al. (2005) have shown that a combination of exercise, social interactions, and learning, or exercise alone during adulthood, gave total protection against MPTP-induced Parkinsonism. They found also that changes in mRNA expression suggested that increases in glia-derived neurotrophic factors, coupled with a decrease of dopamine-related transporters (e.g., dopamine transporter, DAT; vesicular monoamine transporter, VMAT2), contributed to the observed neuroprotection of dopamine neurons in the nigrostriatal system following MPTP exposure. Tajiri et al. (2010) observed that exercise induced behavioral recovery in an animal model of PD and caused increased BDNF and glial-derived neurotrophic factor (GDNF) in the striatum of 6-OHDA-treated rats.

In the pathophysiology of PD symptom profiles, not least with regard to the cardinal symptoms and fatigue, L-Dopa treatment, despite certain drawbacks, has been found to improve ventilator function (Vincken et al. 1989) and work endurance and efficiency without affecting exercise hemodynamics (LeWitt et al. 1994). As DA precursor, the compound, following acute administration, reduced cortisol concentrations in PD patients in resting positions that reduced stress conditions (Müller and Muhlack 2007; Müller et al. 2006); this effect has been related to alterations in serotonergic and dopaminergic transmission (Höglund et al. 2001; Khakimova et al. 2011; Lopez et al. 2001). Pickrell et al. (2011) have presented a mouse model that expresses a mitochondria-targeted restriction enzyme, **PstI** or **mito-PstI**, damaging mitochondrial DNA (mtDNA) in DA neurons by inducing double-strand breaks in the mtDNA, leading to an oxidative phosphorylation deficiency, mostly due to mtDNA depletion. Using a dopamine transporter (DAT) promoter-driven tetracycline transactivator protein (tTA), they expressed mito-PstI exclusively in DA neurons, thereby presenting a novel PD transgenic mouse model (PD-mito-PstI mouse). They have shown that the PD-mito-PstI mice present the major features of PD: possessing a motor phenotype that is reversible with L-Dopa treatment, a progressive neurodegeneration of the SN dopaminergic population, and striatal DA depletion. Their results showed also that behavioral phenotypes in

PD-mito-PstI mice were associated with striatal dysfunctions preceding SN loss of tyrosine hydroxylase-positive neurons and that other neurotransmitter systems [noradrenaline (NE) and serotonin (5-HT)] were increased after the disruption of DA neurons, potentially as a compensatory mechanism. The eventual effects of regular physical exercise upon the PD-mito-PstI mice are awaited. The administration of L-Dopa, despite development of tolerance, generally alleviates bradykinesia (Fredriksson and Archer 1994; Fredriksson et al. 1990, 1999), but clinically, the DA precursor by itself will not elevate movement unless assertive physical exertion in the early stages is provoked (Weiner and Singer 1989). It has been found that exercise induced a significantly faster stimulation of growth hormone release following L-Dopa release, in comparison with the rest condition, in patients with PD (Müller et al. 2007).

Although endurance training aerobic sessions enhance cortical release proportional to exercise intensity (Kanaley et al. 2001), intensive physical exercise sessions also reduced cortisol plasma concentrations (Kemmler et al. 2003). Forced exercise initially increased, and then reduced, adrenocorticotropic hormone (ACTH) in control, non-brain damaged animals, followed by marked increases in BDNF (Griesbach et al. 2012). Exercise effects upon Parkinsonian conditions are complex: it appears that PD patients treated with L-Dopa may report a decreased capacity for physical exercise (Reuter et al. 2000; Ziv et al. 1998). The influence of physical exercise as an intervention affecting the efficacy of L-Dopa upon Parkinson symptoms is a central issue: Müller and Muhlack (2008) reported that while endurance exercise did not affect the reduction in cortisol release by L-Dopa, grip strength increased only during rest. Although exercise seems not to affect the pharmacokinetics of L-Dopa in PD patients (Carter et al. 1992), there is an abundance of evidence showing that it impacts upon L-Dopa effects on motor parameters in PD (Muhlack et al. 2007; Reuter et al. 1999; Scandalis et al. 2001; Viliani et al. 1999). Frazzitta et al. (2012) have found that intensive rehabilitation treatment, that included treadmill and stabilometric platform training, reduced the daily medication dosage of L-Dopa in treated (exercised) patients, whereas it was significantly increased in control (non-exercised) patients. In addition, the beneficial effects of intensive rehabilitation treatment persisted over time with a second rehabilitation cycle administered after one year as effective as the initial treatment. Endurance exercise has the effect of increasing L-Dopa-induced growth hormone availability in PD patients (Keranen et al. 1996; Manetta et al. 2002): Müller et al. (2007) observed that during exercise the resulting higher blood pressure mobilized blood flow and thereby growth hormone-releasing hormone, secreted into the hypothalamic portal capillaries, toward the growth hormone-producing cells in the pituitary gland. In highlighting the unique importance of exercise in the disorder perspective, a recent review (Ahlskog 2011) made the following recommendations for clinicians: (1) ongoing vigorous exercise and physical fitness should be encouraged, (2) PD physical therapy programs ought to include structured, graduated fitness instruction and guidance for deconditioned patients with PD, and (3) levodopa and other forms of dopamine replenishment therapy should be utilized to achieve the maximum capability and motivation whereby patients maintain fitness.

The purpose of the present study was to examine whether or not physical exercise in a running wheel would ameliorate the functional and DA deficits induced by MPTP under a progressive dose regime of the neurotoxin.

2 Material and Methods

2.1 Animals

Male C57 Bl/6 mice were purchased from B&K, Sollentuna, Sweden, and were maintained, five to a cage, in plastic cages in a room at temperature of 22 ± 1 °C and a 12/12 h constant light/dark cycle (lights on between 06.00 and 18.00 h). They were placed and maintained in groups of 4–6 animals in a room maintained for male mice only following arrival at the laboratory for about 2 weeks in order to acclimatize. Free access to food and water was maintained throughout, except for the day previous to the initiation to running-wheel exercise which occurred at the end of the second week following arrival. They were housed in groups of six animals, running-wheel exercised and activity chamber tested only during the hours of light (08.00–15.00 h). All exercising and testing were performed in a normally lighted room. Half of the mice in the MPTP treatment condition (MPTP-Exercise) were given running-wheel exercise, whereas the other half were placed in a clean laboratory cage for the same period in a room in which the running wheels were placed. Motor activity was tested in a specially arranged test room. This test room, in which all 12 ADEA activity test chambers, each identical to the home cage, were placed, was well secluded and used only for this purpose. Each test chamber (i.e., motor activity test cage) was placed in a sound-proofed wooden box with 12 cm thick walls and front panels and a small double-glass window to allow observation; each box had a dimmed lighting.

Three weeks following arrival, three groups (n = 10) of DSP4-treated and two groups of vehicle-treated mice were administered either MPTP (2 × 40 mg/kg, s.c., 24 h between injections) or vehicle (0.9 % physiological saline injected s.c. in a volume of 2 ml/kg body weight). Milmed (see below for details of preparation) or vehicle were administered on one occasion per week (Experiment I) or twice weekly (Experiments II and III).

Experiments were carried out in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC) after approval from the local ethical committee (Uppsala University and Agricultural Research Council) and by the Swedish Committee for Ethical Experiments on Laboratory Animals (license S93/92 and S77/94, Stockholm, Sweden).

2.2 Drugs

MPTP (Research Biomedical Inc., MA, USA; 2 × 20 mg/kg or 2 × 40 mg/kg, s.c., with a 24-h interval between injections in each case) was dissolved in saline and

administered s.c. in a volume of 2 ml/kg body weight. Melmid . . .. Saline was used as vehicle in each case.

3 Behavioral Measurements and Apparatus

Activity test chambers: An automated device, consisting of Makrolon rodent test cages (40 × 25 × 15 cm), each placed within two series of infrared beams (at two different heights, one low and one high, 2 and 8 cm, respectively, above the surface of the sawdust, 1 cm deep), was used to measure spontaneous motor activity (RAT-O-MATIC, ADEA Elektronik AB, Uppsala, Sweden). The distance between the infrared beams was as follows: the low-level beams were 73 mm apart lengthwise and 58 mm apart breadthwise in relation to the test chamber and the high-level beams, placed only along each long side of the test chamber, were 28 mm apart. According to the procedures described previously (Archer et al. 1986), the following parameters were measured: LOCOMOTION was measured by the low grid of infrared beams. Counts were registered only when the mouse is in the horizontal plane, ambulating around the test cage. REARING was registered throughout the time when at least one high-level beam was interrupted, i.e., the number of counts registered was proportional to the amount of time spent rearing. TOTAL ACTIVITY was measured by a sensor (a pickup similar to a gramophone needle, mounted on a lever with a counterweight) with which the test cage was constantly in contact. The sensor registered all types of vibration received from the test cage, such as those produced both by locomotion and rearing as well as shaking, tremors, scratching, and grooming. All three behavioral parameters were measured over three consecutive 20-min periods. The motor activity test room, in which all 12 ADEA activity test chambers, each identical to the home cage, were placed, was well secluded and used only for this purpose. Each test chamber (i.e., activity cage) was placed in a sound-proofed wooden box with 12 cm thick walls and front panels, and daylighting. Motor activity parameters were tested on one occasion only, over three consecutive 20-min periods, at the age of 3–4 months.

4 Design and Treatment

On Friday, week 1, mice were injected single weekly injections of MPTP (1 × 30 mg/kg, s.c.) or vehicle after a test of spontaneous motor activity, without access to wheel-running activity prior to the first administration of MPTP. Access to wheel-running activity was given on 1 day only for the Vehicle and MPTP groups (Wednesdays, 30 min) but on 4 days each week for the MPTP+Exercise (Mondays to Thursdays, 30 min), and this 1-day versus 4-day exercise regime was continued up to and during the 7th week. On Friday, weeks 2 and 3, mice were injected single weekly injections of MPTP (1 × 30 mg/kg, s.c.) or vehicle after a test of spontaneous motor activity. In each case, each mouse in each of the four groups received a 10-min access to the running wheel just prior to the 60-min spontaneous motor activity test (Table 1).

4.1 Neurochemical Analysis

4.1.1 Dopamine

Mice were killed by cervical dislocation within 1–2 weeks of completion of behavioral testing. Determination of DA was performed using a high-performance liquid chromatography with electrochemical detection (HPLC-EC), according to Björk et al. (1991), as modified by Liu et al. (1995). Striatal regions were rapidly dissected out and stored at -80 °C until neurochemical analysis. DA concentration was measured as follows: the frozen tissue samples were weighed and homogenized in 1 ml of 0.1 M perchloric acid, and alpha-methyl-5-hydroxytryptophan was added as an internal standard. After centrifugation (12,000 rpm, i.e., 18,600 g, 4 °C, 10 min) and filtration, 20 µl of the supernatant was injected into the HPLC-EC to assay DA. The HPLC system consisted of a PM-48 pump (Bioanalytical Systems, BAS) with a CMA/240 autoinjector (injection volume: 20 µl), a precolumn (15 × 3.2 mm, RP-18 Newguard, 7 µm), a column (100 × 4.6 mm, SPHERI-5, RP-18, 5 µm), and an amperometric detector (LC-4B, BAS, equipped with an Ag/AgCl reference electrode and a MF-2000 cell) operating at a potential of +0.85V. The mobile phase, ph 2.69, consisted of K2HPO4 and citric acid buffer (pH 2.5),

10 % methanol, sodium octyl sulfate, 40 mg/l, and EDTA. The flow rate was 1 ml/min, and the temperature of the mobile phase was 35 °C.

4.2 Statistical Analysis

The locomotion, rearing, and total activity data over three consecutive 20-min periods in the activity test chambers from the spontaneous motor activity data were submitted to a split-plot ANOVA design (Kirk 1995). Brain (striatal) regional levels of dopamine, locomotion, rearing, and total activity over the full 60-min period following administration of apomorphine, each were submitted to a one-way ANOVA based on a completely randomized design (Kirk 1995). Pairwise testing between the different treatment groups was performed with the Tukey's HSD test (Kirk 1995). The 1 % level of significance was maintained throughout unless where otherwise stated.

4.2.1 Results

Distance/30 min: Wednesday Tests

Neither the MPTP nor the vehicle groups showed any increase in distance run over 30 min in the running wheels, whereas the MPTP+Exercise group increased significantly distance run over 30 min from test week 2 to test week 7. The former received only one 30-min exposure (Wed.) per week to the wheels, while the latter received four 30-min exposures (Mon.–Thurs.) per week. Split-plot ANOVA indicated a significant Groups x test week interaction effect $F(20, 251) = 25.83$, $p < 0.0001$, for distance during 30 min. Figure 1 presents the distance run by each group during 30 min in the running wheels on the Wednesday tests.

Pairwise testing with Tukey's HSD test indicated significant differences between the three groups over test weeks 2–7 and a significant increase by the MPTP+Exercise group over test weeks 2–7.

Distance/10 min: Friday Tests

Neither the MPTP nor the vehicle groups showed any increase in distance run over 10 min in the running wheels, whereas the MPTP+Exercise group increased significantly distance run over 10 min from test week 2 to test week 7. Split-plot ANOVA indicated a significant Groups x test week interaction effect $F(20, 251) = 47.36$, $p<0.0001$, for distance during 10 min. Figure 2 presents the distance run by each group during 10 min in the running wheels on the Friday tests.

Pairwise testing with Tukey's HSD test indicated significant differences between the three groups over test weeks 2–7 and a significant increase by the MPTP+Exercise group over test weeks 2–7.

Spontaneous Motor Activity: Friday Tests

Running-wheel exercise over 4 days/week (30 min, Mon.–Thurs.) improved all three parameters of motor activity: locomotion, rearing, and total activity, in the activity test chamber during test weeks 2–7, compared to the MPTP group

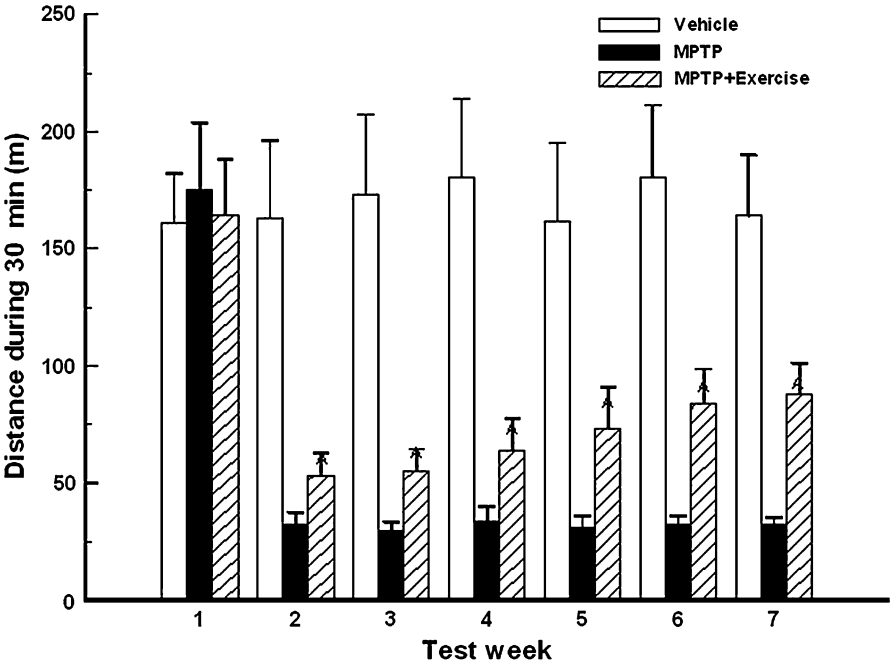

Fig. 1 Distance covered during the 30-min Wednesday test by the Vehicle, MPTP, and MPTP+Exercise groups

following the MPTP administration. Thus, split-plot ANOVA indicated a significant Groups x test week interaction effect for locomotion, rearing, and total activity: $F(20, 209) = 18.82$, $p<0.0001$; $F(20, 2309) = 15.36$, $p<0.001$; and $F(20, 209) = 7.44$, $p<0.0001$, respectively. Figure 3 presents the locomotion, rearing, and total activity by each group during 60 min in the activity test chambers on the Friday tests.

Pairwise testing with Tukey's HSD test indicated significant differences between the three groups over test weeks 2–7 and a significant increase by the MPTP+Exercise group over test weeks 2–7.

L-Dopa-Induced Activity: Friday Tests

Running-wheel exercise over 4 days/week enhanced locomotor and rearing but not total activity following the subthreshold dose of L-Dopa for the MPTP-Exercise group but not the MPTP No-exercise group. Thus, one-way ANOVA indicated a significant Groups effect for locomotion, rearing, and total activity: $F(2, 23) = 39.95$, $p<0.0001$; $F(2, 23) = 81.21$, $p<0.0001$; and $F(2, 23) = 4.77$, $p<0.02$, respectively. Figure 4 presents the locomotion, rearing, and total activity by each group during 180 min in the activity test chambers, following L-Dopa (5 mg/kg) on the Friday tests.

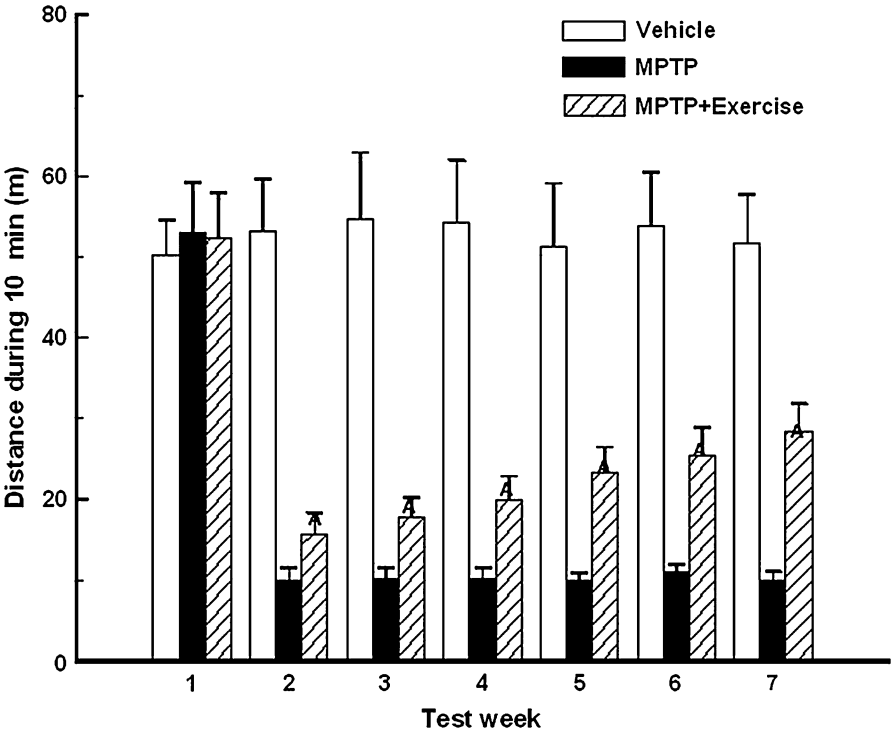

Fig. 2 Distance covered during the 10-min Friday test by the Vehicle, MPTP, and MPTP+Exercise groups

Pairwise testing with Tukey's HSD test indicated significant differences between the three groups over test weeks 2–7 and a significant increase by the MPTP+Exercise group over test weeks 2–7.

Dopamine Analysis

Running-wheel exercise over 4 days/week increased the DA concentrations in the striatum of MPTP+Exercise mice. Thus, one-way ANOVA indicated a significant Groups effect for DA concentration: $F(2, 17) = 121.03$, $p<0.0001$. Figure 5 presents the DA concentrations in the striatum of the Vehicle, MPTP, and MPTP+Exercise groups.

Percent of Vehicle control analyses indicated that striatal DA in the MPTP group was 11 % compared with 31 % in the MPTP-Exercise group.

