Preface

Handbook of Neurotoxicity is a compendium intended to provide an overview on neurotoxins. In addition, processes and mechanisms attending neuronal necrosis, necroptosis, and apoptosis are discussed in detail. Also, glial perturbations, as these relate to associated neuronal dysfunction, and both in vivo and in vitro methodological approaches toward the study and use of neurotoxins are discussed.

The ***first theme*** in the *Handbook* on selective neurotoxins provides a listing of individual neurotoxins, with a description of relative selectivity of each, including cellular mechanisms of action and overall neurologic and behavioral outcome deriving from these neurotoxins' effects. The ***second section***, on dopamine-derived neurotoxins, provides highlights of neuronal mechanisms associated with the production of reactive dopamine quinones and semiquinones and reactive oxygen/nitrogen species formed by the reactive dopamine analogs. These processes and mechanisms are related to purported genesis of Parkinson's disease.

The ***third section***, on glutamate receptor agonists, is focused on the theme of neuronal excitotoxicity as an outcome of over-excitation of neurons possessing kainate receptors, AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors, and NMDA (N-methyl-D-aspartate) receptors. These excitotoxins are discussed in detail as to their known and putative roles in neurodegenerative and psychiatric disorders. Similarly, the roles of exogenous and endogenous glutamate receptor antagonists as neuroprotectants and as neurotoxins per se are described.

The ***fourth section*** highlights the roles of neurotrophins in neuronal development and relates their involvement in a host of neurotoxicity events in neurologic and neurodegenerative disorders. The ***last section*** of the *Handbook*, focused on diseases and disorders relevant to neurotoxins, describes processes and mechanisms associated with specific neural disorders, including effects of some of the most prominent neurotoxins in relation to human dysfunction. Additionally, impugned neurotoxicity mechanisms in neurological disorders, protective strategies for averting and delaying onset of neurologic and psychiatric disorders, and highlights of newer strategies towards therapy are also discussed.

Handbook of Neurotoxicity is intended to be useful to students, scientists, and clinicians as an initial introduction to neurotoxin-associated processes. Simultaneously, the *Handbook* is expected to be a valuable guide for those employing specific neurotoxins as there are specific details on the use of individual neurotoxins along with dosages, delineation of mechanisms of action, expected neuronal

degenerative effects, behavioral outcome, and possible duration of effect and recovery from damage.

In essence, the *Handbook* is to represent an authoritative reference resource on neurotoxins and neurotoxicity processes and mechanisms in the medical and scientific arena.

Editor-in-Chief

Richard M. Kostrzewa, Ph.D., Dr.h.c., obtained a Ph.D. (1971) in Pharmacology from the University of Pennsylvania. After positions as Research Pharmacologist at the Veterans Administration Medical Center in New Orleans, Louisiana (1971–1975); adjunct Assistant Professor in the Department of Pharmacology at Tulane Medical School (1974–1976) and Department of Psychology at the University of New Orleans (1974–1977); and Associate Professor at the Louisiana University Medical Center in New Orleans (1975–1978), Dr. Kostrzewa joined the faculty of Pharmacology at the newly established Quillen College of Medicine at East Tennessee State University in Johnson City, Tennessee (Assoc. Prof./ Professor, 1978 to present). He actively collaborated in research for 20 years with Prof. Ryszard Brus of the Medical University of Silesia in Katowice, Poland, where Dr. Kostrzewa was Visiting Professor (1997–2003) and from which he received the *Doctorate Honoris Causa* (2005). In 2001, Dr. Kostrzewa was made an Honorary Member of the Polish Pharmacological Society. His research focus has remained on selective neurotoxins, with applications in the areas of nerve regeneration, neurodegenerative disorders, and dopamine receptor supersensitivity. He has authored and edited several books and more than 200 scientific papers, including the article coauthored with Dr. David M. Jacobowitz, his former Dissertation Advisor, and designated as a "Citation Classic" in *Current Contents*: "Pharmacological Actions of 6-Hydroxydopamine." Dr. Kostrzewa was the inaugural President of the Neurotoxicity Society and served as the Society's Treasurer for ten years. He has been Editor-in-Chief of the journal *Neurotoxicity Research* from the time of its inception (1998).

Section Editors

Trevor Archer obtained an Honour's degree in Psychology and Physiology from Newcastle-upon-Tyne University in 1974, and a Ph.D. from Uppsala University, Uppsala, Sweden, in 1979. From 1978 to 1988, he was Head of CNS Drugs at Astra Läkemedel AB. He was then appointed Professor and Chair of Biological Psychology at the University of Gothenburg, Sweden. He has been Guest or Visiting Professor at: the University of Hawaii at Manoa; Örebro University; Karlstad University; Kalmar University; and Madrid University. He received an Outstanding Lifetime Achievement Award from St. Joseph's College, North Point in 2010, and Honorary Doctorship, Professorship, and Membership Awards from the Polish Academy of Science Pharmacological Society in 2013.

Gilles Guillemin is CORE Professor and Co-Director of the newly-created "MND and Neurodegenerative Diseases Research Centre" at Macquarie University. He is an Honorary Associate of the University of Sydney and the Visiting Senior Research Fellow at the Australasian Research Institute, Sydney Adventist Hospital, Wahroonga. Professor Guillemin has published over 110 papers and edited a book, *Neuroanatomie fonctionnelle: La cellule microgliale*. He has also contributed to 12 other books and presented at over 90 conferences. Dr. Guillemin is heavily involved in tryptophan research, as his group is one of the world's leading research groups working on neuroactive metabolites derived from tryptophan. He is the newly-elected President of both the International Society for Tryptophan Research (ISTRY) and the Neurotoxicity Society (NTS). His current research interest is studying the involvement of tryptophan catabolism (via the kynurenine pathway) in human neurodegenerative diseases such as amyotrophic lateral sclerosis, multiple sclerosis, Parkinson's disease, Alzheimer's disease, and brain tumors.

Juan Segura-Aguilar studied chemistry with special mention in microbiology at the University of Stockholm, Sweden, and received his bachelor's degree in 1983. In 1989, he received his Ph.D. in biochemistry from the University of Stockholm. In 1999, he was awarded a stay at the University of Valencia by the European Community. From 1993 to 1998, he was at Uppsala University, Sweden, where he obtained "Docent" competence in 1994. In 1998, he moved to Chile and has been Full Professor at the University of Chile. He has been awarded several competitive research grants, including FONDECYT grants. Currently, he leads a research group

that studies the role of dopamine oxidation in the degenerative process of the nigrostriatal dopaminergic system. With Prof. Richard Kostrzewa, he founded and organized the Neurotoxicity Society, and has also organized several international NTS meetings, both regular and satellite.

Xin-Fu Zhou received his undergraduate medical degree from Third Military Medical University in China in 1977, M.Sc. in neurology from Beijing PLA Postgraduate College in 1982, and Ph.D. in biochemistry from the University of Melbourne in 1990. He was awarded an Australian Postdoctoral Fellowship by the Australian Research Council (ARC) in 1991 and completed his postdoctoral research at Flinders University. Since 1997, he has been awarded four times Research Fellowships and named Senior Research Fellow by the National Health and Medical Research Council (NHMRC). He has been awarded numerous competitive research grants by ARC and NHMRC. His main research interest has been in neurotrophins and their receptors in neural development and in neurological disorders. Recently, he is interested in functions of proneurotrophins and their receptors in neurological diseases such as Alzheimer's disease, spinal cord injury, and depression. Currently, he is NHMRC Senior Research Fellow and Research Chair in Neuroscience at University of South Australia.

Abstract

There has been an awareness of nerve poisons from ancient times. At the dawn of the twentieth century, the actions and mechanisms of these poisons were uncovered by modern physiological and biochemical experimentation. However, the era of selective neurotoxins began with the pioneering studies of R. Levi-Montalcini through her studies of the neurotrophin "nerve growth factor" (NGF), a protein promoting growth and development of sensory and sympathetic noradrenergic nerves. An antibody to NGF, namely, anti-NGF – developed in the 1950s in a collaboration with S. Cohen – was shown to produce an "immunosympathectomy" and virtual lifelong sympathetic denervation. These Nobel Laureates thus developed and characterized the first identifiable selective neurotoxin. Other selective neurotoxins were soon discovered, and the compendium of selective neurotoxins continues to grow, so that today there are numerous selective neurotoxins, with the potential to destroy or produce dysfunction of a variety of phenotypic nerves.

Selective neurotoxins are of value because of their ability to selectively destroy or disable a common group of nerves possessing (1) a particular neural transporter, (2) a unique set of enzymes or vesicular transporter, (3) a specific type of receptor or (4) membranous protein, or (5) other uniqueness.

The era of selective neurotoxins has developed to such an extent that the very definition of a "selective" neurotoxin has warped. For example, (1) *N*-methyl-D-aspartate receptor (NMDA-R) antagonists, considered to be neuroprotectants by virtue of their prevention of excitotoxicity from glutamate receptor agonists, actually lead to the demise of populations of neurons with NMDA receptors, when administered during ontogenetic development. The mere lack of natural excitation of this nerve population, consequent to NMDA-R block, sends a message that these nerves are redundant – and an apoptotic cascade is set in motion to eliminate these nerves. (2) The rodenticide rotenone, a global cytotoxin that acts mainly to inhibit complex I in the respiratory transport chain, is now used in low dose over a period of weeks to months to produce relatively selective destruction of substantia nigra dopaminergic nerves and promote alpha-synuclein deposition in brain to thus model Parkinson's disease. Similarly, (3) glial toxins, affecting oligodendrocytes or other satellite cells, can lead to the damage or dysfunction of identifiable groups of neurons. Consequently, these toxins might also be considered as "selective neurotoxins," despite the fact that the targeted cell is nonneuronal. Likewise, (4) the dopamine D_2-receptor agonist quinpirole, administered daily for a week or more, leads to development of D_2-receptor supersensitivity – exaggerated responses to the D_2-receptor agonist, an effect persisting lifelong. Thus, neuroprotectants can become "selective" neurotoxins; nonspecific cytotoxins can become classified as "selective" neurotoxins; and receptor agonists, under defined dosing conditions, can supersensitize and thus be classified as "selective" neurotoxins. More examples will be uncovered as the area of selective neurotoxins expands.

The description and characterization of selective neurotoxins, with unmasking of their mechanisms of action, have led to a level of understanding of neuronal activity and reactivity that could not be understood by conventional

physiological observations. This chapter will be useful as an introduction to the scope of the field of selective neurotoxins and provide insight for in-depth analysis in later chapters with full descriptions of selective neurotoxins.

Keywords

6-OHDOPA	6-Hydroxydopa
AF64A	Ethylcholine aziridinium ion
AMPA	α-amino-2,3-hydroxy-5-methyl-3-oxo-isoxazole-propionic acid
AMPH	Amphetamine
AOAA	aminooxyacetic acid
BMAA	β-N-methylamino-L-alanine
BOAA	β-N-oxalylamino-L-alanine
BoNT	Botulinum neurotoxin
DSP-4	2-chloroethylamines N-(2-chloroethyl)-*N*-ethyl-2-bromobenzylamine
EAAs	excitatory amino acids
GLU	Glutamic acid
HPTP	4-(4-chlorophenyl)-1,4-(4-fluorophenyl)-4-oxobutyl-1,2,3,6-tetahydropyridine
MDMA	Methylenedioxymethamphetamine
METH	Methamphetamine
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
PCA	Parachloroamphetamine
$RHPP^+$	4-(4-chlorophenyl)-1,4-(4-fluorophenyl)-4-hydroxybutyl-pyridinium (see)

1 Introduction

The renowned physiologist Walter B. Canon promoted the principle that the function of a nerve can be deduced by denoting the deficits produced when that nerve is destroyed. The implication is that the nerve normally acts in a way to promote functions that prevent the "absence deficits." This reasoning is sound, and this experimental

approach has been proven to be invaluable. However, while it is practical to section axons and while certain neuronal nuclei can be electrolytically destroyed with only minor injury to surrounding nerves, this approach is not so useful for brain and spinal cord because of the unintended and consequential destruction of neuronal nuclei and axons, particularly if attempting to surgically disrupt deep brain nuclei.

The advantage of selective neurotoxins is that these agents can target specific neuronal phenotypes while leaving surrounding tissue unaffected and while leaving virtually all other nerve types intact. It matters not that the target group of neurons is deep in the brain or dispersed in the spinal cord. In this way, the "absence deficit" can be discerned, and the normal function of this population of nerves can be deduced. This experimental approach is now commonplace.

Another arena for selective neurotoxins is in the modeling of neurological and psychiatric disorders. The neurotoxin 6-hydroxydopamine (6-OHDA), possessing high affinity for the norepinephrine (NE) transporter (NET), has been used to produce sympathectomy in experimental animals (Thoenen and Tranzer 1968) and also used to model attention deficit hyperactivity disorder (ADHD) (Shaywitz et al. 1976) and Lesch-Nyhan syndrome (Breese et al. 1984b). The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) has been used to model Parkinson's disease (Langston and Ballard 1984). N-methyl-D-aspartate receptor (NMDA-R) antagonists have been used to model schizophrenia (Farber et al. 1995; see Coyle 1996). More recently, repeated treatments with the dopamine (DA) D_2-receptor agonist quinpirole have likewise modeled schizophrenia (Peng et al. 1990; see Brown et al. 2012) as well as obsessive-compulsive disorder (Szechtman et al. 1998). Reversible and permanent models of tardive dyskinesia have been produced by haloperidol in intact and in 6-OHDA-lesioned rats, respectively (Waddington et al. 1983; Huang et al. 1997b). Quinolinic acid lesions have modeled Huntington's disease (Schwarcz et al. 1984; Beal et al. 1988). Neurotoxins have been used to model additional neurological and psychiatric disorders, and the list will continue to grow with time.

With anti-NGF having been developed in the 1950s and with both 6-hydroxydopamine and glutamate having been used as neurotoxins since the 1960s, the era of selective neurotoxins is 6 decades in the making. During the twenty-first century, the number of selective neurotoxins will inevitably grow, thereby expanding the potential and usefulness of these agents in increasing our understanding of the processes and mechanisms entailed in neuronal function. Additionally, selective neurotoxins will model ever more neurological and psychiatric disorders and thereby improve the template for development of better treatments for human disorders.

2 Terminology

The term "selective neurotoxin" refers to an agent which has toxic potential and relative selectivity for a neuron with:

1. A defined phenotype (e.g., dopaminergic nerve)
2. A specified receptor population which confers susceptibility to damage by agonists (e.g., glutamate-induced excitotoxicity)

3. A cellular protein that is inactivated by a particular agent (e.g., DSP-4 and noradrenergic nerves)
4. A metabolic schema that is specifically inactivated by an agent (e.g., rotenone inhibition of mitochondrial complex I, leading to degeneration of dopaminergic nerves)
5. A protein, uniquely targeted by an immunotoxin (e.g., IgG-saporin and cholinergic nerves)
6. Surface protein targeted by an agent that renders the nerve inactive (e.g., botulinum neurotoxin and cholinergic nerves)
7. Ion channels rendered inactive by an agent (e.g., tetrodotoxin and sodium channels)

Agents and antibodies directed towards neurotrophins can similarly prevent development of a population of neurons which are dependent on neurotrophic actions particularly at defined stages in ontogeny (e.g., anti-nerve growth factor [anti-NGF] and paravertebral sympathetic noradrenergic nerves).

As more elements in nerves become targets, the list above will expand with time. And with time, the definition of a neurotoxin will blur. Already recognized is the fact that NMDA-R antagonists can result in a neurotoxic effect by virtue of their neuroprotective action (Olney et al. 1991; Farber et al. 1995). Also, when administered particularly in ontogeny, NMDA-R antagonists prevent neural excitation by endogenous glutamate – thereby sending a "message" that the now quiescent population of neurons is unnecessary. This group of developing neurons dies, and the net effect of the neuroprotective antagonist is overt neurotoxicity (see Olney et al. 2002).

In another vein, repeated treatments with some agonists – notably the DA D_2-receptor agonist quinpirole – result in prolonged or even permanent supersensitization of D_2 receptors. Following the development of receptor supersensitivity, animals when challenged acutely with quinpirole display exaggerated behaviors; and this disposition to a D_2 agonist is lifelong (Kostrzewa and Brus; 1991; Kostrzewa 1995; Kostrzewa et al. 2003). Thus, in the absence of overt neuronal cell loss, and with no discernible anatomical effect, altered behavioral outcome represents an abnormal response and thereby an index of neurotoxicity.

A neurotoxin thus can be classified as such, even in the absence of neuronal apoptosis or necrosis. Therefore, a selective neurotoxin can be defined only loosely, and the definition surely will be more ambiguous over time. Nevertheless, the utility and advantages of neurotoxins will grow over the next century and beyond, and those who employ selective neurotoxins will recognize this spectrum of agents by outcomes in the experimental realm.

The topic of selective neurotoxins has been reviewed recently (Kostrzewa 1999b, 2009; Segura-Aguilar and Kostrzewa 2004; 2006; Herrera-Marschitz et al. 2007).

3 Early History of Selective Neurotoxins

The stage for selective neurotoxins was constructed in the 1930s by the noted physiologist Walter B. Canon, who promoted the thesis that the function of

a nerve can be deduced by denoting altered effect when the nerve is destroyed by surgery or other physical means (Cannon and Rosenblueth 1937). While this thesis has proven to be valuable, limitations of a surgical experimental approach relate to the fact that multiple types of neurons [phenotypically different (i.e., having different neurotransmitter systems) or with different populations of receptor types] are simultaneously damaged. Accordingly, it is not possible to ascribe a physiological alteration to a phenotypically distinct type of neuron.

The initial discovery of a selective neurotoxin was conceivably that by Lucas and Newhouse (1957) who found that the amino acid glutamate (Glu) produced overt destruction of neurons in immature mouse retina. Years later this effect was attributed to excess neuronal excitation, resulting in "excitotoxicity."

However, the age of selective neurotoxins arrived with the seminal work of the Nobel Laureate Rita Levi-Montalcini. During her fellowship with Viktor Hamburger in the 1950s, the discovery was made that there is a factor in mouse sarcoma 180 and 37, also in snake venom and mouse salivary glands, that profoundly promotes the growth of sensory and sympathetic ganglia. In collaboration with the biochemist Stanley Cohen, this neurotrophin was ultimately isolated and termed "nerve growth factor" (NGF) (Cohen et al. 1956; Levi-Montalcini et al. 1954; Levi-Montalcini and Cohen 1956; Cohen and Levi-Montalcini 1957; Levi-Montalcini and Booker 1960b; Levi-Montalcini 1964). Subsequently, an antiserum to NGF was developed and shown – when administered to neonatal mice – to prevent the development of sympathetic (noradrenergic) ganglia, thereby resulting in a relative noradrenergic denervation of peripheral organs. While intermediary ganglia (e.g., mesenteric ganglion) and terminal ganglia remained partially or largely intact, paravertebral ganglia were near-totally destroyed. The outcome was predominate removal of the sympathetic nervous system – an "immunosympathectomy" (Levi-Montalcini and Booker 1960a; Levi-Montalcini 1966; 1987 (reviews); Levi-Montalcini and Angeletti 1966). R. Levi-Montalcini and S. Cohen shared the 1987 Nobel Prize for their work. Anti-NGF ushered in the era of selective neurotoxins.

While anti-NGF was a milestone in providing discrete denervation of a phenotypically selective class of nerves, anti-NGF was not a neurotoxin per se. Rather, anti-NGF prevented the action of a specific neurotrophin, which thus prevented programmed ontogenetic development of sympathetic noradrenergic nerves. Anti-NGF had limitations: (1) Noradrenergic fibers originating in intermediary sympathetic ganglia (e.g., mesenteric ganglia) partially survived the effects of anti-NGF, and (2) sympathetic terminal ganglia, largely to genitourinary regions, largely survived anti-NGF treatment. As an experimental strategy, anti-NGF (3) had virtually no discernible effect in adult species, and (4) it had no effect on noradrenergic nerves in the brain. Anti-NGF thus was the prologue of agents that are specifically classified as selective neurotoxins.

4 The Era of Synthetic and Small Molecule Selective Neurotoxins

Beginning in the 1960s and into the present, there has been a series of discoveries of small molecule selective neurotoxins. These agents represent a valuable resource towards determining the roles of identifiable (i.e., sometimes phenotypically distinct) neurons in physiological and behavioral processes. Moreover, these neurotoxins have been useful likewise in producing animal models of human psychiatric, neurologic, and neurodegenerative disorders. The brief survey of selective neurotoxins herein provides a brief history of discovery as well as a description of their effects and resulting utility.

5 Survey of Individual Selective Neurotoxins

5.1 6-Hydroxydopamine (6-OHDA)

5.1.1 Historical Perspective

Porter et al. (1963; 1965) and Stone et al. (1963; 1964) in their mutually collaborative studies made the discovery that the compound 2,4,5-trihydroxyphenethylamine (6-hydroxydopamine, 6-OHDA) produced long-lived depletion of NE in the heart and other tissues. However, its mechanism of action was undefined. Several years later, in search of an electrophilic marker for electron microscopic visualization of synaptic granules in sympathetic neurons, Hans Thoenen and J.P. Tranzer found a near ideal candidate in 5-hydroxydopamine (5-OHDA) (Tranzer and Thoenen 1967a). However, the startling finding was that the analog 6-OHDA produced overt neurotoxicity, destroying sympathetic (noradrenergic) neurons (Tranzer and Thoenen 1967b; 1968; Thoenen and Tranzer 1968). In short time, it was shown that 6-OHDA, when injected into brain tissue or into a brain ventricle, destroyed dopaminergic as well as noradrenergic neurons (Bloom et al. 1969; Uretsky and Iversen 1969; 1970). Many facets of 6-OHDA actions were described in review articles, shortly after discovery of 6-OHDA neurotoxicity (Thoenen and Tranzer 1973; Kostrzewa and Jacobowitz 1974). The key terms "6-hydroxydopamine" or "6-OHDA" appear in 10,846 papers in PubMed, as of January 30, 2013. 6-OHDA is still widely used today.

5.1.2 Selectivity of Action

6-OHDA is a relatively selective neurotoxin for noradrenergic and dopaminergic neurons. Owing to its chemical similarity to DA (Fig. 1), 6-OHDA (Fig. 2) has high affinity for the NET and DA transporter (DAT) and entry into NE neurons and DA neurons resulting in a high intraneuronal concentration of 6-OHDA. The K_i of 6-OHDA for the NET is <50 μM (Iversen 1970; Ma et al. 1995). When selective damage to dopaminergic nerves is the objective, an NET inhibitor such as desipramine is administered as pretreatment (Breese and Traylor 1971; Peters et al. 1977). During the process of uptake by the NET, 6-OHDA releases NE to produce a sympathomimetic effect (De Champlain and Nadeau 1971; De Champlain and Van Amerigen 1972).

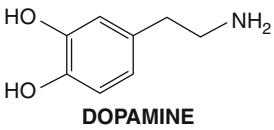

Fig. 1 (From Kostrzewa 1999b)

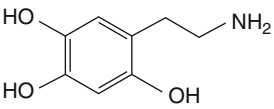

Fig. 2 (From Kostrzewa 1999b)

5.1.3 Mechanism of Action

Because 6-OHDA has micromolar affinity for the vesicular monoamine transporter-2 (VMAT-2) on NE granules and DA granules (Jonsson and Sachs 1975; Sachs et al. 1975), 6-OHDA is accumulated by granules and stored as a false transmitter.

Inside the nerve, 6-OHDA auto-oxidizes to a number of intraconvertible reactive oxygen species (ROS) including 6-OHDA-quinones, aminochrome, 5,6-dihydroxyindole, indolines, and indole-quinones (Senoh and Witkop 1959; Saner and Thoenen 1971a, b; see Kostrzewa and Jacobowitz 1974). The destructive role of 6-OHDA-derived quinoid species is likely due not so much to their binding to cellular elements, but rather to their generation of a family of other ROS which overwhelms the endogenous cellular neuroprotective processes (Graham et al. 1978). 6-OHDA-ortho-quinone and 6-OHDA-para-quinone are resonant tautomers, each of which is capable of destroying noradrenergic nerves (Heikkila et al. 1973a). However, it appears that 6-OHDA-o-semiquinone is the paramount neurotoxic auto-oxidative species producing neurotoxicity (Segura-Aguilar 2001).

Most of the above ROS generate intraneuronal hydrogen peroxide (H_2O_2), which itself is toxic (Heikkila and Cohen 1971, 1972a, b). Intraneuronal catalase inactivates H_2O_2, converting it to water. Superoxide radical also is generated by 6-OHDA auto-oxidation (Heikkila and Cohen 1973; Cohen and Heikkila 1974), as well as highly reactive hydroxyl radical (Cohen and Heikkila 1974).

5.1.4 Effects of 6-OHDA Treatment of Adult Rodents

Being ionized, 6-OHDA is unable to cross the blood-brain barrier (BBB). If administered peripherally, 6-OHDA produces marked sympathetic denervation to most peripheral organs.

To produce a CNS effect in adults, 6-OHDA must be administered into a cerebral spinal fluid compartment (i.e., intraventricular, intracisternal, or intrathecal spaces) or directly into CNS parenchyma (e.g., intrastriatal, intranigral).

5.1.5 Intraparenchymal 6-OHDA Treatments in Rat Brain

Direct injection of 6-OHDA into substantia nigra pars compacta (SNpc) – to model Parkinson's disease (PD) – results in profound (>90 %) destruction of dopaminergic perikarya, with associated near-total dopaminergic denervation of neostriatum (Ungerstedt 1968, 1971a). Because such bilateral 6-OHDA lesions are accompanied

by aphagia, adipsia, immobility, lack of grooming, and ultimate death, intranigral 6-OHDA lesions are commonly given unilaterally. Rats with a unilateral intranigral 6-OHDA lesion are able to eat, drink, groom, and otherwise remain mobile but with a circling towards the lesioned side, which abates to a large degree over time (Ungerstedt 1971d).

Intrastriatal 6-OHDA administration results in an acute moderate destruction of dopaminergic striatal terminals, followed by progressive dopaminergic denervation of this brain region over a period of 4 months, with ultimate death of 50–70 % of SNpc dopaminergic perikarya (Berger et al. 1991; Sauer and Oertel 1994; Przedborski et al. 1995; Blandini et al. 2007).

6-OHDA directly administered into the locus coeruleus results in noradrenergic denervation of neocortex, hippocampus, cerebellum, and other regions, to a lesser extent (Ungerstedt 1971c).

5.1.6 Intracisternal (i.c.) and Intraventricular (i.vtr.) 6-OHDA Treatments of Rats

In adult rats i.c. and i.vtr. 6-OHDA treatments produce modest effects on noradrenergic and dopaminergic innervation of the brain, with potency increased by pretreatment with a monoamine oxidase inhibitor (MAO-I) and with selectivity for dopaminergic neurons increased by pretreatment with the NET inhibitor desipramine (see *Handbook of Neurotoxicity* chapter by Papadeas and Breese 2013). DA D_2-receptor (D_2-R) supersensitivity is prominent in rats so-lesioned (Ungerstedt 1971b).

5.1.7 Effects of 6-OHDA Treatment of Neonatal Rodents

When administered non-centrally to perinatal rodent species, 6-OHDA and related neurotoxins have a dual action in destroying peripheral sympathetic noradrenergic nerves. 6-OHDA initially destroys sympathetic noradrenergic nerves via generation of intraneuronal ROS, and this effect results in the inability of noradrenergic nerve endings to enact the effects of NGF which would promote further ontogenetic development of these nerves. In perinatal rats, 6-OHDA crosses the blood-brain barrier and produces noradrenergic neuronal degeneration in the brain. When administered to rats on the day of birth, 6-OHDA (60 mg/kg ip) produces lifelong partial noradrenergic denervation of spinal cord (∼75 % decrease) and neocortex (∼50 %), with eventual noradrenergic sprouting and hyperinnervation of midbrain (∼50 %), pons-medulla (∼50 % increase), and cerebellum (∼100 % increase). When administered up to 5 days post-birth, 6-OHDA results in an approximate 40 % permanent decrease in noradrenergic innervation of hippocampus; when given from 3 days to 14 days post-birth, 6-OHDA decreases noradrenergic innervation of cerebellum by ∼50 %. The blood-brain barrier forms in different parts of the brain at different postnatal times, accounting for 6-OHDA access to different brain regions at different postnatal times (Kostrzewa 2007).

Both i.c. and i.vtr. 6-OHDA treatments in perinatal rodents result in near-total destruction of SNpc (Berger et al. 1985; Fernandes Xavier et al. 1994) and associated near-total DA depletion (Breese et al. 1984a, b, 1985a, b, 1987; Bruno et al. 1987; Jackson et al. 1988; Dewar et al. 1990), with near-total dopaminergic

denervation of neostriatum (Snyder et al. 1986; Descarries et al. 1992). Selectivity of 6-OHDA for dopaminergic neurons is provided by desipramine pretreatment. In the absence of desipramine perinatal 6-OHDA largely destroys the noradrenergic system as well, with locus coeruleus perikarya being susceptible to damage. Notably, neonatal 6-OHDA lesioning of dopaminergic systems results in reactive serotoninergic sprouting and eventual 5-HT neuronal hyperinnervation of forebrain (Breese et al. 1984a, b; Stachowiak et al. 1984; Snyder et al. 1986; Luthman et al. 1987; Towle et al. 1989; Descarries et al. 1992).

In adult rats that are largely DA denervated by neonatal 6-OHDA treatment, the first challenge dose of a DA D_1-R agonist induces marked perioral activity (vacuous chewing movements, VCMs), with the effect being dose related and with sensitivity to the DA D_1 agonist being 1,000-fold greater than observed in adult controls (Kostrzewa and Gong 1991). This effect is mediated or moderated by the serotoninergic system, as indicated by the fact that a 5-HT_2-R antagonist attenuates the D_1 agonist effect (Gong et al. 1992) as does 5-HT fiber denervation produced by 5, 7-dihydroxytryptamine (5,7-DHT) treatment (Brus et al. 1994). This DA D_1-R supersensitivity is accompanied by an increase in DA D_1-receptor mRNA levels in neostriatum but without a change in the number of high-affinity D_1-R in striatum (Gong et al. 1994; see Kostrzewa et al. 1998).

In the adult rats that were lesioned neonatally with 6-OHDA, the serotoninergic hyperinnervation of forebrain is accompanied by 5-HT-R supersensitivity, as evidenced by enhanced perioral activity in response to low-dose 5-HT_2 agonist treatment (Gong and Kostrzewa 1992; Gong et al. 1993).

For locomotor and classical stereotypic behaviors, there is latent D_1-R supersensitivity, as exemplified by the findings of Breese et al. (1985a, b, 1987), demonstrating that the first and second weekly adulthood challenge doses of a D_1 agonist produce no enhanced behavioral response in the neonatally 6-OHDA-lesioned rats. However, the third and all subsequent doses of a D_1-R agonist produce profound locomotor and stereotypical responses – and the effect is lifelong (Breese et al. 1985a, b, 1987). The neonatally 6-OHDA-lesioned rat represents a unique animal model for studying DA-R supersensitivity (see Kostrzewa 1995; Papadeas and Breese (2013 – this *Handbook of Neurotoxicity*)).

The effects of 6-OHDA treatments of both adult rats and neonatal rats are discussed in several reviews (Kostrzewa and Jacobowitz 1974; Breese 1975; Zigmond and Stricker 1989; Breese et al. 1990, 1994, 2005; Zigmond et al. 1993; Breese and Breese 1998; Zigmond and Keefe 1998).

5.2 6-OHDA Analogs

A number of analogs of 6-OHDA [6-OHDA = 2,4,5-trihydroxyphenethylamine] have been described (Tranzer and Thoenen 1973), having effects similar to that of 6-OHDA: 6-aminodopamine (6-ADA) (Fig. 3) (Blank et al. 1972; Heikkila et al. 1973b; Jonsson and Sachs 1973); 2-methyl-6-OHDA (Lundstrom et al. 1973; Borchardt et al. 1977); 5-methyl-6-OHDA; 2,5-dimethyl-6-OHDA

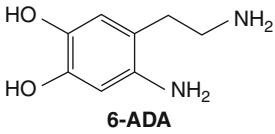

Fig. 3 (From Kostrzewa 1999b)

(Borchardt et al. 1977); 4-amino-6-OHDA (Cheng and Castagnoli 1984); 2,3,5-trihydroxyphenethylamine; 2,3,4,5-tetrahydrophenethylamine (Lundstrom et al. 1973); all eight of the trisubstituted phenyl analogs of phenethylamine; alpha-methylphenethylamine; and 1-(5-amino-2,4-dihydroxyphenyl)-2-aminopropane (Ma et al. 1995). 6-OHDA analogs that form para-quinoidal species represent the neurotoxic forms (Cheng and Castagnoli 1984); however, the ease of oxidation is not directly correlated with neurotoxic potential (Ma et al. 1995). In early studies, 2,3,4-trihydroxy-; 2,3,6-trihydroxy-; 3,4,5-trihydroxy-; 2,4,6-trihydroxy-; and N, N-dimethyl-2,4,5-trihydroxyphenethylamine had no long-term effect on noradrenergic systems (Lundstrom et al. 1973).

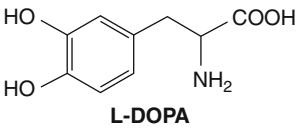
5.3 6-Hydroxydopa (6-OHDOPA)

On the basis of knowledge that L-3,4-dihydroxyphenylalanine (L-DOPA) (Fig. 4) is effective as an anti-parkinsonian agent by virtue of its being able to cross the blood-brain barrier, to then be converted in dopaminergic nerves to DA, 6-hydroxydopa (6-OHDOPA) (Fig. 5) was developed as a protoxin specifically for its ability to likewise cross the blood-brain barrier and then be converted to 6-OHDA and thereby destroy noradrenergic and/or dopaminergic nerves in the brain.

5.3.1 Historical Background

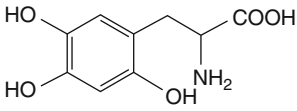
Ong et al. (1969) and Berkowitz et al. (1970) demonstrated that 6-OHDOPA effectively reduced NE content of the rat brain and that the detrimental effects of 6-OHDOPA on sympathetic noradrenergic nerves could be prevented by pretreatment with a dopa decarboxylase inhibitor. On the basis of these findings, RM Kostrzewa, under auspices of his dissertation advisor David M. Jacobowitz, undertook a series of biochemical and histochemical studies to determine the neurotoxic potential of 6-OHDOPA. Using a histofluorescence method to visualize noradrenergic neurons, the first evidence of 6-OHDOPA neurotoxicity was indicated by the loss of noradrenergic fiber number in the mouse brain, particularly forebrain – accompanied by the associated reduction in NE content in various brain regions (Jacobowitz and Kostrzewa 1971). Additionally, swollen preterminal axons were prominent in 6-OHDOPA-lesioned mice, thereby highlighting noradrenergic tracts – which ordinarily are not visible – and thereby facilitating the mapping of noradrenergic fiber tracts in the brain (Jacobowitz and Kostrzewa 1971).

Shortly thereafter, Sachs and Jonsson (1972a, b) reported analogous neurochemical findings, demonstrating NE reductions in the brains of 6-OHDOPA treated animals. While the advantage of 6-OHDOPA relates to its ability to be administered



L-DOPA

Fig. 4 (From Kostrzewa 1999b)



6-OHDOPA

Fig. 5 (From Kostrzewa 1999b)

non-centrally, 6-OHDOPA does actually produce neurotoxic effects when administered centrally (Richardson and Jacobowitz 1973). Definitive proof of 6-OHDOPA overt neurotoxicity was subsequently demonstrated by a decrease in the V_{max} for the NE transporter in brain (Kostrzewa and Garey 1976), loss of tyrosine hydroxylase activity in locus coeruleus (Kostrzewa et al. 1978), silver staining, and electron microscopic evidence of necrotic noradrenergic locus coeruleus neurons in the brain of 6-OHDOPA treated rats (Kostrzewa and Harper 1974, 1975). Cell counts of paraffin-embedded serial sections through the locus coeruleus established that neurons in the caudal half of the locus coeruleus (50 % cell loss) were most susceptible to 6-OHDOPA neurotoxicity (Clark et al. 1979).

5.3.2 Advantages of 6-OHDOPA Versus 6-OHDA

1. The protoxin 6-OHDOPA, unlike 6-OHDA, can be administered peripherally (ip, sc, iv) to adults to destroy noradrenergic nerves in the brain, thus avoiding direct intracisternal, intraventricular, or intraparenchymal injections of the brain.
2. Peripheral noradrenergic/sympathetic nerves can be protected and left virtually intact after 6-OHDOPA treatment by administering a peripherally acting dopa decarboxylase inhibitor, as pretreatment – analogous to the conventional combination of a peripheral decarboxylase inhibitor with L-DOPA therapy of Parkinson's disease.
3. 6-OHDOPA is relatively selective for noradrenergic versus dopaminergic nerves.
4. Destruction of noradrenergic terminals results in retrograde accumulation of NE in swollen axons, which become clearly visible by a histofluorescence method for NE (see below), and thus facilitates the mapping of noradrenergic tracts in the brain.

5.3.3 Disadvantages of 6-OHDOPA Versus 6-OHDA

1. Because 6-OHDOPA is relatively selective for noradrenergic neurons, dopaminergic neurons are left largely intact and unaffected by 6-OHDOPA treatment.
2. 6-OHDOPA has low neurotoxic potency for noradrenergic neurons in adults. Consequently, it is not possible to produce near-total noradrenergic denervation of regions of the brain.

3. In high dose, 6-OHDOPA produces lethal effects, thus eliminating the possibility to use a large 6-OHDOPA dose.
4. 6-OHDOPA is much more expensive than 6-OHDA.

5.3.4 Effects in the Periphery and Brain of Rodents Lesioned as Adults with 6-OHDOPA

When administered peripherally to adults, 6-OHDOPA damages sympathetic noradrenergic terminals, thereby reducing sympathetic innervation of peripheral organs such as the heart and spleen, and this is accompanied by NE depletion of the same organs. In time, because sympathetic ganglia remain intact along with preterminal axons, nerve terminals to peripheral organs regenerate, and after a period of 4–8 weeks, most or all peripheral organs are fully reinnervated by sympathetic noradrenergic nerves (Kostrzewa and Jacobowitz 1972, 1974).

5.3.5 Long-Lived Effects in the Brain of Rodents Lesioned as Neonates with 6-OHDOPA

6-OHDOPA finds greatest utility when administered to ***neonatal*** rats or mice, in order to determine developmental effects on noradrenergic neurons and to study their regenerative capacity. In prenatal mice (Kostrzewa et al. 1978) and in postnatal rats, 6-OHDOPA produces long-lived near-total noradrenergic denervation of hippocampus and >85 % long-lived noradrenergic denervation of neocortex and also spinal cord (Kostrzewa 1975; Kostrzewa and Garey 1976; Kostrzewa and Jacobowitz 1973; Sachs and Jonsson 1972a, b; Zieher and Jaim-Etcheverry 1973, 1975). These regions are provided with noradrenergic innervation by axons originating from locus coeruleus, a nucleus prominently damaged by neonatal 6-OHDOPA treatment (Kostrzewa and Harper 1974; Clark et al. 1979). Noradrenergic innervation in ventral brain is less affected by 6-OHDOPA (e.g., hypothalamus and thalamus), and recovery in these regions occurs by 8 weeks (Kostrzewa and Garey 1976).

The pons-medulla and cerebellum of neonatally 6-OHDOPA-lesioned rats display noradrenergic hyperinnervation in adulthood, subsequent to reactive noradrenergic collateral fiber sprouting (Kostrzewa 1975; Kostrzewa and Garey 1976, 1977; Kostrzewa et al. 1978). Noradrenergic fiber sprouting in brain regions proximal to the locus coeruleus appears to be related to damage to the dorsal bundle and consequent noradrenergic denervation of forebrain (Jacobowitz and Kostrzewa 1971), because the effect is duplicated by non-pharmacological surgical transection of the dorsal bundle in neonatal rats – resulting in noradrenergic fiber hyperinnervation of regions proximal to the locus coeruleus, including the pons, medulla, and cerebellum (Klisans-Fuenmayor et al. 1986).

Sympathetic noradrenergic neurons are damaged by neonatal 6-OHDOPA, but recovery from damage – evidenced by return of NE content of the heart, spleen, and other organs – is complete by 8 weeks after birth. Dopaminergic innervation is virtually unaltered by neonatal 6-OHDOPA treatment, as evidenced by retention of normal DA content of striatum throughout the developmental period, up to 8 weeks and through 1 year and longer (Kostrzewa 1975; Kostrzewa and Garey 1976).

6-OHDOPA neurotoxicity is discussed in greater detail in several reviews (Kostrzewa and Jacobowitz 1974; Kostrzewa 1989, 1998).

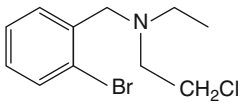
5.4 DSP-4 and Xylamine

5.4.1 Overview

2-Chloroethylamine nitrogen mustards, N-2(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4) (Fig. 6) and xylamine (Fig. 7) (Ross 1976; Ross and Reny 1976; Cho et al. 1980; Kammerer et al. 1979; Kreuger and Cook 1975) are able to cross the blood-brain barrier to selectively target noradrenergic neurons. These agents form quaternary aziridinium ions which have high affinity for the NET. Both covalently bind to the NET and are accumulated by noradrenergic neurons. These agents alkylate and inactivate proteins, thus effectively reducing the number of active NET sites (Fischer and Cho 1982) and impairing the function of intracellular cytochromes, enzymes (e.g., dopamine-beta-hydroxylase) (Ross 1976), and other proteins. In the process, NE stores are depleted in both the periphery and central nervous system (CNS) (Jonsson et al. 1981; Zieher and Jaim-Etcheverry 1980; Ross 1976) and overt noradrenergic neuronal destruction ensues (Fritschy and Grzanna 1989, 1991a, b; Fritschy et al. 1990; Grzanna et al. 1989; Jaim-Etcheverry and Zieher 1980; Zieher and Jaim-Etcheverry 1980).

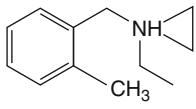
5.4.2 Mechanism of Action of DSP-4 and Xylamine

DSP-4 and xylamine are amines that intracyclize to form aziridinium ions (Ross et al. 1973) – nitrogen mustards (alkylating agents) that covalently and irreversibly bind to electrophilic sites such as thiols and amines in proteins, to effectively impair function of the protein and other molecules (Ranson et al. 1982). DSP-4 and xylamine have high affinity for the NET, and it is this property that confers selectivity of the molecules for noradrenergic neurons. Also, it is via the NET that DSP-4 and xylamine gain entry to the neurons. When DSP-4 binding to the NET is prevented by desipramine, the neurotoxic effect of DSP-4 is abated (Ross 1976). Although the precise mechanism is unknown, monoamine oxidase-B (MAO-B) inhibition by deprenyl (selegiline) also prevents DSP-4 neurotoxicity (Gibson 1987).



DSP-4

Fig. 6 (From Kostrzewa 1999b)



XYLAMINE

Fig. 7 (From Kostrzewa 1999b)

However, because the MAO-B inhibitor MDL 72974 is not neuroprotective, it is not MAO-B inhibition per se that accounts for deprenyl's neuroprotective effect (Finnegan 1993; Finnegan et al. 1990). Perhaps it is the propargylamine moiety of deprenyl that is responsible for its inhibition of DSP-4 neurotoxicity (Maruyama et al. 2000).

5.4.3 Specificity of DSP-4

Generally, because DSP-4 is preferred over xylamine, the latter is used in few studies today. Consequently, most of the following discussion relates to DSP-4.

Because of its high affinity for the NET, DSP-4 is selective for noradrenergic neurons and has little direct effect on dopaminergic, cholinergic, GABAergic, glutamatergic, and glycinergic neurons (see Dudley et al. 1990; Jaim-Etcheverry and Zieher 1983). In the brain, DSP-4 has greatest neurotoxic effects on noradrenergic nerve terminals of locus coeruleus origin (Fritschy and Grzanna 1989, 1991a). DSP-4 degenerative effects in the brain are long-lived. In contrast, in the periphery, sympathetic noradrenergic neurons recover from DSP-4 effects often in less than 1 week (Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1981). Serotoninergic nerves are the only other monoaminergic nerve prominently affected by DSP-4, and the effect on serotonin (5-HT) content and serotoninergic innervation of the brain is long-lived (Jonsson et al. 1981).

5.4.4 Long-Lived Effects of DSP-4 Treatment

When adult rats are treated with a high dose of DSP-4, noradrenergic innervation of projection areas of the locus coeruleus (i.e., neocortex, hippocampus, cerebellum, spinal cord) is markedly reduced, and the effect is long-lived (Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1982). Regions of the brain that are innervated by noradrenergic fibers originating from non-coerulear nuclei are little affected by DSP-4.

When neonatal rats are treated with a high dose of DSP-4, noradrenergic innervation of projection areas of the locus coeruleus is markedly reduced, as is observed in rats treated as adults. In contrast, regions of the brain proximal to the locus coeruleus (i.e., cerebellum, pons, medulla) become hyperinnervated by noradrenergic neurons, and regional NE content is thus elevated. Hyperinnervation is the consequence of collateral axonal fiber sprouting, a reactive sprouting attributable in large part to the degeneration of distal projection of locus coeruleus axons to the neocortex, hippocampus, and spinal cord. This effect is analogous to that seen after surgical transection of the dorsal bundle, the axonal tract projecting from locus coeruleus to forebrain (Kostrzewa et al. 1988). Regions of the brain innervated by non-coerulear nuclei are little affected by DSP-4, as are the sympathetic noradrenergic fibers in the periphery (Bortel et al. 2008; Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1982; Nowak et al. 2006).

5.4.5 Summary on DSP-4

Although 6-OHDA is the most frequently used neurotoxin for noradrenergic neurons, there are occasional studies in which DSP-4 is advantageous. This relates to DSP-4 (1) relative selectivity, particularly for locus coeruleus neurons;

also (2) there is the outcome of long-lived noradrenergic terminal denervation and (3) lack of effect on dopaminergic neuronal fields. Additionally, (4) DSP-4 is able to cross the blood-brain barrier, and thus DSP-4 can be administered in the periphery to produced CNS effects in adults, unlike 6-OHDA. (5) When stored, DSP-4 is more stable than 6-OHDA.

DSP-4 and xylamine neurotoxicity are discussed in greater detail in several reviews (Bortel 2013 [in this *Handbook of Neurotoxicity*]; Dudley et al. 1990; Jaim-Etcheverry 1998; Jaim-Etcheverry and Zieher 1983).

5.5 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)

5.5.1 Historical Perspective

In 1976, a graduate student chemist in Maryland synthesized the meperidine analog 1-methyl-4-phenyl-4-propionoxypiperidine (MPPP), to be used as an opioid substance of abuse. However, during the process of synthesis, the chemical mixture was heated to too high a temperature, resulting in the formation of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This contaminant, 1–3 % of the MPPP product, proved to be neurotoxic to dopaminergic neuronal perikarya in the pars compacta substantia nigra (SNpc). Within days, he developed the permanent symptomology spectrum of Parkinson's disease (PD) (see Shafer 1985).

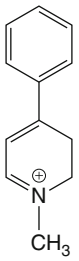
In 1979 in Southern California, a similar synthetic street drug, termed "China White" – the moniker for the purest Southeast Asia heroin – produced the same PD symptomology in substance abusers, again a permanent effect. Three years later, the same event occurred in Northern California, resulting in multiple young substance abusers developing PD-like symptoms (lifelong) and death to more than 50 people. The neurologists J. William Langston and Philip Ballard in San Jose recognized that a bad batch of a heroin-like drug was responsible, and they succeeded in alerting the public to the link between China White and PD/death. As a consequence, that street drug disappeared and the appearance of new cases of early-age PD abated (Langston and Ballard, 1984; Ballard et al. 1985).

Subsequently, MPTP was identified as the neurotoxic contaminant in China White, as testing in animals replicated the forensic finding of SNpc cell destruction found in China White substance abusers. Ultimately, MPTP became the prime neurotoxin to replicate PD in animals. MPTP is of value for probing cellular mechanisms and processes associated with PD and in studying neuroprotectants and new treatment approaches (Shafer 1985; Pasquali et al. 2013).

The key terms "MPTP" or "1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine" appear in 5,746 papers in PubMed, as of January 30, 2013. Key terms for the MPTP metabolite neurotoxic species "1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium" or "MPP^+" appear in 2,664 papers in PubMed as of January 30, 2013.

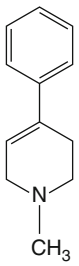
5.5.2 MPTP Mechanism and Selectivity of Action

MPTP (Fig. 8) crosses the blood-brain barrier (BBB) (Riachi et al. 1988) and is converted by monoamine oxidase-B (MAO-B) in astrocytes (Chiba et al. 1984;



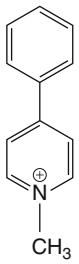
MPTP$^+$

Fig. 8 (From Kostrzewa 1999b)



MPTP

Fig. 9 (From Kostrzewa 1999b)



MPP$^+$

Fig. 10 (From Kostrzewa 1999b)

Westlund et al. 1985; Di Monte et al. 1991) [and to a lesser extent by MAO-A in other cells (Singer et al. 1986)] to the intermediate 1-methyl-4-phenyl-1,2,3-dihydropyridinium ion ($MPDP^+$) (Fig. 9) which undergoes spontaneous two-electron oxidation to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium ion (MPP^+) (Fig. 10) (Castagnoli et al. 1985). MPP^+, released from astrocytes and having high affinity for the DAT, is actively accumulated by dopaminergic neurons (Chiba et al. 1985; Javitch and Snyder 1984; Javitch et al. 1985). Inside DA nerves, the mitochondrial membrane potential actively drives accumulation of MPP^+ to a level in mitochondria as much as 40 times the concentration in cytoplasm (Wu et al. 1990). Here, MPP^+ inhibits complex I in the respiratory transport chain, between NADH dehydrogenase and coenzyme Q, thereby preventing

ATP formation (Chan et al. 1993) and promoting formation of reactive oxygen species (ROS). MPP^+ additionally inhibits alpha-ketoglutarate dehydrogenase in the tricarboxylic acid cycle, thereby preventing succinate formation, a substrate for complex II (Mizuno et al. 1987). Cellular energy depletion (Di Monte et al. 1986; Denton and Howard 1987) and ROS damage to critical elements result in neuronal damage and subsequent neuronal degeneration (Ramsay et al. 1991; see Pasquali et al. 2013). Glial-derived inflammatory cytokines add to stresses on the neuron (see Teismann et al. 2003). DA innervation of neostriatum and DA neuronal perikarya in SNpc are largely affected, although DA neurons in the ventral tegmental nucleus (VTN) and noradrenergic (melanized) neurons in locus coeruleus also are damaged (Seniuk et al. 1990).

5.5.3 Interspecies Effects of MPTP

C57 BL/6 black mice are more sensitive than other mouse strains to MPTP (Sonsalla and Heikkila 1988; Muthane et al. 1994), while rats are largely resistant to MPTP partly because of the abundance of MAO-B in the cerebrocapillary endothelium which constitutes the BBB. MPTP in rats is thereby converted to MPP^+ before crossing the BBB; MPP^+, being ionized, is unable to cross the BBB to enter the brain (Kalaria et al. 1987). Additionally, DA neurons in rats are imbued with a greater abundance of vesicular monoamine transporter-2 (VMAT-2) versus mice. This facet relates to a greater reservoir of MPP^+ inside the vesicle, which translates to a lower cytoplasmic concentration of MPP^+ in rats versus mice (Staal and Sonsalla 2000). This too accounts for a lowered neurotoxic potential for MPP^+ in rats. Nonhuman primates are highly susceptible to MPTP neurotoxicity, with MPTP resulting in effects similar to that observed in human parkinsonian patients (Jenner et al. 1984). It has become conventional to produce unilateral MPTP lesioning in nonhuman primates (e.g., intracarotid administration on one side), so that animals are able to remain mobile and eat without assistance (Bankiewicz et al. 1986; see Fox and Brotchie 2010).

Royland and Langston (1998), Teismann et al. (2003), as well as Carta et al. (2013) and Pasquali et al. (2013) in this *Handbook of Neurotoxicity* provide detailed discussion and analysis of MPTP neurotoxicity mechanisms and MPTP modeling of Parkinson's disease in rodents and nonhuman primates.

5.6 Haloperidol-Related Chemical Species

The classical antipsychotic drug haloperidol (Fig. 11), a pyridinium chemically similar in structure to MPTP, is regarded as a neurotoxin or protoxin (Roberts et al. 1995). Haloperidol and its dehydration product 4-(4-chlorophenyl)-1,4-(4-fluorophenyl)-4-oxobutyl-1,2,3,6-tetrahydropyridine (HPTP) (Fig. 12) are oxidatively metabolized to HPP^+ (Fig. 13) and 4-(4-chlorophenyl)-1,4-(4-fluorophenyl)-4-hydroxybutylpyridinium ($RHPP^+$) (Subramanyam et al. 1991; Eyles et al. 1994, 1996; Igarashi et al. 1995; Usuki et al. 1996) – analogs of MPTP. In vitro HPP^+ is

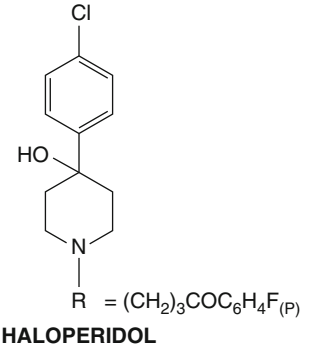


Fig. 11 (From Kostrzewa 1999b)

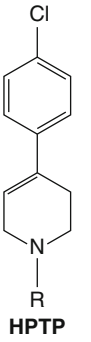

Fig. 12 (From Kostrzewa 1999b)

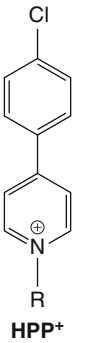

Fig. 13 (From Kostrzewa 1999b)

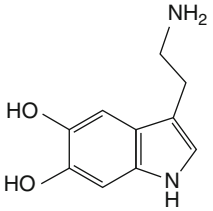
neurotoxic to both mesencephalic cells (Bloomquist et al. 1994) and neuroblastoma cells (Fang and Yu 1995). In vivo HPP^+ is an inhibitor of the mitochondrial respiratory chain (Rollema et al. 1994) and overtly neurotoxic to DA nerves (Subramanyam et al. 1990). It is these chemical derivatives that perhaps account for the overt neuronal destruction (Benes et al. 1984, 1985a, b) of gamma-aminobutyric acid (GABA) neurons, glutamate neurons (Meshul and Casey 1989;

Fig. 14 (From Kostrzewa 1999b)



5,6-DHT

Meshul et al. 1994), and cholinergic neurons (Mahadik et al. 1988) associated with long-term haloperidol treatment of schizophrenics, in whom tardive dyskinesia has developed. The neurological aspect of haloperidol in tardive dyskinesia is developed further in the *Handbook of Neurotoxicity* chapter on tardive dyskinesia (Kostrzewa et al. 2013).

5.7 2′-Amino-MPTP

2′-Amino-MPTP (2′-NH_2-MPTP), unlike the parent MPTP, had virtually no effect on dopaminergic neurons but did effectively reduce striatal 5-HT and 5-HIAA (Johannessen et al. 1987). Ultimately 2′-NH_2-MPTP was found to also produce a long-term reduction of NE as well as 5-HT contents in rodent forebrain (Andrews and Murphy 1993a, b; Luellen et al. 2003). A substrate for both MAO-A and MAO-B, 2′-NH_2-MPTP likely exerts its effects via the metabolite 2′-NH_2-MPP^+ which has affinity to the NET and SERT. Effects of 2′-NH_2-MPTP on NE and 5-HT in the brain are blocked by desipramine and fluoxetine, respectively (Andrews and Murphy 1993c). Intracellular 2′-NH_2-MPP^+, like MPP^+, apparently acts on mitochondria and other cellular elements to form superoxide. Mice overexpressing Cu-Zn superoxide dismutase, which converts superoxide to less reactive H_2O_2, are protected from the effects of 2′-NH_2-MPP^+ (Andrews et al. 1996). Unlike MPP^+, 2′-NH_2-MPP^+ is a poor substrate for VMAT-2 (Numis et al. 2004).

The neurotoxicity of 2′-NH_2-MPTP is discussed in detail in this *Handbook of Neurotoxicity* by Ochroch et al. (2013).

5.8 5,6- and 5,7-Dihydroxytryptamine (5,6-DHT, 5,7-DHT)

5,6-Dihydroxytryptamine (5,6-DHT) (Fig. 14), a di-/ortho-phenolic analog of 5-hydroxytryptamine (5-HT, serotonin) (Fig. 15), and 5,7-dihydroxytryptamine (5,7-DHT) (Fig. 16), a di-/meta-phenolic analog of 5-HT, were characterized as serotoninergic neurotoxins by Hans Baumgarten in early 1970s – shortly after the discovery of 6-hydroxydopamine (6-OHDA) as a neurotoxin for noradrenergic and dopaminergic neurons (Baumgarten et al. 1971, 1972a, b; Baumgarten and Schlossberger 1973; Baumgarten and Lachenmeyer 1972).

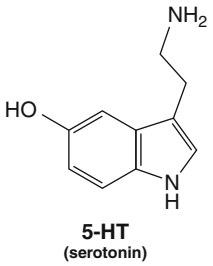


Fig. 15 (From Kostrzewa 1999b)

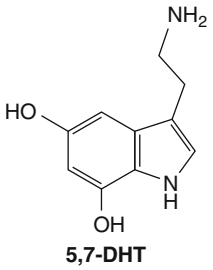

Fig. 16 (From Kostrzewa 1999b)

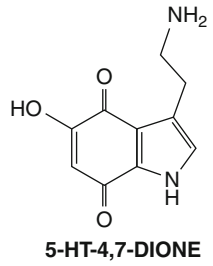

Fig. 17 (From Kostrzewa 1999b)

5.8.1 Mechanisms of Action of 5,6- and 5,7-DHT

5,6- and 5,7-DHT owe their high degree of selective serotoninergic neurotoxicity to their high affinity to the serotonin transporter (SERT) (Björklund et al. 1973a, b, 1975b), which selectively transports the DHTs into the 5-HT neuron. Once present in high intraneuronal concentration, 5,6- and 5,7-DHT intracyclize to generate quinones and additional putative neurotoxic indolamine semiquinoidal and quinoidal species, with 5-HT-4,7-dione (Fig. 17) and its dimer 6,6′-bi(5-HT-4,7-dione) being the principle derivatives (Tabatabaie and Dryhurst 1992, 1998). All are highly reactive. The resulting formation of cellular ROS (e.g., hydrogen peroxide, H_2O_2; superoxide, O_2^{-}; hydroxyl radical, $HO^{\bullet}$) further burdens the protective capacity of 5-HT neurons. Ultimate damage of mitochondrial cytochromes (Cohen and Heikkila 1978), cellular lipids, and cellular proteins thus compromises function, resulting in cellular destruction (Baumgarten et al. 1978a, 1981, 1982; Tabatabaie and Dryhurst 1992; Tabatabaie et al. 1990, 1993).

5,6- and 5,7-DHT neurotoxicity are discussed in greater detail in several reviews (Baumgarten et al. 1973, 1978a, b; Tabatabaie and Dryhurst 1998; Pranzatelli 1998; Baumgarten and Lachenmayer 2004) and in a later chapter of this *Handbook of Neurotoxicity* (Paterak and Stefański 2013).

5.8.2 Limitations of 5,6-DHT

Although the biological effects of 5,6-DHT are similar to those of 5,7-DHT, higher doses of 5,6-DHT become less selective for 5-HT neurons and produce convulsions and death (Baumgarten and Lachenmeyer 1972; Baumgarten et al. 1972b, 1973; Björklund et al. 1973b). Consequently, 5,7-DHT has supplanted 5,6-DHT as a serotoninergic neurotoxin.

5.8.3 Effects of 5,7-DHT in Adults

Long-Lived Effects in the Brain of Animals Lesioned as Adults with 5,7-DHT

Although 5,7-DHT is relatively selective for serotoninergic neurons, a low dose of 5,7-DHT will nonetheless produce both 5-HT and NE depletion in the brain (Baumgarten et al. 1973). The effects of 5,7-DHT on NE neurons can be largely prevented by pretreatment with the NET inhibitor desipramine (Björklund et al. 1975a).

A high dose of 5,7-DHT will destroy 5-HT innervation in virtually all regions of the CNS. The pons and medulla – the brain regions nearest to the most prominent 5-HT perikarya, the dorsal and midbrain raphe nuclei – are least affected by 5,7-DHT treatment, as 5-HT content is only modestly altered after 5,7-DHT. In contrast, regions of the CNS most distal to the dorsal and medial raphe are prominently affected by 5,7-DHT treatment, as 5-HT content of the neocortex, hippocampus, and spinal cord is depleted about 85–90 %. Serotoninergic denervation of striatum by 5,7-DHT is profound. These 5,7-DHT-induced alterations in 5-HT innervation in the brain are long-lived (Baumgarten et al. 1973).

Long-Lived Effects in the Brain of Animals Lesioned as Neonates with 5,7-DHT

When administered to neonatal rats, a single high dose of 5,7-DHT produces lifelong, marked (~90 %) 5-HT denervation and 5-HT depletion of the neocortex, hippocampus, and striatum (Jonsson et al. 1978). In neonatally 5,7-DHT-lesioned rats studied in adulthood, there is prominent DA D_2-receptor supersensitivity, as evidenced by enhanced behavioral responses to the D_2 agonist quinpirole (Brus et al. 1995). In these neonatally 5,7-DHT-lesioned rats, there is also a reduction in histamine levels in the brain and enhanced histamine H_3 receptor antagonist-evoked oral and locomotor activity – indicative of alterations in histaminergic neuronal systems and their effects (Jośko et al. 2011).

In rats co-lesioned as neonates with 5,7-DHT and the noradrenergic neurotoxin DSP4, prominent D_2-receptor supersensitivity is evident in adulthood (Nowak et al. 2009).

In rats lesioned neonatally with 6-OHDA, there is lifelong supersensitization of DA D_1 receptors, as evidenced by enhanced locomotor and oral activity responses and stereotypic responses to the D_1 agonist SKF 38393 (Kostrzewa and Gong 1991;

Gong et al. 1993). However, when 5,7-DHT is administered neonatally, simultaneous with 6-OHDA treatment, there is long-term (into adulthood) suppression of D_1-receptor supersensitivity (Brus et al. 1994). Spontaneous locomotor activity is normally increased in adulthood rats that were lesioned as neonates with 6-OHDA; and there is even greater spontaneous locomotor activity in those rats simultaneously lesioned as neonates with 6-OHDA and 5,7-DHT. Rats so-lesioned as neonates with 6-OHDA and 5,7-DHT have been proposed as an animal model of attention deficit hyperactivity disorder (ADHD) (Kostrzewa et al. 1994).

Summary on 5,7-DHT

5,7-DHT, a relatively selective neurotoxin for 5-HT neurons, provides a means to reasonably study acute and long-lived effects of 5-HT denervation – in both neonatal and adult animals. 5,7-DHT likewise is useful for determining the influence of prominent 5-HT denervation on the effects of other neuronal phenotypic systems and in elucidating the role of 5-HT per se in a variety of functions, including behaviors.

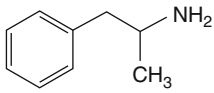
5.9 Amphetamines

5.9.1 Amphetamine (AMPH)

Amphetamine (AMPH) (Fig. 18), chemically similar to DA and NE, has high affinity for the DAT, NET and also for the serotonin transporter, SERT. By virtue of these effects, AMPH gains entry into DA-, NE-, and 5-HT neurons. Intraneuronal AMPH accumulates in both cytoplasm and vesicles, displacing these monoamines and reversing the transporters to evoke monoamine release. In additon, as a consequence of AMPH competition with DA and NE for the DAT and NET, respectively, extraneuronal and synaptic effects of both DA and NE are prolonged and enhanced. Nevertheless, acute treatment or intermittent AMPH treatments are not neurotoxic (Westfall and Westfall 2006).

However, when continuously administered for a prolonged period ($\geq$3d), AMPH becomes overtly neurotoxic to striatal dopaminergic nerves, as evidenced by long-term striatal DA depletion (Wagner et al. 1980), loss of tyrosine hydroxylase (TOH) activity (Ellison et al. 1978), loss of DAT number and DAT protein (Scheffel et al. 1996; Krasnova et al. 2001), presence of swollen histofluorescence axons, reduced numbers of dopaminergic terminals, and overt indices of neurodegeneration – deposition of argyrophilic granules (silver degeneration staining) and ultrastructural evidence of terminal damage (Ellison et al. 1978; Nwanze and Jonsson 1981; Ryan et al. 1988, 1990; Ellison 1992). AMPH neurotoxicity extends to TOH-positive mesencephalic neurons and cortical cells (Stumm et al. 1999; Jakab and Bowyer 2002).

AMPH neurotoxicity is associated with hyperthermia (Freh 1975; Clausing and Bowyer 1999) which magnifies the effect of AMPH-induced production of superoxide and hydroxyl radical (Lin et al. 1991; Kil et al. 1996; Huang et al. 1997a; Krasnova et al. 2001) as well as DA-quinone (LaVoie and Hastings 1999).



AMPHETAMINE

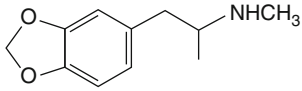
METHAMPHETAMINE

Fig. 19 (From Kostrzewa 1999b)



MDMA

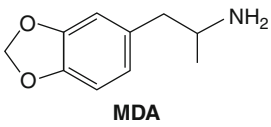
Fig. 20 (From Kostrzewa 1999b)

5.9.2 Methamphetamine (METH, Speed, Crank)

The overall acute effects of methamphetamine (METH) (Fig. 19) are analogous to those of AMPH (see Krasnova and Cadet 2009). Likewise, neurotoxic effects are similarly related to generation of ROS including DA-quinones (LaVoie and Hastings 1999), hydrogen peroxide, and superoxide (Stokes et al. 1999; Miyazaki et al. 2006). However, when METH was added to an in vivo microdialysis perfusate into striatum, the hydroxyl radical level was not elevated (Pereira et al. 2004). It appears that METH-induced glutamate exocytosis (Marshall et al. 1993; Abekawa et al. 1994; Mark et al. 2004) may be largely responsible for generation of nitric oxide (NO) and other ROS (Itzhak et al. 1998; Imam et al. 2001; Itzhak and Ali 2006). Serotoninergic neuronal degeneration is prominent with METH (Ricaurte et al. 1982). The DA D_1-receptor antagonist SCH 23390 [R-(+)-7-chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine] attenuates neurotoxic effects of METH on DA and 5-HT systems, while the DA D_2 antagonist sulpiride attenuates METH neurotoxic effects on DA systems (Sonsalla et al. 1986).

5.9.3 Methylenedioxymethamphetamine (MDMA, Ecstasy)

Methylenedioxymethamphetamine (MDMA) (Fig. 20), a substrate for the 5-HT transporter (SERT), is accumulated by 5-HT nerves; then MDMA is accumulated by vesicles via the vesicular monoamine transporter (VMAT), whereby it releases 5-HT from vesicles and into the synapse (Baumann and Rothman 2009). This action ultimately results in DA exocytosis. MDMA is selectively neurotoxic to 5-HT terminals in rats and nonhuman primates (Green et al. 1995). In mice, MDMA damages nigrostriatal dopaminergic fibers (Commins et al. 1987; Cadet et al. 1995). Methylenedioxyamphetamine (MDA) (Fig. 21) acts similarly to MDMA.



MDA

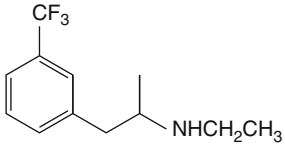
PCA

Fig. 22 (From Kostrzewa 1999b)



FENFLURAMINE

Fig. 23 (From Kostrzewa 1999b)

5.9.4 Parachloroamphetamine (PCA)

Parachloroamphetamine (PCA) (Fig. 22) was initially found to produce long-term reduction in tryptophan hydroxylase (Trp-OH) activity and 5-HT in the rat brain (Sanders-Bush et al. 1972a, b). Silver staining later established that PCA actions were related to overt neurotoxic effects, primarily on the serotoninergic B9 cell group (Harvey et al. 1975). PCA neurotoxicity is dependent on 5-HT release; prior 5-HT depletion with parachlorophenylalanine and reserpine prevents PCA neurotoxic actions (Berger et al. 1992). However, prior destruction of striatal dopaminergic innervation does not negate the neurotoxic effect of PCA (Perry et al. 1995).

AMPH, METH, MDA, and analogs have been the subject of many reviews (Cadet et al. 2007; Yamamoto and Raudensky 2008; Gouzoulis-Mayfrank and Daumann 2009; Yamamoto et al. 2010; Steinkellner et al. 2011) including the chapter by Bisagno and Cadet (2013) in this *Handbook of Neurotoxicity*.

5.9.5 Fenfluramine

Another analog of amphetamine, namely, fenfluramine (Fig. 23), also is neurotoxic towards serotoninergic fibers. Fenfluramine, in high dose or in repeated doses, depletes 5-HT in brain (Harvey and McMaster 1975; Steranka and Sanders-Bush 1979; Schuster et al. 1986), also reduces tryptophan hydroxylase, the rate-limiting enzyme in 5-HT synthesis (Steranka and Sanders-Bush 1979), additionally reduces SERT number (Schuster et al. 1986; Appel et al. 1990; Zaczek et al. 1990) and reduces the numbers of 5-HT immunoreactive fibers in the brain (Appel et al. 1989; Molliver and Molliver 1990). The combination of phentermine with fenfluramine as an anorectic agent was withdrawn from the market because of the association with valvular heart disease (Connolly et al. 1997).

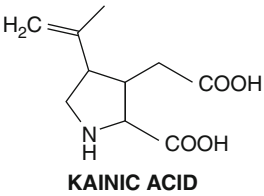
5.10 Excitatory Amino Acids

5.10.1 Historical Perspective

In 1957, Lucas and Newhouse (1957) reported that iontophoretic application of glutamic acid (GLU) (Fig. 24) produced overt destruction of the inner layers of immature mouse retina. Curtis et al. (1959) next showed that GLU and aspartic acid (ASP) (Fig. 25) are excitatory (i.e., produce depolarization) to spinal neurons. And Olney and colleagues (Olney 1969; Olney and Sharpe 1969) demonstrated that GLU is specifically neurotoxic in mice and monkeys, giving birth to the concept of "excitotoxicity" and the range of action of excitatory amino acids (EAAs) (Olney et al. 1971).

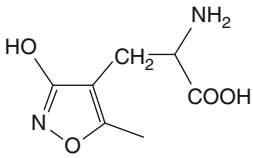
5.10.2 Mechanisms of GLU Excitotoxicity

GLU-mediated neurotoxicity is related to its agonist action at NMDA (N-methyl-D-aspartate) (Fig. 26) receptors (NMDA-R), kainate-R (Fig. 27), or AMPA-R (AMPA = alpha-amino-2,3-hydroxy-5-methyl-3-oxo-isoxazole-propionic acid) (Fig. 28), resulting in massive influx of Na^+, Cl^-, and Ca^{2+} into postsynaptic neurons (Rothman 1985; Choi 1987) and delayed activation of Ca^{2+}-sensitive proteases (Frandsen and Schousboe 1992; Tymianski et al. 1993). As a consequence of these actions and in concert with release of intracellular Ca^{2+} stores, ultimate dendrosomal swelling with vacuolization and mitochondrial edema of postsynaptic neuronal elements concludes in neuronal cell death (see Olney 1981;



KAINIC ACID

Fig. 27 (From Kostrzewa 1999b)



AMPA

Fig. 28 (From Kostrzewa 1999b)

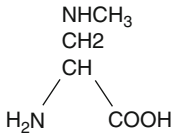
Mody and MacDonald 1995). A variety of intracellular proteins, when activated by ionic events, play a major role in cellular events relating to metabolic inhibition, apoptosis, or necrotic cellular demise (Zeevalk and Nicklas 1991; Ikonomidou and Turski 1996).

As a consequence of the above cellular events, cellular ROS are generated, and these add to the challenge of cellular viability. Neuronal $O_2^{-\cdot}$ is converted by superoxide dismutase to oxygen (O_2) and hydrogen peroxide (H_2O_2). Neuronal nitric oxide synthase (nNOS) activation leads to cellular NO formation (Dawson et al. 1996). In turn, NO reacts with $O_2^{-\cdot}$, forming peroxynitrite ($ONOO^-$) (Huie and Padmaja 1993), a highly reactive species that produces protein nitration, lipid peroxidation, impairment of GAPDH, inhibition of complexes I and II of the electron transport chain, and DNA injury (Radi et al. 1991, 1994; van der Vliet et al. 1998; Hara et al. 2005).

5.10.3 Excitotoxicity in Neurological and Neurodegenerative Disorders

Ischemia, Anoxia, and Traumatic Brain Injury

During transient hypoxia, there is impaired uptake of GLU and ASP from extracellular spaces, leading to a 5-fold or greater increase in GLU and ASP extracellular levels (Beneviste et al. 1984; Globus et al. 1988). This is accompanied by neurotoxicity in cerebral cortex (Jorgensen and Diemer 1982), in hippocampal CA1 pyramidal neurons, and in striatal medium size neurons (Rothman and Olney 1986). Reperfusion results in augmented release of GLU and ASP (Silverstein et al. 1986), resulting in greater excitotoxicity. Prior lesioning of the afferent glutamatergic pathway prevents neurodegeneration during ischemia (Wieloch et al. 1985), as does NMDA-R antagonist treatment (Pulsinelli et al. 1993; Waner et al. 1995) including group I metabotropic GLU-R antagonists (Kingston et al. 1999). In traumatic brain injury (TBI), similarly there is an increase in extracellular glutamate (Faden et al. 1989; Nilsson et al. 1990) accompanied by neurodegeneration, with neuroprotection conferred by NMDA-R antagonists (McIntosh et al. 1989).



BMAA

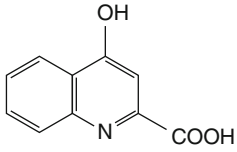
BOAA

Fig. 30 (From Kostrzewa 1999b)



KYNURENIC ACID

Fig. 31 (From Kostrzewa 1999b)

Neurodegenerative Disorders

The involvement of glutamatergic systems in the neurogenesis of PD is indicated by the findings that MPP^+-induced neurodegeneration is attenuated by NMDA-R antagonists (Turski et al. 1991; Santiago et al. 1992). The naturally occurring excitatory amino acids β-N-methylamino-L-alanine (L-BMAA) (Fig. 29) and β-N-oxalylamino-L-alanine (L-BOAA) (Fig. 30) are linked, respectively, to Guam ALS-parkinsonism dementia syndrome (Spencer 1987) and neurolathyrism (Spencer et al. 1986). The kainic acid analog domoic acid, identified as the active principal in contaminated mussels, was responsible for an outbreak of toxic encephalopathy in Canada, resulting in motor neuronopathy and partial paralysis (Perl et al. 1990; see Pérez-Gómez and Tasker 2013). Kainate per se is associated with degeneration of GABA- and substance P-containing neurons (Coyle and Schwarcz 1976; McGeer and McGeer 1976).

Quinolinic acid produces a striatal lesion the models Huntington's disease (HD), associated with chorea in humans (Schwarcz et al. 1983; Beal et al. 1986), although quinolate levels are not elevated in HD (Reynolds et al. 1988; Heyes et al. 1991). Rather, animal modeling of HD is best replicated by aminooxyacetic acid (AOAA) (Urbanska et al. 1989, 1991), a synthesis inhibitor of the endogenous EAA antagonist kynurenic acid (Fig. 31) (Turski et al. 1989; see Urbanska et al. 2013). Moreover, AOAA neurotoxicity is attenuated by NMDA-R antagonists (Urbanska et al. 1991). In HD, kynurenine aminotransferases – enzymes forming kynurenine – are deficient in basal ganglia, thereby implicating dysfunctional kynurenine synthesis in the genesis of HD (Jauch et al. 1995). The overt mechanism of AOAA

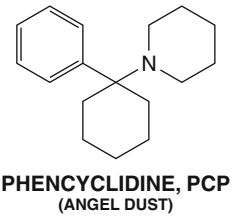


Fig. 32 (From Kostrzewa 1999b)

neurotoxicity relates to impaired cellular metabolism (Beal et al. 1991), and the mitochondrial toxin 3-nitropropionic acid (3-NP) is additionally engaged in rodents and primates to replicate the lesions attending HD (Palfi et al. 1996), with this neurotoxicity likewise being attenuated by NMDA-R antagonists (Brouillet et al. 1995).

The accumulation of extraneuronal beta-amyloid in Alzheimer disease (AD) is an incipient contributor to the neuropathology of this disorder. Beta-amyloid promotes microglial exocytosis of an unknown NMDA-R agonist (Giulian et al. 1995), stimulates NO production (Goodwin et al. 1995), enhances GLU excitotoxicity (Arias et al. 1995), impairs GLU uptake by astrocytes (Harris et al. 1996), and destabilizes intraneuronal Ca^{2+} (Koh et al. 1990).

In amyotrophic lateral sclerosis (ALS), there is an apparent loss of glial EAAT-2 glutamate transporter in the brain and spinal cord (Rothstein et al. 1992, 1995), and this perhaps accounts for elevated CSF levels of GLU in a population of ALS patients (Shaw et al. 1995). The CSF of ALS patients was found to be neurotoxic to neurons in culture, by virtue of kainate-R and AMPA-R action (Couratier et al. 1993, 1994). Motor neurons in ALS display atypical Ca^{2+}-permeable AMPA-R, conferring selective vulnerability to GLU excitotoxic action (Williams et al. 1997).

Comprehensive and insightful reviews have been written on the topic of glutamate, excitatory amino acids, and excitotoxicity (Urbanska et al. 1998; Turski and Ikonomidou 2013).

5.11 NMDA Receptor Antagonists

While NMDA-R antagonists are known to attenuate the neurotoxic effects of NMDA-R agonists (Wieloch 1985; Weiss et al. 1986; Choi et al. 1988; Park et al. 1988; Clifford et al. 1990), paradoxically NMDA-R antagonists are associated with neurotoxicity – according to the dosing schedule and stage of ontogeny at the time of treatment (Olney et al. 1989; Fix et al. 1995, 1996; Farber et al. 1995; Wozniak et al. 1996). Also, noncompetitive NMDA-R antagonists exact a greater toll than competitive NMDA-R antagonists (Ellison 1994). Dizocilpine (MK-801), ketamine, and phencyclidine (PCP) (Fig. 32) produce neurotoxicity to pyramidal neurons in cortical layers II and IV of posterior cingulate/retrosplenial cortex (Olney et al. 1989), also in striatum, subiculum and hippocampal areas CA1 and CA3 (Fix et al. 1995), cingulate cortex, fasciculus retroflexus (FR), and lateral habenula (Ellison 1995).

As proposed by Olney et al. (1991), NMDA-R antagonists disinhibit GABA neurons, which results in excess cholinergic activity. Glycine agonists and polyamine agonists attenuate the toxicity of NMDA-R antagonists without themselves causing neurotoxicity (Duval et al. 1992; Hargreaves et al. 1993). This hypothesis is based on the findings that NMDA-R neurotoxicity is prevented by muscarinic-, σ-, and α_2-R antagonists and both typical and atypical antipsychotics (Olney et al. 1991; Farber et al. 1993, 1995).

NMDA-R neurotoxicity has been the topic of several reviews (Olney et al. 1991; Rajdev and Sharp 1998; Olney 2002; Low and Roland 2004).

5.12 Cocaine

Neurotoxic effects of the abused drug cocaine have come to light, largely in the past two decades. Cocaine is known to impair mitochondrial complex I, II, and III activity and reduce state 3 respiration (Devi and Chan 1997; Yuan and Acosta 2000; Dietrich et al. 2004). This is followed by loss of the mitochondrial membrane potential and release of cytochrome c (see Cunha-Oliveira et al. 2008). At the neurotoxic stage, changes occur in Bcl-2 and Bax (Dey et al. 2007). Apoptosis is the outcome (see Cunha-Oliveira et al. 2008).

Prolonged (5-day) continuous administration of cocaine to adult rats via a cocaine-silicone pellet produced degeneration of the lateral habenula (LHb) in the dorsal thalamus and its projection – the fasciculus retroflexus (FR) – to midbrain dopaminergic nuclei (substantia nigra, ventral tegmental nucleus) and serotoninergic nuclei (dorsal and medial raphe) (Ellison 1992). AMPH, METH, MDMA, and cathinone were later found to produce similar but not identical effects as cocaine (Ellison 2002). Also, when cocaine was administered to pregnant rats for the remainder of pregnancy, starting on gestation day 17, the LHb and FR of rat pups underwent analogous neurodegeneration (Murphy et al. 1999).

The neurotoxicity of prolonged administration of cocaine and related agents (e.g., AMPH) resembles that of phencyclidine (Ellison 1995) and is thought to be related to a reduction in glucose metabolism in LHb (London et al. 1986; Wirtshafter et al. 1994), consequent to loss of GABA inhibition and associated excitotoxic neurotoxicity (Ellison 1998).

The neurotoxic effects of relatively short-term cocaine administration are discussed in papers by Cunha-Oliveira et al. (2008, 2013). The neurotoxic effects of continuous and prolonged cocaine administration are discussed by Ellison (1998).

5.13 AF64A (Ethylcholine Aziridinium Ion)

AF64A is a Trojan horse neurotoxin with relative selectivity for cholinergic nerves. Chemically similar to choline but with an aziridinium moiety on the nitrogen atom, AF64A is a nitrogen mustard (alkylating agent) that targets the choline uptake site on

acetylcholine (Ach)-containing nerves (Fisher and Hanin 1986, Hanin 1988, 1996). In high concentration (>22 μM), AF64A alkylates both low- and high-affinity choline transporter sites, impairing its own uptake by the nerve and producing nonspecific damage to any tissue but notably to the cerebral endothelium which maintains a choline transport system (Gomez-Ramos et al. 1990).

In low concentration (<5 μM), AF64A is reversibly bound to the choline transporter and then largely enters the cholinergic nerve and alkylates many sites, predominately enzymes and proteins with affinity for choline: choline acetyltransferase, choline kinase, acetylcholinesterase, and choline dehydrogenase (Curti and Marchbanks 1984; Hortnagl and Hanin 1992; Hortnagl et al. 1988; Rylett and Colhoun 1984; Uney and Marchbanks 1987). Alkylated enzymes and other macromolecules become inactivated, rendering the nerve dysfunctional (Barlow and Marchbanks 1984; Leventer et al. 1987; Potter et al. 1987; Sandberg et al. 1985). Cell death is related to alkylation at N-7 guanine sites on DNA, resulting in strand breaks and termination of RNA transcription (Futscher et al. 1992). AF641-induced alterations in cholinergic nerves are often delayed by as much as 48 h (Hanin 1996).

Unable to cross the blood-brain barrier, AF64A is commonly administered into the cerebral ventricles to model for Alzheimer's type senile dementia (Fisher and Hanin 1986). Although the levels of neurotransmitters other than Ach are acutely altered by AF64A, these changes are short-lived and thus considered to be secondary to the abrupt alteration of cholinergic neural function after AF64A treatment (see Hanin 1990).

AF64A is used infrequently, largely having been supplanted as a cholinergic neurotoxin by 192-IgG-saporin.

5.14 IgG-Saporin

The immunotoxin IgG-saporin consists of (1) a monoclonal antibody directed towards $p75^{NGF}$, the low-affinity membranous receptor for nerve growth factor (NGF), coupled with (2) saporin, a ribosome-inactivating protein derived from seeds of Saponaria officinalis (soapwort) (Wiley 1992; Wiley et al. 1991).

5.14.1 Selectivity of IgG-Saporin

IgG-saporin is a selective toxin for cholinergic neurons in basal forebrain, by virtue of their expression of the $p75^{NGF}$ receptor on the nerve membrane (Book et al. 1994). Once IgG-saporin is complexed to the $p75^{NGF}$ receptor, saporin is internalized by receptor-mediated endocytosis and then transported to the cell body where it enzymatically inactivates ribosomes to inhibit protein synthesis and produce neuronal cell death. IgG-saporin produces near-total destruction of the CBF (see Wiley 1992).

In rat basal forebrain, the cholinergic tract (CBF) is the only one expressing $p75^{NGF}$ on the plasma membrane. IgG-saporin thereby selectively destroys these

neurons and thereby produces cholinergic denervation of the CBF target regions – neocortex, hippocampus, amygdale, and olfactory bulb (Rossner et al. 1995; Schliebs 1998; Walsh et al. 1996). Other neuronal tracts of the forebrain survive IgG-saporin treatment because they lack the $p75^{NGF}$ receptor; this includes striatal cholinergic interneurons and GABAergic neurons within the striatum (Heckers et al. 1994; Wiley et al. 1995).

However, in the cerebellum, the subset of Purkinje cells, which express $p75^{NGF}$ receptors during development and into adulthood (Pioro and Cuello 1988), are damaged by IgG-saporin treatment (Berger-Sweeney et al. 1994; Heckers et al. 1994).

5.14.2 Effect of IgG-Saporin Lesioning

The CBF is the neuronal tract that degenerates in Alzheimer disease (AD), and the extent of CBF loss correlates with the degree of dementia (Perry et al. 1978). Because IgG-saporin selectively destroys the CBF, this neurotoxin is used to model AD (Schliebs et al. 1996; Wiley et al. 1995).

The neurotoxicity of IgG-saporin has been described in numerous reviews: Bassant et al. 1998; Petrosini et al. 2013 [this *Handbook of Neurotoxicity*]; Rossner 1997; Schliebs et al. 1996; Walsh and Potter 1998; Wiley (1992); Wrenn and Wiley (1998).

5.15 3-Nitropropionic Acid (3-NP)

3-Nitropropionic acid (3-NP) ($O_2NCH_2CH_2COOH$), a suicide (irreversible) inhibitor of succinate dehydrogenase (Alston et al. 1977), is a plant and fungal neurotoxin with relative selectivity for basal ganglia (caudate and putamen in humans; striatum in rodents) (Ludolph et al. 1991), although high-dose 3-NP additionally damages hippocampus. In humans who consumed foods with 3-NP and in nonhuman primates treated with 3-NP, the spectrum of neurodegeneration and motor disability, with overall spectrum of effects, resembles/models Huntington's disease (HD).

5.15.1 3-NP Mechanism of Action

Coles et al. (1979) identified 3-NP as a suicide inhibitor of succinate dehydrogenase (Huang et al. 2006). Gould and Gustine (1982) first showed that 3-NP produced overt neurotoxicity in basal ganglia.

As succinate dehydrogenase is the major element of mitochondrial respiratory chain complex II, 3-NP inactivation of this site leads to reduced ATP formation, cellular energy depletion, and ultimate preferential degeneration of medium spiny neurons in basal ganglia. NADPH-diaphorase-positive aspiny neurons and cholinergic interneurons survive 3-NP treatment (Beal et al. 1993; Brouillet et al. 1993). Neurodegenerative effects of 3-NP arise when there is prolonged partial (>50%) SDH inhibition (Alexi et al. 1998; Brouillet et al. 1998), resulting in loss of the mitochondrial membrane potential (Leventhal et al. 2000; Maciel et al. 2004), cytochrome c release from mitochondria with calpain activation (Bizat et al. 2003a, b; Nasr et al. 2003), caspase-3 activation (Bizat et al. 2003b),

translocation of Bcl-2, and ultimate neuronal apoptosis (Galas et al. 2004). Calpain activation is considered to be a signature event. Notably, 3-NP-induced calpain activation is preferential to basal ganglia, with calpain remaining active in neocortex and other brain regions where neurodegeneration is generally absent (Galas et al. 2004).

The above processes are also associated with the generation of cellular ROS including $O_2^{-\cdot}$, $HO^{\bullet}$, and NO formation (Schulz et al. 1995, 1996; Fontaine et al. 2000). Compromise of the energy status of medium spiny neurons is thought to sensitize to glutamate-mediated effects at the NMDA-R, with promotion of glutamate excitotoxicity (Hamilton and Gould 1987; Novelli et al. 1988; Zeevalk and Nicklas 1992; Kim et al. 2000). This latter event was postulated as being responsible for the neurodegeneration with 3-NP and in HD (Albin and Greenamyre 1992; Beal 1992).

3-NP is commonly administered by osmotic minipumps in rodents, producing dystonia with motor incoordination (Beal et al. 1993; Borlongan et al. 1995). In primates, daily 3-NP administration produces the characteristic striatal neurodegeneration and choreiform movements with cognitive deficits (Brouillet et al. 1995; Palfi et al. 1996). Processes and mechanisms of 3-NP have been described in detail (Brouillet et al. 2005).

5.16 Toxic Vanilloids, TRPV1 Receptor Agonists

5.16.1 Overview

Vanilloids, so-named by virtue of their vanillyl (4-hydroxy-3-methoxybenzyl) moiety, are comprised of three chemical classes: capsaicinoids, resiniferanoids, and diterpenes. Capsaicin (Fig. 33), the best known of the vanilloids, is a capsaicinoid derived from hot chili peppers (Szallasi 1998; Szallasi and Blumberg 1999) – flavoring foods by producing a spicy-hot sensation. The effect is related to activation of TRPV1 receptors (TRPV1-R) on fine-diameter unmyelinated C fibers or thinly myelinated Adelta sensory axons (Holzer 1991) of ~25 % of sensory nerves in bipolar dorsal root ganglia and trigeminal ganglia (Liu et al. 1996). Capsaicin, given repeatedly, desensitizes the TRPV1-R (Jancsó and Jancsó 1949; Buck and Burks 1986; Holzer 1991) which undergoes a conformational change in a ligand-gated cation channel (Bevan and Docherty 1993). Additionally, capsaicinoids suppress the expression of peptide neurotransmitters in sensory ganglia (Farkas-Szallasi et al. 1995) while enhancing the expression of galanin, an inhibitor of excitatory neurons (Yanagisawa et al. 1986). High-dose vanilloids are capable of producing overt destruction of sensory neurons (Jancsó et al. 1978).

Insect and animal venoms often contain peptide toxins able to activate the vanilloid receptor (Siemens et al. 2006; Bohlen and Julius 2012) or inhibit it. Capsaicinoids are used in the treatment of neuropathic pain (Rumsfield and West 1991; Winter et al 1995) and are found in “pepper” sprays and in squirrel-free bird food (birds’ TRPV1-R lack the vanilloid binding motif).

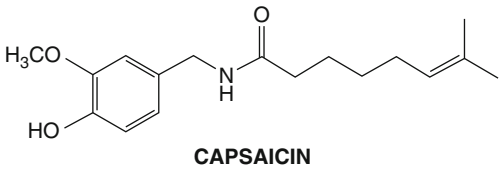

Fig. 33 (From Kostrzewa 1999b)

5.16.2 Mechanism of Vanilloid Action

Vanilloid neurotoxicity is associated with an increase in the Ca^{2+} current in sensory neurons, leading to a rise in the cytoplasmic level of Ca^{2+} (Chard et al. 1995) and activation of calcineurin and other proteases (Docherty et al. 1996) which dephosphorylate the vanilloid receptor or channel complex and thereby desensitize the receptor complex (Bevan and Docherty 1993). Capsaicin in high concentration (EC_{50}, 6.9 μM) also reduces the mitochondrial membrane potential (Dedov et al. 2001) and can produce DNA fragmentation, with apoptotic cell death.

The topic of toxic vanilloids is the subject of several reviews (Buck and Burks 1986; Holzer 1991; Bevan and Docherty 1993; Szallasi 1998; Szallasi and Blumberg 1999; Kumar et al. 2013).

5.17 Botulinum Neurotoxin

The name botulinum neurotoxin (BoNT) is derived from the Latin "botulus" (i.e., sausage), reflecting discovery of BoNT's ill effects during the Middle Ages – consequent to consumption of poorly prepared or preserved sausage. BoNT and the related tetanus neurotoxin are members of the group of anaerobic bacterial clostridial neurotoxins.

There are seven serological BoNTs, BoNT-A through BoNT-G, with A, B, E, and F subtypes having effects in humans. BoNT consists of a 100kDA heavy chain, paired by a disulfide bond with a 50 kDa light chain. One segment of the BoNT molecule, the binding domain, specifically binds to sites on the cholinergic nerve, thus imparting selectivity of BoNT neurotoxicity to cholinergic nerves (i.e., motoneurons and parasympathetic nerves). A translocation domain is considered to govern pore formation in the cholinergic plasma membrane, for entry of the catalytic domain into the cholinergic nerve. The catalytic domain inactivates V-snare or T-snare proteins, thus preventing the binding of cytoplasmic vesicles to the cholinergic plasma membrane and thereby preventing exocytosis of the neurotransmitter acetylcholine. BoNT poisoning results in skeletal muscle flaccid paralysis, with death from asphyxiation. However, in regulated dosages, BoNT has proven to be a clinically useful agent for a variety of disorders (Foster et al. 2006; Kostrzewa and Segura-Aguilar 2007; Mehanna and Jankovic 2013; Singh et al. 2013).

Mechanisms, actions, and clinical utility of BoNT are the topic of several recent reviews (Foster et al. 2006; Singh 2006; Kostrzewa and Segura-Aguilar 2007; Mehanna and Jankovic 2013; Singh et al. 2013).

5.18 Quinpirole, a Dopamine D_2-Receptor Agonist

The definition of a "selective neurotoxin" has become somewhat obscure, when taking the actions of the DA D_2-receptor agonist, quinpirole, into consideration. Quinpirole, when administered repeatedly – at specified stages of ontogeny – produces long-term sensitization (i.e., a "priming" phenomenon) of the D_2-R, so that subsequent quinpirole dosing results in exaggerated, sometimes abnormal, behavioral responses. Yet, there is no overt evidence of neurotoxicity, other than the abnormality of behavioral effects to challenge doses of this D_2-R agonist.

Eilam et al. (1989) first observed that quinpirole challenge in adult rats produced hyperactivity and perseveration in routes (restricted paths in an open environment) without perseveration in movements. Subsequently, ontogenetic postnatal daily quinpirole treatments (2.6 mg/kg/day × 32 day, base form, ip) of rats were shown to produce enhanced quinpirole-induced behavioral effects. The same abnormal stereotypic response (i.e., licking, grooming, digging, eating) to quinpirole was observed in rats that had been both 6-OHDA lesioned (134 μg, i.c.v., 3 days after birth) as neonates and challenged daily for the first 32 days after birth either with quinpirole or with the DA D_1-R agonist SKF 38393 (Kostrzewa et al. 1990).

When quinpirole (2.6 mg/kg/day) was administered ip to rats once a day for the first 28 days after birth, quinpirole challenge (25–200 μg) at 8–10 weeks produced a dose-related enhanced yawning response, without there being evidence of a change in the B_{max} or K_d for [^{3}H]spiperone binding in the striatum (Kostrzewa and Brus 1991). This enhancement of quinpirole-induced yawning was evident at 6 weeks, even in rats that had been primed by low-dose quinpirole (50 μg/kg/day) for 11 consecutive day periods: birth (P0) to P11 (11 days after birth), P12 to P22, or P23 to P33 (Kostrzewa et al. 1993a). In contrast to quinpirole which primes the D_2-R, the reputedly D_3-R agonist 7-OH-DPAT [(±)-2-(dipropylamine)-7-hydroxy-1,2,3,4-tetrahydronaphthalene] failed to prime a yawning response to either quinpirole or 7-OH-DPAT in rats (Oswiecimska et al. 2000).

Postnatal ontogenetic quinpirole priming (2.6 mg/kg/day) of rats was also associated with adulthood enhancement of a quinpirole (100 or 1000 μg/kg)-induced antinociceptive effect (hot plate response time) (Kostrzewa et al. 1991). Bizarre quinpirole-induced vertical jumping was observed during the interval of postnatal ontogenetic quinpirole priming (2.6 mg/kg/day, P0–P28) of rats, starting at P18. Quinpirole-induced vertical jumping was evident with quinpirole challenge doses in the range of 0.1–3.0 mg/kg), and the effect of high-dose quinpirole persisted for hours. Notably, vertical jumping was observed only if the cage lid was removed. Otherwise jumping was suppressed, so that rats did not harm themselves by hitting against the cage lid. Typically, paw treading against the cage wall was evident during the duration of the jumping episode (Kostrzewa et al. 1993b). In rats that had been both 6-OHDA lesioned (134 μg, i.c.v., 3 days after birth) as neonates and challenged daily from birth with quinpirole, quinpirole-induced vertical jumping was enhanced (Kostrzewa and Kostrzewa 2012).

While changes in striatal D_2-R number or affinity do not accompany D_2-R supersensitivity (Kostrzewa and Brus 1991), an acute challenge dose of amphetamine (1.0 mg/kg ip) in 3-month old rats that had been primed with quinpirole during postnatal ontogeny (50 μg/kg/day ip, P0–P11) produced a five-fold increase in striatal DA exocytosis, as evidenced in the in vivo microdialysate DA level in awake freely moving rats. In contract, a quinpirole challenge dose in adulthood did not evoke DA exocytosis. In rats that were primed from P0 to P11 by daily quinpirole treatment, there was suppression of striatal DA exocytosis by quinpirole, identical to that observed in control non-primed rats. And in rats that were primed at approximately 2 months of age by 3 increasing doses of quinpirole (25, 50, and 100 μg/kg, 1 dose per day), an acute quinpirole challenge dose (100 μg/kg) produced even greater suppression of striatal DA exocytosis (Nowak et al. 2001). These findings indicate that D_2-R supersensitivity has a postsynaptic component (i.e., D_2-R agonists produced enhanced behavioral effects) as well as a presynaptic component (i.e., AMPH-evoked exocytosis).

In neonatally 6-OHDA-lesioned rats (134 μg, i.c.v., 3 days after birth) that were additionally primed during postnatal ontogeny with quinpirole (2.6 mg/kg/day, P0–P28), a quinpirole challenge dose (2.6 mg/kg) in adulthood failed to produce an enhanced quinpirole-induced locomotor response. However, quinpirole priming did enhance D_1-R agonist SKF 38393-induced locomotor responses in adulthood (Brus et al. 2003). This effect is analogous to adulthood heterologous priming of D_1-R by weekly quinpirole challenge doses in rats that had been lesioned as neonates with 6-OHDA (Criswell et al. 1989).

While DSP-4 neonatal lesioning of noradrenergic innervation prevents ontogenetic quinpirole priming of D_2-R (Nowak et al. 2006), neonatal co-lesioning with DSP-4 and 5,7-DHT results in enhanced quinpirole-induced and 7-OHDA-induced yawning as well as enhanced apomorphine-induced stereotypies (Nowak et al. 2009). These findings indicate that both noradrenergic and serotoninergic nerves have a prominent influence on D_2-R priming.

In quinpirole-primed rats, spatial memory deficits and enhanced skilled reaching were observed in adulthood (Brown et al. 2002). Enhanced quinpirole-induced locomotor and stereotyped responses observed in adult rats that were quinpirole primed during postnatal ontogeny are attenuated by acute nicotine pretreatment in adulthood; and this effect was accompanied by increased [^{125}I]α-bungarotoxin binding in striatum and hippocampus and greater [^{3}H]cytisine binding in midbrain and cerebellum. These findings indicate that nicotinic α_7 and $\alpha_4\beta_2$ receptor parameters, respectively, are regionally altered in quinpirole-primed rats (Tizabi et al. 1999). In separate studies, nicotine adulthood treatments (0.3 mg/kg x 2/day) for 14 consecutive days reversed performance deficits in quinpirole-primed rats on the Morris water task and skilled reaching task and partially reversed a 36 % decrease of choline acetylcholine transferase in hippocampus. This finding supports the role of nicotinic receptors in quinpirole priming and projects involvement of cholinergic systems in the priming phenomenon (Brown et al. 2004).

D_2-R supersensitivity is implicated in obsessive-compulsive disorder (Eilam et al. 1989, 2006; Szechtman and Woody 2004, 2006; Alkhatib et al. 2013) and is

regarded as a major component of schizophrenia in which there is an elevation in the number of D_2^{high} receptors (Seeman et al. 2005, 2007; Seeman 2011). So-called breakthrough DA-R supersensitivity is also regarded as a factor in antipsychotic treatment failure (Samaha et al. 2007).

The process of D_2-R supersensitivity, as relating to quinpirole-induced ontogenetic priming, appears to be a lifelong permanent effect, still evident in rats approaching 2 years of age (Brus et al. 1998; Oswiecimska et al. 2000). Quinpirole induction of D_2-R supersensitivity is discussed in several reviews (Kostrzewa 1995; Kostrzewa et al. 2004, 2008a, 2011; Nowak et al. 2004; Brown et al. 2012). Permanent sensitization of D_2-R and resulting alteration of behaviors, despite lack of evidence of neuropathology, does nonetheless represent a neurotoxicity.

5.19 Other Neurotoxins

The overview of selective neurotoxin in this chapter is intended to highlight the most commonly known neurotoxins and most commonly used neurotoxins. Not all neurotoxins have been listed and/or described in detail in this overview. There are a number of other EAAs and other types of neurotoxins that are used, and some are described in greater detail in other chapters of the *Handbook of Neurotoxicity*.

6 The Future of Neurotoxins in Biomedicine

For the past 50 years, selective neurotoxins have been instrumental in:

1. *Mapping nerve tracts in the CNS*: Destruction of the nerve terminal field is often followed by axonal swelling, retrograde throughout its entire length, back to the perikaryon. A marker for this phenotypic nerve provides an excellent means to map the route of the axons. For example, by lesioning the terminal field for noradrenergic nerves and treating with a fluorescent-tagged antibody for dopamine-beta-hydroxylase, noradrenergic axons will glow brightly green and thereby show the exact course of the noradrenergic nerve tract through the brain.
2. *Demonstrating nerve fiber sprouting*: When neurotoxins destroy one axon of a bipolar (i.e., 2 axons) or multipolar nerve, the more proximal branch(es) of the nerve often sprout and ***hyperinnervate*** regions that are normally innervated by the surviving axonal branch(es). At times, the surviving branch(es) extends their geographic domain to innervate new regions which are not normally innervated by this nerve (***neo-innervation***). Neurotoxins have provided the means to uncover these phenomena. Also, by virtue of selective neurotoxicity, these findings are "pure" – not encumbered by complications ensuing, were more than one neuronal phenotype damaged.
3. *Determining the physiological role played by specific neuronal tracts*: As indicated by WB Canon, the function of a nerve can be deduced by denoting altered effect when the nerve is destroyed (Cannon and Rosenblueth 1937). Accordingly, the importance of dopaminergic innervation in nucleus accumbens

with the euphoric and other effects of drugs of abuse can be deduced. The same approach is successfully used to link other nerve phenotypes with a particular brain region and associated behavioral effect.

4. *Ascribing neuronal denervation with receptor supersensitization phenomena*: The proliferation in numbers of receptors following selective destruction of a nerve can be reasonably quantified; and possible changes in the affinity of these receptors can be studied. Also, the relative contribution of high- and low-affinity states of the receptor can be elucidated. Selective neurotoxins are especially valuable for such studies. However, since the time that selective neurotoxins have been employed for such studies, it has become clear that receptor supersensitization (i.e., ability of the receptor to produce an exaggerated response) is not necessarily related to a change in receptor number. Additional receptors do not necessarily correlate with increased receptor sensitization.
5. *Characterizing specific neuronal phenotypes with human neurological and psychiatric disorders*: Selective lesioning of particular nerve types or specified nerve tracts has been of immense value in animal modeling of human neuropathological and psychiatric states. Ideally, one seeks (a) face validity (mirroring of a behavioral deficit), (b) construct validity (conforming with a pathophysiological basis of a disorder), and (c) predictive validity (ability to project a therapeutic intervention) in an animal model. Some models relate to merely "predictive validity." For example, perinatal 6-OHDA treatment of rats leads to an adolescent and adulthood hyperactivity and attention deficit, which is responsive to amphetamine – just as human ADHD is responsive to amphetamine (see Kostrzewa et al. 2008b). Yet, human ADHD has no relationship with near-total dopaminergic denervation of forebrain – as found in this animal model. Other animal modeling of human disorders is reliant on use of selective neurotoxins.
6. *Identifying intraneuronal mechanisms and processes that lead to cell death by apoptosis, necrosis, and necroptosis*: Neurotoxins commonly evoke a number of processes that lead to cellular instability and compromised viability. Classically there is an increase in intracellular Ca^{2+} levels, also in the number of ROS and reactive nitrogen species, changes in oxidative phosphorylation accompanied by altered mitochondrial membrane potential, mitochondrial release of cytochrome c into the cytoplasm, increased phosphorylation of proteins, promotion of aggregates of abnormal proteins, activation of Bax and other proapoptotic elements along with suppression of bcl and other protective cellular elements, translocation of proteins to the nucleus, and other changes. Neurotoxins have aided immensely in the study of cell death phenomena.
7. *Recognition of the role played by microglia, astrocytes, and immune cells in neurodegeneration*: Selective neurotoxins have been instrumental in evoking neuronal damage and thereby provoking nonneural cellular responses to injury. These include astrocytes, activated microglia, and immune cells which arise in a uniquely timed and ordered array. The incentive to understand mechanisms of neurotoxicity has aroused interest in the role played by other cells in neuropathological processes.

8. *Broadening the understanding that there are multiple cellular targets whereby drugs may intervene to disrupt an otherwise programmed cell death*: There was an awakening of interest in new means by which drugs can conceivably target one or another process to facilitate recovery of an injured neuron. In addition, there is now global interest in neuroprotectants, which can prevent an otherwise deleterious effect on nerves.

   Looking ahead we can foresee the introduction of multiple kinds of selective neurotoxins, in order to broaden the horizon for these agents in elucidating the association between specified nerve and nerve tracts with biological and behavioral actions. We can envision:

   1. An increase in the number of phenotypically selective neurotoxins
   2. Introduction of neurotoxins that act on novel intracellular targets
   3. More neurotoxins tagged to antibodies
   4. Trojan horse botulinum toxins, engineered with binding proteins that target an ever-expanding field of susceptible cells, and conveying a toxic load into these cells
   5. Engineered immunotoxins, altered to target specified cells – analogous to IgG-saporin
   6. Agonists/antagonists directed towards neurotrophin receptors, so as to compromise development of specified neuronal phenotypes
   7. Antibodies for specific neurotrophins, analogous to that of anti-NGF, producing immuno-disarray of specified types of nerves
   8. Alkylating agents analogous to DSP-4
   9. Added excitatory amino acids (EAAs)
   10. Inhibitors of (endogenous) neuroprotectants
   11. Agents that desensitize nerves, akin to capsaicin
   12. A host of agents that act by unanticipated means

In the process, there will be a discovery of novel neuroprotectants, some with targeted specificity and others with generalized effects. As more becomes known of cellular processes and mechanisms in the neuronal response to injury, so too does the number of possible neuroprotectants increase.

We cannot foresee changes that will occur in the next century. So many more revolutions are certain, and someone looking back 100 years from now will likely be confused by what will probably seem to be limited scope in the assumed "direction" of this field. When tomorrow sees today's views as too narrow in scope, this will be proof that we, today, recognized how important the topic of neurotoxins is, for the development of neuroscience and an ever increasing understanding of how nerves work (adapted from Kostrzewa 1999a).

Abstract

Necrosis is considered to be an unregulated and chaotic cell death. However, recent advances in cell death strategies support necroptosis as a form of regulated programmed necrotic cell death. In response to TNF-α or Fas ligands, necroptosis can be induced by cell death receptors in multiple cell lines in the presence of a caspase inhibitor z-VAD; necroptotic cell death has been found to play an important role in normal development, immunity, inflammation, cancer, and human diseases. In this chapter, the molecular mechanisms governing necroptosis, recent findings about the upstream and downstream schema of necroptosis, and potential therapeutic targets in neurological disorders are discussed. After being activated by TNF-α (or Fas ligands) and death receptors, receptor-interacting proteins 1 and 3 (RIP1 and RIP3) form a complex, which play a central role in the induction of necroptosis. RIP3 phosphorylates and activates mitochondrial proteins mixed lineage kinase domain-like protein (MLKL) and PGAM5, resulting in the execution of necroptosis by dynamin-related protein 1, the GTPase that controls mitochondrial fission. Some small molecules such as necrostain-1 and necrosulfonamide target different steps of necroptosis and impede the progress of necroptosis. FADD, caspase-8, CLIP, and CYLD positively or negatively regulate RIP1-/RIP3-dependent necroptosis by different mechanisms. Recent studies demonstrate the involvement of necroptosis in many neurological disorders including stroke, trauma, neonatal hypoxic–ischemic encephalopathy, and Huntington's disease. As a potential therapeutic target, the understanding of necroptotic mechanisms will provide new insights to develop more potent neuroprotectants and specific therapeutic strategies for clinical treatments of neurological disorders.

Keywords

Necroptosis • Neurological diseases • RIP1 • RIP3

List of Abbreviations

AIF	Apoptosis-inducing factor
ANT	Adenine nucleotide translocase
Aur-A	Aurora-A kinase
BHA	Butylated hydroxyanisole
CCI	Controlled cortical impact
cIAP1/2	Apoptosis protein 1/2
CypA	Cyclophilin A
CypD	Cyclophilin D
DRP1	Dynamin-related protein 1
FADD	Fas-associated protein with death domain
FLIPL	FLICE-like inhibitory protein long
GLUD1	Glutamate dehydrogenase 1
GLUL	Glutamate–ammonia ligase
HI	Hypoxia–ischemia

HIE	Hypoxic–ischemic encephalopathy
HMGB1	High-mobility group box 1 protein
HSP90	Heat shock protein
IAPs	Inhibitors of apoptosis
MEFs	Mouse embryonic fibroblasts
MKRN1	Makorin Ring Finger Protein 1
MLKL	Mixed lineage kinase domain-like protein
OGD	Oxygen–glucose deprivation
Plk1	Polo-like kinase 1
RHIM	RIP homotypic interaction motif
RIP	Receptor-interacting protein
ROS	Reactive oxygen species
TNFR1	TNF receptor 1
TNF-α	Tumor necrosis factor-α
z-VAD	z-VAD-fmk

1 Introduction

Neurological disorders, from the gamut of acute medical emergencies such as stroke to debilitating chronic neurodegenerative disorders such as Parkinson's disease and Alzheimer's disease, are related to neuronal cell damage, cell repair, and final cell death or survival. For the prevention or therapeutic intervention for these neurological disorders, the process of cell death still is one of major targets.

Neuronal loss is observed in many neurological disorders including stroke, Parkinson's disease, and Alzheimer's disease (Ekshyyan and Aw 2004). However, the kinds of cell death existing in the pathological process of the multiplicity of neurological diseases are still not clear. On the basis of intracellular morphological changes, it was considered that there were three types of cell death in embryonic developmental processes (Schweichel and Merker 1973). Type I cell death is characterized by cytoplasmic shrinkage, pyknosis, nuclear condensation, and late cell fragmentation, which is identical to "apoptosis," as described by Kerr (Kerr et al. 1972). Type II cell death is characterized by substantial autophagic vacuolization in the cytoplasm, termed lately as "autophagy." Type III cell death is characterized by clumping of chromatin, swelling of organelles, and cell disintegration including the rupture of nuclei, mitochondria, lysosomes, and plasma membrane; and this is considered to be "necrosis" (Kitanaka and Kuchino 1999). In the past decades, accumulating evidences demonstrate that many alternative cell death mechanisms exist during the development and pathology of diseases including necroptosis, elimination by shedding, keratinocyte death by cornification, and cell–cell cannibalism by entosis (Yuan and Kroemer 2010). Among the reported forms of cell death, "apoptosis," "autophagy," and "necroptosis" are regarded as the major types most closely associated with neuropathology in neurological and neurodegenerative disorders

(Edinger and Thompson 2004). Apoptotic and autophagic cell death regulation pathways have been extensively studied and well established in the past two decades. Unlike apoptosis and autophagy – the forms of programmed cell death – necrosis has long been considered as an uncontrolled nonprogrammed cell death characterized by rapid chaotic breakdown of the cell under intolerable conditions. More recently, necrosis has been recognized as a programmed and regulated cell death process (Degterev et al. 2005; Edinger and Thompson 2004). Since necroptosis – a form of necrotic cell death – was proposed in 2005 (Degterev et al. 2005), the concept of regulated necrosis stirred cell death research, while regulation of signal pathway transduction became one of the hot topics in biomedical research.

Necroptosis represents a specific form of caspase-3-independent programmed necrotic cell death that is induced by cell death ligands such as TNF-α and Fas ligand via cell death receptors in multiple cell types, in the presence of an apoptosis inhibitor (Degterev et al. 2005). The increasing evidences have demonstrated the existence of necroptosis in a variety of neurological disorders. In this chapter, the regulative pathway of necroptosis and its potential therapeutic application in neurological disease will be discussed.

2 The Cellular Signal Transduction of Necroptosis

Necroptosis, as a form of necrotic cell death, was identified by Degterev and his colleagues based on the observation of cell death induced by TNF-α or Fas ligand in the presence of an apoptosis inhibitor (Degterev et al. 2005). Initially, necroptosis was not considered to share signal pathways with apoptosis and was thereby accorded as an independent cell death process distinct from apoptosis. However, recent advances have shed greater insight into the mechanisms by which necroptosis is regulated and executed. Actually, as an alternative form of cell death, necroptosis can not only cross talk with apoptosis and autophagy but under some circumstances can also recruit other cell death processes such as apoptosis or autophagy (Duprez et al. 2012; Lu and Walsh 2012; Simenc and Lipnik-Stangelj 2012; Vandenabeele et al. 2010; Zhang et al. 2009). In most pathological situations, different kinds of cell death may exist and lead to both cell loss and tissue damage (Long and Ryan 2012; Yahiro et al. 2012). However, one form of cell death will dominate the pathological process. When the signal pathways of this dominant cell death process are blocked (e.g., caspase inhibitor block of apoptosis), an alternative cell death process such as necroptosis can be increased and become the dominant form of cell death (Han et al. 2011). By understanding the conversion or switch between different forms of cell death, it becomes possible to identify new clinical targets – thus enabling the advance of new therapeutic strategies. As for necroptotic cell death, the deciding factors for the conversion from/to apoptosis are the central protein complexes RIP1 and RIP3; but positive regulators (such as deubiquitinase CYLD) and negative regulators (such as caspase-8, FADD) also closely control the fate of cells (survival, necroptosis, or other forms of cell death converted from necroptosis). The advances on regulation of necroptosis are discussed below.

2.1 The Central Signals for Necroptosis: RIP1 and RIP3

Receptor-interacting protein (RIP) kinase family has been identified as having seven members so far (Zhang et al. 2010). RIP kinase family members share a homologous kinase domain but have different functional domains. Since their discovery as a novel form apoptosis-inducing protein, RIP kinases have emerged as essential sensors of cellular stress (Stanger et al. 1995). RIP kinases not only trigger pro-survival through the activation of transcription factors such as NF-κB and AP-1 but also initiate the death-inducing programs (Meylan and Tschopp 2005). Hence, RIP kinases are regarded as crucial regulators of cell survival and death (Festjens et al. 2007). Among these family members, RIP1 and RIP3 are specifically related to necroptosis (Cho et al. 2009) (Fig. 1).

RIP1, the first member of the RIP kinase family, contains three domains: an N-terminal kinase domain, an intermediate domain, and a C-terminal death domain. Although the death domain of RIP1 was shown to bind to several death receptors, such as TNFR1 to activate NF-κB and induce apoptosis (Holler et al. 2000; Stanger et al. 1995), the serine/threonine activity of RIP1 is essential for necroptosis (Degterev et al. 2005). Moreover, RIP1 is regarded as a crucial adaptor kinase and a switch between different forms of cell death in response to extracellular stress or damaging stimuli such as TNF-α and Fas ligands (Festjens et al. 2007). TNF-α is the most extensively studied extracellular signal that leads to apoptosis or necroptosis. Under the apoptosis situation, TNF-α stimulation sequentially induces the formation of two protein complexes: complex I and complex II. In the cytoplasmic membrane, TNF-α binds to TNF receptor 1 (TNFR1) and induces the formation of protein complex I including TRADD, TRAF2, RIP1, and cIAP1. RIP1 is recruited to the protein complex via its death domain to TNFR1. After the formation of protein complex I, these proteins dissociate from TNFR1, and RIP1 enters the cytosol. In the cytosol, RIP1 forms protein complex II with caspase-8, Fas-Associated protein with Death Domain (FADD), and other proteins to activate the caspase cascade to execute apoptosis. In the presence of pancaspase inhibitor z-VAD-fmk (z-VAD), caspase-8 activity is inhibited and the apoptotic pathway is blocked. In this situation, RIP1 interacts with RIP3 to form Ripsome and initiate necroptosis as an alternative cell death. In the apoptosis-deficient condition, the expression of an inactive RIP1 or the inhibition of RIP1 activity by Nec-1 inhibits TNF-induced necroptosis (Degterev et al. 2005; Holler et al. 2000). Mice lacking RIP1 appear normal at birth but fail to thrive, displaying extensive apoptosis in both the lymphoid and adipose tissues and dying at 1–3 days of age (Kelliher et al. 1998). Therefore, RIP1 kinase activity is crucial for this alternative cell death pathway of necroptosis.

The increasing body of evidences demonstrate that RIP3 is a determinant for necroptosis (Challa and Chan 2010). Recent studies show that cells which lack RIP3 expression are resistant to necroptosis, despite the normal RIP1 expression (Cho et al. 2009; He et al. 2009). When RIP3 expression was restored with an shRNA-resistant RIP3 transgene, necroptotic cell death was reestablished (He et al. 2009). However, if RIP3 Kinase-Dead Mutant K50A abolishes RIP3 kinase

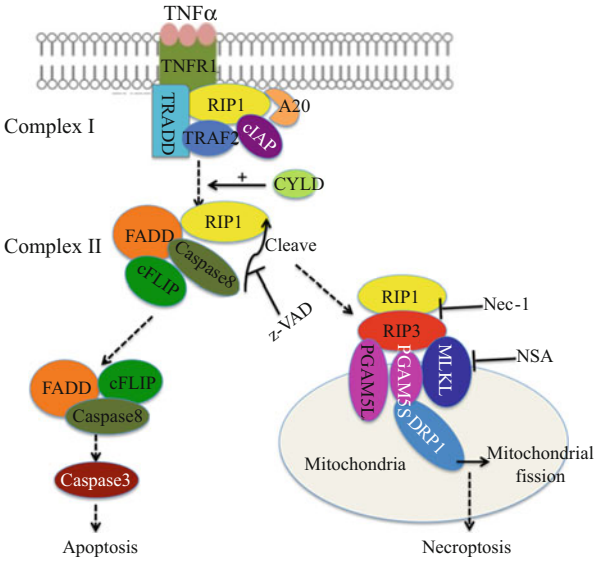

Fig. 1 TNF-α-elicited signaling pathways on apoptosis and necroptosis. Upon TNF-α stimulation, TNFR1 induces the formation of protein complex I including TRADD, TRAF2, and RIP1 at the plasma membrane. RIP1 is modified by polyubiquitination via cIAP1 and A20. After the dissociation from TNFR1, RIP1 enters the cytosol and deubiquitinates by CYLD. In the cytosol, RIP1 forms protein complex II with FADD, caspase-8, and cellular FLIP (cFLIP). The composition of protein complex II and its activation determine the directions of the cell death: apoptosis or necroptosis. FADD contains a death-effector domain, which recruits and causes the autocatalytic activation of the initiator caspase-8; caspase-8 directly cleaves intracellular substrates or activates other caspases such as caspase-3, finally resulting in apoptosis. The apoptotic machinery FADD, caspase-8, and cFLIP suppress necroptosis via the cleavage of RIP1 by activated caspase-8. In apoptosis-deficient conditions such as in the presence of pancaspase inhibitor z-VAD, caspase-8 activation is inhibited and blocks the RIP1 cleavage. RIP1 then interacts with RIP3 to form a RIP1–RIP3 complex. RIP3 phosphorylates two proteins in the outer mitochondrial membrane: a protein kinase MLKL and a phosphatase PGAM5. After the activation of MLKL, short form of PGAM5 (PGAM5S) activates DRP1, the GTPase that controls mitochondrial fission, in a hydrophobic environment, leading to mitochondrial fission and necroptosis. The necroptosis inhibitors necrostain-1 (Nec-1) and necrosulfonamide (NSA) block necroptotic cell death by targeting the interaction of RIP1 and RIP3 and MLKL, respectively

activity, necroptosis remains blocked, indicating that the kinase domain is still essential for the role of RIP3 (He et al. 2009).

The interaction of RIP1 and RIP3 is required for mutual and autophosphorylation of RIP1 and RIP3 and the activation of the downstream necrotic signaling pathway (Cho et al. 2009; He et al. 2009). Both the intermediate domain of RIP1 and the unique C-terminus of RIP3 have a RIP homotypic interaction motif (RHIM), which is required for mediating the interaction between RIP1 and RIP3 (Meylan and Tschopp 2005). The small-molecule necrostain-1, an inhibitor of RIP1 kinase activity, blocks necroptosis by impairing the interaction between RIP1 and RIP3 (Cho et al. 2009; He et al. 2009). The mutation in the

RHIM domain of RIP proteins inhibits necroptotic cell death (Cho et al. 2009), suggesting that the interaction of RIP1 and RIP3 or RIP1–RIP3 complex is crucial for death receptor-mediated necroptosis. The apoptotic pathway seems to be controlled by a caspase network, whereas necroptotic signaling is controlled by a kinase cascade and highly regulated by an intracellular protein platform (Gunther et al. 2013).

2.2 The Upstream Positive and Negative Regulators of Necroptosis

2.2.1 FADD/Caspases-8/FLIP

FADD is an adaptor molecule that bridges the Fas receptor or other death receptors such as TNFR1 to caspase-8 through its death domain to form the death-inducing signaling complex during apoptosis (Bodmer et al. 2000; Kreuz et al. 2004). FADD containing a death-effector domain can recruit and cause the autocatalytic activation of the initiators caspase-8 and caspase-10, which can directly cleave intracellular substrates or activate other caspases including caspase-3 (Tourneur and Chiocchia 2010). When caspase-8 is activated, it mediates apoptosis; at the same time, caspase-8 prevents necroptotic cell death by cleaving RIP1 and/or RIP3 or by binding FLICE-like inhibitory protein long (FLIPL) to form an "inhibitory" caspase-8–FLIPL heterodimer (Lu et al. 2011; Oberst et al. 2011; Rebe et al. 2007). While caspase-8 is inactivated by a pancaspase inhibitor z-VAD or caspase-8 knockout, the proteolytic inactivation of RIP1 and RIP3 is prevented and the inhibitory effect of caspase-8 on necroptosis is abolished. These are confirmed by in vitro and in vivo experiments. In antigen-activated T cells, the ablation of caspase-8 or FADD can lead to RIP1-dependent necroptosis (Bell et al. 2008; Ch'en et al. 2008). Similarly, caspase-8- and FADD-deficient mice demonstrated severe embryonic phenotype including cardiac malformations and hemorrhage mediated by RIP1- and RIP3-dependent necroptosis (Gunther et al. 2013; Kaiser et al. 2011). Interestedly, caspase-8/RIP1 or caspase-8/RIP3 double knockout mice are viable and survive into fertile adults; RIP1 or RIP3 knockout rescues embryonic lethality phenotype observed in caspase-8- or FADD-deficient mice (Kaiser et al. 2011; Oberst et al. 2011; Zhang et al. 2011a). These experiments demonstrate the regulation of caspase-8 and FADD on RIP1- and/or RIP3-mediated necroptosis.

FLIP has a similar structure to caspase-8, but lacks the catalytic activity. FLIP may be involved in the regulation of necroptotic cell death via RIP kinase, as FLIP knockout mice have a similar phenotype to that of caspase-8- and FADD-deficient mice (Yeh et al. 2000). However, in a recent study, RIP3 ablation rescued embryonic phenotype of FADD-deficient mice, but did not rescue the phenotype of FLIP-deficient mice (Dillon et al. 2012), suggesting distinct functions of FLIP from FADD and caspase-8 on the regulation of necroptosis. Surprisingly, embryos at E9.5–E10 in the FLIP and RIP3 double knockout mice display obvious apoptotic cell death (Dillon et al. 2012), demonstrating the antiapoptotic activity of FLIP on FADD-/caspase-8-mediated apoptosis. Therefore, in the absence of FLIP, caspase-8

may form homodimers to activate apoptotic pathways and result in cellular apoptosis; in the presence of FLIP, the heterodimer of caspase-8 and FLIP forms a complex with FADD to prevent RIP kinase-dependent necroptosis (Dillon et al. 2012; Feoktistova et al. 2011). There is constant interplay between death and survival complexes, which compete with each other until one eventually dominates and determines the cell's fate (Declercq et al. 2009). The regulation of FADD/caspase-8/FLIP on necroptosis and apoptosis demonstrates that various death pathways are closely intertwined, and cellular processes are in tight control of each other.

2.2.2 Deubiquitinase (CYLD/A20/Cezanne) and Ubiquitinase (IAPs/MKRN1)

Protein ubiquitylation and deubiquitylation are important processes to regulate numerous signal pathways and proteins. Ubiquitylation status of RIP1 determines the type of RIP1-mediated cell death. When RIP1 is recruited to TNFR1, RIP1 is heavily modified by ubiquitination; however, ubiquitinated RIP1 was not found in the RIP1–RIP3 complex (Cho et al. 2009; Teng et al. 2005). The different ubiquitination patterns imply that RIP1 is deubiquitinated in the process of necroptosis. Therefore, the enzymes for ubiquitination and deubiquitination of RIP1 protein are the regulators of necroptosis.

CYLD is a lysine-63 (K63)-specific deubiquitinase, which was identified as an important regulator of necroptosis in a genome-wide RNAi screen (Hitomi et al. 2008). Knockdown of CYLD inhibits TNF-α-induced necroptosis in cultured human Jurkat cells (Hitomi et al. 2008), which suggests that CYLD may be responsible for the deubiquitination of RIP1 during necroptosis. A recent study confirmed that RIP1 is a substrate of CYLD (Wright et al. 2007). Consistent with this, CYLD promotes assembly of the RIP1–FADD–caspase-8 complex in response to TNF-α treatment, indicating that deubiquitination of RIP1 by CYLD is an essential step in this process (Wang et al. 2008). CYLD was recently found to be cleaved by caspase-8 and thereby prevents necroptosis in mouse embryonic fibroblasts (MEFs) upon TNF-α stimulation; however, overexpression of a non-cleavable CYLD mutant rapidly promotes necroptotic cell death in response to TNF-α treatment (O'Donnell et al. 2011), which connects CYLD, caspase-8, and necroptosis together. Therefore, RIP1 polyubiquitylation may hinder the recruitment of downstream proteins of necroptosis such as RIP3; CYLD facilitates necroptosis by removal of the polyubiquitin chains on RIP1. The positive regulation of CYLD on necroptosis is also controlled by caspase-8 activity, a negative regulator of necroptosis. Similar to CYLD, ubiquitin-editing enzymes A20 and Cezanne are also reported to deubiquitinate RIP1 protein (Enesa et al. 2008; Shembade et al. 2010).

2.2.3 cIAPs

Inhibitors of apoptosis (IAPs) characterized by a variable number of highly conserved baculoviral IAP repeat motifs including cellular inhibitor of apoptosis protein 1/2 (cIAP1/2) and X-linked inhibitor of apoptosis protein (XIAP) have been thought to function primarily to inhibit apoptosis. A "Really Interesting

New Gene" (RING) domain with ubiquitin protein ligase (E3) activity in the C-terminal of IAPs implies that IAPs are multifunctional proteins to regulate the modification of its target protein via ubiquitylation. Recent studies demonstrate that IAPs also regulate RIP1 ubiquitination and RIP1-dependent necroptotic cell death (Bertrand et al. 2008; McComb et al. 2012; Tenev et al. 2011). IAPs can directly conjugate polyubiquitin chains to RIP1 and block RIP1-dependent ripoptosome formation containing the core components RIP1, FADD, and caspase-8 by targeting the components of ripoptosome for ubiquitylation and degradation. Deletion of IAPs enhances ripoptosome formation and the association of RIP1 and caspase-8, resulting in ripoptosome-mediated apoptosis or necroptosis (Tenev et al. 2011). In tumor cells, cIAP1 inhibition by its antagonists or RNA interference facilitates TNF-induced necroptosis (He et al. 2009; Vanlangenakker et al. 2011). Consistent with this, McComb et al. found that cIAPs also regulate RIP3 via ubiquitination to inhibit the RIP1–RIP3 death complex, and reduced cIAP activity in vivo by the exposure to SMAC mimetics or cIAP1/2 knockout leads to elevated macrophage necroptotic cell death (McComb et al. 2012). Therefore, cIAPs are important targets for preventing apoptosis and necroptosis in acute and chronic diseases or inducing cell death in cancer therapy.

2.2.4 Ubiquitinase on FADD–Makorin Ring Finger Protein 1 (MKRN1) E3 Ligase

A recent study shows that FADD regulates cell death and survival via a ubiquitination-induced degradation pathway (Lee et al. 2012). Makorin Ring Finger Protein 1 (MKRN1) E3 ligase, a ubiquitinase, ubiquitinates FADD; ubiquitinated FADD is subjected to degradation through a proteasomal pathway. The knockdown of MKRN1 increases the stability of FADD and facilitates caspase-8- and caspase-3-mediated apoptosis in response to death signals; however, the overexpression of MKRN1 suppresses extrinsic apoptosis by increasing FADD degradation (Lee et al. 2012). In the presence of caspase inhibitors, MKRN1 knockdown significantly increases RIP1–RIP3–FADD complex formation and enhances necroptotic cell death upon TNF-α and z-VAD treatment (Lee et al. 2012). This suggests that ubiquitinase MKRN1 also regulates apoptosis and necroptosis via the ubiquitination and degradation of FADD.

2.2.5 Polo-Like Kinase 1 (Plk1) and Aurora-A Kinase (Aur-A)

Plk1 and Aur-A are two important mitotic kinases in the regulation of multiple mitotic processes (Macurek et al. 2009). A recent study has shown that Plk1 and Aur-A are involved in the phosphorylative modification of FADD and cooperatively phosphorylate FADD at S194 and S203, respectively (Jang et al. 2011). The double-phosphorylated FADD results in its dissociation from RIP1, which is activated to necroptotic cell death; however, the single-phosphorylated FADD cannot induce cell death, suggesting that double phosphorylation of FADD is critical for RIP1-dependent necroptosis (Jang et al. 2011). Therefore, inhibition of double phosphorylation of FADD by mitotic kinases Plk1 and Aur-A may block necroptosis. In contrast, another study indicates that the small-molecule BI2536, an

inhibitor of Plk1, increases PARP-1-mediated necroptosis (Deeraksa et al. 2013). This inconsistency of two studies may be explained by the specificity of small molecules on Plk1 and the difference of cell lines. However, both studies demonstrate the involvement of mitotic kinase Plk1 on the regulation of necroptosis. More information on how Plk1 regulates RIP1-dependent necroptosis should be investigated in future studies.

2.3 Downstream Signals of Necroptosis

While the upstream signaling of RIP1–RIP3 and RIP1 ubiquitination are important to determine how necroptosis is initiated, the identification of downstream components is necessary to determine how necroptosis is executed. Caspases are the executioners for apoptotic cell death; however, these proteases have no positive role in necroptosis (Pop et al. 2011). Thus far, an analogous class of executioner proteins has not been identified for necroptosis. Some downstream signals relevant to necroptosis are reported, and this information may provide clues for future studies to unveil necroptosis.

2.3.1 Mixed Lineage Kinase Domain-Like Protein (MLKL)

MLKL belongs to the protein kinase superfamily, since a kinase domain is identified within the C-terminus of the protein; however, its function and substrates are still unknown. Recently, two research groups independently demonstrated that MLKL is a substrate of RIP3 and the direct downstream signal of RIP1–RIP3 complex-mediated necroptosis (Sun et al. 2012; Zhao et al. 2012). Sun and colleagues identified MLKL as an interacting protein of RIP3, by immunoprecipitation and mass spectrometry analysis (Sun et al. 2012). Knockdown of MLKL prevents the enlarged RIP3 punctae during necrosis progress and arrests necrosis at a specific step, which is an effect identical to that caused by necrosulfonamide, a newly identified necroptosis inhibitor and MLKL inhibitor (Sun et al. 2012). Their further findings show that the interaction of MLKL and RIP3 is initiated by autophosphorylation of RIP3, and then two critical residues of MLKL for necrosis are phosphorylated at threonine 357 and serine 358 by RIP3 (Sun et al. 2012). Zhao et al. also demonstrated that MLKL is a key downstream mediator of necrosis directly regulated by RIP3 kinase (Zhao et al. 2012). By a kinase/phosphatase shRNA library screening in a human colon adenocarcinoma cell line, they found that a lack of MLKL blocks TNF-induced necrosis but does not affect the interaction of RIP1 and RIP3, suggesting that MLKL is the downstream of RIP1–RIP3 complex (Zhao et al. 2012). Further findings indicate that MLKL is recruited to RIP1–RIP3 complex by interacting with RIP3, but not mutant RIP3 without kinase activity (Zhao et al. 2012), which is consistent with Sun et al.'s results (Sun et al. 2012). Although MLKL is proven to be directly downstream of RIP3, the downstream of signals of MLKL remains elusive.

2.3.2 PGAM5

PGAM5 is a mitochondrial protein phosphatase in the outer membrane of the mitochondria. A recent study found that PGAM5 coprecipitates with RIP3 under necroptosis-inducing conditions (Wang et al. 2012). More importantly, RIP3 phosphorylates PGAM5 and consequently increases PGAM5 phosphatase activity (Wang et al. 2012), suggesting that PGAM5 is also the substrate of RIP3. Knockdown of either splice variant of PGAM5 (PGAM5L or PGAM5S) by siRNA reduces necroptosis induced by different stimuli, indicating that both isoforms of PGAM5 are essential for necroptosis; however, only PGAM5S phosphorylation is dependent on the presence of MLKL and is blocked by the MLKL inhibitor necrosulfonamide (Wang et al. 2012). These findings suggest that PGAM5S is also recruited to the RIP1–RIP3–MLKL complex. Further study indicates that PGAM5S is phosphorylated after the necrosome (RIP1, RIP3, MLKL, and PGAM5L) is shifted to a more hydrophobic environment that contains dynamin-related protein 1 (DRP1), the GTPase that controls mitochondrial fission. Interestingly, knockdown of DRP1 prevents necroptosis, and knockdown of PGAM5S attenuates DRP1 activation (Wang et al. 2012), demonstrating that DRP1 is required for necroptosis and is regulated by PGAM5S. Therefore, PGAM5S is also a substrate and downstream signal of RIP1–RIP3 complex, and DRP1 may be one of the executioners in the necroptotic pathways.

2.3.3 Poly(ADP-Ribose) Polymerase-1/Apoptosis-Inducing Factor (PARP-1/AIF) Pathway

PARP is a family of nuclear enzymes that catalyze poly(ADP-ribosyl)ation reaction to modulate other proteins to maintain chromatin structure, transcription, and genomic integrity (Krishnakumar and Kraus 2010). It is widely known that PARP-1 activation mediates AIF translocation from the mitochondria to nucleus, resulting in caspase-independent cell death (Andrabi et al. 2008; Hong et al. 2004; van Wijk and Hageman 2005). Since the concept of programmed necrosis is accepted, PARP-1-/AIF-mediated caspase-independent cell death has begun to be regarded as necroptosis (Delavallee et al. 2011). However, how the RIP1–RIP3 complex in cytosol signals to PARP-1 in the nucleus is still unclear. In our previous studies, the relationship between PARP-1/AIF and necroptosis by using a hippocampal cell line HT-22 was explored. Glutamate-induced oxidative stress causes a caspase-3-independent necrosis-like cell death in HT-22 cells; the necroptosis-specific inhibitor necrostatin-1 almost completely blocks this kind of cell death (Xu et al. 2007). Necrostatin-1 not only prevents glutamate-induced glutathione depletion in HT-22 cells but also blocks the translocation of AIF from the mitochondria to nucleus (Xu et al. 2007). The effect of necrostain-1 on the AIF upstream signal PARP-1 activity is further examined, and it is found that necrostain-1 inhibits glutamate-induced PARP-1 activation but not total expression. However, necrostain-1 cannot directly inhibit PARP-1 activation induced by the DNA-alkylating agent MNNG (Xu et al. 2010a), indicating that PARP-1-/AIF-mediated signal pathway in HT-22 cell is

downstream of necroptosis and that necrostain-1 targets upstream of PARP-1/AIF, which is consistent with the fact that necrostain-1 inhibits RIP1 activity and blocks the interaction of RIP1 and RIP3 (He et al. 2009). Increasing evidences demonstrate that PARP-1/AIF signal pathway is involved in the downstream signals of necroptosis and may be one of the executioner proteins for necroptosis (Cabon et al. 2012; Deeraksa et al. 2013; Dunai et al. 2012; Jouan-Lanhouet et al. 2012). The mechanisms attending PARP-1/AIF regulation of necroptosis need further investigation.

2.3.4 Mitochondrial Targets

The mitochondrial protein families are involved in the regulation and execution of apoptosis; however, many mitochondrial proteins have been recently found to function in necroptosis. Adenine nucleotide translocase (ANT) and cyclophilin D (CypD), two important components of the mitochondrial permeability transition, regulate the exchange of ADP and ATP between the cytosol and the mitochondria (Halestrap and Brenner 2003). TNF-α and z-VAD-fmk treatment results in a mitochondrial defect in ADP/ATP exchange through the inhibition of ANT activity, which is dependent on RIP1 activation (Temkin et al. 2006). Mice lacking CypD are more resistant to cardiac ischemia and reperfusion injury than control animals and have reduced incidence of necrotic cell death (Nakagawa et al. 2005), suggesting that mitochondrial proteins such as ANT and CypD are important players in necroptosis and that mitochondria functions are also influenced in necroptosis.

Because mitochondria are the major producers of reactive oxygen species (ROS), which are important in executing necroptotic cell death (Festjens et al. 2006b; Moquin and Chan 2010), it is conceivable that RIP1 may directly or indirectly target the mitochondria. Treatment with butylated hydroxyanisole (BHA), a ROS scavenger, inhibits necroptosis in many cell types (Festjens et al. 2006a; Lin et al. 2004). RIP1 and RIP3 act on upstream signals to regulate ROS production during necroptosis. A recent study shows that RIP3 interacts with several mitochondrial enzymes including glycogen phosphorylase (PYGL), glutamate–ammonia ligase (GLUL), and glutamate dehydrogenase 1 (GLUD1) and leads to TNF-/z-VAD-induced ROS production. RIP3 overexpression activates these enzymes and enhances mitochondrial energy metabolism, a process that correlates with enhanced ROS production and necroptosis (Zhang et al. 2009). In contrast, RIP3 deficiency results in reduced ROS production and necroptotic cell death (Cho et al. 2009). Thus, the mitochondria and mitochondrial proteins are important targets for RIP3 or RIP1–RIP3 complex in necroptotic cell death.

2.3.5 JNK/ERK

In a siRNA screen for searching the regulators of necroptosis, transcription factors c-Jun and Sp1 are identified. However, both transcription factors can be activated by JNK signaling (Chuang et al. 2008; Coffey et al. 2002; Hitomi et al. 2008), suggesting that JNK may be downstream of necroptosis (Vanlangenakker et al. 2012). Biton and Ashkenazi recently reported that RIP1 is activated and further

activates NF-κB in the early-phase response upon extensive DNA damage; however, in the absence of caspase activation, RIP1 activates JNK3 pathway in the late-phase response, resulting in the activation of the transcription factor AP-1 and FADD-mediated caspase-8 activation (Biton and Ashkenazi 2011). As discussed above, MLKL contains a kinase-like domain which is similar to the mixed lineage kinase that functions as MAPKKs in the JNK pathway (Gallo and Johnson 2002). Therefore, after activation of MLKL by RIP3, MLKL may activate the downstream JNK pathway to execute necroptotic cell death. This is confirmed by Zhao et al.'s findings that MLKL is required for the late-phase activation of JNK in TNF-induced necroptosis in human colon adenocarcinoma HT-29 cells (Zhao et al. 2012). Although current evidences demonstrate the involvement of JNK in the downstream of necroptosis, more studies on its role in necroptosis are needed.

3 Cellular Markers of Necroptosis

For apoptosis and autophagy, many markers were used for the in situ detection in vitro and in vivo, including active caspase-3, cleaved PARP, DNA ladders, Beclin-1 and, microtubule associated protein 1 light chain 3 (Klionsky et al. 2007; Sarkar and Li 2006). Thus far, no specific morphological or biochemical markers are available for the detection of necroptosis. Regardless, many necrotic biomarker candidates and methods for the determination of necroptosis have been proposed recently.

Because the cellular nuclei, mitochondria, lysosomes, and plasma membrane are ruptured upon lethal stimuli on cells, intracellular cytoplasmic contents are released to extracellular spaces. Released proteins, such as high-mobility group box 1 protein (HMGB1), cyclophilin A (CypA), and cytokeratin-18, are regarded as candidate biomarkers of necroptosis (Christofferson and Yuan 2010; Kramer et al. 2004; Scaffidi et al. 2002). HMGB1 protein is a nuclear factor that acts as an architectural chromatin-binding factor, promoting protein assembly on specific DNA targets. When released from the cell, HMGB1 interacts with the receptors for advanced glycation end products and becomes a potent mediator of inflammation, signaling the demise of individual cells to its neighbors (Scaffidi et al. 2002). Since apoptotic cells do not release HMGB1 and fail to promote inflammation (Scaffidi et al. 2002), therefore, released HMGB1 is used to distinguish necrotic cell death from apoptotic cell death. However, its specificity is compromised because HMGB1 can also be actively secreted from immune cells or passively released from cells dying by secondary necrosis following apoptosis (Kazama et al. 2008; Scaffidi et al. 2002). Similar to HMGB1, CypA, a cytosolic peptidyl-prolyl *cis–trans* isomerase, is released in the early stage of necroptosis due to early permeabilization of the plasma membrane (Christofferson and Yuan 2010). Like HMGB1, CypA is also actively secreted; therefore, CypA release may combine with other methods together to determine the existence of necroptosis (Christofferson and Yuan 2010). Intact soluble cytokeratin-18 is released from necrotic cells; but cleaved cytokeratin-18 by caspases is released from apoptotic cells. The ratio of cleaved cytokeratin-18 to

intact cytokeratin-18 in the blood has been proposed as a marker to determine the extent of both types of cell death in patients with endometrial tumors (Kramer et al. 2004). Because not only necrotic cells contribute to intact cytokeratin-18 in the blood, this ratio may provide quantitative and qualitative information in those patients who have a significantly high level of cytokeratin-18 (Linder et al. 2010).

The combination of Tdt-mediated dUTP nick end labeling (TUNEL) staining and cleaved caspase-3 staining has been used recently to determine cell death types in dying cells (Gunther et al. 2011; Welz et al. 2011). Those cells with positive TUNEL staining and positive cleaved caspase-3 staining are considered as apoptotic cells; on the contrary, those cells with positive TUNEL staining and negative cleaved caspase-3 staining are considered as necroptotic cells. Since necroptotic cell death cannot be easily determined using a single method, it should be identified by a combination of methods.

4 Inhibitors and Interventions for Necroptotic Cell Death

Necroptosis is an important cellular death mechanism likely to be involved in human pathology, from viral infections to neurodegenerative disorders. Necroptotic features are commonly observed in a wide range of human pathologies, including stroke, myocardial infarction, brain trauma, and possibly some forms of neurodegeneration. Therefore, inhibition of necroptotic cell death by specific small-molecule inhibitors, necrostatins, may represent an exciting new direction for therapy.

4.1 Nec-1 and Its Analogs

Nec-1, a specific inhibitor of necroptosis, acts by inhibiting RIP1 kinase activity (Degterev et al. 2005). Nec-1 has become an important tool for evaluating the contribution of necrotic cell death in vitro and in many experimental animal models in vivo. By using Nec-1, necroptosis has been found in a wide range of cell death paradigms, including ischemic brain injury (Degterev et al. 2005; Xu et al. 2007). Nec-1 shows promising neuroprotection on cerebral ischemia injury for the reduction of infarct volume and the improvement of neurological deficits in middle cerebral artery occlusion (MCAO) mouse models (Degterev et al. 2005; Gu et al. 2010), suggesting that necroptosis is an alternative mechanism to activate delayed ischemic injury, due to its slow-onset kinetics. Nec-1 reduced acute cellular injury, brain tissue damage, motor dysfunction, and spatial learning deficits after controlled cortical impact (CCI) in mice; therefore, Nec-1 and other necrostatins may be promising therapeutic agents to reduce the pathological and functional impairment of traumatic brain injury (You et al. 2008). Moreover, Nec-1 rescues retinal neurons in the inner retinal layers, attenuates retinal degeneration, and reduces functional impairments after retinal ischemic injury (Rosenbaum et al. 2010).

Since the discovery of Nec-1, several structurally distinct Nec-1 analogs for necroptosis blockage have been developed: Nec-3 (Teng et al. 2008), Nec-4

(Teng et al. 2007), Nec-5 (Wang et al. 2007), and Nec-7 (Zheng et al. 2008). Nec-1, Nec-3, Nec-4, and Nec-5 all inhibit RIP1 kinase; however, Nec-7 does not, suggesting that Nec-7 may target a different regulatory pathway from Nec-1.

4.2 Necrosulfonamide

Like Nec-1, necrosulfonamide (molecular weight, 461) – another newly identified specific inhibitor of necroptosis – was selected by screening a chemical library of 200,000 compounds (Sun et al. 2012). Unlike Nec-1 which blocks the interaction of RIP1 and RIP3, necrosulfonamide specifically inhibits necroptosis by targeting MLKL, a key signaling molecule from the mitochondria in the necroptotic cell death pathway, downstream of the active RIP3 (Sun et al. 2012). Necrosulfonamide can block necroptosis at a specific step in different cells such as Jurkat cells, HeLa cells, and mouse 3T3 cells in response to TNF-α stimuli, by binding to the N-terminal of MLKL and covalently modifying MLKL at the reactive amino acid residue cysteine 86 (Sun et al. 2012). Moreover, necrosulfonamide also blocks staurosporine-induced primary necrosis in the presence of a caspase inhibitor in U937 cells (Dunai et al. 2012). Whether necrosulfonamide has inhibitory effects on necroptosis in different disease models in vivo or in vitro is unknown and needs further studies.

4.3 Geldanamycin

Because RIP1 has a critical role in RIP1–RIP3 complex formation and RIP1–RIP3-dependent necroptosis, RIP1 or RIP3 may be promising new targets for neuroprotection in neurological or other pathological disorders. Our recent study demonstrates that degradation of RIP1 offers an intriguing possibility to rescue necroptotic cells from death induced by oxygen–glucose deprivation (OGD) in the presence of the caspase inhibitor z-VAD (Chen et al. 2012b). RIP1 has low expression in normal cortical neurons, but OGD and z-VAD treatment significantly increases RIP1 expression and induces neuronal necroptosis. However, geldanamycin decreases RIP1 level and rescues OGD- and z-VAD-induced necroptosis (Chen et al. 2012b). Further study indicates that geldanamycin promotes the reduction of heat shock protein (HSP90), which is known to decrease the stability of RIP1 and facilitate the degradation of RIPK1 (Lewis et al. 2000). Therefore, geldanamycin and its analogs may be used for the treatment of stroke or other neurological disorders, by targeting the degradation of RIP1.

5 Necroptotic Cell Death in Neurological Diseases

5.1 Stroke

Stroke is the third leading cause of death and a leading cause of serious long-term disability. Due to the heavy economic and social burden caused by stroke

patients, an understanding of the pathophysiology of stroke is regarded as an urgent and critical research topic in many countries. Recent in vitro and in vivo studies demonstrated that necroptosis is an important process that contributes to neuronal cell death and functional impairment after cerebral ischemic injury (Chen et al. 2012b; Degterev et al. 2005; Meloni et al. 2011; Xu et al. 2010b).

Degterev et al. showed that the specific and potent inhibitor of necroptosis, Nec-1, when administered by intracerebroventricular injection along with the caspase inhibitor z-VAD, significantly reduces infarct volume and improves neurological functions in an MCAO animal model (Degterev et al. 2005). These findings imply that Nec-1 may protect against brain injury by blocking necroptosis when neuronal apoptosis is inhibited by caspase inhibitor z-VAD. Consistent with this, our findings indicate that the combination of apoptosis inhibitor humanin and necroptosis inhibitor Nec-1 provides synergistic protective effects on cerebral infarction and neurological function in mice (Xu et al. 2006; Xu et al. 2010b). By using an in vitro OGD ischemia model, a recent study demonstrated RIP1-dependent necroptosis induced by z-VAD treatment; geldanamycin, which promotes the degradation of RIP1, rescues OGD- and z-VAD-induced necroptotic cell death in culture cortical neurons (Chen et al. 2012b). A recent study with cell death biomarkers also identified that different forms of cell death including necroptosis exist in both acute and delayed OGD models (Meloni et al. 2011). These studies imply that necroptosis is a potential therapeutic target for the treatment of stroke.

5.2 Neonatal Hypoxic–Ischemic Encephalopathy (HIE)

Neonatal HIE is the most common cause of perinatal brain injury, resulting from pulmonary and/or cardiac dysfunction. Because of the similarity, rodent neonatal hypoxia–ischemia (HI) injury models are used to study the mechanisms of HIE (Ashwal and Pearce 2001). West et al. (West et al. 2006) demonstrates that caspase-3-deficient mice have greater tissue loss than controls after cerebral HI injury; caspase-3 knockout results in increased PARP-1-mediated caspase-independent cell death following HI. By using the same animal model, Northington et al. (Northington et al. 2011) found that Nec-1 significantly decreases brain injury in the forebrain and thalamus and decreases necrotic cell death, suggesting the existence of necroptosis in HI brain injury. They also showed that HI brain injury promotes necroptosis by increasing RIP1–RIP3 complex formation and inhibiting RIP3–FADD interaction and that mitochondrial dysfunction in neurons and astrocytes following neonatal hypoxia–ischemia is prevented by RIP1 activity inhibition (Chavez-Valdez et al. 2012; Northington et al. 2011). Therefore, the protection of necrostatin-1 on HI brain injury may represent a therapeutic strategy and new direction for therapy of neonatal HI.

5.3 Trauma

A recent study also demonstrates that RIP1-/RIP3-dependent necrosis appears to be involved in the mechanism of cell death and neurological dysfunction after traumatic brain injury (You et al. 2008). Necrostatin-1 administration significantly reduces brain lesion volume and motor deficits after controlled cortical impact in a trauma animal model but also improves spatial memory acquisition by Morris water maze performance. However, Nec-1 did not reduce caspase-3-positive cells in dentate gyrus or cortex, indicating that Nec-1 is not an apoptosis inhibitor, but a necroptosis inhibitor (You et al. 2008).

5.4 Huntington's Disease

Huntington's disease is a neurodegenerative genetic disorder characterized by movement abnormalities, psychiatric symptoms, and cognitive deficits. Zhu et al. (Zhu et al. 2011) recently examined the role of necroptosis in Huntington's disease by using Nec-1 as tool in immortalized striatal ST14A cells and R6/2 transgenic mice. In ST14A cells stably expressing mutant Htt fragment (N548-128Q), a cell model of Huntington's disease, the pancaspase inhibitor z-VAD induces caspase-3-independent cell death. Caspase-8-specific inhibitor (IETD-fmk), but not caspase-3- and caspase-9-specific inhibitor, induces a similar cell death as z-VAD in ST14A cells. Nec-1 almost completely rescues this kind of cell death and inhibits RIP1 cleavage induced by z-VAD or caspase-8 inhibitor IETD-fmk, supporting the notion that Nec-1 blocks RIP1-dependent necroptosis in ST14A cells (Zhu et al. 2011). In the R6/2 transgenic mouse model of Huntington's disease, Nec-1 treatment significantly delays the onset of Huntington's disease as well as behavioral deterioration and extends the life span, suggesting the involvement of necroptosis in the pathogenesis of Huntington's disease (Zhu et al. 2011). This study implies that necroptosis may be involved in other neurodegenerative disorders such as Parkinson's disease and Alzheimer's disease. Moreover, Nec-1 may be a promising protector in these diseases.

5.5 Glutamate Toxicity

Glutamate excitotoxicity is linked to neurological disorders such as stroke, Parkinson's disease, Huntington's disease, and Alzheimer's dementia (Beal 1992; Lau and Tymianski 2010). Glutamate excitotoxicity also causes neuronal death in cultured primary neurons in vitro (Chen et al. 2012a; Zhang et al. 2011b). Nec-1, as a necroptosis inhibitor and in the absence of caspase inhibitors, protects against glutamate analog *N*-methyl-D-aspartate (NMDA)-induced cell death in primary cortical neurons (Li et al. 2008). In this study, Nec-1 partially blocked NMDA effects, suggesting necroptotic involvement in NMDA-induced cell death. However, necroptosis only occupies a small portion of cell death without the induction of

caspase inhibitors. Non-receptor-mediated glutamate toxicity causes necroptosis in neuronal cells, as well (Xu et al. 2007; Xu et al. 2010a). In a hippocampal HT-22 cell line that has no ionotropic glutamate receptor, again, glutamate produces caspase-3-independent cell death. Nec-1 almost completely blocks glutamate-induced cell death, suggesting the involvement of necroptosis in glutamate-induced cell death in HT-22 cells (Xu et al. 2007). Further study indicates that the PARP-1/AIF pathway mediates necroptosis induced by glutamate in HT-22 cells (Xu et al. 2007; Xu et al. 2010a). These in vitro studies imply that glutamate toxicity may cause necroptosis in many neurological disorders, thus providing a new direction for treatments.

6 Conclusion

Necroptosis is a recently identified regulated cell death that has the morphological features of necrosis. Investigation into the regulation and signaling pathways of necroptosis represents one of the hot topics in cell death research. Recent findings throw light on the importance of necroptotic cell death in normal development, immunity, inflammation, cancer, and neurological disorders (Han et al. 2011; Vanlangenakker et al. 2012; Yuan and Kroemer 2010). An explosion of recent articles begins to unravel the mysteries centering on the necroptotic process. In response to external or internal stimuli, RIP1 and/or RIP3 are the determining factors at the central of the regulation platform of necroptosis to function as the switches between apoptosis to necroptosis. Pro-apoptotic proteins such as caspase-8, FLIPL, and FADD negatively regulate RIP1–RIP3 complex formation and inhibit the process of necroptosis. However, some factors such as CYLD, which deubiquitinates or modifies RIP1 and induces RIP1–RIP3 complex formation, positively promote necroptotic cell death. Although the complete signaling pathway remains unclear, recent advances have shown that mitochondrial enzymes MLKL and PGAM5 are directly downstream from RIP3 activation and that DRP1 may be one of the executioners of necroptosis. Due to complicated signaling pathways in the cells, more investigations are needed to remove the veil over this cell death process. The unraveling of the mechanisms governing necropototic cell death will lead to a better understanding of the interplay of necroptosis and other forms of cell death and the identification of new clinical targets.

Because of the lack of clear and distinctive biomarkers for necroptosis, it is difficult to determine the existence of necroptosis in animal disease models. In addition, it is hard to tell whether necroptosis is the only form of necrotic cell death. More specifically biomarkers need to be developed to effectively discern necroptosis in vivo. Thus far, only Nec-1 and NSA are considered as specific inhibitors for necroptosis – used as tools to examine necroptosis. Because these inhibitors may also block other cell death processes, it is possible that there is an overestimate of the portion of cell death deemed to be necroptosis.

Recent studies have examined the existence of necroptotic cell death in many neurological disorders such as stroke, trauma, and Huntington's disease. Because no specific biomarker is available, most studies used the neuroprotection of Nec-1

on cell death as the evidence for necroptosis. In addition, it remains difficult to understand the contribution to neurological pathogenesis; how great a percentage of necroptosis occurring in the pathology of neurological disorders is still difficult to estimate. The extensive studies on necroptosis hopefully will lead to the identification of specific necrotic biomarkers to resolve the many questions. Because caspase inhibitors promote necroptosis in vitro, does necroptosis play a critical role in the pathology of neurological disorders under the circumstances wherein there is no caspase inhibition? This remains an unanswered question. Recent studies demonstrate that mitochondrial dysfunction is involved in the mechanisms of necroptosis (Sun et al. 2012; Wang et al. 2012; Zhang et al. 2009; Zhao et al. 2012) and that mitochondrial dysfunction contributes to the pathophysiology of acute neurological disorders such as stroke and neurodegenerative disorders such as Parkinson's disease (Perez-Pinzon et al. 2012; Schon and Przedborski 2011; Vosler et al. 2009). Therefore, the connection between necroptosis and neuronal cell death in these disorders is in need of further investigation. Because of its potential involvement in neurological disorders, necroptosis has become a potential therapeutic target for these disorders. A clearer understanding of necroptotic mechanisms will provide new targets and exciting opportunities to develop more potent neuroprotective agents such as Nec-1 or necrosulfonamide for clinical treatments of neurological disorders.

RCSN Cell System for Identifying Dopaminergic Neurotoxicity

Pablo Caviedes, Raúl Caviedes, and Juan Segura-Aguilar

Contents

Abstract

Dopaminergic toxicity represents a potential mechanism underlying Parkinson's disease (PD) neuropathology. Nevertheless, the study of such a mechanism is hampered by the lack of permanent and stable in vitro models that bear relevant cellular traits, namely, neuronal dopaminergic function. Although various permanent cell lines exhibiting variable dopaminergic properties do exist, such properties are not necessarily stable and may require the application of complex and costly differentiation protocols for induction. The latter is particularly true when inducing in vitro differentiation from more undifferentiated tissue, such as stem cells. Also, cell lines may lose viability or eventually undergo permanent differentiation. This chapter discusses

a permanently growing cell line, named RCSN-3, which was established from the substantia nigra of an adult Fisher 344 rat. The cell line retains dopaminergic traits, including dopamine production and secretion, and the presence of catecholamine reuptake transporters. Notably, these properties have remained expressed in RCSN-3 cells for decades. This chapter also addresses the contribution of RCSN-3 to dopaminergic-mediated toxic phenomena, in particular, and to the identification of potential therapeutical targets in dopaminergic neurons. Finally, RCSN-3 cells are also presented as a model for cell transplant therapy, in animal models of PD, and their contribution in this field is discussed in relation to more recently available cell sources, such as stem cells and induced pluripotent stem cells (iPSCs).