5 Discussion

The present account of the utility of physical exercise (daily wheel-running activity, 4 days/week as opposed to 1 day/week) in alleviating the functional and

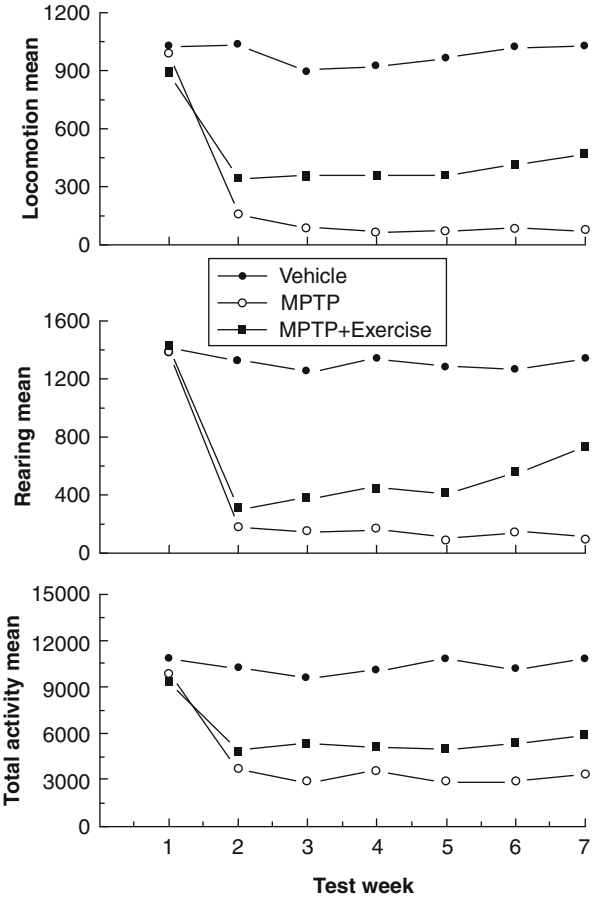

Fig. 3 Spontaneous motor activity by the Vehicle, MPTP, and MPTP+Exercise groups

neurochemical deficits induced by MPTP may be summarized as follows: (1) Only the MPTP+Exercise group, not the Vehicle and MPTP groups, showed significant increases in distance run over 30 min from test week 2 to test week 7 on the Wednesday tests. (2) Only the MPTP+Exercise group, not the Vehicle and MPTP groups, showed significant increases in distance run over 10 min from test week 2 to test week 7 on the Friday tests, given prior to the tests in the motor activity test chambers. (3) The tests of spontaneous motor activity indicated that running-wheel exercise over 4 days/week (30 min, Mon.–Thurs.) improved all three parameters of motor activity, locomotion, rearing, and total activity, in the activity test chamber during test weeks 2–7 (on Fridays), compared to the MPTP group following the MPTP administration. (4) The L-Dopa-induced activity tests indicated that running-wheel exercise over 4 days/week enhanced locomotor and rearing but not total activity following the subthreshold dose of L-Dopa administered on Fridays after the spontaneous motor activity tests. (5) Running-wheel exercise over 4 days/week

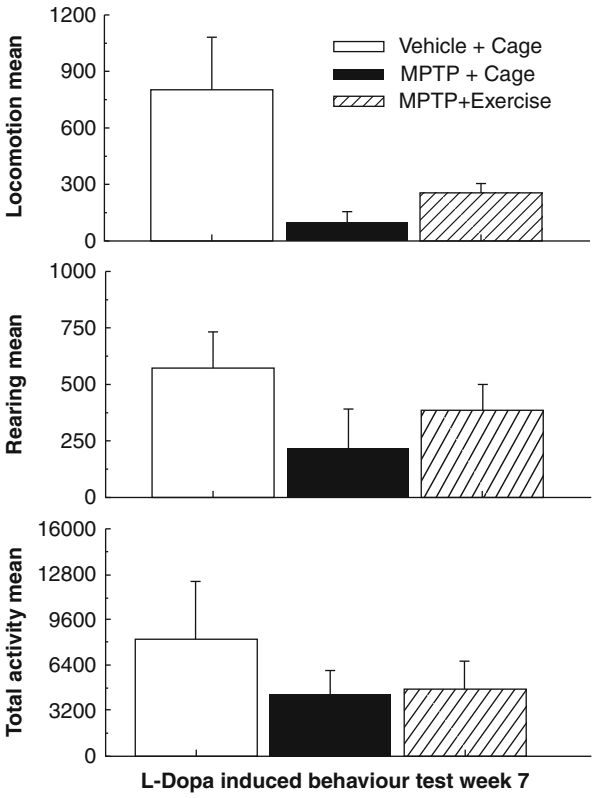

Fig. 4 Motor activity following L-Dopa (5 mg/kg) by the Vehicle, MPTP, and MPTP+Exercise groups

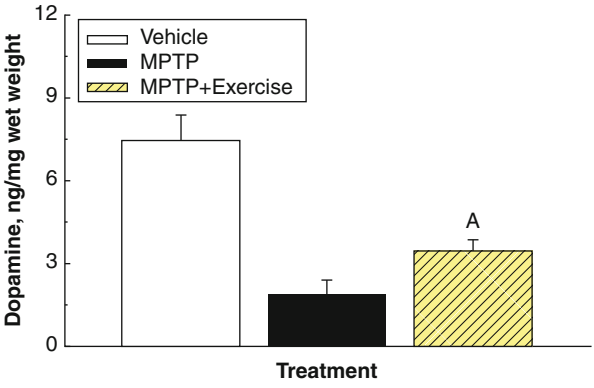

Fig. 5 Dopamine concentrations in the Vehicle, MPTP, and MPTP+Exercise groups

increased the DA concentrations in the striatum of MPTP+Exercise mice compared with the MPTP (one-day/week exposure to the running wheels only) group.

The present findings confirm and extend out previous observations (Archer and Fredriksson 2010, 2012; Fredriksson et al. 2011) in several respects. As observed

previously, physical exercise (30 min/day, 4 days/weeks) reduced the hypokinesic effects of MPTP and the DA loss induced by the neurotoxin under various conditions and parameters. However, none of the previous studies incorporated any method for establishing the exact distance run during each exercise bout by each mouse in its running wheel at any determined time interval, i.e., how much did each day of exercise. The present study incorporated also the condition that "non-exercised" groups in fact received one 30-min wheel-running exposure per week (Wednesdays) such that the exercise variable in fact involved one (non-exercise condition) as opposed to four (exercise condition). As the results (see Figs. 1 and 2, particularly) indicate, a single 30-min exercise session/week does nothing to affect exercise propensity, whereas four sessions/week produced a limited, but significant, and steady increase in distance run.

In the Archer and Fredriksson (2010) study, DA analyses indicated that after 4 × 40 mg/kg MPTP accompanied by 5 weeks of exercise (four 30-min/day sessions per week), the MPTP no-exercise group indicated 11 % of Vehicle control values, whereas the MPTP-Exercise group indicated 24 % of control values. In Experiment II of the Fredriksson et al. (2011) study applying the same 4 × 40 mg/kg MPTP administration regime but accompanied by a 4-week exercise schedule (four 30-min/day sessions per week), DA analyses indicated that the MPTP no-exercise showed 17 % of vehicle controls, whereas the MPTP-Exercise showed 64% of the vehicle controls. Taken together, a comparison of the results from these two studies suggests that longer periods of weekly exercise promote improved recovery from the MPTP-induced DA depletions. In the Archer and Fredriksson (2012) study, both experiments employed a 4 × 30 mg/kg MPTP administration regime accompanied by an 8-week exercise schedule (four 30-min/day sessions per week) in both Experiments I and II. For both experiments, exercise was introduced only after the second injection of MPTP. It was observed that DA levels in Experiment I were 20 % of control value for the MPTP no-exercise group and 39 % of control values for the MPTP-Exercise group; in Experiment II, DA concentrations were 23 % and 43% for the MPTP no-exercise and MPTP-Exercise groups, respectively. In the present experiment, a 3 × 30 mg/kg MPTP administration regime, with exercise introduced after the 1st MPTP injection (except for Wednesday) accompanied by a 6-week exercise schedule (four 30-min/day sessions per week). DA concentrations were 11 % of control values for the MPTP no-exercise group and 31 % for the MPTP-Exercise group. A plausible consensus from these MPTP experiments, employing single, weekly doses of MPTP, appears to be that independent of MPTP dose level or number of injections, the introduction of a multiple weekly exercise regime, rather than a single weekly session regime, significantly restores DA concentrations in the striatum as well as some restoration of motor activity.

The recovery from loss of DA presents an essential aspect of physical activity-mediated interventions in animal models of Parkinsonism and in particular those applying MPTP dose regimes. Petzinger et al. (2007) administered a series of 4 injections of MPTP (i.p.), or saline at 2-h intervals for a total of 80 mg/kg; physical exercise consisted of treadmill running sessions on an accelerating rotarod was initiated for half of the MPTP and half of the saline mice 5 days later. All the mice that were provided access to running-wheel exercise showed increased latencies to

fall off the accelerating rotarod, thereby demonstrating an improved balance, compared with the non-exercised mice. Kurz et al. (2007) administered male C57/BL6 mice with 10 injections of MPTP (25 mg/kg) and probenecid (250 mg/kg) over 5 weeks; the control group of mice received probenecid only, and all the mice were monitored on a motorized treadmill. They observed that the MPTP-treated mice showed significantly more variable stride length and less certain gait pattern than the control mice. In the Ahmad et al. (2009) study, the effects of physical exercise using a motorized rodent treadmill (speeds up to 15 m/min, 40 min/day, 5 days/week for 10 and 18 weeks) for mice given chronic treatment with MPTP (12.5 mg/kg × 10, with a 3.5-day interval between doses, and in combination with probenecid, 250 mg/kg) were examined. This chronic MPTP treatment regime induces a 52 % loss of neurons in the ventral tegmental area (VTA), including decrease in cell volume and irregular or disparaging axonal and dendritic projections that express deficits in dendritic arborization morphology in animals that remain sedentary (German et al. 1996). Positron emission tomography (PET)-imaging studies applying DA-D2R radiotracers have provided the prospect of performing longitudinal studies of the effects of exercise in both humans and animals. Nevertheless, no alteration in DA release or alteration in the binding of [^{11}C]raclopride as a result of aerobic exercise was observed although DA release was triggered (Wang et al. 2000). Vuckovic et al. (2010) found that in MPTP mice high-intensity treadmill exercise, using PET imaging with [^{18}F]fallypride, induced an increase in striatal DA-D2R expression.

In PD patients treated with L-Dopa, elevated serum homocysteine (Hcy) concentrations are commonly observed (Müller 2011: Müller and Muhlack 2010; Sui and Zhang 2010). Nascimento et al. (2011) have showed that Hcy concentrations in PD patients who exercised regularly were significantly lower than in sedentary patients but were similar in healthy controls. Regular exercise improves other aspects of brain health and integrity: for example, endurance exercise promoted cardiorespiratory rehabilitation in MPTP mice with severe neurodegeneration (Al-Jarrah et al. 2007). PD results in significant decreases in blood vessel density (Geny et al. 1994). Al-Jarrah et al. (2010) showed that four weeks of treadmill exercise training induced an increased striatal blood vessel density in chronic Parkinsonian mice that had received 10 administrations of MPTP (25 mg/kg) and probenecid (250 mg/kg) over 5 weeks. They found also that exercise induced an increase in striatal blood vessel density in the control mice although this effect did not attain significance. Smith et al. (2011) measured recovery of gait performance and amount of spontaneous physical activity using a "parallel rod activity chamber" (PRAC) in MPTP-treated and control mice provided with treadmill running (1h/day at 18 cm/s, 5 days/week) or not. They observed that the treadmill exercise program improved gait performance and increased physical activity as well as promoting increased protein expression of striatal dopamine transporter and tyrosine hydroxylase in both MPTP and control mice, but most markedly in the former.

Also applying the chronic MPTP mouse model of PD with moderate neurodegeneration, Lau et al. (2011) observed that exercise improved mitochondrial function and produced increases in region-specific levels of brain-derived and glial cell line-derived neurotrophic factors (BDNF and GDNF). They have demonstrated the impact of exercise upon protection against nigrostriatal neuronal,

mitochondrial, and locomotor deficits in the moderate chronic mouse model of PD. Tajiri et al. (2010) examined the effects of compulsive exercise on Parkinson's disease model of rats. Bromodeoxyuridine (BrdU) was injected to label proliferating cells prior to 6-hydroxydopamine (6-OHDA, 20 μg) lesion into the right striatum of female SD rats. Later, at 24 h after the lesion, the rats were forced to run on the treadmill (5 days/week, 30 min/day, 11 m/min). For behavioral analysis, cylinder tests were performed at 1, 2, 3, and 4 weeks and amphetamine-induced rotational test was performed at 2 and 4 weeks followed by sacrifice for immunohistochemical investigations. The exercise group showed better behavioral recovery in cylinder test and significant decrease in the number of amphetamine-induced rotations, compared to the non-exercise group. Correspondingly, significant preservation of tyrosine hydroxylase (TH)-positive fibers in the striatum and TH-positive neurons in the substantia nigra pars compacta (SNc) was demonstrated, compared to the non-exercise group. In addition, the number of migrated BrdU- and doublecortin-positive cells toward the lesioned striatum was increased in the exercise group. BDNF and GDNF were increased in the striatum by exercise. Their observations suggest that exercise exerts neuroprotective effects or enhances the neuronal differentiation in Parkinson's disease model of rats with subsequent improvement in deteriorated motor function. Finally, Patki and Lau (2011) have demonstrated that long-term exercise (over 18 weeks) attenuated both cytochrome c release and elevated levels of p53; both proteins are associated with mitochondrial dysfunction in the chronic MPTP mouse model. Cytochrome *c* is released by the mitochondria in response to proapoptotic stimuli. The p53 pathway responds to stresses that can disrupt the fidelity of DNA replication and cell division. A stress signal is transmitted to the p53 protein by posttranslational modifications that causes the activation of the p53 protein as a transcription factor that initiates a program of cell cycle arrest, cellular senescence, or apoptosis (e.g., Culmsee and Mattson 2005; Mihara et al. 2003).

6 Conclusion

Taken together, the present findings and the accumulation of laboratory and human studies reinforce the contention that physical exercise may be highly beneficial in conditions of mild to moderate Parkinsonism.

Protective Agents in Parkinson's Disease: Caffeine and Adenosine A2A Receptor Antagonists

Nicola Simola, Annalisa Pinna, Lucia Frau, and Micaela Morelli

Contents

Abstract

The pharmacologic management of Parkinson's disease is based on drugs that act on the motor symptoms, whereas there are currently no drugs available that can alter the progressive neurodegeneration of dopaminergic neurons. Based on recent findings suggesting that the adenosinergic system is one of the most interesting in the field of neuroprotection in Parkinson's disease, this chapter describes the functions of adenosine and its receptors in the central nervous system, with particular emphasis on their role in neurotoxicity/neuroprotection. Results of epidemiologic surveys demonstrating that intake of caffeine, an adenosine A_1/A_{2A} receptor antagonist, is inversely correlated with Parkinson's

disease are summarized. Moreover, evidence originating from preclinical studies showing that the antagonism of the adenosine A_{2A} receptor is responsible for the neuroprotective effects of caffeine is also presented. This chapter therefore provides a comprehensive analysis of the current literature concerning the adenosinergic-based neuroprotective intervention strategy for Parkinson's disease.

1 Introduction

Parkinson's disease (PD) is the second most prevalent neurodegenerative disease, with an occurrence that tends to rise dramatically with increasing age, thereby amplifying the social relevance of the disease as life expectancy increases (de Rijk et al. 2000). The degeneration of dopaminergic neurons of the substantia nigra pars compacta (SNc) that project to the striatum, the hallmark of PD, provokes functional modifications within the basal ganglia (BG) circuitry causing the typical motor symptoms (tremor, rigidity, and bradykinesia). PD is a classic movement disorder; however, the motor symptoms, which appear when the dopaminergic neuron degeneration has reached at least 70–80 %, are preceded by numerous non-motor symptoms, including autonomic dysfunction, sleep disorders, psychiatric symptoms, olfactory deficits, and gastrointestinal and cognitive dysfunctions (Poewe 2008). Idiopathic PD is a complex disorder characterized by the involvement of selected neuronal populations throughout the central and peripheral nervous systems; however, neurotransmitters other than dopamine (DA) are involved in the disease, including noradrenaline, serotonin, and acetylcholine (Jellinger 1991).

The primary cause of the degenerative process underlying PD remains unknown; however, several contributing factors have so far been identified for the idiopathic form of the disease. The most important of these include mitochondrial defects, oxidative damage, anomalous protein aggregation, and neuroinflammation (Schapira 2006). These processes, once initiated, continue to produce dopaminergic neuron liability contributing to the loss of efficacy of DA-replacement therapy.

The main therapeutic developments in the field of PD have focused, first, on improvement of DA-replacement therapies in order to better manage or prevent the onset of motor complications and, second, on the discovery of compounds that could modify the course of neurodegeneration. Among the various therapeutic approaches aimed at addressing these objectives, the manipulation of adenosine neurotransmission is one of the most valuable.

The first suggestion that manipulating adenosine neurotransmission might have a beneficial effect on PD onset or progression came from epidemiologic evidence showing that consumption of caffeine, a nonselective A_1/A_{2A} receptor antagonist, reduced the risk of developing PD (Ascherio et al. 2001; Costa et al. 2010) (see Sect. 5). Furthermore, preclinical studies investigating the adenosine receptor type involved in these effects suggested that the blockade of the A_{2A} receptor subtype provides the best neuroprotective effect (Schwarzschild et al. 2006).

2 Neuromodulatory Role of Adenosine

Adenosine is an endogenous purine nucleoside constitutively present in mammalian tissues, where it plays a regulatory role in a variety of important physiologic processes by acting as a homeostatic modulator. Adenosine is produced as a result of hydrolysis of adenosine monophosphate (AMP) by means of an action of ecto-5'-nucleotidase (Fredholm et al. 2005); thus, its formation depends upon the metabolism of adenosine triphosphate (ATP). In the extracellular compartment, the level of adenosine also depends on the rate of hydrolysis of ATP, which is released from either neurons or glial cells, and on the adenosine carrier, which keeps adenosine at a stable level. The actions of adenosine are mediated by specific G-protein-coupled receptors. To date, four adenosine receptors have been cloned and characterized: A_1, A_{2A}, A_{2B}, and A_3 (Fredholm et al. 2005).

Adenosine plays different roles in normal physiology, which include promoting and/or maintaining sleep, regulating the general state of arousal, and coupling cerebral blood flow to energy demand (Dunwiddie and Masino 2001). Many of the effects of adenosine that are observed in normal conditions are modified during pathologic events, and the multiple roles of adenosine may produce dual neuroprotective/neurotoxic effects based on the type of insult and cellular condition (Cunha 2001).

Endogenous adenosine released during hypoxia, ischemia, electrical activity, hypoglycemia, or aglycemia reduces the subsequent damage to the neuronal tissue. The neuroprotection offered by adenosine is also effective against other kinds of damage that are not as directly related to energy metabolism, such as mechanical cell injury (Mitchell et al. 1995), methamphetamine and 3,4-methylenedioxymethamphetamine (MDMA)-induced neuroinflammation, and neurotoxicity (Delle Donne and Sonsalla 1994; Khairnar et al. 2010). In these conditions, the neuroprotective actions of adenosine are mediated primarily via A_1 receptor activation, whereas it seems that the action on the A_{2A} receptor could result in a neurotoxic effect. Caffeine and other A_{2A} antagonists, in fact, have induced neuroprotection and reduced glial cell activation in animal models of dopaminergic neurotoxicity utilizing 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) or 6-hydroxydopamine (6-OHDA) (Schwarzschild et al. 2006; Carta et al. 2009; Frau et al. 2011).