1 Neurons in Culture: What Can They Do for Us?

The culture of neuronal cells has been widely used, as it presents an unparalleled opportunity to provide model systems for ready and unrestricted access to living tissue. Neurons, however, exhibit quite distinct features when taken from an in vivo to in vitro environments, which must be addressed to provide adequate answers for the questions to be asked. Indeed, neuronal tissue inherently has greater demands (i.e., oxygen, nutrients, trophic factors), which must be provided to insure adequate survival and maintenance of differentiated function in culture conditions (Freshney 2000). Among them, one can count the use of special matrixes for attachment and differentiation (collagen, laminin, fibronectin, extracellular matrix preparations, etc.), along with the supplementation of soluble factors in the media, which have a very wide range of complexity, ranging from monovalent ions to molecules of high molecular weight (Levi-Montalcini 1979; Marchionni 1993). These demands, associated with limitations in the quantities of procurable tissue, particularly from human origin, have prompted the interest in developing immortalized cell lines from neurons, which would potentially provide a limitless amount of cells and, hopefully, stable models for years to come. However, many such cell lines tend to exhibit problems in their stability and/or viability, with end results ranging from death to irreversible loss of differentiated functions (Cárdenas et al. 1999). Yet, if such drawbacks can be overcome, they appear as a feasible alternative, as they can generate genetically homogeneous cell populations that can be suitable models to explore physiological and pathophysiological phenomena at the cell level and also identify pharmacological targets which can be used for drug screening.

Following this line of thought, the use of tissue culture in dopaminergic systems appears as an adequate tool to study problems of clinical relevance, especially those related to relevant degenerative diseases such as Parkinson's disease (PD). Indeed, the discrete localization of the neuropathological hallmark

in this condition – namely, the degeneration of the *substantia nigra pars compacta* (SN) – presents dopaminergic culture systems as ideal models for the study of PD cell pathophysiology. This chapter will refer to such models, and it will particularly address a specific neuronal cell line, named RCSN-3, which was established from the substantia nigra of an adult Fisher 344 rat. Evidence of its use in the study of potential toxic mechanisms relevant to PD will be discussed, along with future directions.

2 Parkinson's Disease: Where We Stand...

Parkinson's disease is a neurodegenerative disorder affecting an estimated 0.3 % of the population in the industrialized world (de Lau and Breteler 2006), the elderly being the highest population at risk. The disease is progressive in nature, and there are no effective treatments to arrest or revert the evolution of the disease. The clinical manifestations of PD are several, and presentations vary greatly among patients. The most evident include signs and symptoms that affect voluntary movement, which include resting tremor in the extremities and muscular rigidity, which leads to difficulties in walking with a characteristic shuffling gait. Also, impaired writing, speaking, and masking of facial expression are present. Bradykinesia, or slowness in initiating and executing movements, and stooped posture and instability are also commonly observed signs (Sian et al. 1999). Neuropsychiatric manifestations (mood disorders, altered thought process, cognitive decline) may also be present (Jankovic 2008), particularly in later stages of the disease, thus presenting PD as a far more complex condition than one that merely compromises motor function. At the neuropathological level, the most remarkable finding is the degeneration of the dopaminergic neurons present in the SN. These neurons project to the striatum, providing the latter with a basal dopaminergic input necessary for the adequate function of the regulatory circuit of the basal nuclei. The degeneration of the SN determines an imbalance in the regulation of the circuitry of the basal ganglia, whose GABAergic output to the thalamus is increased, resulting in an overall inhibition of this projection nucleus (Lozano et al. 1998). Hence, messages processed in the basal ganglia which project to the cerebral cortex via the thalamus have an increased inhibitory component in PD, especially those coding for voluntary movement, resulting in reduced motility.

The mechanisms for the progressive degeneration of the SN in PD remain largely unknown, in particular for sporadic forms of PD. A small minority of patients with mutations in certain genes such as alpha-synuclein, parkin, leucine-rich repeat kinase 2 (LRRK2), or PTEN-induced putative kinase 1 (PINK1) will develop the disease with a high degree of certainty (Davie 2008; Lesage and Brice 2009). Yet, the mechanisms of toxicity remain obscure, in particular at the cellular and molecular level. Therefore, the development of neuronal in vitro cell models

that resemble SN function is of the essence in order to address such questions and in turn identify relevant intracellular therapeutical targets.

3 Ex Vivo Dopaminergic Cells: What can They do to Help?

Many strategies are being pursued to develop new therapies for PD patients, mainly targeting to the prevention of the damage of the nigrostriatal system (neuroprotection or rescue) and/or to replacing neurons that were lost due to the underlying condition. Efforts in this regard have included the use of trophic factors (Takayama et al. 1995) and viral vectors (Choi-Lundberg et al. 1997) for protection and rescue, to the transplantation of primary xenogeneic or allogeneic tissue for repair (Deacon et al. 1997). Nevertheless, progress in the knowledge of mechanisms is hampered, firstly, by the lack of animal models that adequately reflect the human condition. Indeed, PD does not occur naturally in other mammals, and most animal models involve acute destruction of the SN by use of toxins, most of which share structural resemblance to dopamine (DA) (i.e., 6-OH-dopamine intoxicated rats; 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-intoxicated monkeys) (see Fig. 1). Hence, such models do not reproduce the inherent chronic damage of the SN in PD and tend to target a reduced number of many potential mechanisms involved in dopaminergic degeneration. Indeed, such toxins result in rapid and sizable oxidative stress and/or energy depletion, which are most probably not solely responsible for cell damage. Other models have incorporated transgenics for known PD-related genes, including knockouts of alpha-synuclein (SNCA) or overexpression of mutated forms of this protein (Blandini and Armentero 2012). In spite of such progress, no such models reproduce all the characteristics of PD, and the aforementioned models tend to address specific questions of a given mechanism.

The first approach to a given condition must address alterations at the cellular level, a goal that is difficult to attain in a full animal, where many variables escape from the control of the researcher. Initially, in vitro models comprised primary cultured cells, which tend to reflect more closely the traits of the tissue of origin. Yet, the inherent variability of such preparations and limitations in the amounts of tissue procurable conspire against presenting these models as a universal preparation. The use of neuronal cell lines overcame the noted limitations in quantities of tissue, yet long-term instability and eventual permanent dedifferentiation are but two factors that can hinder their usefulness. Nevertheless, dopaminergic cell lines have been used for quite some time. The PC12 cell line, which is derived from the pheochromocytoma of a rat (Greene and Tischler 1976), has been and is still largely used to study dopaminergic and neuronal function, yet it is tumorigenic, it is difficult to grow, and it requires nerve growth factor (NGF) for neuronal differentiation in vitro. Another interesting cell line, SH-SY5Y, derived from the neuroblastoma of a child, has also been used to study dopaminergic function, especially since it has dopamine-β-hydroxylase activity (Oyarce and Fleming 1991), thus suggesting the presence of catecholaminergic function, yet it does not derive from a dopaminergic precursor.

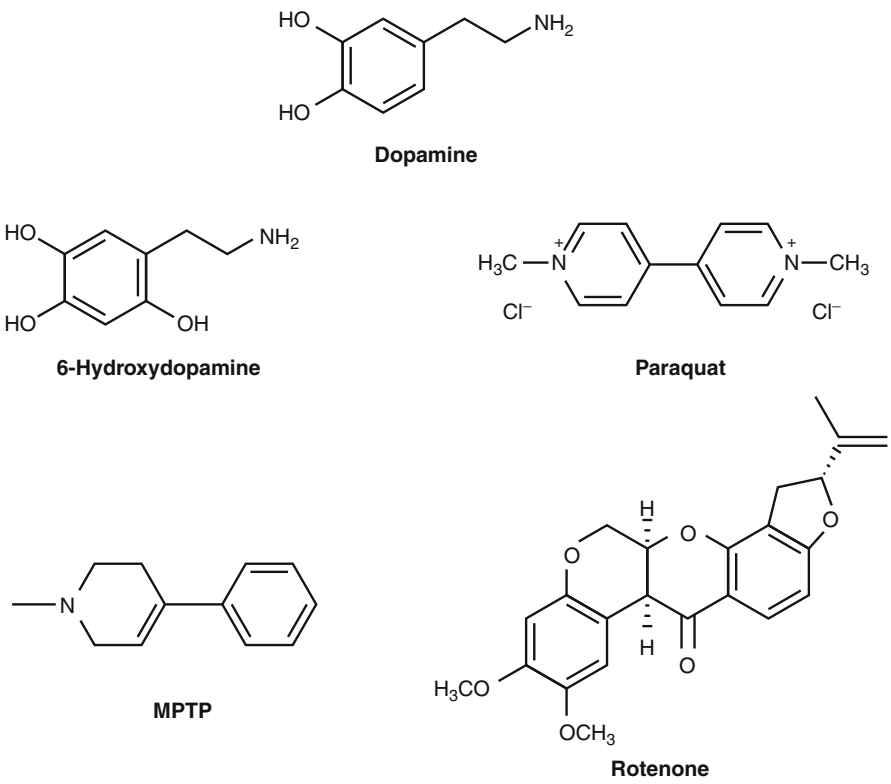

Fig. 1 Dopamine and toxins of dopaminergic system. Many known toxins of dopaminergic neurons share structural similarities with dopamine, thus entering dopaminergic neurons via dopaminergic reuptake transporters. 6-Hydroxydopamine generates reactive oxygen species such as superoxide radical inside the cells. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is the precursor of the neurotoxin MPP^+ (1-methyl-4-phenylpyridinium), which, once inside dopaminergic neurons, interferes with complex I of the electron transport chain. Rotenone interferes with the electron transport chain in mitochondria, particularly by inhibiting the transfer of electrons from iron-sulfur centers in complex I to ubiquinone, in turn interfering with NADH in the creation of ATP. Paraquat, a known herbicide, can catalyze the formation of reactive oxygen species (ROS), particularly superoxide

Lately, stem cells, derived from the nervous system (neural stem cells), have been used to generate sufficient cell mass to later differentiate to dopaminergic cells. Yet, the reduced amount of cells, slow in vitro proliferation, and the ethical and practical difficulties involved in procuring viable human nervous tissue do introduce difficulties in this line of work. At present, one of the most interesting lines of research involves reprogramming human fibroblasts from patients to generate induced pluripotent stem cells or iPSCs. Such cells can generate patient-specific cells that can later be differentiated to dopaminergic neurons (Swistowski et al. 2010).

4 RCSN-3: A Permanent In Vitro Neuronal Dopaminergic Model

All of the aforementioned cell models are and have been useful in the study of the neuronal physiology and pathophysiology of PD. Yet, limitations in growth rate, in differentiation, and in the source of tissue define most of their limitations, whereas lack of stable, relevant dopaminergic functional traits is another drawback. Hence, a stable dopaminergic neuronal cell line, derived from SN tissue that retains differentiated traits, would provide a valuable model to test PD-related phenomena at the cell level. In this regard, RCSN-3 appears as an interesting candidate for such tasks.

RCSN-3 was established in the early 1980s, from primary cultures of the SN dissected from a 4-month-old Fisher 344 rat (Arriagada et al. 2002). The cell line was established from the said primary cultures by means of the UCHT1 immortalization protocol (Caviedes et al. 1993, 1994; Cárdenas et al. 1999, 2002). This original procedure has managed to successfully generate neuronal cell lines in permanent culture from diverse origins, obtained from both normal and pathological subjects (Caviedes et al. 1993; Liberona et al. 1997; Allen et al. 2000). Briefly, the immortalization procedure entails maintaining neuronal primary cultures in the presence of media conditioned by the rat thyroid cell line UCHT1. This treatment induces tissue immortalization in variable periods of time (Caviedes et al. 1993). This procedure has allowed the establishment of continuously growing cell lines that express stable neuronal phenotypes and lack glial characteristics. These and other lines so established retain differentiated traits, some for decades (Caviedes et al. 1993; Liberona et al. 1997; Cárdenas et al. 1999; Allen et al. 2000 and 2005).

After a period of 7–8 months of UCHT1 treatment, transformation foci of rapid proliferation became evident, after which the cultures were weaned from UCHT1 media. The resulting motherline, named RCSN, was subsequently cloned. Of these, RCSN clone 3, or RCSN-3, has been the line that stably retains dopaminergic traits. The RCSN-3 cell line grows in monolayers and can also be induced to grow in suspended, attachment-free clusters (Fig. 2) (Caviedes et al. 2012). RCSN-3 has a doubling time of approximately 50 h, a plating efficiency of 21 %, and a saturation density of 50,000 cells/cm^2 when grown in basal growth media composed of DMEM/HAM-F12 nutrient mixture (1:1), 10 % adult bovine serum, 2.5–5 % fetal bovine serum, and 40 mg/l gentamicin (Dagnino-Subiabre et al. 2000; Paris et al. 2001; Martinez-Alvarado et al. 2001).

Regarding their neuronal trails, RCSN-3 cells are immunohistochemically positive for neuron-specific enolase (NSE), MAP-2, 200 kD neurofilament, and parvalbumin. Further, RCSN-3 cells exhibit intracellular melanin deposits, as evidenced by Fe^{2+} ion capture cytology studies (Arriagada et al. 2002). On the other hand, glial markers such as GFAP and S-100 are negative (Arriagada et al. 2002). Regarding dopaminergic function, the cells express tyrosine hydroxylase (TH) in basal culture conditions, with increased labeling after differentiation with serum deprivation (Arriagada et al. 2002; Paris et al. 2008). They also

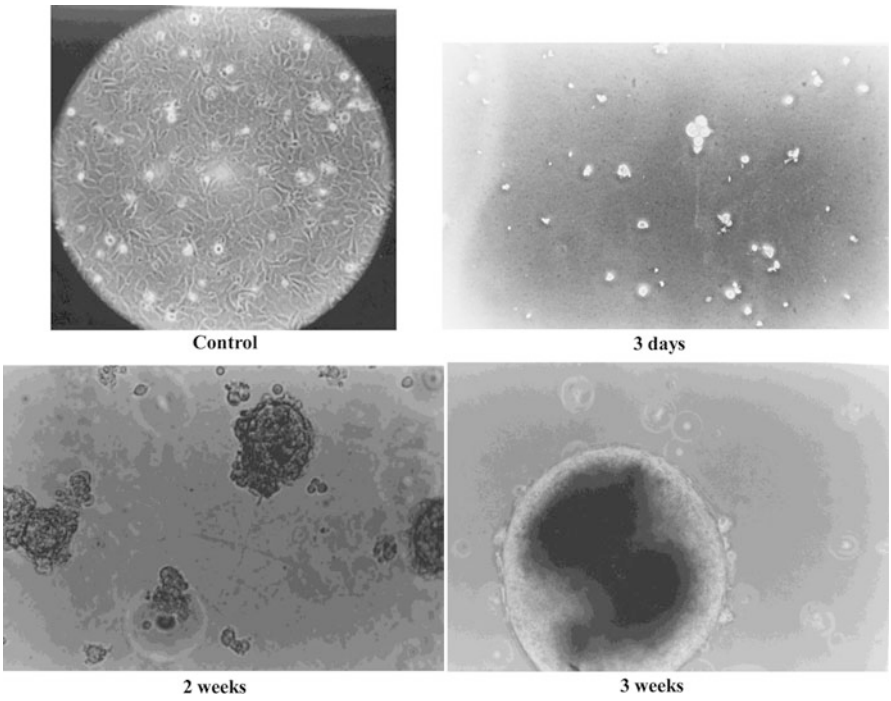

Fig. 2 RCSN-3 cells grow in monolayers when kept in standard growth media. When subjected to culture protocols that disfavor attachment (Caviedes et al. 2012), RCSN-3 cells grow in suspension and cluster progressively

show fluorescent labeling in the cytoplasm after treatment with paraformaldehyde-glyoxylic acid, suggesting the presence of catecholamine content. Experimental evidence of active DA release by RCSN-3 cells has been obtained with HPLC studies of culture supernatant and single cell amperometry with carbon electrodes, both of which are highly suggestive that RCSN-3 is capable of secreting this neurotransmitter. Further, RCSN-3 cells express a number of transporters, such as norepinephrine, serotonin, and, interestingly, DA (Paris et al. 2008). Hence, this is the only known dopaminergic cell line that originated from the SN of an adult animal and thus an attractive model to study PD-related mechanisms, in particular those related to dopaminergic toxicity.

5 Can Dopamine be Harmful? How?

Firstly, the causes for the discrete compromise of dopaminergic neurons of the SN in PD patients remain a mystery. Yet, DA itself may have a role. As a catecholamine, DA has a catechol ring with two hydroxyl groups in positions 4 and 5 (Fig. 1). In physiological conditions, such hydroxyl groups may remain

reduced due to several mechanisms, such as inclusion in low-pH secretory vesicles, reduction by several scavenging enzymes, and formation of neuromelanin. An imbalance in such mechanisms could shift the balance of the redox state of such hydroxyl groups to a more oxidative stage – namely, superoxide – this introducing a potential pro-oxidative state. Considering the specificity of the lesions in PD, it is possible then that the high oxidative state associated with DA metabolism may cause deterioration of dopaminergic neurons. The mechanism underlying increased oxidative stress may involve DA itself, because oxidation of cytosolic levodopa/DA may be deleterious to neurons. Indeed, DA causes apoptotic cell death as shown by morphological nuclear changes and DNA fragmentation (Luo et al. 1998). DA and its metabolites seem to exert cytotoxicity mainly by generating highly reactive quinones through auto-oxidation (Martinez-Alvarado et al. 2001). On the other hand, the toxicity of DA may be due to the generation of reactive oxygen species (ROS) that could disrupt cellular integrity, causing cell death. Indeed, aberrant regulation of DA is accompanied by accumulation of DA metabolites that could induce toxicity (Arriagada et al. 2004; Hattori et al. 2009).

The possibility that environmental factors may play a role in sporadic PD was addressed over a decade ago (Tanner et al. 2009). Epidemiological risk factor analyses of typical PD cases have identified several neurotoxins, including the aforementioned active metabolite of MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium ion (MPP^+), paraquat, dieldrin, manganese, copper, and salsolinol (Chun et al. 2001; Paris et al. 2008). Regarding MPP^+, Chun et al. (2001), using a nigral dopaminergic cell line, SN4741, demonstrated that such neurotoxins can induce apoptotic cell death through a common molecular mechanism. These authors observed initial increases in H_2O_2-related ROS activity, followed by activation of JNK1/2 MAP kinases; activation of the PITSLRE kinase, p110, by both caspase-1- and caspase-3-like activities; and, finally, apoptotic cell death. Pharmacological intervention with combinations of the antioxidants significantly protected the cells against such damage.

The SN4741 model would then appear as an interesting model to study PD-relevant pathophysiology. Yet, this line was established from transgenic mouse embryos containing the targeted expression of the thermolabile SV40Tag in SN neurons. Cell lines generated in this fashion tend to show instability and loss of function (Frederiksen et al. 1996), a problem not reported for UCHT1-established cell lines. Further, SN4741 cells are embryonic in origin and require differentiation in vitro. In this regard, RCSN-3 cells express dopaminergic traits without need of lengthy or costly differentiation protocols, and it has retained such traits for years. Interestingly, they also undergo toxicity and death upon exposure to such the aforementioned neurotoxins (Paris et al. 2008). Also, the RCSN-3 cell line expresses the reuptake transporters for DA (DAT) and norepinephrine (NET) (Paris et al. 2005). These properties of RCSN-3 cells allowed the discovery of a novel mechanism involving heavy metal toxicity (Cu^{2+}, Fe^{2+}) related to formation of complexes with dopamine (Paris et al. 2001, 2005); and their subsequent entry into the cell specifically by these transporters has provided new

light on how such environmental factors can contribute to PD pathogenicity. Indeed, by using highly efficient transport systems, heavy metals can then enter rapidly, generating oxidative stress in submitochondrial compartments via the Fenton reaction (Thomas et al. 2009).

Inside the cell, DA can induce toxicity, in particular when its redox state is shifted toward more pro-oxidizing conditions. Indeed, DA-oxidized metabolites can inhibit the respiratory chain in mitochondria (Ben-Shachar et al. 2004), thus producing an energy crisis in the cell. In this regard, RCSN-3 cell can undergo toxicity phenomena with treatment of DA oxidation products such as aminochrome treatment, once reductases such as DT-diaphorase are inhibited (Arriagada et al. 2000, 2004). RCSN-3 cells also express the vesicular monoamine transporter-2 – VMAT-2 (Fuentes-Bravo et al. 2007). When this transporter was selectively inhibited with reserpine, exposure of cell to external DA induced clear apoptotic phenomena, such as blebbing and chromatin condensation. Also, mitochondrial damage was evident at the electron microscopy level (Fuentes-Bravo et al. 2007).

6 Cell Transplantation in PD: The Final Frontier?

Cell transplantation therapy was proposed several decades ago as a curative therapy for PD. The rationale for such an approach was based on the discrete anatomical location of the neuronal population compromised and the fact that dopaminergic output from the SN to the striatum has a rather tonic form of discharge. Hence, replacing such tissue with new, DA-secreting cells appeared as clinically promising experimental treatments, in particular in late-stage PD, where tissue replacement is essential. Efforts so far have reached the clinical setting in PD and other neuropathological conditions, using sources such as fetal tissue (Olanow et al. 2006), xenografts from porcine tissue (Borlongan and Sanberg 2002; Poncelet et al. 2009), and immortalized cell lines (Prasad et al. 1998; Paul et al. 2007; Miljan et al. 2009). Indeed, considering that PD patients develop symptoms when approximately 50–70 % of the dopaminergic neurons in the SN are lost (Lozano et al. 1998), the development of cell transplant models appears as a necessary step in the cure for the disease. This is also relevant in light of the lack of predictive markers of the disease; hence, diagnosis is clinical and essentially tardy. Further, the discrete anatomical localization of the degenerating tissue and the large size of the target nucleus (striatum) make it a likely candidate for cell transplant therapy with minimally invasive stereotaxic procedures. In this regard, dopaminergic cell lines can provide a model for testing such therapeutical approaches, considering the existence of relevant animals models such as the 6-OHDA rat and MPTP-intoxicated monkeys. Cell lines are easy to manipulate, and genetic modifications set forth to improve dopaminergic function and/or life expectancy of the graft (i.e., transfection with genes that encode for neurotrophic factors) may provide pertinent, useful information to determine conditions that optimize these functions in transplantable dopaminergic cells.

7 Cell Therapy: RCSN-3 Contribution and the Use of Induced Pluripotent Stem Cells (iPSCs)

RCSN-3 cells have also been used as in cell transplant approaches, using induced PD animal models. Indeed, implant of RCSN-3 in the striatum of 6-OHDA-intoxicated rats resulted in a stable reduction of around 50 % in apomorphine-induced rotations. Lately, the development of methodologies to generate pluripotent stem cells from somatic tissues (iPSCs) has provided researchers with an interesting source of stem cells, with the important added value of being patient specific. Hence, the first advantage of iPSC technology is the generation of relevant in vitro models for diseases and drug treatment assays (Soldner et al. 2009). Further, protocols to increase the yield of dopaminergic neuron generation from iPSC from either humans or mice are now available (Park et al. 2008; Soldner et al. 2009; Hargus et al. 2010; Devine et al. 2011). Indeed, neural precursor cells and dopaminergic neurons have been generated from healthy iPSC (Wernig et al. 2008), which when transplanted in the brain can integrate in the parenchyma, migrate, differentiate, and display neuronal function such as action potentials. Most interestingly, grafts derived from iPSC are capable of restoring motor function in animal models for PD (Wernig et al. 2008), suggesting that dopaminergic neurons derived from iPSC can survive implantation and remain functional in vivo.

In humans, iPSC-derived dopaminergic neurons have been obtained from healthy donors (Swistowski et al. 2010), sporadic PD patients (Soldner et al. 2009; Hargus et al. 2010), or PD patients bearing some of the known mutations (Devine et al. 2011; Martínez-Morales and Liste 2012). For instance, DA neurons can be generated from iPSCs that carry a mutation in *LRRK2* gene (p.G2019S), the most common PD-related mutation (Drolet et al. 2011). After reprogramming, and applying a culture differentiation protocol using feeders, iPSC-p.G2019S generated significant amounts of DA. This constitutes the most interesting application for such models, as "custom" therapies can potentially derive from such unique models.

8 Conclusion

Overcoming neurodegenerative diseases, of which PD represents an important fraction, is the most demanding challenge. Relevant therapies will come from the understanding of cellular and molecular mechanisms involved in cell damage, along with the development of predictive markers. The lack of the latter introduces yet another limitation in the quest for new therapies, where neuroprotective strategies are clearly at a loss.

Relevant cell models are a must in the undertaking of both the aforementioned tasks. Novel treatments require models such as RCSN-3 cells for first-level screening and may also play a part in the study of predictive markers. The development of iPSCs is the most exciting chapter in the field, as they can provide disease-specific models from patients. Eventually, they may constitute adequate

sources for cell transplant therapy. Yet, much is to be said about the long-term stability of iPSCs; hence, their routine application to cell transplant therapy may be further away than desired, as well as their application as in vitro models. Until that day, well-established models like RCSN-3 will have a role in addressing the problem at hand.

Microglia: Neuroprotective and Neurodestructive Properties

G. Jean Harry and Christopher A. McPherson

Contents

Abstract

In the central nervous system, resident macrophages, microglia, and perivascular macrophages perform similar functions to peripheral macrophages yet display highly specialized features. They maintain some phenotypic characteristics and lineage-related properties common to their cells of origin and their rapid response in areas of neuronal death led to the contention that microglia serve as brain macrophages. While microglia are often considered the immune cell of the brain, they also show distinct features that make them unique from other tissue macrophages. They are maintained in a relatively quiescent and monitoring state by regulatory factors released by neurons and astrocytes. Via contact-dependent and receptor-dependent signaling, microglia rapidly respond to various events in the brain in an effort to return the microenvironment to homeostasis, to assist in refining the neural network

during development and with repair, and to remove excess and aberrant proteins. Depending on the nature of the response and the physiological function of the microglia, a release of immune-related signaling factors can accompany a morphological change. It was initially thought that the immune-related response of microglia mirrors that of peripheral macrophages and considered to be adverse to the nervous system. However, further evaluation of these cells suggests that overall their responses are ones critical to the maintenance and function of the nervous system. This chapter will serve to set the framework for evaluating the microglia within the context of data available on their varied functions within the nervous system.

Keywords

Cytokines • Microglia • Neurodegeneration • Neuroinflammation • Pattern recognition receptors

List of Abbreviations

AD	Alzheimer's disease
AMPA	Alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid
ApoE	Apolipoprotein
ATP	Adenosine triphosphate
$A\beta_{42}$	Amyloid-beta 42
BBB	Blood–brain barrier
Ca^{2+}	Calcium
CNS	Central nervous system
COX	Cyclooxygenase
CR	Complement receptor
CSF	Colony-stimulating factor
CX3CL1	Fractalkine
DAMPs	Danger-associated molecular patterns
Fc	Fragment, crystallizable region
HO-1	Heme oxygenase-1
HSP	Heat shock protein
IFN	Interferon
IL	Interleukin
iNOS	Inducible nitric oxide synthase
LPS	Lipopolysaccharide
mGluR	Metabotropic glutamate receptor
MHC	Major histocompatibility complex
MMP	Matrix metalloproteinase
MPP+	1-methyl-4-phenylpyridinium
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
NF-κB	Nuclear factor kappa B
NLRs	NOD-like receptors
NO	Nitric oxide

NOS	Nitric oxide synthase
NOX2	NADPH oxidase
P2	Purinergic
PAMPs	Pathogen-associated molecular patterns
PD	Parkinson's disease
PRRs	Pattern recognition receptors
RAGE	Receptor for advanced glycation end products
RNS	Nitric oxide-dependent reactive nitrogen species
ROS	Reactive oxygen species
SN	Substantia nigra
TGF	Transforming growth factor
TLR	Toll-like receptor
TNF	Tumor necrosis factor
TREM-2	Triggering receptor expressed on myeloid cells-2

1 Introduction

Macrophages are phagocytic cells originating from precursor cells in the bone marrow that are transported via the peripheral blood as monocytes to become tissue-specific macrophages (Davoust et al. 2008; Ginhoux et al. 2010; Morris et al. 1991). These cells maintain a first line of defense against injury and infection to return the system back to homeostasis by recruiting various effector molecules and other immune cells to assist in the task of killing pathogens and restoring tissue integrity (Gordon and Martinez 2010; Mosser and Edwards 2008). Two arms of the immune system, a rapid innate immune response and a slow adaptive immune response, are responsible for these functions (Lo et al. 1999). Innate immune receptors are preformed and stably encoded in the genome, while those of the adaptive immune system are both stochastically generated and shaped by the types and frequency of pathogens the cell encounters. First-responder cells rapidly recognize and respond to cell damage or infection-related danger-associated molecular patterns (DAMPs) increasing phagocytic activity. They also respond to pathogen-associated molecular patterns (PAMPs) expressed by pathogens (e.g., lipopolysaccharide (LPS)) but not by host cells. In responding, there is a production of cytotoxic reactive oxygen species (ROS), nitric oxide (NO), and proinflammatory cytokines such as tumor necrosis factor (TNF), interleukin (IL)-1, and IL-12. The second arm provides adaptive immunity to detect and respond to novel as well as evolutionarily conserved pathogenic molecules, i.e., antigens (Lo et al. 1999; Schwartz and Kipnis 2011). The adaptive immune system is comprised of long-lived lymphocytes (T cells and B cells) and antigen-presenting cells. The antigen-driven expansion of clonal populations of lymphocytes allows for experience to shape the response and for establishment of memory lymphocytes that are able to more rapidly attack a reencountered antigen.

Under such conditions, antigen-presenting cells play a critical role by phagocytizing material, loading the captured antigen into the pocket of the major histocompatibility complex (MHC) molecule for cell-surface antigen presentation on B cells, macrophages, and dendritic cells to facilitate recognition and clearance (Lo et al. 1999).

In the central nervous system (CNS), resident macrophages, microglia, and perivascular macrophages perform similar functions to peripheral macrophages yet display highly specialized features. In a temporal and spatial manner, monocyte colonization of the brain occurs with tissue vascularization and contact with vascular sprouts prior to birth (Cuadros and Navascues 1998; Marin-Padilla 1985; Rymo et al. 2011). The resulting microglia are yolk-sac derived cells maintained independently of blood-borne hematopoietic progenitors (Ajami et al. 2007; Ginhoux et al. 2010). They maintain some phenotypic characteristics and lineage-related properties common to macrophages, e.g., phagocytosis, expression of Fc (fragment, crystallizable region) receptors, and complement receptor (CR)3. The rapid response of microglia to areas of neuronal death and shift in morphology to an amoeboid phagocytic phenotype support early contentions that microglia served as brain macrophages. While T cells actively monitor the brain and can be recruited to sites of injury or infection, they do not remain or become functionally active unless a stimulating antigen is present. In the CNS, infiltrating and resident myeloid cells express MHC class II (Carson et al. 2006; Siffrin et al. 2007), while neurons, astrocytes, and oligodendrocytes are not players in antigen-mediated activation or retention of CD4+ T cells. Similarities between peripheral and central macrophages have led to assumptions that the innate immune system in the CNS equates to the parallel peripheral system and that expression of various factors such as MHC II or cytokines by resident cells of the brain represents neuroinflammation that can occur in the absence of peripheral immune cells. However, this independent capability of CNS immune cells comes under question with regard to whether the cellular response of microglia demonstrates neuroinflammation or simply the diverse nature of the cell (Graber et al. 2011).

Microglia are distinct from other tissue macrophages by their relatively quiescent phenotype and tight regulation by the microenvironment. Microglia display a small amount of perinuclear cytoplasm; small, dense, and heterochromatic nucleus; and several long processes with multiple branches covered with very fine protrusions. They are located outside of the vascular basement membrane; however, the cytoplasmic processes intermingle with astrocytic foot processes in the perivascular glia limitans (Lassmann et al. 1991). Perivascular microglia are limited along vascular walls and distinct from perivascular cells (Graeber et al. 1990). Microglia comprise approximately 15–20 % of the total number of cells in the mature brain. Occupying defined spatial territories, they actively survey the surrounding parenchyma via dynamic movement of processes, while the soma remains static, allowing each cell to sample its environment over the course of a few hours (Davalos et al. 2005; Nimmerjahn et al. 2005). The physical extent of this surveillance depends upon distribution, individual cell ramification, regional location, and rate of process remodeling.

2 Distribution of Microglia

Differences in microglia localization and morphology (Fig. 1) are suggested to be associated with functional differences and the phenotypic heterogeneity, including receptor expression patterns (Olah et al. 2011). Early evaluations by Lawson et al. (1990) showed a relatively uniform distribution of microglia in the adult rodent brain, with the exception of a higher relative number of microglia with similar phenotype in the dentate gyrus of the hippocampus, the substantia nigra (SN), and portions of the basal ganglia and the highest number of microglia in the olfactory telencephalon. Microglia modify their morphology and expression of cell-surface antigens depending upon their environment (Kaur and Ling 1991). Ramified microglia in gray matter show processes extending in multiple directions, while in the white matter, cells align cytoplasmic extensions in parallel or at right angles to nerve processes. In regions lacking a blood–brain barrier (BBB) such as circumventricular organs, a less ramified morphology is observed (Perry and Gordon 1987).

3 Microglia Network and Response

Microglia are in constant contact with other cells of the brain maintaining interactions with astrocytes, oligodendrocytes, and neurons, as well as brain vasculature. However, the cells do not normally demonstrate a direct intercellular coupling such as through gap junctions (Eugenin et al. 2001); therefore, communication is considered to rely heavily on auto- and paracrine signaling. It is thought that microglia are maintained in a relatively quiescent state due to signals derived from neuronal and astrocyte-derived factors specifically targeted to this regulatory task (Biber et al. 2007; Cardona et al. 2006; Simard et al. 2006). Healthy neurons are able to maintain microglia in an inactive state via secreted and membrane-bound signals including CD200, CX3CL1 (fractalkine), neurotransmitters, and neurotrophins (Biber et al. 2007; Neumann 2001; Pocock and Kettenmann 2007). In the absence of these signals or in the presence of stimulatory signals, the dynamic surveillance feature allows microglia to rapidly respond to changes in the environment. This is demonstrated in mice deficient of CD200 in which microglia exhibit a less ramified and shorter processes morphological phenotype, increased expression of CD11b and CD45, and elevated production of inflammatory mediators following immune challenge (Hoek et al. 2000).

With stimulation, microglial response patterns are highly varied across morphological changes. Often the initial response of microglia is to monitor and control the extracellular environment. These ever-changing phenotypes represent the unique nature of the insult as well as the ability of the cells to respond in a graded manner to changes in their environment (Graeber and Streit 2010) and to shift within any specific stage of the response (Stout et al. 2005). The phagocytic feature of these cells serves to remove excess cellular debris and aberrant proteins such as apolipoprotein E (ApoE), mutant huntingtin, or amyloid beta 42 ($A\beta_{42}$).

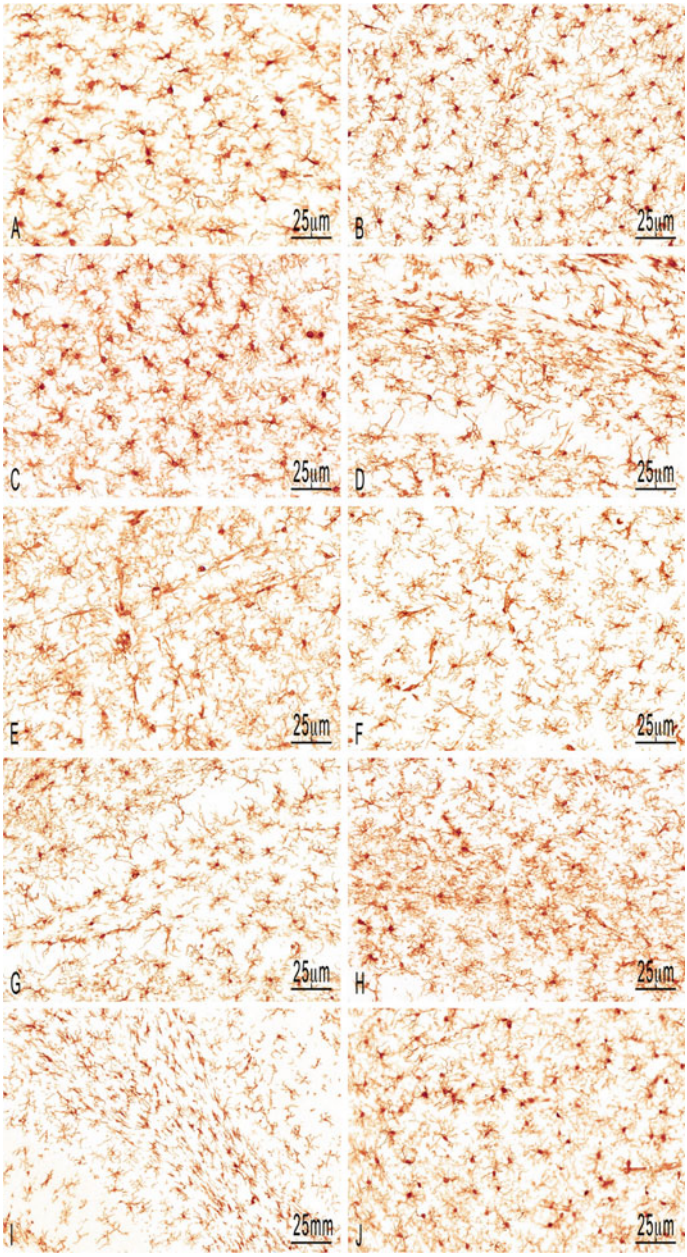

Fig. 1 Representative Iba-1+ microglia in various regions of the rat brain. (**a**) Frontal cortex, (**b**) motor cortex, (**c**) retrosplenial agranular cortex, (**d**) corpus callosum, (**e**) striatum, (**f**) thalamus, (**g**) hippocampal dentate hilus, (**h**) hippocampus molecular layer, (**i**) cerebellum, (**j**) olfactory bulb. Images from 40 m sections were scanned at 20× magnification using an Aperio Scanscope T2 Scanner (Aperio Technologies, Inc., Vista, CA) and viewed using Aperio Imagescope v. 6.25.0.1117

Microglia activities observed in neuroimmunological disorders, such as multiple sclerosis, and their related function to remove myelin debris are a classical representation of the cell's macrophage and antigen-presentation role. This is characterized by prototypical pathology dominated by perivascular mononuclear infiltrates, residual fibrosis of blood vessels, and demyelinating lesions (Barnett et al. 2009; Stadelmann 2011). In an autoimmune disease such as MS, microglia serve in reactivation of infiltrating T cells (Coyle 2011). In contrast, microglial activation observed with a sterile insult does not involve antigen-based interactions with T cells or a predominant infiltration of peripheral immune cells. A strong microglia reaction occurs at the primary site of injured neurons progressing temporally and spatially to recruit responses in areas that are projection sites to and from the area of damage (Graeber and Kreutzberg 1988; Jensen et al. 1999; Sanders and Jones 2006). While anterograde and retrograde degeneration of neuronal projections most likely causes a microglial reaction in the first-order projection areas, other mechanisms, like neuronal ionic balance, likely drive the microglia response in more distant and remote areas. Even within a focal injury site, a graded level of response can be observed. For example, with an ischemic or physical lesion to the brain, the microglia rapidly wall off areas of the CNS from non-CNS tissue and remove dead, damaged, or dysfunctional cells, while in the periphery of the injury, the cells likely perform a survival function.

4 Cell-Responsive Interactions

While a number of mechanisms have been proposed for cell-responsive interactions of microglia, many associated with ionic balance are related to the presence of inwardly rectifying potassium channels (Kettenmann et al. 1993) and multiple neurotransmitter receptors (Pocock and Kettenmann 2007). Microglia can be induced to produce several agonists of excitatory amino acid receptors including glutamate, quinolinate, and D-serine (Barger 2004). Several types of glutamate receptors are expressed, including the mGluR (metabotropic glutamate receptor) and AMPA (alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) classes (D'Antoni et al. 2008) and individual receptor subunits of the metabotropic groups I, II, and III (Byrnes et al. 2009; Noda et al. 2000). Activation of mGluR from group I or III inhibits microglia activation; group II evokes mal-activation, and activation of mGluR3 inhibits toxicity of microglia toward oligodendrocytes (Pinteaux-Jones et al. 2008). Recent work demonstrated that activation of Gai-coupled receptors, including group II and group III mGLuRs, suppresses the export of glutamate from activated microglia (McMullan et al. 2012).

A multitude of signals, both physical and secreted factors, posing a potential threat to brain homeostasis are sensed by microglial receptors (Hanisch and Kettenmann 2007). Microglial activation, in addition to being stimulus dependent, is also likely to be a multistep process (Ponomarev et al. 2006). Specific factors released by stressed or damaged neurons can stimulate the production of proinflammatory cytokines by microglia including matrix metalloproteinase-3 (MMP-3), α-synuclein, neuromelanin, and adenosine triphosphate (ATP). In an in vitro transmigration assay, conditioned media from mesencephalic cultures

treated with MPP+ (1-methyl-4-phenylpyridinium) were sufficient to trigger microglia attraction. This response occurred even at early stages of the neuronal injury, suggesting signaling from the neuron to trigger microglia activation. The rapid response to injury of directed process extension relies on purinergic signaling mediated by ATP and P2 (purinergic) receptors. In addition to local process extension, microglia can sense a chemical gradient of ATP and exhibit chemotaxis to the source. The P2Y12 receptors mediate chemotaxis and the P2Y6 receptors stimulate phagocytosis (Koizumi et al. 2007; Langosch et al. 1994).

Depending upon the stimulus, inflammatory responses by microglia can be initiated by pattern recognition receptors (PRRs) that include Toll-like receptors (TLRs), the receptor for advanced glycation end products (RAGE), and scavenger receptors to detect the aberrant expression of phosphatidylserine on the extracellular surface of dying cells. Microglia detect ligands for CD40, CD91, and the intracellular NOD-like receptors (NLRs) that initiate the signaling process by binding to PAMPs. Ligation of PRRs leads to the activation of signal transduction pathways and regulation of diverse transcriptional and posttranscriptional molecules including members of the nuclear factor kappa B (NF-κB), activator protein 1, and interferon regulator factor families, which modulate proinflammatory target genes encoding cytokines, chemokines, enzymes, and other molecules essential for pathogen elimination (Akira et al. 2006).

TLRs are a major family of PRRs for a diverse set of novel pathogen-associated molecules (Takeuchi and Akira 2001) that, with their related signaling proteins, are expressed in the CNS (Bowman et al. 2003; Kielian et al. 2002) with microglia expressing TLRs 1–9 (Farina et al. 2005). In vivo, TLR2 expression is exclusively in microglia activated with cerebral ischemia (Lehnardt et al. 2007) or entorhinal cortex lesion (Babcock et al. 2006). Microglia derived from human white matter and in primary rat cell cultures express TLR4 (Lehnardt et al. 2003; Visintin et al. 2001) that recognizes the fragment of gram-negative bacteria and LPS and can initiate innate immune responses to infection in mammals. A large proportion of the data suggests that TLR signaling mediates beneficial effects essential for pathogen elimination, but additional data suggests that TLR-induced microglia activation and release of proinflammatory molecules can contribute to neurotoxicity. Based upon studies examining the various TLRs, it has been suggested that activation of innate immune responses in the brain is tailored according to the cell type and environmental signal. As an example, TLR3 signaling induces a strong proinflammatory response in microglia as characterized by the secretion of IL-12, TNF-α, IL-6, CXCL-10, and interferon (IFN)-β. TLR2-mediated responses are primarily associated with secretion of IL-6 and IL-1β (Jack et al. 2005).

More recently, PRRs have been found to respond to factors released from necrotic cells and by molecules that may be secondary to a pathogenic process and may facilitate neuronal damage. TLRs, especially TLR2 and TLR4, are capable of sensing damage induced by ischemia and, as such, boost the proinflammatory response such that the infarct size is increased (Caso et al. 2008; Kilic et al. 2008; Lehnardt et al. 2007). There are several host-derived ligands for TLR. One of these, heat shock protein (HSP)60, is released from dying CNS cells and, upon binding to

microglia, TLR4- and MyD88-dependent secretion of NO is induced (Lehnardt et al. 2008). Similarly, necrotic neurons have been shown to activate microglia in an MyD88-dependent manner with the subsequent proinflammatory response leading to an increased neurotoxic activity through the induction of the glutamate enzyme, glutaminase (Pais et al. 2008). While TLR activation can contribute to neurotoxicity during CNS infection, there is evidence that TLR signaling can mediate beneficial effects (Glezer et al. 2006). Microglia appear to be the major initial sensors of danger or stranger signals recognized by TLR4, and they secrete inflammatory mediators such as TNF-α and IL-1β. These cytokines can then act on astrocytes to induce a secondary inflammatory or growth factor repair response (Saijo et al. 2009). With an acute injury, the release of TNF from microglia may serve to counter any secondary injury (Nawashiro et al. 1997), while activation of microglia to remove cellular debris following acute damage may serve to prevent subsequent tissue inflammation (Glezer et al. 2007; McPherson et al. 2011). TLR4 is also used by microglia and astrocytes to detect Aβ (Landreth and Reed-Geaghan 2009), leading to activation of signal-dependent transcription factors for downstream inflammatory response genes and clearance of aberrant proteins (Reed-Geaghan et al. 2009; Walter et al. 2007). Supporting data suggests that stimulation of the system with TLR ligand encourages the appropriate phenotype of resident or invading monocytes to promote the clearance of Aβ (Yong and Rivest 2009).

RAGE, a cell-surface receptor belonging to the immunoglobulin superfamily (Neeper et al. 1992; Schmidt et al. 1992), is present on the surface of microglia, astrocytes, vascular endothelial cells, and neurons. Activation occurs with production of advanced glycation end products in prooxidant and inflammatory environments. RAGE contributes in the clearance of Aβ and is involved in apolipoprotein E (ApoE)-mediated cellular processing and signaling. It recognizes other ligands, including serum amyloid A, S100 protein, and high-mobility group box 1. NLRs are soluble, cytoplasmic PRRs that act as sensors of cellular damage. In Alzheimer's disease (AD), Aβ oligomers and fibrils induce lysosomal damage, triggering the NOD-like receptor, NALP3, in microglia (Halle et al. 2008). NALPs activate downstream signaling proteins, such as apoptosis-associated speck-like protein containing a caspase recruitment domain. This induces apoptosis, but it also contributes to the maturation of proinflammatory mediators like IL-1β and IL-18. In addition to peptide fragments, a decrease in cellular potassium concentration can activate NALP1 in neurons, leading to a similar activation of ASC, apoptosis, and IL-1β and IL-18 maturation.

Additional receptors that recognize apoptotic cellular material, such as phosphatidylserine on the inner membrane leaflet, are important for phagocyte clearance processes and may stimulate an anti-inflammatory response (Ravichandran 2003). Recent identification of such receptors includes T-cell immunoglobulin- and mucin-domain-containing molecule-4 (TIM4) (Miyanishi et al. 2007), the metabotropic P2Y6 receptor that recognizes the nucleotide UDP released from injured neurons (Koizumi et al. 2007), and the triggering receptor expressed on myeloid cells-2 (TREM-2; Schmid et al. 2002) to facilitate debris clearance in the absence of inflammation (Takahashi et al. 2005). A critical role for TREM-2 signaling has been demonstrated in polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy,

or Nasu-Hakola disease, with early-onset dementia possibly due to the inability of microglia to clear tissue debris via TREM-2 signaling (Neumann and Takahashi 2007). The differential expression of these receptors in response to the intensity or stage of tissue injury, type of injurious stimuli, and presence of other soluble signals can exert significant control over the potency of the microglial response.

5 Microglia Cytokine Expression and Regulation

Microglia are a source of a number of cytokines such as IL-1, IL-6, and TNF and are responsive to growth factors such as granulocyte-macrophage-CSF and CSF-1. Cytokines can induce or modulate a broad spectrum of cellular responses including cell adhesion, migration, survival, differentiation, replication, secretory function, and cell death. In the same cell, a cytokine can either induce death or promote survival or proliferation depending upon the function of the context in which it acts. Cell death can be actively triggered by a cytokine as a physiologically necessary role during development, differentiation, and in host defense responses to injury and subsequent repair. However, the same cytokine can also provide critical survival factors, and thus, its absence can result in cell death at a specific point in the cell cycle.

A specific phenotype or function has yet to be directly linked to specific altered or activated microglia morphology. A specific classification of microglia phenotypes has been proposed for microglia cells based upon peripheral myeloid cell responses and cytokine release (Martinez et al. 2008; Michelucci et al. 2009; Mosser and Edwards 2008). For example, proinflammatory (Th1, Th17) CD4+ T cells promote myeloid cells toward a classical activation state (M1 state) characterized by high expression levels of proinflammatory cytokines (IL-1β, IL-12, IL-23, IL-6, TNF-α) (Colton and Wilcock 2010; Gordon and Martinez 2010; Graeber and Streit 2010). In contrast, Th2 CD4 + T cells promote myeloid cells toward alternative activation states (M2a and M2b) characterized by expression of macrophage mannose receptor (CD206), YM-1, stabilin-1, and arginase I. Under this alternative activation, cells are functionally associated with enhanced phagocytosis, tissue repair, and parasite elimination. A regulatory activation state (M2c) is promoted by IL-10 and TGFβ characterized by expression of molecules related to tissue repair and immunosuppression. Each state may have its own particular phenotype with likely transitional phenotypes between wound healing classical and regulatory macrophages (Mosser and Edwards 2008). While this stage distinction has been established for peripheral cells, whether this will translate to the CNS has yet to be clearly established, as neither a temporal nor a spatial transition from an M1 to an M2 phenotype has been clearly described in models of neuroinflammation or neurodegeneration (Ajami et al. 2007; Colton and Wilcock 2010; Hume et al. 1983). Rather, as a general pattern, data suggest heterogenous populations of M1 and M2 microglia throughout an injury response or neurodegenerative disease process.

To understand the impact of a cytokine response, the basal level and regulatory mechanisms need to be considered. Under normal homeostatic conditions, the majority of cytokines are either not expressed or are expressed at low levels.

In the early phase, host defense responses to injury are triggered by microbial antigens, extracellular matrix antigens, or by activation products or preformed components of humoral defense systems. This process consists of cell recruitment and induction of cytokines that contribute to activation of proinflammatory, immunostimulatory, and catabolic responses. Cytokine mRNA transcripts have a short half-life of 10–30 min; thus, cytokines are rapidly translated and secreted into the extracellular space, producing a burst of cytokine release. Some cytokines are secreted upon complete intracellular processing, while others are stored intracellularly, and additional stimuli are required to trigger secretion. For example, transcription without translation can be observed for IL-1 following such things as adherence of blood monocytes to surfaces or exposure to calcium ionophore. In these cases, steady-state mRNA levels for IL-1β are comparable with those following induction by endotoxin; however, there is no protein translation. Alternatively, the system may effectively regulate the downstream effects of IL-1 by the induction of IL-1 receptor antagonist to bind the protein and prevent receptor activation.

Most cytokines are biologically active when secreted; however, some, such as TNF-α and transforming growth factor (TGF)β, are secreted in a biologically inactive or latent form and require further extracellular processing by proteases. Cytokines regulate the expression of cytokine receptors involved in the modulation of activity. For IL-1 and TNF-α, these effects are mediated primarily by IL-1 type I receptor and TNF receptor TNFR1 (p55) or TNFR2 (p75), respectively. IL-6 and other members of this family, oncostatin M, leukemia inhibitory factor, IL-11, and ciliary neurotrophic factor, are induced by IL-1 and TNF and protect against the proinflammatory and catabolic effects. As one primary example, microglial functions related to an innate immune response are associated with TNF signaling. TNF can induce apoptosis via activation of receptors containing an intracellular death domain such as TNFR1 and CD95 (APO-1/Fas) with their corresponding death ligands, TNF, and the structurally related type II transmembrane protein, FasL. Release of TNF-α and FasL shedding by microglia are implicated in neurotoxicity. Signaling by TNF is dependent upon constitutive and induced target cell expression of TNFRs (Tartaglia and Goeddel 1992). Membrane receptor mechanisms of apoptosis are implicated in neuronal death, while soluble TNFR1 can offer protection by binding TNF and preventing receptor signaling. TNFR1 activation has been proposed as a molecular mechanism for rapid apoptosis of injured or sick neurons through a caspase 3-mediated pathway (Yang et al. 2002). Recent studies examining cell death and survival following an ischemic insult or induced by a systemic injection of the organometal, trimethyltin, suggest that the level of TNF-α produced by microglia and the neuronal expression pattern of TNF receptors serve as critical determining factors for neuronal death (Harry et al. 2008).

6 Release of Factors Associated with Oxidative Stress

In vitro, microglia are capable of releasing several potentially cytotoxic substances, such as free oxygen intermediates, NO, proteases, arachidonic acid derivates,

excitatory amino acids, quinolinic acid, prostaglandins, cytokines, and other factors that, if occurring in vivo, may contribute to the exacerbation of neurons already compromised by disease or injury. In parallel with the production of proinflammatory cytokines, microglial neuroinflammation is commonly associated with the production of ROS and NO-dependent reactive nitrogen species (RNS). In excess concentrations, NO forms peroxynitrite and, through nitrosylation of cell signaling messengers, functions in immune regulation (Guix et al. 2005). ROS are oxygen-containing molecules that react with and oxidize vulnerable cellular constituents, including proteins, nucleic acids, and lipids. In neural tissues, oxidative stress can result in disrupted signaling processes and ion homeostasis and is held accountable for events ranging from protein mis-folding to death of newly generated neurons (Lipton et al. 2007; Taupin 2010). Superoxide, in particular, is implicated in microglial activation, cellular redox imbalance, and associated neurodegeneration. The translation of these processes to humans is hindered by the fact that levels induced by activating stimuli significantly differ across species and are relatively low in humans (Colton et al. 1996).

Endogenously produced ROS and RNS are essential components of brain homeostatic processes. ROS are commonly released by microglia to eliminate pathogens and elicit the controlled destruction of neuronal debris. In general, superoxide production by myeloid cells is mediated by the phagocytic NADPH oxidase (NOX2), consisting of membrane-bound (gp91 and p22) and cytosolic (p47, p67, and p40) subunits, as well as a requirement for the GTPase, Rac, for full activity (Lambeth 2004; Sumimoto et al. 2004). The microglial respiratory burst in response to certain tissue-disrupting stimuli involves Ca^{2+} and K^{+} channels and NADPH-dependent signaling to induce the release of superoxide (Colton et al. 1994; Khanna et al. 2001). Opening of cell-surface ion channels on microglia specific for induction of ROS as opposed to NO, including P2X7, Kv1.3, TRPV1, and KCa3.1, causes an "acute phase" of activation, often involving protein kinase C (PKC)-dependent signaling to NADPH oxidase and downstream NF-κB prior to superoxide release and gene induction (Fordyce et al. 2005; Infanger et al. 2006; Parvathenani et al. 2003; Schilling and Eder 2010).

NOX2 can be activated in mononuclear cells by TNF-α, IFN-γ, IL-1β, prion protein, ATP, and fibrillar Aβ. In addition, although phagocytosis can cause activation of NOX2, microglia do not uniformly undergo a respiratory burst when they initiate a phagocytic action (Savill et al. 2003). Notably, activation of NOX2 alone is not always sufficient to cause neurotoxicity (Mander and Brown 2005), suggesting that microglial superoxide production may have to occur in connection with other stressors to induce neurodegeneration. Some of these other factors that may contribute to neurodegeneration include free radicals (i.e., hypochlorous acid and reactive nitrites) produced via myeloperoxidase activity in astrocytes or peripheral leukocytes (Choi et al. 2003; Chung et al. 2010), and ROS-stimulated microglial proliferation and cytokine production (Jekabsone et al. 2006; Mander et al. 2006). The work of Barger et al. (2007) suggested that glutathione (GSH) depletion and oxidative stress resulting from the NADPH-dependent respiratory burst induce glutamate release from microglia, resulting in neuronal loss. Induction

of NADPH oxidases has been shown to be involved in the neurotoxic response in various Parkinson's disease (PD)-type models, including LPS, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), rotenone, and paraquat, with a possible requirement for protein kinase C (PKC) delta phosphorylation of p67 and p47 (Miller et al. 2009; Qin et al. 2004; Tieu et al. 2003).

A key event in a ROS stress response is the induction of heme oxygenase-1 (HO-1) in microglia and other cells that can help protect against subsequent insults (Lee and Suk 2007). Although increased HO-1 activity and CO production can have neurotoxic effects in response to select insults, the regulated activation of this system in microglia is hypothesized to be involved in resolving neuroinflammation and preventing accessory tissue damage (Syapin 2008). While NO-mediated stress is implicated in the progression of multiple brain insults, including AD, PD, and stroke (Guix et al. 2005), it can also induce neuroprotective signaling events such as inactivation of caspases, modulate release of neurotransmitters (e.g., dopamine, acetylcholine, GABA, and glutamate), and regulate synaptic plasticity by facilitating the induction of long-term potentiation via soluble guanylyl cyclase (Bon and Garthwaite 2003; Calabrese et al. 2007). Inducible NOS (iNOS; NOS2) present in microglia is Ca^{2+} independent and can be upregulated in response to TNF-α and IFN-γ or downregulated in response to TGF-β and IL-1β (Tichauer et al. 2007). Microglial NO can be cytoprotective and neuroprotective against select insults, such as ischemia. At high levels, iNOS can be cytotoxic to oligodendrocytes and can lead to excitotoxicity and/or synapse strengthening and influence BBB permeability. Thus, the induction of an oxidative stress response in microglia may likely underlie much of the neurodestructive effects attributed to microglia activation.

7 Microglia Aging and Senescence

The progressive, age-related change in MHC II antigen expression by microglia led to the assumption that microglial activation occurs with aging. The expression pattern was reported as similar to what occurs in experimental animal models of injury (Letiembre et al. 2007; Perry et al. 2002). Systemic challenge of aged mice with LPS suggested a primed phenotype for the microglia based upon the elevated basal level of cytokine synthesis as compared to young animals (Dilger and Johnson 2008). Further investigation showed morphological changes of microglia cytoplasmic structure in the aged human brain reflective of dystrophy and senescence but no evidence of priming (Sheng et al. 1998). Thus, while the cells change as a function of age, the morphological phenotype is suggestive of a decreased ability to mount a normal host-resistance response rather than a transformation to an activated cell. It has been suggested that age-related neurodegeneration might be due to not only a loss of neuroprotective properties but also the actual loss of microglia (Streit 2006; Streit and Xue 2012). One of the more prominent features of microglia is their function to clear aberrant proteins and debris from the CNS. Thus, the loss of efficiency in this function would result in a more toxic microenvironment.

A recent hypothesis put forth to explain phenotypic changes in aging microglia suggests that microglial senescence is triggered by an intracellular oxidative stress response due to enhanced intracellular accumulation of iron (Streit 2006). Under this hypothesis, a prolonged oxidative stress response would lead to senescence rather than activation. Additional support for microglial replicative senescence in normal and pathological aging comes from the demonstration of telomere shortening and decreased telomerase activity with aging. Whether this occurs with age-related diseases remains in question; however, data suggest that microglia from AD brains have shorter telomerase, as compared to control brains (Streit 2006). Using Aβ clearance as a phagocytic function of microglia that may be compromised with aging, a number of studies have examined a possible cellular process that could contribute to plaque accumulation in aging brains. Microglia cultured from aged mice showed a diminished ability to internalize Aβ peptide. CD47-dependent ability to phagocytize Aβ fibrils seen in postnatal day 0 microglia was lost in microglia isolated from 6-month-old mice and appeared to manifest between the ages of 2 and 6 months. This effect was not due to a generalized loss of phagocytic capability as no age-related difference was observed in clearance of bacteria but rather appeared specific for Aβ. In mouse models of AD, the increased plaque deposition that can occur as early as 6 months of age may be related to the loss of selective phagocytic function of microglia (Westerman et al. 2002). It has also been reported that between 6 and 18 months of age, microglia show an increase in mRNA levels for the alternative activation marker, YM-1. By comparison in a transgenic AD mouse line expressing human mutant amyloid precursor protein (APP) and presenilin 1 (PS1), significantly higher levels of YM-1 mRNA were demonstrated at 6 months of age (Jimenez et al. 2008). In contrast to previous reports suggesting that mRNA levels for proinflammatory cytokines increased with age, AD transgenic but not wild-type microglia displayed decreased Aβ phagocytic ability and increased mRNA levels of classic activation markers such as TNF-α at 18 months in non-plaque areas of the brain. One hypothesis put forth is that interactions of Aβ peptide with other inflammatory stimuli in the diseased brain drive the cells to an early and maintained alternative activation state that shifts the ability of the cells to respond in a normal manner (Floden and Combs 2011). In support of an age-related decrease in responsiveness of microglia, ApoE4 transgenic mice displayed a deficit in the resident microglia host-resistance and proinflammatory cytokine response to injury as a function of age (Harry et al. 2000). The deficit was not observed at 2 months of age but only became apparent at 8 months of age.

8 Acute Injury

Several studies demonstrate that, with acute injury, microglia can be destructive or protective (Butovsky et al. 2005; Nelson et al. 2002). With an acute physical disruption of the brain, the cellular response of the brain macrophage is primarily limited to the immediate focal site and the surrounding parenchyma. With a slightly

deeper penetration to include the corpus callosum, responses along the myelinated tracts can be observed. The nature of a puncture wound injury involves recruitment of blood-borne cells to the reaction including leukocytes, granulocytes, and monocytes. Within the lesion itself, round hematogenous macrophages are primarily found. At the edge of the lesion, process-bearing, hypertrophic, resident microglia are evident. This initial response occurs within the first 12 h or so, peaks between days 2 and 3, and by day 5, hypertrophied microglia express MHC class II and the CD4 antigen. This response then declines over the next 5 days. With the injection of IFN-γ/LPS, the response is slightly modified given the more active recruitment of peripheral immune cells. Interactions with CD4+ T cells with influence microglial phenotype and effects on neurons with fewer neurotoxic factors produced and an increase in anti-inflammatory and growth mediators and a reverse of glutamate transporters resulting in a buffering rather than a release of glutamine (Shaked et al. 2004, 2005). Thus, acute injury models offer critical information on the interaction between peripheral and central immune cells for consideration in more delayed neuronal death or progressive neurodegenerative models.

9 Progressive Degenerative Disease States

While the presence of reactive and activated microglia has been observed in numerous animal models of human neurodegenerative disease and in patients, the overall evidence suggests that, in the context of a pathogen-free environment, a relatively benign innate immune response is evoked. However, how, and if, this environment can be altered or stressed in a manner to change this balance remains a critical question. In murine prion disease models, particular prion agents can induce pathology in specific regions of the brain. The pathology is often characterized by protease-resistant protein deposition, spreading through the brain, accompanied by an increase in morphologically activated microglia with hypertrophied cell bodies. In the ME7 model in C57BL mice, at the time of first detectable synaptic loss, microglia in the hippocampus show an activated morphology and elevated expression of antigens such as CR3, ERM1, and CD68 (Betmouni et al. 1996). With further activation and during the progression to terminal stages of the disease, an increase is observed in TGFβ, cyclooxygenase (COX)-2, and its product PGE2 and the chemokine CCL2/MCP-1 (Perry et al. 2002), which often function in an anti-inflammatory manner. While the expression of TGFβ and PGE2 often represents macrophages that have phagocytosed apoptotic cells (Savill et al. 2002), there is no evidence of neuronal apoptosis in these early stages. It is possible that the activation occurring with synapse loss reflects a microglia phenotype as a consequence of clearing degenerating synapses; however, in this model, it is the dendritic spine that envelops the degenerating synapse and not the microglia (Siskova et al. 2009).

A similar benign role has been suggested in models of AD. In postmortem brain tissue of AD patients, an atypical inflammation occurs with both activation of the resident microglia and infiltrating monocytes surrounding dense-core

amyloid-β1-40/42 plaques showing increased expression of cell-surface antigens (D'Andrea et al. 2004; McGeer and McGeer 2003; Simard et al. 2006). In transgenic mice expressing human APP, amyloid plaque formation and amyloid-associated neuritic dystrophy occur independent of microglia presence (Grathwohl et al. 2009). In many of these animal models, microglia are a major component of the dense-cored amyloid plaques but not diffuse plaques, and it has been hypothesized that in the absence of effective phagocytosis, microglia potentiate the toxicity of Aβ peptide (Streit et al. 2005). Current data support the idea that inflammatory mediators do not promote Aβ accumulation but limit Aβ deposition (Chakrabarty et al. 2010). While the phagocytic activation serves in a beneficial manner to eliminate aggregated and toxic proteins from the brain, it has been proposed that an extended activation or dysregulation of this system can lead to an adverse environment and toxicity to surrounding cells. A recent study using the Tg-SwDI mice as a model for AD demonstrated that activated microglia localized around microvascular amyloid deposits increased synthesis of native complement proteins C1q, C3, and C4 (Fan et al. 2007). In transgenic mouse models of AD, less neuropathology is demonstrated in the absence of C1q; however, inhibition of complement activation diminishes microglial activity, increases amyloid load, and enhances neuronal degeneration (Fonseca et al. 2004; Wyss-Coray et al. 2002).

In PD, dopaminergic and non-dopaminergic neurons in the nigrostriatal pathway are compromised, contributing to the motor-related symptoms. A number of mechanisms have been proposed for the death of dopamine-containing neurons in the SN pars compacta including mitochondrial dysfunction, oxidative stress, and impairment of protein degradation. The detection of elevated levels of proinflammatory cytokines and evidence of oxidative stress-mediated damage in postmortem PD brains gave rise to the hypothesis of a microglia involvement. However, observations of the presence of cytotoxic T cells in the SN of a patient with PD and an increased density in insulin-like growth factor γ+ cells in the brains of PD patients suggest a role for the cellular arm of the adaptive immune system. A critical role for T cells was demonstrated in two different strains of immunodeficient mice lacking mature T lymphocytes (*Tcrb*−/− and *Rag1*−/− mice) by a reduction in MPTP-induced dopaminergic cell death. Further work demonstrated CD4+ T cell-mediated cytotoxicity of MPTP (Brochard et al. 2009) possibly via microglia activation and release of free radicals and proinflammatory cytokines. However, the recent description of an IL-17 secreting Th17 lymphocyte suggests an alternative cellular source for proinflammatory cytokines. One could envision that with progressive changes in the neuron, a microglia response to α-synuclein occurs, recruiting CD4+ T cells, leading to an induction of proinflammatory cytokines and NO secretion by microglia alternatively or in conjunction with the infiltration of TH17 lymphocytes. When a progressive model of PD was examined with reference to the adverse impact of microglial activation and inflammation on dopaminergic neurons, Wright and colleagues (2008) demonstrated in vivo that while the immunosuppressant drug, tacrolimus (FK506), reduced the initial stage of neuronal death in the SN, it did not alter the morphological response of microglia, suggesting a lack of direct correlation between the two cellular responses.

10 Conclusion

The fact that microglial activation correlates with neurodegenerative disease progression has led to the hypothesis of a causal link; however, the rapid nature of microglia response to neuronal injury, both physical and chemical signals, and death makes it difficult to determine an initiating role for microglia. There is a critical need to gain a better understanding of the plethora of responses representing the dichotomy of microglial reactivity for beneficial versus destructive effects. Identifying what can trigger a microglia response and identifying characteristics of the various types of responses will further advance the ability to interpret the role being played by microglia under normal and aberrant brain conditions.

Abstract

Over 45 years ago, it was discovered that the compound 6-hydroxydopamine (6-OHDA) destroys catecholamine (CA)-containing neurons when injected directly into the brain. Refinements in the use of 6-OHDA led to the development of dopamine (DA)-denervated rats to model Parkinson's disease (PD) and Lesch-Nyhan syndrome (LNS), in which loss of DA-containing neurons is a prominent feature. Differing functional characteristics were eventually discovered in DA-denervated rats depending on the age at which the DA was reduced. With 6-OHDA lesioning of CA neural systems in the brain, key discoveries were made regarding how these systems control specific physiological functions and behavioral responses. Important neurobiological concepts emerged as well, including receptor supersensitivity, D_1/D_2-DA receptor interaction, and D_1-DA priming of supersensitivity, including neural mechanisms likely relevant to clinical symptoms modeled by the 6-OHDA treatment. In this chapter, behavioral, neurochemical, structural, and pharmacological studies carried out in adult and neonatal 6-OHDA-treated rats are reviewed, and findings are compared and contrasted. To date, age-dependent lesioning of DA neurons in rats with 6-OHDA continues to play an important role in the development and validation of new therapies for clinical disorders with brain DA reduced.

Keywords

Adult 6-OHDA • DA-receptor interactions • Lesch-Nyhan disease • Neonate-6OHDA • Parkinson's disease

1 Introduction

The neurotoxicant 6-OHDA was the first agent to produce long-term depletion and destruction of norepinephrine (NE) in peripheral sympathetic neurons without affecting central CA content (Porter et al. 1963; Laverty et al. 1965; Thoenen and Tranzer 1968). Subsequently, the toxin was found to produce a selective destruction of CA-containing neurons when administered directly into the brain (Ungerstedt 1968; Bloom et al. 1969; Breese and Traylor 1970; Uretsky and Iversen 1970).

Over the last 4 decades, administration of 6-OHDA into the brain has been used effectively in both adult (Ungerstedt 1968; Breese and Traylor 1970; Breese et al. 1974) and neonatal (Breese and Traylor 1972; Smith et al. 1973) animals to investigate age-dependent behavioral, physiological, and biochemical effects of midbrain CAergic neuronal loss in disease symptoms and for identification of drug action. From these efforts, DA and NE neurons were found to be essential for the action of psychostimulant drugs, control of movement, and behavioral processes such as emotion, attention, reward, body temperature, and stress responses. Additionally, the basic information collected with 6-OHDA on brain function allowed for defining the role of these CAs in the pathogenesis and/or symptoms of PD, Lesch-Nyhan syndrome (LNS), and a number of other neuropsychiatric disorders, including attention deficit hyperactivity disorder (ADHD), schizophrenia, and drug addiction.

In the present chapter, an extensive overview of 6-OHDA lesioning in rats is provided, highlighting the distinctions between adult and neonatal CA-depleted animals. First, the history, scientific basis, and application of 6-OHDA lesioning techniques to selectively destroy nigrostriatal DA and/or NE neurons of the adult and neonatal rats are discussed. Next, important contributions from previous investigations regarding the behavioral and compensatory neural responses to age-dependent 6-OHDA lesioning of these neurons are reviewed. Focus is placed on characteristics unique to rats lesioned with 6-OHDA to destroy DA neurons during the neonatal period, particularly with regard to the differential sensitivity of these rats to various agonists and antagonists of DA receptors and to changes in other transmitter receptors in comparison to adult DA-depleted animals. Finally, potential mechanisms associated with the neural and behavioral plasticity in 6-OHDA-lesioned rats are presented, and the usefulness of these animals to model symptoms and features of specific central disorders is emphasized.

2 The 6-OHDA-Lesioned Rat Model

2.1 Mechanism of Action of 6-OHDA

6-OHDA does not pass the blood-brain barrier, so it must be directly injected into the brain to destroy central CA-containing neurons (Schober 2004; Bove et al. 2005). As an analog of DA and NE neurons, the toxin is readily taken up by CA neurons through the high-affinity DA and NE transporters, DAT and NET, respectively (Jonsson and Sachs 1970; Ljungdahl et al. 1971; Saner and Thoenen 1971). Once inside the neuron, the 6-OHDA initiates degeneration of CA neurons likely through a combination of oxidative stress and mitochondrial respiratory dysfunction (Schober 2004; Bove et al. 2005). The 6-OHDA-induced destruction of DA or NE nerve endings, and possibly cell bodies (depending on dose), results in the denervation of DA- and/or NE-containing brain neurons, which ultimately induces development of DA and/or NE receptor supersensitivity and other adaptations to compensate for this neural loss.

2.2 Microinjections of 6-OHDA into the Brain to Lesion Nigrostriatal DA Neurons in Adult Rats

In 1968, Ungerstedt showed that injection of 6-OHDA into the pars compacta region of the SN (SNpc) of adult rats produced anterograde degeneration of the nigrostriatal DA system, thereby generating the first animal model of PD (Ungerstedt 1968). In subsequent studies to disrupt DA function, 6-OHDA was injected either into the medial forebrain bundle (MFB), through which the nigrostriatal pathway ascends, or into the striatum, where axon terminals of SNpc neurons are located (Deumens et al. 2002). With high doses of 6-OHDA (>6 μg) injected bilaterally into either the SNpc or MFB of adult rats, nigral DAergic cell death begins within 12 h of injection, followed by a near-complete lesioning of nigrostriatal DA neurons (>90 %) within 2–3 days (Ungerstedt 1968; Jeon et al. 1995; Zuch et al. 2000) – a loss of neurons which mirrors the pattern of DA loss seen in postmortem brains of PD patients. After injection into the SNpc, neighboring DA neurons in the ventral tegmental area (VTA), which give rise to the mesolimbic and mesocortical pathways, are somewhat compromised by 30–40 % as well (Perese et al. 1989; Carman et al. 1991).

Bilateral injections of 6-OHDA into the SNpc or MFB are usually avoided due to a profound acute aphagia and adipsia that follows – an approach which can result in mortality if rats are not tube-fed to maintain nutrition (Ungerstedt 1968, 1971a). Rather than bilateral site injections of 6-OHDA, administration is typically performed unilaterally, with the opposite, or contralateral, side serving as the control. This approach is particularly suitable for evaluating turning behavior to a drug challenge (Ungerstedt 1971d). However, following unilateral lesioning of the nigrostriatal DA pathway, it should be noted that the rat initially exhibits a severe body circling posture to one side for a few days, after which time this deficit nearly subsides – a recovery that obviously depends upon a neural adaptation to allow this functional correction. Consequently, for defining the basis of this adaptation in these unilateral 6-OHDA-lesioned rats, the inclusion of an unlesioned rat would be wise. Robinson and colleagues have provided extensive data documenting the need for appropriate controls to understand the basis of the initial adaptation to unilateral 6-OHDA lesioning in adult rats (Robinson 1991).

Another approach to investigate the consequences of lesioning DA neurons was to inject 6-OHDA (12–25 μg) into the striatum to produce a more selective and slowly developing partial lesion of nigrostriatal DA neurons (50–70 %) in this site to mimic earlier stages of PD. Though damage to the striatal DAergic terminals is acute (within 24 h of injection) with this method, degeneration of the parent nigral cell bodies begins at 5–7 days postinjection and progresses for at least 4 months after the insult (Sauer and Oertel 1994; Przedborski et al. 1995; Blandini et al. 2007; Berger et al. 1991). This protracted time course of degeneration has provided an in vivo experimental platform for studying neuroprotective strategies aimed at slowing or halting the degeneration of DA neurons in PD (Deumens et al. 2002). Since central administration of 6-OHDA can also reduce brain NE, direct injections of 6-OHDA into the locus coeruleus, the region of the

brainstem where NE neurons originate (Ungerstedt 1971c), have also been performed (Ungerstedt 1971e). This strategy of lesioning NE neurons has allowed for the determination of what functional role these particular neurons play in brain function.

2.3 Intracisternal Injection of 6-OHDA to Lesion CA-Containing Neurons in Adult Rats

Subsequent to the initial work by Ungerstedt (1968), Breese and Traylor administered 6-OHDA into the cisterna magna of adult rats to produce lesioning of CA-containing neurons (Breese and Traylor 1970). This initial use of intracisternal (i.c.) administration of 6-OHDA to lesion CAergic neurons in the brain was then followed by others (Bruno et al. 1984, 1987; Lytle et al. 1972; Smith et al. 1973). Because initial unpublished efforts demonstrated that 6-OHDA i.c. utilization did not produce the profound reduction of DA observed with injection of 6-OHDA into the SNpc (Ungerstedt 1968), Breese and Traylor pretreated rats with the monoamine oxidase (MAO) inhibitor, pargyline, to produce a comparable reduction of brain DA as seen when 6-OHDA was microinjected into the MFB (Breese and Traylor 1970). Like pargyline, several MAO inhibitors were subsequently demonstrated to also enhance the destruction of DA-containing neurons (Breese 1975). Additionally, the degree of destruction of DA neurons was found to be further enhanced if an additional dose of 6-OHDA was administered 7–10 days after the initial pargyline/6-OHDA exposure (Breese and Traylor 1971; Breese et al. 1973, 1974). Because the 6-OHDA also shows high affinity for the NE transporter, NET (Luthman et al. 1989b), systemic injection of the NET inhibitor, desipramine, administered prior to 6-OHDA ensures increased selectivity of the toxin for DA neurons (Evetts and Iversen 1970; Breese and Traylor 1971). Owing to the high affinity of 6-OHDA for NET (Porter et al. 1963), Breese and Traylor found that small doses of 6-OHDA administered i.c. to adult rats reduced brain NE with little effect on DA content in the brain (Breese and Traylor 1971). These approaches allowed evaluating the distinct functions related to either DA or NE in the brain (Breese et al. 1974; Ungerstedt et al. 1974), a strategy which provided a critical understanding of how the loss of CA neurons differentially affected brain functions.

2.4 Intracisternal Injection of 6-OHDA to Lesion CA-Containing Neurons in Neonatal Rats

In 1972, Breese and Traylor administered 6-OHDA into the cisterna magna of developing rats to determine whether the 6-OHDA would destroy CA-containing neurons during this period (Breese and Traylor 1972). They found that this procedure produces a marked reduction in brain DA, NE, and tyrosine hydroxylase activity (TH; the rate limiting enzyme required for DA synthesis) (Breese and Traylor 1972). In subsequent studies to reduce only brain

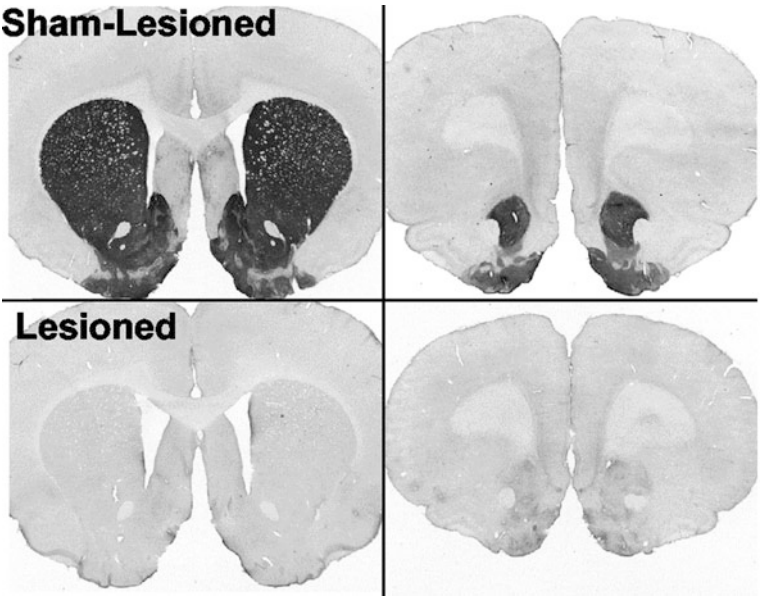

Fig. 1 Tyrosine hydroxylase immunohistochemistry after neonatal 6-OHDA lesioning in rats. Immunohistochemical detection of tyrosine hydroxylase in coronal sections representing the striatum, nucleus accumbens, and medial prefrontal cortex of adult rats after neonatal sham (*top*) and 6-OHDA (*bottom*) lesioning

DA, selective destruction of DA neurons was achieved by pretreating rats with desipramine prior to injection of 6-OHDA either into the cisterna magna or into the cerebral ventricles (Smith et al. 1973). At 100–150 μg doses of 6-OHDA, injection into either of these ventricular sites was found to produce a major destruction of DA- and NE-containing neurons (>95 %) within 72 h (Breese et al. 1984a, 1985a, b, 1987a; Berger et al. 1985; Snyder et al. 1986). In fact, as early as 4 days postinjection into the ventricles, DAergic cell bodies and dendrites were reported to disappear entirely from the SN (Fernandes Xavier et al. 1994) and cause a considerable reduction in number in the VTA (Fernandes Xavier et al. 1994; Breese et al. 1984a, 1985a, b, 1987a; Berger et al. 1985; Snyder et al. 1986). Consequently, the DAergic terminal fibers in the striatum are drastically reduced by 6-OHDA (Snyder et al. 1986; Descarries et al. 1992), as are neurons in certain target regions of the VTA, including the septum, nucleus accumbens, and frontal cortex (Luthman et al. 1990a). This extensive DAergic denervation explains the profound loss of brain DA content measured in these animals during adulthood (Breese and Traylor 1972; Breese et al. 1984a; Stachowiak et al. 1984; Bruno et al. 1987; Jackson et al. 1988; Dewar et al. 1990). In Fig. 1, the extent of DA depletion in the striatum and frontal cortex of adult rats lesioned with 6-OHDA as neonates is revealed through the immunohistochemical detection of TH. This perinatal loss of DA in neonatal

rats has been the focus of investigations aimed at understanding how this loss relates to the pathophysiology of the developmental brain disorder LNS in which DA is reduced during development (Breese et al. 2005).

3 Behavioral Responses After 6-OHDA Lesions

3.1 Behavioral Impairment and Recovery of Function in Rats Lesioned as Adults

As noted earlier, extensive bilateral lesions of nigrostriatal DA neurons in adult rats produce a syndrome that is analogous to PD in humans (Marshall et al. 1974; Ungerstedt 1971a; Zigmond and Stricker 1984). The rats exhibit symptoms such as bradykinesia/akinesia, rigidity, sensorimotor neglect, excessive bracing and clinging reactions, festination, aphagia, adipsia, and cognitive dysfunction (Marshall 1979; Stricker and Zigmond 1984; Ungerstedt 1971a; Zigmond and Stricker 1972; Zis et al. 1974). The occurrence and severity of these behavioral deficits appears to be strongly correlated with the degree of DA depletion in the striatum (Lees et al. 1985). For example, adult rats with essentially total bilateral depletions of striatal DA (>95 %) can perish as a consequence of these behavioral impairments if they are not tube-fed intragastrically with nutrients. In spite of this tube-feeding effort over an extended period, the rats rarely regain normal ingestive behavior and continue to show sensorimotor neglect and profound motor and cognitive impairments (Marshall 1979; Zigmond and Stricker 1973). These 6-OHDA-lesioned adult rats continue to suffer from residual regulatory deficits, particularly in their ability to respond to stress and acute homeostatic imbalances (Snyder et al. 1985; Stricker and Zigmond 1974; Marshall and Teitelbaum 1974). In fact, when challenged with an exposure to stressor, the severe ingestive and motor impairments can be reinstated in these animals to the level of severity seen acutely after the lesion (Robinson et al. 1990). Adult rats with extensive, yet less severe, bilateral 6-OHDA lesions of striatal DA (80–90 %) initially display behavioral deficits (Baez et al. 1977; Fibiger et al. 1973; Spirduso et al. 1985) but show significant recovery over time (Altar et al. 1987; Creese et al. 1977; Dravid et al. 1984; Neve et al. 1982; Nisenbaum et al. 1986). Similarly, patients with PD manifest clinical symptoms only after a loss of 80 % of the DAergic input into the striatum (Bernheimer et al. 1973; Fearnley and Lees 1991). Therefore, while nigrostriatal DAergic activity is required for normal behavioral function, only 10–20 % of nigrostriatal DA input is actually needed to maintain fairly normal function in both rats and humans.

3.2 Sparing of Behavioral Impairment and Recovery of Function in Rats Lesioned as Neonates

The behavior of rats lesioned with 6-OHDA as neonates is very different from that of rats lesioned with 6-OHDA during adulthood. Rats lesioned with 6-OHDA as

neonates do not display any outward symptoms of aphagia or adipsia associated with adult bilateral lesions (Breese and Traylor 1972; Smith et al. 1973). In fact, while these neonatal lesioned rats are smaller in stature (Breese and Traylor 1972), they show few overt behavioral deficits that distinguish them from non-lesioned rats during development or in subsequent adulthood, even when their DA levels are depleted by 99 % (Breese et al. 1984a; Bruno et al. 1984; Erinoff et al. 1979; Smith et al. 1973). Near-total depletion of striatal DA incurred prior to postnatal day 27 (P27) produces no obvious deficits in sensorimotor function either soon after the lesion or after the rats reach adulthood (Weihmuller and Bruno 1989a), nor is there any evidence of profoundly impaired ingestive or motor function (Potter and Bruno 1989; Weihmuller and Bruno 1989b). In early studies, Breese and Traylor showed that neonatal rats with reductions in both DA and NE remained virtually indistinguishable from non-lesioned controls except for a slight decrease in body weight and a lack of self-grooming (Breese and Traylor 1972). Smith and colleagues later showed that the reduced body weight induced by the 6-OHDA reduction in food consumption was related to reduced DA and not to a loss of NE (Smith et al. 1973). Although neonatal rats with DA or with both CA-containing neurons destroyed exhibit reduced body weight (Breese and Traylor 1972; Smith et al. 1973), they are still able to suckle and grow and can be weaned readily onto solid food and water as early as 27 days of age (Bruno et al. 1984, 1986; Weihmuller and Bruno 1989b; Smith et al. 1973).

The apparent sparing of behavioral function in neonatal lesioned rats, however, is not a complete one. Deficiencies in rats with DA selectively reduced during development were eventually uncovered with rigorous behavioral assessments of challenges to functional measures (Smith et al. 1973). For example, Smith and colleagues found that neonatal lesioned rats with selective reduction of brain DA do not ingest sucrose even though intake of water was normal (Smith et al. 1973), whereas rats with only brain NE reduced exhibit an increase in the sucrose drinking over that of controls. Others found that the neonatal lesioned rats with DA reduced do not eat in response to acute glucoprivation and do not drink water or saline in response to hypovolemia (Bruno et al. 1986). These deficits in response to acute homeostatic imbalances are similar to those seen in rats with adult lesions (Bruno et al. 1986). Further, studies showed that neonatal lesioned rats with only DA reduced exhibit a total deficiency in acquiring the shuttle-box avoidance response in adulthood, while rats with only NE reduced exhibit an elevated acquisition in this task (Smith et al. 1973). As adults, the neonatal lesioned rats show significant deficits in classical and aversive conditioning (Raskin et al. 1983; Whishaw et al. 1987), escape and avoidance learning (Shaywitz et al. 1976b; Pappas et al. 1980), spatial navigation (Whishaw et al. 1987; Pappas et al. 1992), and independent limb/tongue use and limb posture (Whishaw et al. 1987), suggestive that the neonatal DA depletion produces lasting impairments in learning ability and skilled motor control. Rats depleted of DA as neonates also show deficits in motoric capacity for high-rate operant responding (lever-pressing) during intracranial self-stimulation to the lateral hypothalamus (Stellar et al. 1988) and VTA (Takeichi et al. 1986), as well as acquisition deficits in operant responding for water and other reinforcing

stimuli (Heffner and Seiden 1983; Moy 1995), just as do adult lesioned rats (Cooper and Breese 1975). Adult rats with DA destroyed as neonates with 6-OHDA also exhibit reduced locomotion, whereas those that had NE selectively reduced exhibit a nearly doubling of locomotion (Smith et al. 1973). Other reports have shown that animals lesioned with 6-OHDA during development exhibit hyperactivity in adolescence similar to patients with ADHD (Shaywitz et al. 1976b; Miller et al. 1981; Luthman et al. 1989a). Thus, while rats with neonatal DA-specific lesions cope quite well in the absence of challenges, exposure of these animals to such confrontations clearly reveals that severe functional deficiencies persist.

4 Compensatory Neural Responses After 6-OHDA Lesions

4.1 Adaptations in the DA System of Adult Lesioned Rats

In both neonatal and adult 6-OHDA-lesioned rats, a number of compensatory responses have been identified in the striatal DA system that could be involved in counterbalancing the effects of the lesion. While adaptive changes related to 6-OHDA lesioning likely occur when the toxin destroys NE-containing neurons, this following section focuses only on adaptations that occur after the selective lesioning of DA neurons with 6-OHDA. The adaptive changes in the DA system that occur in response to 6-OHDA lesioning are largely neurochemical, involving presynaptic changes in the remaining DA terminals as well as postsynaptic changes in target cells that are dependent upon lesion size. Such changes at synapses likely enable the spared DA neurons to upregulate their activity in order to regain functional control of their targets (Zigmond 1997). Initially, the adaptations observed in adult lesioned rats will be reviewed followed by those changes observed after neonatal lesioning of DA neurons.

Presynaptic DA Changes. In adult rats receiving 6-OHDA lesions of the nigrostriatal DA pathway, presynaptic changes occur that are largely related to an enhanced metabolism of surviving DA neurons. Well established is that the remaining DA neurons greatly increase their rate of DA synthesis at striatal terminals (Agid et al. 1973; Hefti et al. 1980, 1985; Wolf et al. 1989), a finding attributed to the ability of these cells to upregulate their intrinsic TH activity presumably to meet the increased demand for releasable DA (Zigmond et al. 1984). In fact, a direct correlation exists between the degree of DA depletion by 6-OHDA and the extent of upregulation of TH activity in the spared terminals, an increase which in most cases can be greater than sixfold (Zigmond et al. 1984). Using intracerebral microdialysis techniques in adult rats with unilateral DA lesions, Robinson and Whishaw showed that the extracellular concentrations of DA in the denervated striatal hemisphere are much higher than predicted given the extent of DA depletion measured in the postmortem tissue (Robinson and Whishaw 1988). Later microdialysis studies in adult rats with bilateral 6-OHDA lesions showed that the extracellular DA concentrations remain close to normal even when the DA destruction in both striatal hemispheres was nearly complete

(Castaneda et al. 1990b). Additionally, an increase in the rate of firing and burst firing activity of the remaining striatal DA neurons occurs (Hollerman and Grace 1990), which together can contribute to the increased levels of DA release as well as to the amount of DA release per action potential in the lesioned striatum (Stachowiak et al. 1987). At the same time, a decrease in DA reuptake, produced by the destruction of DAT on DA terminals by 6-OHDA, contributes to a slower rate of DA clearance from the extracellular space which, in combination with the disappearance of presynaptic DA autoreceptors, results in an increased diffusibility of DA throughout the lesioned striatum (Zigmond et al. 1984; Snyder et al. 1990).

An additional contributing factor to the functional sparing or recovery related to presynaptic function seen after extensive 6-OHDA lesions in adult rats appears to relate to sprouting of remaining DA neuronal terminals into denervated striatal regions. This growth occurs from an undamaged axon, possibly a neighboring axon in the same tract or an axon from a different tract, to fill a vacated adjacent space. Although the nigrostriatal DA projection is predominately ipsilateral, there is also a minor crossed projection that arises from the contralateral SN (Fallon and Loughlin 1982; Gerfen et al. 1982; Morgan et al. 1986). While DA fibers of the ipsilateral projection have a clear capacity to undergo this regenerative sprouting (Bohn et al. 1987; Hansen et al. 1995; Onn et al. 1986), Pritzel and colleagues used a retrograde labeling technique to show an increased number of contralaterally labeled nigral neurons that innervated the striatum 7 days after an extensive unilateral lesion of the ipsilateral nigrostriatal bundle in adult rats (Pritzel et al. 1983). This sprouting of DA neurons to reinnervate the DA-denervated striatum could be a possible basis for the eventual recovery of unilaterally lesioned adult rats from their initial turning posture after exposure to the 6-OHDA. Ultrastructural tracer studies have also revealed the appearance of hypertrophic DAergic fibers and growth-cone-like structures and the expansion of a terminal arbor network over a period of 1–4 months after the adult unilateral 6-OHDA lesioning (Blanchard et al. 1996; Liberatore et al. 1999; Finkelstein et al. 2000). Evidence suggests that this process is regulated by both supersensitive postsynaptic receptors and glial cells activated by the lesion (Batchelor et al. 1999; Parish et al. 2002; Tripanichkul et al. 2003). It has been hypothesized that the enlargement of synaptic varicosities and terminal arborizations observed after adult lesions could help compensate for the loss of DA by delivering larger boluses of DA to the denervated striatum, especially after presynaptic DA reuptake mechanisms and autoreceptors have been disrupted by the 6-OHDA lesion (Castaneda et al. 1990b; van Horne et al. 1992). Studies with DA-rich fetal SN or adrenal medulla transplants showed that replacement of only a very small fraction of the normal complement of DA is sufficient to restore some functional control of the striatum (Carder et al. 1987, 1989; Snyder-Keller et al. 1989).

Collectively, these studies suggested that the presynaptic adaptations in the remaining DA terminals likely exist to normalize the extracellular DA concentrations in the denervated striatum – changes which contribute to the recovery of function in the 6-OHDA-lesioned rats (Robinson and Whishaw 1988; Robinson et al. 1990, 1994; Abercrombie et al. 1990; Castaneda et al. 1990b; Parsons et al. 1991; Touchet and Bennett 1989). However, when striatal DA depletion exceeds 95 %, a marked

drop in extracellular levels of DA occurs, presumably reducing drastically the degree of behavioral function because of the extensive loss of presynaptic DA adaptation (Abercrombie et al. 1990; Castaneda et al. 1990b; Robinson et al. 1990). Therefore, at least 5 % of the DAergic cells must be present to produce an adequate supply of extracellular DA to maintain control over striatal targets and ultimately to sustain some function in the adult lesioned animals (Robinson et al. 1990).

Postsynaptic DA Changes. In adult 6-OHDA-lesioned rats, postsynaptic changes are manifested when the degree of striatal DA depletion by 6-OHDA becomes more extreme – an additional adaptation that is likely to contribute to the recovery process induced by the lesioning (Zigmond 1997; Zigmond and Stricker 1980; Staunton et al. 1981). This recovery process can enable the lesioned animals to amplify a weak DA signal (Zigmond 1997). A number of quantitative autoradiography and small animal positron tomography (PET) studies have consistently reported an increase in the density of postsynaptic D_2-DA receptors in the striatum of rats with extensive 6-OHDA lesioning of DA during adulthood (Creese et al. 1977; Savasta et al. 1987; Staunton et al. 1981; Murrin et al. 1979; Neve et al. 1982; Graham et al. 1990; Przedborski et al. 1995; MacKenzie et al. 1989; Joyce 1991a; Nikolaus et al. 2003; Hume et al. 1995; Nguyen et al. 2000). While the majority of these studies have been conducted in rats with unilateral DA depletions, a similar increase has been found in rats with bilateral loss of 90 % or more of total DA content in both striatal hemispheres (MacKenzie et al. 1989; Joyce 1991a). Autoradiography studies using [^{3}H] spiroperidol to localize the changes in D_2 receptors revealed increases in the lateral parts of the striatum after short survival times (Savasta et al. 1987), with a more diffuse upregulation into medial parts by 7 months after such lesions (Chritin et al. 1992). Other studies showed that the increase in D_2 receptor density is accompanied by an upregulation in D_2 receptor mRNA levels (Gerfen et al. 1990; Angulo et al. 1991; Neve et al. 1991; Cadet et al. 1992; Lisovoski et al. 1992; Chritin et al. 1993). Brene and colleagues found a D_2 receptor mRNA increase on medium-sized γ-aminobutyric acid (GABA)-containing neurons in the lateral striatum 3 weeks after a unilateral 6-OHDA lesion (Brene et al. 1990). Reports have suggested that the increase in D_2 receptors is due to a propensity of mRNA for the D_2-long spliced variant (Martres et al. 1992). Interestingly, this isoform of the D_2 receptor is preferentially involved in postsynaptic responses to DA under normal conditions (Usiello et al. 2000; Wang et al. 2000). Consistent with the changes in D_2 receptor synthesis, the recovery rate of D_2 receptor binding following irreversible blockade with *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) was found to be enhanced in lesioned striatum 4–5 weeks after unilateral 6-OHDA treatment in adult rats (Neve et al. 1985). This increase in recovery was attributed to an increase in the rate of reappearance of D_2 receptors into synaptic membranes. Irrespective of these findings, the physiological consequences of D_2 receptor upregulation on striatal function remain unknown, as increased D_2 receptor density was found to have no effect on the inhibitory responsiveness of spontaneously firing striatal neurons after exposure to iontophoresed DA or to the D_2 receptor agonist 2-(*N*-phenyl-ethyl-*N*-propyl)amino-5-hydroxytetralin in adult lesioned animals (Radja et al. 1993b). Nonetheless, this

adaptive increase in D_2 receptors could provide another means by which to amplify a weak DA signal induced by the DA lesioning (Zigmond 1997).

In adult lesioned rats, the effects of 6-OHDA-induced destruction of DA neurons on the regulation of other DA receptor subtypes, in particular the D_1 receptor, remain a contentious issue (Reader and Dewar 1999). Studies have reported that the density of D_1 receptors is either increased (Buonamici et al. 1986; Fornaretto et al. 1993; Narang and Wamsley 1995), unaltered (Altar and Marien 1987; Savasta et al. 1988; Lawler et al. 1995), or decreased in the striatum of these animals (Marshall et al. 1989; Stromberg et al. 1995). Further studies have reported either no change (Brene et al. 1990; Fornaretto et al. 1993; Narang and Wamsley 1995) or a slight decrease in D_1 mRNA levels after such lesions (Stromberg et al. 1995). Such variability might be due to (1) the amount of damage induced by the adult 6-OHDA lesion (Iwata et al. 1996; Reader and Dewar 1999), (2) the period of survival following the lesion (Fornaretto et al. 1993; Narang and Wamsley 1995), and/or (3) the site and conditions selected for the 6-OHDA treatment (Narang and Wamsley 1995; Reader and Dewar 1999). Therefore, parameters such as time course and spatial distribution of the lesion must be considered when comparing and interpreting the various changes reported for D_1 receptor function after 6-OHDA lesions in adult rats.

4.2 Adaptations in the DA System of Neonatal Lesioned Rats

Presynaptic DA Changes. While adult 6-OHDA-lesioned rats remain exclusively dependent upon the amount of DA that remains after 6-OHDA treatment, rats lesioned as neonates survive quite well and continue to exhibit sparing of function even when only 1–2 % of the nigrostriatal DA neurons remain. In this respect, an adaptive change which appears to be unique to neonatal 6-OHDA-lesioned rats includes an increased ability of post-lesion residual neurons to release DA, even when 99 % of the DA content in both striatal hemispheres is lost (Carder et al. 1989; Castaneda et al. 1990b). The few surviving DA neurons after neonatal lesions undergo presynaptic metabolic changes that persist well into adulthood and are similar to those seen after adult lesions (Molina-Holgado et al. 1994). These changes include an increase in the synthesis of DA, suggestive of an enhanced release of DA from spared DA terminals (Molina-Holgado et al. 1994). As with adult lesions, it has been suggested that these presynaptic adaptations in the neonatal lesioned rats account for the maintenance of a relatively high extracellular DA concentration in the denervated striatum during the resting state, as measured by intracerebral microdialysis (Castaneda et al. 1990a). These higher levels of extraneuronal DA are quite surprising given the meager 1–2 % survival rate of striatal terminals after such lesions. It has been hypothesized that the storage capacity of the remaining terminals may be increased to protect DA from intraneuronal oxidative deamination (Reader and Dewar 1999), particularly since studies have shown that the actual size of the terminals becomes larger (Pickel et al. 1992). An alternative hypothesis is that the membrane properties of the

DA-containing vesicles may become altered to facilitate the increased transmitter release (Reader and Dewar 1999). Regardless, the normalization of extracellular DA levels in the denervated striatum is likely a crucial component in the sparing of behavioral function seen in rats after destruction of neonatal DA neurons.

When neonatal lesioned rats are administered an additional 6-OHDA treatment in adulthood to further reduce presynaptic function, these animals show symptoms of aphagia, adipsia, and akinesia similar to adult lesioned rats, suggesting that the residual DA activity is involved in the sparing of these particular functions subsequent to the neonatal lesion (Rogers and Dunnett 1989b). Likewise, neonatal lesioned rats are hypersensitive to the disruption of residual DA function with the catecholamine synthesis inhibitor α-methyl-para-tyrosine (α-MT) that results in deficits in feeding as well as other behaviors (Rogers and Dunnett 1989a), just as observed in adult 6-OHDA-lesioned rats (Cooper et al. 1972, 1973b). Collectively, such outcomes provide convincing evidence that the residual DA neurons are necessary for functional sparing in these neonate lesioned animals.

Postsynaptic DA Receptor Changes. In rats lesioned as neonates, early studies reported no changes in the binding of [^{3}H]-spiperone to D_2 receptors after i.c. administration of 6-OHDA (Breese et al. 1987a; Duncan et al. 1987; Kostrzewa and Brus 1991; Kostrzewa and Hamdi 1991). However, subsequent studies in lesioned rats using [^{3}H]-raclopride demonstrated significant increases of 30–40 % in D_2 receptor density over that in controls (Dewar et al. 1990). This change occurred in the rostral portion of the striatum between 1 and 3 months after the 6-OHDA lesion (Dewar et al. 1990), but increased throughout the entirety of the striatum at a later time after the lesion (Radja et al. 1993b). Because studies showed that the recovery of D_2 binding after in vivo receptor alkylation with EEDQ was unaltered, this D_2 receptor proliferation after the neonatal lesioning was proposed to be the result of posttranscriptional modifications (Dewar et al. 1997).

Unlike adult 6-OHDA-lesioned animals, the increase in density of the D_2 receptors in the bilaterally lesioned neonates is not accompanied by a sustained increase in mRNA levels (Chen and Weiss 1991; Radja et al. 1993b). In contrast to this finding, unilateral lesions of the nigrostriatal DA pathway in neonatal rats were found to produce a 20–25 % increase in the density of D_2 receptors (radiolabeled with the D_2 antagonist quinpirole, LY 171555) which was accompanied by an upregulation of D_2 mRNA levels in the rostral striatum 9 months after the lesion (Mennicken et al. 1995). This latter finding is consistent with the increase in the density of D_2 receptors being related to an increase in the synthesis of the D_2 receptor. Further, since binding in a control was the same as the contralateral side to the lesion, receptor changes were not likely related to adaptation on the unlesioned side of the brain (Mennicken et al. 1995). The increase in D_2 receptor binding and mRNA levels was not observed in similarly lesioned rats that received DA-rich grafts intrastriatally 5 days after the 6-OHDA lesion (Mennicken et al. 1995), a finding supportive of the view that the adaptive increase in D_2 receptors was related to the destruction of the striatal DA neurons.

Similar to the D_1 receptor binding studies in adult 6-OHDA-lesioned rats, there are conflicting reports of slight increases (Broaddus and Bennett 1990), slight

decreases (Dewar et al. 1990; Dewar et al. 1997; Molina-Holgado et al. 1995), large decreases (Gelbard et al. 1990), or no change at all (Breese et al. 1987a; Luthman et al. 1990b) in the density of striatal D_1 receptors in neonatal 6-OHDA-lesioned rats. Also, there is no change in the percentage of low-affinity (R_L) and high-affinity (R_H) binding sites for striatal D_1 receptors in adult rats that were lesioned as neonates with 6-OHDA (Gong, Kostrzewa et al. 1994). So far, studies attempting to explore changes in mRNA encoding for the D_1 receptor in these neonatal lesioned rats have failed to find any significant changes in these rats compared to controls (Duncan et al. 1993). In contrast to the latter findings, Gong et al. found that D_1 receptor mRNA is reduced by 25–50 % in neonatally 6-OHDA-lesioned rats at 6 weeks post-birth and that 4 weekly treatments with the D_1 receptor agonist SKF 38393 restore D_1 receptor mRNA to control levels (Gong et al. 1994). It is also important to note here that there are at least six different forms of the DA receptor, and the terms D_1 and D_2 refer more to subfamilies of receptor type and not to a single DA receptor isoform (Strange 1993). The D_1 class of DA receptors, which consists of the D_1 and D_5 subtypes, stimulates adenylate cyclase (AC) activity, while the D_2 class, comprised of the D_2 short, D_2 long, D_3, and D_4 subtypes, generally inhibits it. It is possible that some of the compensation seen after 6-OHDA lesioning in rats is related to changes in DA receptor types other than D_1 and D_2 receptors, although such changes could also facilitate some of the behavioral disturbances seen in neonatal lesioned animals. Specifically, Zhang and colleagues found an increase in the density of D_4 receptors in the striatum and a decrease in the nucleus accumbens at P25, but not at P37 or P60 after neonatal 6-OHDA lesions (Zhang et al. 2002a, b), with only minor changes in D_1 and D_2 receptor binding in various forebrain regions. The change in D_4 receptors, but not in D_1 and D_2 receptors, was positively correlated with the time course of motor hyperactivity exhibited by the neonatal lesioned animals, suggesting that D_4 receptors may play a pivotal role in this response (Zhang et al. 2002a, b). In subsequent studies, Zhang and colleagues also showed that the administration of D_4 antagonists L-745,870 and U-101,958 dose-dependently inhibits the motor hyperactivity in neonatal lesioned animals (Zhang et al. 2002a).

4.3 Adaptations in the 5-HT System by 6-OHDA Lesions

5-HT Hyperinnervation. An alternative view to the direct role of residual DA and receptor changes in the sparing or recovery of function in rats after 6-OHDA lesions is that compensatory mechanisms within the 5-HT system might provide some replacement for the loss of DA function. In this respect, following lesioning of DA neurons in neonatal animals, an extensive hyperinnervation of 5-HT of axon terminals or varicosities arising from the dorsal raphe nucleus is found in the striatum that is accompanied by an increase in 5-HT levels (Breese et al. 1984a; Berger et al. 1985; Luthman et al. 1987; Snyder et al. 1986; Stachowiak et al. 1984; Towle et al. 1989; Descarries et al. 1992; Molina-Holgado et al. 1994). So long as 80 % of the striatal DA is lost, both unilateral and bilateral DA depletions can

produce this 5-HT hyperinnervation in neonatal lesioned rats (Towle et al. 1989; Gong et al. 1993b; Penit-Soria et al. 1997). In rats lesioned at 3 days of age, this extent of DA loss can produce a severalfold increase in 5-HT content in the rostral striatum 2–5 months post-lesioning, along with an upregulation in high-affinity 5-HT uptake (Breese et al. 1984a; Stachowiak et al. 1984) and 5-HT transporter density (Molina-Holgado et al. 1994). While initially reported that this adaptive 5-HT hyperinnervation was not seen in adult rats after a comparable bilateral DA lesion of the striatum (Breese et al. 1984a), striatal 5-HT hyperinnervation was later reported to occur after unilateral 6-OHDA lesions in adult rats if striatal DA content was severely reduced by over 95 % (Zhou et al. 1991; Guerra et al. 1997; Maeda et al. 2003).

Apparently, the trigger for this proliferation of 5-HT-containing fibers is the extensive loss of striatal DA neurons (Kostrzewa et al. 1993; Towle et al. 1989) even though the loss of DA occurs several days before the development of 5-HT innervation (Lidov and Molliver 1982). Further evidence in accord with this view is that the 5-HT terminals do not occupy synaptic sites vacated by the loss of DA neurons and do not interfere with DA outgrowth arising from transplanted DA-rich cells derived from the ventral mesencephalon (Snyder-Keller et al. 1989; Abrous et al. 1993a). Additionally, replacement of lost DA innervation by transplanted DA-rich cells shortly after the lesion prevents the 5-HT hyperinnervation (Snyder-Keller et al. 1989; Abrous et al. 1993a). The sprouted axons that accumulated significant amounts of 5-HT (Molina-Holgado et al. 1994) tripled their extracellular 5-HT levels under stimulatory release conditions (Jackson and Abercrombie 1992). However, intracerebral microdialysis studies under resting conditions demonstrated that the striatal 5-HT hyperinnervation is not associated with enhanced levels of basal extracellular 5-HT, probably due to an increase in high-affinity 5-HT uptake (Jackson and Abercrombie 1992). Further, Descarries et al. revealed that the hyperinnervation is not accompanied by an increase in the number of synaptic contacts made by the 5-HT varicosities (Descarries et al. 1992). On the other hand, Jackson and colleagues found that that endogenously released 5-HT could affect acetylcholine (Ach) release in neonatally denervated striatum (Jackson et al. 1988). Additionally, 5-HT release could exert effects on striatal DA terminals through indirect diffusion processes (Descarries and Mechawar 2000; Umbriaco et al. 1995). For example, the release of 5-HT from hyperinnervated fibers could contribute to enhancing DA release from residual DA terminals by entry into the presynaptic DA terminals, which could in turn facilitate DA release from these remaining neurons (Navailles et al. 2010).

While initially hypothesized that the increased striatal 5-HT might be responsible for the sparing phenomenon in neonatal DA-lesioned animals (Towle et al. 1989), a combination of 6-OHDA with the 5-HT neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) (Breese et al. 1978) given to 3-day-old rat pups to lesion both 5-HT and DA neurons produced no greater behavioral dysfunction than 6-OHDA lesions alone (Bruno et al. 1987). Consequently, if indeed 5-HT was serving as a substitute for the lost DA, then it would be expected that rats with co-lesions of the two transmitter systems would exhibit severe impairments,

perhaps similar to rats lesioned in adulthood. Further, behavioral sparing was still observed in rats treated with 6-OHDA at P15 and P27 (Bruno et al. 1987), even though the neurochemical effects of 6-OHDA lesions given at this point in development do not include the elevated 5-HT levels typical of early lesioning of neonatal DA neurons (Bruno et al. 1987). Given these various findings, the 5-HT hyperinnervation does not appear to be a critical component in the functional sparing seen in neonatal 6-OHDA-lesioned rats.

5-HT Receptor Binding. In adult rats, the effect of 6-OHDA lesions on various 5-HT receptors and their mRNA levels in the brain is controversial, as a number of receptor autoradiographic and in situ hybridization studies have provided conflicting results. Early studies suggested that 6-OHDA-induced DA depletion in adult rats does not alter either 5-HT receptor densities or the inhibitory responsiveness of striatal neurons to iontophoretic application of 5-HT or its agonists (el Mansari et al. 1994). Despite this reported lack of effect of DA destruction on 5-HT receptor function, later studies found an increase in 5-HT_{2A} receptor mRNA levels in the striatum after unilateral 6-OHDA lesions in adult rats (Numan et al. 1995; Zhang et al. 2007) in which 5-HT is elevated (Zhou et al. 1991; Guerra et al. 1997; Maeda et al. 2003). This striatal 5-HT receptor increase was abolished by L-dopa treatment (Zhang et al. 2007), suggestive that the regulation of striatal 5-HT_{2A} receptors is primarily dependent upon DA acting on DA receptors. At odds with these results, a more recent study performed in adult 6-OHDA-lesioned animals using [^{3}H] ketanserin-binding autoradiography showed reduced 5-HT_{2A} receptor levels in the striatum, as well as in the cingulate, insular, prefrontal, and primary somatosensory cortices (Li et al. 2010). In contrast to this increase, studies in adult 6-OHDA-lesioned rats have also shown a decrease in 5-HT_{2C} receptor mRNA levels in the striatum (Zhang et al. 2007). L-dopa treatment had no effect on 5-HT_{2C} mRNA levels in this region (Zhang et al. 2007), suggesting that the 5-HT_{2C} and 5-HT_{2A} receptors are differentially regulated by the nigrostriatal DA function. Also in adult 6-OHDA-lesioned animals, one study found no change in striatal 5-HT_4 receptor levels upon binding with the selective radioligand [^{125}I] SB 207710 (Patel et al. 1995), while another found increases in the caudal, but not rostral, striatum and globus pallidus upon binding with the 5-HT_4 receptor antagonist [^{3}H] GR113803 (Compan et al. 1996). Such discrepancies could be due to methodological factors, such as the type of ligand used, the state of receptor affinity measured, the actual placement of the 6-OHDA lesion, and/or the part of the brain region analyzed.

In striatum of neonatal 6-OHDA-lesioned rats in which 5-HT was elevated, quantitative ligand binding utilizing autoradiography has revealed changes in several 5-HT receptor subtypes at adulthood (Radja et al. 1993a; Reader and Dewar 1999; Kostrzewa et al. 1998; Laprade et al. 1996). Binding of [^{3}H] 5-HT revealed an increase throughout the striatum and SN after neonatal lesioning, but not in the globus pallidus (Radja et al. 1993a), suggestive that this upregulation occurs primarily on striatonigral as opposed to striatopallidal projection neurons. Labeling of 5-HT_{1B} receptors with the nonselective radioligand [^{125}I] cyanopindolol revealed an increase in the binding density of these receptors

throughout the striatum (i.e., both rostral and caudal halves), globus pallidus, and SN 3 months after the neonatal lesions (Radja et al. 1993a). Since previous studies showed that 5-HT_{1B} mRNA was present in the striatum but not in SN or globus pallidus of rats (Bruinvels et al. 1994), the increase in 5-HT_{1B} binding seen in the striatum, globus pallidus, and SN was suggested to result from an upregulation and increased transport of these receptors on striatal GABAergic projection neurons (Reader and Dewar 1999). Moreover, labeling of 5-HT_{2A} receptors with [^{125}I] iodimethoxyphenylamino-propane, or [^{125}I] DOI, revealed a marked increase in this receptor subtype in the rostral striatum of adult rats lesioned as neonates (Radja et al. 1993a). The anatomical distribution of increased 5-HT_{2A} receptors strongly correlated with that of 5-HT hyperinnervation in the rostral striatum, initially suggestive of a relationship between the two phenomena. However, studies established that the majority of 5-HT_{2A} receptors are postsynaptic to 5-HT neurons (Mengod et al. 1990) and that the increase in 5-HT_{2A} receptors occurs independent of the 5-HT hyperinnervation (Laprade et al. 1996; Basura and Walker 1999; Fox and Brotchie 2000; Kostrzewa et al. 1998). The increased 5-HT_{2A} binding density in the rostral striatum was also associated with a considerable increase in mRNA encoding for this receptor within lateral parts of the striatum of the neonatal lesioned rats (Laprade et al. 1996). In these neonatal lesioned animals, both changes were abolished after chronic treatment with apomorphine or the D_1 receptor agonist SKF-38393, suggesting that D_1 receptor activation participates in the degree of 5-HT_{2A} receptor expression (Laprade et al. 1996). Examination of the 5-HT_{1A} receptor subtype upon specific labeling with [^{3}H] 8-hydroxy-dipropyl-aminotetralin or [^{3}H] 8-OH-DPAT revealed no changes in the binding density of these receptors in adult striatum after neonatal 6-OHDA lesions (Radja et al. 1993a), nor was there any changes in 5-HT_{1A} mRNA levels (Numan et al. 1995).

4.4 Adaptations in GABA and Other Amino Acid Transmitter Systems by 6-OHDA

Discrete populations of GABAergic medium-sized spiny neurons in the striatum project their axons to the globus pallidus, entopeduncular nucleus (internal pallidum), and SN (Beckstead and Cruz 1986; Bolam and Smith 1990; Loopuijt and van der Kooy 1985). The inhibitory activity of these GABAergic neurons (van der Heyden et al. 1980) appears to be modulated by the ascending nigrostriatal DA fibers arising from the SNpc (van der Heyden et al. 1980; Samuel et al. 1988; Vernier et al. 1988; Reid et al. 1990). This efferent GABAergic population from the striatum is predominately subdivided into two subclasses, defined by the nature of their co-transmitters (Penny et al. 1986; Reiner and Anderson 1990) and the differential expression of D_1 and D_2 receptor subtypes on their surface. The striatal GABAergic neurons that project to the SN and entopeduncular nucleus mainly express D_1 receptors and their axons contain the neuropeptides substance P, neurokinin A, and dynorphin, while those that project to the globus pallidus predominately express D_2 receptors and contain the neuropeptide enkephalin

(Gerfen and Young 1988; Gerfen et al. 1990, 1991; Gerfen 1992). These striatonigral and striatopallidal pathways work in concert to regulate thalamic output to motor areas of the cortex and thus play an integral role in the execution of movement. More recently, a third, smaller population of striatal GABAergic neurons has been identified that co-expresses both D_1 and D_2 receptors as well as the neuropeptides substance P and enkephalin (Perreault et al. 2011). Unlike the striatal GABAergic neurons expressing only D_1 or D_2 receptors, these D_1/D_2 receptor striatal projection neurons terminate in regions within both the striatonigral and striatopallidal pathways, as well as regions containing DAergic cell bodies such as the VTA (Deng et al. 2006; Wang et al. 2006, 2007). While little is known about the functional relevance of these latter neurons, they are thought to contribute to the regulation of thalamic neurotransmission, perhaps with the purpose of maintaining homeostatic balance between the striatonigral and striatopallidal pathways (Perreault et al. 2011). An imbalance between the striatonigral and striatopallidal pathways, such as seen with DAergic degeneration in humans and in animals (Albin et al. 1989; DeLong 1990; Hikosaka et al. 2000; Bezard et al. 2001; Obeso et al. 2004), can affect the final outflow to the thalamus and contribute to motor disturbances (Gerfen et al. 1990; Gerfen 2000; Mallet et al. 2006).

Increased GABA Levels. In adult rats, unilateral DA depletion with 6-OHDA has been reported to increase endogenous GABA levels (Tanaka et al. 1986; Lindefors et al. 1989), to increase potassium (K^+)-stimulated in vivo release of GABA (Lindefors et al. 1989; Tossman et al. 1986), and to increase the activity of glutamic acid decarboxylase (GAD), the enzyme responsible for converting glutamic acid to GABA (Nagy et al. 1978; Segovia et al. 1990; Samuel et al. 1988), and GAD mRNA levels (Vernier et al. 1988; Lindefors et al. 1990; Segovia et al. 1990; O'Connor et al. 1991). In neonatal rats, bilateral DA depletions have also resulted in increased tissue GABA levels in the striatum as well as in target regions of the striatopallidal and striatonigral projections, namely, the globus pallidus and SN 2–3 months after the lesion (Molina-Holgado et al. 1993a, b). This increase in GABA levels in the neonatally lesioned striatum was found to correspond to increased GAD mRNA expression (Soghomonian 1993; Laprade and Soghomonian 1999). Because nigrostriatal DA terminals that synapse on GABAergic medium-sized neurons exert an inhibitory effect over striatal GABA neurons (van der Heyden et al. 1980; Reid et al. 1990), attenuation of this inhibition after lesioning DA neurons is likely responsible for the increase in striatal GABA levels. In this respect, studies have shown that enhanced GABAergic activity after neonatal 6-OHDA lesions is influenced substantially by DA receptor status, since irreversible blockade of DA receptors by N-ethoxycarbonyl-2ethoxy-1,2-dihydroquinoline (EEDQ) decreased both D_1 and D_2 sites (73–84 %) in control and neonatal lesioned striatum, but increased GABA levels by 25 % only in rats that received 6-OHDA after birth (Molina-Holgado et al. 1995). Further, following acute inhibition of DA synthesis or catabolism, GABA levels remain unchanged. While not found in control rats, a positive correlation occurred between increased GABA levels and the density of D_2 receptors, but not D_1 receptors, in the striatum of neonatal

6-OHDA-lesioned rats, a finding suggestive of a direct role for D_2 receptors in this regulation (Molina-Holgado et al. 1995). The increase in D_2 receptors in the striatum, presumably on GABAergic neurons that project to the globus pallidus (striatopallidal pathway) may play a key role in maintaining this permanent increase in GABAergic transmission in rats with neonatal 6-OHDA lesions.

Altered GABA Receptors. Accompanying the 6-OHDA increase in GABA-containing neurons is an increase in density of some GABA receptors in the striatum of neonatal lesioned rats (Molina-Holgado et al. 1995) – a change which likely produces plasticity of GABA-mediated signaling in neurons that form the major output systems of the striatum (i.e., the striatonigral and striatopallidal neurons). In rats lesioned unilaterally with 6-OHDA as adults, $GABA_A$ receptors were decreased in the striatum and globus pallidus, but increased in the SNr and entopeduncular nucleus (Pan et al. 1985). In neonatal 6-OHDA-lesioned rats, $GABA_A$ receptors labeled with the radioligand [^{3}H] muscimol were increased in the striatum, but not in the cerebral cortex or thalamus (Molina-Holgado et al. 1993a). It has been postulated that the increased [^{3}H] muscimol labeling in the striatum of neonatal lesioned rats targets $GABA_A$ receptors situated on hyperinnervated 5-HT fibers in the rostral striatum (Molina-Holgado et al. 1993a). Intracerebral microdialysis studies have shown that the striatal 5-HT hyperinnervation is not associated with enhanced basal levels of extracellular 5-HT (Jackson and Abercrombie 1992).

Changes in Other Amino Acid Transmitters. In addition to GABA, studies have demonstrated lasting increases in several other amino acids in the striatum and other regions of the basal ganglia in neonatal 6-OHDA-lesioned rats (Molina-Holgado et al. 1993a, b). In the striatum, aspartic acid and glycine were increased 3 months after the lesion, while in the globus pallidus, taurine, glutamine, aspartic acid, serine, and alanine were elevated (Molina-Holgado et al. 1993a, b). In the SN, only increases in taurine, glutamic acid, and glutamine were documented. When the amino acid profiles were compared to the relative amino acid composition of the tissues, the ratio of glutamic acid to GABA was decreased in the striatum and SN, but remained unchanged in the globus pallidus (Molina-Holgado et al. 1993b). Since the glutamic acid/GABA ratio can serve as an index for precursor product availability for GABA (Molina-Holgado et al. 1993b; Berl 1973), the decreased glutamic acid/GABA ratio implied an enhanced inhibitory influence relative to glutamic acid-mediated excitations in the striatum and SN (Molina-Holgado et al. 1993b). Such persistent and regionally distinct biochemical adjustments in amino acids within these basal ganglia regions demonstrate the extraordinary ability of the developing system to reorganize itself after early neonatal damage to DA neurons.

4.5 Altered Cholinergic Function

Studies using the technique of in vivo microdialysis have demonstrated a decrease in the release of endogenous acetylcholine (ACh) in the striatum in response to D_2 receptor agonists administered either systemically or locally through the dialysis

probe (Damsma et al. 1990; de Boer et al. 1990; De Boer et al. 1992). This finding is consistent with evidence that there is an important functional and anatomical relationship between D_2 receptors and cholinergic interneurons in the striatum. In addition to changes in striatal D_2 receptor density after 6-OHDA lesions to DA neurons, an increase in [^{3}H]hemicholinium-3 binding, a marker for cholinergic terminal density has been reported (Joyce 1991b). Moreover, systemic or local administration of D_2 blockers produces an increase in endogenous ACh release in the striatum (Damsma et al. 1991; De Boer et al. 1992). A study by Guyenet et al. revealed that there is a loss of tonic DA inhibitory control over the release of ACh after 6-OHDA treatment in adult rats (Guyenet et al. 1975). This effect was found to be reversed several weeks later, suggesting that the DA control is eventually reinstated in the lesioned animals (Guyenet et al. 1975; MacKenzie et al. 1989). This reinstatement has been suggested to be dependent upon increases in both the number of D_2 receptors and the activity of the high-affinity choline transport system associated with cholinergic terminals (Joyce 1991b).

4.6 Altered Expression of Neuropeptides

The enkephalin and tachykinin (substance P and neurokinin A) peptides have been shown to be present in high concentrations in the basal ganglia (Graybiel and Ragsdalev 1983). As mentioned earlier, two predominant subpopulations of GABAergic output neurons have been identified in the striatum that have distinct neuropeptide profiles. The striatopallidal pathway expresses enkephalin, whereas the striatonigral pathway expresses tachykinins and dynorphin (Gerfen and Young 1988; Gerfen et al. 1990, 1991; Gerfen 1992). Early ultrastructural studies showed that nigrostriatal DA neurons directly synapse on the enkephalin- and tachykinin-containing GABAergic neurons in rats (Kubota et al. 1986a, b; Kawai et al. 1987). This observation is consistent with the work demonstrating that these neuropeptide systems are regulated by nigrostriatal DA input (Bannon et al. 1987; Basura and Walker 2000; Campbell et al. 2001; Engber et al. 1992; Gerfen et al. 1990; Hanson et al. 1981; Li et al. 1987; Sivam 1989; Sivam et al. 1986, 1987; Sivam and Krause 1990; Walker et al. 1991; Young et al. 1986; Obeso et al. 2000).

6-OHDA Treatments on Neuropeptides. In adult unilateral 6-OHDA-lesioned rats, immunohistochemical studies showed that striatal enkephalin is increased ipsilateral to the lesion (Voorn et al. 1987; Engber et al. 1991; Taylor et al. 1992; Cenci and Bjorklund 1993; Campbell and Bjorklund 1994; Thal et al. 1983), while substance P is decreased in the striatum (Voorn et al. 1987; Engber et al. 1991; Sivam 1989, 1991; Sivam et al. 1987). Electron microscopic analysis revealed that the enkephalin-immunoreactive synaptic bouton profiles in the striatum are increased by the lesion, without affecting the boutons on postsynaptic targets (Ingham et al. 1991). Furthermore, the unilateral 6-OHDA lesions were found to be accompanied by an increase in mRNA enkephalin levels (Gerfen et al. 1991; Campbell et al. 1992; Cenci et al. 1993; Nisenbaum et al. 1994a, b; Voorn et al. 1994; Zeng et al. 1995) and a decrease in preprotachykinin mRNA levels

(Campbell et al. 1992; Campbell and Bjorklund 1994; Nisenbaum et al. 1994a, b; Zeng et al. 1995). Studies also showed that transplants with DA-rich fetal cells are able to reverse the increased striatal enkephalin levels (Abrous et al. 1993b; Bal et al. 1993) consistent with striatal enkephalin levels being controlled by nigrostriatal DA neurons (Bannon et al. 1987; Basura and Walker 2000; Campbell et al. 2001; Engber et al. 1992; Gerfen et al. 1990; Hanson et al. 1981; Li et al. 1987; Sivam 1989; Sivam et al. 1986, 1987; Sivam and Krause 1990; Walker et al. 1991; Young et al. 1986; Obeso et al. 2000).

Although bilateral 6-OHDA lesions in both neonatal and adult rats have consistently increased both enkephalin protein and its mRNA levels (Sivam et al. 1986, 1987, 1991; Sivam and Krause 1990; Kurumaji et al. 1988; Cimino et al. 1991; Soghomonian 1994), only neonatal lesions consistently produce a decrease in the tachykinin peptides substance P and neurokinin A in the striatum (Sivam 1989; Sivam et al. 1987, 1991; Sivam and Krause 1990). Snyder-Keller and colleagues reported that the neonatal DA depletions do not affect the patchy distribution of substance P immunostaining, nor do they affect the distribution of enkephalin in the matrix of the striatum (Snyder-Keller 1991), suggesting that the basic organization of the striatal patch and matrix compartments develop normally in the absence of DA innervation early in development. In addition, while neonatal DA depletion was found to enhance the release of ACh, it has no effect on the action of substance P- or neurokinin A-induced ACh release in rat striatal slices (Perez-Navarro et al. 1993), indicating that striatal cholinergic neurons are modulated by tachykinin peptides independently of the presence of nigrostriatal DA neurons.

The effect of adult and neonatal 6-OHDA lesions on enkephalin, tachykinin, and other peptide levels has also been examined in the SNr, globus pallidus, and nucleus accumbens of rats. Immunohistochemistry and in situ hybridization studies showed that enkephalin and its mRNA levels are enhanced in the SNr after either adult unilateral or neonatal 6-OHDA lesions (Sivam et al. 1987; Vankova et al. 1991; Gerfen et al. 1991). In rats with adult unilateral lesions, neurotensin was reported to be increased and substance P reduced in the SNr (Taylor et al. 1992). In the SNr of rats with neonatal 6-OHDA lesions, no change in neurotensin was reported (Luthman et al. 1990a), although both substance P and neurokinin A were significantly reduced, an effect not observed in adult bilateral-lesioned rats (Sivam et al. 1987). Moreover, enkephalin and its mRNA (Schuller et al. 1999), neurotensin, and substance P were all increased in the globus pallidus of adult rats with unilateral lesions, but the increases were found within distinct neuronal subpopulations (Martorana et al. 2003). The contents of mRNA for enkephalin and peptides for leu- and met-enkephalin were increased, whereas mRNA for dynorphin and substance P were decreased in more rostral parts than caudal parts of the nucleus accumbens after adult unilateral 6-OHDA lesions (Taylor et al. 1992; Voorn et al. 1994). Similarly, neonatal 6-OHDA lesions produced reductions in substance P in the nucleus accumbens (Luthman et al. 1990a). Generally, the changes in peptide levels observed in the SNr, globus pallidus, and nucleus accumbens appear to reflect the peptide and mRNA changes documented in the striatum. A functional relationship between the nigrostriatal DA system and enkephalin or tachykinin

systems in the basal ganglia has been suggested by several investigators (Hong et al. 1978a, b, 1979, 1985; Joyce and Iversen 1979; Bannon et al. 1986; Hanson et al. 1981; Tang et al. 1983).

Evidence has also indicated the participation of corticostriatal afferents and cholinergic function in the regulation of these neuropeptides in the striatum. For example, frontal cortical transections after 6-OHDA treatment in adult animals were found to reverse the lesion-induced increase in preproenkephalin mRNA in the medial striatum, but have no effect on the upregulation found in the lateral striatum (Campbell and Bjorklund 1994). The decrease in preprotachykinin mRNA within the striatum was unaffected by interruption of the corticostriatal afferents (Campbell and Bjorklund 1994). Systemic administration of the muscarinic cholinergic receptor antagonist scopolamine to adult 6-OHDA-lesioned rats prevented the increase in enkephalin mRNA levels in the striatum (Nisenbaum et al. 1994b). Similarly, high doses of systemic scopolamine blocked the lesion-induced decrease in striatal substance P mRNA levels, possibly as a result from an action of scopolamine within other brain areas (Nisenbaum et al. 1994b). In addition to cortical influences, neuropeptide changes induced by adult unilateral 6-OHDA lesions have been shown to be inhibited by lesions of the subthalamic nucleus (Delfs et al. 1995), suggesting that this region can influence peptide function in the striatum through polysynaptic pathways. This latter conclusion is based upon the observation that lesions of the subthalamic nucleus inhibit neuropeptide changes induced by the 6-OHDA in brain regions that do not receive a direct input from the subthalamus.

In addition to the enkephalin and tachykinin peptides, 6-OHDA lesions have also been shown to alter levels of other peptides, including cholecystokinin, neurotensin, and somatostatin in the striatum. In adult rats, nigrostriatal DA depletion induced cholecystokinin and neurotensin mRNA in the striatum (Schiffmann and Vanderhaeghen 1992; Engber et al. 1992). The cholecystokinin mRNA expression was limited to dorsolateral parts of the ipsilateral denervated striatum (Schiffmann and Vanderhaeghen 1992). The increase in cholecystokinin was particularly unexpected, since cholecystokinin co-localizes with TH in the SNpc and VTA, even though not all DA neurons contain this peptide (Savasta et al. 1989). Furthermore, dynorphin mRNA expression in striatal patch neurons showed a marked reduction, while matrix neurons showed no change after lesioning of DA neurons in adult animals (Gerfen et al. 1991). Finally, a unilateral 6-OHDA lesion performed in neonatal rats had no effect on somatostatin mRNA (Cimino et al. 1991), but was found to increase neurokinin B, a member of the tachykinin family, on the ipsilateral side of the lesion (Burgunder 1991).

Drug Challenges on Neuropeptides After 6-OHDA. Treatment with DA agonists further implicated nigrostriatal DAergic control of neuropeptides located in the striatum. It has been shown that chronic treatment with either a D_1 or D_2 receptor agonist in adult unilateral 6-OHDA-lesioned rats affects several neuropeptides, but in distinct ways. Systemic administration of the D_2 receptor agonist quinpirole inhibited the increase in enkephalin mRNA levels in these lesioned animals (Nisenbaum et al. 1994b; Engber et al. 1992). Moreover, systemic administration and direct infusion of quinpirole for 7 days to lesioned animals elevated

somatostatin and neuropeptide Y levels in the striatum, but decreased the lesion-induced increase in neurotensin and enkephalin (Nisenbaum et al. 1994b; Engber et al. 1992). Administration of the D_1 receptor agonist SKF-38393 had no effect on enkephalin, but reduced somatostatin and neuropeptide Y levels, and increased neurotensin and dynorphin levels in the striatum of unilateral 6-OHDA-lesioned animals (Engber et al. 1992). These findings suggested that a reciprocal relationship exists between the function of these neuropeptides and the DA receptor subtypes in rats with a unilateral lesioning of DA neurons. In neonatal lesioned animals, administration of SKF-38393 beginning 24 h after 6-OHDA treatment reversed the lesion-induced increase in enkephalin and decrease in substance P in the striatum, while quinpirole (LY-17155) had no effect (Sivam and Cox 2006), suggesting an important role for D_1 receptors in the postnatal development of enkephalin and substance P systems in this region. Kaakkola and colleagues found that circling behavior induced by an enkephalin analog, FK 33-824, microinjected into the SNr is antagonized by 6-OHDA lesions, suggesting that the response is mediated by the nigrostriatal DA pathway (Kaakkola 1980). In contrast, increased locomotor and rearing behavior in rats induced by microinjection of the peptidase-resistant enkephalin analog D-ala-met-enkephalamide (DALA) into the nucleus accumbens was found to be unaffected by the destruction of the mesolimbic DA system with 6-OHDA, indicating that this action occurred independent of an intact mesolimbic DA system (Kalivas et al. 1983).

5 Behavioral Supersensitivity After 6-OHDA Lesions

5.1 Hyperlocomotor and Stereotyped Responses to DA Agonists

Since the early 1970s, it has been established that all treatments resulting in the inhibition or loss of DA transmission in the adult striatum induce a behavioral supersensitivity to agonist administration. This phenomenon is most commonly examined by testing rats for their rotational response to mixed D_1/D_2 receptor agonists (e.g., apomorphine) following adult unilateral lesions of the nigrostriatal DA pathway (Schwarting and Huston 1996). The behavioral supersensitivity after adult unilateral 6-OHDA lesions has been associated with the increase in D_2 receptor number found in the striatum, suggesting that the change in D_2 receptor density is one mechanism by which the DA denervation-induced supersensitivity occurs (Creese et al. 1977; Marshall and Ungerstedt 1977). Although rats unilaterally lesioned with 6-OHDA provide a useful model to examine drug actions in the CNS, one major problem is that the behavioral response to DA agonists cannot be examined in non-lesioned animals. An additional problem is that the intact control hemisphere may undergo a rapid reorganization (morphological and/or neurochemical) subsequent to the unilateral DA depletion which would allow for compensatory function on the contralateral side of the lesion (Tillerson et al. 2001; Woodlee et al. 2008), necessitating the assessment of biochemical changes in non-lesioned striatum as well in order to avoid a possible misinterpretation of data.

Bilateral destruction of DA neurons in adult rats has also been used to examine supersensitive responses to DA agonists. While systemic administration of low doses of apomorphine and L-dopa in controls produces a minor increase in locomotor responsiveness that is accompanied by sniffing, these D_1/D_2 receptor agonists induce a major increase in locomotion in the bilaterally lesioned rats. The elevated locomotor response to apomorphine in the adult rats was found to be blocked by haloperidol, *cis*-flupentixol, and SCH-23390 (Breese et al. 1985a). Likewise, these adult bilaterally lesioned rats exhibited a major increase in activity when administered a D_2 agonist, with only a variable, but modest limited increase being observed after D_1 agonist administration (Breese et al. 1985a). In this latter case, haloperidol prevented the locomotor response to the D_2 agonist, but SCH-23390 did not (Breese et al. 1985a).

Systemic treatment of intact adult rats with amphetamine or apomorphine also induces a repetitive occurrence of distinct stereotypic behaviors (Costall and Naylor 1974; Costall et al. 1975, 1977; Creese and Iversen 1974). The DA agonist-induced stereotypic behaviors are thought to reflect short-term changes in activity of DA receptors in the striatum of intact rats (Breese et al. 1984a; Costall and Naylor 1981; Silbergeld and Pfeiffer 1977). Increased locomotor activity and concomitant floor sniffing are the first components to occur following low doses of DA agonist (Breese et al. 1984a, 1985a), followed by repetitive limb and head movements such as rearing, paw treading, head bobbing, and floor/wall sniffing (Breese et al. 1984a, 1985a). At higher doses, locomotor components drop out and repetitive head and mouth movements (perioral responses) such as licking, biting, and gnawing predominate. Administration of apomorphine or an additional mixed D_1/D_2 receptor agonist, L-dopa, to rats after adult bilateral 6-OHDA lesions produces a marked increase in locomotor activity over non-lesioned animals (Hollister et al. 1974) that is accompanied by stereotypic behaviors such as intense sniffing, rearing, paw treading, and head bobbing, reflecting a supersensitivity of DA receptors (Creese and Iversen 1974). In contrast, D-amphetamine does not produce any behavioral effects following its administration to these adult animals (Hollister et al. 1974). In unilaterally lesioned adults, d-amphetamine induces contralateral turning, a response opposite to that seen with apomorphine (Ungerstedt 1971b, d). Since amphetamine exerts its behavioral effects through the release of DA and blockade of its uptake into the nerve terminal, its ineffectiveness is the consequence of the 6-OHDA-induced DA loss (Breese et al. 1974).

Breese and colleagues were the first to show that certain behavioral responses to apomorphine and L-dopa in neonatal 6-OHDA-lesioned rats were significantly different from those in adult 6-OHDA-lesioned rats (Breese et al. 1984a, b, 1985b). While increased locomotion, sniffing, paw treading, and head nodding were behaviors characteristically associated with the mixed D_1/D_2 agonist administration to rats bilaterally lesioned with 6-OHDA as adults or as neonates, self-biting and a distinct behavior involving the repeated drawing of the forepaws up to and away from the nose referred to as "taffy pulling" were common unique responses in the neonatal lesioned rats. Both groups showed elevated rearing after either L-dopa or apomorphine treatment, indicative of their supersensitivity to these

challenges (Breese et al. 1984a, b, 1985b). However, a high percentage of rats with neonatal 6-OHDA lesions exhibited self-injurious behavior (SIB) to a D_1/D_2 DA agonist challenge, an effect not found in rats bilaterally lesioned with 6-OHDA as adults (Breese et al. 1984a, b, 1985b). While haloperidol reduced some behaviors including SIB induced by L-dopa in the neonatal lesioned rats, Breese and colleagues (1984a) further showed that *cis*-flupentixol was more potent than haloperidol in antagonizing the self-biting induced by L-dopa. In light of the report by Hyttel that *cis*-flupentixol was more selective for the D_1 receptor site than the D_2 receptor site (i.e., the haloperidol binding site) (Hyttel 1978), inhibition of SIB by *cis*-flupentixol suggested that D_1 receptors might be involved in the behavioral supersensitivity observed in rats depleted of DA during development (Breese et al. 1984a). Later studies showed that pretreatment with SCH-23390, a D_1 receptor antagonist, blocked self-biting and the SIB induced by L-dopa in neonatal 6-OHDA-lesioned animals, while D_2 receptor antagonists had a lesser effect (Breese et al. 1985a, 1989). Surprisingly, Breese et al. also reported that individual treatment with either a D_1 or D_2 receptor antagonist did not block the supersensitive locomotor response to L-dopa in adult or neonatal rats lesioned with 6-OHDA (Breese et al. 1985a). However, when these antagonists were combined, the enhanced locomotor activity induced by the L-dopa was virtually eliminated.

In subsequent studies, responses to specific D_1 and D_2 receptor agonists provided further evidence for distinct differences in responsive to these agonists depending on the age at which the DA was destroyed. When administered the specific D_2 receptor agonist LY-171555 (quinpirole), adult rats with bilateral 6-OHDA lesions exhibited a much greater locomotor responsiveness than did neonatal lesioned animals (Breese et al. 1985a). In contrast, neonatal lesioned rats demonstrated a significantly greater behavioral responsiveness to administration of SKF-38393, a specific D_1 receptor agonist, than did the adult lesioned group (Breese et al. 1985a). These findings suggested that the supersensitivity to DA agonists in the neonatal lesioned rats is primarily mediated by D_1 receptors, whereas D_2 receptors show greater sensitivity in the adult lesioned rats (Breese et al. 1985a). Such data provide further support for the view that the neonate and adult 6-OHDA lesions of the DA system induce adaptations that result in an altered functional relationship between D_1 and D_2 receptor function.

Altered Responses to DA Antagonists. As noted before, both neonatal and adult 6-OHDA-lesioned rats can be profoundly affected by doses of the catecholamine synthesis inhibitor α-MT that have no impact in non-lesioned animals – a further demonstration of the importance of residual DA function in the lesioned animals (Cooper et al. 1973a; Luthman et al. 1995; Moy 1995; Potter and Bruno 1989; Rogers and Dunnett 1989a). Therefore, studies were undertaken to evaluate whether treatment with selective DA receptor antagonists to minimize the action of residual DA function in neonatal and adult lesioned rats would provide further support for the concept that age-dependent differences exist between the two groups. In this respect, adult rats lesioned as neonates show a subsensitivity to the D_2 receptor antagonist haloperidol and the D_1 receptor antagonist SCH-23390 compared to the action in adult lesioned rats (Bruno et al. 1984; Duncan et al. 1987).

In non-lesioned controls and adult 6-OHDA-lesioned rats, Duncan and colleagues demonstrated that acute administration of either haloperidol or SCH-23390 produced a dose-dependent increase in akinesia (measured as movement on an inclined screen) (Duncan et al. 1987). In contrast, no significant alteration in immobility was observed in neonatal 6-OHDA-lesioned rats, even at a dose of SCH-23390 twice that necessary to produce akinesia in controls (Duncan et al. 1987). In another study, Bruno and colleagues reported subsensitivity to the akinesia-producing effect by haloperidol and fluphenazine, another neuroleptic, in neonatal rats lesioned at P3, but not those lesioned at P10, when tested during adulthood (Bruno et al. 1987). Rats with neonatal 6-OHDA lesions have also shown a subsensitivity to the effect of DA antagonist pimozide on lateral hypothalamic self-stimulation (Stellar et al. 1988), a finding which led researchers to suggest that a non-DA process mediates the observed behavioral sparing in these animals.

5.2 Priming of D_1 Agonist-Induced Supersensitivity

In rats lesioned as neonates, maximal supersensitivity of locomotor and stereotyped responses to SKF-38393 is achieved by administering multiple doses of the D_1 agonist at weekly intervals over a period of 4 weeks (Breese et al. 1985a). This effect, referred to as "priming of D_1 receptor supersensitivity," does not occur in rats with adult bilateral 6-OHDA lesions (Breese et al. 1985a). Such a sensitization process was not found after repeated D_2 agonist treatment to neonatal 6-OHDA-lesioned rats, nor did a D_2 antagonist block the priming sensitization caused by SKF-38393 (Criswell et al. 1989). From studies involving intra-accumbens and intrastriatal antagonist-induced suppression of these behaviors, the enhanced locomotor effects could be attributed mainly to activation of D_1 receptors in the nucleus accumbens and stereotypies to activation of D_1 receptors in either the accumbens or the striatum (Breese et al. 1987a). Treatment with a full D_1 receptor agonist such as A-68390 or SKF-82958 can also induce priming in neonatal 6-OHDA-lesioned rats (Johnson et al. 1992; Bishop et al. 2003), although a major disadvantage is that large doses of these D_1 receptor agonists desensitize the D_1 receptors. Still, at a reasonable dose, full D_1 agonists are more potent at inducing the priming phenomenon than SKF-38393 (Johnson et al. 1992; Bishop et al. 2003). The subsequent evaluation of priming of D_1 receptor supersensitivity demonstrated that this effect was long-lasting and possibly permanent (Criswell et al. 1989). Another line of research focusing on increased oral activity in neonatal lesioned rats demonstrated a marked supersensitivity of these animals to SKF-38393 even at 8 months of age (Kostrzewa and Gong 1991). Furthermore, the repeated administration of a D_1 receptor agonist to pre-weanling rat pups was found to cause a partial priming effect in adulthood (Gong et al. 1993a). Additionally, Kostrzewa and Kostrzewa found that quinpirole-induced vertical jumping induced during postnatal ontogeny was enhanced by neonatal 6-OHDA lesioning (Kostrzewa and Kostrzewa 2012).

Although adult animals given bilateral 6-OHDA lesions do not exhibit a priming effect with repeated DA agonist treatments, Morelli and DiChiara demonstrated that priming to SKF-38393 can be observed in adult animals given unilateral 6-OHDA lesions (Morelli and Di Chiara 1987). In this case, prior exposure to either a D_1 or D_2 receptor agonist results in an enhanced behavioral response to SKF-38393. While neonatal 6-OHDA-lesioned rats do not show a sensitization process to quinpirole after repeated treatments, they do, like adult unilateral lesioned animals, show a supersensitized response to SKF-38393 following a previous exposure to the selective D_2 agonist (Criswell et al. 1989). This evidence suggested that both neonatal and adult unilateral lesions may result in comparable adaptations of the DA system, while bilateral lesions in adult animals produce different compensatory changes.

5.3 Functional Uncoupling of D_1 and D_2 Receptors by 6-OHDA

In non-lesioned rats, evidence has accumulated that D_1 and D_2 receptors are functionally "coupled." In this regard, Breese and colleagues reported that the locomotor stimulant effect of apomorphine, which has its primary effects on the D_1/D_2 receptor sites, could be inhibited in non-lesioned animals by SCH-23390 (Breese and Mueller 1985; Breese et al. 1986), receptor antagonist with documented specificity for the D_1 receptor (Billard et al. 1984; Molloy and Waddington 1984). Subsequently, Breese and Mueller demonstrated that this specific D_1 receptor antagonist also prevented the locomotor response to the specific D_2 agonist, quinpirole, in control rats, just as did haloperidol, a D_2 receptor antagonist (Breese and Mueller 1985). In contrast to this finding, SCH-23390 was then found to be without effect on the response to this D_2 agonist in rats with DA neurons lesioned with 6-OHDA. These findings suggested that the coupled functional interaction between D_1 and D_2 receptor subtypes to reach a maximal response appears to be dependent upon having an intact DA system (Breese and Mueller 1985). In additional studies, disruption of CAergic activity via the administration of reserpine and α-MT was found to reduce the ability of SCH-23390 to block the effects of quinpirole in non-lesioned animals (Breese et al. 1986). These data collectively demonstrated clearly that D_1 receptors can modulate D_2 receptors in rats by a mechanism dependent upon intact DA function (Breese and Mueller 1985). Such disruption in the functional coupling of D_1 and D_2 receptors after impaired DAergic transmission has subsequently documented by several other investigators (Walters et al. 1987; Jackson and Hashizume 1987; Longoni et al. 1987).

In additional studies by Breese and colleagues in which the role of D_1 and D_2 receptor involvement of L-dopa induced SIB was explored, D_1 and D_2 agonists were administered alone and in combination to neonatal lesioned rats (Breese et al. 1985a). Repeated administration of the selective D_1 agonist SKF-38393 to rats with neonatal 6-OHDA lesions at doses that produced priming did not lead to SIB, even though L-dopa-induced SIB could be blocked by a selective D_1 receptor

antagonist. Moreover, treatment with the D_2 agonist quinpirole alone likewise did not lead to SIB (Breese et al. 1985a). Importantly when a low dose of quinpirole was combined with a low dose of SKF-38393, SIB was observed in the majority of neonatal 6-OHDA-lesioned rats treated (Breese et al. 1985a). This later finding suggested that while D_1 receptor activation is essential for SIB to develop in rats with neonatal lesions, D_2 receptor activation, which also occurs with L-dopa treatment, is needed for the maximal expression of this SIB response. Johnson and Bruno showed that treatment with either a specific D_1 or D_2 receptor antagonist decreased food intake and induced akinesia in non-lesioned rats at doses that had no effect in neonatal lesioned animals (Johnson and Bruno 1992). Only when both agonists were administered together did the lesioned animals exhibit a response comparable to non-lesioned rats. A functional uncoupling of D_1 and D_2 receptors by minimizing DA function may also explain the subsensitivity of neonatal 6-OHDA-lesioned rats to DA receptor antagonists (Johnson and Bruno 1990, 1992). Collectively, these observations provide further evidence for a functional relationship between the two DA receptor subtypes (D_1/D_2 coupling) being required for maximal effectiveness of DA function (Breese et al. 1985a).

The mechanisms involved in the D_1 and D_2 receptor interaction have been suggested to occur by receptor activation on discrete neurons (Gerfen et al. 1995; LaHoste et al. 2000) or by changes in D_2 receptor-mediated cholinergic interneuron activity with subsequent impact on D_1 receptor-expressing striatonigral neuronal transmission (Di Chiara et al. 1994). These possibilities would seem consistent with the fact that GABAergic striatonigral and striatopallidal pathways have distinct DA receptor subtypes (Gerfen 1992) and that lesioning of DA neurons disrupting D_1/D_2 receptor integration (Breese and Mueller 1985). However, more recent studies suggest that an interaction between D_1 and D_2 receptors occurring within the same cell may also be involved. For example, single medium spiny-to-medium spiny neuron synaptic connections in neonatal striatal cultures have been reported to exhibit modulation by both D_1 and D_2 receptor agonists (Geldwert et al. 2006), and the selective activation of D_1 or D_2 receptors in single striatal neurons has been shown to differentially modulate tetrodotoxin-sensitive sodium channels (Aizman et al. 2000). It is also now known that D_1 and D_2 receptors can form a heteromeric complex via a direct protein-protein interaction on medium spiny neurons that requires activation of both DA receptor subtypes for activation of the G-protein-coupled pathway (Rashid et al. 2007), an observation consistent with the striatal GABAergic neurons that co-expresses both D_1 and D_2 receptors (Perreault et al. 2011). Consequently, possibly neurons with single as well as both DA receptor subtypes could account for the "uncoupling" of DA function described with lesioning. Regardless, the uncoupling of D_1 and D_2 receptor function has been suggested to be linked to a number of psychiatric illnesses related to DA dysfunction, including schizophrenia, drug abuse, and depression (Lee et al. 2009; Pei et al. 2010; Fuxe et al. 2008).

5.4 Hyperlocomotor Responses to NMDA Antagonists

Distinct pharmacological profiles also emerge when neonatal and adult 6-OHDA-lesioned rats are administered MK-801, a noncompetitive antagonist of the *N*-methyl-D-aspartate (NMDA) receptor (Criswell et al. 1993; Morelli and Di Chiara 1990a). Rats lesioned as neonates show a latent supersensitivity to the hyperlocomotor stimulant action of MK-801 and CGS-19755, a competitive NMDA receptor antagonist. Rats lesioned as adults, either bilaterally or unilaterally, do not show this enhancement in MK-801-induced locomotor activity (Criswell et al. 1993; Morelli and Di Chiara 1990a; Carlsson and Carlsson 1989; Klockgether and Turski 1990; Morelli et al. 1992). Because pretreatment with α-MT inhibits some, but not all, of the stimulant effects of MK-801 in neonatal lesioned rats (Criswell et al. 1993), a portion of the increased locomotor response can be attributed to some mechanism other than catecholamine or DA release. Additional evidence that the effects of MK-801 are mediated by at least two distinct mechanisms arises from the observation that the coadministration of D_1 and D_2 receptor antagonists attenuates some, but not all, of the actions of the NMDA antagonist in neonatal lesioned animals (Criswell et al. 1993). In contrast, α-MT pretreatment in rats with adult lesions not only prevented the effects of MK-801 but also markedly attenuated any locomotor response (Criswell et al. 1993). The severity of α-MT-induced akinesia seen in the adult lesioned rats further underscores the importance of the residual DAergic activity in these animals.

Studies have also shown that MK-801 and other NMDA antagonists can potentiate the effects of DA agonists. In non-lesioned rats pretreated with reserpine and α-MT, the ability of L-dopa to diminish the resulting motor symptoms can be markedly potentiated by administering a single dose of MK-801 or CPP (a competitive NMDA antagonist), which on their own has no observed effects (Klockgether and Turski 1990). MK-801 also improves the effects of SKF-38393 on contralateral turning in rats given adult unilateral 6-OHDA lesions (Morelli and Di Chiara 1990a; Morelli et al. 1992), although the effects of MK-801 on L-dopa-induced turning remain variable (Morelli et al. 1994; Spooren et al. 2000; Paquette et al. 2010; Dupre et al. 2008). Interestingly, MK-801 can prevent L-dopa-induced SIB in a dose-dependent manner in neonatal 6-OHDA-lesioned rats, while potentiating some stereotyped behaviors, i.e., paw treading, paw licking, and rearing, produced by DA agonists (Criswell et al. 1990). It has been postulated that the differential effects of MK-801 in DA-depleted rats are owed to distinct interactions between MK-801 and the D_1 and D_2 receptor subtypes (Morelli and Di Chiara 1990a, b; Morelli et al. 1992).

In line with these earlier findings with MK-801 and CGS-19755, more recent studies have revealed that neonatal 6-OHDA-lesioned rats also exhibit supersensitivity to the effects of phencyclidine (PCP), another NMDA receptor antagonist (Moy and Breese 2002). The PCP supersensitivity, displayed as an enhanced locomotor activity, was most pronounced after repeated PCP treatment or after a brief priming regimen with a D_1 receptor agonist. This latter observation was

consistent with the process of sensitization of PCP that might be linked to changes in D_1 receptor function as noted in Sect. 5.5 to follow. Nonetheless, non-DAergic mechanisms may play a more important role in the acute attenuation of PCP effects in sensitized animals, since the enhanced locomotor responses in the neonatal lesioned animals could be blocked by the atypical antipsychotic agent olanzapine, a compound with activity at D_1, D_2 and specific 5-HT receptors (Bymaster et al. 1996), but not by haloperidol or SCH-23390 (Moy and Breese 2002). Later studies showed that the selective 5-$HT_{2A/2C}$-receptor antagonist ketanserin could significantly reduce PCP activation in lesioned rats, suggesting that the efficacy of olanzapine against PCP-induced sensitized responses may be mediated by one of these 5-HT_2 receptor subtypes (Moy et al. 2004).

5.5 NMDA Antagonist Inhibition of D_1 Agonist-Induced Supersensitivity

Apart from the stimulant effects on locomotor activity, blockade of the NMDA receptor can suppress some forms of neuronal plasticity, such as long-term potentiation (Morris et al. 1986), and can inhibit excitotoxic cell death induced by ischemia, trauma, and other insults (Hetman and Kharebava 2006). Important to this discussion of DA function, the long-lasting nature of priming of D_1 receptor supersensitivity to repeated doses of SKF-38393 in neonatal 6-OHDA-lesioned rats led to the hypothesis that this form of sensitization involves neural processes involving NMDA receptors similar to other forms of neuronal plasticity in CNS (Criswell et al. 1989). In line with this proposal, Criswell and colleagues showed that coadministration of MK-801 or CGS-19755 along with each priming dose of SKF-38393 blocked the behavioral sensitization (priming) observed by this repeated D_1 agonist administration to neonatal 6-OHDA-lesioned rats (Criswell et al. 1990). Since earlier work had demonstrated that the D_1 antagonist SCH-23390 also blocked the priming effect in neonatal lesioned rats (Criswell et al. 1989), it became clear that the concomitant activation of D_1 and NMDA receptors is likely necessary for priming of D_1 receptor supersensitivity in neonatal lesioned rats to occur. The indication that NMDA receptor activation is also a necessary prerequisite for other responses that convey long-term consequences suggested that these phenomena share a common biochemical mechanism with D_1 receptor-mediated priming (see Sect. 5.2).

5.6 IEG and Signal Transduction Pathway Involvement in D_1 Agonist-Induced Supersensitivity

To date, a number of mechanisms potentially responsible for the development of priming of D_1 receptor sensitivity in neonatal lesioned rats have been explored (Breese et al. 2005). The lack of any substantially significant changes in D_1 receptor mRNA and/or expression in the striatum of rats after neonatal 6-OHDA lesions led

to the speculation that perhaps enhanced intraneuronal second messenger levels or efficiency likewise accompanied D_1 agonist-induced priming in these animals (Gong et al. 1994). However, Gong and colleagues showed that basal as well as DA-, aluminum tetrafluoride-, and forskolin-stimulated adenylyl cyclase activities were not changed following repeated SKF-38393 treatment to neonatal lesioned rats during adulthood (Gong et al. 1994). Simson and colleagues also reported that SKF-38393-stimulated adenylyl cyclase activity was not altered in the striatum of these animals (Simson et al. 1992). These findings suggested that D_1 receptor-linked adenylyl cyclase is not a major determinant of enhanced behavioral responses in neonatal lesioned rats to repeated D_1 agonist administration. Likewise, other studies showed that adenosine 3–5′-monophosphate-regulated phosphoprotein (DARPP-32), a cyclic AMP-regulated phosphoprotein functionally linked to striatal D_1 receptors (Barone et al. 1994), remained unaffected in the adult striatum of neonatal lesioned rats primed with multiple SKF-38393 treatments (Luthman et al. 1990a; Breese et al. 1994).

Because earlier studies had linked the proto-oncogene *c-fos* to behavioral supersensitivity to L-dopa or D_1 agonists in rats either unilaterally or bilaterally lesioned with 6-OHDA as adults (Robertson et al. 1989a, b; Dragunow et al. 1991; Cole et al. 1993; Morelli et al. 1993), *c-fos* expression was examined in neonatal lesioned rats after D_1 agonist treatment. Expression of *c-fos* occurred only after a dose of D_1 agonist that was much higher than the behaviorally active dose and was not increased to a greater extent following repeated D_1 agonist treatments (Johnson et al. 1992). Moreover, while NMDA receptor antagonists could block the D_1 agonist-induced sensitization, it did not block *c-fos* expression in these animals (Johnson et al. 1992). Thus, it was concluded that *c-fos* is not a critical component in the priming phenomenon.