3 Adenosine A_{2A} Receptors

Among the different adenosine receptors, of particular interest for PD are the A_{2A} receptors, specifically located in the BG circuit (Fig. 1). The adenosine A_{2A} receptors interact functionally and are co-expressed with dopaminergic D_2 receptors on the striatal GABAergic neurons of the "indirect" BG pathway projecting from the striatum to the globus pallidus (Hettinger et al. 2001). In the BG circuit, A_{2A} receptors are prevalently localized in the axons, soma, dendrites, and dendritic

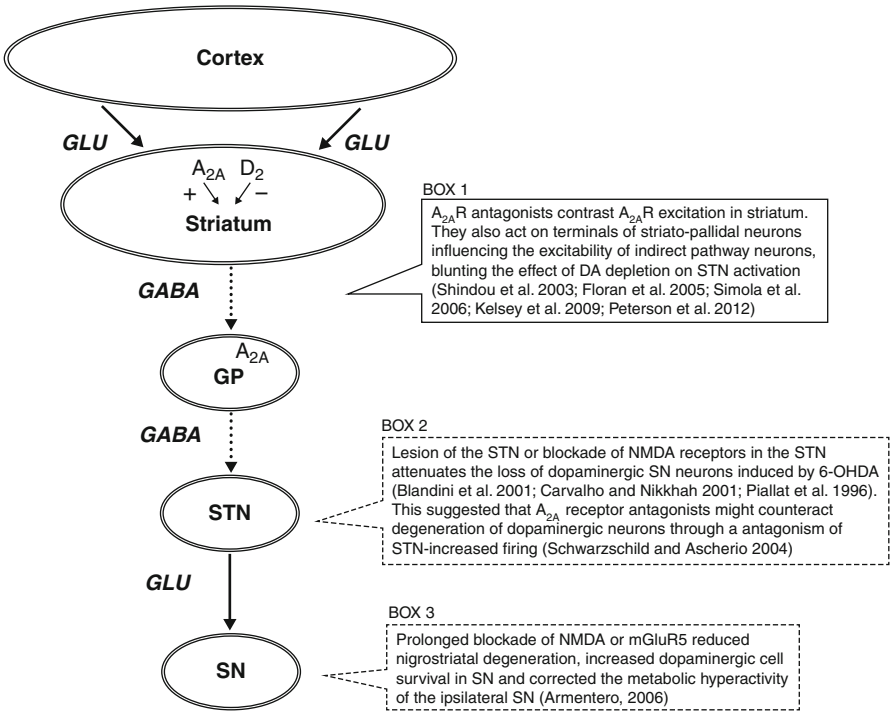

Fig. 1 Proposed actions of A_{2A} receptors on the indirect striatonigral pathway. Classical view of BG functions demonstrating that dopaminergic neuron degeneration provokes an increase in glutamatergic input from the cortex to the striatum and an increase in GABAergic indirect output from the striatum to the GP, leading to an increase in STN activity. In turn, an increase in STN glutamatergic activity contributes to excitotoxic dopaminergic neuron degeneration in the SN. As shown in *Box 1*, several reports indicate that A_{2A} receptors control excitability of the striatopallidal GABAergic pathway and that A_{2A} receptor antagonism counteracts the effects of dopaminergic neuron degeneration. As a result, the GABAergic control from the GP to the STN is increased, leading to a decrease in STN activity. As shown in *Box 2*, a decrease in STN activity and glutamatergic output from the STN to the SN counteracts excitotoxic degeneration of the dopaminergic neurons in the SN. As shown in *Box 3*, blockade of glutamatergic receptors in the SN reduces excitotoxic degeneration of dopaminergic neurons. Therefore, one of the mechanisms of neuroprotection by A_{2A} receptor antagonists may be the indirect inhibition of STN activity. *Box 1* (*continuous line*) represents a direct action of A_{2A} receptor antagonist; *Boxes 2* and *3* (*dashed line*) represent an indirect action of A_{2A} receptor antagonist on neurotransmitter release. Abbreviations: *BG* basal ganglia, *DA* dopamine, *GLU* glutamate, *GP* globus pallidus, *mGluR5* metabotropic glutamate receptor 5, *SN* substantia nigra, *STN* subthalamic nucleus, *6-OHDA* 6-hydroxydopamine

spines of the striatal GABAergic neurons of the indirect pathway. In contrast, very few striatonigral neurons of the "direct" pathway, containing dopaminergic D_1 receptors, express A_{2A} receptors (Schiffmann and Vanderhaeghen 1993) (Fig. 1). However, activation or blockade of A_{2A} receptors in the indirect striatopallidal pathway impairs or facilitates dopaminergic D_1-mediated responses as well (Ferre et al. 1997).

In light of the neuromodulatory role of adenosine, A_{2A} receptors have been described to interact directly or indirectly with several receptors, such as dopaminergic D_2 and D_3 receptors, NMDA, metabotropic glutamate receptor types 4 ($mGLUR_4$) and 5 ($mGLUR_5$), cannabinoid receptor type 1 (CB1), and 5-hydroxytryptamine receptor type 1A ($5\text{-}HT_{1A}$), and to form heteromeric complexes with some of them (Kurokawa et al. 1996; Gerevich et al. 2002; Łukasiewicz et al. 2007; Armentero et al. 2006, 2011; Bogenpohl et al. 2012; Jones et al. 2012).

Besides the presence of A_{2A} receptors in neurons, their existence has been described in astrocytes: specifically, about 3 % of A_{2A} receptors were found in glial cells of the striatum (Hettinger et al. 2001).

4 Caffeine Properties

Caffeine is a natural xanthine alkaloid, contained in several popular dietary sources, such as coffee, tea, chocolate, and soft drinks. Its ability to elicit psychostimulatory effects, that are usually not accompanied by harmful unwanted consequences, renders caffeine the most consumed psychoactive substance (Fredholm et al. 1999).

At doses in the range of normal consumption, caffeine induces its effects by blocking the central adenosine A_1 and A_{2A} receptors (Fredholm et al. 1999). Caffeine-induced psychostimulant effects appear to be influenced by the dopaminergic transmission since enhancement of caffeine-elicited psychomotor activation is observed in experimental rodents following administration of dopaminergic agonists (Cauli and Morelli 2005), whereas an attenuation of the effects of caffeine is present after administration of dopaminergic antagonists (Green and Schenk 2002). The influence that caffeine exerts on dopaminergic transmission is of great interest, considering the critical involvement of DA in the modulation of important functions, such as movement, attention, goal-directed behavior, and associative learning (Robbins and Roberts 2007; Phillips et al. 2008).

The existence of negative correlations between PD and dietary factors, such as caffeine, is of particular interest, in the light of caffeine's safety and widespread consumption (see Sect. 5). In this regard, the results from preclinical studies demonstrating that caffeine can exert protective effects in different models of neurotoxicity add further importance to the finding (Table 1).

Caffeine administration has been shown to have a neuroprotective effect in rodent and primate models of dopaminergic neuron degeneration, such as the MPTP and 6-OHDA paradigms (Table 1). Caffeine neuroprotection is particularly important since it is afforded by a substance with negligible toxic or adverse effects. Often, substances proposed to be neuroprotective impair neuronal functions essential for correct cellular homeostasis or alter the levels of neurotransmitters, such as glutamate, which are important for cognitive functions. Caffeine, in contrast, is a safe substance used worldwide with no unwanted effects in the broad population.

Table 1 Overview of the most common paradigms of toxin-induced neurodegeneration used to investigate neuronal damage and neuroprotection in PD

Model	Type	Toxic effects observed	Main features of the model	Effect of caffeine administered before or concomitantly to the toxin
Cell cultures	Acute Can use different cells (e.g., neuroblastoma or mesencephalic cells) and toxins (e.g., 6-OHDA, MPP^+, rotenone)	Decrease in cell viability	Allows to rapidly identify putative neuroprotective agents and to study their molecular mechanisms Can be used as a complement of in vivo models	Cytoprotection[a; b]
6-OHDA in rats	Acute Employs the direct intracerebral infusion of the toxin	Degeneration of DA neurons in the SNc Reduction in the striatal content of DA and its metabolites	The degeneration is rapid and reaches a near terminal stage few days after infusion Oxidative stress is the major mechanism of neurotoxicity Allows to selectively target different brain regions according to the site of toxin infusion	Attenuation in the demise of SNc neurons[c] Restoration of the levels of DA and its metabolites in the striatum[c]
Lipopolysaccharide in rats and mice	Acute or chronic Can use either intracerebral infusion or systemic administration	Loss of DA neurons in the SNc Activation of glial cells Elevation in the levels of neuroinflammatory mediators	Induces a selective degeneration of DA neurons in SNc, while sparing other DA neurons Degeneration of DA neurons is delayed, progressive, and irreversible Neuroinflammation is the main mechanism underlying neuronal death	Attenuation of neuroinflammation[d]
Paraquat or Paraquat + maneb in mice	Chronic	Degeneration of DA neurons in the SNc Loss of DA terminals in the striatum	This model may yield variable results and significant mortality The toxins used are clinically relevant, since they have been suggested as a potential causative factor of PD	Attenuation in the degeneration of DA neurons[i]

MPTP in mice	Acute or acute-repeated with multiple administration at a fixed interval The toxin is administered systemically	Degeneration of DA neurons in the SNc Loss of DA terminals in the striatum Reduction in the striatal levels of DA and its metabolites Glial activation	The severity of DA lesion can be adjusted by varying the protocol of administration It is still questioned whether the lesion is progressive The model can be used to study both neurotoxicity and neuroinflammation The toxin acts chiefly on mitochondrial function The toxin is clinically relevant, as MPTP can induce PD in humans	Attenuation in the degeneration of SNc neurons[e,] Restoration of the levels of DA and its metabolites in the striatum[e,f,g] Counteraction of neuroinflammation[h]
Rotenone in rats and mice	Chronic The toxin is administered by osmotic minipumps or parenteral injection	Degeneration of SNc DA neurons Loss of striatal DA terminals accompanied by reduction in striatal DA content	DA neuron degeneration is often accompanied by other nonspecific brain damages Systemic toxicity and high mortality is often associated with, or precedes, neurodegeneration There is a high variability in the results obtained with the use of this model Differently from other commonly used models, chronic rotenone can generate proteinaceous inclusions in DA neurons resembling those observed in human PD The toxin used is clinically relevant, since exposure to rotenone has been suggested as a possible causative factor of PD	Not tested

The table describes some of the most common toxin-based experimental models of parkinsonian-like neuron degeneration. The main characteristics of each model are reported, together with the effects of caffeine on the degenerative process, when available

Abbreviations: *DA* dopamine, *MPP^+* 1-methyl-4-phenylpyridinium, *MPTP* 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, *PD* Parkinson's disease, *SNc* substantia nigra pars compacta, *6-OHDA* 6-hydroxydopamine

5 Epidemiologic Studies on the Neuroprotective Role of Caffeine in Parkinson's Disease

Numerous findings suggest that the two decades before the manifestation of motor impairments in PD are fundamental in the onset of the progressive demise of dopaminergic neurons. Therefore, epidemiologic studies investigating habits, health status, and lifestyle of individuals who developed PD are very important in order to obtain new information about PD development and to identify new approaches to prevent neurodegeneration in PD.

One of the most interesting results that has emerged from these epidemiologic studies is the inverse correlation between caffeine intake and risk of developing PD. The three main epidemiologic studies, that provided consistent suggestions regarding this relationship, are the Honolulu Heart Program (HHP, 30 years of follow-up of ~8,000 Japanese-American men), the Health Professionals Follow-up Study (HPFS, 10 years of follow-up of ~47,000 men), and the Nurses' Health Study (NHS, 16 years of follow-up of ~88,500 women) (Ross et al. 2000; Ascherio et al. 2001, 2003). In these surveys, besides information of lifestyles and health status of individuals, nutritional behaviors, including data about consumption of coffee and/or other caffeinated or decaffeinated beverages, were collected. The results of the investigation demonstrated that individuals consuming medium to high quantities of caffeine have a decreased risk of developing PD (Ross et al. 2000; Ascherio et al. 2001, 2003). Importantly, this finding was dose dependent and was adjusted for age, smoking status, alcohol use, other nutrients, or potential confounding variables (Ascherio et al. 2001, 2003). The studies described that individuals consuming caffeine (including tea and all caffeine sources) had a lower risk of developing PD compared with non-regular caffeine drinkers (less than one cup a day), whereas no association was found with consumption of decaffeinated coffee. Moreover, a 50 % risk reduction of PD was observed among men consuming less than one cup a day compared with male non-coffee drinkers (Ross et al. 2000; Ascherio et al. 2001). Notably, this inverse relationship between caffeine intake and PD risk was not so evident in women (Ascherio et al. 2001, 2003). Indeed, a clear gender difference was demonstrated by Ascherio and coworkers (2001), regarding the association between caffeine intake and risk of PD in women in the NHS. Similar findings have been reported by Benedetti and coworkers (2000). Since gender difference with regard to the effect of caffeine suggested a possible hormonal cause, in the women reported in the NHS, the correlation between use of postmenopausal estrogens, caffeine intake, and risk of PD was examined. Generally, use of postmenopausal estrogens was not correlated with risk of developing PD. On the other hand, among estrogens users, women consuming more than five cups of coffee per day were found to have a higher risk of PD compared with women who never drink coffee. In contrast, similar to men, women who were coffee drinkers and had never taken postmenopausal estrogens had a lower risk of PD than non-coffee drinkers (Ascherio et al. 2001). These data were confirmed by two separate prospective studies involving men and women which provided evidence that caffeine may decrease risk of PD only in men and in women who did not take postmenopausal

estrogens, but not among estrogen consumers (Ascherio et al. 2003, 2004). Furthermore, the potential beneficial effect of caffeine might be prevented by estrogen therapy (Ascherio et al. 2003, 2004). Conversely, two prospective studies of Finnish individuals reported no gender differences in the opposite correlation between coffee intake and PD risk (Hu et al. 2007; Sääksjärvi et al. 2008). However, in the study by Saaksjarvi and coworkers (2008), the percentage of women was only about 5 % of the cohorts; therefore, the effect of estrogen therapy could not be examined for this small number of women.

Recently, an experimental study in the MPTP mouse model of PD investigated the biologic basis of the interaction between estrogen and caffeine consumption on risk of PD. This study showed that caffeine attenuated, dose dependently, the MPTP-induced striatal DA loss in both male and ovariectomized female compared with female non-ovariectomized mice (Xu et al. 2006). Moreover, chronic estrogen treatment prevented the neuroprotection induced by caffeine in male and in female ovariectomized mice, confirming that the hormonal therapy might prevent the neuroprotective effect of caffeine in this model of PD (Xu et al. 2006). Metabolic or pharmacokinetic interactions between caffeine and estrogens have been supposed, but it is not clear whether this interaction is fundamental in the reduced neuroprotective effect observed when estrogen therapy and caffeine are combined (Xu et al. 2006).

A recent statistical study by Costa and coworkers (2010) collected and statistically analyzed the majority of epidemiologic studies, which better evaluate the effect of caffeine intake and the incidence of PD, up to September 2009. This statistical review, which includes 26 studies, unequivocally confirms the inverse association between caffeine exposure and the risk of developing PD (Costa et al. 2010).

In spite of the epidemiologic and experimental findings strongly supporting the concept that dietary caffeine decreases the possibility of developing PD, very little is known about the correlation between caffeine intake and the degree of disease progression in PD patients. Two clinical studies, in which the progression of the disease and the consumption of several caffeinate beverages were evaluated by the modified Unified Parkinson's Disease Rating Scale (UPDRS), did not demonstrate clear evidence of the neuroprotective role of caffeine with respect to degree of PD progression (Schwarzschild et al. 2003b; Simon et al. 2008). Therefore, further larger investigations are required to fully assess the neuroprotective role of caffeine on disease progression in PD patients.

6 Mechanisms of Dopaminergic Neuroprotection by Caffeine and A_{2A} Receptors Blockade

Studies of neuroprotection in PD should carefully consider a number of factors with regard to the features of neurodegeneration, as well as to the experimental model in which the study is performed. In recent years, PD has been increasingly envisaged as a multifactorial pathology, and several factors have been proposed to be involved in the degeneration of dopaminergic neurons (Schapira 2006). Therefore, it is

hypothesized that neuroprotective drugs should act by means of multiple mechanisms rather than a single mechanism. Moreover, it is worth mentioning that most of the experimental models of PD in use employ toxins according to an acute, or acute-repeated, protocol of administration (Table 1). This may significantly differ from idiopathic PD, with respect to time course of degeneration and mechanisms involved in neuronal demise. Therefore, the choice of experimental model is a critical step when addressing the mechanisms of neuroprotective agents.

Several studies in rodent models of PD demonstrate that A_{2A} receptor antagonists counteract both the demise of dopaminergic neurons in the SNc and the drop of DA levels in the striatum (Schwarzschild et al. 2003a; Morelli et al. 2010). However, A_{2A} antagonists exert beneficial effects not only in models of PD neurodegeneration but also in paradigms of Alzheimer's and Huntington's disease-like neurotoxicity (Stone et al. 2009). This evidence suggests that A_{2A} receptor antagonists counteract PD-like neurodegeneration by means of mechanisms which are not selective towards dopaminergic neurons but are part of a broader neuroprotective action. In the light of these observations, the two major hypotheses proposed to explain the neuroprotective effects of A_{2A} antagonists on dopaminergic neurons concern the modulation of glutamate-induced excitotoxicity and neuroinflammation, two mechanisms involved in several neurodegenerative pathologies.

Glutamate-mediated excitotoxicity has long been envisaged as an important player in PD neurodegeneration. Thus, dopaminergic neurons are vulnerable to changes in glutamate extracellular concentrations, on the one hand, while a dysregulation of glutamate transmission has been described in PD, on the other (Lancelot and Beal 1998; Greenamyre 2001). Remarkably, the stimulation of adenosine A_{2A} receptors can elevate the extracellular concentrations of glutamate, while blockade of A_{2A} receptors decreases glutamate extracellular levels which, in turn, may relieve the excitotoxic insult and afford neuroprotection towards dopaminergic neurons (Popoli et al. 1995). Recent evidence supports a role for nonneuronal cells in the modulation of glutamate release by A_{2A} receptor blockade (Melani et al. 2003; Yu et al. 2008), which is in line with the localization of these receptors on glial cells (see Sect. 3).

Several reports have shown that A_{2A} receptor antagonists modulate the activity of the indirect pathway by acting on the terminals of striatopallidal medium spiny neurons or by influencing the intrinsic excitability of indirect pathway spiny projection neurons, blunting the effects of DA depletion (Shindou et al. 2003; Floran et al. 2005; Simola et al. 2006; Kelsey et al 2009; Peterson et al. 2012) (Fig. 1). Moreover, independent investigations have shown that both lesion of the subthalamic nucleus (STN) and blockade of the NMDA receptors in the STN attenuate the loss of dopaminergic neurons induced by 6-OHDA (Piallat et al. 1996; Blandini et al. 2001; Carvalho and Nikkhah 2001). Based on these considerations, release of glutamate from the STN can be envisioned as an important mechanism in dopaminergic neuron degeneration. Moreover, it has to be considered that the overactivation of the STN progresses in the course of PD, and this can eventually exacerbate the loss of dopaminergic neurons over time. Therefore, it is

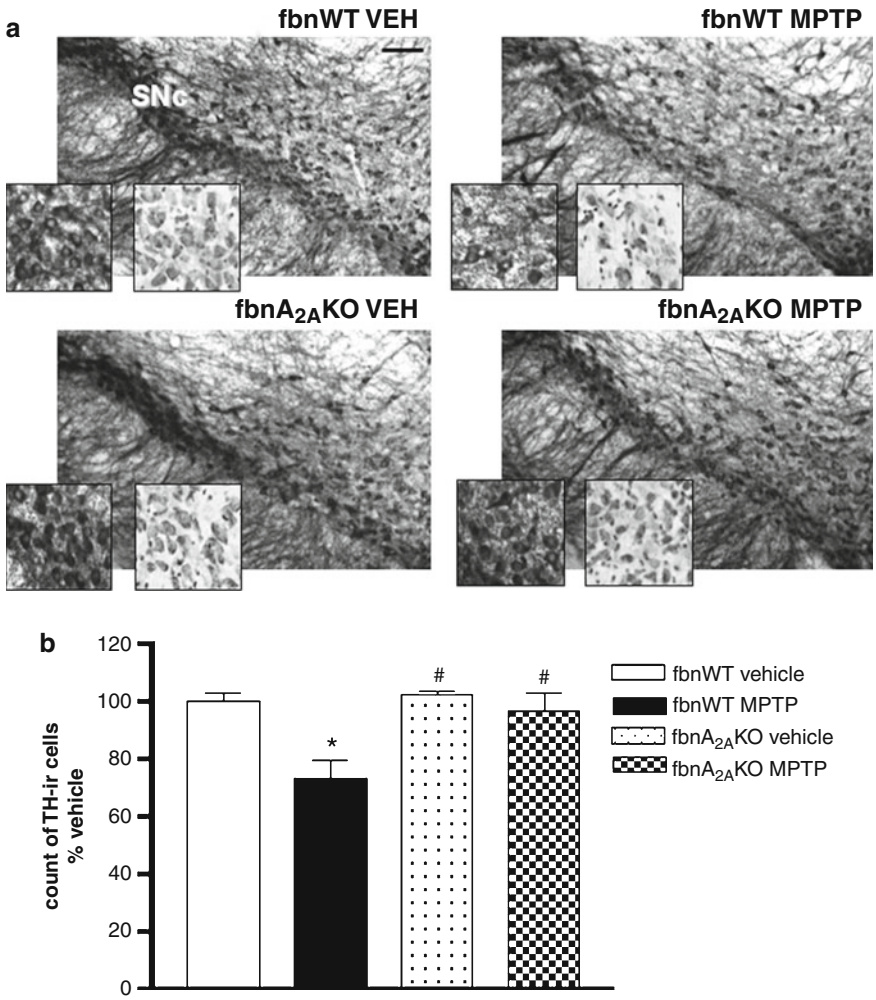

Fig. 2 $FbnA_{2A}$ KO mice are protected against MPTP-induced loss of dopaminergic cells in the SNc. (**a**) Representative sections from SNc immunostained for TH. Insets show higher magnification of TH-labeled (*left*) and cresyl violet-labeled (*right*) cells. Mice were treated with MPTP (20 mg/kg once a day for 4 days) or vehicle. (**b**) Graph shows analysis of TH immunostaining in $fbnA_{2A}$ KO mice, reported as a percentage of TH-positive cells compared with vehicle-treated mice. *$p < 0.05$ versus WT vehicle-treated group; #$p < 0.05$ versus WT MPTP-treated group, by Tukey's post hoc test. Scale bar, 50 μm. Abbreviations: *Fbn* forebrain neurons, *KO* knock-out, *MPTP* 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, *SNc* substantia nigra pars compacta, *TH* tyrosine hydroxylase, *WT* wild type. (Reproduced from Carta et al. 2009)

conceivable that A_{2A} antagonists, by regulating the activity of the striatopallidal pathway, besides counteracting motor disability, may also attenuate degeneration of the dopaminergic neurons through a modulation of STN firing (Schwarzschild and Ascherio 2004) (Fig. 1).