Mitogen-activated protein kinases (MAPKs) are intracellular mediators of signal transduction that are activated in response to a variety of extracellular stimuli (Johnson and Lapadat 2002; Pearson et al. 2001). There are three major classes of MAPKs: extracellular signal-regulated kinases (ERKs) (Sweatt 2001, p. 38; Johnson and Lapadat 2002), and stress-activated protein kinase/c-Jun amino-terminal kinase (SAPK/JNK) (Davis 2000). Among these, the most well studied are the closely related extracellular signal-regulated kinases 1 and 2 (ERK1/2). Biological processes involving ERK1/2 include stimulation of cell proliferation and survival, neoplastic transformation, neuronal differentiation, and plasticity (Seger and Krebs 1995; Paul et al. 1997). Several studies in both non-lesioned and adult 6-OHDA-lesioned animals showed that the stimulation of D_1 receptors can activate ERK1/2 to produce long-lasting adaptive changes in the brain (Vossler et al. 1997; Yao et al. 1998; York et al. 1998; Valjent et al. 2000; Gerfen et al. 2002). Thus, Papadeas and colleagues suggested that ERK1/2 may be involved in the adaptive processes that underlie the behavioral supersensitivity of neonatal lesioned rats to repeated D_1 agonist treatments (Papadeas et al. 2004, 2008). Similar to reports in adult 6-OHDA-lesioned rats (Gerfen et al. 2002), the researchers found that single as well as multiple doses of SKF-38393 to rats with neonatal 6-OHDA lesions produces an acute, transient increase in ERK1/2 activity that peaks at 15 min following

drug treatment (Papadeas et al. 2004). In conjunction with findings in adult lesioned animals, this finding suggested that the D_1 agonist-induced increases in locomotor activity could arise from strengthened ERK1/2-mediated signal transduction mechanisms involving in particular D_1 receptor-expressing striatonigral neurons. The researchers also showed that the priming of D_1 receptor sensitivity to multiple doses of SKF-38393 in rats with neonatal 6-OHDA lesions is coupled to a chronic, NMDA receptor-mediated ERK1/2 kinase activity (>7 days) in the medial prefrontal cortex and other cortical regions (i.e., the ventrolateral orbital, cingulate, motor, somatosensory, and piriform cortices) that promotes the phosphorylation of cAMP response element-binding protein (CREB), a transcription factor integral for neuronal plasticity (Lonze and Ginty 2002), and produces enduring structural changes in prefrontal cortical neurons (Papadeas et al. 2004, 2008). The lasting increase in ERK1/2 activity appears to be dependent upon D_1 receptor function, as SCH-23390 antagonist pretreatment blocked the prolonged ERK1/2 response to repeated administration of SKF-38393 to neonatal lesioned rats (Papadeas et al. 2004). Importantly, the SCH-23390 did not inhibit ERK1/2 activation through its interaction with 5-HT_2 binding sites (Bischoff et al. 1988; McQuade et al. 1988), since systemic injections of the nonselective 5-$HT_{2A/2C}$ antagonist ketanserin prior to SKF-38393 had no effect on the prolonged ERK1/2 response.

In addition, intracerebroventricular or systemic pretreatment with the MAPK kinase (MEK)/ERK1/2 inhibitor SL327, and the structurally dissimilar PD 98059, prior to each of three of four weekly sensitizing doses of SKF-38393 was found to alter the character of the supersensitive behavioral response elicited by D_1 agonism (Papadeas 2006). Priming-induced locomotor behaviors such as running, walking, and trotting were augmented, while stereotyped behaviors such as rearing, paw treading, and taffy pulling were inhibited. It could be hypothesized that the augmentation of locomotor behaviors concomitantly inhibited the expression of rearing and paw-fixation behaviors in these animals (Bernardi et al. 1986; Chinen et al. 2006) or, alternatively, that the opposite effects of MEK inhibitor on locomotor and stereotyped behaviors may have occurred because the behaviors are driven by the activation of different neural systems. The microinjection of PD 98059 directly into the medial prefrontal cortex prior to SKF-38393 treatments inhibited the stereotyped behaviors, but did not affect locomotor behaviors (Papadeas 2006). This documentation suggested that forebrain ERK1/2 activation contributes to some but not all of the sensitized responses seen with D_1 agonist priming of neonatal lesioned rats and further that medial prefrontal cortical ERK1/2 activation may be critical for the sensitization of specific stereotyped behaviors exhibited by these animals.

5.7 Hyperlocomotor and Oral Responses to 5-HT Receptor Agonists

Evidence that neonatal 6-OHDA-lesioned rats show, in addition to the 5-HT hyperinnervation, increased 5-HT receptor density prompted several investigators to explore the role of 5-HT in spontaneous behavior and/or behavioral

responsiveness to DA agonists in these animals. Gong and Kostrzewa showed that systemic administration of the 5-$HT_{1B/2C}$ receptor agonist m-CPP could considerably increase oral activity in neonatal DA-depleted rats compared to control animals (Gong and Kostrzewa 1992). This enhanced oral response was dependent upon a selective supersensitivity of 5-HT_{2C} receptors and was elevated to an even greater extent than that after D_1 agonist treatment in these animals (Gong and Kostrzewa 1992). In addition, the motor hyperactivity characteristic of these rats during adolescence (Shaywitz et al. 1976a; Erinoff et al. 1979; Heffner and Seiden 1982) was found to be reversed by systemic administration of the 5-HT_{2A} receptor antagonists ketanserin and mianserin (Luthman et al. 1991), suggesting that the striatal increase in 5-HT_{2A} receptors facilitates this abnormal behavior. Studies demonstrating the increased responses of striatal neurons to iontophoresed 5-HT and to 5-HT_{1B} (m-CPP) and 5-HT_2 (DOI) agonists after neonatal 6-OHDA lesions further confirmed that increases in the corresponding 5-HT receptors were indeed functional (el Mansari et al. 1994). More recent studies have shown that the stimulation of 5-HT_2 receptors in neonatal or adult unilateral DA-depleted rats with the 5-HT_2 receptor agonist DOI can induce enhanced motor behaviors (Bishop et al. 2004; Bishop and Walker 2003), likely as a consequence of increased 5-HT_{2A} receptor expression in the dorsal striatum (Radja et al. 1993a; Laprade et al. 1996; Basura and Walker 1999) and enhanced 5-HT_2 receptor-mediated activation of the direct striatal pathway (Gresch and Walker 1999; Basura and Walker 2000, 2001). Thus, in neonatal lesioned animals, striatal function may be enhanced significantly due to an elevated number of 5-HT receptors, even in the presence of extracellular 5-HT levels that remain near normal because of increased uptake (Jackson and Abercrombie 1992).

In the intact striatum, studies have consistently demonstrated that intrinsic 5-HT_2 receptors can modify DA function and have postulated divergent roles for 5-HT_{2A} and 5-HT_{2C} receptor subtypes (Lucas and Spampinato 2000; Porras et al. 2002). 5-HT_{2A} antagonists reduce hyperlocomotion induced by cocaine, amphetamine, and 3,4 methylenedioxymethamphetamine (MDMA) (Kehne et al. 1996; O'Neill et al. 1999). Conversely, 5-HT_{2C} receptor antagonists have been shown to enhance or reduce these effects depending upon which compounds and neural sites are studied (Filip and Cunningham 2002; Filip et al. 2004; Fletcher et al. 2002). While less is known about the interaction of these receptors following 6-OHDA-induced DA depletions, DA-related behaviors can be modified by 5-HT_2 receptor antagonists. For example, elevated oral dyskinesia induced by the ventral striatal infusion of SKF-38393 into neonatal 6-OHDA-lesioned rats was diminished by 5-$HT_{2A/2C}$ antagonism (Gong and Kostrzewa 1992; Plech et al. 1995). O'Boyle and colleagues demonstrated that hyperlocomotor activity induced by systemic or intrastriatal administration of SKF-82958 to adult unilateral 6-OHDA-lesioned rats (O'Boyle et al. 1989) can be reduced by pretreatment with the 5$HT_{2A/2C}$ antagonist ritanserin (Bishop et al. 2003). Further studies revealed that the D_1 agonist-induced hyperlocomotor activity could be reduced by antagonism of striatal 5-HT_{2A} receptors with M100907 (volinanserin), but not 5-HT_{2C} receptors with RS102221 (Bishop et al. 2005). Volinanserin also significantly reduced

SKF-82958-induced hyperlocomotor activity in neonatal lesioned animals (Bishop et al. 2005). Taken together, these data suggest that adaptations in 5-HT receptors not only account for various aspects of spontaneous behavior, but can also influence supersensitive D_1 receptors in rats with neonatal or adult unilateral 6-OHDA lesions.

5.8 Increased Stereotyped Responses to GABA Agonists

Differences in the behavioral profiles observed between neonatal and adult 6-OHDA-lesioned rats can also be seen following the administration of the $GABA_A$ receptor agonist, muscimol, into the SNr of these animals (Breese et al. 1987b). As mentioned earlier, the GABAergic neurons are projecting from the striatum into the SNr function as secondary mediators of DAergic activity (Albin et al. 1989; Gerfen et al. 1987). Additionally, DA neurons of the nigrostriatal pathway exert an inhibitory influence over these striatonigral neurons (Reid et al. 1990). Once the neurons of the nigrostriatal DA pathway are destroyed by 6-OHDA, the GABAergic activity in the SNr becomes enhanced. This presumably results in the increase in GABA levels observed in the SNr after neonatal 6-OHDA lesions (Molina-Holgado et al. 1993a). Elevated GABA activity in this region has been shown to play a role in SIB, as injections of muscimol into this region can elicit self-mutilation in normal animals (Baumeister and Frye 1986; Breese et al. 1987b). In both adult and neonatal DA-depleted rats, unilateral injections of muscimol into the SNr produced a supersensitive turning response as compared to non-lesioned animals (Breese et al. 1987b), a finding consistent with the reported increase in [^{3}H]muscimol binding and immunostaining of $GABA_A$ receptors in the SNr after adult unilateral 6-OHDA lesions (Pan et al. 1985; Katz et al. 2005). Only neonatal lesioned rats (and few non-lesioned rats) showed SIB and taffy-pulling behavior in response to bilateral injections of muscimol into the SNr (Breese et al. 1987b). Together, these data support the idea that lesions of DA neurons produce an increased functional responsiveness of $GABA_A$ receptors in the SNr and that the increased susceptibility for SIB in neonatal DA-depleted rats is likely determined by neurons distal to the $GABA_A$ receptor complex in the SNr. Clearly, some other factor in the plasticity of these neurons to neonatal DA loss must account for the SIB that does not occur in the adult DA-depleted animals.

6 Modeling Specific Brain Disorders Using Rats with 6-OHDA Lesions

6.1 Parkinson's Disease

The first of the clinical neurodegenerative disorders known to have reduced levels of DA and its metabolite HVA in the brain and CSF was PD (Hornykiewicz 1975).

PET studies with labeled agents that bind to DA uptake sites or to DA neurons via uptake sites such as fluorodopa confirmed that DA neurons were reduced (Eidelberg 1992; Shinotoh and Calne 1995). The availability of 6-OHDA has enabled the specific lesioning of DA neurons in adult rats to model the DA deficiency seen in PD (Ungerstedt 1968; Albin et al. 1989) and has allowed for the study of pathogenic mechanisms and pathophysiological aspects of PD as well as the testing of various neuroprotective compounds and innovative therapeutic strategies (Duty and Jenner 2011). Recently, adult lesioned rats have been used to investigate abnormal involuntary movements (AIMs) to prolonged use of L-dopa (Cenci et al. 1998; Winkler et al. 1999; Steece-Collier et al. 2003) and have provided invaluable information regarding the potential neurochemical and molecular mechanisms involved in L-dopa-related side effects in PD patients, such as dyskinesia (Cenci et al. 1998; Andersson et al. 1999; Sgambato-Faure et al. 2005; Pavon et al. 2006; Santini et al. 2007; Westin et al. 2007; Cenci and Konradi 2010). Further, it was revealed that striatal 5-HT terminals can cause or aggravate L-dopa-induced dyskinesias by mishandling exogenous L-dopa and by releasing DA from the 5-HT terminals (Carta et al. 2007; Lindgren et al. 2010). In support of these actions related to 5-HT, administration of 5-HT_{1A} and 5-HT_{1B} agonists can have anti-dyskinetic effects (Carta et al. 2007; Lindgren et al. 2010). Currently, clinical investigations are underway to examine the efficacy of such 5-HT agonists in dyskinetic L-dopa-treated PD patients.

Still, the adult 6-OHDA-lesioned rat does not mimic all of the clinical features of PD. The depletion of DA, nigral DA cell loss, and neurobehavioral deficits have been successfully achieved with the model, but this lesioning does not appear to affect changes associated with other brain regions in PD, including olfactory structures, lower brain stem areas, or the locus coeruleus. Also, the adult 6-OHDA lesion does not produce or induce proteinaceous aggregates or Lewy-like inclusions like those seen in PD, although it has been reported that the 6-OHDA interacts with α-synuclein (Blandini et al. 2008). Moreover, the nature of the symptoms in the unilateral adult 6-OHDA-lesioned rat, the most frequently used rodent model of PD, does not reflect that of the human disease. Despite these limitations, the adult 6-OHDA-lesioned rat model has contributed enormously to our understanding of PD and remains at the forefront of preclinical drug discovery for PD.

6.2 Lesch-Nyhan Syndrome

In addition to PD, the developmental disorder LNS (Lesch and Nyhan 1964; Nyhan 1968) is a second clinical disorder in humans with a documented destruction of central DA (Lloyd et al. 1981). The symptoms of LNS include motor dysfunction, mental impairment, and a particularly alarming form of SIB wherein patients bite away their own lips and fingers (Lesch and Nyhan 1964). The SIB is observed in about 85 % of LNS patients (Stout and Caskey 1989). The disease is caused by an almost complete deficiency of the enzyme hypoxanthine-guanine

phosphoribosyltransferase (HPRT) which also is associated with hyperuricemia. The main outcome of this genetically based defect is an increase in purine levels and a buildup of uric acid in the tissues. However, the severe neurological symptoms, including the behavioral abnormalities, are not affected by treatment that attenuates the overproduction of uric acid, indicating that some other consequence of the HPRT deficiency underlies the neurological deficits (Christie et al. 1982; Kopin 1981).

Research involving the examination of postmortem brain tissue revealed that LNS patients have a loss of 65–90 % of DA terminals in the mesolimbic and nigrostriatal pathways (Lloyd et al. 1981). Moreover, the spinal fluid of children with LNS has diminished levels of the DA metabolite HVA (Jankovic et al. 1988; Silverstein et al. 1985). Studies using PET technology to evaluate the integrity of DAergic neurons in LNS showed that a labeled marker for the DA transporter was markedly reduced in the brains of patients with LNS compared to either normal controls or patients with Rett's syndrome (Wong et al. 1996). In addition, labeled fluorodopa accumulation was reduced in the brains of patients with the disease (Ernst et al. 1996). It is likely, then, that these alterations in DA function account for the majority of the neurological symptoms observed in LNS (Jankovic et al. 1988; Lloyd et al. 1981).

Currently, the neonatal 6-OHDA-lesioned rat is the most widely accepted model to emulate the neonatal destruction of DA-containing neurons in LNS (Breese et al. 1984a, b, 1994), as these lesioned rats display characteristics that are similar to neurological changes and symptoms seen in patients with LNS. First, in both LNS patients and the neonatal lesioned rats, reduced DA during development is accompanied by an increase in striatal serotonin levels (Breese et al. 1984b; Lloyd et al. 1981; Stachowiak et al. 1984). Second, patients with LNS suffer from cognitive impairments (Lesch and Nyhan 1964), and considerable evidence suggests that neonatal lesioned rats do not learn behavioral tasks at the rate of non-lesioned animals (Archer et al. 1988; Smith et al. 1973). Third, similar to LNS patients, neonatal lesioned rats show an increased susceptibility for SIB (Breese et al. 1984b). Fourth, patients with LNS also show aggressive and combative behavior under the appropriate conditions (agitation and anxiety) (Lesch and Nyhan 1964), a characteristic feature of neonatal lesioned animals (Breese et al. 1984b). Fifth, patients with LNS are small in stature (Lesch and Nyhan 1964), as are neonatal lesioned rats compared to their non-lesioned counterparts (Smith et al. 1973). Sixth, antipsychotic drugs have little effect on SIB in LNS patients (Jankovic et al. 1988) and in neonatal lesioned rats administered sensitizing doses of L-dopa (Breese et al. 1984b). Finally, similar to neonatal lesioned rats, motor and behavioral symptoms are worsened when LNS patients are administered L-dopa (Jankovic et al. 1988). It is notable that the symptoms in PD patients are alleviated by L-dopa treatment, but neither PD patients nor adult 6-OHDA-lesioned animals exhibit self-biting or SIB. Collectively, the evidence clearly suggests that the early age of onset of loss of DA function is the key factor in the outcome of the DA deficiency in LNS (Breese et al. 1984b; Watts et al. 1982; Baumeister and Frye 1985).

6.3 Other Psychiatric Conditions

There are three additional clinical disease states outlined below in which 6-OHDA lesions may be of potential usefulness in defining the basis of symptoms or sensitivity to drug responses observed after such lesions that are comparable to those observed in schizophrenia, drug addiction, or ADHD.

Schizophrenia. The enhanced susceptibility to NMDA antagonists production of psychosis observed in schizophrenia has led to the suggestion that a state of NMDA receptor hypofunction may be inherent to this psychiatric disorder (Javitt and Zukin 1991; Jentsch and Roth 1999; Olney 1989). Consequently, the exacerbated responsiveness to NMDA antagonists such as MK-801 and PCP in the neonatal 6-OHDA-lesioned rats could serve as a model of this NMDA dysfunction in schizophrenia. Rats with neonatal 6-OHDA lesions have been shown to have impaired habituation and alterations in startle responses and sensory gating (Moy et al. 1994; Schwarzkopf et al. 1992, 1996), as well as a marked susceptibility to the stimulant impact of pharmacological challenges and environmental stressors (Moy et al. 1994; Schallert et al. 1989). These characteristics are also similar to those observed in schizophrenia (Javitt and Zukin 1991; Jentsch and Roth 1999; Malhotra et al. 1997; Olney et al. 1999). Thus, the neonatal 6-OHDA-lesioned rat could be a valuable model to investigate the neural basis of the enhanced negative responsive to NMDA-receptor antagonists observed in schizophrenics.

Drug Addiction. The development of a behavioral sensitization occurs in non-lesioned rats following chronic, intermittent exposure to psychostimulant drugs such as cocaine, amphetamine, and methamphetamine (Segal and Mandell 1974; Nishikawa et al. 1983; Epstein and Altshuler 1978). Furthermore, increasing evidence suggests that this sensitization to psychostimulant drugs involves alterations in the sensitivity of postsynaptic D_1 receptors (McCreary and Marsden 1993; Kuribara 1995a, b; Yoshida et al. 1995; Henry and White 1991). For example, pretreatment with the D_1 receptor antagonist SCH-23390 antagonizes the locomotor-activating effects of repeated cocaine and methamphetamine treatment and prevents the development of sensitization (McCreary and Marsden 1993; Kuribara 1995a, b; Yoshida et al. 1995). Pretreatment with a D_2 receptor agonist, at least in the case of cocaine-induced sensitization, has no such effect on the sensitization (McCreary and Marsden 1993). Pretreatment with NMDA receptor antagonists such as MK-801 also blocks the sensitized response to psychostimulant drugs (Karler et al. 1989; Wolf 1998). These characteristics are similar to those related to priming of the behavioral responsiveness of neonatal 6-OHDA-lesioned rats to repeated doses of D_1 agonist (Criswell et al. 1989). In this respect, both D_1 and NMDA receptor antagonists block the "priming" of neonatal 6-OHDA-lesioned rats to repeated D_1 agonist treatments (Criswell et al. 1990). Finally, both forms of sensitization are accompanied by adaptive responses that converge upon common cellular and molecular signal transduction pathways (e.g., ERK1/2 and CREB) that are associated with D_1 and NMDA receptor activation and long-term plasticity (Fornai et al. 2009; Chao and Nestler 2004; Valjent et al. 2000; Girault et al. 2007; Papadeas et al. 2004). Given these similarities, neonatal lesioned rats primed with

D_1 agonist could provide a model for investigating further the basis of the priming of D_1 receptor sensitivity that occurs in normal rats to multiple doses of psychostimulant drugs. As neural adaptations that underlie the sensitization process in rats are thought to contribute to the development of the compulsive patterns of drug craving that characterizes drug addiction in humans (Robinson and Berridge 2008), investigations of the neural adaptations that develop in response to D_1 priming in neonatal lesioned animals could help uncover D_1 receptor-specific processes involved in human addictive behavior, such as drug craving to stress. One major advantage of this model is the persistence of the sensitized response to D_1 agonists following priming.

ADHD. The neonatal 6-OHDA-lesioned rat has also been proposed to be a useful model for ADHD. Similar to ADHD patients, rat pups lesioned with 6-OHDA exhibit hyperactivity (Shaywitz et al. 1976b) and impaired learning in a spatial discrimination task (Archer et al. 1988) which improves after methylphenidate or amphetamine treatment (Davids et al. 2002, 2003). In addition, as in ADHD, the neonatal lesioned rats show an initial decrease in spontaneous motor behavior when placed in a novel environment, but after repeated testing, increased activity is observed, thus providing useful information regarding the mechanisms that cause hyperactivity (Luthman et al. 1989a). The hyperactivity in neonatal 6-OHDA-lesioned rats is accompanied by decreased striatal DAT and increased D_4 receptor expression, as well as altered 5-HT function (Luthman et al. 1989a; Zhang et al. 2001). While the hyperactivity is not altered by DAT inhibitors, it can be greatly reduced by D_4 antagonists as well as inhibitors of NET and 5-HT transporters (Davids et al. 2002, 2003; Zhang et al. 2001, 2002a). These findings suggested that psychostimulants reduce the hyperactivity of neonatal lesioned rats by inhibiting NET and 5-HT transporters rather than DAT. Consistent with this conclusion, it has been demonstrated that administration of the NET inhibitor atomoxetine strongly antagonizes motor hyperactivity in juvenile rats with neonatal 6-OHDA lesions (Moran-Gates et al. 2005). When neonatally 6-OHDA-lesioned rats are lesioned in adulthood with 5,7-DHT, the level of hyperactivity is increased (Kostrzewa et al. 1994). Also, a 5-HT_2 receptor antagonist attenuates the spontaneous hyperlocomotor activity in neonatal 6-OHDA-lesioned rats (Brus et al. 2004). These findings further add support for involvement of the central 5-HT system in modulating hyperactivity. Furthermore, a possible role for 5-HT in stimulant treatment for ADHD has been proposed based on the demonstration of an inhibitory role of brain 5-HT systems in the actions of methylphenidate and amphetamine (Breese and Cooper 1975; Hollister et al. 1976).

7 Conclusion

The research on monoamine systems has greatly benefited from the discovery of 6-OHDA, the first compound implemented as a selective neurotoxin for CA-containing neurons (Porter et al. 1963; Ungerstedt 1968). Since the 1960s, 6-OHDA has been successfully employed in animals to biochemically dissect the roles of DA and NE neurotransmitter systems in the brain while at the same time

providing interesting models to study compensatory adaptations that occur in the metabolism, uptake mechanisms, sprouting, and plastic properties of the spared neurons and of the alternate neuronal projections that could replace the lesioned terminals. Eventual refinements in the use of 6-OHDA to selectively lesion DA neurons led to the proposal that DA-denervated rats provide a valuable model for human PD, a disease in which the loss of DA neurons is its main pathological hallmark. It soon became evident that while 6-OHDA-lesioned rats display many of the neurochemical characteristics found in human PD, they do not emulate all of the neurological features exhibited by patients. Clearly, the behavioral, neurochemical, morphological, and receptor alterations found in 6-OHDA-lesioned rats are dependent upon the degree of DA denervation, the site and route of 6-OHDA administration, and, most importantly of all, the age at which the lesioning is carried out. Furthermore, behavioral and receptor changes and the activation of associated signaling pathways are found not only in the central DA system as expected, but also in other transmitter systems, as demonstrated by some of the modifications in 5-HT and GABA and their receptors as reviewed above. Nonetheless, studies in both the adult and neonatal 6-OHDA-lesioned rat models still remain of interest, as they enable the examination of such alterations within a reasonable time frame, inevitably leading to the development and a better understanding of innovative therapeutic strategies to treat PD and other DA deficiency states like LNS, ADHD, and schizophrenia.

Abstract

Selective neurotoxins have the ability to exert their neurotoxic effects in some specific neuronal systems. In dopaminergic neurons, the selectivity of exogenous neurotoxins depends on their affinity to the dopamine transporter. However, dopamine and 3,4-L-dihydroxyphenylalanine (L-dopa) are synthesized in dopaminergic neurons and are likewise able to induce neurotoxicity. The possible molecular mechanisms involved in dopamine and L-dopa neurotoxicity in dopaminergic neurons are discussed. Dopamine seems to be neurotoxic in dopaminergic neurons by undergoing oxidation to aminochrome, which is the precursor to neuromelanin. However,

aminochrome can be neurotoxic when it forms adducts with proteins such as alpha-synuclein, parkin, mitochondrial complexes I and III, actin, tubulin, and the dopamine transporter, or when aminochrome is one-electron reduced by flavoenzymes that use NADH, generating redox cycling with the concomitant depletion of energy and the formation of reactive oxygen species. L-dopa is also neurotoxic in cell cultures after oxidizing to a quinone species, but L-dopa seems to be a transient precursor of dopamine in that it is not able to induce neurotoxicity in vivo due to the efficient decarboxylation to dopamine catalyzed by amino acid decarboxylase. In fact, the only metabolite found in vivo is L-3-*o*-methyldopa, as detected in microdialysis experiments in animals treated with L-dopa. L-dopa is used in Parkinson's disease treatment, and it is still questionable whether L-dopa accelerates the degeneration of remaining dopaminergic neurons. It seems that L-dopa itself does not accelerate dopaminergic neuron degeneration because L-dopa is efficiently converted to dopamine, both in the peripheral and the central nervous systems. However, L-dopa induces dyskinesias in approximately 40 % patients with 4–6 years of treatment, and although the mechanism for L-dopa-induced dyskinesias is very complex, the rapid oscillation of striatal dopamine during L-dopa treatment has been found to be required for the induction of dyskinesias. The remaining dopaminergic neurons convert L-dopa to dopamine and release dopamine to the striatum under regulated conditions, but the majority of dopamine release to the striatum is mediated by serotonergic neurons without regulation, resulting in dyskinesias.

List of Abbreviations

AADC	Aromatic amino acid decarboxylase
COMT	Catechol ortho-methyltransferase
DA	Dopamine
GST M2-2	Glutathione S-transferase M2-2
L-dopa	L-dihydroxyphenylalanine
MAO	Monoamine oxidases
TH	Tyrosine hydroxylase
VMAT-2	Vesicular monoaminergic transporter-2

1 Synthesis of L-dopa and Dopamine

De novo synthesis of dopamine is mediated by two enzymes using the amino acid tyrosine as precursor. The first step is catalyzed by the enzyme tyrosine hydroxylase (TH), in which tyrosine is used to form L-dihydroxyphenylalanine (L-dopa). L-dopa is decarboxylated by the enzyme aromatic amino acid decarboxylase (AADC) to generate dopamine and CO_2. This dopamine is stored in monoaminergic

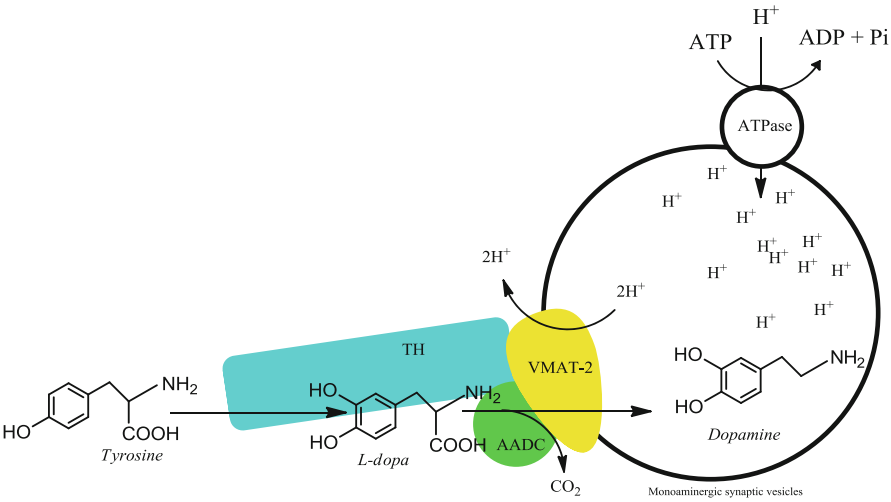

Fig. 1 *Dopamine synthesis*. Dopamine synthesis from tyrosine is catalyzed by tyrosine hydroxylase (TH) and aromatic amino acid decarboxylase (AADC), and uptake into monoaminergic synaptic vesicles is mediated by VMAT-2

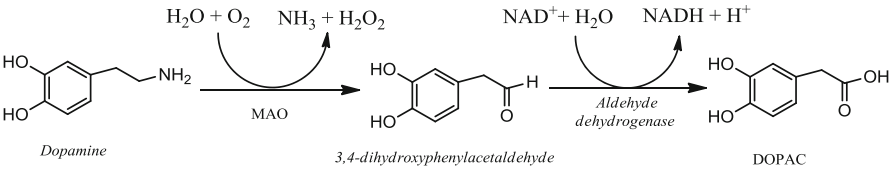
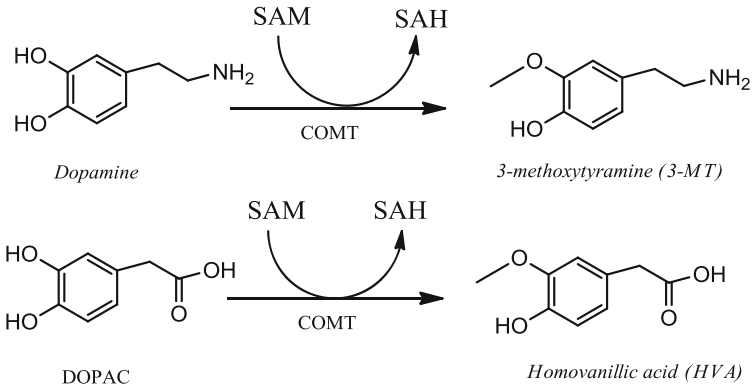
vesicles with a weak acid pH that prevents dopamine oxidation to *o*-quinone species, as dopamine autoxidizes at physiological pH due to the dissociation of the protons of hydroxyl groups. Dopamine oxidation to *o*-quinones after the synthesis of L-dopa and dopamine is prevented by the association of the enzymes TH and AADC with the vesicular monoaminergic transporter-2 (VMAT-2), which is present in the membranes of monoaminergic synaptic vesicles, generating a kind of complex that prevents free cytosolic dopamine (Cartier et al. 2010). Dopamine inside monoaminergic synaptic vesicles is hard protonated, preventing the oxidation of catechol groups to *o*-quinone. Monoaminergic synaptic vesicles express a vesicular ATPase that hydrolyzes ATP to ADP plus inorganic phosphate with one proton (H^+) translocation into the vesicles, creating a proton gradient with a weak acid pH inside the vesicles (Guillot and Miller 2009; Fig. 1).

1.1 Dopamine Degradation

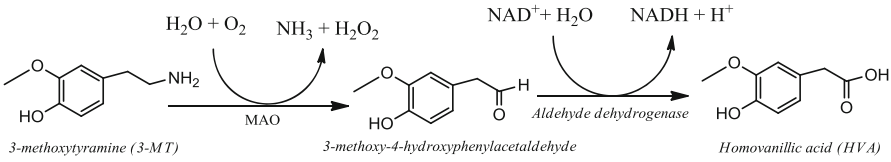
Dopamine accumulates inside monoaminergic synaptic vesicles for neurotransmission, which is an essential process in the control of movements. However, the catechol group of free cytosolic dopamine can be oxidized to neurotoxic *o*-quinones (Arriagada et al. 2004; Paris et al. 2010, 2011). To prevent this effect, dopamine participates in a neurotoxic reaction, and there are two types of enzymes that degrade dopamine. The first is the monoamine oxidases (MAO, E.C. 1.4.3.4), which catalyze the oxidative deamination of the dopamine amino group to 3,4-dihydroxyphenylacetaldehyde with concomitant formation of ammonia and hydrogen peroxide. Aldehyde dehydrogenase then catalyzes the oxidation of 3,4-dihydroxyphenylacetaldehyde to 3,4-dihydroxyphenylacetic acid (DOPAC) with the formation of a molecule of NADH.



The MAO enzymes have multiple isoforms (A and B forms) that are 70 % identical and are localized to the outer membranes of the mitochondria in neurons, glial cells, and other cells (Weyler et al. 1990; Shih et al. 1997). MAO-B is found in histaminergic and serotonergic neurons, as well as in astrocytes, while MAO-A is mainly found in catecholaminergic neurons (Westlund et al. 1988; Saura et al. 1994). MAO-A uses the compounds dopamine, noradrenaline, adrenaline, and serotonin as substrates, while MAO-B uses compounds such as phenylethylamine and tyramine (Strolin-Benedetti et al. 1992). The second enzyme that degrades dopamine is catechol ortho-methyltransferase (COMT; EC 2.1.1.6), which catalyzes the methylation of dopamine by using S-adenosylmethionine (SAM) as a cofactor to form 3-methoxytyramine and S-adenosylhomocysteine (SAH). COMT also plays a role in MAO-catalyzed degradation of dopamine, as DOPAC is methylated to homovanillic acid (HVA).



MAO also participates in dopamine degradation catalyzed by COMT because 3-methoxytyramine is a substrate for MAO, which catalyzes the oxidative deamination of 3-methoxytyramine to 3-methoxy-4-hydroxyphenylacetaldehyde. Aldehyde dehydrogenase catalyzes the oxidation of 3-methoxy-4-hydroxyphenylacetaldehyde to homovanillic acid with the concomitant formation of NADH.



COMT is expressed in pyramidal neurons, striatal spiny neurons, cerebellar Purkinje, and granular cells (Myöhänen et al. 2010), and it has two isoforms – a soluble form (S-COMT) and a membrane-bound form (MB-COMT). Inhibition of COMT by entacapone has been used in the treatment of Parkinson's disease, prolonging the half-life of L-dopa (Marin and Obeso 2010).

2 Dopamine Neurotoxicity

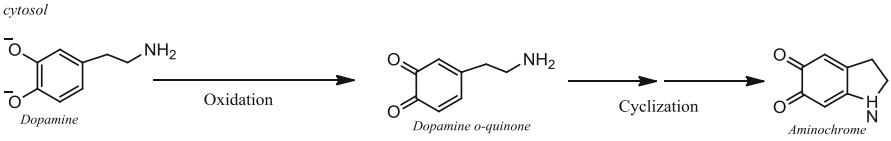
Dopamine exposure at different cell cultures or cell lines resulted in the induction of cell death, suggesting a neurotoxic role for dopamine (Hoyt et al. 1997; Jeon et al. 2010). Dopamine-dependent cell death has been reported to be dependent on an apoptotic cell death mechanism (Ziv et al. 2001). Dopamine exposure of human neuroblastoma NMB cells, which are able to take up dopamine, induces morphological changes, such as cell shrinkage, apoptosis-like atrophy, accumulation of apoptotic particles, DNA fragmentation, and protein synthesis-dependent cell death (Simantov et al. 1996). A study conducted with SH-SY5Y neuroblastoma cells displayed caspase-9 and caspase-3 activation, cleavage of poly(ADP-ribose) polymerase, and nuclear condensation, accompanied by the activation of p38 mitogen-activated protein kinase. The presence of the antioxidant N-acetyl-L-cysteine prevents dopamine-induced p38 kinase activation, caspase-9 and caspase-3 cleavage, and subsequent apoptosis (Junn and Mouradian 2001). Overexpression of Bcl-2, which blocks physiological apoptosis, in PC-12 cells results in a marked resistance to dopamine-induced cell death (Offen et al. 1997). The activation of the JNK pathway precedes dopamine-induced apoptosis and is persistently sustained during the process of apoptosis. Overexpression of a dominant negative mutant SEK1, an upstream kinase of JNK, inhibits both dopamine-induced JNK activation and apoptosis (Luo et al. 1998). Another study reported that dopamine activates SAPK/JNK and p38, but not MEK or ERK/MAPK (Gómez-Santos et al. 2003). It has been reported that dopamine oxidation activates the DNA-binding activity of NF-kappaB and the suppression of NF-kappaB transcriptional activity in PC-12 cells, inducing apoptotic cell death during dopamine oxidation (Lee et al. 2001b). The formation of adducts between alpha-synuclein and the presynaptic human dopamine transporter facilitates the membrane clustering of the dopamine transporter (DAT), thereby accelerating cellular dopamine uptake and dopamine-induced cellular apoptosis (Lee et al. 2001a). Interestingly, parkin prevents dopamine-induced alpha-synuclein-dependent cell death by blocking DAT-mediated dopamine uptake, which is accelerated by alpha-synuclein (Moszczynska et al. 2007). Another study showed that parkin protects against dopamine toxicity by decreasing oxidative stress and the subsequent activation of the JNK/caspase pathway (Jiang et al. 2004). The apoptosis induced by dopamine in PC-12 cells was found to be accompanied by an impairment of mitochondrial bioenergetic functions (Jana et al. 2011). The treatment of human SH-SY5Y cells with dopamine induced an early increase in the expression of hypoxia-inducible factor-1alpha (HIF-1alpha) followed by increases in p53, Puma, and Bnip3, in

which caspase-3, caspase-7, and PARP were activated after 12 h (Giménez-Xavier et al. 2009). The agonist of protein kinase A, forskolin, stimulated dopamine uptake in SK-N-SH cells and blocked dopamine-induced apoptosis (Liu et al. 2001). Dopamine-induced cell death was found to be preceded by a decrease in proteasome activity (Keller et al. 2000). Antioxidants were found to protect against dopamine-induced cell death (Junn and Mouradian 2001; Jana et al. 2011), and the glutathione-depleting compound L-buthionine sulfoximine enhanced dopamine-induced cell death (Stokes et al. 2000).

Why does dopamine induce neurotoxicity when it is an essential neurotransmitter for the control of movement? A possible explanation is that dopamine inside monoaminergic synaptic vesicles is completely inert because the protons of dopamine groups are hardbound to the oxygen as a consequence of the weak acid pH inside the vesicles, which is 2–2.4 pH units lower than the pH in the cytosol (Guillot and Miller 2009). However, the protons of dopamine hydroxyl groups are dissociated at cytosolic pH and can oxidize in the presence of oxygen, even in the absence of metal catalysis (Linert et al. 1996). The dopamine catechol structure oxidizes to orthoquinones, which can induce neurotoxicity.

3 Dopamine Oxidation to Orthoquinones

The protons of dopamine hydroxyl groups are dissociated when dopamine is in the cytosol at physiological pH and spontaneously oxidizes in the presence of oxygen and in the absence of metal traces (Linert et al. 1996). Dopamine oxidizes to dopamine *o*-quinone, which cyclizes to form aminochrome at physiological pH. Dopamine *o*-quinone is not stable at physiological pH because the amino group of dopamine *o*-quinone spontaneously rearranges and undergoes cyclization; thus, dopamine *o*-quinone is only stable at a pH below 2.0 (Segura-Aguilar and Lind 1989).



Dopamine oxidation can also be catalyzed by metals such as manganese(III), copper sulfate(II), iron chloride(III), and sodium periodate (Segura-Aguilar and Lind 1989; Paris et al. 2001, 2005a; Graham et al. 1978) or by enzymes such as prostaglandin H synthase, cytochrome P450, xanthine oxidase, lactoperoxidase, tyrosinase, and dopamine β-monooxygenase (Galzigna et al. 2000; Thompson et al. 2000; Segura-Aguilar 1996; Foppoli et al. 1997; Hastings 1995; Segura-Aguilar et al. 1998; Jimenez et al. 1984). It is important to remember that aminochrome formation is dependent on the presence of free cytosolic dopamine that can oxidize to aminochrome, and VMAT-2 and MAO prevent dopamine oxidation, as VMAT-2 mediates dopamine accumulation in monoaminergic synaptic vesicles and MAO catalyzes the degradation of dopamine.

4 Aminochrome Metabolism

Aminochrome is able to participate in five different reactions, including (i) the polymerization of aminochrome to neuromelanin. Neuromelanin is a pigment present in dopaminergic neurons, which is localized in the substantia nigra and accumulates with age (Zecca et al. 2002) in healthy individuals; it is also dramatically decreased in patients with Parkinson's disease. Therefore, neuromelanin seems to play a protective role in dopaminergic neurons because it chelates metals and binds proteins such as alpha-synuclein (Gerlach et al. 2003; Hong and Simon 2007; Fasano et al. 2006). The localization of neuromelanin in double-membrane vesicles seems to be very important for its protective role, as free neuromelanin has been found to be neurotoxic in cell cultures (Naoi et al. 2008) and extracellular neuromelanin induces microglial activation in the substantia nigra (Zhang et al. 2011; Fig. 2). (ii) Aminochrome also forms adducts with proteins. Aminochrome induces and stabilizes the formation of neurotoxic protofibrils of alpha-synuclein (Conway et al. 2001; Norris et al. 2005). Aminochrome forms adducts with other proteins, such as actin and α- and β-tubulin, and it disrupts the architecture of the cytoskeleton and complexes I and III of the mitochondria (Paris et al. 2010; Van Laar et al. 2009). Dopamine *o*-quinone, the transient precursor of aminochrome at physiological pH, forms adducts with and inactivates parkin, which is a ubiquitin ligase of the proteasomal system (LaVoie et al. 2005); tyrosine hydroxylase; the human dopamine transporter; and tryptophan hydroxylase (Xu et al. 1998; Whitehead et al. 2001; Kuhn and Arthur 1998). (iii) Aminochrome can be one-electron reduced, catalyzed by flavoenzymes that transfer one electron by using NADH or NADPH ions. The leukoaminochrome *o*-semiquinone radical is extremely reactive under aerobic conditions, generating a redox cycle between the leukoaminochrome *o*-semiquinone radical and aminochrome (Baez et al. 1995; Segura-Aguilar et al. 1998). This redox cycling depletes the NADH and O_2 required for ATP production in the mitochondria or the NADPH required for the reduction of oxidized glutathione, which is an important antioxidant. There is significant evidence that supports the neurotoxic role of the one-electron reduction of aminochrome (Paris et al. 2001, 2005a, b, 2009, 2010, 2011; Arriagada et al. 2004; Fuentes et al. 2007; Díaz-Véliz et al. 2008; Muñoz et al. 2012a, b; Fig. 2). (iv) Aminochrome can be two-electron reduced to leukoaminochrome, catalyzed by DT-diaphorase (EC.1.6.99.2), which is a flavoenzyme that uses both NADH and NADPH as electron donors. DT-diaphorase has been proposed to play a protective role in aminochrome metabolism because this enzyme prevents the neurotoxic reactions of aminochrome, including the one-electron reduction of aminochrome and the formation of adducts with proteins (Arriagada et al. 2004; Lozano et al. 2010; Paris et al. 2011; Muñoz et al. 2012a, b; Segura-Aguilar et al. 2006; Cardenas et al. 2008; Paris et al. 2010; Fig. 2). (v) Aminochrome can be glutathione-conjugated by glutathione S-transferase M2-2 (GST M2-2) to 4-*S*-glutathionyl-5,6-dihydroxyindoline, which is a stable molecule that is resistant to biological oxidizing agents (Segura-Aguilar, et al. 1997; Baez et al. 1997). GST M2-2 also conjugates the precursor of aminochrome dopamine *o*-quinone to 5-glutathionyl-dopamine, preventing the

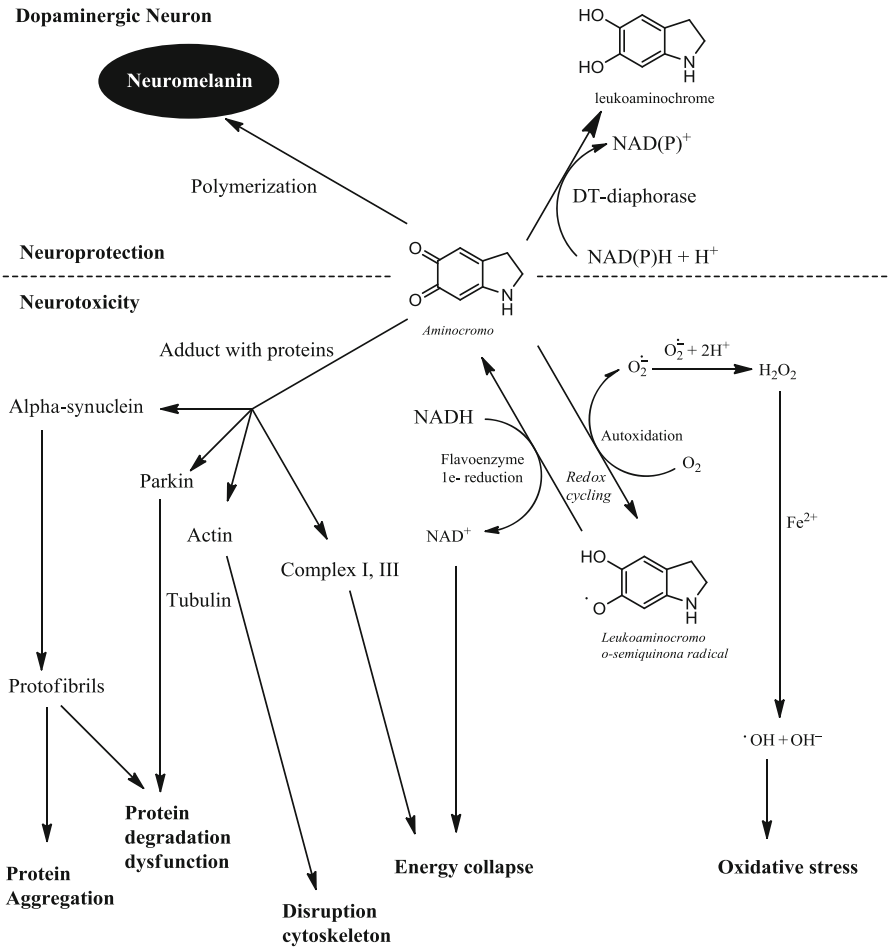


Fig. 2 *Possible metabolism of aminochrome in dopaminergic neurons*. Aminochrome is able to participate in two neurotoxic reactions, such as the formation of aminochrome adducts with alpha-synuclein, parkin, actin, tubulin, and mitochondrial complexes I and III, along with aminochrome one-electron reduction to the leukoaminochrome *o*-semiquinone radical. However, aminochrome can polymerize into neuromelanin, or it can be two-electron reduced to leukoaminochrome, catalyzed by DT-diaphorase, a reaction that prevents aminochrome-induced neurotoxicity

formation of aminochrome (Dagnino-Subiabre et al. 2000). The 5-glutathionyl-dopamine is finally converted to 5-cysteinyl dopamine (Shen et al. 1996), which has been detected in the cerebrospinal fluid of Parkinson's disease patients and in dopamine-rich brain regions such as the caudate nucleus, putamen, globus pallidus, and substantia nigra, as well as in neuromelanin (Cheng et al. 1996; Rosengren et al. 1985; Carstam et al. 1991). Therefore, the conjugation of glutathione has been proposed to be a protective reaction against aminochrome neurotoxicity in astrocytes (Fig. 3).

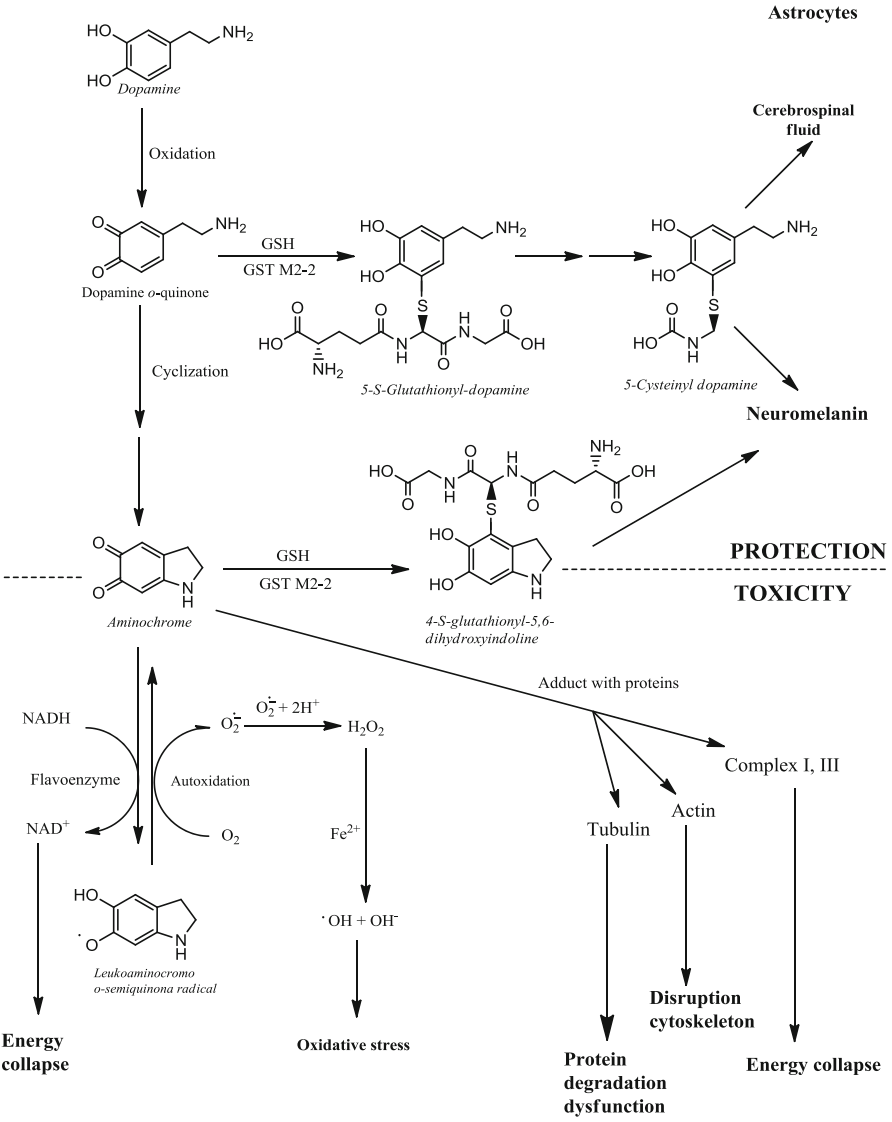

Fig. 3 *Possible metabolism of aminochrome in astrocytes*. Dopamine is taken up into astrocytes and is able to oxidize into dopamine *o*-quinone. GST M2-2 is able to conjugate this compound with glutathione to form 5-glutathionyl-dopamine, which is degraded to 5-S-cysteinyl dopamine, a compound that is found in the cerebrospinal fluid and in neuromelanin. Dopamine o-quinone cyclizes to aminochrome, which can also be conjugated with GSH by GST M2-2 to 4-S-glutathionyl-5,6-dihydroxyindoline, which is resistant to biological oxidizing agents. Both conjugations prevent aminochrome-induced neurotoxicity

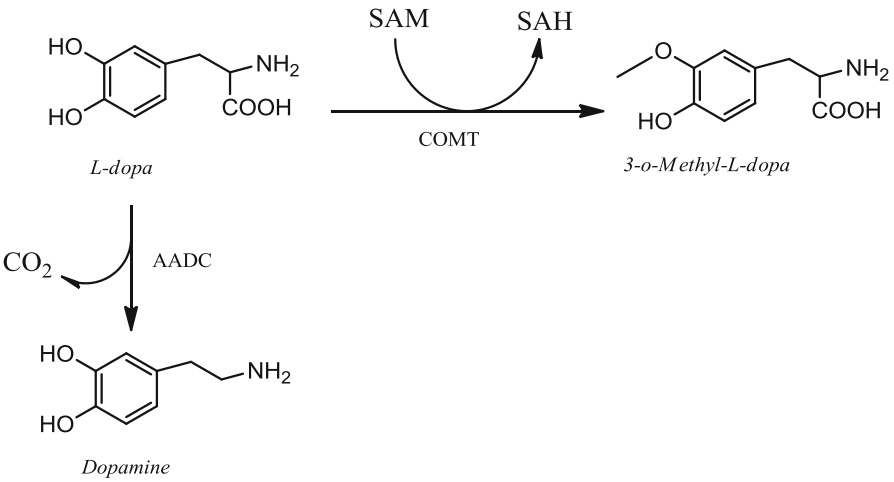
5 Aminochrome and Parkinson's Disease

The progressive loss of nigral dopaminergic neurons containing neuromelanin in the substantia nigra most likely begins long before the symptomatic phases of Parkinson's disease are present (Braak et al. 2004). Intensive research has been conducted over the past few decades to understand the molecular mechanism of the neurodegeneration of neuromelanin-containing dopaminergic neurons, with the discovery of mutations associated with Parkinson's disease. It is generally accepted that the mechanism that results in the loss of dopaminergic neurons in the substantia nigra involves the aggregation of alpha-synuclein to neurotoxic protofibrils, a dysfunction of protein degradation, mitochondrial dysfunction, oxidative stress, and neuroinflammation (Schapira 2011; Conway et al. 2001; McNaught et al. 2004; Cuervo et al. 2010; Schapira and Jenner 2011). There is growing evidence that supports the role of aminochrome in the degeneration of dopaminergic neurons that contain neuromelanin, including the following findings: (i) Aminochrome forms adducts and inactivates complexes I and III and isocitrate dehydrogenase, an enzyme of the citric acid cycle in the mitochondria (Van Laar et al. 2009). One-electron reduction of aminochrome depletes NADH, thereby decreasing ATP production in cell culture (Muñoz et al. 2012b). (ii) Aminochrome was found to induce the formation and stabilization of alpha-synuclein protofibrils (Norris et al. 2005). (iii) Aminochrome inactivates the proteasomal system of degradation of proteins by forming adducts with parkin (Zafar et al. 2006; La Voie et al. 2005). Interestingly, alpha-synuclein protofibrils inhibit chaperone-mediated autophagy (Xilouri et al. 2009) and the 26S proteasomal system (Zhang et al. 2008). Aminochrome forms adducts with tubulin (Van Laar et al. 2009), and one-electron reduction of aminochrome induces the aggregation of α- and β-tubulin, disrupting the cytoskeletal structure (Paris et al. 2010; Muñoz et al. 2012a). Tubulin aggregation prevents the microtubule formation required for the fusion of autophagocytic vacuoles and lysosomes (Monastyrska et al. 2009). (iv) Aminochrome one-electron reduction induces oxidative stress (Arriagada et al. 2004). Interestingly, aminochrome is involved in four of the five mechanisms that are generally accepted to be involved in the degeneration of neuromelanin-containing dopaminergic neurons in Parkinson's disease.

6 L-dopa Metabolism

The amino acid tyrosine is used as a substrate in the production of L-dopa, a reaction catalyzed by tyrosine hydroxylase in dopaminergic neurons. However, L-dopa is immediately converted to dopamine in a reaction catalyzed by AADC. It has been reported that the enzymes TH and AADC are associated with the membrane-bound VMAT-2, forming a kind of complex to prevent L-dopa and dopamine from remaining free in the cytosol (Cartier et al. 2010). It is unknown whether free L-dopa in the cytosol is able to undergo metabolism under

normal conditions because in Parkinson's patients, L-dopa undergoes metabolism, an important part of treatment. L-dopa can be decarboxylated to dopamine even outside the central nervous system, and L-dopa can be converted to L-3-*o*-methyldopa by COMT (Okada et al. 2011).



7 L-dopa Neurotoxicity In Vitro

Experiments in vitro with cultured neurons exposed to L-dopa resulted in apoptosis that included cell shrinkage, membrane blebbing, and nuclear and DNA fragmentation (Melamed et al. 1998; Walkinshaw and Waters 1995). L-dopa was found to be neurotoxic when it increased the expression of cytosolic cytochrome c, cleaved caspase-3, and decreased phosphorylated Akt (Ser473), phosphorylated glycogen synthase kinase-3beta (GSK-3beta) (Ser9), and heat shock transcription factor-1. The activation of PI3K protects the cells against L-dopa neurotoxicity (Park et al. 2009). L-dopa has been reported to induce cell death in SH-SY-5Y cells with the concomitant deactivation of glutaredoxin. This compound was deactivated in a dose-dependent manner, suggesting an irreversible adduction of L-dopachrome to its nucleophilic active-site Cys-22. L-dopa also decreases thioredoxin and thioredoxin reductase activity and protein content. Knockdown of glutaredoxin increases L-dopa-induced apoptosis (Sabens et al. 2010). L-dopa activates apoptosis signaling kinase 1 (ASK1), as indicated by the phosphorylation of its downstream mitogen-activated protein kinases (MAPK), p38 and JNK. The inhibition of either p38 or JNK or the knockdown of ASK1 provides protection against L-dopa-induced apoptotic neuronal cell death in the SH-SY-5Y cell line (Liedhegner et al. 2011). L-dopa has also been found to impair proteasome activity through the D_1 dopamine receptor (Berthet et al. 2012). The ability of L-dopa to be neurotoxic is dependent on its ability to oxidize to L-dopa *o*-quinone, which

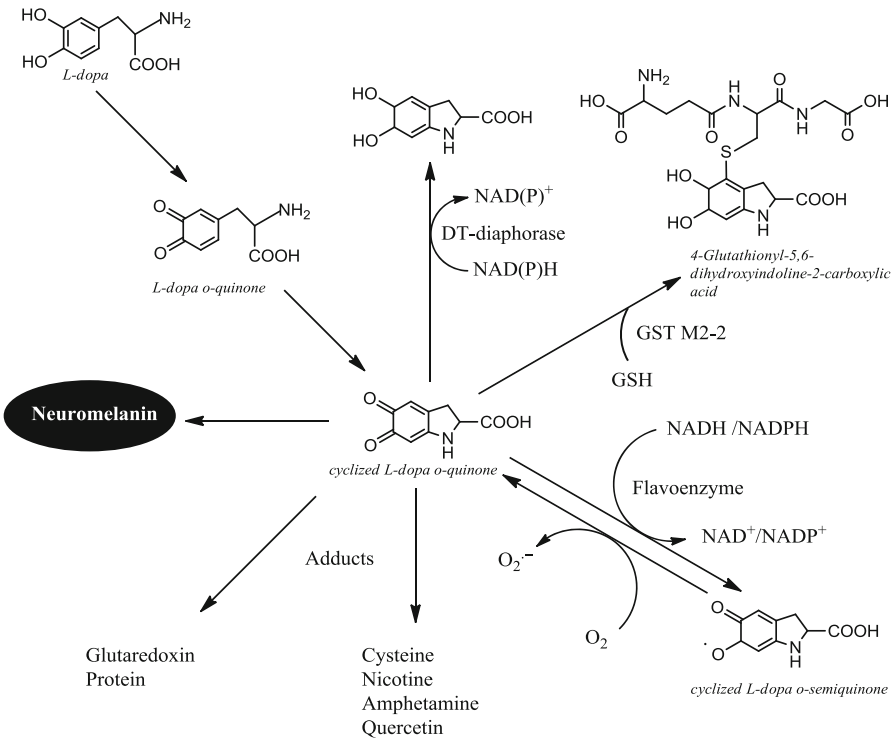


Fig. 4 *Possible metabolism of cyclized L-dopa o-quinone*. L-dopa oxidizes to L-dopa o-quinone, which cyclizes to cyclized L-dopa o-quinone. This compound is able to (i) polymerize to form neuromelanin, (ii) form adducts with proteins, (iii) form adducts with biomolecules, (iv) be one-electron reduced to the cyclized L-dopa o-semiquinone radical, (v) be conjugated by GSH to 4-glutathionyl-5,6-dihydroxyindoline-2-carboxylic acid, or (vi) be two-electron reduced, catalyzed by DT-diaphorase

spontaneously cyclizes to cyclized L-dopa *o*-quinone at physiological pH (Baez et al. 1994; Takeshima et al. 2011; Kostrzewa et al. 2002).

The cyclized L-dopa *o*-quinone is able to participate in several reactions, such as (i) polymerization to melanin (for review, see Prota 1995) and (ii) the formation of adducts with proteins such as glutaredoxin (Sabens et al. 2010). A significant increase in cell death and the formation of quinoproteins were observed when CATH.a cells were incubated with L-dopa (Asanuma et al. 2012). (iii) The formation of adducts with molecules such as cysteine, nicotine, amphetamine, and quercetin has also been reported (Dehn et al. 2001; Claffey and Ruth 2001; Kubo et al. 2007; Caudle et al. 2007; Müller and Muhlack 2012). (iv) L-dopa can be one-electron reduced with flavoenzymes that transfer one electron and use NADH or NADPH. (iv) L-dopa can also be two-electron reduced by DT-diaphorase (Baez et al. 1994), and (v) it can be conjugated by glutathione transferase M2-2 (Baez et al. 1997) (Fig. 4).

8 L-dopa-Induced Dyskinesia

L-dopa induces neurotoxicity in cell lines that are used as a model for in vitro studies of Parkinson's disease or primary cell cultures (Melamed et al. 1998; Walkinshaw and Waters 1995; Park et al. 2009; Sabens et al. 2010; Liedhegner et al. 2011). However, these neurotoxic effects in dopaminergic neurons are not observed in animal models of L-dopa, most likely as a consequence of the efficient conversion of L-dopa to dopamine. In fact, only one L-dopa metabolite is found in the literature (L-3-*o*-methyldopa), supporting the idea that the major route of metabolism of L-dopa is its conversion to dopamine and that under normal conditions, L-dopa is not found, free or accumulated. Although L-dopa does not induce neurotoxicity of dopaminergic neurons, as observed in cell cultures, L-dopa induces dyskinesia in approximately 40 % patients with 4–6 years of treatment (Ahlskog & Muenter 2001). The mechanism for L-dopa-induced dyskinesias is very complex, but a role for serotonergic neurons has been proposed. The rapid oscillation of striatal dopamine during L-dopa treatment has been found to be required for the induction of dyskinesias (Meissner et al. 2006; Pavese et al. 2006). In L-dopa treatment of a Parkinson's disease patient, the dopaminergic neurons that are still functioning convert L-dopa to dopamine, which is stored in monoaminergic synaptic vesicles. Dopamine is released by the axon terminal, which is regulated by D_2 dopamine receptors and the dopamine transporter (DAT). However, serotonergic neurons express both AADC and VMAT-2 and release dopamine, but without the regulation of the D_2 receptor and DAT (for review, see Cheshire and Williams 2012). Studies in animals with experimental Parkinsonism showed that serotonergic neurons are responsible for 80 % of dopamine release during L-dopa treatment (Tanaka et al. 1999)

9 Dopamine and L-dopa as Selective Neurotoxins

Dopamine is an essential neurotransmitter in dopaminergic neurons, accumulating inside monoaminergic synaptic vesicles for use as a neurotransmitter. Dopamine released into the intersynaptic space is recaptured by dopaminergic neurons with DAT, whereas cytosol dopamine can be (i) accumulated into monoaminergic synaptic vesicles mediated by VAMT-2, (ii) degraded by MAO and COMT, or (iii) autoxidized into aminochrome. However, dopamine induces neurotoxicity when undergoing oxidation to aminochrome, which can be neurotoxic by (i) forming adducts with proteins, such as alpha-synuclein, parkin, mitochondrial complexes I and III, isocitrate dehydrogenase, actin, tubulin, or the dopamine transporter or by (ii) being one-electron reduced by flavoenzymes that use NADH or NADPH as an electron donor. It was proposed that aminochrome is the endogenous neurotoxin that is responsible for the neurodegenerative process of neuromelanin-containing dopaminergic neurons (Lozano et al. 2010; Paris et al. 2010, 2011; Muñoz et al. 2012 a, b). Aminochrome is a selective neurotoxin, as it is formed inside a single dopaminergic neuron. Aminochrome can induce

neurotoxicity, resulting in a focalized neurotoxic event, which is in line with the slow neurodegeneration that occurs in neuromelanin-containing dopaminergic neurons, which takes years.

Experiments with cell cultures demonstrate the potential neurotoxic effects of L-dopa, but depending on the cellular model used for these experiments, it is possible that a part or all of the L-dopa added to the cell cultures was decarboxylated to dopamine before it induced neurotoxicity. It seems plausible that L-dopa is only a transient precursor in the synthesis of dopamine because the synthesis of dopamine is performed in a type of complex with TH and AADC, which are associated with VMAT-2, localized in monoaminergic synaptic vesicles. This suggests that L-dopa is not free in the cytosol because free L-dopa is immediately converted to dopamine and transported into the vesicles (Cartier et al. 2010). In Parkinson's therapy, L-dopa also acts as dopamine, as the decarboxylation of L-dopa and the unregulated release of dopamine from serotonergic neurons occur in both the peripheral and central nervous system, a process that seems to be involved in L-dopa-induced dyskinesias (Cheshire and Williams 2012).

Nature of DSP-4-Induced Neurotoxicity

Aleksandra Bortel

Contents

Abstract

N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4) is a noradrenergic neurotoxin which selectively damages noradrenergic projections originating from the locus coeruleus (LC) and transiently alters sympathetic neurons in the periphery. DSP-4 accumulates intraneuronally and produces nerve terminal degeneration via alkylation of diverse neuronal structures. DSP-4 inhibits norepinephrine (NE) reuptake, stimulates NE release, and increases turnover rate of NE. Systemic administration of DSP-4 has a rapid dose-dependent depleting effect on the endogenous NE level. The effect of DSP-4 is largely restricted to

noradrenergic neurons; however, DSP-4 slightly reduces the level of 5-hydroxytryptamine and dopamine. The rat age at the time of DSP-4 injection is important in determining the nature of the long-term changes in the noradrenergic system. Thus, DSP-4 treatment of adult rats produces morphological changes of NE neurons with a pronounced decrease in NE levels in the cerebral cortex, hippocampus, spinal cord, and cerebellum. Less affected are the hypothalamus and pons-medulla. This process is not long lasting and after several months a regeneration of NE nerve terminals is observed. DSP-4 injected to newborn rats induces an alteration of the postnatal development of noradrenergic system with a permanent NE denervation in brain areas distal to LC cell bodies (cortex and hippocampus) and a hyperinnervation in regions proximal to LC (brainstem, cerebellum, and pons-medulla). This type of hyperinnervation does not exist after DSP-4 treatment of adult animals. The noradrenergic lesion obtained with DSP-4 is highly reproducible; therefore, DSP-4 may represent a suitable tool to discern LC neuron degeneration and recovery and to investigate the projections of non-coerulean NE neurons.

Keywords

Degeneration • Depletion • Dopamine-β-hydroxylase • DSP-4 • Hyperinnervation • Locus coeruleus • Monoamine oxidase • Neurotoxin • Non-coerulean innervation • Noradrenergic neurons • Noradrenergic receptors • Norepinephrine transporter • Norepinephrine • Tyrosine hydroxylase

List of Abbreviations

5-HIAA	5-hydroxyindoleacetic acid
5-HT	Serotonin
AD	Aldehyde dehydrogenase
AR	Aldehyde reductase
CNS	Central nervous system
COMT	Catechol-O-methyl transferase
DA	Dopamine
DAT	Dopamine transporter
DBH	Dopamine-β-hydroxylase
DHPG	3,4-dihydroxyphenylethylene glycol
DOPAC	3,4-dihydroxyphenylacetic acid
DSP-4	N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine
GABA	γ-aminobutyric acid
i.p.	Intraperitoneal injection
i.v.	Intravenous injection
LC	Locus coeruleus
MAO	Monoamine oxidase
MHPG	3-methoxy-4-hydroxyphenylethylene glycol
NE	Norepinephrine
NET	Norepinephrine transporter

OCTs	Organic cation transporters
s.c.	Subcutaneous injection
SERT	Serotonin transporter

1 Introduction

N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4) was originally described by Ross (1976) who reported its effects on peripheral and central norepinephrine (NE) tissue levels. DSP-4 is a noradrenergic neurotoxin which crosses the blood–brain barrier and selectively damages noradrenergic projections originating from the locus coeruleus (LC). DSP-4 is a 2-chloroethylamine that interacts with the NE transporter (NET), whereby DSP-4 is then accumulated intraneuronally to induce degeneration of noradrenergic terminals (Ransom et al. 1985; Dudley et al. 1990; Howard et al. 1990). DSP-4 administration into rodents permanently inactivates NE reuptake, stimulates NE release, increases NE turnover rate in some brain regions, and produces morphological changes in NE cells (Jaim-Etcheverry 1998; Prieto and Giralt 2001).

2 Molecular Mechanism of Action

DSP-4 undergoes intramolecular cyclization to form an aziridinium ion, an electrophilic intermediate that can subsequently hydrolyze or react with other nucleophiles, including those present in biological tissues (thiols or amines) (Fig. 1). The aziridinium ion is a structural analogue of bretylium that is a substrate for the NET. Thus, the aziridinium ion covalently bonds with electrophilic centers on or near the site of action, disrupts the function of the NET binding site, and thereby inhibits NE reuptake (Ransom et al. 1982;

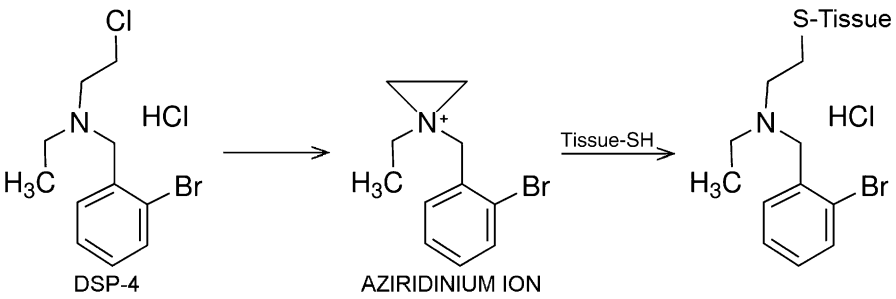

Fig. 1 DSP-4 cyclization and reaction with nucleophiles present in biological tissues (Based on Dudley et al. 1990)

Dudley et al. 1990; Jaim-Etcheverry 1998). Inactivation of the transport system is attributable to DSP-4 alkylation at this site (Lee et al. 1982; Hallman and Jonsson 1984; Dudley et al. 1990) and requires a functional transporter to inhibit NE reuptake (Dudley et al. 1990). DSP-4 in aqueous solutions has a half-life of 7 min at pH 7.4 and 37 °C.

3 DSP-4 Neurotoxic Effects

3.1 DSP-4 Specificity and Monoamine Reuptake

DSP-4 treatment, while having no major influence on NE cell bodies, dendrites, and preterminal axons, exerts neurotoxic effects on the terminal part of NE axons (Jonsson et al. 1981; Fritschy and Grzanna 1989, 1991a). Moreover, the part of NE axons along their pathways positioned between its origin and its entry into a terminal field is not sensitive to DSP-4. Complete loss of NE axons is found in brain regions such as the cerebral cortex, hippocampus, tectum, cerebellum, and spinal cord dorsal horn, and any changes are noted in the basal forebrain, hypothalamus, and some brainstem nuclei (Fritschy and Grzanna 1989, 1991a). Thus, DSP-4 has a preferential, selective neurotoxic effect on nerve terminal projections originating from NE perikarya of LC and does not affect NE axons in brain regions receiving a dense innervation from non-coerulean NE cells (Jonsson et al. 1981; Fritschy and Grzanna 1989, 1991a). Non-coerulean neurons provide the major NE innervation to the regions involved in the regulation of autonomic and motor activities. In contrast, LC neurons innervate brain regions involved in the processing of sensory inputs (Fritschy and Grzanna 1989, 1991a). DSP-4 initially induces degeneration of LC axon terminals that in the long term is responsible for LC cell death. The delayed death of LC neurons is probably a consequence of the loss of terminal axons rather than a result of a direct effect of DSP-4 on LC cell bodies (Fritschy and Grzanna 1991b). Initially, it was suggested that DSP-4 specificity to the noradrenergic projections originating from LC depends on the pharmacologically distinct affinity of DSP-4 for the NET in LC and non-coerulean NE axons (Fritschy and Grzanna 1989, 1991a). Subsequently, Zaczek et al. (1990) proposed that NET binding sites have distinct kinetic characteristics in the cerebral cortex (receiving LC innervation) and hypothalamus (receiving non-coerulean innervation), and therefore, DSP-4 shows a higher affinity for NET in LC versus non-coerulean nerve terminals. There are two components of NE reuptake, and only the high-affinity sites of NET are abolished by DSP-4 treatment. Low-affinity sites remain unaffected by DSP-4 (Lee et al. 1982; Hughes and Stanford 1998a). However, several studies deny NET heterogeneity and demonstrate that NETs are similar in all brain regions (Snyder and Coyle 1969; Ghraf et al. 1983). More plausibly, there may be greater intra-axonal DSP-4 accumulation in LC than non-coerulean NE axons. Interaction of DSP-4 with NET is a prerequisite for NE depletion because the NET is responsible for intracellular accumulation of DSP-4 or its aziridinium ion (Landa et al. 1984). Thus, the cytotoxic DSP-4 effect is not

due to DSP-4 affinity to the transporter but depends on DSP-4 accumulation within the cells by the NET, which then disables DSP-4 outward transport. The outward transport becomes inhibited and DSP-4 remains intracellularly trapped. DSP-4 ultimately leads to ATP depletion and other cytotoxic reactions (Wenge and Bönisch 2009). NE storage is ATP dependent; therefore, DSP-4 inhibition of ATP synthesis results in NE depletion (Dudley et al. 1990).

Neuronally released monoamines are removed from the synaptic cleft by rapid reuptake into presynaptic neurons via Na^+- and Cl^--dependent neuronal monoamine transporters such as NET. Additionally, monoamines are accumulated in extraneuronal tissues by Na^+- and Cl^--independent extraneuronal monoamine transporters and organic cation transporters (OCTs). These transporters are involved in the absorption, distribution, and elimination of endogenous compounds (Wenge and Bönisch 2009). DSP-4 interacts at the level of neuronal membrane and forms covalent bonds with thiol groups of proteins (Jaim-Etcheverry and Zieher 1980; Dudley et al. 1990). DSP-4 and aziridinium ion are competitive inhibitors of NE reuptake, while due to the alkylation of NET, DSP-4 blocks the transporter irreversibly (Zaczek et al. 1990). DSP-4 also inhibits other transporters such as that for dopamine (DAT) and serotonin (SERT). About 80 % and 60 % of the transport activity of DAT and SERT, respectively, is inactivated by the neurotoxin. DSP-4 inhibits, as well, OCTs with a potency 3.2-fold (OCT2), 7.5-fold (OCT1), or 9-fold (OCT3) higher than for the NET. The neurotoxic DSP-4 effect is completely irreversible at NET; only partially irreversible at DAT, SERT, and OCT3; and fully reversible at OCT1 and OCT2 (Wenge and Bönisch 2009).

3.2 Synaptic Norepinephrine Levels and Noradrenergic Receptors

DSP-4-induced imbalance between NE release and reuptake leads to an increase in the extracellular NE concentration and NE efflux in the frontal cortex of freely moving rats (Hughes and Stanford 1998a, b). However, DSP-4 treatment does not alter the basal extracellular NE level in the frontal cortex of anesthetized rats, although NE release evoked by administration of an α_2-adrenergic receptor antagonist results in lower but still significant increase in extracellular NE levels (Kask et al. 1997; Harro et al. 1999). The same, lower but still significant increase in NE release induced by a $GABA_A$ antagonist (bicuculline) was observed by Giorgi et al. (2003) in the piriform cortex. Long-term NE depletion and the resulting decreased presynaptic NE release affect the function of pre- and postsynaptic NE receptors that are exposed to the environment of reduced synaptic NE concentration (Dudley et al. 1990). DSP-4 is a blocker of α-adrenergic receptors; therefore, DSP-4 initially reduces α-adrenergic receptor binding. This blocking effect is not long lasting because already 14 days after the neurotoxin application α- and β-adrenergic receptor binding recovers (Jonsson et al. 1981). DSP-4 exerts a consistent upregulation of β-adrenergic receptors in the somatosensory cortex and hippocampus at 1–3 weeks after treatment (Zahniser et al. 1986). DSP-4 likewise increases

the number of β-adrenergic receptors and does not change the affinity of these receptors. The density of binding sites of β-adrenergic receptors is enhanced at 1 day, 7 days, and up to 1 year after central NE denervation induced by DSP-4 (Theron et al. 1993; Wolfman et al. 1994). The number and the affinity of α_1-adrenergic receptors are unchanged in somatosensory cortex and hippocampus 1–3 weeks after DSP-4 treatment (Zahniser et al. 1986; Szot et al. 2010). As well, the properties of α_2-adrenergic receptors are unaltered (Zahniser et al. 1986). Another study shows that the activity of α_2-adrenergic receptors is reduced in the parietal cortex and hippocampus 3 weeks after DSP-4 treatment, but not in the hypothalamus (Prieto and Giralt 2001). Interestingly, it was reported that the number of α_2-adrenergic receptors is reduced in the cortex (20 %), hippocampus (18 %), cerebellum (24 %), and hypothalamus (39 %) at 3 days after DSP-4 (100 mg/kg; DSP-4 dose is mentioned only when is different from 50 mg/kg) treatment and unchanged or even increased 15 days after treatment. Thus, decreased density of cortical presynaptic α_2-adrenergic receptors is progressively masked by increased sensitivity of postsynaptic α_2-adrenergic receptors (Heal et al. 1993). The density of binding sites of α_1- and α_2-adrenergic receptors is increased in cerebral cortex and cerebellum 7 days after DSP-4 administration, while α_1- and α_2-adrenergic receptor number attains control values 3 months and 1 year later, respectively (Theron et al. 1993; Wolfman et al. 1994).

The enhancement of α-adrenergic receptor density is an adaptative change of postsynaptic receptors as a consequence of the long-term disruption in NE transmission. However, an irreversible increase of β-adrenergic receptors may be linked with the adaptative changes that are independent of the endogenous NE concentration (Dooley et al. 1987).

3.3 Norepinephrine Synthesizing and Metabolizing Enzymes

DSP-4 induces a profound loss of both NE and dopamine-β-hydroxylase (DBH) from noradrenergic axons, with an uncorrelated time course (Fig. 2) (Ross 1976; Jaim-Etcheverry and Zieher 1980; Fritschy et al. 1990). Tissue NE levels decline within hours, and DBH activity is reduced within 4 days after DSP-4 treatment (Fritschy et al. 1990). Therefore, two phases in the response of NE axons to DSP-4 are suggested: (1) an acute phase that is characterized by a marked loss of neurotransmitter and (2) a neurodegenerative phase associated with loss of DBH and structural disintegration of NE axons (Fritschy et al. 1990). LC cells which survive the injury induced by DSP-4 exhibit greater DBH immunocytochemical reaction (Fritschy and Grzanna 1991b).