An important mechanism involved in the neurodegenerative process that characterizes PD is neuroinflammation, as suggested by preclinical and epidemiologic evidence (Hirsch and Hunot 2009; Halliday and Stevens 2011). Neuroinflammation gives rise to a complex cascade of events in the brain, resulting in the activation of glial cells (microglia, astrocytes, and oligodendrocytes) and the subsequent generation of inflammatory mediators (e.g., cytokines, interferons, interleukins) (Reale et al. 2009). Even though transient neuroinflammation can be beneficial, as it may help the brain in coping with noxious insults, protracted neuroinflammation is detrimental and may lead to neuronal damage. It has been recently suggested that glial activation plays an important role in the initiation of early response and in the progression of degenerative diseases, such as PD, in which α-synuclein accumulation in astrocytes causes recruitment of phagocytic microglia that attack selected neurons causing neuronal degeneration (Halliday and Stevens 2011). Furthermore, not only can neuroinflammation promote neurodegeneration, but neuronal death itself can trigger inflammatory responses, which may aggravate the ongoing neuronal damage (Litteljohn et al. 2010).

Both microglia and astrocytes express A_{2A} receptors, the stimulation of which promotes the recruitment of these cells in neuroinflammatory responses (Lopes et al. 2011). Conversely, blockade of A_{2A} receptors suppresses the activation of microglia and astrocytes, as well as the stimulation of the proinflammatory signal cascade (Armentero et al. 2011). Interestingly, recent evidence obtained in the mouse MPTP model of PD demonstrates that the increased survival of dopaminergic neurons mediated by A_{2A} antagonists is accompanied by a significant attenuation in microgliosis and astrogliosis (Yu et al. 2008; Carta et al. 2009; Frau et al. 2011).

Based on these premises and on the current knowledge of A_{2A} antagonists and neuroprotection, it is feasible that attenuation of glutamate-mediated excitotoxicity and neuroinflammation may participate in the protective effects of A_{2A} antagonists on dopaminergic neurons. However, it is important to consider that in experimental models of PD, adenosine A_{2A} receptor antagonists counteract the degeneration of dopaminergic neurons at doses lower than those required to elicit motor stimulation (Yu et al. 2008; Carta et al. 2009). It is therefore hypothesized that excitotoxicity and neuroinflammation are phenomena clearly distinct from regulation of motor function, as for the mechanisms involved. Furthermore, excitotoxicity and neuroinflammation have been envisaged as causative factors in neurodegenerative disorders other than PD (Glass et al. 2010). Therefore, an attenuation, or regulation, of these noxious phenomena by A_{2A} antagonists, besides justifying the protective effect observed in PD models, would be in agreement with the data demonstrating that these drugs can protect neurons from a wide array of insults.

Even though the hypotheses on excitotoxicity and neuroinflammation are intriguing, caution should be taken when addressing the mechanisms underlying the neuroprotection mediated by A_{2A} antagonists in models of PD. In this connection, it is interesting to point out that astrocytes, the activation of which has been found to be increased in the MPTP model of PD (Carta et al. 2009), regulate not only neuroinflammation but also glutamate extracellular levels and, accordingly, excitotoxicity (Melani et al. 2003). Therefore, astrocytes could be a crucial point at

which A_{2A} antagonists may promote the survival of dopaminergic neurons, perhaps by attenuating both excitotoxicity and neuroinflammation. Even though the evidence supporting the involvement of glial elements in the dopaminergic neuroprotection by A_{2A} antagonists is increasingly growing, neuronal mechanisms cannot be disregarded. Thus, recent evidence demonstrates that the inactivation of neuronal forebrain A_{2A} receptors completely counteracts the degeneration of dopaminergic neurons in the MPTP model of PD (Carta et al. 2009) (Fig. 2). Furthermore, it has to be considered that a number of factors have been proposed to promote and/or sustain the degeneration of dopaminergic neurons in PD, besides excitotoxicity and neuroinflammation. These include, for example, oxidative stress, proteolytic damage, and mitochondrial defects (Schapira 2006). Therefore, it is conceivable that several different mechanisms may participate in the rescue of dopaminergic transmission by A_{2A} antagonists. In this connection, it is interesting to note that A_{2A} antagonists have been reported to protect dopaminergic neurons in a model of mitochondrial dysfunction (Alfinito et al. 2003). In addition, it has been suggested that the different causative factors of PD neurotoxicity may engender a sort of vicious cycle, with some triggering initial neuronal damage and others perpetuating it until neuronal death is reached. Therefore, A_{2A} antagonists could intervene at different steps of this cycle and, by interrupting it, afford neuroprotection.

To date, blockade of adenosine A_{2A} receptors has been demonstrated to efficiently restore motor function in PD, without exacerbating dyskinesia, both in animal models and in clinical trials of PD patients (Hauser and Schwarzschild 2005; Schwarzschild et al. 2006; Morelli et al. 2010). Therefore, their role as disease-modifying drugs in PD is of specific relevance since A_{2A} antagonists may unequivocally affect PD with regard to both symptoms and neuroprotection.

7 Conclusion

Caffeine and adenosine A_{2A} receptor antagonists have given new impetus to the research on PD in the latest 10 years. In the absence of effective neuroprotective treatments for PD, epidemiologic studies investigating dietary factors, such as caffeine, that may allow individuals to lower the risk of PD became compelling. Remarkably, preclinical studies have shown that the neuroprotective potential of caffeine extends to chronic administration of pesticides (Kachroo et al. 2010), suggesting that caffeine can prevent degeneration of dopaminergic neurons induced by a broad range of agents, including environmental toxins, in addition to pathophysiologic mechanisms.

Moreover, the preclinical and clinical investigations suggesting that A_{2A} receptor antagonists represent a class of drugs that might counteract motor deficits symptomatically and, at the same time, delay or halt the progression of dopaminergic neuron degeneration are very important for future delineation of effective therapies for this disease. It should, however, be underlined that the

discovery of neuroprotective strategies in chronic neurodegenerative diseases, such as PD, largely depends on the possibility of monitoring the progression of the neurodegeneration. The availability of biomarkers associated with disease progression therefore becomes crucial for the advancement of this strategy. Although the research on biomarkers is very promising (Halperin et al. 2009), none of them can predict PD with 100 % confidence nor provide a clear definition of subgroups at risk. Therefore, the future of research in PD clearly depends on the possibility of developing reliable and affordable biomarkers in order to facilitate and render the clinical trials of new molecules consistent.

Stem Cell Therapies for Age Associated Neurodegeneration

Stephanie Merchant, Sarah Stegeman, and Kiminobu Sugaya

Contents

Abstract

Regenerative medicine is the newly emerging field of this decade, namely, stem cell therapeutics. Interestingly, the field of stem cell therapeutics has been around for decades, such as the treatment of Leukemia using bone marrow transplantations; however, little momentum has been generated in the field until recently. During this predominantly stationary period of the regenerative movement, many issues have been debated regarding stem cell therapeutics. Many questions to these past issues are now starting to rise to the forefront due to breakthrough research being conducted in the regenerative field: adult versus embryonic stem cell populations, ethics, ease of access to these populations, and, more importantly, what types of diseased states can these stem cell populations be effective in? In order to answer this last question, it is imperative to

understand not only basic stem cell pathologies but also the pathological conditions of the diseased state to be treated. Perhaps one of the most challenging to overcome is Alzheimer's disease (AD), a neurodegenerative condition characterized by a predominant loss of adult stem cell populations. What makes AD a challenge is the need to overcome both the natural effects of aging as well as the caustic environmental conditions. In order to introduce new neuronal networking through stem cell therapeutics, a better understanding of the pathological environment is needed. With new and upcoming technology, such as induced pluripotent stem cells, used to produce neural cells from somatic cells, and small molecular compounds which increase endogenous stem cell populations, it will be possible to perform autologous regenerative therapies, thus providing potential cures for age-related diseases such as AD.

List of Abbreviations

AD	Alzheimer's disease
APOE4	Apolipoprotein E-e4
APP	Amyloid precursor protein
AS	Adult stem cells
β-amyloid	Beta amyloid
BACE	Beta-site APP-cleaving enzyme
BBB	Blood–brain barrier
bFGF	Basic fibroblast growth factor
BMPs	Bone morphogenetic protein
CCg	Glycosylated form of cysteine C
CDC	Center for Disease Control
ChEIs	Cholinesterase inhibitors
CNS	Central nervous system
CNTF	Ciliary neurotrophic factor
DNA	Deoxyribonucleic acid
DS	Down syndrome
EGF	Epidermal growth factor
eNS	Endogenous neural stem cells
ES	Embryonic stem
FDA	Food and Drug Administration
GFAP	Glial fibrillary acidic protein
gp130	Glycoprotein 130
hNSC	Human neural stem cells
IGF-1	Insulin-like growth factor
IL-6	Interluekin-6
iPS	Induced pluripotent stem
JAK	Janus kinase
Klf4	Krüppel-like family of transcription factors
LIF	Leukemia inhibitory factor
MAPK	Mitogen-activated protein kinase
MS	Mesenchymal stem

NFT	Intracellular neurofibrillary tangles
Ngn-1, Ngn-2	Neurogenin 1 and 2
NP	Neural progenitor
NS	Neural stem
Oct 3/4	Octamer-binding transcription factor 3/4
PS-1, PS-2	Presenilin 1 and 2
RNA	Ribonucleic acid
sAPP	Secreted amyloid protein precursor
SCI	Spinal cord injury
Sox 2	Sex-determining region Y-box 2
STAT3	Signal transducer and activator of transcription 3
SVZ	Sub-ventricular zone
TUNEL assay	Terminal deoxynucleotidyl transferase dUTP nick-end labeling

1 Introduction

Aging is something that all living things must endure; however, how we approach aging as individuals can be vastly disparate due to genetics or environmental conditions. Each time cellular division occurs, telomeres, the protective noncoding deoxyribonucleic acid (DNA) sequences found at the ends of chromosomes on the 3' end, are shortened due to the replication mechanism of the lagging strand. Each cell can undergo a predetermined number of replications before telomeres have been exhausted, at which point the cell receives signaling to become senescent and die. This continual process of telomere shortening and cell death is commonly known as the process of aging.

In the 1980s, an enzyme was discovered that allowed cells to bypass cellular aging and divide without exhausting their telomeres. For the past two decades, researchers have toiled away at unlocking the secrets of this enzyme, telomerase, thought to be the modern-day fountain of youth. Telomerase is a reverse transcriptase containing its own template ribonucleic acid (RNA) molecule, allowing it to add additional telomeres to the ends of chromosomes. Somatic human cells have been found to be severely lacking in telomerase and continue to experience telomere shortening at each division, causing DNA damage and cell death. In contrast, stem cells, cells that are described as any cell that has the ability to renew itself and differentiate into different types of cells, were found to be rich in telomerase.

Due to their high levels of telomerase activity, stem cells are capable of dividing without experiencing telomere shortening. These unique properties allow the body to continue to thrive, as stem cells replace damaged or exhausted somatic cells throughout the body. However, not even stem cells are invincible to the aging process. As the body ages, stem cells become less active, and the rate of cellular turnover decreases. It is the current belief that if the stem cell population could be increased or reactivated, it would be possible to slow the effects of aging and even mitigate many age-related and degenerative diseases.

The limitless possibilities for the use of stem cells have sparked a new era in the field of regenerative medicine and have led the scientific community to recognize stem cell therapeutics as the key to unlocking future treatments for many disabling and currently incurable diseases. Companies and medical institutions around the globe have poured billions into the development of stem cell technologies and are now offering various stem cell-related products and therapies. Many of these technologies are currently in the process of clinical trials to seek approvals from officials, making it possible for treatments to be available in the European Union and United States in the near future.

2 Embryonic versus Adult Stem Cell Therapeutics

There are two prominent types of stem cells: embryonic stem (ES) cells, isolated from blastocysts, and adult stem (AS) cells, referring to more specialized stem cells present throughout the body after embryonic development. AS cells have been found in tissues and organs such as brain, skin, heart, liver, gut, testis, blood, and bone marrow. Over the past few decades, it has been widely debated as to which of these sources is the most effective for the development of safe and successful treatments.

ES cells are rapidly self-renewing cells capable of giving rise to any of the three germ layers. Their ability to be kept in culture indefinitely also makes them a valuable research and treatment tool. However, ES cells are only available 4–5 days postfertilization up until the end of embryogenesis (Thomson et al. 1998). The limited time for collection, as well as the availability of willing donors, increases both the difficulty and cost of production. In addition to challenges regarding the availability of this cell population, the use of ES cells has sparked many political debates regarding the ethics pertaining to the use of embryonic tissue, which some view to be the morally adverse destruction of human life. Furthermore, there are two very serious scientific concerns: the bodies' ability to recognize foreign materials – immunorejection can be just as lethal as the potential cure – as well as the presence of tumorigenesis, which occurs when ES cells are transplanted (Wiles and Johansson 1999; Yu et al. 2007).

In contrast, AS cells are more ethically accepted than ES cells since they are isolated from tissues, which does not involve termination of embryogenesis. They are readily available and can be isolated from sources such as umbilical cord, bone marrow, and peripheral blood, thus increasing cost-effectiveness. Also, it allows us to use a patient's own cells to for treatment, known as autologous therapy, which eliminates the concern of immunorejection. Since AS cells are already committed to becoming certain types of cells, there is no issue of tumorigenesis upon transplantation. However, their limited potency also poses a challenge in that easily available AS cells (bone marrow, blood, umbilical cord, etc.) are limited to the treatment of diseases within the scope of the tissue of origin, and cannot be used in instances such as neurological disorders. Nonetheless, many researchers feel that

the above concerns regarding the use of ES cells outweigh the benefits and that AS cells may be a much more viable choice for potential therapeutics.

Embryonic stem cells versus adult stem cells			
Embryonic stem cells		Adult stem cells	
Pro	Con	Pro	Con
Can give rise to all three germ layers	Available only from human blastocysts	Source of cells is more ethically accepted	Limited in its ability to differentiate into cell types
Fast self-renewal	Immunorejection	Easy maintenance	Slow self-renewal
Embryonic stem cells can be kept in culture indefinitely	Ethics issue on destruction of human life	Can be isolated from patients at any time	Limited expansion in culture
	Tumorigenesis	Easy access to the source of cells	
	Limiting funding for R&D	Autologous use of cells to eliminate immunorejection	
	Patent protection on hES cell lines in the USA by the University of the Wisconsin Alumni Research Foundation		

In order to bypass potency limitations of AS cells, researchers have developed induced pluripotent stem (iPS) cells, which are cells that have been reprogrammed to an embryonic-like state. In 2006, researchers used a retroviral vector to transfect mouse fibroblasts with four factors: Oct-3/4, Sox2, Klf4, and with the oncogene Myc. The results from this study showed that these cells represented the morphology of ES cells, as well as expressed ES marker genes, and showed that iPS cells can be directly generated from mouse fibroblasts in culture (Yamanaka 2008), (Meissner et al. 2007; Nakagawa et al. 2008; Okita et al. 2007; Takahashi and Yamanaka 2006). These results were replicated by several independent groups using human somatic cells (Takahashi and Yamanaka 2006; Park et al. 2008) and were also repeated using combinations of Nanog, Oct-4, Sox2, and Lin28 (Yu et al. 2007).

Although these studies represent a major breakthrough in the scientific community for the creation of patient- and disease-specific stem cells, the use of viral vectors and oncogenes in human cells has raised safety concerns. Also, the starting material used for these studies, skin blasts, is highly differentiated with a high level of DNA methylation. This may prevent certain gene expression and stop cells from becoming fully functional. In order to overcome this problem, alternative starting material with less DNA methylation, such as adult stem cells, which have less methylation and may be more flexible, needs to be explored. One such study used mesenchymal stem (MS) cells as the starting material for the induction of pluripotency. Not only was this study successful in creating MS cell-derived iPS

cells, but it was done using a single factor, Nanog, as well as a nonviral transfection method (Alvarez et al. 2010). In addition, this study went on to show that the generated iPS cells were capable of developing into cells exhibiting neural cell-like characteristics, demonstrating their ability to transdifferentiate (Alvarez et al. 2010).

These promising studies show incredible potential for the development of treatments for a limitless number of diseases, and with momentum continually building in the field of iPS research, it is not unreasonable to predict that iPS cells will soon be implemented in clinical therapeutic studies.

3 Alzheimer's Disease

Alzheimer's disease (AD) is a neurological disorder effecting the central nervous system characterized by the progressive loss of memory and intellectual functioning, typically becoming apparent after age 65 (Cruts and Van Broeckhoven 1998). AD is the most common type of dementia associated with aging, which is now the sixth leading cause of death for those 18 years of age and above and the fifth for those 65 and above. It is expected that 2.6–5.2 million Americans will be diagnosed with AD; if this current trend continues we will have over 16 million Americans diagnosed with AD by the year of 2050. The economic impact is projected to increase from 183 billion for 2011 to 1.1 trillion in 2050 (an executive summary progress report on the CDC Healthy Brain Initiative 2006–2011). As an incurable, progressive, and terminal disease with limited treatment options, this changes the status of what was once considered a rare disorder to a major medical disease that impacts a vast amount of both families and patients (Brookmeyer et al. 2011).

4 Alzheimer's Disease Pathology

As AD progresses, cell-to-cell communication is disrupted, ultimately leading to cell death and loss in brain mass. This devastating reduction of cells affects nearly all brain functions. Symptoms of AD may include memory loss which disrupts daily life, challenges in problem solving and planning, difficulty completing common daily tasks, confusion with time or place, difficulty interpreting spatial relationships and visual images, problems with speaking and writing, misplacing objects without the ability to retrace one's steps, poor judgment, withdrawal from social activities or work, and changes in mood and personality.

The mechanism behind AD is still greatly researched and debated. The most widely recognized theory for the pathology of this disease is the amyloid cascade hypothesis, which describes the hallmark formation of plaques. In this model, plaques are caused by the accumulation of beta amyloid (β-amyloid) between neurons. β-amyloid is a normally occurring, sticky protein fragment produced in the brain when it is snipped from amyloid precursor protein (APP) via sequential scission, the β-APP-cleaving enzyme (BACE) (Hussain et al. 1999; Lin et al. 2000;

Sinha et al. 1999; Vassar et al. 1999; Yan et al. 1999; Karran et al. 2011); however, in the AD brain, it is undigested and gathers into hard, insoluble plaques. Another widely studied hallmark of AD is the formation of tangles. Intracellular neurofibrillary tangles (NFT) occur when the tau protein, a highly soluble microtubule-associated protein, which aids in the formation of microtubules (Cleveland et al. 1977; Obulesu et al. 2011), is hyperphosphorylated. Hyperphosphorylated tau is incapable of binding to and stabilizing microtubules, and they therefore collapse, thus creating insoluble twisted fibers inside brain cells (Obulesu et al. 2011; Mandelkow et al. 2007; Larbig et al. 2007; Metcalfe and Figueiredo-Pereira 2010). Some researchers argue that these two hallmarks, plaques and tangles, may occur at the late-stage of the disease, and that they do not address the initial biochemical mechanisms of AD. Other researchers have focused on what drives the loss of connections between brain cells, disruption in cells signaling pathways, and inflammation as alternative possible pathways for AD.

Both risk and deterministic genes have been identified in AD. Four genes have been found to play a crucial role in the onset of Alzheimer's disease: amyloid precursor protein (APP), presenilin-1 (PS-1), presenilin-2 (PS-2), and apolipoprotein E-e4 (APOE4). One crucial pathological condition of AD is the amyloid beta deposition, plaques, in the brain. This occurs through both excess production and miscutting of amyloid beta (A4) precursor protein (APP).