There are contradictory studies concerning the DSP-4 influence on tyrosine hydroxylase, a synthesizing enzyme that is localized in noradrenergic neurons and regulated independently (Fig. 2). It is proposed that DSP-4 treatment induces a decrease of basal tyrosine hydroxylase activity in the hippocampus and parietal cortex, whose axon terminals arise exclusively from LC, but not in the hypothalamus which is innervated by noradrenergic terminals originating from the tegmental lateral

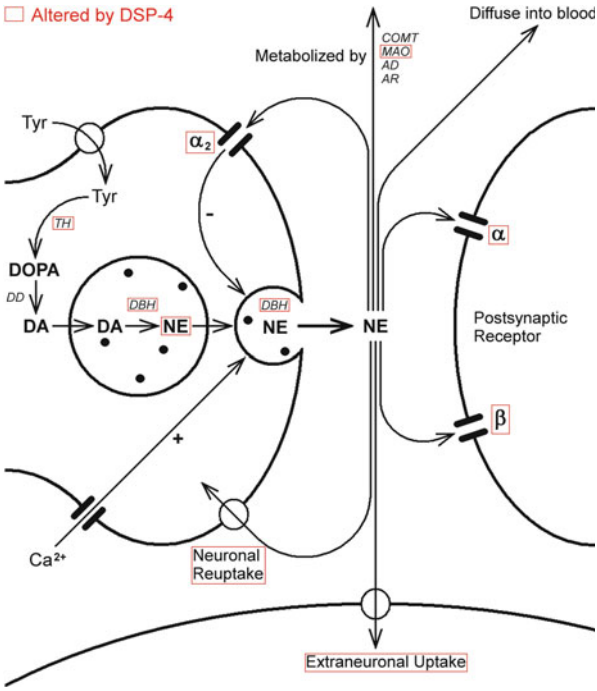

Fig. 2 DSP-4-induced alterations in noradrenergic nerve terminals. DSP-4 directly or indirectly affects norepinephrine synthesis, release, transport and metabolism. Abbreviations are shown in the abbreviation list

nuclei (Prieto and Giralt 2001). However, other studies show that DSP-4 exerts a long-lasting NE depletion with compensatory increased accumulation of tyrosine hydroxylase in noradrenergic neurons (Booze et al. 1988; Dudley et al. 1990).

It was suggested that DSP-4 may also interfere with some enzymes involved in NE metabolism. First, DSP-4 inhibits monoamine oxidase (MAO) activity in peripheral tissues (Lyles and Callingham 1981). Furthermore, the MAO-B inhibitor deprenyl effectively blocks the neurotoxic action of DSP-4 on noradrenergic neurons. However, MAO-B inhibition of DSP-4 toxicity is unrelated to NE metabolism, because MAO-A plays a central role in metabolizing endogenous monoamines including NE (Gibson 1987). Finnegan et al. (1990) have proposed that deprenyl neuroprotective effects are unrelated to MAO-B inhibition but to other properties such as the effects on the monoamine release, reuptake and metabolism, as well as the effects on other central neurotransmitter systems. Indeed, DSP-4 or aziridinium ion binds to the active catalytic site of MAO-B but is not further metabolized. Therefore, the neuroprotective deprenyl action depends on the blockade of DSP-4 reuptake into noradrenergic neurons (Dudley et al. 1990; Finnegan et al. 1990). However, the neuroprotective action of highly potent and selective MAO-B inhibitors, that do not interfere with DSP-4 reuptake within NE terminals (as it is observed with deprenyl), likewise fully prevents DSP-4-induced NE depletion (Yu et al. 1994; Zhang et al. 1996). Conversely, some selective

MAO-B inhibitors are inactive against DSP-4-induced neurotoxicity (Bertocci et al. 1988; Finnegan et al. 1990), and the absence of MAO-B (i.e., MAO-B knockout mice) does not influence the mechanism of neurotoxic DSP-4 action (Fornai et al. 2001). Therefore, the neuroprotective and/or neurorescue effects of some MAO-B inhibitors are unclear.

3.4 Electrophysiological Responsiveness

DSP-4 increases NE turnover in brain regions in which NE depletion is greater than 85 % (cerebral cortex and hippocampus), but has no effect on NE turnover when NE is depleted by only 30–60 % (cerebellum, hypothalamus, brainstem, and LC). Firing rates of monoaminergic neurons increase only after 75 % NE depletion. Thus, increased firing represents a compensatory response to the injury, resulting in increased transmitter release from the terminals spared by the lesion (Chiodo et al. 1983; Logue et al. 1985). Olpe et al. (1983) reported that DSP-4 decreases the mean neuronal LC firing rate without altering the structural appearance of LC perikarya. Precisely, DSP-4 does not affect the basal activity of LC noradrenergic neurons but increases the irregularity and the burst firing of noradrenergic neurons 2 weeks after DSP-4 treatment (Szot et al. 2010).

4 DSP-4 Doses and Routes of Administration

Systemic administration (s.c., i.p. or i.v.) of DSP-4 has a rapid dose-related effect on tissue levels of NE (Table 1). Effects are achieved with a DSP-4 dose of 20–100 mg/kg i.p. by 0.5 h after treatment (Hallman and Jonsson 1984; Jaim-Etcheverry 1998). Newborn rats are typically treated s.c., while adult rats are routinely given i.p or i.v. injections. Notably, NE depletion is much greater after i.v. than after i.p. injection of adult rats (Jaim-Etcheverry and Zieher 1980); however, i.p. administration is sufficient to produce pronounced NE depletion (up to 95 %). A dose of 50 mg/kg of DSP-4 is the most efficient in producing pronounced, long-lasting reduction of NE reuptake in the CNS without causing any lethal effects in rats (Jonsson et al. 1981) and mice (Dailly et al. 2006).

Neonatal DSP-4 treatment leads to dose-dependent adulthood changes of NE concentrations in assorted brain regions. The lowest tested DSP-4 dose (10 mg/kg s.c.) produces about 50 % NE reduction in cerebral cortex and spinal cord and small changes in cerebellum and pons-medulla. A large DSP-4 dose (50 mg/kg s.c.) produces near complete NE depletion in cerebral cortex and spinal cord and associated increases in NE concentration, both in the cerebellum and pons-medulla (Jonsson et al. 1982). The latter effect is reflective of reactive collateral sprouting of bi- or multipolar NE neurons of LC, following DSP-4 injury of NE terminals and/or axons projecting to cerebral cortex and hippocampus – as was found in similar studies with the neurotoxins 6-hydroxydopamine (Sachs and Jonsson 1975) and 6-hydroxydopa (Kostrzewa and Garey 1977).

Table 1 Dose-dependent changes of NE tissue levels in different brain areas observed 6 weeks after DSP-4 treatment (Based on Jaim-Etcheverry and Zieher 1980)

DSP-4 doses	<25 mg/kg	25 mg/kg	50 mg/kg	100 mg/kg
Cortex	–	–	X	X
NE degeneration				
Spinal cord	–	X	X	X
NE degeneration				
Brainstem	–	X	X	–
NE degeneration (A)				
NE hyperinnervation (N)				
Cerebellum	X	X	X	–
NE degeneration (A)				
NE hyperinnervation (N)				

(*A*) NE degeneration observed after DSP-4 injection to adult animals, and (*N*) NE hyperinnervation after DSP-4 injection to newborn animals

5 The Nature and Extension of DSP-4-Induced Neurotoxicity in Adulthood

DSP-4 treatment does not have significant sex differences with respect to the regional alterations in the monoamine levels (Jonsson et al. 1981, 1982). Also, body weight gain in both sexes is virtually identical after DSP-4 and similar to that of control litters. As adults, the weight of neonatally treated rats of both sexes is approximately 95 % of the weight of age-matched controls (Jonsson et al. 1981, 1982). The age of rats at the time of DSP-4 treatment is critical in determining the nature and extent of the long-term changes in noradrenergic neurons (Jaim-Etcheverry 1998).

5.1 DSP-4 Treatment of Adult Rats

5.1.1 Noradrenergic System

DSP-4 treatment of adult rats generally causes a decrease of tissue levels of NE and its two principal metabolites: 3,4-dihydroxyphenylethylene glycol (DHPG) and 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) (Dudley et al. 1990; Hallman et al. 1984; Logue et al. 1985). However, this process is not long lasting, and after several months a regeneration of NE nerve terminals is observed (Hallman et al. 1984). DSP-4 neurotoxic effects are rapid, being maximal 2 h after DSP-4 injection for NE reuptake in vitro and by 4–6 h for endogenous NE levels. Maximal NE depletion is achieved most rapidly in the occipital cortex, hippocampus, hypothalamus, pons-medulla, cerebellum, and spinal cord, but later, in the frontal cortex, striatum, and mesencephalon. Acutely, DSP-4 has a profound NE-depleting effect in the cortex and cerebellum, but only a modest effect in ventral forebrain and hypothalamus (Grzanna et al. 1989). Simultaneously, a profound reduction in NE

axon staining is found in the cerebral cortex and cerebellum after DSP-4 treatment, whereas the ventral forebrain and hypothalamus appear to be unaffected (Grzanna et al. 1989). Ten days after DSP-4 treatment, NE concentrations are decreased by about 90 % in the cerebral cortex, hippocampus, spinal cord, and cerebellum. Less affected are the hypothalamus and pons-medulla, known to have a mixed NE innervation (both from LC and other noradrenergic nuclei in brainstem). DSP-4 decreases endogenous tissue levels of NE, not only at noradrenergic nerve terminals but also at both noradrenergic and serotoninergic cell body levels. Seven days after DSP-4, NE concentrations are decreased in LC perikarya and dorsal raphe nucleus (Cassano et al. 2009). Thus, DSP-4 neurotoxicity is exerted on the LC via retrograde degeneration (Fritschy and Grzanna 1991a) as well as from direct DSP-4 action at the LC itself, where NET is highly expressed (Cassano et al. 2009). Alterations in NE reuptake in assorted brain areas are compatible with observed changes in tissue levels of NE after DSP-4 (Jonsson et al. 1981).

NE depletion induces profound adaptive changes in other neuronal phenotypes. DSP-4 does not modify endogenous levels of brain acetylcholine, γ-aminobutyric acid (GABA), glutamic acid, glycine, or aspartic acid. However, DSP-4 depletes tissue levels of 5-HT and slightly depletes DA (Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1981; Fornai et al. 1996b).

5.1.2 Serotoninergic System

DSP-4 induces an acute decrease of 5-HT concentrations in the cerebral cortex, mesencephalon, and spinal cord (Jackisch et al. 2008), and at 8 weeks 5-HT is depleted as much as 85 % in the cerebral cortex (Jonsson et al. 1981). DSP-4 does not alter the level of 5-HT and its metabolite 5-hydroxyindoleacetic acid (5-HIAA) in hippocampus (Jackisch et al. 2008) and dorsal raphe nucleus (Cassano et al. 2009). However, one day after DSP-4 treatment, a prominent increase in 5-HIAA is observed in the cortex, hippocampus, and hypothalamus (Theron et al. 1993). Because NE normally inhibits presynaptic 5-HT release (Vizi and Kiss 1998), noradrenergic denervation of hippocampus is associated with an increase in basal and evoked 5-HT release and reduced 5-HT accumulation in the hippocampal slices (Cassano et al. 2009). The neurotoxic effect of DSP-4 on 5-HT neurons can be prevented by pretreatment with the SERT blocker (zimelidine) (Jonsson et al. 1981).

5.1.3 Dopaminergic System

DSP-4 alters DA levels in several brain regions (Jonsson et al. 1982). Thus, DSP-4-induced noradrenergic lesioning reduces DA levels in hippocampus, cerebellum, prefrontal cortex, LC, and dorsal raphe nucleus (Jonsson et al. 1981; Cassano et al. 2009). Moreover, DSP-4 treatment decreases (Lategan et al. 1992) or does not change (Hatip-al-Khatib et al. 2001; Häidkind et al. 2002) the extracellular DA concentration and reduces the extracellular 3,4-dihydroxyphenylacetic acid (DOPAC) level in nucleus accumbens (Lategan et al. 1992; Hatip-al-Khatib et al. 2001). A reduction in extracellular DA concentration is attributable to a reduction in basal DA release (Lategan et al. 1992; Weinshenker et al. 2008).

5.1.4 Other Neuronal Phenotypic Systems

The hippocampal endogenous acetylcholine level (Hörtnagl et al. 1989) and activity of the acetylcholine transporter (Harrell et al. 2005) are unaltered following DSP-4 treatment. However, DSP-4-induced lesion of noradrenergic neurons facilitates cholinergic transmission in the hippocampus (Jackisch et al. 2008). DSP-4 treatment likewise induces an upregulation of the turnover and activity of cholinergic neurons. Acetylcholine accumulation is enhanced in the hippocampus, while basal and evoked acetylcholine efflux are increased in DSP-4-treated rats (Jackisch et al. 2008).

5.1.5 Peripheral Sympathetic Neurons

Related DSP-4 effects are observed in peripheral sympathetic neurons as compared with central NE neurons. However, a complete recovery of peripheral adrenergic nerves is observed 1 week after DSP-4, and a gradual recovery of decreased NE tissue levels and reuptake occurs by 2–4 weeks after DPS-4 treatment (Jaim-Etcheverry et al. 1980; Jonsson et al. 1981).

5.2 DSP-4 Treatment of Newborn Rats

5.2.1 Noradrenergic System

Systemic DSP-4 treatment of newborn rats results in an alteration in postnatal development of the noradrenergic system, with a permanent denervation of distal NE projection regions and associated NE hyperinnervation in regions proximal to LC cell bodies. The total number of NE nerve terminals is considered to be unaltered (Jaim-Etcheverry and Zieher 1980). NE hyperinnervation is considered to be a consequence of collateral NE accumulation and/or sprouting of noradrenergic neurons (Jaim-Etcheverry and Zieher 1980). Neonatal DSP-4 treatment leads to adulthood changes of tissue NE levels in several brain regions. In adulthood NE is depleted approximately 90 % in cerebral cortex, olfactory bulb, hippocampus, and spinal cord of rats treated as neonates with DSP-4 (Jonsson et al. 1982; Nowak et al. 2006; Bortel et al. 2008b), with less pronounced NE effects in hypothalamus and septum. No significant effects are noted in the striatum, olfactory tubercle, and medulla oblongata (Jonsson et al. 1982; Nowak et al. 2006), while a pronounced increase in NE concentrations are present in the cerebellum, brainstem, mesencephalon, and pons-medulla after DSP-4 (Jonsson et al. 1982; Bortel et al. 2008b). It is notable that NE concentrations are decreased in the cerebellum, mesencephalon, and pons-medulla 6 h after DSP-4 administration, in contrast to the marked increase in NE tissue levels in these regions in adulthood (Jonsson et al. 1982).

When administered at birth, DSP-4 decreases in vitro NE reuptake in cerebral cortex and spinal cord by approximately 90 %, but does not alter NE reuptake in the striatum and increases NE reuptake in the cerebellum (Jonsson et al. 1982).

Permanent NE denervation in cerebral cortex and spinal cord is present at all developmental stages, although more pronounced when animals are treated with DSP-4 up to the 5th day after birth. However, NE hyperinnervation in the cerebellum

and pons-medulla is only observed when DSP-4 is administered to 1 and 3 days old rats (Jonsson et al. 1982; Bortel et al. 2008b). By the age of 8 days, permanent NE depletion is present in these structures of the brain of animals treated at birth with DSP-4 (Jonsson et al. 1982). Acutely (1 day after DSP-4 treatment) NE depletion is observed in animals of all ages (Jonsson et al. 1982).

5.2.2 Serotoninergic System

DSP-4 induces dose-dependent changes of 5-HT tissue levels in several brain regions. DSP-4 reduces the endogenous 5-HT concentrations in the cerebral cortex and spinal cord and reduces 5-HT reuptake in the occipital cortex, hippocampus, and cerebellum. No significant effects are noted in other brain regions (Jonsson et al. 1981).

Neonatal DSP-4 treatment does not induce any change in 5-HT levels and 5-HT reuptake when whole brain is analyzed (Jonsson et al. 1982). SERT blocker zimelidine attenuates the effects of DSP-4 on 5-HT and 5-HIAA in the frontal cortex, hippocampus, striatum, and hypothalamus (Jonsson et al. 1981; Dabrowska et al. 2007).

5.2.3 Dopaminergic System

Although neonatal DSP-4 treatment does not acutely (i.e., directly) affect DA and DOPAC levels in the hippocampus and striatum (Nowak et al. 2006), there is an adaptive decrease in DA content of occipital cortex, hippocampus, cerebellum, mesencephalon (Jonsson et al. 1982), and dorsal raphe nuclei (Cassano et al. 2009) in adulthood.

5.2.4 GABAergic System

Neonatal DSP-4 treatment of rats does not alter GABA tissue levels in prefrontal cortex, hippocampus, brainstem, and cerebellum (Bortel et al. 2008b) and does not alter the extracellular GABA concentration in prefrontal cortex (Bortel et al. 2008a). However, DSP-4-induced noradrenergic denervation of the cerebral cortex reduces the number of $GABA_A$ receptors that are localized on the presynaptic axons and nerve terminals of noradrenergic neurons (Medina and Novas 1983; Suzdak and Gianutsos 1985). This significant decrease in density of benzodiazepine receptors persists even 1 year after DSP-4 treatment (Wolfman et al. 1994). Moreover, DSP-4 increases the number of benzodiazepine receptors in the cerebellum and brainstem (Medina and Novas 1983).

5.2.5 Peripheral Sympathetic Neurons

The effect of DSP-4 on the peripheral sympathetic nervous system is minor. DSP-4 fails to permanently alter the NE concentration in peripheral organs (Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1982). At 1 month after DSP-4 treatment, NE tissue levels approximate control values (Jonsson et al. 1982). Neonatal DSP-4 treatment does not produce long-lasting changes in NE content of heart, salivary glands, and spleen (Jaim-Etcheverry and Zieher 1980; Jonsson et al. 1981).

5.3 Prenatal DSP-4 Treatment

Prenatal DSP-4 administration (at the end of gestation; twice 25 mk/kg i.v.) modifies NE tissue levels to the same extent as when DSP-4 is administered to newborn animals (Jaim-Etcheverry and Zieher 1980). DSP-4 prenatal treatment permanently decreases NE levels in cerebral cortex and spinal cord, demonstrating that the neurotoxin passes the blood-placenta barrier and has a potent neurotoxic effect in the prenatal stage. Interestingly, there is no ensuing increase in NE concentration in the cerebellum and pons-medulla of treated prenates when observed as adults – in contrast to effects after DSP-4 treatment of newborn animals (Jonsson et al. 1981).

6 Rodent Differences in the Susceptibility to DSP-4

DSP-4-induced neurodegenerative changes in noradrenergic neurons in the CNS are qualitatively similar in both rats and mice (Jonsson et al. 1981). However, NE depletion in forebrain regions such as cortex and hippocampus appears to be more pronounced and persistent in mice versus rats (Fornai et al. 1996a; Dailly et al. 2006; Cassano et al. 2009; Szot et al. 2010). As well, sympathetic adrenergic nerves of the mouse are more sensitive than rats to the neurotoxic action of DSP-4. This effect is likely due to the differences in diffusion conditions or size of NE varicosities (Jonsson 1980). It is notable that various mouse and rat strains show a different sensitivity in the CNS to the neurotoxic DSP-4 action, as exemplified by the finding that Long-Evans rats are less sensitive than Sprague–Dawley rats to DSP-4 (Schuerger and Balaban 1995).

7 Conclusion

DSP-4 is an alkylating agent with high specificity for NE and 5-HT neurons in vivo. The neurotoxin transiently alters sympathetic neurons in the periphery and produces persistent alterations in the central noradrenergic system. DSP-4, having high affinity for the NET, and being accumulated within NE nerve endings, depletes monoamines by reducing mitochondrial function and ultimately destroying noradrenergic neurons in the periphery and brain (Jaim-Etcheverry and Zieher 1980; Dudley et al. 1990). Moreover, DSP-4 is able to cross the blood-placenta barrier in pregnant animals, thereby enabling DSP-4 to alter noradrenergic neuronal development in early stages of ontogeny.

DSP-4 has the capacity to produce destruction of NE axons in brain regions innervated by LC, without affecting non-coerulean NE axons (Fritschy and Grzanna 1989). Therefore, DSP-4 appears to be a useful denervation tool to study the projections of non-coerulean NE neurons in isolation. Additionally, DSP-4 may serve as a useful experimental tool to discern LC neuron degeneration and recovery. The long-term NE depletion and irreversible inhibition of neuronal reuptake induced by DSP-4 can be used in pharmacological investigations. Thus, the

alterations in NE tissue levels and release may be used to investigate synaptic biochemistry including mechanisms of noradrenergic receptor up- or downregulation. The NE-depleting DSP-4 effects can be used to study behavioral disorders. Until now, we know that DSP-4 treatment decreases exploratory activity in rats that results from increased anxiety (Delini-Stula et al. 1984; Harro et al. 1995). DSP-4-induced NE depletion exerts deficits in working memory without affecting reference memory (DSP-4 did not affect the previously learned pattern) (Ohno et al. 1993; Sontag et al. 2008). Moreover, NE possesses an anticonvulsant effect; therefore, central NE depletion facilitates induction of seizures evoked by bicuculline, pentylenetetrazol, or maximal electroshock (Mishra et al. 1994; Giorgi et al. 2003, 2006).

The noradrenergic lesion obtained with DSP-4 is remarkably reproducible and the usefulness and impact of DSP-4-lesioned models have enormous pharmacological potential. Despite these obvious successes, limitation still exists for DSP-4 because of unspecificity in its mechanism of action. DSP-4 interacts not only with NE reuptake systems, but alters, as well, other monoamine reuptake systems as well as enzymes involved in NE synthesis. Adaptive changes in noradrenergic receptors, relative to NE depletion, further complicate the actions of DSP-4. Therefore, all experiments based on DSP-4 should be carefully interpreted.

MPTP Neurotoxicity: Actions, Mechanisms, and Animal Modeling of Parkinson's Disease

Livia Pasquali, Elena Caldarazzo-Ienco, and Francesco Fornai

Contents

Abstract

The study of neurotoxicity induced by MPTP led to drastically change the perspective on Parkinson's Disease. In fact the selective neurotoxicity induced by MPTP rejuvenated PD research and generated a number of studies aimed at

elucidating the mechanisms of action of MPTP. Remarkably, these molecular mechanisms turned out to be critical also for the survival of DA neurons in idiopathic PD. In this chapter we report the main concepts developed over the last three decades to understand key molecular steps which are pivotal in MPTP toxicity. This is the case of the role played by DAT and VMAT-2 in conditioning the sensitivity to MPTP neurotoxicity. Similarly, the mitochondria as targets of MPTP toxicity appear similarly affected by selective mutation of genes leading to PD. Again, the fate of mitochondria and the ability to clear these organelles when being dysfunctional is key in the modulation of MPTP toxicity. This also applies for misfolded proteins such as alpha synuclein. Again, multiple brain areas as well as peripheral sites are increasingly recognized to be affected both during MPTP toxicity and sporadic PD patients. Nowadays it seems that MPTP per se did not lead to discovery of the environmental compound which causes PD, nonetheless the study of MPTP did disclose several molecular and cellular pathways which are critical in the genesis of PD. This latter point fairly corresponds to what we enthusiastically expected from MPTP when it was identified as a causal agent of what it remains, a toxic form of environmental parkinsonism.

Keywords

Animal models • MPP+ • Parkinsonism

List of Abbreviations

AMPA	Alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid
ATG	Autophagy
ATP	Adenosine triphosphate
BBB	Blood–brain barrier
COX	Cyclooxygenase
DA	Dopamine
DAT	DA transporter
DSP-4	*N*-(−2-chloroethyl)-*N*-ethyl-2-bromobenzylamine
EAA	Excitatory amino acids
ENS	Enteric nervous system
GI	Gastrointestinal
GSH	Glutathione
i.c.v.	Intracerebroventricular
IP_3	Inositol(1,4,5)trisphosphate
JNK	c-Jun N-terminal kinase
KO	Knockout
LC	Locus coeruleus
MAO-B	Monoamine oxidase type B
METH	Methamphetamine
MK-801	Dizocilpine
Mn-SOD	Manganese superoxide dismutase
$MPDP^+$	1-Methyl-4-phenyl-2,3-dihydropyridine
MPP^+	1-Methyl-4-phenylpyridinium

MPPP	1-Methyl-4-phenyl-4-propionoxy-piperidine
MPT	Mitochondrial permeability transition
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
NAD	Nicotinamide adenine dinucleotide
NE	Norepinephrine
NET	NE transporter
NMDA	*N*-methyl-D-aspartate
NO	Nitric oxide
PD	Parkinson's diseases
ROS	Reactive oxygen species
SC	Spinal cord
SNpc	Substantia nigra pars compacta
SOD	Superoxide dismutase
TH	Tyrosine hydroxylase
UP	Ubiquitin–proteasome
VMAT-2	Vesicular monoamine transporter type 2

1 Introduction

The history of MPTP began in 1947, when researchers from a North American pharmaceutical company named Hoffmann-La Roche while developing compounds as painkillers synthesized a novel opioid derivative named meperidine (Demerol$^{(R)}$). In this context, Dr. Ziering synthesized a meperidine derivative, 1-methyl-4-phenyl-4-propionoxy-piperidine (MPPP, Fig. 1), which possesses the meperidine structure, containing an esteric group (Ziering et al. 1947). Since MPPP turned out not to be more effective than Demerol, it was never marketed. In 1976, a 23-year-old Maryland chemistry graduate named Barry Kidston, in the attempt to synthesize MPPP to explore its potential as a recreational drug, esterified the intermediate tertiary alcohol of MPPP with propionic anhydride at a drastically high temperature. This led to the synthesis of 3 % of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) as a by-product of MPPP (Fig. 1). Within 3 days following MPTP intake, Kidston developed parkinsonism, which was successfully treated with L-DOPA. However, he died 18 months later due to cocaine overdosing. The neuropathological exam was in line with neurological symptoms showing dopamine (DA) neuron loss in the substantia nigra *pars compacta* (SNpc) (Davis et al. 1979). Kidston's case remained unique for a few years; in 1982, in Northern California during a very short time, a sort of epidemic parkinsonism was reported in Santa Clara Valley Medical Center in San Jose (CA) by Dr. J. William Langston, the hospital's chief neurologist. Dr. Langston initially described seven cases, but this number increased soon after, when several cases of severe parkinsonism occurring in young adults were described in the same area. It was evident that these patients were drug addicts and all of them injected *intravenously* an illicit street drug called "Super Demerol"

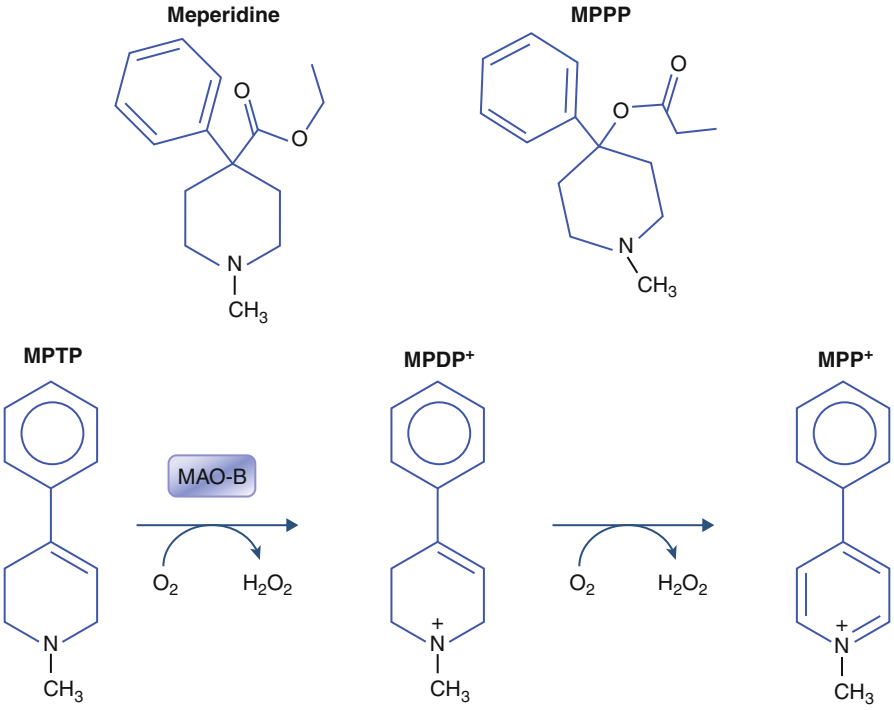

Fig. 1 Structural formula of meperidine analogues. The cartoon shows the structural affinity between MPTP and its metabolites with meperidine and MPPP. MPTP was produced as by-product in the effort to synthesize MPPP. Occurrence of MPTP and administration of the compound to a variety of animal species lead to the enzymatic oxidation by monoamine oxidase (*MAO*) type B to produce the intermediate $MPDP^+$ which, in turn, undergoes spontaneous oxidation to MPP^+

which turned out to contain significant amount of MPTP (Langston et al. 1983). Also these patients showed the clinical features of idiopathic Parkinson's disease (PD), including bradykinesia, rigidity, and, in some cases, resting tremor (Ballard et al. 1985). Again, these symptoms were relieved by the intake of oral L-DOPA, while postmortem analysis confirmed the occurrence of massive cell loss in the SNpc (Ballard et al. 1985). Only later on the occurrence of Lewy bodies in these patients was demonstrated thus adding on to the remarkable overlapping with idiopathic PD (Langston et al. 1999).

The complete story of these patients was reported by Dr. William Langston in his monograph "The Case of the Frozen Addicts" (Langston and Palfreman 1996).

After identification of MPTP as the causal agent for the epidemic environmental parkinsonism, neuroscientists involved in PD research evaluated its neurotoxic effects in a variety of animal species including nonhuman primates, rodents, cats, pigs, dogs, sheep, rats, and goldfishes (Kopin and Markey 1988; Gerlach and Riederer 1996; Przedborski et al. 2001). It was soon evident that the neurotoxic properties of MPTP vary depending to which animal it was administered. In fact,

when MPTP is administered to monkeys, most clinical and pathological hallmarks of PD can be reproduced (Langston et al. 1984a; Chiueh et al. 1984; Doudet et al. 1985; Crossman et al. 1985; Nomoto et al. 1985; Vezoli et al. 2011), while rats are quite resistant to MPTP toxicity (Chiueh et al. 1984).

The discovery of selective neurotoxicity induced by MPTP rejuvenated PD research and generated a number of studies aimed at elucidating the mechanisms of action of MPTP.

In fact, it was postulated that MPTP analogues such as pesticides may represent environmental neurotoxins responsible for the etiology of idiopathic PD. Moreover, for the first time, an experimental model mimicking both neurological symptoms and key neuropathological features of PD was available. This experimental setting appeared to be ideal to dissect the most intimate molecular mechanisms generating selective neurodegeneration underlying PD. A bulk of studies now demonstrate that MPTP analogues are not primarily involved in PD etiology. Moreover, now we are aware that PD possesses a strong genetic background which limits the role of environmental factors. Again, even in primates, some discrepancies between PD and MPTP-induced parkinsonism do exist. For instance, the striatal pattern of DA loss in PD involves more the putamen than caudate nucleus (as witnessed by pathobiochemistry, neuropathology, and more recently brain imaging, Kish et al. 1988; Jellinger 2002; Brooks and Pavese 2011), while MPTP does not discriminate between DA innervations of various neostriatal regions (Pifl et al. 1988). Nonetheless, MPTP intoxication still represents the best experimental tool to mimic very closely the selective and specific features which characterize PD. This extends also to those neuropathological features which were not immediately evident in MPTP-intoxicated patients, such as the occurrence of neuronal inclusions. In fact, neuronal inclusions known as Lewy bodies which are considered a hallmark of PD were not described at first following sporadic injections of MPTP. Now we are aware that in MPTP-intoxicated patients, Lewy bodies do occur (Langston et al. 1999).

Again, clinical and pathological research on PD in the last three decades demonstrated that despite the multiple etiology (various genetic forms or idiopathic), the disease is constantly characterized by degeneration of multiple areas both within the CNS (Braak et al. 2003) and outside the brain, the spinal cord, and periphery. Accordingly, research on MPTP intoxication cops quite perfectly with such novel findings in PD. In fact, nowadays we are aware that by selecting the appropriate animal species and MPTP dosing regimen, we can reproduce most of these extra-nigral degenerations in multiple brain and peripheral areas. Thus, apart from discrepancies in the topography of nigral cell loss and nigrostriatal denervation, at present we can firmly establish the occurrence of neuronal inclusions and the involvement of multiple brain sites and peripheral regions following MPTP intoxication. This renders the MPTP model constantly updated in following progress in PD research. In fact, some potential discrepancies were resolved progressively adapting in-depth studies on MPTP intoxication to the extended degeneration which was increasingly described in PD.

In order to analyze MPTP toxicity, it is mandatory to dissect those molecular steps which characterize MPTP metabolism and the dynamics of MPTP in target cells. At the same time, after reviewing main concepts which characterize MPTP

toxicity at neuronal level, we will mention briefly those neurotransmitter and biochemical pathways which either contribute to detrimental effects or mediate compensatory mechanisms which counteract MPTP intoxication.

2 MPTP Metabolism

MPTP is a highly lipophilic substance (Fig. 1) that easily crosses the blood–brain barrier (BBB) (Fig. 2). In the brain, MPTP is metabolized to 1-methyl-4-phenylpyridinium (MPP^+) (Figs. 1 and 2) via the formation of the intermediate 1-methyl-4-phenyl-2,3-dihydropyridine ($MPDP^+$, Fig. 1), this oxidation being catalyzed by monoamine oxidase type B (MAO-B) (Chiba et al. 1984; Kopin 1987) (Figs. 1 and 2). Once formed, MPP^+, which is a polar compound, cannot cross back the BBB. MPP^+ is the real neurotoxin at cellular level; in fact MAO inhibitors (which impede the generation of MPP^+ from MPTP) provide complete protection against MPTP toxicity (Heikkila et al. 1984a; Langston et al. 1984b). When MPP^+ is administered systemically, there is no damage within the CNS due to the high polarity of the MPP^+ ion which impedes the crossing of the BBB. On the other hand, when MPP^+ is administered intracerebroventricularly (*i.c.v.*), toxicity in the CNS does occur (Sundström et al. 1986; Giovanni et al. 1994a, b; Sonsalla et al. 2008). Once crossed the BBB, MPTP can interact with MAO-B placed in several cell types (including astrocytes and serotonergic neurons). Since glial cells are abundant in the CNS, MAO-B in astrocytes are thought to be mainly involved in MPTP metabolism (Brooks et al. 1989), while a damage to serotonin neurons fails to protect from MPTP toxicity (Melamed et al. 1986). Once formed MPP^+ is released from glia in the extracellular space, and it enters within DA neurons via the high-affinity DA transporter (DAT, Javitch et al. 1984) (Fig. 2). This was first demonstrated by preventing MPTP-induced DA toxicity using selective DAT inhibitors (Pileblad and Carlsson 1985; Ricaurte et al. 1985; Sundstrom & Jonsson 1985). Uptake selectivity contributes to the selective toxicity of MPP^+. In fact, MPP^+ is also taken up by norepinephrine (NE) neurons through the NE transporter (NET). Indeed, the uptake within NE neurons exceeds that occurring in DA cells in spite of the fact that NE neurons were originally considered not to be involved in MPP^+ toxicity (Herkenham et al. 1991). Now we are aware that the dosing protocol of MPTP is critical in producing a damage which also involves NE neurons (Seniuk et al. 1990). Remarkably, this point provides a further convergence between MPTP and PD since the damage to NE neurons mostly placed in the nucleus locus coeruleus (LC) is a typical feature of PD patients (Gesi et al. 2000; Zarow et al. 2003, see also in this chapter the Sect. 8). Once entered the DA/NE axons, MPP^+ is accumulated in the cytoplasm where it forms a complex with neuromelanin (D'Amato et al. 1987), being otherwise stored within DA/NE vesicles through the vesicular monoamine transporter type 2 (VMAT-2) (Fig. 2). From these storage sites, MPP^+ is released into the cytoplasm where it may enter the mitochondrion (Ramsay and Singer 1986), which is believed to be the ultimate target to produce neurotoxicity (Fig. 2). Therefore, it is expected that reducing the entry of MPP^+ into

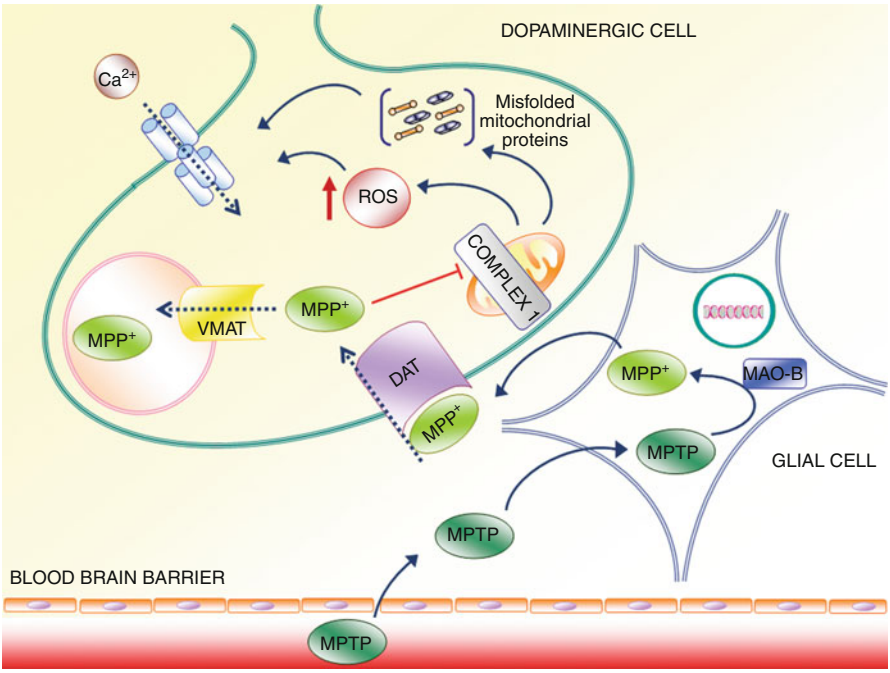

Fig. 2 Kinetics and dynamics of MPTP in the CNS. Once injected MPTP, which is a lipophilic compound, easily crosses the blood–brain barrier. This allows MPTP to enter within the CNS, where it is converted by monoamine oxidase (*MAO*)-B into MPP^+ which is actively secreted from glia in the extracellular space. MPP^+ is taken up quite selectively mostly by catecholamine neurons through the high-affinity DA transporter (DAT as shown in the cartoon) by also the NE transporter (*NET*, not shown). This allows MPP^+ to access DA axons where it can be stored either within synaptic vesicles through the vesicular monoamine transporter (*VMAT*) or within mitochondria. MPP^+ within mitochondria binds to complex I to inhibit NADH dehydrogenase. The production of reactive oxygen species (*ROS*) and other free radicals may be the consequence of mitochondrial impairment and the direct oxidative effects of MPP^+ on specific proteins and the oxidative effects of DA which is released by MPP^+ from synaptic vesicles on specific targets. Increased amount of oxidative species produced by all these mechanisms is expected to alter the folding of a variety of cell proteins. This leads to the accumulation of misfolded proteins which mostly consist of co-chaperones such as alpha-synuclein. The amount of oxidative stress is increased by the concomitant opening of calcium (Ca^{2+}) channels which may derive from the overactivation of glutamate receptors

the axons or increasing the storage into the vesicles should protect from MPTP toxicity (Staal and Sonsalla 2000). In fact, MPTP toxicity does not occur in DAT knockout (KO) mice (Gainetdinov et al. 1997), while MPTP toxicity is increased in VMAT-2 heterozygote KO mice (Gainetdinov et al. 1998). In line with this, mice with a 50 % depletion of VMAT show increased vulnerability to MPTP (Takahashi et al. 1997). Thus, synaptic vesicles represent storage sites which buffer MPP^+ and prevent its interaction with mitochondria and other cytosolic targets of toxicity (i.e., chaperone proteins). Intracellular compartmentalization of MPP^+ is critical to understand species differences in MPTP toxicity (Fig. 2).

3 MPP^+ and Mitochondria

Although the ultimate mechanisms of cell death induced by MPP^+ remain unclear, strong evidence indicates that MPP^+ inhibits mitochondrial function. MPP^+ enters into mitochondria to inhibit NADH dehydrogenase within mitochondrial respiratory chain (complex I, Fig. 2, Nicklas et al. 1985; Ramsay et al. 1986), thus binding to the same site as rotenone, which is a classic complex I inhibitor (Heikkila et al. 1985; Ramsay and Singer 1986; Krueger et al. 1990). This leads to morphological damage of mitochondria as shown in Fig. 3. As shown in Fig. 4, impairment of mitochondrial respiration by MPP^+ is believed to decrease the levels of oxidized nicotinamide adenine dinucleotide (NAD) (Sonsalla et al. 1992). In line with this, MPP^+ neurotoxicity is related to the failure of energy supplies in a number of in vitro and in vivo experimental settings (Di Monte et al. 1986; Denton and Howard 1987). For instance, within synaptosome preparations, MPP^+ dose-dependently decreases adenosine triphosphate (ATP) content (Scotchner et al. 1990). These effects produce a failure of electrogenic pumps such as $3Na^+$-$2K^+$ ATPases (Storey et al. 1992), which determines depolarization which leads to a sudden release of neurotransmitters. In fact, acute DA depletion caused by MPTP is preceded by a decrease in ATP levels in vivo within mouse striatum (Chan et al. 1993a). Consistently, the depletion of energy stores occurs more in those regions which take up selectively MPP^+ such as the nigrostriatal DA system (and other catecholamine-containing areas both in the CNS and periphery). This is

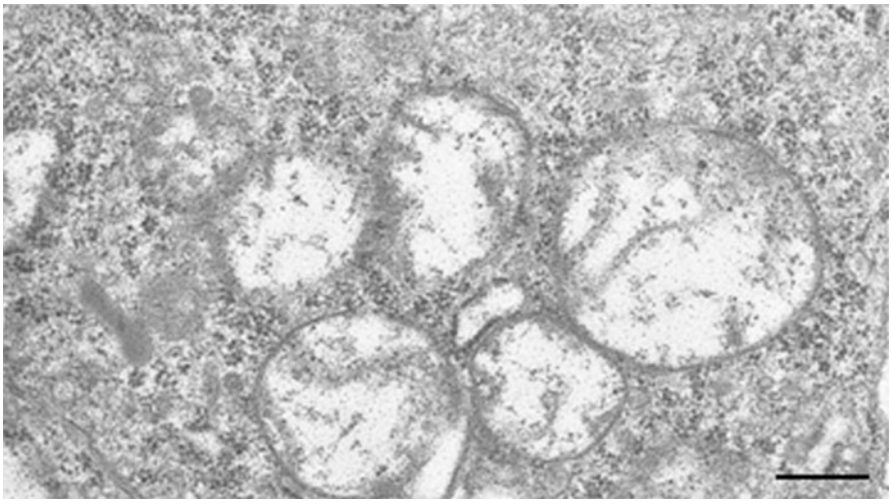

Fig. 3 Electron micrograph of mitochondria following MPTP exposure. MPTP exposure targets mitochondria which are functionally impaired but also deranged in their fine structure. This electron micrograph shows mitochondria within DA neurons from a C57 black mouse treated with MPTP (20 mg/Kg, X4, 2 h apart). Mitochondria lose their crests and undergo severe matrix dilution. Bar=0.24μm (Unpublished data, courtesy of Dr. P Lenzi, University of Pisa)

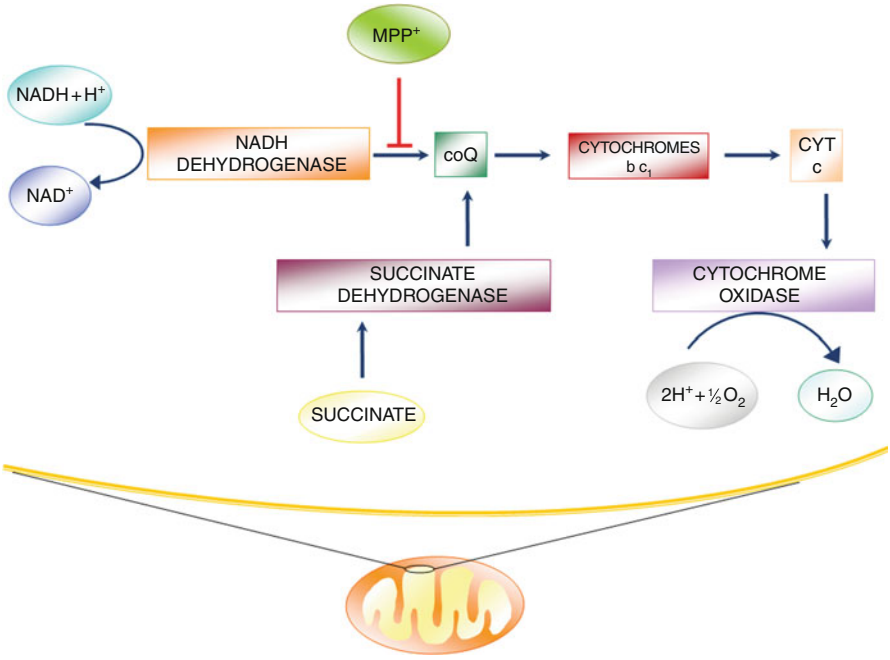

Fig. 4 The effects of MPP^+ on mitochondrial respiratory chain. The cartoon shows the molecular target of MPP^+ within the mitochondrial respiratory chain at the level of complex I. This corresponds mainly to the same site targeted by rotenone (see "▶ Rotenone as Preclinical Model Compound in Parkinson Disease" in this book) and it affects the enzyme NADH dehydrogenase. Thus, MPP^+ blocks NADH dehydrogenase, which produces a variety of downstream effects consisting of ATP loss, formation of ROS, and induction of apoptotic proteins

why, apart from DA toxicity, even the transient DA depletion, which occurs suddenly following MPTP administration, can be prevented by DA uptake inhibitors (Chan et al. 1991).

The identification of mitochondria as the primary target of MPTP-induced toxicity cops well with mitochondrial defects occurring in idiopathic parkinsonian patients as well as the mutations in mitochondrial proteins described in genetic forms of PD (Gu et al. 1998; Dodson & Guo 2007; Büeler 2009).

4 MPP^+ and Free Radicals

In physiological conditions free radicals, including reactive oxygen species (ROS), are constantly produced as the consequence of several chemical reactions in the cell including mitochondrial metabolism (Figs. 2 and 4). Routinely, this is balanced by antioxidants, free radical scavengers, and a variety of chaperones, which lead to either innocuous end-products or detrimental compounds. Antioxidants include

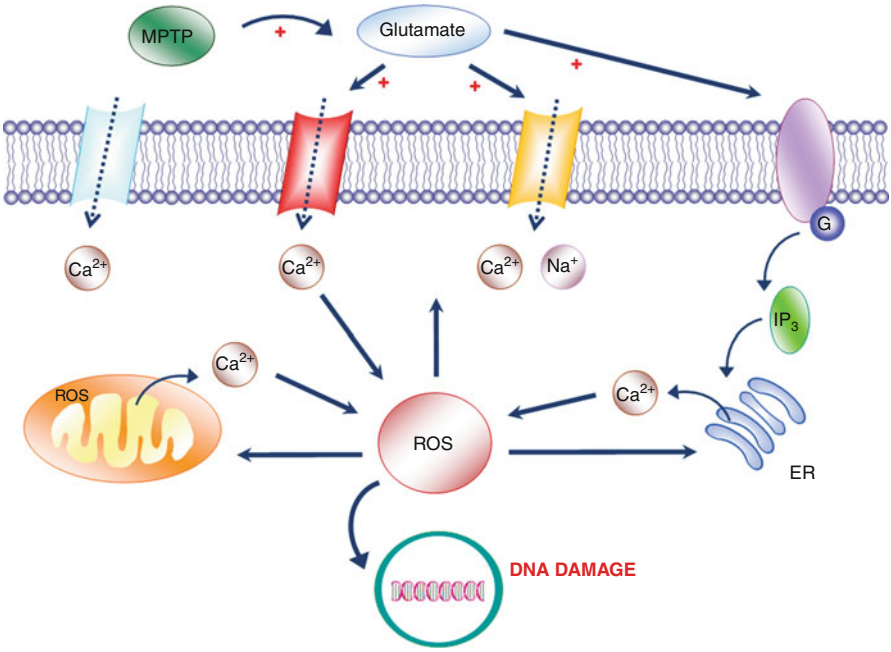

Fig. 5 Glutamate binds to ionotropic and metabotropic receptors. MPTP exposure increases the level of extracellular amino acid transmitters. In the case of this cartoon, glutamate overactivity stimulates both ionotropic (NMDA, kainate and AMPA) receptors and several subtypes of metabotropic receptors. This glutamate overactivity leads to the entry of a variety of ions. In particular, calcium entry, which is also modulated by metabotropic receptors acting on IP_3, is a strong candidate to contribute to free radical and ROS increase in DA neurons

superoxide dismutase (SOD), glutathione peroxidase, catalase, glutathione (GSH) and coenzyme Q10, essential nutrients (vitamin C, vitamin E, selenium, etc.), and dietary compounds (such as bioflavonoids). Oxidative stress results from an imbalance between formation and neutralization of pro-oxidants.

Mitochondrial impairment increases the production of free radicals (Fig. 2), and these effects may be enhanced by glutamate overactivity (Fig. 5; see also the Sect. 6, in this chapter), being one the consequence of the other. Impairment of mitochondrial function and decrease of cellular ATP may increase free radicals and mostly ROS (Cleeter et al. 1992).

Mitochondrial ROS react with several targets, including manganese SOD (Mn-SOD, SOD2), nitric oxide (NO), and susceptible iron–sulfide (Fe–S)-containing proteins. Mn-SOD is an antioxidant enzyme which protects against ROS produced by mitochondria. In fact, overexpression of Mn-SOD in transgenic mice protects against MPP^+ toxicity (Klivenyi et al. 1998; Maragos et al. 2000). On the other hand, heterozygous Mn-SOD KO mice show higher DA depletion and significantly larger striatal lesions after systemic MPTP treatment compared with controls (Andreassen et al. 2001). Again, overexpression of copper–zinc SOD

(Cu–Zn SOD, SOD1) in transgenic mice protects against MPTP neurotoxicity (Przedborski et al. 1992), and similar effects occur in mice overexpressing either human wild-type SOD1 or human mutant SOD1-G93A (Fornai et al. 2002). This may be due to the interaction of SOD1 with mitochondrial complex I activity thus competing with MPP^+ (Browne et al. 1998; Fornai et al. 2002).

It is puzzling that, apart from conferring protection against MPTP toxicity, the mutation in the gene coding for the human SOD1 leads to a spontaneous loss of nigral DA neurons (Andreassen et al. 2001).

5 MPTP, Protein Clearing Mechanisms, and Apoptosis

When acutely administered, MPTP does not affect much protein clearance, but directly targets the mitochondria. In contrast, when MPTP intoxication is continuously protracted for a few weeks, it impairs protein clearing mechanisms (Fornai et al. 2005). This is due mainly to the oxidation of specific proteins such as alpha-synuclein which works as co-chaperone (Fig. 6, Chandra et al. 2004, 2005). In fact following MPTP administration, there is an increased expression of alpha-synuclein in the cytoplasm (Fornai et al. 2005; Purisai et al. 2005) which may induce the formation of toxic alpha-synuclein oligomers (Stefanis et al. 2001; Tanaka et al. 2001; Bucciantini et al. 2002; Walsh et al. 2002; Giorgi et al. 2006), thus leading to neuronal toxicity (Fig. 6).

In this way, despite of its role as co-chaperone (Chandra et al. 2005), alpha-synuclein may become a detrimental compound for the survival of both DA and NE neurons once oxidized in excess during MPTP intoxication (Figs. 6 and 7, Conway et al. 2000; Fornai et al. 2005). In fact, chronic or continuous exposure to MPTP (Fornai et al. 2005; Meredith et al. 2008) is accompanied by pathological protein aggregates containing ubiquitin and alpha-synuclein since free radicals and ROS react with alpha-synuclein producing toxic oligomers which cannot be metabolized (Conway et al. 2000; Sulzer 2001) (Figs. 6, 7 and 8).

In order to counteract the formation of detrimental protein adducts, the proper activity of protein clearing pathways is critical. This explains why, in recent years, a variety of research studies both on MPTP toxicity and PD focussed on protein clearing systems. The ubiquitin–proteasome (UP) system (Fig. 7) and autophagy (ATG, Fig. 8) are the major systems that degrade intracellular components in eukaryotic cells. The UP system (Fig. 7) mainly serves to degrade short-lived misfolded proteins (Ciechanover 2006). These proteins are targeted by polyubiquitin conjugation, which addresses them to proteolytic degradation within the proteasome core. The ATG pathway is involved in the degradation of long-lived proteins, protein aggregates, and organelles, such as mitochondria, which are delivered to lysosomes for digestion (Fig. 8, Mariño and López-Otín 2004). ATG was found to be increased within the substantia nigra of PD patients by Anglade and collaborators (1997). These authors found the coexistence of ATG vacuoles and apoptosis within melanized neurons of the human substantia nigra. The neurons undergoing an excess of ATG possess condensation of chromatin, moderate vacuolation of endoplasmic

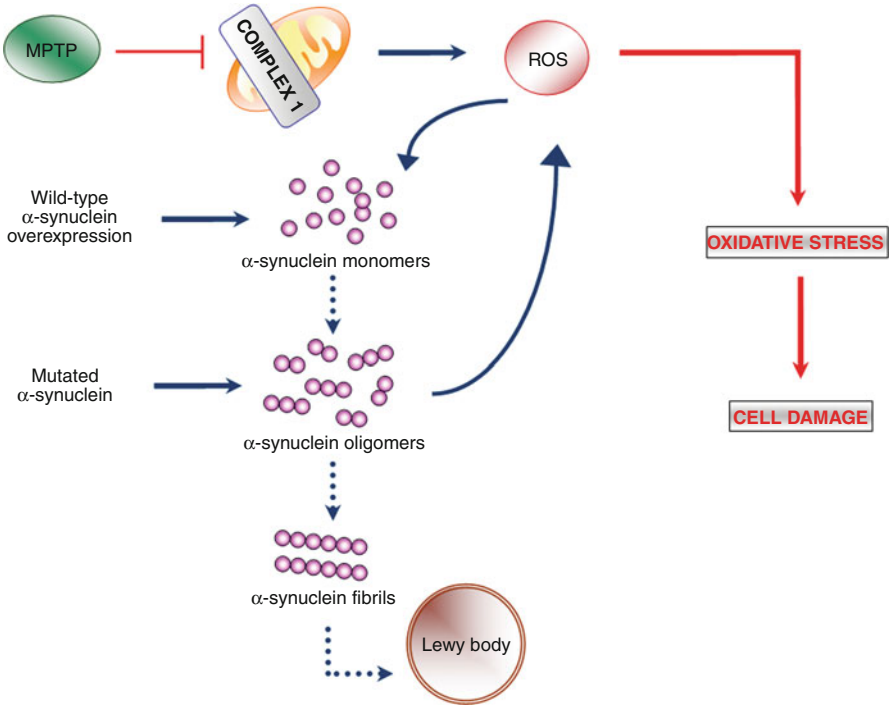

Fig. 6 MPTP recapitulates protein misfolding which may primarily occur in genetic PD. MPTP administration, mainly via inhibition of mitochondria, or directly, or via DA release, produces high amount of oxidative species which can interact with co-chaperones such as alpha-synuclein to stabilize this protein in oligomeric forms. These oligomers are also produced as a consequence of genetic mutations in alpha-synuclein gene as occurs in a few cases of inherited PD. In all cases alpha-synuclein adducts are toxic for the cells and can either precipitate to form Lewy bodies or spread to specific cell compartments to impair key biochemical pathways thus contributing to DA toxicity

reticulum, and lysosome-like vacuoles containing cytoplasmic material. The existence of dual neuronal death suggests the occurrence of both ATG and apoptosis at different time intervals during degeneration of DAergic cells, with apoptosis being the final stage. This is in line with the recent evidence showing that in DAergic cells dysfunctional ATG triggers apoptosis (Fig. 9, Castino et al. 2008).

A defective protein clearance is supposed to lead to protein accumulation even when misfolded proteins are not produced in great amount. This is in line with the fact that MPTP intoxication, just like PD, produces both ATG alterations and apoptosis (Fig. 9). This is witnessed by the accumulation of altered mitochondria (Fig. 3) and large ATG vacuoles which follows MPTP intoxication. This explains why rapamycin, by activating ATG and promoting lysosomal activity (Fig. 10), attenuates MPTP-induced DA neurodegeneration, thus promoting neuroprotection (Dehay et al. 2010). In addition, in MPTP-treated mice rapamycin has been reported to block the induction of RTP801 gene that promotes neuronal death,

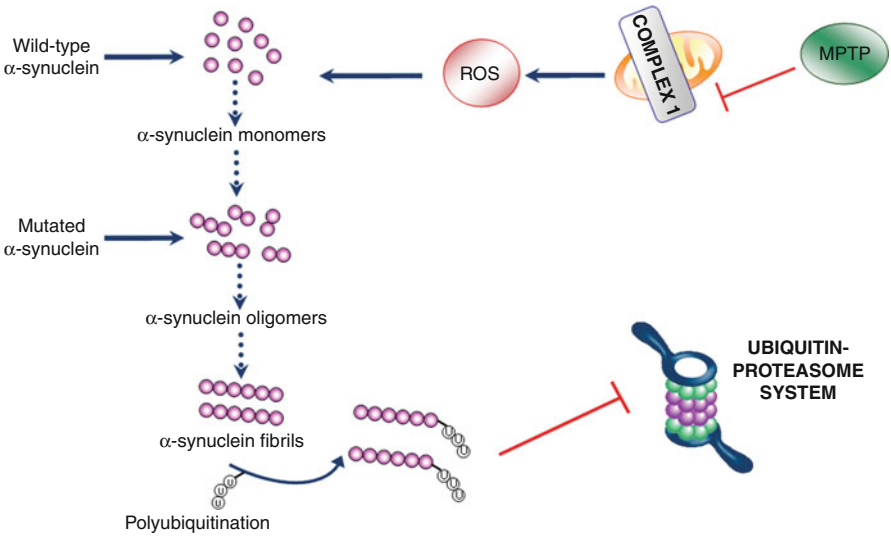

Fig. 7 During MPTP intoxication alpha-synuclein inhibits the proteasome. Among a variety of molecular targets (see Fig. 6 legend), alpha-synuclein can interact with physiological mechanisms which clear short-lived misfolded proteins named ubiquitin–proteasome (*UP*) system. When alpha-synuclein toxic oligomers (which represent a misfolded form of alpha-synuclein) are produced in excess, this saturates the UP system and leads to UP inhibition

which is highly expressed in DA neurons of the substantia nigra both in MPTP-treated mice and PD patients (Malagelada et al. 2006).

Remarkably, Liu et al. (2013) found that rapamycin rescues the number of DA neurons and reduces the increase of alpha-synuclein immunoreactivity induced by MPTP. These studies demonstrate that rapamycin via activation of ATG/lysosome pathways both prevents and reverts MPTP toxicity.

Thus, most evidence indicates that MPTP-induced neuronal death is the consequence of energy failure and oxidative stress that occur early on after MPTP administration. In turn, these phenomena are pivotal in triggering molecular pathways which, once activated, rapidly lead to the death of intoxicated neurons (Przedborski and Vila 2003). In fact, the removal of damaged mitochondria and misfolded proteins occurring following MPTP administration is critical in modulating MPTP toxicity. In fact, the occurrence of misfolded proteins in neuronal bodies following prolonged MPTP administration is accompanied by the impairment of the UP as a protein clearing system (Fig. 7, Fornai et al. 2005). Similarly, defective clearance of damaged mitochondria and long-lived proteins cleared by ATG is the hallmark of cell pathology in PD and following MPTP as well (Fig. 8). The abundance of altered mitochondria and toxic protein species is pivotal in triggering apoptotic cell death (Fig. 9). This is in line with the concomitant occurrence of altered ATG and apoptosis both in PD patients (Anglade et al. 1997) and following MPTP intoxication (Novikova et al. 2006). Thus, MPTP can induce apoptosis by different mechanisms. In fact oxidative stress and impairment

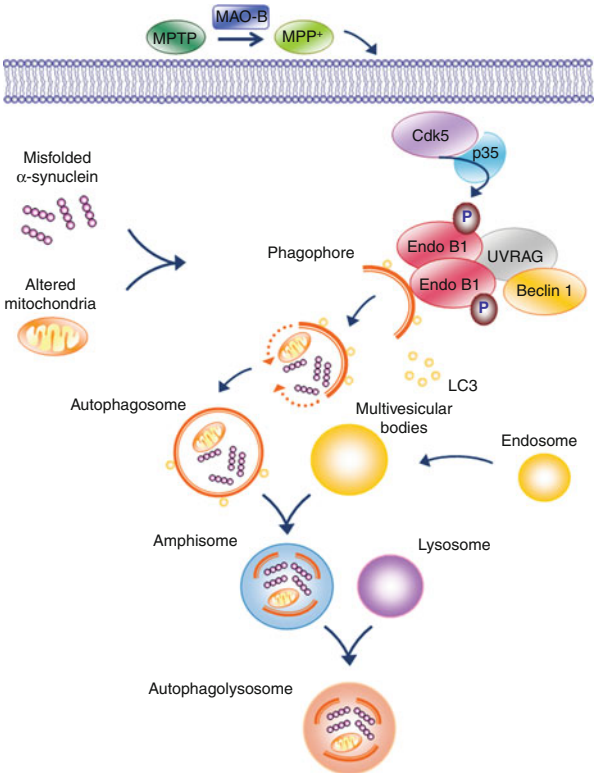

Fig. 8 During MPTP intoxication alpha-synuclein inhibits the autophagy. Among a variety of molecular targets (see Fig. 6 legend) alpha-synuclein can interact with physiological mechanisms which clear long-lived misfolded proteins and organelles named autophagy (*ATG*) system. When alpha-synuclein toxic oligomers (which represent a misfolded form of alpha-synuclein) are produced in excess, this saturates the ATG system and leads to ATG inhibition. On the other hand, during MPTP intoxication the variety of ROS produced and the toxicological effects of MPTP increase ATG activity via the Cdk5 pathway. This compensatory increase in ATG may be overcome by the overproduction of alpha-synuclein

of mitochondrial respiration, following MPTP treatment, can initiate apoptosis (Hartley et al. 1994), and MPTP also induces mitochondrial permeability transition (MPT), which determines mitochondrial swelling and cytochrome c release, with subsequent caspase-dependent apoptosis (Cassarino et al. 1999; Lee et al. 2006). MPTP-induced apoptosis involves different molecules and pathways, including DNA strand breaks, the c-Jun N-terminal kinase (JNK) pathway, caspases, Par-4 protein, p53, Apaf-1, and Bax (Eberhardt and Schulz 2003) (Fig. 9).

6 MPTP and Glutamate

Other sources of free radicals during MPP^+ toxicity besides mitochondria are glutamate and DA itself. Robust experimental evidence indicates that glutamate and other excitatory amino acids (EAA) play a role in MPTP toxicity since chronic MPTP increases extracellular glutamate in the substantia nigra (Meredith et al. 2009) and MPP^+ increases extracellular levels of glutamate in the striatum (Carboni et al. 1990).

The acidic amino acids glutamate, aspartate, and their analogues bind to three main types of ionotropic and also to metabotropic receptors (Fig. 5). These amino acids are well known to be responsible for "excitotoxicity" (Olney et al. 1980),

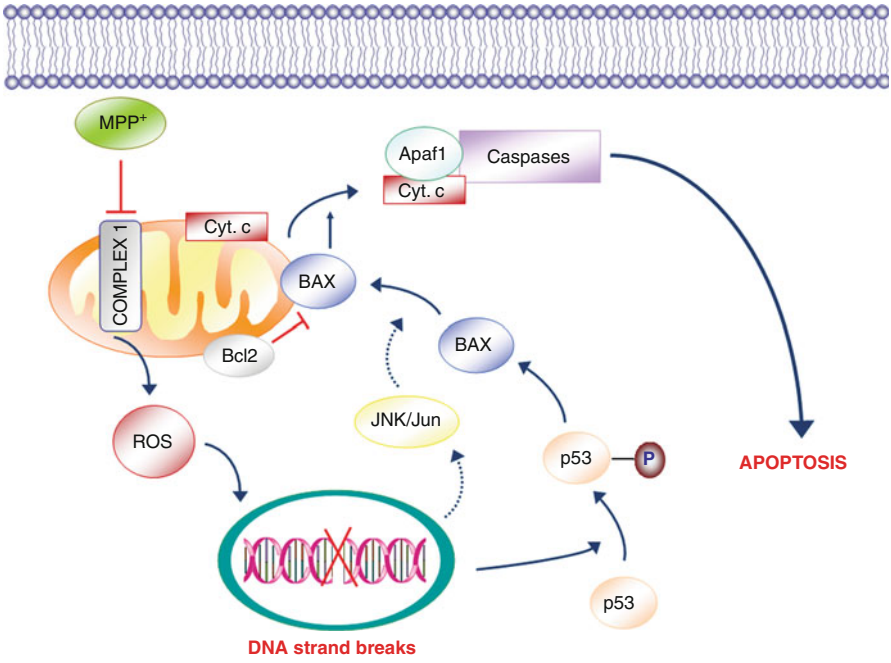

Fig. 9 The effects of MPP^+ on mitochondria trigger apoptotic proteins. The cartoon shows the molecular target of MPP^+ within the mitochondrial respiratory chain at the level of complex I. This inhibition leads to production of a variety of downstream effects consisting of ROS formation and induction of apoptotic proteins such as BAX and Bcl-2

which indicates how endogenous glutamate overactivity becomes frankly toxicant. These conditions include excessive and/or prolonged release of glutamate into the synaptic cleft. In these cases, neuronal loss progresses downstream along synaptically joined neurons, both after repeated acute insults and in neurodegenerative diseases in which the "systemic degeneration" consists of spreading cell loss to neurons interconnected within functional circuits. This might be the case of glutamatergic pathways from the neocortex to the SNpc and striatum (Cotman et al. 1987). In keeping with these concepts, the study of toxicity progression along the circuitries enrolled during acute insults (MPTP) provided the pathophysiological basis to depict the regional impairment occurring also in neurodegenerative diseases (PD). In fact the nigrostriatal pathway receives synaptic terminals from glutamatergic neurons and possesses EAA receptors. Furthermore interrupting the excitatory circuit by lesioning upstream neurons or trans-sectioning the glutamatergic input to the nigrostriatal pathway attenuates the toxic insult. This is in line with the fact that a noncompetitive *N*-methyl-D-aspartate (NMDA) antagonist MK-801 (Chan et al. 1993b) protects against MPTP toxicity in rodents (Turski et al. 1991; Storey et al. 1992) and primates (Zuddas et al. 1992). An

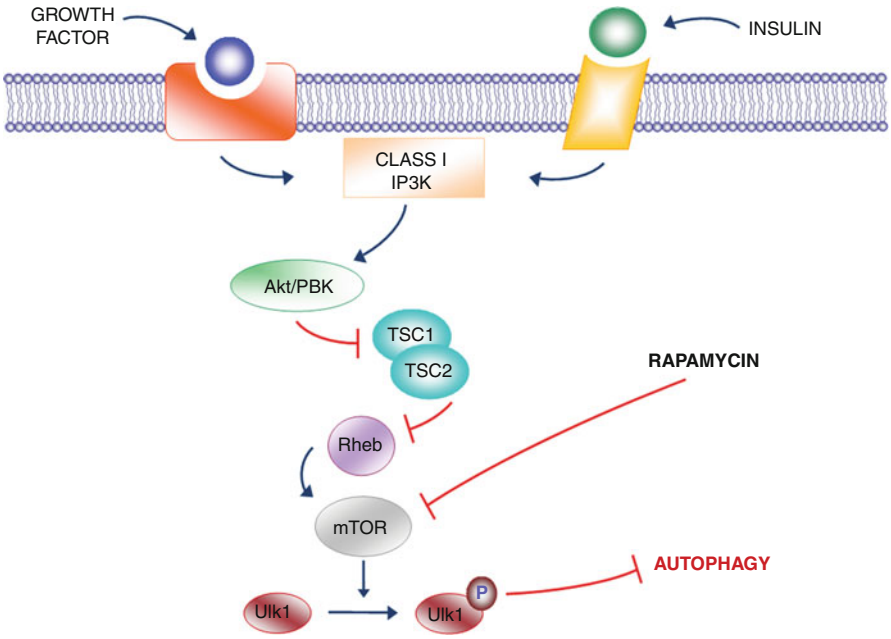

Fig. 10 Effects of rapamycin on autophagy. The ATG pathway can be modulated by a number of compounds among which growth factors and insulin are shown in the cartoon. Independently by the way of inducing ATG, rapamycin is a strong ATG inducer which promotes ATG downstream in the regulatory chain at the level of mTOR which is a strong ATG inhibitor. Rapamycin, by inhibiting mTOR, powerfully activates ATG

analogous protection was obtained by damaging glutamatergic corticostriatal fibers (Storey et al. 1992) suggesting that endogenous excitotoxicity contributes to MPTP toxicity (Brouillet and Beal 1993; Lange et al. 1993; Srivastava et al. 1993; Lange and Riederer 1994; Loschmann et al. 1994; Ossowska 1994; Vaglini et al. 1994; Kanthasamy et al. 1997; Sonsalla et al. 1998; Araki et al. 2001).

Species differences play a major role in the effects of glutamate in MPTP toxicity (Fornai et al. 1997b) leaving under debate the relevance of this point for PD patients.

As mentioned above, some authors have shown an involvement of EAA in the toxicity of MPP^+ injected directly into the substantia nigra (Turski et al. 1991) or the striatum (Storey et al. 1992) which was counteracted by the simultaneous administration of a competitive or noncompetitive NMDA receptor antagonist to the substantia nigra. Other authors could not confirm these results (Sonsalla et al. 1992) nor did they observe any involvement of EAA after systemic injection of MPTP in mice (Sonsalla et al. 1989, 1992; Kupsch et al. 1992). The way of administering MPTP also appears to be crucial. This concept is in line with the results of Storey et al. (1992), who showed that MPP^+ administered within the rat striatum produces long-lasting effects on neuronal energy metabolism, thus causing a three- to fourfold decrease in ATP levels, which persists for over 48 h.

Although rodent data are contradictory, studies performed on MPTP-treated primates, both old- and new-world monkeys: (Zuddas et al. 1992; Lange et al. 1993), respectively, demonstrated a clear protective role of NMDA and non-NMDA ionotropic receptor antagonists (both competitive and noncompetitive) in MPTP-induced parkinsonism (Crossman et al. 1989; Close et al. 1990).

The role of glutamate is not limited to its effects on ionotropic receptors and involves the role of metabotropic receptors which might be a therapeutic target with less side effects. In detail it was demonstrated that mGlu5 receptor agonists exacerbate, while antagonists may counteract MPTP-induced nigrostriatal damage (Battaglia et al. 2004). Nowadays it seems likely that glutamate per se is not the mediator of MPTP toxicity. The neurotoxic mechanisms rather rely on other pathways, and this brings the role of glutamate in the sideshow along the mainstream leading to MPTP toxicity.

7 MPTP and Dopamine

As reported, MPP^+ provokes a sudden, quite generalized neurotransmitter release. This phenomenon is more intense for catecholamine-containing neurons including DA cells. At this level, MPP^+ induces massive DA release from storage vesicles into the cytosol, where DA itself produces free radicals via auto-oxidation or MAO-mediated oxidative deamination, resulting in the formation of hydrogen peroxide, superoxide, and reactive quinone species (Lotharius and O'Malley 2000). The latter are known as DA quinones which also derive by activating cyclooxygenase (COX)-2 (Teismann et al. 2003). This may explain the neuroprotective effects of COX-2 inhibitors against MPTP toxicity. In addition, the activity of tyrosine hydroxylase (TH) may produce ROS as a normal by-product.

To emphasize the detrimental effects induced by DA within DA neurons in experimental parkinsonism induced by MPTP, it is useful to mention the toxic mechanisms induced by methamphetamine (METH), a neurotoxic agent which releases DA even more powerfully than MPTP (refer to specific chapters on ▶ Methamphetamine and MDMA Neurotoxicity: Biochemical and Molecular Mechanisms, this volume). Administration of METH produces experimental parkinsonism by inducing the loss of nigrostriatal DA axons (Ricaurte et al. 1982; Woolverton et al. 1989; Ricaurte and McCann 1992; McCann et al. 1998; Villemagne et al. 1998; Volkow et al. 2001a, b; Battaglia et al. 2002) and DA perikarya (Sonsalla et al. 1996; Castino et al. 2008; Granado et al. 2011). As for MPTP, METH abuse was recently shown to facilitate PD (Callaghan et al. 2010, 2012). As MPTP, METH is transported into DA terminals where it interacts with DAT and VMAT-2. In this way, METH causes massive DA release (O'Dell et al. 1991; Cubells et al. 1994). This reference to METH is key in the context of understanding the toxic potential of DA-releasing neurotoxicants. In fact, a high DA release occurs also during MPTP intoxication. High DA levels promote DA oxidation which is toxic to a variety of key proteins and organelles within DA neurons (Castino et al. 2008). The role of DA toxicity can lead to an understanding of some critical questions about MPTP such as species differences. In fact, rats are

resistant to MPTP toxicity, while mice are more sensitive. When looking at the kinetics and dynamics of MPTP in mice and rats, no difference between mice and rats appears but a remarkable discrepancy in MPTP-induced DA release. Mice, which are sensitive to MPTP toxicity, undergo massive MPTP-induced DA release, while rats which are almost resistant to MPTP toxicity undergo a minimal DA release following MPTP administration. This concept is extensively reviewed in the paragraph titled "Species Differences to MPTP Toxicity" but is useful to be mentioned here to understand the role of DA in MPTP toxicity. It is quite intriguing that DA as a neurotransmitter possesses such a great potential to produce neurotoxicity. This was already demonstrated by pioneer studies injecting DA directly in the striatum and reviewing the potential toxicity which follows DA release. The ability of DA to act as a neurotoxicant relates to the chemical reactivity reviewed so far. In contrast, NE does not produce toxicity but it is rather neuroprotectant against MPTP toxicity (Mavridis et al. 1991; Marien et al. 1993; Fornai et al. 1995, 1996; 1997a).

8 MPTP Toxicity and Norepinephrine

Damage to the NE nucleus LC is known to worsen the onset and progression of experimental parkinsonism induced by MPTP both in rodents and monkeys (Mavridis et al. 1991; Marien et al. 1993; Bing et al. 1994; Fornai et al. 1995; Gesi et al. 2000). Damage to NE axon terminals, induced by the selective NE neurotoxin *N*-(−2-chloroethyl)-*N*-ethyl-2-bromobenzylamine (DSP-4) (Fornai et al. 1996) before MPTP administration, increases the sudden MPTP-induced DA release and enhances MPTP toxicity (Fornai et al. 1997a). The role of NE in MPTP toxicity directly applies to human PD patients where analogous effects were described (Rye and DeLong 2003).

In fact, the loss of NE is thought to facilitate the onset and progression of PD (Tong et al. 2006; Rye and DeLong 2003). Actually, the loss of LC neurons also represents a hallmark of PD since extensive neuropathological analysis demonstrated that LC neurons are lost even more than SNpc cells in PD (Zarow et al. 2003). The loss of LC neurons in PD represents a pioneer finding dating back at the beginning of the last century (Tretiakoff 1919). It remained a smoldering concept up to experimental studies using MPTP and showing a causal link between LC damage and the loss of DA-containing neurons. Mavridis et al. (1991) developed a primate model demonstrating that previous damage to LC NE-containing neurons may impair the recovery of nigrostriatal DA pathway following MPTP intoxication. Further studies demonstrated that a loss of NE innervation causes an increased susceptibility of DA neurons to MPTP (Fornai et al. 1997a). It is worth to be mentioned that such a reduced threshold within DA neurons to MPTP neurotoxicity is not due to a prolonged persistence of MPP^+ within the CNS. In fact, since MPP^+ is taken up within NE neurons at a rate which is faster compared with DA neurons (Herkenham et al. 1991), it is expected that a damage to NE cells would have produced a loss of what may be considered a sort of buffering activity. Paradoxically, LC-damaged brains retain MPP^+ for a longer time compared with LC-intact

brain. This indicates that variations in toxin kinetics are not causing enhancement of MPTP toxicity in NE-damaged brains (Fornai et al. 1997a). It is rather the occurrence of NE or the absence of such a neurotransmitter which occludes or sensitizes, respectively, MPTP-induced DA toxicity. Enhancement of MPTP toxicity occurs also by preventing NE synthesis using a DA beta-hydroxylase inhibitor such as fusaric acid or disulfiram (Corsini et al. 1985; Weinshenker et al. 2008). Thus, the protective effects of NE-containing neurons on MPTP toxicity are demonstrated throughout a variety of experimental approaches and animal species (Fornai et al. 2007a). These findings pose the need for well-preserved LC neurons in order to prevent the occurrence of PD. In fact, in human patients Tong et al. (2006) demonstrated a tight correlation between early loss of NE- and the later damage to DA-containing neurons within specific brain areas of PD patients. These authors suggested that a loss of NE innervations anticipates subsequent damage to DA-containing cells. On the other hand, if PD is characterized by the concomitant loss of LC NE- and SNpc DA-containing neurons, a neurotoxin which is able to mimic PD is also expected to reproduce such a combined neurotoxicity. This poses the following question: Is there a neurotoxic effect of MPTP for NE neurons? The study of Seniuk et al. (1990) indicates that small reiterated doses of MPTP were effective in damaging NE more than DA neurons (Seniuk et al. 1990). Pathobiochemical (Hornykiewicz 1975, 1998; Tong et al. 2006) and pathological findings (Braak et al. 2000; Zarow et al. 2003) clearly established the concomitant NE and DA damage in PD. A number of studies on MPTP toxicity up to the recent findings in mice (Meredith et al. 2002; Fornai et al. 2005) and nonhuman primates by Masilamoni et al. (2011) confirm that prolonged exposure to MPTP does produce a concomitant damage to DA and NE neurons as demonstrated in PD.

These findings introduce the issue of whether we should consider prolonged MPTP exposure more reliable than acute administration to produce toxic effects which mimic PD. This point extends to the evaluation of various protocols of MPTP administration which were developed during the last decades.

9 Acute, Chronic, and Continuous MPTP Administration

In mice a wide range of MPTP administrations were experimented. These vary with respect to the total amount of MPTP administered, the route (intraperitoneally versus subcutaneously), and time between injections, including the acute (usually four doses within 6 h), the subacute (usually 5 days), and the chronic administration (weeks), the latter often accompanied by an adjuvant drug, probenecid (Petroske et al. 2001; Kurosaki et al. 2004; Lau et al. 2005; Anderson et al. 2006). Very recently (Prediger et al. 2011) mice have been treated with intranasal MPTP, showing impairments in olfactory, cognitive, emotional, and motor functions, similarly to those observed in PD. This was accompanied by TH loss in the olfactory bulb and SNpc, with significant DA depletion in different brain areas (Prediger et al. 2011).