5 Current Therapies for Alzheimer's Disease

There is currently no cure for Alzheimer's Disease; however, some strides have been made in slowing down the progression of the disease in the hopes that a viable treatment is on the horizon. Memory loss and confusion, the most debilitating symptoms of AD, are presently being treated using (drugs approved by the FDA) cholinesterase inhibitors (Aricept, Exelon, Razadyne, Cognex, and Namenda). Donepezil (brand name Aricept) is approved for all stages of AD and can present with side effects such as vomiting, nausea, increased bowel movement, and loss of appetite. Galantamine (brand name Razadyne), rivastigmine (brand name Exelon), and tacrine (brand name Cognex) have all been approved for AD presenting as mild to moderate progression. Symptoms for these vary from nausea, vomiting, increased bowel movement, loss of appetite, and possible liver damage. Memantine (brand name Namenda) is for AD presenting as moderate to severe in progression and has side effects such as headache, constipation, confusion, and dizziness. Even though these treatments help in slowing the progression of AD, it tends to equate to putting a Band-Aid on a gashing wound.

6 Stem Cell Replacement Strategies for Alzheimer's Disease

Studies conducted using neural stem (NS) cells isolated from both fetal and adult mammalian cells, (Doetsch et al. 1999; Gould et al. 1999) located within the central

nervous system (Johansson et al. 1999) (CNS), were proliferated in vitro using a variety of culture medium systems (Svendsen et al. 1998) then transplanted in already progressive AD environments with hopes of creating new neuronal connections. These culture systems are crucial in that they contain certain factors that are necessary for successful integration into the host CNS. There are currently established methods of maintaining and expanding NS cells in culture in a serum-free defined medium that contains basic fibroblast growth factor (bFGF) and the epidermal growth factor (EGF) (Brannen and Sugaya 2000), (Fricker et al. 1999). However, there are issues related to NS cells regarding their much shorter telomeres and that they express almost no telomerase after a certain number of passages (Ostenfeld et al. 2000). Other researchers have been successful in keeping these cells in culture long term while maintaining the ability to differentiate into cells that stain positive for beta III tubulin, a neuronal marker, and glial fibrillary acidic protein (GFAP), which is a marker for astrocytes, in neurobasal medium without the addition of exogenous factors. This suggests that these cells, once in the appropriate environment, are able to produce factors on their own. With these studies in mind we are able to expand NS cells in vitro in order to produce a well-defined source of transplantable material to continue investigations into stem cell replacement strategies.

One such study used NS cells that were expanded without exogenous mitogenic factors using serum-free media (Brannen and Sugaya 2000) then injected into the lateral ventricle of both mature (6-month-old) and aged (24-month-old) rats. Cognitive capabilities were tested using a Morris water maze 4 weeks posttransplantation. Results demonstrated a markedly significant increase in cognitive function of memory-impaired rats to that of a level of memory unimpaired or to a level considered normal for the animal's age. Postmortem evaluation by immunohistochemistry showed positive for both beta III tubulin and GFAP. Positively stained neurons were found in the bilateral cingulate, in the parietal cortexes, and in the hippocampus. Morphological identities associate with these locations indicate that the aged brain is still able to guide migration and differentiation patterns. Other researchers have tried to pre-differentiate cells into specific neuronal types in vitro and then transplant to a direct location; however, these efforts showed no host integration or increased cognition (Clarkson 2001). This could be due to the fact that fully differentiated cells are no longer able to migrate and, therefore, cannot successfully integrate into the system. Another issue could be the destruction of tissue produced by injecting cells into a direct location, which could cause an immune response resulting in the destruction of transplanted tissue. These discoveries promote that it is a key element to deliver undifferentiated versus differentiated cells into the brain ventricle instead of using a direct location and overall use of NS cells poses promising opportunities as a stem cell replacement strategy.

Another group used NS cell transplantation in order to reduce cerebral ischemia within the brain. Adult rats were given intracerebral hemorrhages by administering bacterial collagenase intrastriatally. In the study, the NS cell groups showed better function on the rotarod test – a performance test used to evaluate balance and coordination – two weeks posttransplantation and improvement 5 weeks

posttransplantation with the modified limb-placing test assessing sensorimotor integration of the limbs. These results suggest that NS cell transplantation can be a viable treatment format for the restoration of neurological defects (Jeong et al. 2003).

Chemicon, a company that was recently acquired by Millipore, developed two immortalized human neural progenitor cell lines, ReNcell VM and CX. ReNcell VM was derived from the ventral mesencephalon of the fetal brain, whereas CX comes from the cortical region of the fetal brain. Both cell lines share the ability to differentiate into neurons and glial cells along with the ability to continually reproduce themselves. The company further showed that the cells differentiated into high-level neurons and maintained their electrophysiology. With this in mind, these cells have the potential to become a therapeutic treatment for AD (Donato et al. 2007).

Other recent findings promote stroke-based therapies generated through self-repair of neurons. Induced middle cerebral artery occlusions led to the death of striatal neurons, which then triggered an increase in NS cell production through activation of the dormant NS cells already located in the sub-ventricular zone (SVZ). The newly premature neurons were able to migrate to the location of the lesions and repair it through the production of new neurons (Lindvall et al. 2004). The area of spinal cord injury (SCI) is another topic of interest in the research arena. One such group using isolated human fetal central nervous system (CNS)-derived stem cells grown as neurospheres were transplanted into immunodeficient (scid) mice. The cells were able to survive the transplantation, migrate, and differentiate with minimal GFAP-positive expression. Engraftment into the host was demonstrated through improved locomotor functioning. This provides promising results for hNSCs as a potential treatment for spinal cord injuries (Cummings et al. 2006).

As demonstrated by the abovementioned studies, it is possible the NS cells could provide a possible therapeutic approach to many diseases that currently have no productive or readily available cure. However, these studies are still in their infancy and will need much more elucidation before becoming an acceptable treatment choice and many challenges lay in its way.

7 Pharmacological Applications as a Neuroreplacement Strategy

In brain development, production of new nervous system cells occurs in early childhood and fetal stages; however, the adult brain also contains deposits of stem cells all the way into advanced years (Galli et al. 2003). Neurogenesis was first documented in the SVZ (Gould et al. 1999) and the dentate gyrus of the hippocampus (Eriksson et al. 1998; Kuhn et al. 1996; Gage 2000). Specific signaling induces mitogenic factors, such as EGF and bFGF, to direct the division of endogenous neural stem (eNS) cells located in these areas and move them towards differentiation and migration to their final destination. Plasticity of adult eNS cells has also been reported by numerous groups (Eriksson et al. 1998; van Praag et al. 2002).

In the normal brain, the rate of production of proliferating NS cells appears to be balanced by apoptosis, allowing for controlled modeling and maintenance of brain structures. Aging and stress may decrease the proliferation of NS cells (Kuhn et al. 1996), while neuronal production is upregulated in response to brain injury and ischemic diseases (Felling and Levison 2003), suggesting that eNS cells may play a role in repair as well as normal adaptive responses. When the mechanism of self-renewal and repair is no longer able to cope with the loss of neuronal mass, progression of neurodegenerative diseases occurs, leaving patients to suffer functional brain deterioration and behavior patterns ultimately leading to a decline in the quality of life. The rate of neurogenesis from eNS cells tends to rise or fall in response to physiological conditions, such as aging, diseases, and stress (Kuhn et al. 1996; Felling and Levison 2003; McEwen 2001; Jin et al. 2004), indicating that eNS cell proliferation may be controlled by certain intrinsic factors. Many researchers have isolated factors from the conditioned media of neural stem cells and tested these factors in various combinations. Fibroblast growth factor (FGF) and epidermal growth factor (EGF) have been implicated in neural migration, axon navigation, and synaptogenesis (Guillemot and Zimmer 2011) and have the ability to increase proliferation of neuronal precursor cells (Arsenijevic et al. 2001).

It stands to reason that the development of similar compounds that mimic these conditions would be a valuable tool.

Therefore, these factors have become a major pharmacological target. In one study, researchers purified an autocrine/paracrine cofactor, a glycosylated form of cystatin C (CCg), and combined it with the trophic factor, basic FGF (FGF-2), both in vitro and in vivo. The addition of both of these factors showed stimulated neurogenesis in the dentate gyrus, thus suggesting that neurogenesis may be controlled by both trophic factors and autocrine/paracrine cofactors, namely, CCg (Taupin et al. 2000). Similarly, another study showed that FGF or EGF alone cannot stimulate neurogenesis. In this study, researchers considered the early appearance of insulin-like growth factor (IGF-I) receptors during mouse striatum development and its role in NS cell regulation. Combinations of these three factors were used in order to study the action of IGF-I on striatal NS cell proliferation. The results demonstrated that proliferation was not induced in the presence of neither EGF nor FGF-2 alone; however, the addition of IGF-I resulted in large proliferative clusters of multipotent spheres. This data suggests that IGF-I plays a crucial role in the regulation of NSC activation in conjunction with FGF-2 and EGF (Arsenijevic et al. 2001).

Although these factors seem to play a pivotal role in neurogenesis, there is a major pitfall associated with this treatment course. Since factors are incapable of penetrating the blood–brain barrier (BBB), these types of pharmaceutical would need to be injected directly to the brain. An alternative method of treatment would involve the use of small molecules capable of crossing the BBB, such as antidepressants, shown to increase stem cell proliferation. In one study, human hippocampal cells from untreated subjects with major depressive disorder were used to test the effect of selective serotonin reuptake inhibitors and tricyclic antidepressants on increasing neural progenitor (NP) cells and proliferation in the human dentate gyrus. Results showed that these antidepressants were capable of increasing NP

cells in the anterior human dentate gyrus (Boldrini et al. 2009). Another study confirms these findings and reports that chronic treatment with antidepressants increased cell proliferation in the hippocampus of a rodent model (Malberg et al. 2000). Although these finding may be significant for the treatment of depression, the increase of cell proliferation will most likely not be significant enough for the treatment of neurodegenerative diseases such as AD.

One such small molecular compound, a pyrrolopyrimidine (MS-818) (Itoh et al. 1999), may be a promising target for increasing stem cell proliferation. This compound was initially identified for its ability to promote neurite outgrowth in isolated neurons maintained in vitro (Awaya et al. 1993). In another cell culture study using neurons isolated from rodent cortex, MS-818 was reported to be active primarily in the presence of various growth factors, including bFGF, nerve growth factor (NGF), EGF, and insulin-like growth factor (IGF-1) (Sanjo et al. 1998; Torigoe and Awaya 1998; Sugiyama et al. 2002; Watanabe et al. 1998). The mechanism of action of MS-818 is not known, although some evidence implies the activation of the MAPK (mitogen-activated protein kinase) pathway, a cascade that is also activated by peptide growth factors, may play a key role (Sanjo et al. 1998). In the same report, it was suggested that MS-818 promoted the survival of rodent cortical neurons by reducing the rate of apoptosis, as measured by TUNEL assays. MS-818 has been tested in isolated animal models, axon growth in mice (Torigoe and Awaya 1998), and muscle regeneration in rats (Sugiyama et al. 2002), with evidence of but no mechanistic details relating to function.

Recent studies have shown that MS-818 induces the proliferation of endogenous NSCs, which may explain mechanism of this compound's function (Sugaya 2005; Sugaya and Merchant 2008). In these studies, they have shown that MS-818 increased NS cell population 600 % in the cortex of aged rodent models. It was also found that MS-818 treatment improved behavior of Parkinson's disease model in rotarod test with association of increased proliferation of NS cells. Although toxicity studies using MS-818 have not been reported, the compound was not found to have obvious side effects in rodents in these studies, and even at the high dose, it may be a good candidate for a pharmacological treatment of AD (Sugaya et al. 2007, 2006; Kwak et al. 2006a).

8 Obstacles for Neuroregeneration Therapy for Alzheimer's Disease

The ability to increase eNS cells populations via a small molecular compound, MS-818, as well as transplanted NS cells in order to recover cognitive function in aged rats has been demonstrated. However, we may need to consider that AD pathologies may affect NS cells and reduce the efficacy of these neuroregenerative treatments. Over the past decade, scientists have uncovered much about AD pathologies such as the APP and tau defects, along with other related gene mutations, but how these modify the AD environment needs to be elucidated in order to the successful stem cell therapy of this disease.

One such example of the challenges associated with the diseased environment of the AD brain is induction of glial differentiation of NS cells as a result of high concentration of APP in the environment. In a recent study, NS cells were transplanted in the brain of APP transgenic mice where human APP is highly expressed to find whether NS cell can be used to treat AD. The hope of this study was that the transplanted cells would differentiate into functional neurons. However, this research lead to the conclusion that the high concentration of APP induced glial differentiation of NS cells instead of the much needed neuronal differentiation (Marutle et al. 2007; Kwak et al. 2011, 2010, 2006b, 2006c; Keilani and Sugaya 2008). It has shown that recombinant secreted amyloid precursor protein (sAPP) dose dependently differentiated NS cells into astrocytes.

A further study was conducted in order to elucidate the pathway of APP induced glial differentiation through the activation of interleukin-6 (IL-6) and glycoprotein (gp130) signaling pathways, which are associated with inflammation. Gliogenesis, the formation of glial populations derived from multipotent neural stem cells, is modulated through certain external factors: leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), bone morphogenetic protein (BMPs), and Notch along with integral factors neurogenin 1 (Ngn1), neurogenin (Ngn2), and deoxyribonucleic acid (DNA) methylation. It has been revealed that all of these above factors are responsible for glial differentiation through the activation of the IL-6/gp 130 signaling pathway. Ligands, LIF and CNTF, bind to receptors and subsequently phosphorylates gp130, Janus kinase (JAK), and signal transducer and activator of transcription 3 (STAT3) pathways. STAT3 then translocates into the nucleus in order to stimulate gene expression of the target gene such as glial fibrillary acidic protein (GFAP). The IL-6/gp130 signaling pathway is modulated by an autoregulatory loop which eventually coordinates with other pathways related to glial differentiation, such as Notch and BMP {Kwak, 2010 #1990}. This helps to confirm previous studies showing that sAPPα in high concentrations works as a gliogenic factor in stem cell differentiation.

The APP gene is located on chromosome 21. Trisomy of chromosome 21 is responsible for most cases of Down syndrome (DS). DS patients have shown AD symptoms as early as 40 years of age (Schnabel 2011); this may be due to the extra copy of chromosome 21, which produces an extra copy of APP gene also. Svendsen (Svendsen et al. 2001) found that DS patient's do not produce normal level of neurons and even those that are produced, the morphology is altered (Sugaya et al. 2007; Schnabel 2011; Svendsen et al. 2001; Svendsen and Caldwell 2000). When APP genes are overexpressed in the normal NS cells, they show exactly the same, less production of neurons and altered morphology.

One of the symptoms in aging and AD is the loss of AS cells, for it is this cell population that will ultimately be needed to replace neuronal functioning within the AD brain. In a healthy individual, AS cells will remain quiescent within the body in a nondividing state until they are called upon to perform duties for the purpose of tissue maintenance, disease-related repairs, or when injury has occurred. The slow exhaustion of these cells over an extended time course may lead to the natural symptomatic aging process; however, under diseased conditions such as AD, the number of AS cell may decline more rapidly than normal aging. Abovementioned

APP functions to induce glial differentiation of NS cells and induce premature differentiation of NS cell population in the AD or DC. Thus, regulation of APP level in the AD may be a useful prevention therapy as well.

9 (+)-Phenserine's Ability to Overcome Pathological Effect of Alzheimer's Disease

Before treatment for AD can begin, modification must be made to the environment which will allow for the differentiation of neuronal cells. The challenge is in discovering how to go about this without disrupting other normal functioning. There are several cholinesterase inhibitors (ChEIs) currently available for the treatment of mild to moderate AD (e.g., Donepezil, Galantamine, and rivastigmine). These ChEIs have been found to improve memory, thinking, language, and judgment through the increase of acetylcholine levels in the brain. It is believed that this increase of acetylcholine may increase cognition by compensating for loss of functioning brain cells as stated by an Alzheimer's Association report regarding FDA-approved treatments for Alzheimer's disease. Additionally, ChEIs have been found to regulate APP levels. (−)-Phenserine is one such inhibitor known to decrease levels of APP. However, the dosing of (−)-phenserine has presented a challenge. In order to suppress the appropriate amount of APP and Aβ levels, the concentration of (−)-phenserine must be significantly increased. At such high concentrations, (−)-phenserine has been known to produce severe side effects, such as increased production of acetylcholine, resulting in the autonomic nervous system to become unbalanced. In order to efficiently regulate APP levels and bypass the side effects associated with (−)-phenserine, an isoform, (+)-phenserine, was developed. When using this isoform, it is possible to give the drug at the required doses without eliciting the associated side effects (Marutle et al. 2007).

10 Conclusion

Aging is the highest risk factor for AD. Although the role of stem cells in the adult remains unclear, reduction of the stem cell population associated with aging may significantly affect brain function. If the other factors are combined, such as a high concentration of APP or inflammation in the brain, the reduction of NS cells during the aging could be accelerated. Thus, augmentation of the stem cell population or transplantation of stem cells may help to find a cure for AD. However, we have to always consider the effect of the pathological condition of AD on stem cell biology as the mature neurons may not be able to incorporate into the host brain as functional cells. We have iPS cell technology to produce neural cells from somatic cells and small molecular compound which increases endogenous stem cell population, which allow us to perform autologous regenerative therapies. As our knowledge increases in clear understanding the pathological changes in AD brain, we will be able to fight against aging and AD.

Abstract

Tardive dyskinesia (TD), marked by abnormal involuntary movements and frequently expressed as perioral activity, represents an adverse outcome of prolonged antipsychotic therapy, occurring in approximately 5 % of patients per treatment year. Although neuronal mechanisms underlying TD are largely unknown, more recent experimental studies in animal models of TD are providing insight into the neuronal mechanisms associated with TD and implicating newer treatment approaches. It is now evident that a predominance in the ratio of dopamine (DA) D_1:D_2 receptor (R) activation accounts for induction of perioral movements in rodent models of TD, in nonhuman primate models of TD, and in humans with TD. Experimentally, TD is produced in animal models of TD, in a manner analogous to that by which TD is produced in humans – by continuous and prolonged administration of a DA D_2R antagonist (i.e., an antipsychotic drug). More recently, in a rodent model of TD, it has been shown that a lesion of dopaminergic – mainly nigroneostriatal – neurons reduces the time latency for occurrence of TD, also increases the severity of perioral activity, and results in permanence of TD after complete removal of D_2R antagonist treatment. The induction of perioral activity is related to DAR supersensitivity but unrelated to numbers of D_1R and D_2R in the neostriatum, a brain region associated with perioral activity. More apropos, serotoninergic systems are now recognized as having a greater role in effecting perioral activity, and it appears that 5-HT_{2C} receptor antagonists are most effective in abating perioral activity in a rodent model of TD. These processes and mechanisms, topics addressed in this chapter, highlight a newer understanding of mechanisms underlying TD and provide insight into new approaches towards treatment of TD in humans.

5-HT_2 receptor • 5-Hydroxytryptamine • 5,7-Dihydroxytryptamine • 6-Hydroxydopamine • D_1 receptor • D_2 receptor • Dopamine • Haloperidol • Perioral movements • Receptor supersensitivity • Serotonin • Tardive dyskinesia • Vacuous chewing

1 Introduction

On the website of the National Institute of Neurological Disorders and Stroke (NINDS) (http://www.ninds.nih.gov/disorders/tardive/tardive.htm), tardive dyskinesia (TD) is classified as an extrapyramidal syndrome arising from long-term use of neuroleptic agents (i.e., antipsychotics). TD is characterized by repetitive involuntary purposeless movements of specific muscle groups which may include fingers, arms, legs, and trunk but generally presents as oral dyskinesia

(typically, chewing movements) which may include lip smacking and tongue protrusion. A person with TD may appear to be chewing gum.

TD arises in humans, nonhuman primates (Blanchet et al. 2012), and rodents by chronic (exclusive) treatment with a dopamine (DA) D_2 receptor (R) antagonist (Saifee and Edwards 2011) – the class of agents oft used for treating schizophrenia. The incidence rate of TD is approximately 5 % per year of treatment with a "classical" (first-generation) antipsychotic drug (e.g., haloperidol) (Kane et al. 1985) and two to threefold less so when an atypical antipsychotic agent (e.g., clozapine) is used (Tarsy et al. 2011). TD tends to be long lived, sometimes lifelong, and is usually refractory to treatment. TD remains a serious problem today. Tetrabenazine is the only approved drug for TD, but a variety of other drugs is often attempted.

2 Multineuronal Associations with Tardive Dyskinesia

Although TD arises from prolonged administration of a D_2R antagonist, it is recognized that many different neuronal phenotypes may have a role in the development or persistence of TD (Casey 1987; Egan et al. 1995; Jeste and Caligiuri 1993; Gong et al. 1992; Gunne and Häggström 1983; Knable et al. 1994; Kostrzewa 1995; Waddington 1990). Cholinergic (Kostrzewa and Neely 1993; Rupniak et al. 1983; 1985; Salamone et al. 1990), GABA-ergic (Gunne et al. 1988; Lloyd et al. 1985; Mithani et al. 1987; Tamminga et al. 1979), and serotoninergic (Gong and Kostrzewa 1992; Gong et al. 1992) involvements have been implicated in TD. Nevertheless, the focus in this chapter will remain on dopaminergic systems and the recently uncovered important role of serotoninergic systems in TD.

3 Oral Dyskinesia Arising in Rodents from Acute Dopamine Receptor Agonist or Antagonist Treatments

Acute administration of a DA D_2R antagonist to rats or mice results in the onset of oral dyskinesias, which are prominent over the following hour or more. The short-lived effect is related to the dose of the D_2R antagonist. Similarly, acute administration of a DA D_1R agonist is associated with a short-lived and dose-related induction of oral dyskinesia. These correlated findings give credence to the possibility that oral dyskinesia may be related to an imbalance in D_1R/D_2R activation by the endogenous neurotransmitter, DA (Rosengarten et al. 1983). Moreover, when a D_2R antagonist is administered chronically, as per animal modeling of TD, or when psychiatric patients are treated long term with an antipsychotic drug, one must consider the long-term effect of such treatment on the overall balance of D_1R/D_2R activation – and the effect this might have on the origin of TD.

3.1 Experimental Induction of Oral Dyskinesia in Rodents by Acute Dopamine D_1R Agonist Treatment or D_2R Antagonist Treatment

Antipsychotics and D_2R antagonists in general induce the occurrence of spontaneous oral activity – the so-called oral dyskinesias in humans and the so-called vacuous chewing movements in rodents (Clow et al. 1979; Iversen et al. 1980; Waddington and Gamble 1980). In contrast, DA D_1R agonists induce oral activity (Arnt et al. 1987; Koshikawa et al. 1987; Levin et al. 1989; Molloy and Waddington 1988; Murray and Waddington 1989; Rosengarten et al. 1983; 1986a, b; Rupniak et al. 1985), and it is the presumed balance in D_1R/D_2R activation that is considered to be important for this behavioral response (Rosengarten et al. 1983). For example, in rodents, there is an increase in oral activity when there is an increase in D_1R/D_2R activation, as occurs with D_2R antagonists, also after D_1R agonist treatment (Johansson et al. 1987; Molloy and Waddington 1987; 1988; Rosengarten et al. 1983), and in rat strains with reduced numbers of D_2R (Rosengarten et al. 1986a, b).

3.2 Effect of Neonatal Dopaminergic Denervation on Induction of Oral Dyskinesia in Rodents by Dopamine D_1R Agonists or D_2R Antagonists

When rats are lesioned perinatally with the neurotoxin 6-hydroxydopamine (6-OHDA; desipramine pretreatment), repeated D_1R agonist treatments "prime" DA D_1R. Initial D_1R agonist treatments have no marked effect, but repeated D_1R agonist treatments permanently sensitize D_1R, so that exaggerated behavioral responses are observed. This process is known as homologous priming of D_1R, and the resulting D_1R supersensitization is lifelong (Breese et al. (1985, 1987). Also, repeated D_2R agonist treatments of 6-OHDA-lesioned rats can induce the D_1R supersensitization, a process known as heterologous D_1R priming (Criswell et al. 1989).

When rats so-lesioned neonatally with 6-OHDA were challenged with a single dose of a D_2R antagonist, there was an increased in perioral movements when compared to the effect in non-lesioned control rats (Kostrzewa and Hamdi 1991). In an analogous manner the first challenge dose of a D_1R agonist to 6-OHDA-lesioned rats in adulthood surprisingly produced an increased number of perioral movements in comparison to non-lesioned control rats (Kostrzewa and Gong 1991). Thus, in contrast to the latent D_1R supersensitivity for locomotory and stereotyped activities that required unmasking by repeated D_1R agonist treatments (Breese et al. 1985; 1987), there was overt supersensitization of D_1R for D_1R agonist induction of perioral activity. Moreover, in the 6-OHDA-lesioned rats, perioral activity was induced by a D_1R agonist dose that was 100–1,000 times lower than was needed for induction of perioral activity in intact control rats (Kostrzewa and Gong 1991). The D_1R supersensitivity for this effect developed if the nigroneostriatal dopaminergic fiber lesioning by 6-OHDA occurred within the first week postbirth (Kostrzewa et al. 1993) and if neostriatal DA depletion was

98.5 % or more (Gong et al. 1993). This D_1R supersensitization was also lifelong. Moreover, the effect was unaccompanied by an increase in the B_{max} for D_1R (i.e., relative number of D_1R) or change in the K_d (i.e., relative affinity of the receptor for an agonist) (Gong et al. 1994).

Perinatal 6-OHDA treatment which produces near total destruction of nigroneostriatal dopaminergic neurons (Doucet et al. 1986) leaves the ventral tegmental nucleus largely intact and able to provide dopaminergic innervation to limbic regions (Snyder et al. 1986; Fernandes Xavier et al. 1994). Thus, the important element of the above studies is that a lesion of dopaminergic innervation to the neostriatum resulted in overt D_1R supersensitization for the induction of oral activity (Kostrzewa 1995; Kostrzewa et al. 1998, 2003, 2008).

4 Oral Dyskinesia Arising in Rodents from Acute Serotonin Agonist Treatment

When neonatally 6-OHDA-lesioned rats were challenged in adulthood with the serotonin (5-HT) 5-HT_2R agonist m-chlorophenylpiperazine (mCPP), the initial mCPP dose produced an enhanced increase in the number of perioral movements in comparison to that of intact control rats (Gong and Kostrzewa 1992). This finding and others indicate that 5-HT_2R is supersensitized by 6-OHDA lesioning (El Mansari et al. 1994). The effect was not replicated by 5-$HT_{1A}R$ agonist 8-OH-DPAT [(±)8-hydroxydipropylaminotetralin] or 5-$HT_{1B}R$ agonist CGS-12066B (7-trifluoromethyl-4(4-methyl-1-piperazinyl)-pyrrolo [1,2-alquinoxaline]); nor was the effect attenuated by 5-$HT_{1A/1B}R$ antagonist pindolol, nor by the predominate 5-$HT_{2A}R$ antagonist ketanserin, nor by 5-HT_3R antagonist MDL 72222 (3-tropanyl-3,4-dichlorobenzoate) (Gong et al. 1993). However, the selective 5-HT_2R antagonist mianserin blocked the effect of mCPP, indicating that 5-HT_2R, perhaps 5-$HT_{2C}R$ specifically, represents the subtype that is overtly supersensitized by 6-OHDA lesioning and associated with perioral movements (Gong et al. 1993).

In fact, the number of perioral movements after mCPP treatment was greater than that following D_1R agonist treatment (Gong et al. 1992). Mianserin pretreatment, in addition to blocking the effect of the 5-HT_2R agonist mCPP, blocked the effect of a D_1R agonist on perioral activity (Gong et al. 1992), and the dorsal striatum was one site for this interaction (Plech et al. 1995; Salamone et al. 1990). By contrast, a D_1R antagonist did not block the effect of mCPP (Gong et al. 1992). These findings indicate that DAR supersensitivity for perioral activity is mediated via a serotoninergic system and notably at the 5-HT_2R (Gong et al. 1993).

5-HT fiber hyperinnervation of neostriatum and the forebrain is prominent in rats lesioned perinatally with 6-OHDA (Berger et al. 1985; Snyder et al. 1986; Mrini et al. 1995; see Kostrzewa and Descarries 1998), and this is accompanied by an approximate 30–60 % increase in the number of 5-$HT_{1A}R$, 5-$HT_{1B}R$, 5-$HT_{1nonAB}R$, 5-$HT_{2A}R$, and 5-$HT_{2C}R$ (Radja et al. 1993). Therefore, to further explore the effect of 5-HT innervation on perioral activity, the neurotoxin 5,7-dihydroxytryptamine

(5,7-DHT) was coadministered with 6-OHDA to perinatal rats which were then studied as adults. In rats co-lesioned with 6-OHDA and 5,7-DHT, the supersensitized perioral response to a D_1R agonist was eliminated, indicating that 5-HT fibers indeed mediate the D_1R agonist effect on perioral movements (Brus et al. 1994).

5 Abatement of Oral Dyskinesia in a Rodent Model of Tardive Dyskinesia

Although acute effects of D_1R agonists on perioral activity are attenuated by acute D_1R antagonist treatment, a 5-HT_2R antagonist is just as effective (Gong et al. 1994). In the rodent model of TD, produced by chronic administration of a D_2R antagonist – over a period of months – acute treatment during the haloperidol-withdrawal phase with a D_1R antagonist does not reduce the incidence of perioral movements (Kostrzewa et al. 2007). Nor does a D_2R antagonist (spiperone), muscarinic receptor antagonist (scopolamine), histamine H_1R antagonist (cyproheptadine), opioid mu receptor agonist (morphine) or antagonist (naloxone), adenosine $A_{2A}R$ antagonist (theophylline), alpha-adrenoceptor antagonist (phentolamine, phenoxybenzamine), beta-adrenoceptor antagonist (propranolol); neither a 5-$HT_{1A}R$ agonist (pindolol) nor 5-$HT_{2A}R$ antagonist (ketanserin). However, agents with 5-$HT_{2C}R$ antagonist activity were all effective in acutely reducing the number of perioral movements in the rodent model of TD, produced by year-long administration of a D_2R antagonist. Thus, mianserin, mesulergine, ritanserin, and clozapine each acutely reduced spontaneous oral activity during 8 months of the haloperidol-withdrawn phase in the rodent model of TD (Kostrzewa et al. 2007).

Despite the fact that neural reorganization that occurs consequent to months-long continuous administration of a D_2R antagonist, it appears that it is an action mediated by serotoninergic 5-HT_2R that is most consequential (Gong et al. 1992). This is somewhat surprising, because 5-HT innervation in the brain is considered to be an afferent input, not an efferent output system. 5-HT innervation in the brain arises from the brainstem in the dorsal and medial raphe nuclei (see Kostrzewa et al. 1998). Also, from studies in rodents it is recognized that perinatal 6-OHDA destruction of dopaminergic nerves results in supersensitization of DA D_1R as well as 5-HT_2R (Gong et al. 1992; Brus et al. 1994). Therefore, in TD it may be that supersensitized 5-HT_2R has the major influence on the induction of spontaneous perioral activity.

6 Tardive Dyskinesia Arising in Rodents from Chronic Dopamine Receptor Antagonist Treatment

Waddington and colleagues (Waddington and Gamble, 1980; Waddington et al., 1983) produced the first rodent model of TD by administering haloperidol in

drinking water to rats for 6 consecutive months. An increase in spontaneous perioral movements developed only at 4 months, thus fulfilling the characteristic "tardive" element of TD (i.e., tardive signifies an onset of symptoms after chronic drug treatment). The increase in spontaneous oral activity persisted for as long as haloperidol continued to be administered, then waned and reverted to normal over a period of a month (see also Waddington 1990). Ultimately, Ellison and See (1989) showed that the form and periodicity of oral dyskinesias in haloperidol-treated rats was similar in form to those of humans with TD. A disadvantage to this model of TD was that the high level of oral activity in rats dissipated over a period of 1 month, back to control level, after haloperidol was withdrawn. This was unlike the persistence of perioral activity in people with TD.

Gunne et al. (1982) and Glassman and Glassman (1980) had observed that there is an increase in neuroleptic-evoked perioral activity in rats following damage to the brain. In the interest of developing a somewhat more novel model and possibly permanent model of TD, it occurred that DA denervation, as occurs with 6-OHDA lesioning, may be an important element in both the prominence and persistence of oral dyskinesia in rodents. Accordingly, we perinatally lesioned rats with 6-OHDA, then added haloperidol to drinking water when these rats were 2 months of age. In these largely DA-denervated rats, an increase in spontaneous oral activity occurred at 3 months, one full month earlier than in intact rats receiving haloperidol via drinking water. Also, the number of perioral movements induced in 6-OHDA-lesioned rats by chronic haloperidol was twice the level for chronic haloperidol-exposed intact rats. At 1 year the neostriatal Bmax for the D_2R antagonist [^{3}H] raclopride was increased ~25 % in 6-OHDA-lesioned rats and ~65 % in haloperidol-treated rats (both intact and 6-OHDA-lesioned). Notably, when 6-OHDA-lesioned rats were withdrawn from haloperidol at 1 year, increased perioral activity did not revert to control levels. The high level of perioral activity observed during the haloperidol phase continued to persist in the group during the withdrawal phase until the study was terminated 8 months later. Further, it is notable that there was no increase in the neostriatal D_2R (i.e., B_{max} for [^{3}H]raclopride binding to striatal homogenates) during the haloperidol-withdrawal phase in which there was a persistent high level of perioral activity (Huang et al. 1997). Andersson et al. (1990) have shown that humans with TD do not have an increase in D_2R in the brain.

7 Neural Mechanisms Attending Animal Modeling of Tardive Dyskinesia: Relevance to Human Tardive Dyskinesia

The multiple animal modeling studies relating to TD indicate the following neural mechanism relating to TD. The balance of DA D_1R/D_2R activation appears to be of critical importance. Both D_1R agonists and D_2R antagonists promote oral activity. However, acute effects do not represent a modeling of TD.

TD is, by definition, a "tardive" effect, one that develops over a period of months during prolonged or chronic treatments, specifically with a D_2R antagonist. TD appears to be induced by prolonged imbalance of D_1R/D_2R activation, consequent to a tip in the balance towards D_1R overactivation, possibly in neostriatum or other regions of the forebrain. The nigroneostriatal dopaminergic tract appears to relate most closely to TD. A remodeling of neural circuitry in the brain, over a period of months, represents an adaptive mechanism to the imbalance of D_1R/D_2R activation, which ultimately results in induction of spontaneous perioral movements. The neural adjustments and reorganization involved in the process are still a mystery.

Nevertheless, prolonged overactivation of DA D_1R appears to be the genesis for TD. Furthermore, it is apparent that damage to brain circuitry can accelerate the appearance of TD and impact on its permanence. From the most recent experimental studies, it is obvious that damage to dopaminergic innervation to neostriatum promotes earlier onset of TD and permanence. From studies by Gunne et al. (1988), it is possible that damage to other neural circuits in the brain can have similar influence on TD.

8 Implications for Treatment of Tardive Dyskinesia in Humans

Because chronic D_2R antagonist treatment of both humans and rodents produces TD, it is reasonable to assume that similar neural adaptive mechanisms occur in the brain of both rats and humans. Also, because nonspecific injury in the brain (see Gunne and Häggström 1983) as well as nigrostriatal dopaminergic damage confer permanence to the TD produced by prolonged D_2R antagonist treatment, it is possible that in those patients who develop lifelong TD, there is residual brain damage or dopaminergic fiber degeneration that impacts of the D_2R antagonist treatment. It is speculated that even a mild brain injury could have occurred earlier in life (i.e., head trauma) or perhaps dopaminergic innervation of the brain declines with aging. The latter event is thought to occur and thereby account for the origin of Parkinson's disease in aged humans (Kish et al. 1992).

Moreover, an increase in the number of neostriatal DA D_2R is not correlated with high levels of perioral movements, as noted by Huang et al. (1997). Studies by Breese et al. (1985) and Gong et al. (1994) established that DA D_1R supersensitivity is not necessarily accompanied by an increase in the number of D_1 receptors. Also, DA D_2R supersensitivity is not correlated with an increase in neostriatal DA D_2R number in rodents (Kostrzewa and Brus 1991) nor in humans with TD (Andersson et al. 1990). Therefore, the process of receptor supersensitization is not reliant on changes in DA receptor number or affinity. Regardless of underlying factors for development of TD, the animal experimental findings implicate 5-HT_2R antagonists as reasonable agents for the treatment of TD (Kostrzewa et al. 2007).

Pathogenesis of Alzheimer's Disease

Rudy J. Castellani and George Perry

Contents

Abstract

Alzheimer disease (AD) is a clinically progressive decline in cortical function involving memory and executive function and pathologically defined by two hallmark lesions, the senile plaque and the neurofibrillary tangle. Nearly 30 years ago, these hallmark lesions were purified and their protein constituents identified by quantitative analysis, which led in turn to a substantial expansion of knowledge, as well as optimism about the ultimate success of targeted therapy. Unfortunately, despite copious facts of new knowledge of the biochemical cascades that produce these protein abnormalities, there has been no meaningful progress toward disease modification for AD, a disease only found in humans. The repeated failures in this regard have been attributed to tardiness in intervention rather than instead an overdue need for a paradigm shift. The ruling theories for AD pathogenesis have their root in lesion removal. We argue that the lack of progress may instead reflect the evolving concept that pathological

lesions, be they plaques, tangles, or soluble low-n protein species, signify mechanisms of neuroprotection, in response to a decade-long adaptation to an aging-hostile environment. The lesions themselves may similarly be a manifestation of neuroprotection, and likewise the targeting of such lesions as the offending agents is done at the very real risk of disrupting homeostasis and the body's attempt at fighting disease. Rather than simply shifting the same ideas and interventions to an earlier age or stage of disease, a broadening of the scope of treatment efforts to working with rather than against the biological processes of the brain, and the realities of repeated negative data, should be accepted both in theory and in practice.

Keywords
Aβ • Alzheimer disease • Amyloid-beta • Tau

1 Introduction

Alzheimer disease (AD) is complex and heterogeneous, differing in many respects from case to case, including age at onset, clinical signs and symptoms, presence or absence of various and numerous risk factors, extent and distribution of neuropathology, and genetic alterations including germline mutation and susceptibility alleles. Numerous hypotheses and the treatment implications inherent in them are not unexpected, although the success in treatment has, to date, been absent. Whether or not this failure reflects the complexity of the disease, the now numerous failures in the face of almost limitless knowledge of biochemical facts suggest that prevailing paradigms are significantly, if not fatally, flawed and not salvageable by overlooking theoretical flaws (Castellani et al. 2008a, b, 2009; Castellani and Smith 2011).

Presently, standard thought equates protein constituents of insoluble pathological lesions or their assembly intermediates with toxicity (Hardy and Higgins 1992). AD brains, for example, accumulate neurofibrillary tangles (the major discovery made by Alzheimer in 1906), which are comprised of phosphorylated tau disposed in insoluble fibrils, and those fibrils are derived from soluble tau species which are toxic to neurons in vitro). Thus, the protein "cascade" that produces phosphorylated tau is deleterious (Spires-Jones et al. 2009). Alternatively, one could say that AD brains accumulate amyloid plaques, which contain amyloid beta-protein (AβP) in insoluble fibrils of "amyloid"; the amyloid is itself derived from soluble toxic intermediates of Aβ, which are toxic to neurons. The cascade that produces these soluble intermediates is therefore inherently deleterious (Selkoe 2008). In addition, often included in discussions of toxic soluble intermediates is a direct attack on the synapse, closing the loop so to speak on the process in that lesions are tied directly to cognition, although the degree of separation from the in vivo environment is unclear (Tanzi 2005). To be sure, much work needs to be done (Benilova et al. 2012).

2 Amyloidosis in the Brain

Aβ was initially identified through purification of insoluble pathological lesions – senile plaque cores and cerebral vasculature involved by amyloid angiopathy (Glenner and Wong 1984; Masters et al. 1985). Subsequent identification of Aβ as a metabolic product of amyloid β-protein precursor (AβPP), its localization to the long arm (q) of chromosome 21, the identification of familial AD kindreds with pathogenic AβPP mutations, and the increased AD pathology in Down's syndrome patients who carry an extra copy of chromosome 21 produced a compelling argument in favor of the so-called amyloid cascade as the pathogenic mediator of disease (Castellani et al. 2008a). The cascade was further substantiated by the characterization of presenilin proteins, part of the notch signaling complex with γ-secretase activity (see below) and therefore inherently amyloidogenic.

Aβ is derived from AβPP, an integral membrane protein on chromosome 21q21 (Vetrivel and Thinakaran 2006; Wilquet and De Strooper 2004; Ling et al. 2003). Full expression of AβPP produces a cytoplasmic tail, a transmembrane domain, and a large extracellular domain, although only a fraction of newly synthesized AβPP molecules reach the cell surface. AβPP further exists as multiple alternatively spliced isoforms, three of which predominate: two isoforms AβPP770/751 contain the Kunitz protease inhibitor domain (exon 7) within the extracellular portion and are the predominant forms in cells other than neurons; AβPP695 is devoid of the Kunitz protease inhibitor domain and is the predominant form in neurons.