The different MPTP administrations result in different amount of DA depletion, motor deficits, and time course of recovery (Sonsalla and Heikkila 1986;

Jackson-Lewis et al. 1995; Bezard et al. 1997a, b; Kühn et al. 2003). When injected into mice, MPTP causes a PD-like syndrome with massive loss of nigral DAergic neurons and striatal DA. Acute administration of MPTP leads to striatal loss that can range from 40 % (when MPTP is given at 14 mg/kg per dose four times a day) to approximately 90 % (20 mg/kg per dose four times, 2 h apart in a single day) 7 days after the last MPTP dose and at least 40–50 % loss of nigrostriatal DAergic neurons in young adult C57BL/6 mice by 7 days after MPTP administration (Jackson-Lewis and Przedborski 2007). A subchronic regimen consisting of administration of systemic MPTP 30 mg/kg per day for 5 consecutive days in Swiss mice leads to morphologic features resembling apoptotic cell death occurring on day 6 after the last MPTP administration, with tissue DA depletion of 59 % 1 day after MPTP last administration (Tatton and Kish 1997) and a progressive recovery of DA depletion (about 28 %) from day 3 to day 14 after MPTP discontinuation (Serra et al. 2002). During the acute MPTP administration, necrotic rather than apoptotic features of the neurons of the SNpc were observed (Jackson-Lewis and Przedborski 2007); this suggests that the schedule of MPTP administration does not only influence the time course of nigrostriatal damage but may also provide insights into the underlying mechanisms of PD pathogenesis, such as the induction and manifestation of neuronal death (necrotic or apoptotic), which appears to be correlated to different stages of the human PD (presymptomatic, immediate onset, progressive, and final stage).

Shall we expect that, in order to better reproduce PD, MPTP needs to be administered once in high doses or rather being reiterated in small amount during long time intervals or even administered continuously?

In this context when considering the effects of acute MPTP administration to a variety of animal species, it is evident that despite being able to reproduce a massive neuronal loss in the SNpc, such an experimental protocol leaves NE neurons intact and does not produce the occurrence of neuronal inclusions neither in mice nor in primates. In fact, although intraneural inclusions containing eosinophilic materials and alpha-synuclein aggregates have been described in MPTP-treated monkeys (Forno et al. 1986; Kowall et al. 2000), the classic Lewy bodies, a typical feature of PD, have not been convincingly observed (Forno et al. 1993). The intraneural inclusions containing eosinophilic material and alpha-synuclein that are reminiscent of Lewy bodies have not been observed in young monkeys (Forno et al. 1995). In fact, following acute administrations the time course of MPTP-induced neurotoxicity is rapid, and therefore it does not activate long-acting neuronal mechanisms which are required to build neuronal bodies. In fact, it is likely that neuronal inclusions represent a compromise between long-acting slight neurotoxic mechanisms and the recruitment of compensatory mechanisms. This is what is thought to happen during PD which possesses a chronic progressive disease course.

On the other hand, when MPTP is administered chronically or continuously in mice apart from NE damage, also neuronal bodies can be described (Meredith et al. 2008; Fornai et al. 2005; Gibrat et al. 2009; Beal 2011). Sometimes chronic models based on repetitive small doses remain subthreshold to induce toxicity as reported in one study (Alvarez-Fischer et al. 2008), while most studies found that chronic

(Meredith et al. 2008) or continuous (Fornai et al. 2005; Cleren et al. 2008; Gibrat et al. 2009; Yasuda et al. 2011) MPTP administration protracted for a few weeks does produce alpha-synuclein-positive neuronal bodies in addition to massive striatal DA depletion and SNpc neuronal loss. The amount of MPTP and the time needed to produce inclusions may vary between different studies; this is likely to depend on experimental variability such as purchaser and housing which are well known to modulate the threshold for MPTP toxicity (Heikkila et al. 1984b; see also the Sect. 14).

Prolonged neurotoxin administration is effective also for the active metabolite MPP^+ when this is delivered continuously across the blood–brain barrier both in rodents and primates (Imai et al. 1988; Sirinathsinghji et al. 1988). In the rat, continuous *i.c.v* MPP^+ administration produces striatal DA loss and SNpc cell death as well as neuronal bodies staining for ubiquitin and alpha-synuclein (Yazdani et al. 2006).

10 Spinal Cord and MPTP

The classic pathological features of sporadic PD include the degeneration of DA neurons in the SNpc and NE neurons in the LC. Besides these areas, also the spinal cord (SC) seems to be affected in PD in the presymptomatic stage. This was already demonstrated by significant motor neuron loss in various PD models (Bloch et al. 2006; Klos et al. 2006; Samantaray et al. 2008a), including the A53T mutant mice that express the mutant alpha-synuclein gene of familial PD (Martin et al. 2006). Following MPTP administration in the SC, specific apoptotic proteins are highly expressed (Chera et al. 2002, 2004; Samantaray et al. 2006, 2007). In a very recent paper, it was found that in MPTP-treated mice there is a significant motor neuron loss in the lumbar and cervical SC (Vivacqua et al. 2012). Samantaray and colleagues (2008b) showed that MAO-B are expressed in the SC and DAT is expressed in motor neurons thus suggesting that MPTP can be converted to MPP^+ which in turn might be taken up by motor neurons to induce cell death.

11 MPTP, the Heart, and the Gut

While MPTP toxicity in the CNS is extensively investigated, peripheral autonomic dysfunction following MPTP intoxication received much less attention. Only recent studies demonstrated a parallelism between PD and MPTP in producing cardiac denervation due to a loss of NE axons in the heart (the so-called Parkinsonian heart; Fukumitsu et al. 2006; Fornai et al. 2007b). Similarly, MPTP intoxication was recently reported to reproduce the decrease in plasma testosterone levels observed in PD, and this was related with alteration produced by MPTP in Leydig cells (Ruffoli et al. 2008). Gastrointestinal (GI) dysfunction is a well-recognized feature of PD (Natale et al. 2008) and the entire GI tract may be affected (Edwards et al. 1991; Jost 1997; Pfeiffer 2003). A few studies suggest that GI symptoms in PD may be caused by a neurodegenerative process in the enteric

nervous system (ENS), similar to what occurs in the CNS (Singaram et al. 1995; Wakabayashi et al. 1988), and it is hypothesized that degeneration in the ENS mirrors and precedes analogous pathological events in the brain or SC (Braak et al. 2003, 2006, 2007; Natale et al. 2011).

Only a few experimental studies using MPTP addressed whether such intoxication involves the gut. In rats exposed to MPTP, Szabo et al. (1985) described inhibition of duodenal spike activity. Decreased DA levels were found in the jejunal myenteric plexus, although this occurred only for high doses (Szabo et al. 1985; Eaker et al. 1987).

The effects of MPTP in the mouse colon have been evaluated in vivo, following a total dose of 60 mg/kg of MPTP. This produced a 40 % reduction of TH-positive neurons (Anderson et al. 2007). Whether the loss of TH-positive neurons following MPTP administration was due to DA or NA or both was recently demonstrated by Natale and collaborators (2010). This appears to be due to the selective loss of enteric DAergic neurons, as confirmed by the selective damage to DAT-containing cells and the specific loss of DA in the homogenates from the gut. In the same studies, it was found that MPTP increases alpha-synuclein thus reproducing alterations occurring in the digestive system of PD patients.

12 Species Differences in MPTP Toxicity

A variety of animal species are sensitive to MPTP toxicity including monkeys, rodents, cats, pigs, dogs, sheep, rats, and goldfishes (Kopin and Markey 1988; Gerlach and Riederer 1996; Przedborski et al. 2001); however, different effects are produced by MPTP in different species ranging from massive (primates) to minimal (rats) toxicity.

In monkeys, MPTP administration reproduces most of the clinical and pathological hallmarks of PD (Langston et al. 1984a; Chiueh et al. 1984; Doudet et al. 1985; Crossman et al. 1985; Nomoto et al. 1985; Vezoli et al. 2011) but not in rats, which were found to be resistant to MPTP (Chiueh et al. 1984). In detail, rats can be damaged by MPTP only in the periphery, being necessary to administer MPP^+ at very high doses intracerebroventricularly to produce a damage within CNS to DA neurons (Yazdani et al. 2006). Mice are sensitive to MPTP but require higher amount than primates. In detail, in mice MPTP needs to be administered acutely at doses ranging from 15 to 80 mg/Kg to produce a progressively massive loss of nigral DA neurons, while in monkeys the same effects are induced at doses at least 100-fold lower. Such a discrepancy is not related with species differences in the bioavailability of MPP^+ within the striatum following systemic MPTP (Zuddas et al. 1994; Vaglini et al. 1996); it is likely that species differences in the toxic effects of comparable amounts of nigrostriatal MPP^+ may relate to species differences in the pharmacodynamics of MPTP. In fact, it is well known that comparable amounts of MPP^+ are formed within the striatum of mice and rats following similar doses of systemic MPTP (Zuddas et al. 1994; Vaglini et al. 1996). This rules out the chance that MAO-B works differently in these species to convert MPTP into MPP^+. However, if one

considers that MPP^+ is selectively taken up by DA terminals, this process could differ significantly. In a careful series of experiments, Giovanni et al. (1994a, b) found no species difference in the uptake of MPP^+, ruling out also the difference in DAT efficacy. On the other hand, MPP^+ apart from damaging the mitochondrial respiratory chain is also able to produce a robust DA release (see Sect. 7). It was shown that equimolar amount of MPP^+ produces a pronounced DA release in mice versus a modest effect in rats (Giovanni et al. 1994a, b). This point which remained not further investigated sheds a new light on the potential role of intracellular DA joined with the impairment of mitochondrial respiratory chain in sustaining MPTP neurotoxicity. It would be interesting to test the effects of MPP^+ on striatal DA release in primates.

These latter experiments to our knowledge were never carried out. Nonetheless, it is worth to mention that MPTP toxicity is positively related to the amount of DAT (Watanabe et al. 2005) while is negatively related to the amount of VMAT-2 (Chen et al. 2005). In this scenario, we already reported that MPP^+ is sequestered into synaptic vesicles by VMAT-2, and this mechanism appears to protect rat DA neurons from MPP^+ toxicity (Staal and Sonsalla 2000). In fact, in primates MPTP sensitivity is bound to the lower expression of VMAT-2 compared with other species (Chen et al. 2008). Again, if one looks at the site specificity of DA neuron loss in the substantia nigra following MPTP, there is a negative correlation with the expression of VMAT-2 and MPTP-damaged cells. Conversely, the amount of DAT is higher in those subsets of neurons of the substantia nigra which are more vulnerable to MPTP (Haber et al. 1995).

Among the different animal species, mice are commonly used in MPTP experiments. This is due to easy handling, less ethical restrictions, and lower costs compared with monkeys. Nonetheless, mice are significantly less sensitive to MPTP than primates and do not convincingly develop persistent and progressive motor symptoms unless they are treated following sophisticated protocols (Sundström et al. 1990; Przedborski et al. 2001; Fornai et al. 2005).

13 MPTP in Nonhuman Primates

MPTP administration to monkeys is considered the best model to reproduce PD due to similarities in neuropathology and behavior. This model was routinely applied in preclinical studies aimed to test pharmacological and surgical treatments of PD. The first MPTP administration in common marmosets was described by Jenner and colleagues (1984), who observed profound akinesia, rigidity of the trunk and limbs, postural abnormalities, loss of vocalization, and, occasionally, whole body tremor (Jenner et al. 1984). MPTP can be administered to monkey using different routes, such as gavage or stereotactical injection. One of the most common consists in the parenteral administration (subcutaneous, intravenous, intra-arterial, intraperitoneal, or intramuscular; Przedborski et al. 2001). Among systemic routes, MPTP is administered through multiple i.p. and and i.m. injections which induce a progressive generalized parkinsonism or through unilateral intracarotid infusion

that determines hemiparkinsonism in the injected side. This is critical since bilateral parkinsonism requires L-DOPA to keep the animal alive (Petzinger and Langston 1998). In contrast, unilateral intracarotideal infusions, which determine a chronic model of hemiparkinsonism, enable the monkeys to feed without supporting therapeutics (Bankiewicz et al. 1986; Przedborski et al. 1991).

MPTP can be delivered acutely or chronically, the former being particularly useful in the assessment of treatments aimed at understanding the mechanisms and reducing the amount of L-DOPA-induced dyskinesias (Boraud et al. 2001; Samadi et al. 2008; Johnston et al. 2010; Riahi et al. 2011; Huot et al. 2011; Koprich et al. 2011; Grégoire et al. 2011).

Although both acute and chronic MPTP monkey models are appropriate for testing novel therapies, the chronic model is more appropriate to test neuroprotective drugs.

Even within primates a strong variability to MPTP toxicity exists. For instance old-world monkeys such as macaques are much more sensitive to MPTP than new-world monkeys such as marmosets.

14 MPTP in Mice

In mice, MPTP determines degeneration of DA neurons which again varies depending on the specific mouse strain (Heikkila et al. 1984a). Motor impairment is difficult to be detected in mice although evidence exists showing a correlation between behavioral and pathological findings in MPTP-treated mice (Goldberg et al. 2011). Within mouse strains there is a wide variation in their sensitivity to the MPTP, the C57BL/6 mouse being the most sensitive, whereas CD-1 and BALB/c appear more resistant and Swiss Webster are very resistant to MPTP toxicity (Sonsalla and Heikkila 1988; Muthane et al. 1994; Hamre et al. 1999; Sedelis et al. 2000). Thus, in order to obtain subtotal nigrostriatal damage, it is much better to use C57BL/6 mice.

Sensitivity of mice to MPTP increases with age independently of the strain. A mechanism of strain-dependent sensitivity to MPTP has been hypothesized by Boyd and collaborators (2007), who reported a divergence in the inflammatory response, by examining JNK and COX-2 signaling induction in C57BL/6 J and Swiss Webster mice. A different sensitivity to MPTP within each strain has been reported depending on the purchaser. Thus, Swiss Webster mice from three different commercial suppliers possess different sensitivity to MPTP (Heikkila 1985). Therefore, it is important for investigators to consider both the strain and the vendor used when developing new treatment protocols for MPTP-induced neurotoxicity.

15 MPTP in Rats

Rats injected with MPTP doses comparable to those used in mice do not exhibit any significant DA degeneration. The MPTP toxic doses in rats would be incompatible with rat life if injected systemically; therefore, it is necessary to protect against the peripheral effects of MPTP by coadministering a peripheral adrenergic ganglionic

blocker like guanethidine (Giovanni et al. 1994a). Alternatively one might administer MPP^+ at high doses directly within the CNS. The relative resistance of rats to MPTP toxicity was initially attributed to species differences in MPTP metabolism and/or sequestration of MPP^+. In fact, monkeys have a much longer striatal retention of MPP^+ (half-life about 10 days) compared with mice (half-life about 4 h) (Johannessen 1991). However, Giovanni et al. (1994a, b) found that although the rat is relatively insensitive to MPTP toxicity, the in vitro MPP^+ uptake into DA synaptosomes, the in vivo striatal extracellular MPP^+ concentrations, and the amount of postmortem striatal MPP^+ levels did not correlate with the higher sensitivity to MPTP of mice compared with rats. Unexpectedly, postmortem striatal MPP^+ levels were higher in rats than in mice (Giovanni et al. 1994a, b; Zuddas et al. 1994). Additionally, previous studies showed no difference in mice compared with rats for striatal synaptosomal MAO-B activity and striatal synaptosomal MPP^+ uptake (Giovanni et al. 1991). Zuddas et al. (1994) confirmed the absence of any significant difference between C57 black mouse and various rat strains in striatal MPP^+ kinetics following systemic MPTP administration. Staal and collaborators (2000) confirmed that there was no significant species difference (mice versus rats) in striatal DAT numbers, suggesting a similar accumulation of MPP^+ within the DA neurons in both species. Thus, lower vulnerability to MPP^+ in rats versus mice could not be explained by lower intracellular levels of MPP^+ in rat DA neurons. MPP^+ is actively accumulated into vesicles by VMAT-2 (Del Zompo et al. 1993; Moriyama et al. 1993), and striatal vesicles isolated from rats have a higher density of VMAT-2 compared with mice and a greater ability to sequester MPP^+, suggesting a larger storage capacity for MPP^+ in rat vesicles (Staal and Sonsalla 2000). In turn this produces lower amount of DA release following MPTP in rats compared with mice. Pretreatment of mice and rats with a VMAT-2 inhibitor, Ro 4–1,284 (10 mg/kg i.p.), produces a fivefold leftward shift in the MPP^+ dose–response curve and a significant lowering of the EC_{50} concentration for MPP^+-induced damage in rats. This provides evidence for a substantial accumulation of MPP^+ in vivo in the rat striatum and explains why enhanced MPP^+ toxicity occurs when blocking VMAT-2. In mice VMAT-2 inhibition fails to enhance MPP^+ toxicity in the striata, suggesting that vesicular sequestration may not be as significant in providing protection in this species as it occurs in rats. Although VMAT-2 inhibition increases MPP^+ toxicity to striatal DA nerve terminals in rats, the potency of MPP^+ toxicity in the striatum of rats in which VMAT-2 is inhibited is still less pronounced than that in mouse striata exposed to MPP^+. This implies that mechanisms other than the sole MPP^+ sequestration protect against MPP^+ toxicity to DA neurons in different species (Staal and Sonsalla 2000).

16 Conclusion

The study of neurotoxicity induced by MPTP is a seminal research field to understand PD. In this chapter we reported the main concepts developed over the last three decades which led us to understand key molecular steps which are pivotal in

mediating MPTP toxicity. Remarkably, these molecular mechanisms turned out to be critical also for the survival of DA neurons in idiopathic PD. This is the case of the role played by DAT and VMAT-2 in conditioning the sensitivity to MPTP neurotoxicity and the tendency of DA neurons to undergo progressive degeneration in PD. Similarly, the mitochondria as targets of MPTP toxicity appear similarly affected by selective mutation of genes leading to PD. Again, the fate of mitochondria and the ability to clear these organelles when being dysfunctional are key in the modulation of MPTP toxicity as well as in the course of PD, where certain gene mutations impair the clearance of mitochondria. This is similar for what we discovered about the role of specific misfolded proteins such as alpha-synuclein.

Our perspective on PD is drastically changed in the past three decades, when novel brain areas as well as peripheral sites are increasingly recognized to be affected in PD patients. It is remarkable that progress on MPTP research led to mimic PD even for these additional areas underlying specific additional symptoms. PD is no longer viewed as a highly specific degeneration which involves solely the DA nigrostriatal pathway; similarly MPTP intoxication covers most of the additional features now evident in PD patients. Nowadays, after three decades, we can say that if MPTP per se did not lead to discovery of the environmental compound which causes PD, indeed the study of MPTP did disclose several molecular and cellular pathways which are critical in the genesis of PD. This latter point corresponds fairly to what we enthusiastically expected from MPTP when it was identified as a causal agent of what it remains, a toxic form of environmental parkinsonism.

Cocaine as a Neurotoxin

Teresa Cunha-Oliveira, A. Cristina Rego, and Catarina R. Oliveira

Contents

Abstract

Cocaine is a widely abused psychostimulant drug, with sympathomimetic properties and intense euphoric effects. Cocaine and some of its toxic metabolites cross the blood–brain barrier and induce neurologic impairments, affecting primarily the prefrontal cortex and basal ganglia. In this review, we discuss the mechanisms involved in brain dysfunction induced by cocaine, focusing on pre- and postsynaptic changes in dopaminergic and glutamatergic

neurotransmission, oxidative stress, and mitochondrial dysfunction. Neurotoxic effects of combinations of cocaine with other drugs are also discussed. In summary, cocaine neurotoxicity may underlie brain dysfunction in cocaine and polydrug abusers and may predispose the brain to neurodegeneration.

Keywords

List of Abbreviations

Ca^{2+}_i	Intracellular Ca^{2+} concentration
DAT	Dopamine transporter
DAQ	Dopamine quinone
DARPP32	Dopamine- and cAMP-regulated neuronal phosphoprotein
DOPAC	3,4-dihydroxyphenylacetic acid
DOPAL	3,4-dihydroxyphenylacetaldehyde
ERK	Extracellular-signal-regulated kinase
GPx	Glutathione peroxidase
GSH	Reduced glutathione
H_2O_2	Hydrogen peroxide
MAO	Monoamine oxidase
MAPKK/MEK	Mitogen-activated protein kinase kinase/extracellular signal-regulated kinase kinase
MDA	Malondialdehyde
NMDA	*N*-methyl-D-aspartate
$O_2^{\bullet -}$	Superoxide anion
$^{\bullet}OH$	Hydroxyl radical
PARP	Poly (ADP-ribose) polymerase
PD	Parkinson's disease
PKA	Protein kinase A
PP1	Protein phosphatase 1
Ras-GRF-1	Ras protein-specific guanine nucleotide-releasing factor 1
SOD	Superoxide dismutase
VMAT	Vesicular monoamine transporter

1 Introduction

Cocaine is an alkaloid extracted from the plant *Erythroxylum coca*, cultivated in the South American countries of Bolivia, Colombia, and Peru. This substance is a widely abused psychostimulant drug, with sympathomimetic properties, used recreationally to increase alertness, relieve fatigue, and increase self-confidence and is abused due to its intense euphoric effects. Cocaine is among the most abused

illicit drugs, used annually by 0.3–0.4 % of the world population aged 15–64 years, with higher prevalence in North America (1.6 %), Oceania (1.5–1.9 %) and Western and Central Europe (1.3 %) (United Nations Office on Drugs and Crime 2012).

2 Pharmacology of Cocaine

In the streets, cocaine may be available in water-soluble or insoluble forms. Water-soluble forms include cocaine sulfate and cocaine hydrochloride, which are mainly used intranasally, but may also be administered orally, sublingually, or by injection. Some drug abusers inject cocaine hydrochloride subcutaneously, intramuscularly, or intravenously, alone or with heroin ("speedball") or other drugs. Water-insoluble forms such as free base cocaine or crack are usually smoked. Crack cocaine is abused by inhaling the vapor from cigarettes (usually mixed with tobacco or marijuana) or after heating the drug in a glass pipe. When the drug is consumed in the free base form, thermal degradation leads to the formation of the metabolite anhydroecgonine methyl ester (Fig. 1), recently shown to be neurotoxic (Garcia et al. 2012).

Upon consumption, cocaine rapidly reaches the brain because it is able to cross the blood–brain barrier, due to its high lipophilicity, in contrast to its main metabolites ecgonine methyl ester and benzoylecgonine (Buttner et al. 2003). However, cocaine may be converted into other toxic metabolites, such as norcocaine and cocaethylene (Fig. 1). Norcocaine is formed in the liver, via N-demethylation of cocaine by CYP3A4, and is an active cocaine metabolite that crosses the blood–brain barrier and induces neurotoxicity (Nassogne et al. 1997). In the presence of alcohol, another active metabolite, cocaethylene (Fig. 1), is formed, which is more toxic than cocaine itself (Henry 2007), as discussed in Sect. 6.2.

Cocaine available in the streets is often adulterated with sugars, other central nervous system stimulants and local anesthetics (Karch 2009), to increase profit or to modulate the effects experienced by its users, being an additional factor that may contribute to some of the neuropathology observed in cocaine abusers. Purity of cocaine generally ranges from 20 % to 95 %, for cocaine hydrochloride, and 20 % to 80 %, for crack (Couper and Logan 2004).

3 Neurologic Dysfunction in Cocaine Abusers

Cocaine addiction may be considered a neurological disorder (Majewska 1996) because several neurological impairments are found in cocaine abusers, including seizures, cerebral ischemia, cerebral hemorrhages, infarction, optic neuropathy, cerebral atrophy, cognitive impairment, and mood and movement disorders (Koppel et al. 1996; Majewska 1996). Movement disorders described in cocaine users include choreoathetosis, akathisia, and parkinsonism with tremor (Karch 2009), a phenomenon known as "crack dancing," which may be associated with

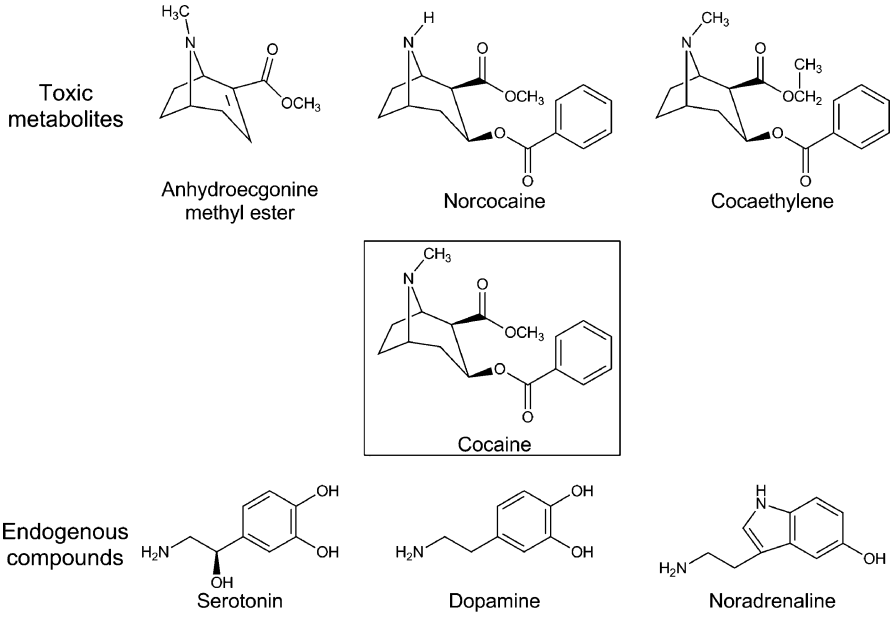

Fig. 1 Chemical structures of cocaine, its toxic metabolites, and monoamine endogenous compounds that share structural similarities with the drug. These similarities are in the basis of many of the drug's effects, due to interference with the same endogenous molecular targets

an increased incidence of basal ganglia abnormalities in cocaine abusers (Bartzokis et al. 1999).

The prefrontal cortex and basal ganglia of cocaine abusers are the brain regions where most brain lesions and cerebral atrophy are observed (Bartzokis et al. 1996; Langendorf et al. 1996). Cocaine abusers also present specific dysfunction of executive functions associated with prefrontal brain regions (Bolla et al. 1998). Cocaine-induced brain dysfunction may be caused by (i) vasoconstriction and consequent hypoxia induced by the drug (Olsen 1995); (ii) impairment of neurotransmission, namely through dopamine and glutamate; and (iii) oxidative stress and mitochondrial dysfunction.

The neurotoxic actions of cocaine in different brain areas involve different mechanisms of action and have specific consequences. Cocaine-induced increase in dopamine activity in the limbic system translates into euphoria, confusion, agitation, and hallucination. Effects in the cortex lead to pressure of speech, excitation, and a reduced feeling of fatigue. Stimulation of lower centers leads to tremor and tonic-clonic convulsions. Cocaine effects in the brain stem lead to stimulation and then depression of the respiratory vasomotor and vomiting centers (International Programme on Chemical Safety 1999). Maternal abuse of cocaine is associated with prenatal brain toxicity, leading to structural, metabolic, and functional brain abnormalities in the offspring (Roussotte et al. 2010).

4 Impairment of Neurotransmission

As most drugs of abuse, cocaine affects neurotransmission in brain areas involved in reward, such as the ventral pallidum; in motivation/drive, such as the orbitofrontal cortex and the subcallosal cortex; in memory and learning, such as the amygdala and the hippocampus; and in impulse control, such as the prefrontal cortex and the anterior cingulate gyrus (Volkow et al. 2003). The addictive effects of cocaine, and virtually all drugs of abuse, are explained by the activation of the brain reward pathway, a neuronal circuit composed of dopaminergic neurons that project from the ventral tegmental area, in the midbrain; to the nucleus accumbens, in the ventral striatum; and to the prefrontal cortex (Hyman et al. 2006).

4.1 Cocaine Effects on Dopamine and Glutamate Signaling

Due to structural similarities with monoamines (Fig. 1), cocaine interferes with the reuptake of these neurotransmitters, particularly dopamine, which is mostly associated with pleasure and movement. Blockade of monoamine reuptake (Ki: 02–0.7 μM) explains most of the effects of cocaine on the central nervous system (Han and Gu 2006). Additionally, at higher concentrations (>5 μM), cocaine may also bind to voltage-gated ion channels and inhibit inward sodium and outward potassium currents, acting as a local anesthetic (Heard et al. 2008). These effects are relevant for the range of cocaine concentrations found in the plasma of cocaine addicts, usually between 0.3 mM and 1 mM, which may even represent higher cocaine concentrations in the brain, because brain cocaine concentrations were reported to exceed the plasma concentration by several times (Heard et al. 2008).

By binding to the dopamine transporter (DAT) (Fig. 2), cocaine blocks its function, leading to increased extracellular dopamine, which results in chronic stimulation of postsynaptic dopamine receptors (Cunha-Oliveira et al. 2008, for review) and leads to the euphoric "rush." Subsequently, dopamine levels fall, resulting in the dysphoric "crash." Cocaine also interferes with the uptake of norepinephrine and serotonin, leading to increased stimulation of postsynaptic receptors for these neurotransmitters (Heard et al. 2008).

Besides inhibiting plasma membrane monoamine transporters, cocaine also interacts with the vesicular monoamine transporter VMAT-2 (Fig. 2), favoring the storage of catecholamines inside synaptic vesicles (Brown et al. 2001). Concomitant inhibition of the DAT and increased vesicular sequestration of dopamine induced by cocaine may cause a shift in the ratio of cytosolic to vesicular dopamine, increasing the amount of neurotransmitter packaged in each vesicle before its release, which may contribute to a greater increase in synaptic dopamine accumulation upon a depolarizing stimulus (Brown et al. 2001).

Several brain structures that receive input from the reward pathway send reciprocal glutamatergic projections back to the ventral tegmental area, which can affect dopamine release (Uys and Reissner 2011). Glutamatergic neurotransmission has been implicated in addiction, in the processes of reinforcement, sensitization, habit

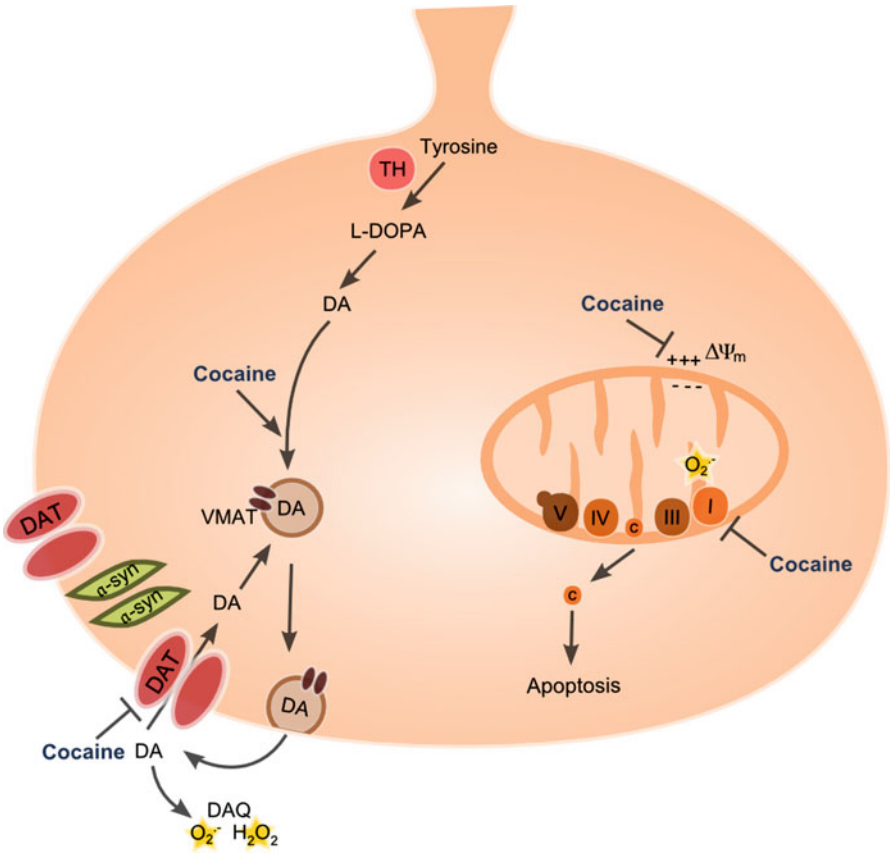

Fig. 2 Presynaptic changes induced by acute cocaine exposure. Cocaine affects neurotransmission in dopaminergic and other monoaminergic nerve terminals. Cocaine inhibits the dopamine (*DA*) transporter (*DAT*), preventing the reuptake of DA into the nerve terminal and prolonging the effects of this neurotransmitter in the synapse. Cocaine also interacts with the vesicular monoamine transporter (*VMAT*)-2, favoring the storage of catecholamines inside synaptic vesicles, which may contribute to a greater increase in synaptic dopamine, upon a depolarizing stimulus. DA is easily auto-oxidized, generating DA quinone (*DAQ*) and reactive oxygen species, such as $O_2^{\bullet-}$ and H_2O_2. Cocaine exposure also affects alpha-synuclein and DAT expression. These two proteins may interact, modulating DA neurotransmission. In addition, since cocaine is positively charged at physiological pH, it may enter into the nerve terminal and interact directly with mitochondria and other intracellular targets, inhibiting complex I-driven mitochondrial respiration, dissipating mitochondrial potential, and activating the mitochondrial apoptotic pathway

learning, context conditioning, craving, and relapse (Tzschentke and Schmidt 2003); moreover, glutamate receptors were shown to play a role in the reinforcement of long-lasting drug-seeking behaviors (Uys and Reissner 2011). Glutamatergic effects of drugs of abuse in the reward pathway may be modulated by dopamine in the nucleus accumbens, which controls the efficacy of glutamatergic corticostriatal synapses (Wickens et al. 2007).

Chronic cocaine exposure induces synaptic plasticity at ventral tegmental area and nucleus accumbens glutamatergic synapses, including changes in structural plasticity (i.e., increase in the number of dendritic spines); in glutamate homeostasis, implicating glial and neuronal impairment; and in postsynaptic glutamate signaling (Uys and Reissner 2011).

Cocaine was shown to increase extracellular glutamate concentrations in brain areas such as the ventral tegmental area, nucleus accumbens, prefrontal cortex, or striatum (Williams and Steketee 2004). An increase in extracellular glutamate has been associated with excitotoxic processes, due to increased activation of *N*-methyl-D-aspartate (NMDA) receptors and subsequent increase in intracellular Ca^{2+} concentration ($Ca^{2+}{}_i$) (Rego and Oliveira 2003, for review), which could contribute to cocaine neurotoxicity. Indeed, an increase in $Ca^{2+}{}_i$ was observed in rat cortical neurons, after cocaine exposure (Cunha-Oliveira et al. 2010).

Plasticity of glutamatergic synaptic transmission in the ventral tegmental area contributes to the development of addictive behaviors in cocaine addicts (Schilstrom et al. 2006; Wolf 2010). Changes in NMDA receptor subunit expression were observed in the brains of cocaine-exposed rats (Huber et al. 2001; Schilstrom et al. 2006; Yamaguchi et al. 2002; Scheggi et al. 2002; Hemby et al. 1999). In neurons from the ventral tegmental area, cocaine was shown to increase the expression of GluN1 and GluN2B (which is mainly extrasynaptic) subunits and their redistribution to synaptic membranes (Schilstrom et al. 2006). GluN2B expression was also shown to increase in the nucleus accumbens and hippocampus of cocaine-exposed rats. This effect was prevented in rats exposed to cocaine and MK-801, an NMDA receptor antagonist (Scheggi et al. 2002). Altered composition of NMDA receptors may increase the susceptibility of cells to the toxicity of drugs of abuse, as demonstrated by the fact that GluN1/GluN2B-transfected HEK293 cells are more susceptible to acute street heroin toxicity when compared to GluN1/GluN2A- and GluN1-transfected cells (Domingues et al. 2006).

The changes in the NMDA receptor subunit expression induced by cocaine may be mediated by extracellular dopamine, via stimulation of dopamine receptors (Schilstrom et al. 2006). Indeed, dopamine receptors D2 and D1 were shown to interact with NMDA receptor subunits, contributing to the stimulant effect of cocaine. Interactions between GluN2B subunits of the NMDA receptor and the D2 dopamine receptor were observed in the neostriatum of cocaine-exposed rats (Liu et al. 2006). In addition, D1 dopamine receptors, NMDA receptors, and extracellular-signal-regulated kinase (ERK) significantly contributed to neuronal morphological changes induced by repeated exposure to cocaine (Fig. 3) (Ren et al. 2010). Activation of NMDA receptors in the striatum was shown to recruit cytoplasmic D1 receptors to the plasma membrane and dendritic spines (Missale et al. 2006; Sun et al. 2008). D1 and NMDA receptors regulate, in opposite directions, the extent of dopamine- and cAMP-regulated neuronal phosphoprotein (DARPP32) phosphorylation, which becomes a potent inhibitor of protein phosphatase 1 (PP1) (Fig. 3). Whereas activation of the D1 receptor leads to increase in cAMP formation and activation of protein kinase A (PKA), which phosphorylates DARPP32, the stimulation of NMDA receptors induces an increase in intracellular calcium, leading

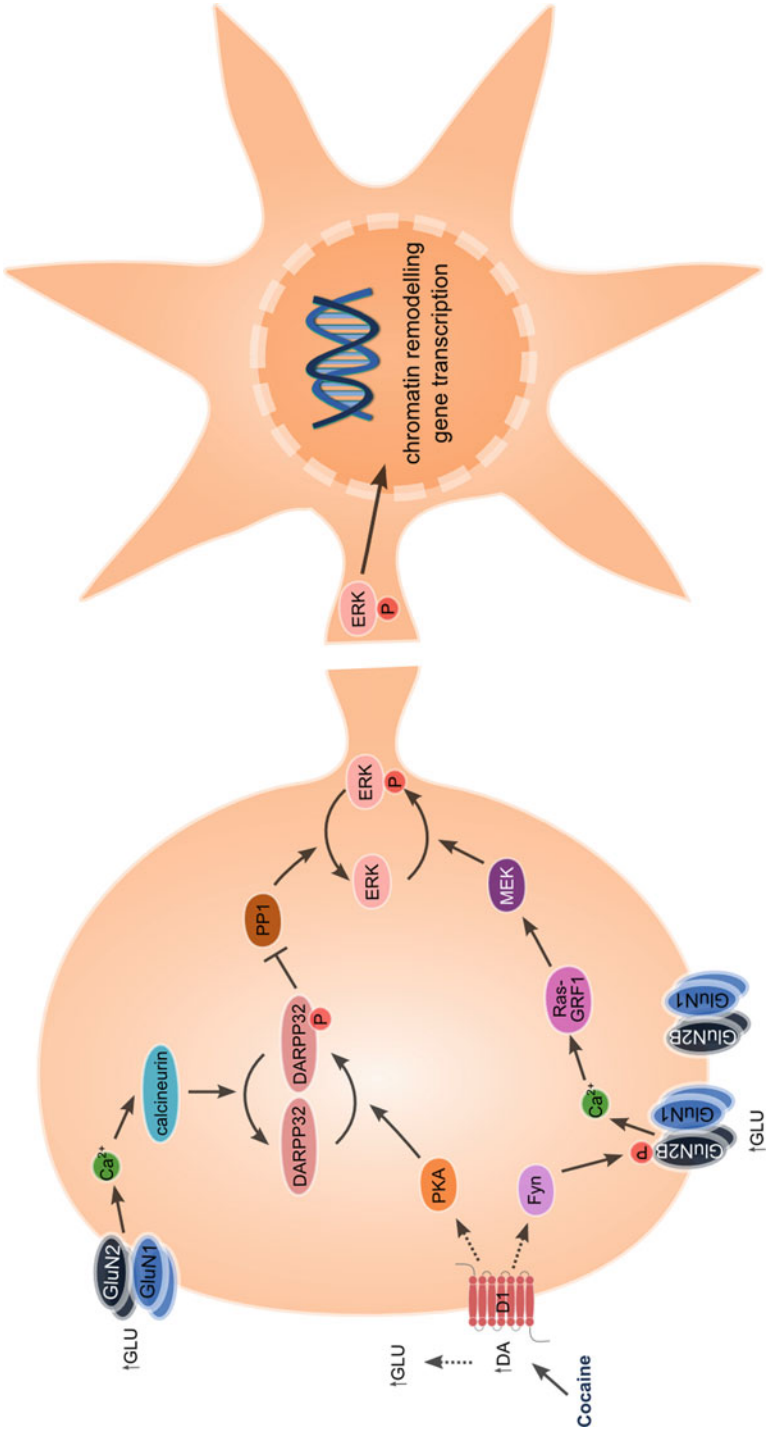

Fig. 3 (continued)

to the activation of calcineurin and dephosphorylation of DARPP32 (Nakano et al. 2010). Interestingly, interaction between glutamate and dopamine signaling in striatal medium spiny neurons seems to be critical for long-term plasticity in the striatum and may play a role in the behavioral alterations induced by cocaine (Pascoli et al. 2011). These adaptations seem to depend on activation of the ERK pathway in the striatum (Ren et al. 2010), which has been pointed out as an essential event for chromatin remodeling and gene expression associated with drug abuse (Brami-Cherrier et al. 2009). Interestingly, ERK activation upon cocaine exposure occurs selectively in dopamine D1 receptor-expressing medium spiny neurons and requires the coincident stimulation of D1 and NMDA receptors (Pascoli et al. 2011). D1 and NMDA receptor interplay upon cocaine exposure may result in ERK activation in medium spiny neurons and may be mediated by two pathways (Fig. 3). Stimulation of D1 receptors leads to PKA activation and DARPP-32 phosphorylation, inhibiting PP1 and preventing ERK dephosphorylation. Alternatively, D1 receptor activation also mediates the phosphorylation and activation of the Src-family kinase Fyn, which phosphorylates GluN2B subunits of NMDA receptors, increasing the entry of Ca^{2+} through these receptors, which leads to the activation of Ras protein-specific guanine nucleotide-releasing factor 1 (Ras-GRF1), mitogen-activated protein kinase kinase (MAPKK)/MEK, and ERK, representing a powerful mechanism of NMDA receptor potentiation (Pascoli et al. 2011).

5 Mechanisms of Neurotoxicity

Cocaine neuropathology shares some common aspects with neurodegenerative disorders, such as Parkinson's disease (PD), which also involves a dopaminergic dysfunction. As described in Sect. 3, chronic cocaine use leads to movement disorders, with similarities to parkinsonism (Karch 2009), although cocaine use does not seem to be a risk factor for the development of idiopathic PD (San Luciano and Saunders-Pullman 2009; Callaghan et al. 2012).

Fig. 3 Postsynaptic signaling in glutamate/dopamine-responsive striatal medium spiny neurons, upon chronic cocaine exposure. By increasing synaptic dopamine (*DA*) and glutamate (*GLU*), cocaine induces changes in the expression of NMDA receptor subunits and alterations in postsynaptic signaling through DARPP-32 and ERK. Stimulation of the D1 receptor leads to PKA activation, which phosphorylates DARPP-32, with subsequent inhibition of PP1, thus preventing ERK dephosphorylation. NMDA receptors also modulate DARPP-32 phosphorylation, since intracellular calcium entering through the receptor activates the phosphatase calcineurin, which dephosphorylates DARPP-32, preventing PP1 inhibition and enabling subsequent ERK dephosphorylation. Cocaine-induced ERK activation occurs selectively in D1 receptor-expressing MSNs and requires the coincident stimulation of D1 and NMDA receptors. This may be explained by the activation of Fyn following D1 receptor stimulation, which leads to phosphorylation of GluN2B subunits, resulting in increased calcium permeability, leading to the activation of Ras-GRF-1, with subsequent MEK activation and phosphorylation of ERK. Thus, activation of D1 receptors may lead to ERK activation by two independent pathways. Active ERK mediates chromatin remodeling and gene transcription that may be involved in behavioral manifestations of cocaine addiction

Cocaine exposure affects the expression of alpha-synuclein, the first protein found to be mutated in genetic cases of PD, whose accumulation in intracellular filamentous aggregates constitutes a pathological feature of PD and other neurodegenerative disorders (Perfeito et al. 2012). An overexpression of alpha-synuclein was found in dopamine neurons of cocaine abusers (Mash et al. 2003) and in the nucleus accumbens of rats exposed to high-dose cocaine (Brenz Verca et al. 2003). Increased alpha-synuclein protein levels were also found in serum from recently abstinent cocaine abusers (Mash et al. 2008). Interestingly, alpha-synuclein was reported to interact with the DAT, a cocaine classic target, modulating dopamine transmission and neuronal function (Swant et al. 2011; Bellucci et al. 2011). The presence of elevated levels of alpha-synuclein and DAT in the striatum of human cocaine abusers (Qin et al. 2005) suggested that cocaine may concomitantly regulate the binding and function of these two proteins (Fig. 3). Thus, overexpression of alpha-synuclein induced by cocaine may play a role in cocaine-induced plasticity and regulation of dopamine synaptic tone (Qin et al. 2005). Accordingly, alpha-synuclein overexpression in rat nucleus accumbens was suggested to modulate cocaine-induced locomotion and self-administration (Boyer and Dreyer 2007).

Other common characteristics observed in cocaine abuse and in several neurodegenerative diseases include oxidative stress, mitochondrial dysfunction, and apoptosis, as described in the next sections.

5.1 Cocaine Toxicity and Oxidative Stress

The occurrence of oxidative stress in neurons upon cocaine exposure has been suggested to occur due to the presence of oxidized metabolites of cocaine (Kovacic 2005), due to an accumulation of dopamine and its metabolites in the brain, or due to the deregulation of antioxidant defenses (Cunha-Oliveira et al. 2008, for review), all of which may ultimately result in increased levels of reactive oxygen species.

As described in Sect. 4.1, cocaine blocks dopamine reuptake by the DAT, resulting in the increase in extracellular dopamine levels in specific brain areas. Dopamine has been shown to be neurotoxic in vitro (Graham et al. 1978; McLaughlin et al. 1998) and in vivo (Hastings et al. 1996). Dopamine has a propensity to form reactive metabolites by enzymatic and nonenzymatic mechanisms and may induce oxidative stress in dopaminergic and neighboring cells, which may contribute to the neurotoxicity of many drugs of abuse, particularly cocaine due to its direct effect in increasing synaptic dopamine concentration. Dopamine may be metabolized intracellularly by monoamine oxidase A (MAO_A) (Fornai et al. 2000) and in a lower extent by MAO_B (Youdim et al. 2006), two isoforms of a mitochondrial enzyme that is present in the cytoplasmic side of the outer mitochondrial membrane in neurons and astrocytes. This enzyme generates 3,4-dihydroxyphenylacetaldehyde (DOPAL), which is highly toxic and rapidly metabolized by aldehyde dehydrogenase, producing 3,4-dihydroxyphenylacetic acid (DOPAC) and hydrogen peroxide (H_2O_2) (Marchitti et al. 2007). In contrast

with enzymatic dopamine oxidation, dopamine auto-oxidation may also occur extracellularly, which is more relevant for explaining cocaine-induced oxidative stress. Auto-oxidation of the catechol ring of dopamine generates dopamine quinones, together with superoxide anion ($O_2^{\bullet -}$) and H_2O_2 (Fig. 2), which may react with transition metal ions, such as iron, via the Haber-Weiss/Fenton reactions, creating the highly toxic hydroxyl radical ($^{\bullet}OH$) (Hastings 2009). $O_2^{\bullet -}$ may also lead to the formation of the highly toxic peroxynitrite, by reaction with nitric oxide. Dopamine quinones are electron-deficient molecules and, thus, readily react with cellular nucleophiles, such as reduced sulfhydryl groups on protein cysteinyl residues, covalently modifying protein structure. Since cysteinyl residues are often localized at the active site of proteins, covalent modification by dopamine quinones often leads to inactivation of protein function, affecting cell survival (Hastings 2009).

Cocaine also affects antioxidant defenses, which protect the cells against free radicals and other reactive species, such as $O_2^{\bullet -}$ and H_2O_2. Superoxide dismutase (SOD) is an antioxidant enzyme that detoxifies $O_2^{\bullet -}$, but may contribute to increase H_2O_2 levels (Cunha-Oliveira et al. 2008, for review). The main antioxidant enzymes involved in H_2O_2 inactivation are glutathione peroxidase (GPx) and catalase, which is present in peroxisomes. These enzymes are regulated by the cells, through the control of protein expression or activity, which allows the maintenance of cellular homeostasis and leads to a contrast in the cellular effects of chronic and acute oxidant exposures. For example, whereas acute exposure to H_2O_2 induces apoptotic cell death (Benedi et al. 2004; Jang and Surh 2004), chronic exposure to low H_2O_2 concentrations induces cellular resistance to the acute toxicity of this compound (Cunha-Oliveira et al. 2006b).

Acute cocaine exposure increased H_2O_2 in the prefrontal cortex and in the striatum of rats (Dietrich et al. 2005) and decreased catalase activity in the same structures in mice (Macedo et al. 2005). The levels of the antioxidants vitamin E and reduced glutathione (GSH) were also shown to be decreased in human neuronal progenitor cells upon acute cocaine exposure (Poon et al. 2007) and in fetal rat brain upon in utero cocaine exposure (Lipton et al. 2003). Biochemical markers of oxidative injury were also found in brain cells, after cocaine exposure. The hippocampus of rats exposed prenatally to cocaine showed an increase in lipid peroxidation (Bashkatova et al. 2006), and protein oxidation was found in human neuronal progenitor cells acutely exposed to cocaine (Poon et al. 2007). Elevated malondialdehyde (MDA) and nitrite levels were also found in rat brain slices from the prefrontal cortex and nucleus accumbens, after acute cocaine exposure. This increase in oxidative damage markers was accompanied by a decrease in total antioxidant content, and both were prevented by tempol, a SOD mimetic antioxidant (Numa et al. 2008).

Repeated cocaine exposure decreased GSH concentration and GPx activity in the hippocampus of rats, which also presented learning and memory impairments (Muriach et al. 2010). Interestingly, chronic exposure of catecholaminergic cells to cocaine seems to induce adaptation to oxidative stress, because PC12 cells chronically exposed to cocaine exhibited a partial resistance against H_2O_2 toxicity (Fig. 4) (Cunha-Oliveira et al. 2006b), which suggests the occurrence of oxidative stress

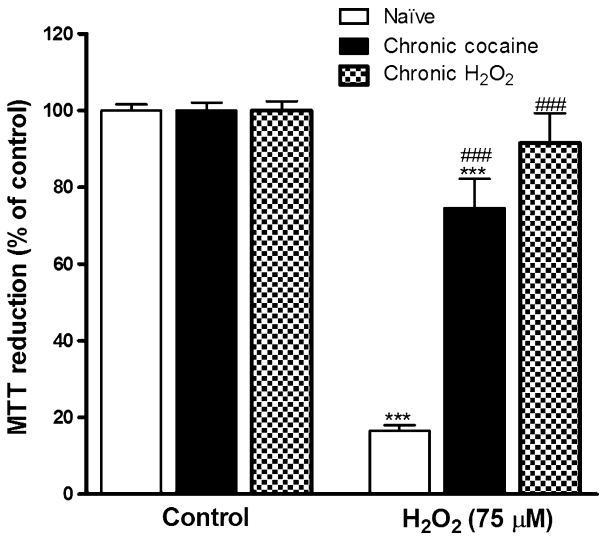

Fig. 4 Involvement of oxidative stress in chronic cocaine effects. PC12 cells were chronically exposed to subtoxic concentrations of cocaine (30 μM) or H_2O_2 (10 μM) for 7–12 months. The toxicity of an acute exposure to H_2O_2 was then assessed by the MTT assay. Cells chronically exposed to H_2O_2 were completely resistant to H_2O_2 acute toxicity, due to cellular adaptation to oxidative stress. Cells chronically exposed to cocaine were partially resistant to H_2O_2 toxicity, suggesting that chronic cocaine exposure also induces cellular adaptation to oxidative stress. Statistical analysis was performed by one-way ANOVA with Bonferroni posttest $^{***}P > 0.001$ compared to respective control; $^{\#\#\#}P > 0.001$ compared to treated naïve cells (Adapted from Toxicology, 217, T. Cunha-Oliveira, A.C. Rego, M.T. Morgadinho, T. Macedo and C.R. Oliveira, Differential cytotoxic responses of PC12 cells chronically exposed to psychostimulants or hydrogen peroxide, 54–62 (Copyright 2006. Cunha-Oliveira et al. (2006b), with permission from Elsevier)

during chronic cocaine exposure. In dopaminergic rat brain structures, repeated cocaine administration induced an increase in antioxidant enzyme activity (Dietrich et al. 2005), and repeated self-administration of cocaine in rats induced an increase in SOD activity and a reduction in MDA levels in the hippocampus, frontal cortex and dorsal striatum (Pomierny-Chamiolo et al. 2012). Induction of antioxidant defenses in models of repeated cocaine exposure may explain the resistance to oxidative agents in these models, and cocaine-induced adaptations in cellular redox balance were suggested to contribute to enduring behavioral plasticity (Uys et al. 2011).

5.2 Cocaine Toxicity and Mitochondrial Dysfunction

Mitochondrial function and energy metabolism were shown to be affected in brains of human cocaine abusers (Lehrmann et al. 2003), and cocaine was demonstrated to influence mitochondrial function in different cell types. Interestingly, acute cocaine

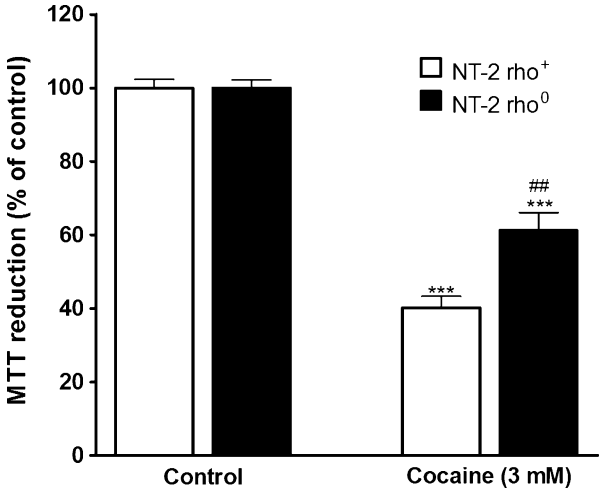

Fig. 5 Partial involvement of functional mitochondria in cocaine toxicity. Mitochondrial involvement in acute cocaine toxicity was analyzed in NT-2 rho-zero cells, depleted from mitochondrial DNA, and thus devoid of a functional mitochondrial respiratory chain. Loss of cell viability induced by cocaine was attenuated in NT-2 rho-zero cells, compared with NT-2 rho-plus cells. Statistical analysis was performed by one-way ANOVA with Bonferroni posttest $***P > 0.001$ compared to respective control; $\#\#P > 0.01$ compared to treated NT-2 rho-plus cells (Adapted from Brain Research, 1089, T. Cunha-Oliveira, A.C. Rego, S.M. Cardoso, F. Borges, R.H. Swerdlow, T. Macedo and C.R. Oliveira, Mitochondrial dysfunction and caspase activation in rat cortical neurons treated with cocaine or amphetamine, 44–54. Copyright 2006. Cunha-Oliveira et al. (2006a), with permission from Elsevier)

toxicity partially required the presence of a functional respiratory chain, because rho-zero cells, which lack functional mitochondria, were more resistant to cocaine toxicity, in comparison with rho-plus cells (Fig. 5) (Cunha-Oliveira et al. 2006a). In addition, exposure to cocaine downregulated mitochondrial gene expression in rat cingulate cortex (Dietrich et al. 2004). Accordingly, mitochondrial complex I activity and subunit expression were reduced after cocaine exposure (Yuan and Acosta, Jr. 2000; Dietrich et al. 2004; Devi and Chan 1997), a defect that is also observed in PD. Cocaine may interact directly with mitochondria and other intracellular targets (Heard et al. 2008), entering the cell due to the weak base effect, because cocaine has a positive charge at physiological pH. Studies in hepatic mitochondria showed that in vivo cocaine administration decreased state 3 respiration, the respiratory control ratio, and the activity of complexes I, II/III, and IV (Devi and Chan 1997). In isolated liver and brain mitochondria, cocaine inhibited complex-I-driven respiration, through a direct effect on this complex (Cunha-Oliveira et al. 2013).

Cocaine neurotoxicity has been associated with apoptotic cell death, and cocaine has been shown to induce biochemical features of apoptosis, including activation of caspases, loss of mitochondrial potential, and cytochrome c release (Cunha-Oliveira et al. 2008, for review). In brains of cocaine addicts, the occurrence of

aberrant cell death was suggested by the enhanced degradation of nuclear poly (ADP-ribose) polymerase (PARP)-1, an apoptotic hallmark, which appeared to be the consequence of oxidative stress and activation of nuclear AIF (Alvaro-Bartolome et al. 2011). Changes in Bcl-2 and Bax expression (Lepsch et al. 2009; Dey et al. 2007), decrease of mitochondrial cytochrome c levels, and caspase-9 activation (Cunha-Oliveira et al. 2006a) were found after in vitro cocaine exposure, suggesting the involvement of the mitochondrial apoptotic pathway. However, controversial results have been reported regarding structural apoptotic hallmarks induced by cocaine. Whereas many reports did not find structural features of neuronal apoptosis upon in vivo (Dietrich et al. 2005) or in vitro (Oliveira et al. 2002; Cunha-Oliveira et al. 2006a) cocaine exposure, others have shown that cultured fetal mouse cortical neurons exposed to cocaine exhibited apoptotic morphology (Nassogne et al. 1997) and apoptotic neurons were also observed in the fetal rat brain, upon in utero cocaine exposure, whereas the maternal brain was spared (Xiao and Zhang 2008).

Interestingly, oxidative stress seemed to precede cell death induced by cocaine, in human neuronal progenitor cells (Poon et al. 2007). Oxidative stress also seems to be involved in cocaine's mitochondrial effects, since cocaine-induced mitochondrial dysfunction could be prevented by the mitochondrial-targeted antioxidant MitoQ, in isolated cardiac mitochondria (Vergeade et al. 2010).

6 Combinations of Cocaine and Other Substances

6.1 Effects of Speedball

Cocaine abusers may also consume other drugs that may interact with cocaine and modify its effects. Speedball is a relatively popular drug combination (European Monitoring Center for Drugs and Drug Addiction 2009), which consists in simultaneous injection of cocaine and heroin, and has been reported to cause more rewarding effects in rats than cocaine or heroin alone (Ranaldi and Munn 1998). The popularity of this drug combination may derive from the reduction of the unwanted side effects of one drug by the other due to compensatory mechanisms of action and/or from enhanced effects of the combination (Leri et al. 2003).

Speedball has serious health consequences. The use of cocaine in combination with heroin is generally associated with the presence of a mental illness and may aggravate underlying psychological problems, such as bipolar disorder (European Monitoring Center for Drugs and Drug Addiction 2008). Moreover, speedball abusers seem to exhibit more severe psychopathology in comparison with other cocaine addicts and more likely fail in drug abuse treatment (Bandettini Di Poggio et al. 2006).

Self-administration of cocaine in rhesus monkeys was shown to be enhanced by otherwise inactive doses of heroin (Rowlett and Woolverton 1997). The pharmacological mechanisms underlying speedball abuse seem to involve an increase in the reward obtained from the drug combination (Rowlett and Woolverton 1997).

In accordance, self-administration of both cocaine and heroin produces synergistic elevations in extracellular dopamine concentration in the reward pathway (Hemby et al. 1999; Smith et al. 2006) that are thought to be mediated by dopamine and μ-opioid receptors (Cornish et al. 2005). This suggests that this drug combination alters the dynamics of dopamine and other neurotransmitters affected in drug addiction.

Interestingly, a chemical interaction between cocaine and morphine was found in cocaine-heroin mixtures, involving the formation of a cocaine-morphine adduct (Garrido et al. 2007), which may play a role in the effects of cocaine-heroin combinations, especially when the co-abuse occurs simultaneously. Thus, besides pharmacodynamic interactions, chemical interactions between drugs could also play a role in speedball neurotoxicity. In previous studies, we exposed primary cultures of rat cortical neurons to heroin and/or cocaine, either sequentially or simultaneously (Cunha-Oliveira et al. 2010) to investigate this possibility. The effects of cocaine seemed to predominate over heroin's effects when the cells were exposed to a mixture of the two drugs (where the probability of chemical interactions between the drugs is enhanced), but not upon sequential exposure (Cunha-Oliveira et al. 2010). Since both drugs were present at the same amounts in both situations, this result suggested that the interaction of the mixture of drugs with opioid receptors may be lower, as compared to a sequential administration of the two drugs, probably due to the presence of cocaine-morphine adducts. In addition, cocaine-morphine combinations induced apoptosis and mitochondrial dysfunction in rat cortical neurons (Cunha-Oliveira et al. 2010) and impaired the bioenergetics of isolated brain mitochondria (Cunha-Oliveira et al. 2013). These data suggest that neurotoxic pathways induced by co-administration of cocaine and heroin differ from those evoked by a sequential administration of the same drugs, possibly due to chemical interactions between the two drugs (or their metabolites), which may interfere with cell death mechanisms and may affect the capacity of cocaine to interact with its cellular targets, such as monoamine transporters or mitochondria. Thus, co-use of cocaine and heroin may lead to different effects depending on the mode of co-exposure, and polydrug abusers may be more prone to neurotoxic damage than single drug abusers.

6.2 Cocaine and Ethanol

As referred in Sect. 2, cocaine and ethanol represent another toxic drug combination. Ethanol use by cocaine abusers leads to the potentiation of cocaine's euphoric effects. However, toxic effects of both drugs are also enhanced (Bolla et al. 2000), since the drugs are combined in the liver to form a very toxic metabolite – cocaethylene (see Fig. 1). Cocaethylene also affects the brain because it is highly lipophilic and, thus, crosses the blood–brain barrier. The behavioral effects of cocaethylene are similar to those of cocaine, but more prolonged due to its longer half-life (Henry 2007).

7 Conclusion

Cocaine is a widely abused psychostimulant drug, popularized by its intense euphoric effects. Cocaine addiction may be described as a neurological disorder because cocaine abusers present several neurological impairments. Cocaine neurotoxicity may be due to vasoconstriction and subsequent hypoxia or to the impairment of neurotransmission, namely through dopamine and glutamate, and may be mediated by oxidative stress and mitochondrial dysfunction. The interaction with the dopaminergic system is the main cause of cocaine's addictive effects, leading to excess synaptic dopamine levels that may induce oxidative stress through dopamine auto-oxidation and reactive oxygen species generation. Neurotoxic cocaine metabolites may also induce oxidative stress. Cocaine also affects glutamate levels and the expression of glutamate receptors, which may mediate excitotoxic cell damage and long-term neuroadaptive effects.

Cocaine abuse shares some common aspects with neurological disorders such as PD, which also involves a dysfunction in the dopaminergic system. Cocaine exposure has been shown to regulate both alpha-synuclein and DAT binding and function, possibly affecting cocaine-induced plasticity, locomotion, and self-administration. Moreover, cocaine has been shown to impair mitochondrial function in several models, namely through the inhibition of mitochondrial respiratory chain complex I, as occurs in PD; furthermore, cocaine toxicity was demonstrated to require a functional respiratory chain. Cocaine may also induce the activation of mitochondrial apoptotic pathways in several models.

Cocaine is frequently co-abused with heroin, in a combination known as speedball, and heroin may modulate or modify cocaine's effects. A chemical interaction between cocaine and morphine was found in drug mixtures similar to those used by speedball abusers and may produce a specific neurotoxic profile and alter cocaine effects. A concomitant use of cocaine and alcohol may have additive negative effects in the brain, due to the formation of a metabolite, cocaethylene, which is more toxic than cocaine itself.

In summary, cocaine-induced neurotoxicity may underlie brain dysfunction in cocaine and polydrug abusers and may predispose the brain to neurodegeneration.

Abstract

Dihydroxytryptamines are able to selectively destroy central serotonin neurons when catecholaminergic neurons are protected. Compared to serotonin, 5,6-dihydroxytryptamine (5,6-DHT) and 5,7-dihydroxytryptamine (5,7-DHT) are indole derivatives that acquire their neurotoxicity due to additional hydroxyl groups on the indole ring. Factors influencing the action of dihydroxytryptamines include the site of injection, the speed and volume of injection, the amount and type of antioxidant used, the type of anesthesia, and the dose and type of catecholamine uptake blocker. Two major hypotheses have been proposed to explain the molecular mechanism that underlies the toxicity of 5,6- and 5,7-DHT. The first suggests that highly reactive (electrophilic) quinonoid intermediates, created as a result of 5,6- and 5,7-DHT auto-oxidation, bind covalently to molecules indispensable for neuronal function. The second hypothesis states that during the auto-oxidation of dihydroxylated tryptamines, reactive oxygen species such as superoxide radical anion (O_2^{-}), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($HO^{\cdot}$) are generated as toxic by-products. The use of 5,6- and 5,7-DHT in both adult and neonatal animals enables the recognition the role of 5-HT in locomotor activity (LMA), prepulse inhibition, seizure susceptibility, sleeping behavior, feeding and drinking behavior, sexual and aggressive behavior, the regulation of body temperature, the response to novel and noxious stimuli, learning and memory, the antinociceptive action of drugs, neuroendocrine regulatory mechanisms, and developmental plasticity.

Keywords

5,6-dihydroxytryptamine (5,6-DHT) • 5,7-dihydroxytryptamine (5,7-DHT) • 5-HT neurotoxins

List of Abbreviations

5-HT	5-hydroxytryptamine, serotonin
5-HTP	5-hydroxytryptophan
5,6-DHT	5,6-dihydroxytryptamine
5,7-DHT	5,7-dihydroxytryptamine
6-OHDA	6-hydroxydopamine
CNS	Central nervous system
DA	Dopamine
DRN	Dorsal raphe nuclei
DTPA	Diethylene triamine pentaacetic acid
FSH	Follicle-stimulating hormone
GH	Growth hormone
GSH	Glutathione
H_2O_2	Hydrogen peroxide
HO	Hydroxyl radical

L-5-HTP	5-hydroxy-L-tryptophan
LMA	Locomotor activity
MAO	Monoamine oxidase
MAOI	Monoamine oxidase inhibitor
MRN	Median raphe nuclei
NA	Noradrenaline
NGF	Nerve growth factor
O_2^-	Superoxide radical anion
PPI	Prepulse inhibition
PTZ	Pentylenetetrazol
REM	Rapid eye movements
ROS	Reactive oxygen species
SOD	Superoxide dismutase

1 Introduction

1.1 The Significance of Serotonin and Serotonergic Neurons

Serotonergic neurons are one of the first to appear during brain and spinal cord development. They are formed very early in gestation in vertebrates (Lidov and Molliver 1982). Serotonin (5-hydroxytryptamine or 5-HT) is a neurotransmitter with developmental functions (Ahmad and Zamenhof 1978) and is involved in more behaviors, physiological processes, and diseases than any other transmitter. It affects developmental events such as cell division, neuronal migration, cell differentiation, and synaptogenesis (Lipton and Kater 1989; Azmitia 2001; Vitalis and Parnavelas 2003). Studies in vertebrates show that even a brief 5-HT deprivation in the brain leads to a loss of spines, dendritic profiles, and synapses (Yan et al. 1997).

1.2 From the First Neurotoxins to the Discovery of Dihydroxytryptamines

The roles of different neuronal types and pathways can be determined by disrupting their function. In the first half of the twentieth century, using the methods of axonal transaction and chemical or electrolytic ablation of nuclei, our knowledge of nerve function was enhanced. However, these techniques have some inherent limitations due to the lack of selectivity. A real breakthrough came in the 1950s with the discovery the first neurotoxin, an antibody to nerve growth factor (NGF), which could destroy sympathetic nerves in

whole animals. The next neurotoxin introduced in the 1960s by Thoenen and Tranzer (1968) was 6-hydroxydopamine (6-OHDA). This hydroxylated analog of dopamine (DA) promoted selective degeneration of peripheral and central noradrenergic neurons. This discovery initiated a novel period in experimental biology. Selective chemical axotomy replaced early mechanical and electrolytic lesioning techniques. After the discovery of 6-OHDA, Baumgarten and collaborators (1971) concentrated on dihydroxytryptamine derivatives. They found that these compounds are able to cause selective destruction of central serotonergic neurons when noradrenergic neurons are protected through pharmacological inhibition of the noradrenaline reuptake carrier (Baumgarten and Lachenmayer 1972; Baumgarten et al. 1973). In 1978, Jacoby and Lytle first used the term "serotonin neurotoxins" in the title of their symposium proceedings volume to describe these compounds.

The mechanism of action of dihydroxytryptamines is analogous to the effects triggered by 6-OHDA in catecholaminergic terminals. Initially, 5,6-dihydroxytryptamine (5,6-DHT) was introduced to neuroscience as a serotoninergic neurotoxin. However, consecutive studies regarding the mechanism of its action revealed the limitations of 5,6-DHT use (Baumgarten and Schlossberger 1973), which motivated scientists to utilize 5,7-dihydroxytryptamine (5,7-DHT), an isomer of 5,6-DHT.

2 Dihydroxytryptamines

2.1 Chemical Structure

Dihydroxytryptamines are indole derivatives that acquire their neurotoxicity due to additional hydroxyl groups (in comparison with 5-HT) on the indole ring (Schlossberger 1978).

2.2 The Mode of Administration

5,6-DHT as well as 5,7-DHT can be administered intracerebroventricularly, intracerebrally, intracisternally, and intrathecally (Baumgarten et al. 1978b).

2.3 Cytochrome-c Oxidase and the Neurotoxicity of Dihydroxytryptamines

Cytochrome-c oxidase is a common feature in the mechanisms of toxicity of both 5,6-DHT and 5,7-DHT (Baumgarten et al. 1982b).

3 Dose-Dependent Action of Dihydroxytryptamines

3.1 5,6-Dihydroxytryptamine

5,6-DHT was the first dihydroxytryptamine introduced to neurobiology. Its injection into the cerebrospinal fluid of rats at doses of 25–75 μg leads to degeneration of indolamine-containing axons and axon terminals in distinct regions of the brain and spinal cord (Baumgarten et al. 1971). At this range of doses, 5,6-DHT causes no considerable changes in DA and noradrenaline (NA) levels in any region of the rat brain (Baumgarten et al. 1972). The same doses injected intracerebroventricularly trigger long-lasting depletion of 5-HT in the spinal cord and smaller effects in the brain (Baumgarten et al. 1971; Daly et al. 1973). Doses higher than 75 μg do not enhance the neurotoxic effects of 5,6-DHT on serotonergic pathways and are extremely toxic to the animals, leading to muscle paralysis, convulsions, tremor, and death in the majority of animals. Furthermore, such doses cause damage to other types of neurons. Studies show nonselective destruction of myelinated fiber systems and glial cells and shrinkage of the striatum on the side of the injection. In doses above 75 μg administered intracerebroventricularly, 5,6-DHT induces a significant reduction of DA and NA levels in distinct areas of the brain (Baumgarten et al. 1972; Bjorklund et al. 1973). Bjorklund and collaborators (1973) demonstrated that this dose restriction can be overcome by infusion of small amounts of the neurotoxin directly into the brain parenchyma.

3.2 5,7-Dihydroxytryptamine

Limitations in the use of 5,6-DHT and need for neurotoxins with less general cytotoxicity inspired the discovery of more selective serotonergic neurotoxins. In 1972, Baumgarten and Lachenmayer described the effects of intracerebral injection of another 5-HT neurotoxin – 5,7-DHT. One of the basic distinctions between 5,6- and 5,7-DHT is the ability to use doses up to 300 μg, which are ordinarily well tolerated. Further, the injection can be made intracerebroventricularly, so the neurotoxin does not have to be injected directly into brain tissue (Baumgarten and Lachenmayer 1972). However, doses up to 100 μg administered intracerebroventricularly in rats often lead to convulsions that can be prevented by previous treatment with barbiturates (Baumgarten and Lachenmayer 1972). Baumgarten and collaborators (1973) demonstrated that even 10 μg of 5,7-DHT injected intracerebroventricularly triggers a significant reduction (approximately 25 %) in the levels of 5-HT and NA in the rat brain. A dose of 50 μg leads to a further decrease in the concentration both of neurotransmitters to approximately 50 % of control values. Successively increasing doses from 75 to 200 μg cause a further decline in the 5-HT level to about 25 % of the control value, without further reduction in the NA level. In early studies, even large doses of 5,7-DHT did not affect the brain levels of DA, a finding that was verified by subsequent

research demonstrating that 5,7-DHT also damages DA axons (Wuttke et al. 1977; Baumgarten et al. 1978b). It is important that the neurotoxic action of 5,7-DHT is not equal in all central nervous system (CNS) regions. Doses as low as 10 μg are sufficient to cause almost complete (85 %) reduction in the 5-HT level in the spinal cord (Baumgarten et al. 1973). Depletion in the 5-HT level in rats after injection of 200 μg ranged from 55 % in the medulla and pons to approximately 85 % in the forebrain and septum (Baumgarten et al. 1973). The most considerable decrease in 5-HT level was noted in the regions of the CNS rich in serotonergic axons and terminals (i.e., the septum, striatum, and hypothalamus), whereas much lower depletion was observed in areas containing serotonergic cell bodies (i.e., mesencephalon, medulla/pons) (Baumgarten et al. 1973).

4 Dihydroxytryptamines: Differences

4.1 Neurotoxicity

A comparison of mono-, di-, and trihydroxylated tryptamines reveals that the principal factor affecting the neurotoxicity of these compounds is the velocity of their oxidation at biological pH. Moderate reaction velocity provides the best potential for toxicity. In the case of 5,6,7-trihydroxytryptamine, a very high oxidation rate causes its immediate transformation into a quinone derivative that does not serve as a substrate for monoaminergic transport mechanisms. A similar mechanism is responsible for the lower in vivo neurotoxicity of 5,6-DHT in comparison to 5,7-DHT, even though 5,6-DHT shows a higher affinity to the amine carrier of serotoninergic neurons (Baumgarten 1981, 1982b). 5,6-DHT undergoes rapid oxidation to o-quinone, which forms melanin-like polymers by aggregation and/or binds covalently and irreversibly to brain proteins (Baumgarten et al. 1975a). These features ensure that 5,6-DHT never penetrates into deeply located 5-HT uptake sites. Moreover, they reduce 5,6-DHT toxicity to 5-HT neurons and increase the risk of nonselective toxic side effects. Conversely, 5,7-DHT is not oxidized as easily, does not create insoluble polymers, and rapidly penetrates into the brain, thus giving it high intrinsic neurotoxicity despite a lower affinity for the 5-HT uptake mechanism (Baumgarten et al. 1975b).

The key feature that determines dihydroxytryptamines activity is the localization of the hydroxyl groups. 5,7-DHT is a meta-substituted dihydroxytryptamine, while 5,6-DHT is ortho-substituted. The meta-substitution enables 5,7-DHT to exist in solution as an equilibrium of distinct tautomeric keto-enol forms, which provide affinity to the 5-HT carrier despite the oxidation of some fraction of 5,7-DHT in vivo. Oxidation does not cause the total loss of 5,7-DHT affinity to the 5-HT carrier (unlike to 5,6-DHT) because one of the hydroxyl groups in the 5,7-DHT structure remains functional (Baumgarten et al. 1982b).

4.2 IC_{50} for 5-HT Uptake Inhibition

IC_{50} values for the inhibition of 5-HT uptake are 4 μM for 5,7-DHT and 0.6 μM for 5,6-DHT, making 5,7-DHT almost seven times less potent than 5,6-DHT (Bjorklund et al. 1975c). However, 5,7-DHT is a better long-term depletor of brain and spinal cord 5-HT than 5,6-DHT, possibly due to differences in metabolism and reactivity of 5,7-DHT (Baumgarten et al. 1975b).

4.3 Selectivity for Catecholamine Uptake

Early studies suggested that 5,7-DHT was a superior serotonergic neurotoxin to 5,6-DHT due to lower nonspecific toxicity and higher specific neurotoxicity (Baumgarten et al. 1973), but further studies by Wuttke et al. (1977) and then by Baumgarten and collaborators (1978b) revealed that 5,7-DHT affects both central NA fibers and DA axons. The results by Bjorklund et al. (1975c) showed that 5,6-DHT is a more specific inhibitor of 5-HT uptake than catecholamine uptake, despite the small differences between the affinity of 5,6-DHT to the 5-HT, NA, and DA transporters (% inhibition of uptake is 59.0 ± 2.3; 43.3 ± 2.7; 44.7 ± 0.7, respectively). 5,7-DHT has a different selectivity pattern. It inhibits the uptake of catecholamines, particularly NA, more effectively than 5-HT (% inhibition of uptake is 25.7 ± 1.2; 32.5 ± 1.3; 15.4 ± 1.7 for 5-HT, NA, and DA, respectively (Bjorklund et al. 1975c)). These results are different from those presented by Baumgarten and collaborators (1978b). On the basis of K_m values for NA uptake (10.0×10^{-6} M) and 5-HT uptake (6.0×10^{-7} M), it appears that 5,7-DHT has a 16-fold higher affinity for the 5-HT transport mechanism. However, there are also studies that show that 5,7-DHT exhibits dose-dependent differences in its selectivity. In doses up to 50 μg, it depletes NA and 5-HT uptake to a similar degree, whereas in doses higher than 50 μg, it affects CNS 5-HT levels substantially more (Baumgarten et al. 1971, 1973, 1975b).

The toxicity of dihydroxytryptamines to non-5-HT neurons can be counteracted by the use of nomifensine, which is a NA/DA uptake blocker (Baumgarten et al. 1979). The effects of 5,7-DHT on NA neurons can be abolished by desmethylimipramine, a blocker of the amine pump of NA neurons. In numerous studies, a combination of desmethylimipramine and 5,7-DHT has been used to achieve selective chemical ablation of 5-HT axons and terminals in the rat brain (Bjorklund et al. 1975a; Sachs and Jonsson 1975). Other methods to block the effect of 5,7-DHT on NA neurons include the use of monoamine oxidase inhibitors (MAOI) such as pargyline, iproniazid, and pheniprazine (Breese and Cooper 1975) and pretreatment with desipramine (Wuttke et al. 1977; Bjorklund et al. 1975b).

4.4 Half-Life and Stability

There are also differences between the half-life and stability of 5,6- and 5,7-DHT. 5,7-DHT is more stable because it lacks autocatalytic promotion of its oxidation

and does not create macromolecular polymers. In contrast, the auto-oxidation of 5,6-DHT is promoted by H_2O_2, and the product of its oxidation, o-quinone, reacts with proteins and peptides to generate high molecular weight polymers through interaction with non-oxidized 5,6-DHT (Baumgarten et al. 1982b).