Cleavage of AβPP by either α-secretase or β-secretase produces soluble N-terminal fragments AβPP, and C83 and C99 membrane-bound C-terminal fragments, respectively. Further cleavage by γ-secretase leads to the release and secretion of nonpathogenic p3 peptide (previous α-secretase cleavage) and Aβ (previous β-secretase cleavage). Moreover, depending on the precise site of γ-secretase cleavage, different lengths of Aβ are produced, varying from 38 to 43 amino acids. The 42-amino acid form, Aβ42, has a greater tendency to form fibrils in vitro compared to other forms, has a tendency to deposit in brain parenchyma in the form of plaques relative to other species, and has traditionally been regarded as the "pathogenic" Aβ species. Aβ40 is generally considered benign as well as the principle component of Aβ that is deposited in cerebral vessels in cerebral amyloid angiopathy, particularly cerebral amyloid angiopathy type 2, which tends to spare cortical capillaries. Aβ42 synthesis and deposition represents the basis for the amyloid cascade hypothesis and therefore the theoretical underpinning of most clinical trials attempted to date.

The constituents and cell biology of γ-secretase have proven a challenge, although these questions were answered in part with the appearance of familial early-onset AD linked not to AβPP mutations but to so-called presenilins 1 and 2, presenilin 1 mutations being much more common. Presenilin mutations markedly increase Aβ deposits as well as phospho-tau accumulation in affected patients (Citron et al. 1997; Duff et al. 1996; Scheuner et al. 1996) and have been linked to γ-secretase activity (Maiorini et al. 2002). On the other hand, despite the presumption of presenilin as an important component of the multimeric secretase

complex, the biochemical mechanism of presenilin action is largely unknown. During development, presenilins appear to cleave a transmembrane protein termed notch, which in turn is a transcriptional activator of gene involvement in cellular differentiation (De Strooper et al. 1999). PS1 and PS2 have also been found to be involved in a range of biological processes, including cell adhesion, G-protein-mediated signal transduction, and unfolded protein response (Baki et al. 2001; Smine et al. 1998; Niwa et al. 1999) (Baki et al. 2001; Smine et al. 1998; Katayama et al. 1999; Niwa et al. 1999). Nicastrin has also been shown to interact strongly with the presenilins and appears to be required for normal notch signaling in *Caenorhabditis elegans* (Yu et al. 2000).

APP cleavage with generation of Aβ fragments also differs as a function of cellular subcompartment. At the cell surface, AβPP is proteolytically processed, primarily by α-secretases, resulting in shedding of the majority of the extracellular domain. Rapid and efficient internalization is mediated by a "YENPTY" internalization motif (Vetrivel and Thinakaran 2006). Once endocytosed, AβPP may be recycled to the cell surface, degraded, or further processed. β-site AβPP cleaving enzyme-1 (BACE1) appears to act on AβPP in late Golgi/TGN and endosomes, as indicated by the acidic optimal pH of BACE1. γ-secretase complex activity on the other hand takes place in multiple cellular compartments including ER, Golgi, and plasma membrane; the last is thought to comprise only a small fraction of the γ-secretase activity.

A key question that has existed since the elucidation of AβPP is the normal cellular function of this molecule, which is unresolved. One candidate ligand, secreted neuronal protein F-spondin, is implicated in neuronal sprouting and development. F-spondin binds AβPP as well as APLP-1 and APLP-2, which may interfere with β-secretase cleavage and cell signaling effected by the cytoplasmic domain (Wilquet and De Strooper 2004). AβPP has been suggested to serve as a receptor for intracellular transport of synaptic vesicles through interaction with kinesin and microtubules (Kamal et al. 2001). Both AβPP and the low-density lipoprotein receptor-related protein have been shown to bind the adaptor protein Fe65 via their cytoplasmic domains which increases AβPP proteolytic processing (Pietrzik et al. 2004). Interestingly, both LRP and AβPP are also γ-secretase substrates after cleavage and removal of their extracellular domains. A role of AβPP in heavy metal binding and as an antioxidant may also be an important role with direct implications in the disease process when dysfunctional (Cho et al. 2010).

In brief, the fundamentally toxic Aβ42, otherwise a product of normal cellular metabolism, is thought to be overproduced in disease resulting in neurodegeneration, or so the amyloid cascade theory postulates. Support for this comes principally from Mendelian diseases with pathogenic AβPP mutations leading to extensive Aβ deposits and early-onset disease. In vitro toxicity of Aβ42 peptides is considered further evidence for the cascade, although toxicity lies within narrow conditions, irrelevant to brain physiology in terms of toxicity. Despite the commonly held notions, whether or not Aβ42 is toxic in vivo remains to be elucidated. On the other hand, a role of Aβ42 in neuroprotection, which is made intuitively difficult by prevailing ideas, has been demonstrated (Nunomura et al. 2006). The significance of

this cannot be understated, given again that the overwhelming majority of clinical trials accept Aβ42 toxicity as fact. The first major and somewhat infamous phase II active immunization approach (AN-1792) may have been the most informative of all trials to date given the now long-term follow-up. The evidence is now clear that removal of Aβ from the brain in mild to moderate AD has no major cognitive benefits. Moreover, the two individuals studied who had almost complete removal of Aβ plaques progressed to dementia at the same rate as placebo, and each expiring with a mini-mental status score of 0. This effectively answered the question of whether dementia progresses in the face of Aβ removal from the brain whether it be fibrillar amyloid or oligomers (Holmes et al. 2008) and objectively speaking leaves considerable doubt as to whether Aβ42 is toxic at all. Yet the enthusiasm for anti-Aβ42 therapy is seemingly undaunted and is now progressing toward earlier intervention, based on perhaps an equally flawed notion that failure to reverse mild to moderate dementia means that intervention was too late, something for which there is no evidence whatsoever.

2.1 Does Aβ Correlate with Clinical and Anatomic Indices of Disease?

While the above question data seems to have closed the case on whether Aβ causes dementia (the lag in acceptance of this evidence notwithstanding), the relationship between Aβ pathology and disease has been the subject of a number of studies prior to the AN-1792 trial, and indeed the data indicate unambiguously that the correlation between Aβ and clinical disease is imprecise at best (Castellani and Smith 2011). An early study in the 1960s showed an overall tendency toward increased disease severity with plaque burden (Blessed et al. 1968; Giannakopoulos et al. 2003), although numerous subsequent studies have refuted this concept (Giannakopoulos et al. 2003; Braak and Braak 1991; Arnold et al. 1991). At present, it is accepted that amyloid burden overall correlates poorly with disease severity, and the distribution of Aβ tends to be diffused throughout the neocortex with no meaningful region specificity. Diffuse deposits of amyloid also occur in the striatum and cerebellar cortex late in disease (Montine et al. 2012), with no discernible selectivity in terms of loss of function subserved by these regions. Relative to neocortical Aβ, it is of some interest that medial temporal allocortical tissue involved in memory processing shows decreased Aβ (Arnold et al. 1991), something that gets little attention in the literature. Given the role of ApoE in facilitating fibrillogenesis of Aβ, it is also interesting that the extent of neocortical Aβ deposits shows variable correlation in the literature with ApoE susceptibility alleles, including ε4 (Berg et al. 1998; Nunomura et al. 2001).

A relatively new paradigm that is more functional than structural has emerged, in part, in response to the growing realization of the imprecise relationship between Aβ and clinical disease and to the clinical trials that have effectively removed Aβ and have not altered the neurodegenerative process. It is now suggested that soluble low-n Aβ oligomers cause synaptic damage and functional neurologic deficits (Selkoe 2008).

Experimental studies involving injection of conditioned medium, derived from oligomer-secreting APP V717F Chinese hamster ovary cells, into rat lateral ventricle, demonstrated alterations in long-term potentiation (LTP) that was related to low-n oligomers per se and not monomers (Walsh et al. 2002). LTP alteration was also shown in vitro in hippocampal mouse slices, along with concomitant changes in cell cycle signaling cascades and behavioral abnormalities. Here again, however, there is a premature juxtaposition of nakedly artificial experimental data and human brain function, separated from each other by so many degrees of relevance that irrelevancy is the only logical conclusion. This is in addition to lack of insight into those soluble species that are the most toxic and to the overall lack of reproducibility of many of the studies (Benilova et al. 2012). The implication is nevertheless present that these soluble low-n species, which are in vitro elaborations that cannot be directly measured or even reproduced between laboratories, are attacking the synapse, which is also not directly assessed either clinically or pathologically, and, moreover, that this combination is the true substrate for cognitive decline, even with implications for so-called mild cognitive impairment. Again, with these data in mind, the failure of treatment efforts is expected and leaves us in urgent need of a reorganization of the way AD pathogenesis is viewed by the medical and scientific communities.

3 Phosphorylated Tau

When the subject of the findings by Alzheimer is discussed by way of introduction to pathogenesis, it is often stated that amyloid plaques were a key discovery. The fact of the matter is that plaques were discovered some 15 years prior to Alzheimer's description, which he knew at the time, and in fact plaques were a known accompaniment of senile dementia. The first description of the neurofibrillary tangle (NFT), however, can be attributed to Alzheimer (Castellani and Smith 2011; Alzheimer 1907). It is also interesting to note that Alzheimer devoted ten sentences and two paragraphs to his initial description of the NFT, compared to only two sentences to the senile plaque (Alzheimer 1907; Wilkins and Brody 1969), suggesting that the NFT was the more intriguing, or at least novel, lesion for him. Alzheimer and his contemporaries were nevertheless hesitant to draw conclusions regarding disease pathogenesis and were more consumed with the age of onset and clinical signs which differed from "senile dementia," a known condition at that time (Moller and Graeber 1998).

Neurofibrillary tangles received relatively little attention in subsequent years, until the advent of electron microscopy (Terry et al. 1964) and, more importantly, the advent of modern molecular techniques which allowed NFT purification and identification of tau protein as a major protein component (Grundke-Iqbal et al. 1986). The enthusiasm for tau phosphorylation as a primary process in AD, however, has always been blunted by the absence of genetic linkage and the association of TAU mutations with the frontotemporal dementia clinicopathological phenotype, rather than the AD phenotype (Cairns et al. 2007). For this reason,

more than any other, phospho-tau is regarded as downstream to Aβ in terms of the pathogenic process, despite greater fidelity in its association with clinical disease (see below).

Tau is the major protein component of neurofibrillary pathology. Similar to the situation with Aβ, knowledge of tau has expanded considerably since it was purified and molecular species elucidated from the insoluble lesions. We now know that the phosphorylated tau is a major protein component of neurofibrillary pathology, which in turn promoted the study of tau in copious detail.

The tau gene is comprised of over 100 kb and contains 16 exons (Hernandez and Avila 2007). Upstream of the first exon are consensus binding sites for transcription factors. Alternative splicing of tau nuclear RNA in the adult brain involving exons two, three, and ten results in six tau isoforms. These six isoforms in turn differ in the presence of either three of four repeats of 31 or 32 peptide residues in the C-terminal region (exon 10). This peptide repeat region also comprises the microtubule-binding domain and therefore has direct implications in tau pathophysiology. Moreover, tau isoforms differ in the expression of zero, one, or two inserts encoded on exons two and three. The relative amounts of these tau isoforms as well as their phosphorylation status change during development; 3-repeat tau with no inserts is expressed in the fetus and early postnatal infant, while heterogeneous isoforms are expressed in the adult brain. This switch in RNA splicing also corresponds to an overall reduction in tau phosphorylation. Tau is relatively abundant in neurons but is present in all nucleated cells given. Its major physiologic function appears to be in binding microtubules and in stabilizing microtubule assembly for polymerization.

In disease, tau is abnormally hyperphosphorylated at proline-directed serine/threonine phosphorylation sites, including Ser-202/Thr-205 (AT8 site), Ser-214 and/or Ser-212 (AT100 site), Thr-231 and/or Ser-235 (TG3 site), and Ser-396/Ser-404 (PHF-1 site). In addition, alternative tau splicing differs according to pathological phenotype, such that tau accumulation in AD is a mixture of 3R and 4R tau, Pick disease tends to be 3R tau, corticobasal degeneration and progressive supranuclear palsy tend to be 4R tau, and so-called argyrophilic grain disease accumulates small inclusions comprised of 3R tau.

Does phospho-tau correlate with clinical and anatomic indices of disease? In spite of the fact that tau tends to appear in the cortex subsequent to Aβ and is generally considered a secondary or downstream phenomenon (Nelson et al. 2009), it is interesting that neurofibrillary pathology correlates closely clinical signs (Braak and Braak 1991) and much more closely than Aβ deposits. Phosphorylated tau deposition, for example, has a striking tendency to involve memory circuitry early in disease as well as in the aging process (Giannakopoulos et al. 2003; Arnold et al. 1991). It is also remarkable that abundant neocortical neurofibrillary pathology is virtually always associated with clinical signs of AD (Nelson et al. 2009, 2012), whereas extensive neocortical Aβ deposits are often seen in aged individuals in the absence of significant cognitive impairment or evidence of neuronal loss. In other words, heavy tau "burden" is generally incompatible with preserved cerebral function, while heavy amyloid burden often is not.

The role of phosphorylated tau in functional disease is progressing in a manner very much similar to Aβ. Recent studies, for example, indicate that insoluble tau accumulation is somewhat benign, while oligomeric phospho-tau intermediates may be more toxic and may be toxic at the specific level of the synapse (Santacruz et al. 2005). Also similar to Aβ studies, support for this concept is limited to highly experimental models (Stokin et al. 2005; Yoshiyama et al. 2007). The results highlight the growing theme that insoluble pathological lesions, and in this case NFT formation is a late stage nontoxic event, and that attention might be better directed toward upstream soluble tau intermediates. That the entire process, from changes in synthesis of soluble species, to putative soluble assembly intermediates, to insoluble pathological lesions, has yet to be embraced as a response to an underlying pathogenic process is remarkable. With recent multiple failures of the cascade concept, testing of biological alternatives is long overdue.

4 Conclusion

Current hypotheses of AD pathogenesis encompass copious and sophisticated data, but nevertheless have their origin in hallmark pathological lesions described more than a century ago. The literature is now contradictory on whether hallmark lesions are best considered manifestations of neurotoxicity or instead insoluble epiphenomena to the more important events involving soluble, toxic intermediates and the synapse, events ironically that cannot be directly observed, and are based on in vitro elaborations which have proven challenging to reproduce between laboratories and have not passed the test of relevance to the human brain. More likely, and based on now considerable evidence, pathological lesions as well as their constituent proteins of whatever species, be they monomeric, oligomeric, or insoluble fibrils, can be tied to molecular pathogenesis on the basis of disease expression, or a host response. This response is likely fundamentally adaptive over a long period of time and more in line with Darwinian theory. Targeting of such lesions, or any individual protein as part of a putative pathogenic cascade for that matter, should be entertained only with considerable care, if not the sober realization that it will more likely do more harm than good, as has been demonstrated in abundance. As the pathogenesis of AD continues to be elucidated, a broadening of the focus, rather than the perseveration on a very narrow set of principles, appears to be needed.

Abstract

Statins are a family of lipid-lowering agents, long known to be beneficial in conditions where dyslipidemia occurs, such as atherosclerosis. Very recently, statins also have been proposed for use in neurodegenerative conditions, including Alzheimer's disease (AD). However, it is clear that the purported effectiveness of statins in neurodegenerative disorders is not directly related to cholesterol-lowering effects of these agents but, rather, to their pleiotropic functions.

Moreover, evidence from randomized, double-blind clinical trials demonstrated that statins have only limited beneficial effects in improving cognitive function in AD patients with moderate dementia. There is also a suggestion that in nondemented elderly people, statin use can be associated with cognitive impairments. Possible mechanisms underlying these effects are discussed along with the pros and cons of the use of statins in neurodegenerative disorders.

Keywords

Alzheimer's disease • Cholesterol • Dementia • Statins

1 Basic Pharmacology of Statins

Statins are a family of drugs with pleiotropic functions. To this class belong eight drugs: mevastatin, lovastatin, pravastatin, and simvastatin, which are natural compounds derived from fungal products, whereas fluvastatin, atorvastatin, rosuvastatin, and pitavastatin are distinct synthetic compounds (Shitara and Sugiyama 2006). In addition, lovastatin and simvastatin have a lactone ring in the chemical structure which increases their liposolubility, whereas the remainder statins have open acid forms (Shitara and Sugiyama 2006). These differences in structure could modify the ability of individual statins to cross the blood-brain barrier.

From a pharmacodynamic viewpoint, statins inhibit hydroxy-methyl-glutaryl-CoA (HMG-CoA) reductase, which makes statins effective for the treatment of dyslipidemias (Shitara and Sugiyama 2006). By inhibiting HMG-CoA reductase, statins block the first step in cholesterol biosynthesis, namely, the conversion of HMG-CoA into mevalonate (Shitara and Sugiyama 2006; Bersot 2011). As a result of statin administration, low-density lipoprotein (LDL) cholesterol synthesis decreases in hepatocytes that in turn leads to reduced cholesterol blood level. In addition to this effect, statins reduce triglyceride and increase HDL cholesterol plasma levels. Taken together, statins are cardiovascular agents, due to their ability to counteract hyperlipidemias that are a major cause of atherosclerosis which, in turn, is a common pathogenic mechanism for coronary artery disease, ischemic cerebrovascular disease, and peripheral vascular disease (Shitara and Sugiyama 2006; Bersot 2011). In addition to this main pharmacological effect, statins are

endowed with other pleiotropic activities. Statins reduce primary cardiac risk in many types of cardiac and vascular surgeries, with greater benefits in high-risk patients (Gajendragadkar et al. 2009). Furthermore, due to the well-known immunomodulatory effect, statins prevent graft versus host disease and allogeneic transplantation (Shimabukuro-Vornhagen et al. 2009).

Although all statins share the same main mechanism of action, their pharmacokinetic profile is quite different. Statins are well absorbed by the intestine when given by oral route, even though they undergo marked first-pass effects by the liver, which reduces the systemic bioavailability (5–30 %) (Bellosta et al. 2004). With the exception of simvastatin and lovastatin, which are prodrugs and require hepatic activation, other statins are administered as β-hydroxy-acids. Upon administration, statins reach C_{max} (peak plasma concentration) ranging from 10 ng/ml (lovastatin and simvastatin) to 448 ng/ml (fluvastatin), with a T_{max} (time to reach C_{max}) from 0.5–2 h (fluvastatin and pravastatin) to 2–4 h (atorvastatin, lovastatin, rosuvastatin, simvastatin) (Bellosta et al. 2004). In the bloodstream, statins are bound to albumin (43–99 %), which accounts for their variable half-life. Atorvastatin and rosuvastatin are the statins with the longest half-life (15–30 h and 20.8 h, respectively), whereas fluvastatin, lovastatin, pravastatin, and simvastatin have half-lives around 0.5–3 h (Bellosta et al. 2004). All statins are metabolized by the liver through the isoforms 3A4 (atorvastatin, lovastatin, and simvastatin) and 2C9 (fluvastatin and rosuvastatin) of the cytochrome P-450 (CYP) system, with the exception of pravastatin which undergoes sulfation (Bellosta et al. 2004). The primary route of elimination is fecal, and only a minor fraction of statins is eliminated via urine (Bellosta et al. 2004; Shitara and Sugiyama 2006; Bersot 2011).

2 Statins' Toxicology

The main adverse effects of statins are hepatotoxicity and myopathy. A transient elevation of serum transaminases (up to three times the baseline value) is a common outcome of statin therapy (Bersot 2011). However, the incidence of this side effect is low and dose dependent and does not imply the contraindication of statins in individuals with concomitant liver diseases such as hepatitis C (Bersot 2011). Myalgia is often associated with statin use and is paralleled by a 10-fold increase in plasma creatine kinase (Bersot 2011). Rhabdomyolysis is quite rare, and the risk of developing this side effect is correlated with the statin dose and plasma concentration (Bersot 2011). About 30 cases of serious hepatic failure and 42 cases of death due to rhabdomyolysis associated with statin administration were reported to the FDA over the last 15 years (Bersot 2011; Law and Rudnicka 2006). Particularly serious was the occurrence of fatal rhabdomyolysis in 31 patients treated with cerivastatin in the USA; among these patients, 12 received cerivastatin and gemfibrozil, thus suggesting that the cerivastatin-induced miotoxicity was potentiated by gemfibrozil (Staffa et al. 2002; Shitara and Sugiyama 2006). Due to this severe adverse effect, Bayer voluntarily withdrew cerivastatin from the market.

Rare adverse effects due to statin therapy are tendinous disorders. Tendinitis and tendon rupture were mainly associated with atorvastatin, simvastatin, and pravastatin therapy (Marie et al. 2008).

The main determinants of statin toxicity are the following.

2.1 Transporters

The organic anion-transporting polypeptide (OATP1B1) is expressed in the sinusoidal membranes of hepatocytes and is the most important influx transporter of statins (Niemi 2010; Neuvonen 2010). The activity of OATP1B1, whose encoding gene *SLCO1B1* undergoes genetic variability among individuals, accounts for important differences in statin plasma levels and toxicity. Two common single nucleotide polymorphism (SNP) variants of the *SLCO1B1* gene were identified: c.388A>G (p.Asn130Asp; rs2306283) and c.521T>C (p.Val174Ala; rs4149056). Individuals who carry the c.388A>G (haplotype *SLCO1B1*1B*) have an increased OATP1B1 activity which is associated with a 35 % reduction in pravastatin bioavailability (measured as area under the concentration-time curve, AUC) but without significant clinical outcomes (Niemi 2010). Conversely, subjects harboring the haplotypes *SLCO1B1*5* (c.521T>C) and *SLCO1B1*15* (c.521T>C together with c.388A>G) have a reduced activity of the OATP1B1 transporter and an increased statin plasma concentration (Niemi 2010). Both the latter haplotypes are differentially distributed in the population, with a combined allele frequency of 15–20 % in Caucasians, 10–15 % in Asians, and 2 % in sub-Saharan Africans and African Americans (Niemi 2010). Individuals with the c.521CC genotype have an increased bioavailability of simvastatin, pitavastatin, atorvastatin, pravastatin, and rosuvastatin of 221 %, 173 %, 144 %, 90 %, and 87 %, respectively, with respect to subjects carrying the c.521TT genotype (Niemi 2010; Neuvonen 2010). These genetic polymorphisms have indeed important clinical outcomes. The administration of 80 mg/day simvastatin to individuals with myocardial infarction was associated with myopathy, and the odds ratios were 4.5 per copy of the C allele and 16.9 in c.521CC as compared with the c.521TT homozygotes (Link et al. 2008; Niemi 2010). More than 60 % of these cases of myopathy were attributable to the C variant (Link et al. 2008). Similar results were obtained when patients were treated with 40 mg simvastatin/day with a relative risk of 2.6 per copy of the c.521C allele (Link et al. 2008; Niemi 2010). It is also important to emphasize the c.521T>C polymorphism could be responsible for the onset of myopathy even when other statins are administered. In order to reduce the risk of adverse effects, Caucasian adults harboring the *SLCO1B1* c.521TC genotype should be treated with a half dose of simvastatin, atorvastatin, pravastatin, rosuvastatin, and pitavastatin, whereas those with the c.521CC genotype should receive a quarter dose of simvastatin, atorvastatin, and pitavastatin (Niemi 2010).

ABCG2 encodes the ATP-binding cassette G2 (ABCG2), an efflux transporter located on the apical membranes of several cell types including intestinal epithelial cells and hepatocytes. The *ABCG2* gene undergoes genetic variability, and the more

common SNP is the c.421C>A (p.Gln141Lys; rs 2231142) which reduces the transport function of ABCG2. Individuals who carry the c.421AA genotype have an increased AUC of simvastatin lactone (111 %) as well as atorvastatin and fluvastatin (72 %) with respect to those with the c.421CC genotype (Niemi 2010). Individuals with a c.421AA genotype have a greater risk to develop myopathy if treated with rosuvastatin, atorvastatin, and fluvastatin, even if no clinical trial definitely proved this possibility (Niemi 2010).

2.2 Drug Interactions

In order to reduce the incidence of hepatotoxicity and myopathy, statins should not be used in association with inhibitors of CYP3A4, including grapefruit juice (see below). Several cases of rhabdomyolysis were associated with the concomitant treatment of simvastatin, lovastatin, or atorvastatin with ritonavir, cyclosporine, azole antifungals, macrolides antibiotics, and calcium channel blockers (Neuvonen et al. 2006; Neuvonen 2010). Also the combination of statins and fibrates should be avoided, in particular gemfibrozil (Bersot 2011). For further information about the potential harmful effects deriving from the interaction of statins with other drugs or nutraceuticals, see below.

3 Rationale for the Use of Statins in Alzheimer's Disease

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by cognitive dysfunction, difficulties in performing the activities of daily living, and mood changes. At autopsy, the AD brain is characterized by the accumulation of amyloid-β peptide (Aβ) and hyperphosphorylated *tau* protein (Sultana and Butterfield 2010; Citron 2010; Querfurth and LaFerla 2010). Amyloid-β peptide is formed by the secretase-mediated cleavage of the amyloid precursor protein (APP). β-Secretase cleaves APP at the N-terminus, generating an extracellular soluble fragment named sAPPβ and leaves an intramembrane fragment called C99 (Mancuso et al. 2011; Querfurth and LaFerla 2010). The latter is cleaved at the C-terminus by γ-secretase and Aβ is released (Mancuso et al. 2011; Querfurth and LaFerla 2010). Once formed, Aβ aggregates as oligomers and fibrils, which form the central core of senile plaques (Sultana et al. 2009; Citron 2010; Querfurth and LaFerla 2010). Current research suggests that Aβ oligomers are more toxic than aggregates (Shankar et al. 2008; Butterfield et al. 2007; Querfurth and LaFerla 2010), and this evidence provides a plausible explanation of the reason why drugs targeted to facilitate the disaggregation of Aβ fibrils into oligomers, e.g., bapineuzumab and solanezumab, failed to improve cognitive function in AD patients (Ayrolles-Torro et al. 2011; Mancuso et al. 2011). Interestingly, the gene encoding APP is located on the chromosome 21; therefore, individuals with down syndrome (DS), who have 3 copies of this chromosome, have an increased risk of developing AD (Bush and Beail 2004). Autopsy findings in individuals with DS

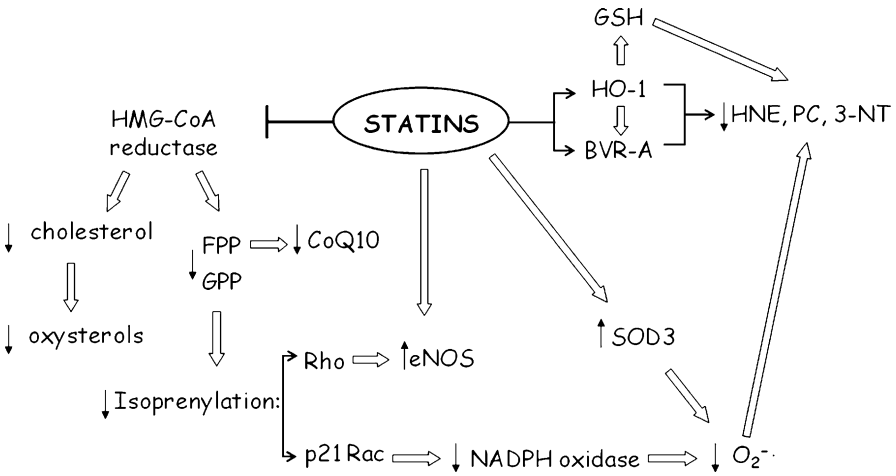

Fig. 1 Cholesterol-dependent and **c**holesterol-independent effects of statins and repercussion on the redox status of the cell. For further information, see text. revealed senile plaques and neurofibrillary tangles in the brain, which are secondary to the formation and deposition of Aβ and tau protein, respectively (Gyure et al. 2001; Itoh and Yagishita 1998).

Amyloid-β peptide and tau protein synergize and exert their neurotoxic effects through several mechanisms: (a) generation of superoxide anion and nitric oxide through the activation of NADPH oxidase and inducible nitric oxide synthase (iNOS), respectively (Butterfield et al. 2007; Querfurth and LaFerla 2010), which react each other and form peroxynitrite ($ONOO^-$); (b) mitochondrial impairment secondary to the inhibition of key enzymes involved in the respiratory chain and Krebs cycle (Querfurth and LaFerla 2010); and (c) stimulation of the ionotropic glutamate receptor NMDA and increase of Ca^{2+} overload thus leading to excitotoxic cell death (Querfurth and LaFerla 2010). Taking into consideration these multiple toxic pathways, statins may be particularly useful for AD. Statins can inhibit endothelial $O_2^{-\bullet}$ formation by preventing the isoprenylation of p21 Rac, which is critical for the assembly of NADPH oxidase after activation of protein kinase C (Wallerath et al. 2003) (Fig. 1). In addition, the cellular superoxide clearance activity is increased given that SOD3 activity is more than doubled by simvastatin. Further, simvastatin treatment also increases the number of functionally active endothelial progenitor cells (Landmesser et al. 2005). Moreover, statins increase the expression of endothelial nitric oxide synthase (eNOS) through the inhibition of Rho isoprenylation (Laufs et al. 1998), and statins can also directly activate eNOS via posttranslational mechanisms involving activation of the PI3K/Akt pathway (Kureishi et al. 2000). Statins showed positive effects

against Aβ-induced oxidative stress in mouse models of AD (Kurinami et al. 2008; Tong et al. 2009) as well as a reduction in the phosphorylation of tau protein in human cerebrospinal fluid (CSF) (Riekse et al. 2006). However, although statins' treatment appears to provide benefits, it is difficult to determine whether the benefits are due to lower cholesterol levels or to statin pleiotropy. Atorvastatin treatment was neuroprotective against cell degeneration induced by Aβ(1-40), reducing inflammatory and oxidative responses and increasing the expression of glutamatergic transporters (Piermartiri et al. 2010). Murphy et al. showed that long-term atorvastatin did not reduce Aβ levels, despite a significant reduction in β-secretase 1 (BACE1) protein levels and activity in the brains of aged beagles (Murphy et al. 2010). Subsequently, Barone et al. found that although no changes in Aβ levels occur, long-term atorvastatin significantly reduced lipid peroxidation, protein oxidation and nitration, and increased GSH levels in the parietal cortex of treated dogs (Barone et al. 2011). This effect was cholesterol and Aβ independent and specific for brain (Barone et al. 2011). Another possible mechanism by which statins exert neuroprotective effects is the enhancement of the cell stress response. The administration of atorvastatin 80 mg/day for 14.5 months to aged beagles increased the expression of the heme oxygenase-1/biliverdin reductase-A (HO-1/BVR-A) system, a main effector of the adaptive stress response (Mancuso and Barone 2009), and this correlated with a significant reduction in both oxidative and nitrosative stress biomarkers in the parietal cortex of treated beagles that showed improved cognition (Barone et al. 2012; Butterfield et al. 2011). Conversely, side effects of long-term statin treatment include a decrease in serum and tissue CoQ10 levels, which could result in an energy metabolism impairment in heart, skeletal muscle, and liver (Martin et al. 2011; Bliznakov and Wilkins 1998). The importance of statin-induced energy metabolism impairment and its role in the development of their side effects was demonstrated also in humans. The administration of 240 mg/day CoQ10 reverted fatigue, myalgia, and peripheral neuropathy in 50 patients chronically treated with statins (Langsjoen et al. 2005).

More detailed research into the pharmacology of statins is necessary, particularly the concentrations achieved in the central nervous system and the level at which they block the production of cholesterol and they modulate all the above pathways, in order to prove their beneficial effect and support the potential use of statins in neurodegenerative disorders.

4 Statins and Dementia: The Support Given by the Evidence-Based Medicine

Although the majority of the preclinical evidence shows neuroprotective effects of statins in ameliorating cognitive dysfunction, clinical data largely do not show similar benefits. In addition, some clinical studies show the opposite results depending on whether they are observational studies or randomized clinical trials (RCT).

Early cohort and case-control studies demonstrated that statins reduced the risk of developing dementia, including AD, and this protective effect was maintained

over a 6-year follow-up period (Beydoun et al. 2010; Li et al. 2010; Smeeth et al. 2009; Haag et al. 2009; Horsdal et al. 2009; Rosenberg and Allard 2008; Sparks et al. 2008; Cramer et al. 2008). These findings were recently challenged by Benito-Leon et al., who demonstrated that statins did not improve cognitive performance in nondemented elderly subjects with a median age of 72 years (Benito-Leon et al. 2010). Similar results were obtained in a large cohort study, which involved more than two million participants aged 30–84 years of whom 10.7 % received statins (Hippisley-Cox and Coupland 2010). A cross-sectional research study, with a follow-up of 5 years, demonstrated that in 123 Caucasian subjects with DS (41–78 years), total cholesterol levels $>$ 200 mg/dl positively correlated with the development of AD (hazard rate 2.59), whereas individuals taking statins had less than half the risk of developing AD with respect to nonusers (hazard rate 0.402) (Zigman et al. 2007).

In order to confirm these epidemiological studies, some RCT were performed with comparable results. The PROSPER study, which enrolled approximately 6,000 people aged 70–82 years, demonstrated that pravastatin (40 mg/day) did not have any effect on cognitive function over a follow-up of 3 years (Trompet et al. 2010; Shepherd et al. 1999). The LEADe study tested the hypothesis that atorvastatin (80 mg/day) over 72 weeks delayed cognitive decline in patients with mild-to-moderate AD. The results of this study did not support any significant positive effect of atorvastatin on cognitive or global function in patients receiving the statin compared to those with placebo (Feldman et al. 2010). In August 2011, Sano et al. published the results of an RCT of simvastatin (20 mg/day for 6 weeks and 40 mg/day for the remainder 18 months) in participants with mild-to-moderate AD that also demonstrated the lack of efficacy (Sano et al. 2011). On the other hand, the ADCLT trial demonstrated that atorvastatin (80 mg/day) for 1 year exhibited a significant positive effect on cognitive performance after 6 months of therapy compared with placebo. However, this beneficial effect was selective for individuals who matched restricted criteria, such as a higher MMSE score at baseline, total cholesterol levels higher than 200 mg/dl, and the presence of an apolipoprotein E-4 allele (APOE-4) (Sparks et al. 2006a, b). When all the RCT study results are combined, a meta-analysis suggests that there is insufficient evidence to recommend statins for the treatment of dementia and AD (McGuinness et al. 2010). This statement matches the guidelines of the British Association for Psychopharmacology who also do not recommend statins for the prevention or treatment of AD (O'Brien and Burns 2010). However, in a pilot clinical trial, a modest improvement in cognition was detected in individuals with mild cognitive impairment (MCI), arguably the earliest form of AD, treated with statins (Sparks et al. 2010).

5 Unresolved Issues

In order to understand the reasons for the inconsistent beneficial effects of statins in aged or demented individuals, several issues need to be addressed and carefully evaluated.

Ability to Cross the Blood-Brain Barrier. As mentioned earlier, the presence of a lactone ring in the chemical structures of simvastatin and lovastatin makes these latter very liposoluble, whereas the open acids atorvastatin, fluvastatin, and pitavastatin have an intermediate liposolubility, and pravastatin has the lowest one (Shitara and Sugiyama 2006). Such different degree of liposolubility might suggest the use of lipophilic statins in demented patients to increase the bioavailability in the brain. However, both the LEADe and CLASP trials failed to demonstrate a beneficial effect of lipophilic atorvastatin and simvastatin on cognitive function in AD patients, similar to the results obtained in the PROSPER study involving the lipophobic pravastatin. Thus, the different degrees of liposolubility are unlikely to be a key determinant of the limited effectiveness of statins in these clinical trials.

Age. Epidemiological data demonstrate that the incidence of AD increases with age and doubles every 5 years after 65 years of age with 1,275 new cases/1,00,000 persons/year (Querfurth and LaFerla 2010). In the Western hemisphere, the prevalence of AD was calculated at approximately 1% in subjects aged 60–64 but increases to between 33 % and 50 % in people aged 85 or older (Mayeux 2010). Much of the epidemiological and clinical studies designed to examine the role of statins in AD enrolled included individuals aged 65–84 years. Although the clinical studies and the meta-analysis discussed above did not support an overall beneficial effect for statins in dementia and AD, it is noteworthy to mention that those studies in which statins had a major effect on cognitive functions included individuals aged 68–74 years (Simons et al. 2002; Li et al. 2010; Haag et al. 2009). Consequently, it is possible that 68–74 years of age should be considered an optimal age for statin efficacy in preventing dementia. On the other hand, both the LEADe and PROSPER studies, which recruited individuals within the same range of age, failed to demonstrate any beneficial effect of atorvastatin and pravastatin in people with AD. Subjects aged 80 or older also did not have any beneficial effects from statins (Li et al. 2010).

Cholesterol Blood Levels Before and After Treatment with Statins. An important question to address when studying the HMG-CoA reductase-independent effects of statins is the concomitant reduction of LDL cholesterol plasma levels. This issue is quite important when the pleiotropic effects of statins are studied in the nervous system because cholesterol is a main component of cell membranes, in particular myelin (Saher et al. 2005), and if cholesterol blood levels fall due to uncontrolled therapy with lipid lowering agents, nervous function would also decrease. The majority of AD patients recruited for clinical trials had serum LDL cholesterol at baseline around 131–147 mg/dL, which was significantly reduced by 50–54 % after the administration of atorvastatin (80 mg for 52 weeks) or simvastatin (40 mg for 26 weeks) (McGuinness et al. 2009; McGuinness et al. 2010). These values of LDL cholesterol, before and after statin treatment, are acceptable and do not imply any possible adverse effects. However, although there is a marked effect of statins on LDL cholesterol plasma levels, no beneficial effects on cognitive function are observed in normocholesterolemic patients (McGuinness et al. 2009; McGuinness et al. 2010). Indeed, even in hypercholesterolemic patients, the administration of statins did not have any disease-modifying effect on AD (Hoglund et al. 2004;

Riekse et al. 2006). Evans et al. showed that in AD patients heterozygous for APOE-4 allele or carriers of PS1 mutations, the administration of simvastatin or atorvastatin only slightly reduced the concentration of CSF cholesterol at 6–7 months followed by a peak at 2 years and a return to baseline levels after 3 years (Evans et al. 2009). This finding suggests that despite changes in plasma cholesterol levels, statins cause only minimal changes in brain cholesterol, and, therefore, the effect on cognitive functions may be independent of systemic cholesterol metabolism.

Interaction with Xenobiotics. Patients with AD, as well as other types of dementia, usually take additional drugs for other age-related disorders or comorbidities. As mentioned above, all statins, with the exception of pravastatin, are metabolized by CYP3A4 or CYP2C9, and their plasma levels could be reduced or increased with concomitant administration of drugs that induce or inhibit these CYP isoforms. Donepezil and galantamine, two acetylcholinesterase inhibitors provided to AD patients, are metabolized by CYP3A4 (Jann et al. 2002) and, therefore, could compete with statins. As a consequence of this competition, statin plasma levels could increase as well as the risk of side effects. Also, AD patients may also be supplemented with nutraceuticals including curcumin, green tea extracts, or grapefruit juice as these natural substances are widely considered to be free radical scavengers and therefore neuroprotective. Unfortunately, these natural substances are inhibitors of CYP3A4 and, therefore, increase plasma concentrations of statins (Kiani and Imam 2007; Stump et al. 2006; Hare and Elliott 2003). Interestingly, it was reported that the concomitant administration of simvastatin and consumption of grapefruit or green tea causes rhabdomyolysis (Dreier and Endres 2004; Werba et al. 2008).

Taking into consideration the results from evidence-based medicine, it is possible to suggest that select individuals with AD may benefit more from statins: aged 65–74 years, carrier of an ApoE-4 allele (Sparks et al. 2006a) but without the haplotype *SLCO1B1*5* or *SLCO1B1*15* or *SLCO1B1*1B*/**1B* (Niemi 2010), normocholesterolemic and sparing user of drugs which inhibit CYP3A4.

6 Conclusion

Although preclinical data suggest beneficial effects of statins in the treatment of dementia and AD, results derived from epidemiological studies and RCT are contradictory. Several critical issues may need to be considered (1) the genetic profile of individuals with regard to specific genes involved in statin absorption, (2) the rate of inhibition of cholesterol synthesis in normocholesterolemic patients, (3) age of the individual, and (4) concomitant administration of drugs or nutraceuticals. Thus, future RCT using statins may consider from recruiting AD patients aged 65–75 years, which is an age range that appears to benefit from statin therapy, with primary endpoint, the analysis of cognitive function, and a significant longer follow-up. Another suggestion is to study the effect of statins in individuals with MCI in order to understand whether or not the neuroprotective effect of statins could block or slow the transition to AD. This recommendation could be especially

important since preclinical studies with atorvastatin decreased oxidative stress in aged dogs, and this benefit was correlated with levels of Aβ(1–42), which is same sequence as that of humans (Barone et al. 2011). Oxidative stress is strongly associated with amnestic MCI and AD (Perluigi et al. 2009; Sultana et al. 2010; Sultana et al. 2009), and Aβ is hypothesized to contribute to this oxidative stress (Butterfield et al. 2001).

In conclusion, the current clinical evidence is not strong enough to support the widespread use of statins to treat dementia and AD. However, it is critical that researchers and clinicians in the near future investigate whether or not statin therapy should be restricted to selected populations of demented individuals with the best chance of efficacy derived from evidence-based medicine is recommended.