4.5 The Rate of Oxygen Consumption

5,6- and 5,7-DHT differ in their rates of oxygen consumption. The initial O_2 consumption is 2.7 nmol O_2/min for 5,6-DHT and 33.4 nmol O_2/min for 5,7-DHT. This difference reflects the fact that oxidation of 5,7-DHT is a second-order reaction. However, the rate of oxidation of 5,6-DHT increases after an initial period of slow oxygen consumption (Baumgarten et al. 1982b).

4.6 Diffusion

5,6-DHT has limited diffusion into the brain parenchyma of the adult rat due to its capacity to create macromolecular polymers (Baumgarten et al. 1977). 5,7-DHT infiltrates much deeper into the brain. Notably, 5,7-DHT has the ability to freely diffuse across the brain and to cross the blood-brain barrier during the first week of life. These features enable denervation of the entire 5-HT neuronal system following the intraperitoneal administration of 5,7-DHT to rat pups (Sachs and Jonsson 1975; Kostrzewa et al. 1994).

5 Factors That Affect the Action of 5-HT Neurotoxins

Factors influencing the action of dihydroxytryptamines include the site of injection, the speed and volume of injection, the amount and type of antioxidant used, the type of anesthesia, and the dose and type of catecholamine uptake blocker. These factors influence the specificity of the treatment, the extent of amine depletion, the time course of degeneration and regeneration, the development and recovery of a postsynaptic supersensitivity, and the symmetry of neurotoxic action (Baumgarten et al. 1982b).

5.1 The Site of Injection

The site of injection affects the degree and selectivity of the serotonin neurotoxin action, as demonstrated by comparing the effects of 5,7-DHT intracerebral injection into the lateral and fourth ventricle. Injection of 100 μg of 5,7-DHT into the left lateral ventricle causes rapid loss of 5-HT from the forebrain with no considerable recovery up to 55 days following injection. Administration of 5,7-DHT into the fourth ventricle (termed intracisternal injection) evokes a less extensive and more delayed 5-HT depletion, with mild but significant recovery occurring

within 2 months of injection (Baumgarten et al. 1978a, b). The route of administration also influences the amount of nonspecific toxic damage to the CNS, which is higher when the neurotoxin is injected into the lateral ventricle than into fourth ventricle (Hedreen 1975).

5.2 The Speed and the Volume of Injection

The speed of 5,7-DHT injection affects the extent and symmetry of its action in periventricular structures when the neurotoxin is administered into one of the lateral ventricles. Comparison of two distinct velocities of injection revealed that slow infusion (1 μl/min) causes a more extensive reduction of amine uptake and leads to a more symmetric loss of 5-HT uptake (75 % and 50 % in the left and right striatum, respectively), while fast injection (3 μl/min) leads to asymmetric decreases in 5-HT uptake (Gershanik et al. 1979). Furthermore, large interindividual discrepancies can result from different times elapsing between the neurotoxin administration and sacrifice (2–7 days). Time of sacrifice is an important factor because the damage of 5-HT axons is a time-dependent process (Baumgarten et al. 1973, 1977). Slow versus fast 5-HT neurotoxin administration also produces entirely different results when observed at different time points. One hour after infusion, rapid injection causes symmetric, whereas slow injection causes asymmetric reduction in the 5-HT content of the brain. However, when assessment of 5-HT levels is performed 24 h after neurotoxin administration, initial differences become equalized (Baumgarten et al. 1982b).

5.3 The Influence of Anesthesia

There are inconsistent results regarding the influence of anesthesia on the efficiency of 5,7-DHT neurotoxicity. Baumgarten and collaborators (1982a) suggest that administration of pentobarbitone with ketamine does not exert a major effect on 5,7-DHT action, whereas in an earlier study, the application of pentobarbitone attenuated the toxicity of 5,6-DHT (Baumgarten et al. 1972). Furthermore, the anesthetic can affect not only the neurotoxin activity but also the activity of the catecholamine uptake blocker that is used to gain the high selectivity of the neurotoxin action. Pentobarbitone was shown to interfere with nomifensine in animals given a slow injection of 5,7-DHT (Baumgarten et al. 1982a).

6 Mechanism of 5,6- and 5,7-Dihydroxytryptamine Neurotoxicity

The mechanism of action of dihydroxylated tryptamines is connected with their uptake into neuronal terminals by the active transport systems that are normally responsible for the reuptake of 5-HT (Baumgarten et al. 1978c). The neurotoxins accumulate

intraneuronally to achieve a critical concentration that causes axonal damage. The specificity and potency of each neurotoxin is determined by its affinity for a given monoamine uptake mechanism, its rate of clearance via cellular metabolism, and the ability of its breakdown products to bind to proteins (Bjorklund et al. 1975c). Two major hypotheses have been proposed to explain the molecular mechanism that underlies the toxicity of 5,6- and 5,7-DHT. The first suggests that highly reactive (electrophilic) quinonoid intermediates, created as a result of 5,6- and 5,7-DHT auto-oxidation, bind covalently to molecules indispensable for neuronal function (Rotman et al. 1976). The second hypothesis states that during the auto-oxidation of dihydroxylated tryptamines, reactive oxygen species (ROS) such as superoxide radical anion (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($HO^{\cdot}$) are generated as toxic by-products (Baumgarten et al. 1978b, 1982a, b). Studies show that free radical scavengers can provide some protection to peripheral nerves against the degeneration caused by 5,7-DHT (Cohen and Heikkila 1978). Moreover, it has been speculated that quinine imine intermediates of 5,7-DHT can also trigger toxicity via an interaction with the electron transport chain (Klemm et al. 1980).

6.1 Mechanism of 5,7-DHT Action

The auto-oxidation of 5,7-DHT in a buffered aqueous solution at pH 7.4 causes the solution to turn pink (Schlossberger 1978; Cohen and Heikkila 1978; Tabatabaie et al. 1990). The auto-oxidation reaction is second order (Klemm et al. 1980) and at physiological pH leads to the formation of two major products – 5-hydroxytryptamine-4,7-dione and 6,6-bi-5-hydroxytryptamine-4,7-dione (Tabatabaie et al. 1990). Auto-oxidation of 5,7-DHT produces molecular oxygen that catalyzes the oxidation of brain mitochondria (Cohen and Heikkila 1978). This result was confirmed in 1980 by Klemm and collaborators. Moreover, they ruled out any pivotal participation of MAO in the catalytic action of mitochondria. Mitochondria play an important role in catalyzing the auto-oxidation of 5,7-DHT and may be sites of accumulation of damage caused by 5,7-DHT (Tabatabaie and Dryhurst 1998). In 1992, Tabatabaie and Dryhurst revealed that in the presence of superoxide dismutase (SOD), catalase, and diethylene triamine pentaacetic acid (DTPA), which eliminate the catalytic action of O_2^-, trace transition metal ions, and organic peroxy intermediates, the auto-oxidation of 5,7-DHT is much slower than normal. Among the transition metal ions, Fe^{3+}, Fe^{2+}, Cu^{2+}, and Mn^{2+} (Tabatabaie and Dryhurst 1992) are strong candidates to catalyze 5,7-DHT auto-oxidation. The rate of auto-oxidation decreases after catalase and SOD application but increases after the addition of O_2^-. The lack of a stimulatory effect after H_2O_2 administration is striking, especially considering inhibitory catalase action. It has been suggested that the ability of catalase to decompose organic peroxides plays pivotal role in the auto-oxidation of 5,7-DHT (Kadlubar et al. 1973). O_2^- also plays a role in auto-oxidation of 5,7-DHT. It is not only a by-product, but it also plays significant role in potentiating the rate of the reaction. Studies suggest that the catalytic action of O_2^- is not directly connected with oxidation of 5,7-DHT because O_2^- is a weak

oxidizing agent (Sawyer et al. 1978). However, it may react with organic hydroperoxides and contribute to a free radical chain reaction (Tabatabaie and Dryhurst 1998). Moreover, it has been proposed that O_2^- stimulates the deprotonation of 5,7-DHT, which is the initial step in auto-oxidation (Tabatabaie and Dryhurst 1992).

Due to its structure similarity to 5-HT, 5,7-DHT is taken up and concentrated in serotonergic nerve terminals (Baumgarten et al. 1978c). There, the result of 5,7-DHT oxidation is the generation of 5-hydroxytryptamine-4,7-dione and 6,6-bi-5-hydroxytryptamine-4,7-dione as major products. Both of these compounds are more toxic than 5,7-DHT. Their LD_{50} values, measured by ventricular administration in mice, are 30 and 25 μg, respectively, whereas the LD_{50} for 5,7-DHT is 52 μg (Tabatabaie et al. 1993). However, they do not have the ability to cause profound and long-lasting depletion of 5-HT as occurs after 5,7-DHT administration (Tabatabaie and Dryhurst 1998). The result of 5,7-DHT oxidation is the formation of O_2^- and H_2O_2, which, in the presence of trace levels of transition metal ions, cause the generation of cytotoxic $HO^{\cdot}$ (Halliwell 1992). The other effect of this auto-oxidation is increased consumption of molecular oxygen, leading to hypoxia, changes in metabolism, and cellular damage (Kappus 1986). The auto-oxidation product 5-hydroxytryptamine-4,7-dione also reacts with glutathione (GSH) to cause depletion of GSH storage, exacerbating damage caused by ROS (Tabatabaie and Dryhurst 1998).

6.2 Mechanism of 5,6-DHT Action

The ultimate product of 5,6-DHT auto-oxidation at physiological pH is a black, insoluble, melanin-like polymer (Klemm et al. 1980). The by-product of this reaction is a high amount of H_2O_2 (Klemm et al. 1980; Singh and Dryhurst 1990). Studies show that H_2O_2, O_2^-, and trace levels of transition metal ions play an important role in 5,6-DHT auto-oxidation because the application of catalase, SOD, and iron-complexing agents inhibit this reaction. However, the removal of agents such as transition metal ions and molecular oxygen from the reaction site causes 5,6-DHT not to be oxidized by H_2O_2 (Singh and Dryhurst 1990). In turn, the application of even very low amounts of Fe^{3+}, Cu^{2+}, and O_2^- augments the oxidation of 5,6-DHT. These results indicate that H_2O_2 does not participate directly in 5,6-DHT auto-oxidation, but it undergoes a transformation (via the transition metal ion-catalyzed Fenton reaction) leading to $HO^{\cdot}$ generation, which directly affects 5,6-DHT. In vitro as well as in vivo studies show that products of 5,6-DHT auto-oxidation undergo covalent binding with protein nucleophiles (Baumgarten et al. 1978b). However, auto-oxidation of 5,6-DHT ultimately leads to melanin-like polymer formation. An assessment of the role of covalent binding products of 5,6-DHT auto-oxidation revealed that they are not essential for the cytotoxic effects of 5,6-DHT (Sinhababu et al. 1985). The other mechanism that triggers the neurodegenerative action of 5,6-DHT is its ability to deplete intraneuronal antioxidants (e.g., GSH) and generate ROS that induce oxidative damage of lipids, proteins, and

DNA (Tabatabaie and Dryhurst 1998). The result of intraneuronal auto-oxidation of 5,6-DHT is the alkylation of proteins and, in favorable conditions, the cross-linking of proteins with GSH. Both reactions can lead to lethal consequences (Tabatabaie and Dryhurst 1998).

7 Behavioral Effects

At the beginning of this subsection, we would like to emphasize that there are age-related differences in the response of 5-HT neurons to dihydroxytryptamines. Young neurons display increased sensitivity to dihydroxytryptamines due to underdeveloped detoxifying mechanisms such as degrading enzymes, 5,7-DHT storage capacity, and the ability to scavenge radicals and neutralize oxidation intermediates through nucleophilic compounds such as GSH (Breese and Mueller 1978). Moreover, the accumulation of 5,7-DHT in the relatively small 5-HT perikarya of neonatal rats is more efficient than in adult rats where the surface/volume relationship is less favorable. Brain weight has to be taken into account because the brain weight of adult rats is about tenfold higher than newborn rats (Baumgarten et al. 1982b). On the other hand, infant brains have a greater potential for functional recovery than adult brains because they have greater potential for neuronal regeneration (Jonsson et al. 1978).

7.1 Adult Animal Studies

7.1.1 Changes in Locomotor Activity

Intraventricular administration of one of the dihydroxytryptamines (5,6- or 5,7-DHT) to rats causes dramatic behavioral changes (Massotti et al. 1974). Behavioral depression and sedation during the first 2 h after the infusion is typical (Baumgarten and Schlossberger 1973; Massotti et al. 1974). Following this initial period, increased irritability, explosive running, disorganized locomotion, and hyperreactivity to any type of sensory stimulation are observed. These responses are accompanied by bizarre social behavior (fighting in a stereotyped position and manner) and increased copulatory activity between the 1st and 3rd day after 5,6-DHT administration (Baumgarten and Schlossberger 1973). The greatest locomotor hyperactivity occurs during the first week after neurotoxin (5,7-DHT) administration (Pranzatelli and Snodgrass 1986b), and increased locomotor activity (LMA) persists 1–3 weeks following the intracisternal (Stewart et al. 1979) and intracerebroventricular (Lyness and Moore 1981) injection of 5,7-DHT. The stimulation of LMA has been observed after stereotactic injection of 5,7-DHT into the nucleus accumbens septi, substantia nigra, and striatum (Lyness and Moore 1981; Carter and Pycock 1981). The destruction of the medial raphe nuclei (MRN) also leads to increased LMA that manifests mainly as nocturnal hyperactivity and is correlated with hippocampal 5-HT depletion and a limbic mechanism (Geyer et al. 1976). The forebrain may be involved in the changes to LMA following the serotonergic manipulations (Geyer et al. 1976; Carter and Pycock 1981).

After this period of increased LMA, behavior returns to normal, and it is difficult to distinguish DHT-treated animals from controls. This normalization is termed "recovery" and is related to functional reorganization and supersensitivity (Glick 1974; Finger and Almli 1985). Despite the recovery of LMA, the supersensitivity to 5-hydroxy-L-tryptophan (L-5-HTP) may remain for at least 12 months after 5,7-DHT administration (Pranzatelli and Snodgrass 1986a). In 1978, Mackenzie and collaborators revealed that serotonin depletion by 5,7-DHT in rats causes tilt-cage hyperactivity but decreases activity in the open-field test. Kusljic et al. (2003) showed differential involvement of serotonergic projections deriving from medial raphe nuclei and dorsal raphe nuclei (DRN) in the regulation of locomotor hyperactivity. 5,7-DHT injected into the MRN causes a marked increase of phencyclidine-induced locomotor hyperactivity, whereas administration of DHT into the DRN does not.

7.1.2 Prepulse Inhibition

Prepulse inhibition (PPI) is a normal reduction of a startle response taking place when a weak stimulus occurs within a very short time period before a startle-evoking stimulus (Graham 1975). PPI measures sensorimotor gating and reflects the ability to filter out irrelevant stimuli. Fletcher et al. (2001) found that severe depletion of 5-HT (by 5,7-DHT injection into the DRN and MRN) disrupts PPI of the acoustic startle reflex without influencing basal startle activity. Kusljic and coworkers (2003) demonstrated that, similar to LMA, the MRN and DRN regulate PPI in different ways. 5,7-DHT injected into the MRN or the DRN leads to disruption of PPI, but the PPI effect is more significant in MRN-lesioned rats, while the startle amplitude is markedly increased in DRN-lesioned animals.

7.1.3 Seizure Susceptibility

The contribution of serotonin to seizure susceptibility was first suggested in 1954 by Chen and collaborators (Chen et al. 1954). They revealed that the seizure-facilitating effects of reserpine derive from its depletion of 5-HT as well as catecholamines. In adult rats pretreated with protriptyline and 5,7-DHT, the severity of pentylenetetrazol (PTZ)-induced seizures is augmented. These animals also display an earlier seizure onset and a greater severity of seizures than control rats that received vehicle pretreatment. Thus, 5,7-DHT-treated rats seem to be more seizure prone than controls (Browning et al. 1978). Similar results have been obtained by Trindade-Filho and coworkers (2008), who assessed the effects of 5,7-DHT administration into the MRN in a rat pilocarpine model of epilepsy. They showed that the frequency of seizures in treated animals was significantly increased compared to control rats.

7.1.4 Serotonin Syndrome

The classical 5-HT syndrome manifests as lateral head "weaving" (side-to-side movement), reciprocal forepaw "treading," "resting tremor," hindlimb abduction, rigidly arched (Straub) tail, hyperreactivity to auditory stimuli, limb and axial rigidity or hypertonicity, and autonomic responses (salivation, erection, and

ejaculation) (Jacobs 1976). Dihydroxytryptamines evoke supersensitivity to 5-HT precursors and agonists. Studies in 5,7-DHT-treated adult rats revealed that application of L-5-HTP (precursor of 5-HT) leads to 5-HT syndrome (Browning et al. 1978). Low doses of 5-hydroxytryptophan (5-HTP) cause a self-limiting syndrome characterized by the appearance of myoclonus, other dyskinesias, stereotypies, and abnormalities of posture and tone (Stewart et al. 1976, 1979; Pranzatelli and Snodgrass 1986b). It has been suggested that the brainstem and spinal cord are the brain areas involved in mediating this serotonergic behavioral syndrome (Jacobs and Klemfuss 1975).

7.1.5 Feeding and Drinking Behavior

Intraventricular injection of dihydroxytryptamines leads to immediate and transient anorexia, hypodipsia, and weight loss. However, treated animals quickly return to normal body weight and show normal patterns of food and water intake; permanent alteration of drinking preference is rare (Myers 1975; Melchior and Myers 1976). Saller and Stricker (1976) suggested that the inability to observe consistent changes in digestive behavior derives from the effect of dihydroxytryptamines on neurons containing NA. They showed that animals treated with desmethylimipramine and subsequently intraventricularly with 5,7-DHT become hyperphagic and obese, but animals injected with only 5,7-DHT show no change or minor reductions in eating, drinking, and body weight (Saller and Stricker 1976). Opposite results were reported by Myers (1978) in monkeys and rats treated with 5,6-DHT infused directly into hypothalamic structures. A significant reduction of food consumption was observed in monkeys following neurotoxin infusion in the anterior hypothalamic, preoptic region. Water consumption was decreased but not significantly different from the baseline intake. In most cases, the decline of food and water intake occurred not only on the day of 5,6-DHT injection but also on the following day. In rats, hypophagia lasts 4–5 days after the infusion. Water consumption in rats was changed in a similar manner as was food intake. Further, rats lost between 30 g and 50 g of body weight at the higher doses of 5,6-DHT (Myers 1978). The comparison of food intake and body weight studies involving administration of 5,6-DHT, 5,7-DHT, and 6-OHDA to different strains of rats reveals that 5,7-DHT injected intraventricularly produces the greatest loss of body weight (Melchior and Myers 1976).

7.1.6 Body Temperature

In 1963, it was first suggested that 5-HT within the anterior hypothalamus participates in the control of heat production (Feldberg and Myers 1963). Currently, we know that neurons containing 5-HT take part in the regulation of body temperature, but we still do not know the exact role of this transmitter in the mechanism due to inconsistent results between different studies. The effects of dihydroxytryptamines depend on the species and the interval between drug injection and examination. In rats, intraventricular injection of 5,6-DHT causes immediate, transient hypothermia (Breese et al. 1974a). On the other hand, studies in rats and monkeys suggest that infusion of 5,6-DHT into the anterior hypothalamus causes not hypo- but

hyperthermia (Waller and Myers 1974; Myers 1975). Myers (1978) emphasizes that the thermic response to 5,6-DHT is dose dependent and if too large a dose of neurotoxin is injected, transient hypothermia always precedes the hyperthermia.

7.1.7 Sexual Behavior

Neurons containing 5-HT mediate the inhibition of copulatory behavior (Meyerson 1964, 1966). Studies using serotonergic neurotoxins confirm that serotonin nerves inhibit sexual behavior and depletion of 5-HT increases sexual activity in rats (Da Prada et al. 1972). Intracerebroventricular injection of 5,6-DHT induces hyperexcitability and fighting in rats. The main characteristic effect of such treatment is mounting activity (Da Prada et al. 1972; Baumgarten and Schlossberger 1973). If 5-HT levels are normalized by 5-HTP administration, mounting behavior is completely abolished. Similar effects were observed in 5,7-DHT-lesioned rats treated with 5-HTP. Grouped female rats injected with 5,7-DHT also exhibit sexual activity analogous to the mounting displayed by male rats. A similar effect can be triggered by 5,6-DHT treatment. In addition, protection of 5-HT neurons with the 5-HT inhibitor Lu 10-171 before 5,7-DHT administration prevents fighting and mounting behaviors (Da Prada et al. 1978).

7.1.8 Aggressive Behavior

Serotonergic neurons may play a pivotal role in predatory and irritable aggression, defined as aggressive behavior against an animal of another species and against animals of any species triggered by an aversive stimulus, respectively (Eichelman and Thoa 1973). Depletion of 5-HT increases predatory aggression toward mice (also termed muricidal behavior). Intracisternal injection of 5,6-DHT evokes a marked increase in muricidal behavior, even 1 week after infusion. Pretreatment with pargyline significantly augments this predatory aggression. Similar results were found in rats injected with 5,6-DHT in the midbrain raphe nuclei. However, pargyline pretreatment did not significantly increase muricidal behavior (Breese et al. 1974a). Intracisternally injected 5,7-DHT also increases muricidal behavior, observed 19 days after neurotoxin administration. Treatment with 5,7-DHT, pargyline + 5,7-DHT, or desipramine + 5,7-DHT causes killing in 71 %, 89 % and 40 % of rats, respectively (Breese and Cooper 1975).

7.1.9 Response to Novel and Noxious Stimuli

The presentation of a novel stimulus triggers exploratory activity and behavioral vigilance. Subsequent exposures to the same stimulus cause a graded attenuation of these behaviors until they completely disappear. Neural processes termed habituation and sensitization are responsible for this behavior (Davis and Sheard 1974). 5-HT is involved in both the sensitization process (Carlton and Advokat 1973) and the response to a noxious stimulus (Messing and Lytle 1977). However, investigations with 5,6-DHT or 5,7-DHT injected intraventricularly (Blasig et al. 1973) or directly into the midbrain (Hole and Lorens 1975) did not reveal any changes in the behavioral response to noxious stimuli. Lieben and collaborators (2006) found that 5,7-DHT lesion of the dorsal raphe nuclei impairs the ability to identify a novel object.

7.1.10 Learning and Memory Functions

It has been suggested 5-HT participates in both short-term and long-term memory (Bailey et al. 1992; Barbas et al. 2003). There is some literature showing that 5,7-DHT injection does not change learning and memory capabilities even when severe 5-HT depletion is induced electrolytically (Asin and Fibiger 1984). However, there are also data providing quite distinct results that show that 5,7-DHT administration affects short-term memory. Hritcu and collaborators (2007) found that disruption of short-term memory does not accompany alterations in long-term memory. Ciobica et al. (2010) found a significant defect in short-term memory, demonstrated by working memory errors in the radial arm maze. Ricaurte and coworkers (1993) noted an impairment of choice accuracy following 5,7-DHT treatment, which also suggests alterations in short-term memory. Moreover, Cassaday et al. (2003) found that rats treated with 5,7-DHT had difficulty in learning new tasks but no impairment in performing previously learned working memory tasks. However, data demonstrating a lack of short-term memory deficits after neurotoxin injection also exist (Wirth et al. 2000).

7.1.11 Effect of Dihydroxytryptamines on the Antinociceptive Actions of Drugs

5-HT is involved in determining the pain threshold and in regulating the perceptual and behavioral responses to painful stimuli (Lorens 1978). Decreasing 5-HT levels (by different methods) reduces the analgesic potency of morphine (Tenen 1968), whereas increasing 5-HT concentrations augments morphine analgesia (Sewell and Spencer 1974). However, not all results confirm this hypothesis. Some studies indicate that mesencephalic raphe lesions and intra-midbrain infusion of 5,7-DHT (10 μg) do not change pain sensitivity (Harvey et al. 1974; Hole and Lorens 1975). Blasig and collaborators (1973) noticed that intraventricular injection of 5,6-DHT did not significantly change the antinociceptive effect of morphine. Moreover, they showed that neurotoxin did not affect the stimulation threshold before morphine administration. These results suggest that a decreased 5-HT level is not sufficient to trigger the development of hyperalgesia (Lorens 1978). On the other hand, the majority of studies show different results. Genovese and collaborators (1973) found that, following intraventricular injection of 5,6-DHT in rats, the pain threshold was modestly but not significantly reduced. Following morphine infusion, the pain threshold was clearly increased in controls and sham-injected animals, but in rats that received 5,6-DHT, it was only slightly augmented. This result demonstrates that 5,6-DHT treatment reduces the antinociceptive action of morphine. Similar effects have been obtained in intrathecally 5,6- and 5,7-DHT-injected rats. Both neurotoxins evoke a decrease in the analgesic action of morphine, and no marked distinctions were noted between animals treated with 5,6- or 5,7-DHT (Rodriguez and Rodriguez 1989).

7.1.12 Sleeping Behavior

Manipulations that reduce forebrain 5-HT also decrease the duration of slow-wave sleep. This suggests a pivotal role for 5-HT in the initiation as well as maintenance

of this stage of sleep (Jouvet 1969, 1972). Studies in cats have shown that intraventricular injection of 5,6-DHT causes long-term reductions in slow-wave and REM (rapid eye movement) sleep time (Jouvet and Pujol 1974). Analogous results were not observed following intraventricular infusion of 5,7-DHT in rats. 5,7-DHT does not prominently affect the circadian pattern of sleep. The interesting difference between 5,7-DHT-treated and control rats was the amount of paradoxical sleep, which was significantly higher for the 5,7-DHT group on days 6 and 8. Additionally, 5,7-DHT rats displayed a large number of long duration paradoxical sleep epochs (Ross et al. 1976). Moreover, Jouvet and Pujol (1974) showed that direct administration of 5,6-DHT into the dorsal raphe or superior centralis nuclei of cats leads to a transient decrease in slow-wave sleep and markedly increases the duration of REM sleep within the first 24 h after treatment. These parameters subsequently return to normal. In 1978, Pujol and collaborators revealed that selective and diffuse damage of 5-HT terminals in cats causes a marked increase in waking time. Such evoked insomnia might be derived from decreases of stage 2 and paradoxical sleep as well as a simultaneous increase of the waking mechanism.

7.1.13 Neuroendocrine Consequences of Dihydroxytryptamine Administration

Many studies of the role of 5-HT in neuroendocrine regulatory mechanisms have used dihydroxytryptamines. In 1974, Ladosky and Noronha (1974) revealed that 5,6-DHT prominently increases the release of gonadotropin. However, other studies have provided different results. Significant changes in plasma and pituitary follicle-stimulating hormone (FSH) levels were not observed in rats treated at 21–23 days of age with 5,6-DHT (Saller and Stricker 1976). The influence of 5,7-DHT on plasma prolactin concentration has also been studied. Gil-ad et al. (1976) demonstrated that 5,7-DHT causes a reduction in prolactin levels, whereas Wuttke et al. (1978) and Clemens (1978) found no impairments in prolactin release in animals injected with 5,7-DHT. There are also inconsistent results in studies of the influence of 5-HT neurotoxins on growth hormone (GH). Collu (1978) showed that 5,6-DHT does not affect GH levels in male prepubertal rats, whereas Baumgarten and Bjorklund (1976) found that administration of 5,7-DHT increases plasma GH concentration.

7.1.14 Effect of 5,7-DHT on the Dopaminergic System

When 5,7-DHT was administered in adulthood to rats that were neonatally lesioned with 6-hydroxydopamine, attenuated dopamine D_1 receptor supersensitivity and intense spontaneous hyperlocomotor activity were observed (Kostrzewa et al. 1994). Amphetamine and m-chlorophenylpiperazine attenuation of the profound hyperlocomotion in rats lesioned with both 6-hydroxydopamine and 5,7-DHT reinforces the suggestion that such rats are a useful animal model of attention deficit hyperactivity disorder (Kostrzewa et al. 1994; Brus et al. 2004; Nowak et al. 2007).

7.2 Neonatal Animal Studies

7.2.1 Locomotor Activity

Studies suggest that serotonergic pathways play an inhibitory role in LMA (Breese et al. 1974b; Hollister et al. 1976). Neonatal rats injected with 5,7-DHT also display hyperactivity that persists for 1 month after the injection of neurotoxin. Breese and Mueller (1978) showed that the depletion of brain amines was greater in juveniles than in adults despite the lower doses of 5,7-DHT used. Moreover, they reported a significant fivefold elevation in LMA at 14 days in animals treated with 50 μg of 5,7-DHT at 3 days of age. The LMA of animals treated with pargyline prior to 5,7-DHT was comparable to rats treated 5,7-DHT alone. This result suggests that rats pup hyperactivity does not require a reduction of NA fibers that increased LMA in adult rats (Smith et al. 1973). However, when the rats are tested at 28 days of age, the neurotoxin-treated groups demonstrate considerably less LMA than the control group (Breese and Mueller 1978).

7.2.2 Seizure Susceptibility

Pranzatelli and collaborators (Pranzatelli et al. 1989) demonstrated that intracisternal application of 5,7-DHT causes transient postinjection convulsions in rat pups. The first infusion leads to continuous paddling and writhing for at least 30 min without forward locomotion or vocalization. Moreover, 11 of 13 rats that received 5,7-DHT were unable to stand upright and fell over on their backs or sides. Subsequent 5,7-DHT injections caused more severe convulsions, whereas intraperitoneal injection of 5,7-DHT did not induce seizures during the 2-hour period of observation (Pranzatelli et al. 1989).

7.2.3 Serotonin Syndrome

Intracisternal and intraperitoneal injection of 5,7-DHT into rat pups, followed by the administration of 5-HTP 2 and 14 weeks later, leads to behavioral supersensitivity in adult rats. Both routes of 5,7-DHT administration provide supersensitivity to 5-HTP, but shaking behavior is greater following intraperitoneal infusion, whereas forepaw myoclonus and head weaving are greater following intracisternal injection (Pranzatelli et al. 1989).

7.2.4 Body Weights

A comparison of body weights between 5,7-DHT-treated rats and control animals at 14 days of age revealed that the former had markedly lower body weights. Pretreatment with pargyline prevents this weight loss. One possible explanation of this difference is that neurotoxin-treated rat pups bite the mother during suckling, which causes them to receive less nutrition (Breese and Mueller 1978).

7.2.5 Learning and Memory Function

Volpe et al. (1992), in their research with intracisternally administered 5,7-DHT to three-day-old rat pups pretreated with pargyline, revealed that 5,7-DHT destroys 5-HT neurons but does not influence spatial memory, tested by the Morris water

maze and the 12-arm radial maze. We also demonstrated that despite a severe and permanent decrease in hippocampal, prefrontal, and striatal 5-HT levels, neonatal treatment with 5,7-DHT caused no spatial learning and memory impairment in the Morris water maze (Piechal et al. 2012).

7.2.6 Emotional and Exploratory Behaviors

In our study, neonatal 5,7-DHT depletion reduced LMA in the open-field test and attenuated social interaction in non-aversive conditions and exploration of a novel objects in adult rats. Ultravocalization, but not freezing, was increased in the contextual fear-conditioning paradigm in 5-HT-depleted rats. There was no difference in the pain threshold between groups (Rok-Bujko et al. 2012).

7.2.7 Prepulse Inhibition

Our results clearly demonstrated that neonatal 5,7-DHT depletion does not interrupt PPI of the acoustic startle reflex. In contrast to the effect on PPI, neonatal treatment with 5,7-DHT increased basal startle activity (Kołomańska et al. 2011).

7.2.8 Developmental Plasticity

Studies using several doses and schedules of 5,6-DHT administration in rat pups revealed that this neurotoxin is not useful for research in developmental studies because most pups died soon after treatment. Conversely, 5,7-DHT is well tolerated by young animals, even when injected repeatedly in doses up to 200 mg/kg. Systemic injection of 5,7-DHT in neonatal rats caused changes in 5-HT neurons that did not occur in adult animals. These changes include significant denervations of most distally located 5-HT nerve terminals, but cell bodies often remain intact. Moreover, in regions adjacent to cell bodies, compensatory outgrowth occurs that causes an increased number of 5-HT nerve terminals. This mechanism leads to redistribution of the terminals and bifurcations of 5-HT neurons and is termed "pruning" and "sprouting," respectively (Jonsson et al. 1978).

7.2.9 Effect of 5,7-DHT on Dopaminergic, Noradrenergic, and Histaminergic Systems

Neonatal 6-hydroxydopamine treatment is associated with supersensitization of dopamine D_1 receptors, and this effect was attenuated by neonatal 5,7-DHT depletion (Brus et al. 1994). In contrast, the neonatal destruction of 5-HT fibers by 5,7-DHT produces supersensitization of the dopamine D_2 receptor complex (Brus et al. 1995). Furthermore, the ontogenic destruction of serotonergic and noradrenergic neurons in rat brain is associated with prominent D_2 and D_3 receptor supersensitivity, as reflected by enhanced dopamine D_2 and D_3 agonist-induced stereotyped activities (Nowak et al. 2009). These findings indicate that both serotonergic and noradrenergic fibers have important influence on the process of dopamine D_1 and D_2 receptor sensitivity.

Finally, there is some evidence that ontogenetic 5-HT depletion alters histaminergic activity in adult rats. Neonatal 5,7-DHT treatment of rats was associated with enhanced oral and locomotor activity induced by the histamine H_3 receptor antagonist thioperamide (Jośko et al. 2011).

8 Conclusion

5,6-dihydroxytryptamine (5,6-DHT) and 5,7-dihydroxytryptamine (5,7-DHT) are serotonin neurotoxins able to selectively destroy central serotonin neurons when catecholaminergic neurons are protected. Both compounds are indole derivatives, and their neurotoxicity derives from the additional hydroxyl group compared to serotonin (5-HT). The administration of 5,6- or 5,7-DHT to animals is a useful method to study the role of serotonin neurons and pathways in the central nervous system (CNS). Despite high structural similarity, 5,6-DHT differs from 5,7-DHT. The basic differences are connected to the ability of 5,6-DHT to rapidly oxidize and form consecutive melanin-like polymers. These features lower the neurotoxicity of 5,6-DHT to 5-HT neurons and make it more generally cytotoxic. Therefore, 5,7-DHT is used more frequently. The action of serotonin neurotoxins depends on the proper selection of injection sites, the speed and volume of administration, the type and amount of antioxidant used, and the type and dose of catecholamine uptake blocker used to prevent nonspecific toxicity. The mechanism of dihydroxytryptamine action assumes that, because of their structurally similarity to 5-HT, they accumulate in 5-HT neurons where the products of their oxidation bind covalently to molecules indispensable for neuronal function. Moreover, reactive oxygen species (ROS) generated as by-products of oxidation also contribute to the destruction of 5-HT neurons. The use of 5,6- and 5,7-DHT in both adult and neonatal animals enables the recognition the role of 5-HT in locomotor activity (LMA), prepulse inhibition, seizure susceptibility, sleeping behavior, feeding and drinking behavior, sexual and aggressive behavior, the regulation of body temperature, the response to novel and noxious stimuli, learning and memory, the antinociceptive action of drugs, neuroendocrine regulatory mechanisms, and developmental plasticity.

2′-NH_2-MPTP: A Serotonin and Norepinephrine Neurotoxin

Jason B. Ochroch, Amanda J. Bressler, Hongyan Yang, Dennis L. Murphy, Stefanie C. Altieri, and Anne M. Andrews

Contents

Abstract

Altered serotonin and norepinephrine neurotransmission has been implicated in a variety of psychiatric and neurodegenerative diseases. Selective ablation of these systems represents one avenue for studying their roles in normal behavior, disease processes, and therapeutic interventions. 2′-NH_2-MPTP, an amine-substituted analog of the dopaminergic neurotoxin MPTP, can be used to degenerate serotonin and/or norepinephrine forebrain innervation to investigate

pathophysiological and behavioral consequences in several strains of mice, rats, and nonhuman primates. 2′-NH_2-MPTP is converted to a toxic metabolite by monoamine oxidase type-A and type-B. This metabolite, a presumed pyridinium, is a substrate for serotonin and norepinephrine transporters. Acute effects immediately following 2′-NH_2-MPTP administration are characteristic of serotonin syndrome. Genetic, biochemical, and immunocytochemical evidence indicates that neurodegeneration caused by 2′-NH_2-MPTP is selective, long lasting, and occurs by an oxyradical mechanism.

List of Abbreviations

2′-NH_2-MPP^+	1-Methyl-4-(2′-aminophenyl)-phenylpyridinium
2′-NH_2-MPTP	1-Methyl-4-(2′-aminophenyl)-1,2,3,6-tetrahydropyridine
5-HIAA	5-Hydroxyindoleacetic acid
5-HT	5-Hydroxytryptamine serotonin
5,6-DHT	5,6-Dihydroxytryptamine
5,7-DHT	5,7-Dihydroxytryptamine
BDNF	Brain-derived neurotrophic factor
CSF	Cerebrospinal fluid
DA	Dopamine
DAT	Dopamine transporter
DOPAC	3,4Dihydroxyphenylacetic acid
DSP-4 N	(2-Chloroethyl)-N-ethyl-2-bromobenzylamine hydrochloride
GFAP	Glial fibrillary acidic protein
HVA	Homovanillic acid
Ip	Intraperitoneal
Iv	Intravenous
LD_{50}	Median lethal dose
MAO-A	Monoamine oxidase type-A
MAO-B	Monoamine oxidase type-B
MHPG	3-Methoxy-4-hydroxyphenylglycol
MPP^+	1-Methyl-4-phenylpyridinium
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
NE	Norepinephrine
NET	Norepinephrine transporter
PET	Positron emission tomography
Ro 4–1284	2-Hydroxy-2-ethyl-3-isobutyl-9,10-dimethoxy-1,2,3,4,5,6,7-hexahydrobenzo[a]chinolizine
SERT	Serotonin transporter
VMAT2	Vesicular monoamine transporter type-2

1 Introduction

Changes in brain monoamine neurotransmitters, i.e., serotonin, norepinephrine, and dopamine, are involved in many neuropsychiatric illnesses and their treatment, including major depressive disorder, anxiety disorders, and schizophrenia (Nestler et al. 2008; López-Muñoz and Álamo 2012). Moreover, degeneration of monoamine neurotransmitter systems is linked with normal aging and late-onset neurological diseases such as Parkinson's disease and Alzheimer's disease. However, studying brain disorders is inherently complicated by difficulties associated with the long time frames over which pathologies develop, the relative inaccessibility of investigating neurotransmission in humans, modeling and relating complex pathophysiology to specific endophenotypes, and a poor understanding of underlying etiologies. As such, chemical neurotoxins that cause controlled and selective damage to monoamine neurotransmitter systems in animals provide avenues to investigate aspects of specific neurotransmitter loss and neurodegeneration as they pertain to brain disorders.

2 Discovery of 2′-NH_2-MPTP

The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) produces degeneration of dopamine (DA) nigrostriatal neurons, which is the hallmark of idiopathic Parkinson's disease. MPTP came to the forefront in the early 1980s when a group of northern California drug users developed irreversible parkinsonian-like symptoms (Langston and Palfreman 1995). MPTP, a by-product of the illicit synthesis of a derivative of the opioid meperidine, was discovered as the causative agent.

Many analogs of MPTP have been synthesized for structure-activity studies (Bradbury et al. 1985; Youngster et al. 1987, 1989; Heikkila et al. 1988; Booth et al. 1989; Johnson et al. 1989; Maret et al. 1990; Saporito et al. 1992). MPTP-related compounds with a substituent at the 2′ position, i.e., 2′-R-MPTP, R = CH_3, CH_2CH_3, Cl, F, and CF_3, have been shown to be potent dopamine neurotoxins. Amine-functionalized MPTP analogs were of interest because of the ability to covalently cross-link primary amines to brain tissue via aldehyde fixation. When coupled with immunohistochemical detection, amine-substituted MPTP compounds could be useful in mapping distribution at the ultrastructural level (Johannessen et al. 1987). However, adding an amine substituent to various positions on the phenyl ring of MPTP led to analogs that were relatively weak dopamine neurotoxins in mice.

Interestingly, the 2′-amino-substituted MPTP derivative, 1-methyl-4-(2′-aminophenyl)-1,2,3,6-tetrahydropyridine (2′-NH_2-MPTP; Fig. 1a), produced reductions in striatal serotonin (5-HT) and its metabolite, 5-hydroxyindoleacetic acid (5-HIAA), while having no effect on dopamine in striatum (Johannessen et al. 1987). Because the goals of Johannessen et al. were to use amino-substituted analogs of MPTP to study toxicity related to Parkinsonism, no further work with

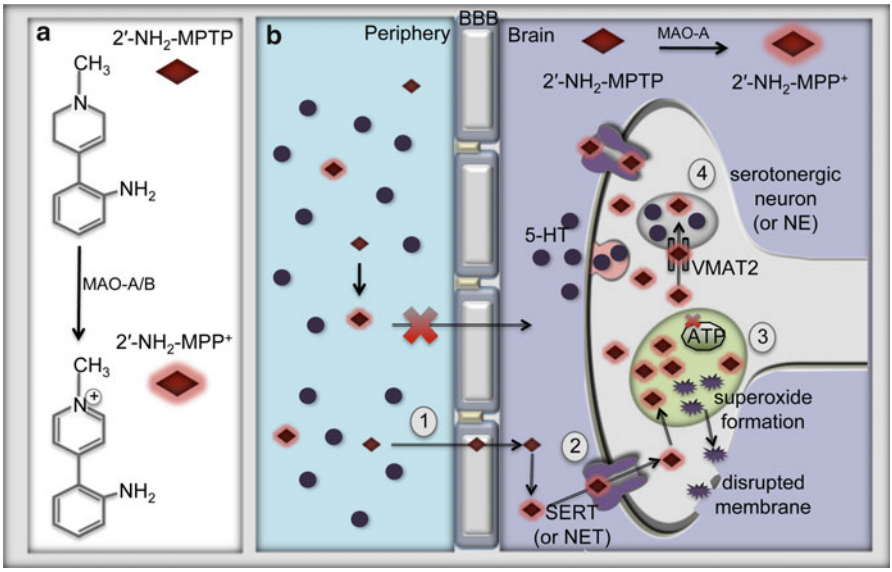

Fig. 1 *Mechanisms of serotonin and norepinephrine neurotoxicity after exposure to 2′-NH$_2$-MPTP*. (**a**) Shown is the chemical structure of 2′-NH$_2$-MPTP, a structural analog of the dopamine neurotoxin MPTP. Toxicity due to 2′-NH$_2$-MPTP is inhibited by pretreating mice with monoamine oxidase type-A (MAO-A) and/or MAO-B inhibitors. Similar to MPTP, which is converted to MPP$^+$ by MAO-B, 2′-NH$_2$-MPTP is hypothesized to be converted to a toxic pyridinium, 2′-NH$_2$-MPP$^+$. (**b**) (1) While 2′-NH$_2$-MPTP appears to cross the blood–brain barrier, 2′-NH$_2$-MPP$^+$ is not expected to do so based on findings with MPP$^+$. 2′-NH$_2$-MPTP toxicity is prevented by inhibiting plasma membrane serotonin transporters (SERT) or norepinephrine transporters (NET), which is hypothesized to block uptake of 2′-NH$_2$-MPP$^+$ into serotonin and norepinephrine (NE) neurons, respectively. (3) Superoxide radicals are thought to be formed at mitochondria leading to membrane instability, DNA damage, and ultimately, axonal degeneration and to a lesser extent, cell death. Increasing superoxide dismutase activity prevents 2′-NH$_2$-MPTP-induced toxicity. (4) Unlike MPP$^+$, which is readily accumulated in synaptic vesicles via vesicular monoamine transporters type-2 (VMAT2), 2′-NH$_2$-MPP$^+$ appears to be a weaker substrate for VMAT2 and only low dose 2′-NH$_2$-MPTP toxicity is potentiated by pharmacologic or genetic inhibition of VMAT2

2′-NH$_2$-MPTP appeared warranted. However, the effects of 2′-NH$_2$-MPTP on serotonin did not escape notice, and several years later, additional research established the unique neurotoxicity of 2′-NH$_2$-MPTP (Andrews and Murphy 1993a, b, c).

3 2′-NH$_2$-MPTP Is a Serotonin and Norepinephrine Neurotoxin in Mice

Initial investigation confirmed striatal serotonin loss in response to 2′-NH$_2$-MPTP administration (Andrews and Murphy 1993a). Furthermore, 2′-NH$_2$-MPTP was

shown to decrease norepinephrine (NE), in addition to serotonin in the forebrain, in contrast to the dopamine-selective toxicity produced by MPTP and its most potent analog, 2′-CH_3-MPTP. When administered to C57Bl/6 mice, 2′-NH_2-MPTP reduced serotonin, 5-HIAA, and norepinephrine levels by 70 % in frontal cortex and 60 % in hippocampus, with depletions occurring to a lesser extent in striatum and brain stem. Dopamine and its major metabolites, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), were relatively unaffected 1 week after 2′-NH_2-MPTP (Andrews and Murphy 1993a). Notably, no other MPTP analogs, including all amino-substituted and 2′-substituted analogs, have been reported to produce similar serotonin and norepinephrine neurotoxicity in mice.

4 Acute Effects of 2′-NH_2-MPTP

The median lethal dose (LD_{50}) is the dose required to kill half of a treated population and is an indicator of the acute lethality of substances. The LD_{50} for 2′-NH_2-MPTP in C57Bl/6 mice is 20–40 mg/kg, ip (Andrews and Murphy 1993a). It is likely to be similar in Swiss Webster mice (Andrews and Murphy 1993b) and somewhat lower in CD-1 mice (Andrews et al. 1996). When treated with high doses of 2′-NH_2-MPTP, i.e., $\geq$40 mg/kg, mice had tonic-clonic seizures and died shortly afterwards (Andrews and Murphy 1993a). Tonic-clonic seizures followed by death in some cases also occurred in rats at 20 mg/kg 2′-NH_2-MPTP (Unger et al. 2002). Acute and massive release of monoamine neurotransmitters has been shown to cause precipitous elevations in blood pressure and heart rate (Fuller et al. 1988). Death subsequent to high-dose 2′-NH_2-MPTP administration is likely to be due to cardiovascular consequences and not neurodegeneration.

Similar to MPTP, the dose regimen most commonly used for 2′-NH_2-MPTP in rodents consists of four intraperitoneal (ip) injections (15–20 mg/kg) at 2-h intervals. Behavioral changes in mice and rats immediately following each injection include piloerection, salivation, Straub (straight) tail, flattened body posture, intermittent walking, forepaw treading (piano-playing), and wet-dog shakes. Behavioral responses generally subside prior to each subsequent injection of 2′-NH_2-MPTP and become less pronounced after repeated injections. Acute behavioral changes in rodents are characteristic of serotonin syndrome, which results from large increases in central serotonin release (Zhang et al. 2009). Serotonin syndrome arising from single drug overdose or multiple serotonergic agents acting via different but converging mechanisms is potentially life threatening in humans (Boyer and Shannon 2005).

Serotonin is also known to be involved in thermoregulation (Murphy et al. 1991). Acutely, 2′-NH_2-MPTP causes a decrease in core body temperature in mice (Numis et al. 2004). This hypothermic effect is similar to that seen after MPTP (Freyaldenhoven et al. 1995; Moy et al. 1998) but opposite to substituted amphetamines, which cause hyperthermia (Miller and O'Callaghan 1995). It is not known why 2′-NH_2-MPTP and substituted amphetamines, both of which are thought to cause acute serotonin release, have differing effects on core body temperature.

Loss of serotonin and norepinephrine in frontal cortex and hippocampus has been detected as early as 30 min after the last injection of 2′-NH_2-MPTP in mice (Luellen et al. 2003). In contrast, decreases in 5-HIAA developed slowly over the first week after treatment. This probably reflects high levels of metabolism of serotonin from degenerating axons. In striatum, hypothalamus, and brain stem, where long-term depletions are more modest, serotonin and norepinephrine levels showed substantial recovery over the 72 h period following treatment. Transient decreases (30–40 %) in striatal dopamine were also reported during the initial 2 h after 2′-NH_2-MPTP, but dopamine levels recovered by 24 h posttreatment. Thus, forebrain serotonergic and noradrenergic axons that project far from their origins in the brain stem show the most pronounced early evidence of toxicity. In addition to acute behavioral, physiological, and neurochemical changes, mice show a 1–2 g decrease in body weight during the first 48 h after 2′-NH_2-MPTP. Throughout the first week after exposure, mice exhibit noise sensitivity and agitation.

5 Mechanism of Action of 2′-NH_2-MPTP

While the mechanisms underlying 2′-NH_2-MPTP-induced neurotoxicity are not fully understood, they have many similarities to those of MPTP. Both are small, lipophilic molecules that cross the blood–brain barrier (Fig. 1b). MPTP is a prodrug that requires oxidation by monoamine oxidase type-B (MAO-B) to exert toxicity as 1-methyl-4-phenylpyridinium (MPP^+) (Markey et al. 1984; Heikkila et al. 1985). 2′-NH_2-MPTP is oxidized by both MAO-B and monoamine oxidase type-A (MAO-A) (Fig. 1b) (Andrews and Murphy 1993b; Andrews 2000). Therefore, like MPTP, 2′-NH_2-MPTP probably exerts its toxic effects through the oxidized pyridinium, 2′-amino-1-methyl-4-phenylpyridinium (2′-NH_2-MPP^+) (Fig. 1a). Preliminary findings show monoamine oxidase-dependent production of 2′-NH_2-MPP^+ in brain tissue incubated with 2′-NH_2-MPTP. 2′-NH_2-MPP^+ was identified by tandem mass spectrometry and comparison with authentic 2′-NH_2-MPP^+ via high-performance liquid chromatography.

The MAO-catalyzed metabolite of 2′-NH_2-MPTP gains access to serotonergic and noradrenergic neurons via serotonin transporters (SERT) and norepinephrine transporters (NET), respectively (Andrews and Murphy 1993b, c; Numis et al. 2004) (Fig. 1b), just as MPTP targets dopaminergic neurons via uptake of MPP^+ by dopamine transporters (DAT) (Melamed et al. 1985; Gainetdinov et al. 1997). Studies have shown that pretreating mice with the serotonin-selective reuptake inhibiting antidepressants fluoxetine or paroxetine prevent 2′-NH_2-MPTP-induced serotonergic neurotoxicity (Andrews and Murphy 1993b, c). Pretreatment with the norepinephrine-selective reuptake inhibitor desipramine prevents norepinephrine depletion. 2′-NH_2-MPTP neurotoxicity can also be limited by genetic inactivation of SERT to produce selective loss of norepinephrine (Numis et al. 2004).

Administration of 2′-NH_2-MPTP to mice genetically deficient in NET (Xu et al. 2000) has not been investigated.

Similar to MPTP, 2′-NH_2-MPTP appears to cause neurotoxicity via generation of oxygen free radicals. MPP^+ has been shown to block the mitochondrial respiratory chain by inhibiting complex I (Cleeter et al. 1992) with two major consequences. First, conversion of NAD^+ to NADH is decreased, which interferes with mitochondrial proton gradients and subsequent production of ATP, depleting neurons of vital chemical energy. Second, metabolic disruption is purported to cause oxidative stress associated with an increase in oxyradicals and damage to DNA, proteins, and the cytoskeleton (Halliwell 1992). Mice genetically engineered to overexpress Cu-Zn superoxide dismutase, the soluble enzyme isoform that converts highly toxic superoxide radicals to hydrogen peroxide, were protected from 2′-NH_2-MPTP toxicity, implicating superoxide mechanistically (Andrews et al. 1996). Together, findings on 2′-NH_2-MPTP and MPTP suggest that inhibition of mitochondrial complex I by pyridiniums to generate oxyradicals is a primary mechanism of toxicity, not release and auto-oxidation of dopamine, which is specific to MPTP.

In addition to differential transporter specificity, there is another key difference between the molecular mechanisms of 2′-NH_2-MPTP and MPTP. Previous studies have shown that MPP^+ is a substrate for the vesicular monoamine transporter type-2 (VMAT2), and sequestration of MPP^+ into synaptic vesicles reduces neurotoxicity (Gainetdinov et al. 1998; Staal and Sonsalla 2000b). Thus, MPP^+ mimics dopamine via high-affinity transport by DAT and VMAT2. In general, vesicular sequestration of exogenous toxins by VMAT2 has been implicated as one of several lines of neuronal defense (Miller et al. 1999). However, 2′-NH_2-MPP^+ appears to be a poor substrate for VMAT2 (Numis et al. 2004). Mice with partial genetic reductions in VMAT2 expression, as well as mice treated with the VMAT2 inhibitor, Ro 4–1284 (2-hydroxy-2-ethyl-3-isobutyl-9,10-dimethoxy-1,2,3,4,6,7-hexahydrobenzo[alpha]chinolizin hydrochloride), showed only slight potentiation of toxicity when treated with low doses of 2′-NH_2-MPTP.

With regard to sex, female mice appear to be less susceptible to the neurotoxic effects of 2′-NH_2-MPTP. Compared to male mice with 60–80 % loss of serotonin in frontal cortex and hippocampus 6 weeks after treatment, female CD-1 mice only showed 30–40 % serotonin depletions in the same brain regions (Fig. 2). Studies have shown that female mice are resistant to dopamine depletion after MPTP treatment (Miller et al. 1998; Dluzen 2000; Morissette et al. 2007). Castrated male mice pretreated with estrogen are also protected from MPTP toxicity (Dluzen et al. 1996). Estrogen may exert neuroprotective effects through direct antioxidant activity (Subbiah et al. 1993). However, these effects are only observed at low physiological concentrations of estrogen (Ramirez et al. 2003), implicating other mechanisms including gene regulation of estrogen receptors (Kenchappa et al. 2004) or altered DAT affinity for MPP^+ (Ookubo et al. 2009). Similar mechanisms may underlie sex-related differences in 2′-NH_2-MPTP neurotoxicity.

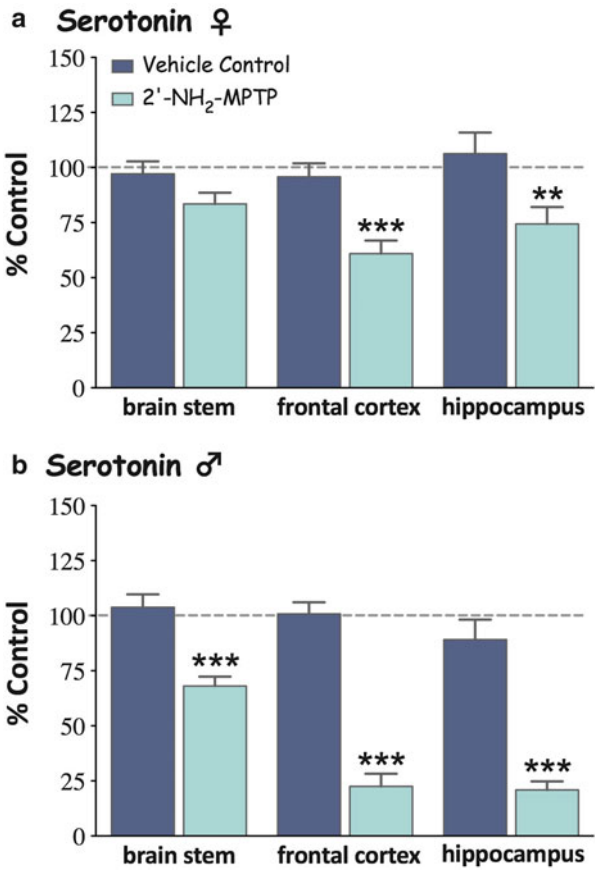

Fig. 2 *Changes in serotonin levels following 2′-NH_2-MPTP treatment*. Brain tissue neurotransmitter levels were analyzed by high-performance liquid chromatography with electrochemical detection. Data are percents of non-injected control levels in vehicle- and 2′-NH_2-MPTP-treated mice. Serotonin levels were analyzed in (**a**) female mice and (**b**) male mice. Statistical significances: $^{**}P < 0.01$ and $^{***}P < 0.001$ 2′-NH_2-MPTP-treated versus uninjected mice. $N = 10$ for control groups of both sexes; $N = 9$ for 2′-NH_2-MPTP-treated group of both sexes

Thus, 2′-NH_2-MPTP produces toxicity by cellular mechanisms with many similarities to those of MPTP, although different neuronal populations are targeted and the neuroprotective role of VMAT2 varies. Recently, α-synuclein was found to be neuroprotective in the context of MPTP but not 2′-NH_2-MPTP toxicity suggesting that α-synuclein plays a role in dopaminergic toxicity but not serotonin and norepinephrine toxicity (Thomas et al. 2011). 2′-NH_2-MPTP differs from other serotonin neurotoxins, such as 5,6- and 5,7-dihydroxytryptamine (5,6- and 5,7-DHT), which must be administered directly into the brain. 2′-NH_2-MPTP is also mechanistically dissimilar from the norepinephrine neurotoxin DSP-4 (N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine hydrochloride) (Hallman and Jonsson 1984; Kostrzewa 2009) and the substituted amphetamines, e.g., 3,4-methylenedioxylmethamphetamine, fenfluramine, and *p*-chloroamphetamine (Baumgarten and Lachenmayer 2004). The toxicity profiles of substituted amphetamines differ from 2′-NH_2-MPTP, particularly in mice, where these amphetamines also affect dopamine levels (O'Callaghan and Miller 1994) (Jayanthi et al. 1999), or in the case of fenfluramine, where long-term neurotoxic effects are questionable.

6 Evidence for Neurodegeneration

Multiple lines of investigation suggest that reductions in forebrain serotonin and norepinephrine are indicative of 2′-NH_2-MPTP-induced neurodegeneration. This is compatible with findings of MPTP-induced dopaminergic neurodegeneration (Markey et al. 1986). Reductions in cortical and hippocampal serotonin and norepinephrine persist up to six months after treatment of mice with 2′-NH_2-MPTP (Luellen et al. 2003). Furthermore, a number of indicators of neurodegeneration are present after 2′-NH_2-MPTP administration.

When some types of neurons, including serotonin neurons, are damaged, i.e., during aging, disease, or injury, they increase production of brain-derived neurotrophic factor (BDNF), a protein involved in synaptic plasticity, neurogenesis, and neuronal survival (Mattson et al. 2004). Along these lines, 2′-NH_2-MPTP-treated mice show acute increases in hippocampal BDNF (Szapacs et al. 2004; Luellen et al. 2006). Further evidence for degenerating neurons is hypertrophy of astrocytes in a process known as astrogliosis. Glial fibrillary acidic protein (GFAP) is an intermediate filament protein whose expression is universally upregulated in astrocytes in response to brain injury (O'Callaghan 1991). In addition to BDNF, 2′-NH_2-MPTP administration to mice causes transient elevations in GFAP in frontal cortex and hippocampus, brain regions showing long-term serotonergic and noradrenergic depletion indicative of neuronal injury (Luellen et al. 2003). Interestingly, administration of 2′-NH_2-MPTP to mice 2 weeks prior to treatment with the dopaminergic neurotoxin 2′-CH_3-MPTP prevents striatal increases in GFAP in response to 2′-CH_3-MPTP suggesting that serotonin is a modulator of astrogliosis (Luellen et al. 2003).

Immunocytochemistry has also been used to study neurodegeneration. A few days after 2′-NH_2-MPTP treatment, serotonin-immunopositive axons exhibited a tortuous, beaded, and punctate appearance indicating ongoing neurodegeneration (Luellen et al. 2006). Three weeks later, significant serotonergic axonal losses were detected. The hippocampus and frontal cortex were the brain regions most severely affected, strongly correlating with reductions in neurotransmitter levels (Fig. 3). Silver staining has also been used for over a century as a histopathological indicator of neuronal death (Uchihara 2007). Immunocytochemical evidence of argyrophilia, the ability of degenerating neurons to take up silver, occurs in serotonin cell bodies in the dorsal raphe further indicating neurodegeneration after 2′-NH_2-MPTP (Luellen et al. 2006). From these converging lines of evidence, it can be concluded that 2′-NH_2-MPTP is a regionally selective, potent, and long-lasting serotonergic and noradrenergic neurotoxin.

7 2′-NH_2-MPTP Toxicity in Rats and Nonhuman Primates

Notwithstanding the physiological and neurochemical similarities between 2′-NH_2-MPTP and MPTP, different patterns of species sensitivity are observed. Notably, key differences between these two compounds occur regarding their effects in rats. Rats are virtually resistant to the effects of MPTP (Chiueh et al. 1984), a phenomenon that

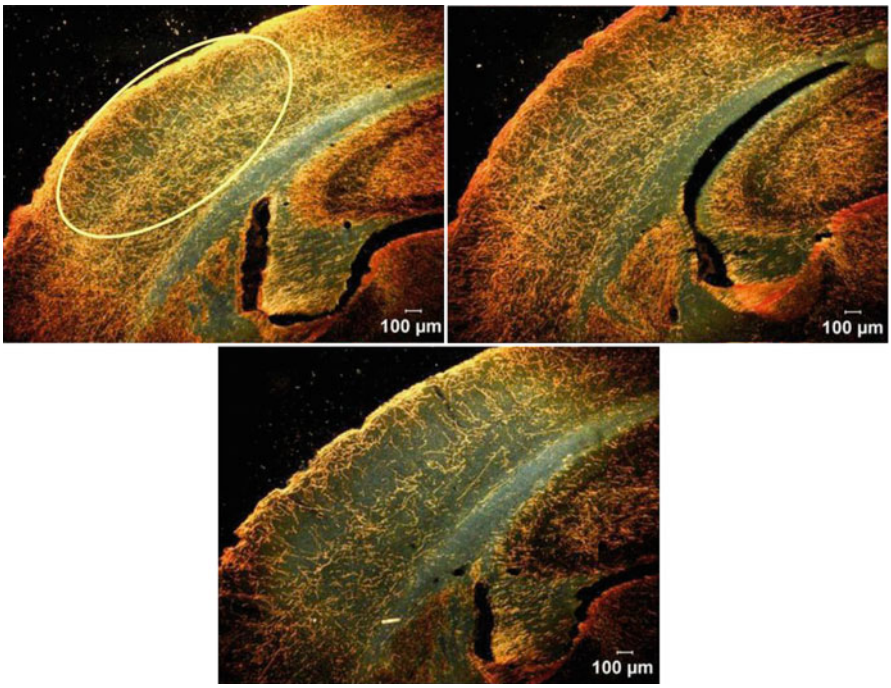

Fig. 3 *Immunocytochemistry of serotonin axons following acute and chronic administration of 2′-NH_2-MPTP*. Representative dark field photomicrographs of sections of primary somatosensory cortex from male CD-1 mice are shown. Serotonin axons are gold threadlike structures. Mice were treated with 4 × 20 mg/kg 2′-NH_2-MPTP at 2 h intervals. Compared to control mice (*upper* left panel), mice sacrificed 21 days (*lower* panel) but not 3 days (*upper* right panel) post-2′-NH_2-MPTP treatment showed significant reductions in serotonergic axon innervation in the barrel field region (*yellow* oval) (Reprinted with permission from (Luellen et al. 2006))

contributed to the difficulties of identifying MPTP as the cause of Parkinsonism in human drug users (Davis et al. 1979; Lewin 1984). However, systemic treatment of Sprague Dawley rats with 2′-NH_2-MPTP (4 × 15 mg/kg, ip, every 2 h) was highly toxic, depleting forebrain serotonin and norepinephrine levels without affecting striatal dopamine (Unger et al. 2002). Conversely, 2′-CH_3-MPTP-treated rats showed no toxic effects.

In terms of molecular mechanisms of MPTP and its analogs, there appear to be several ways in which species can differ. Some animals, rats in particular, have high MAO-B activity at the blood–brain barrier, where effective conversion of MPTP to MPP^+ can take place (Kalaria et al. 1987). Positively charged pyridinium species produced at the blood–brain barrier are then prevented from entering the brain (Fig. 1b). Rats may therefore be partly protected from MPTP toxicity by effective MPTP metabolism at the blood–brain barrier. Furthermore, rats have a greater capacity to sequester MPP^+ compared to mice (Staal and Sonsalla 2000a). However, 2′-NH_2-MPP^+ appears to be a poor substrate for VMAT2 in

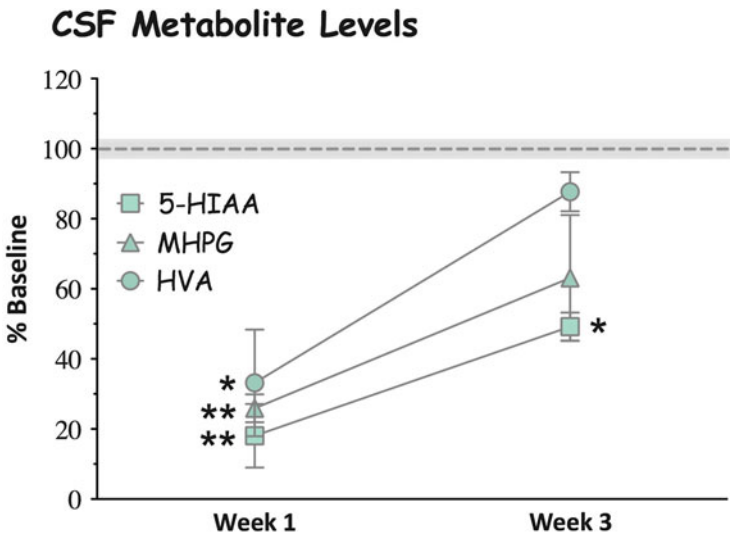

Fig. 4 *Cerebrospinal fluid metabolite levels after administration of 2′-NH_2-MPTP in African green monkeys*. Levels of 5-hydroxyindoleacetic acid (5-HIAA), 3-methoxy-4-hydroxyphenylglycol (MHPG), and homovanillic acid (HVA) were measured in cerebrospinal fluid (CSF) 1 and 3 weeks after administration of 2′-NH_2-MPTP to African *green* monkeys (20 mg/kg total dose). These are metabolites of serotonin, norepinephrine, and dopamine, respectively. All metabolites were decreased 1 week after treatment with 2′-NH_2-MPTP and remained reduced for 5-HIAA 3 weeks after treatment. The *gray-shaded* region represents ± the standard error of the mean (SEM) for all metabolites in saline-treated monkeys. Data are means ± SEMs. *$P < 0.05$ and **$P < 0.01$ versus metabolite levels in saline-treated animals

mice (Numis et al. 2004) and rats (Unger et al. 2002). Lower blood–brain barrier metabolism of 2′-NH_2-MPTP and synaptic vesicular uptake of 2′-NH_2-MPP^+ are hypothesized to contribute to the sensitivity of rats to 2′-NH_2-MPTP toxicity.

In addition to rodents, 2-NH_2-MPTP has been administered to two nonhuman-primate species. In one study, six adult African green monkeys (*C. aethiops*) were given intravenous (iv) 2′-NH_2-MPTP with the objective of investigating serotonin and norepinephrine neurotoxicity in a species more closely related to humans. Initial doses of 2′-NH_2-MPTP (7–10 mg/kg) to one monkey produced behavior indicative of hallucinations followed by nonlethal tonic-clonic seizure at the highest dose. A subsequent dose of 5 mg/kg to the same animal was without overt behavioral effects. Two additional monkeys received 4 × 5 mg/kg 2′-NH_2-MPTP. Bolus iv doses were administered at a 6 h interval twice per day for two consecutive days. This dosing schedule of 2′-NH_2-MPTP is similar to other serotonin neurotoxin regimens in nonhuman primates (Ricaurte et al. 1988).

Cerebrospinal fluid (CSF) was analyzed after 2′-NH_2-MPTP to assess changes in neurotransmitter metabolite levels (Fig. 4). The serotonin and norepinephrine metabolites 5-HIAA and 3-methoxy-4-hydroxyphenylglycol (MHPG), respectively, were significantly reduced 1 week after 2′-NH_2-MPTP treatment compared to levels in

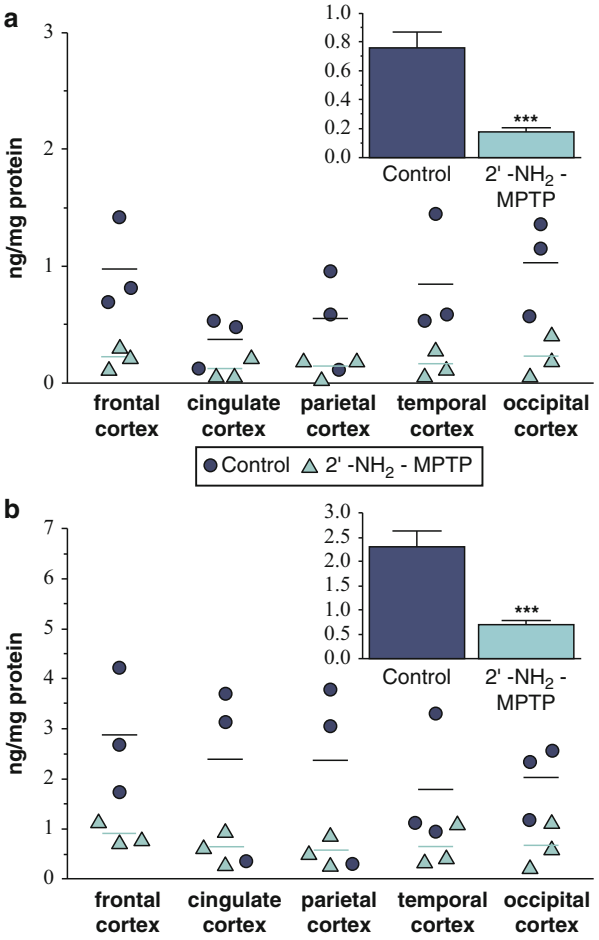

Fig. 5 *Neurotransmitter levels in cortical regions 3 weeks after 2′-NH_2-MPTP treatment in African green monkeys*. (**a**) Serotonin and (**b**) norepinephrine levels are significantly reduced across cortical regions. Data points represent neurotransmitter levels in individual animals. *Horizontal lines* depict means for 2′-NH_2-MPTP-treated versus saline-treated monkeys. Data from different subregions were combined and compared between treatment groups, as depicted in the insets ($[t_{(28)} = 5.0, P < 0.0001]$ and $[t_{(28)} = 4.7, P < 0.0001]$ for serotonin and norepinephrine, respectively)

saline-treated monkeys. Depressed CSF 5-HIAA levels continued to be evident at 3 weeks posttreatment with 2′-NH_2-MPTP. The dopamine metabolite HVA was also moderately reduced 1 week after drug treatment. Changes in CSF metabolite levels could indicate loss of brain serotonergic and noradrenergic (and possibly dopaminergic) axons/neurons. They might also reflect inhibition of MAO activity. Studies have shown that when MPTP is oxidized to form MPP^+, MAO-B is irreversibly inactivated (Singer et al. 1986). "Suicide" inhibition of MAO is expected to reduce monoamine neurotransmitter metabolites. Notably, MAO inhibition by 2′-NH_2-MPTP has not yet been investigated. In addition to CSF metabolites, serotonin and norepinephrine levels across cortical regions were globally decreased in African green monkeys treated 3 weeks earlier with 2′-NH_2-MPTP (Fig. 5) suggesting that like MPTP, nonhuman primates are susceptible to 2′-NH_2-MPTP neurotoxicity. In African green monkeys, brain dopamine levels were modestly affected in the caudate (−24 %) but not the putamen (−9 %).

2′-NH_2-MPTP has also been administered to four adult baboons (*P. anubis*). Here, the neurotoxin was infused unilaterally into the carotid artery. This route of administration has been used with MPTP resulting in dopaminergic neurodegeneration largely confined to the ipsilateral side of the brain (Bankiewicz et al. 1986; Guttman et al. 1990). Intracarotid administration of MPTP produces a hemiparkinsonian nonhuman primate model where animals can still feed and care for themselves (Ding et al. 2008). Additionally, one hemisphere is relatively unaffected and serves as an intra-animal control in morphological studies (Przedborski et al. 1991). Intracarotid administration of 2′-NH_2-MPTP to baboons was carried out to attempt to produce a model of unilateral loss of forebrain serotonergic and noradrenergic axons that could be used to evaluate positron emission tomography (PET) ligands. Like unilateral MPTP, each 2′-NH_2-MPTP-treated animal would serve as its own control in imaging studies.

A 10 mg/kg infusion of 2′-NH_2-MPTP to a single baboon resulted in nonlethal seizure. Doses of 2′-NH_2-MPTP in the remaining baboons were lowered to 6–7 mg/kg. Bilateral biopsies of cortex suggested unilateral reductions in serotonin and norepinephrine. However, the data were inconclusive due to large variations in cortical neurotransmitter levels across samples. Postmortem brain tissue analysis showed evidence for loss of dopamine in the caudate and putamen of 2′-NH_2-MPTP-treated baboons. One baboon treated unilaterally with 2′-NH_2-MPTP underwent PET scanning using [^{11}C]-McN5652 to label SERT in extant neurons (Parsey et al. 2000). SERT density was unilaterally reduced across all brain regions except in the cerebellum. While some studies find SERT (albeit at extremely low levels), and 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{3A} receptors in the cerebellum, direct evidence that 5-HT neurons innervate this region remains inconclusive (Kish et al. 2005; Arpin-Bott et al. 2006; Xie et al. 2006; Yew et al. 2009). In fact, many investigators use the cerebellum to define nonspecific binding when analyzing SERT levels.

Together, findings in nonhuman primates suggest that similar to rats and mice, 2′-NH_2-MPTP may be neurotoxic to serotonin and norepinephrine neurons in primate species. These data also suggest minor dopaminergic neurotoxicity of 2′-NH_2-MPTP in nonhuman primates. The latter might be due to the routes of administration or high doses of 2′-NH_2-MPTP used in monkeys. Small groups of animals and inherent variability across individuals also contributed to the incomplete yet highly suggestive nature of these first studies on 2′-NH_2-MPTP in primates.

8 Long-Term Behavioral Consequences of 2′-NH_2-MPTP

Compared to research on the neurotoxic mechanisms of 2′-NH_2-MPTP in different animal models, relatively little work has been done to understand the behavioral consequences of serotonergic and/or noradrenergic forebrain axonal loss. The effects of 2′-NH_2-MPTP neurotoxicity were recently studied on locomotor activity (Unger et al. 2006), anxiety-related behavior (Walf and Frye 2007), and low-stress spatial learning and memory (Bressler et al. 2010). Here, CD-1 mice were pretreated with desipramine to produce serotonin-selective

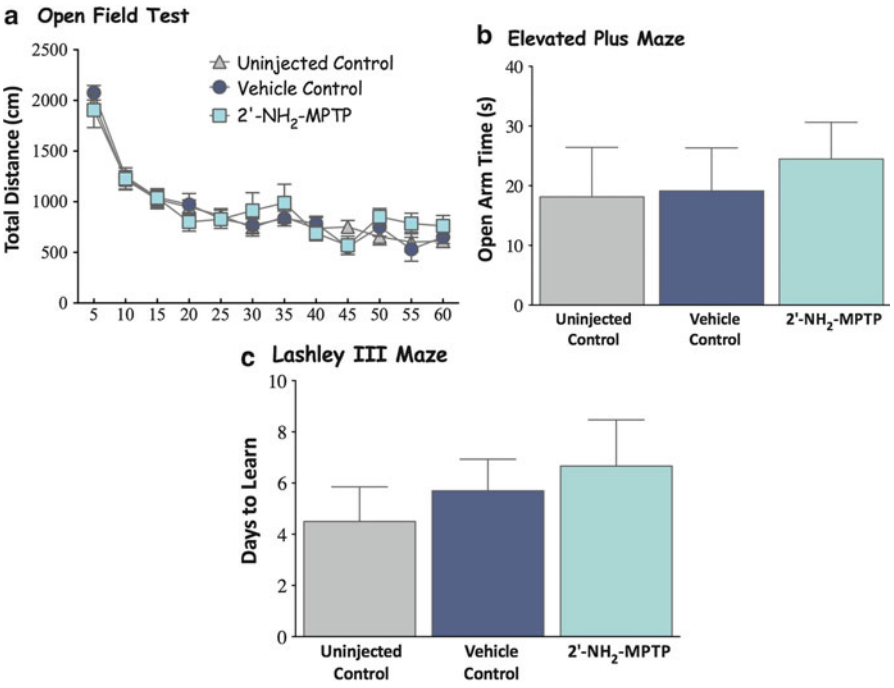

Fig. 6 *Effects of 2′-NH_2-MPTP treatment on behavior in male mice*. (**a**) Locomotor behavior was assessed in open field activity monitors (40 cm × 40 cm × 30 cm), where mice were able to explore freely for 1 h. No changes in total distance traveled were associated with 2′-NH_2-MPTP treatment. (**b**) The elevated plus maze was used to investigate changes in anxiety-related behaviors as indicated by time spent in the aversive open arms of the maze. No changes in anxiety-related behavior were observed after 2′-NH_2-MPTP. (**c**) Low-stress route learning was investigated via the Lashley III maze. A mouse was considered as having learned the maze (reached criterion) after completing two consecutive nightly trials with only 0 errors or 1 error. Mice were tested once per night for seven consecutive nights. Mice treated with 2′-NH_2-MPTP ($N = 9$) took a similar number of days to learn the maze compared with unhandled ($N = 10$) and vehicle controls ($N = 10$) indicating intact learning capabilities

2′-NH_2-MPTP-induced toxicity. It was hypothesized that serotonergic axonal degeneration would be associated with impaired cognition and increased anxiety-related behavior, similar to changes in brain function observed in humans with neurodegenerative disorders having serotonin-system involvement. Nonetheless, 60–70 % reductions in serotonin in frontal cortex and hippocampus (Fig. 2) were not associated with changes in locomotor, anxiety-related, and learning behavior in the open field, elevated plus maze, or Lashley III maze, respectively (Fig. 6).

Studies have shown that disruption of the serotonin system in response to another serotonin neurotoxin, 5,7-DHT, led to changes in learning and memory in rodents and nonhuman primates (Lieben et al. 2006; Clarke et al. 2007), although not all studies have been in agreement (Adams et al. 2008). Anxiety-like behaviors in 5,7-DHT-treated animals were not altered (Lieben et al. 2006). Here, adult mice ages 12–16 weeks were studied. Thus, critical early or late windows of vulnerability could

have been missed when degeneration of forebrain serotonin axons influences behavior. Alternately, behavioral changes might occur in 2′-NH_2-MPTP-treated mice, but the tests focused on were not directed at putative behavioral changes, e.g., depression-related behavior. Further research will also need to be carried out with 2′-NH_2-MPTP in genetically engineered disease-specific models to understand the ramifications of serotonin and norepinephrine degeneration on behavior.

9 Conclusion

A number of studies show that 2′-NH_2-MPTP induces significant serotonergic and noradrenergic neurotoxicity in mice, rats, and probably, nonhuman primates. The mechanisms of 2′-NH_2-MPTP neurotoxicity are similar to those of MPTP, yet significant differences occur with regard to the isoforms of monoamine oxidase that produce proximal pyridinium neurotoxins; 2′-NH_2-MPTP is a substrate for MAO-A and MAO-B while MPTP is metabolized almost exclusively by MAO-B. Moreover, rats are relatively insensitive to the dopamine-depleting effects of MPTP (and 2′-CH_3-MPTP). Conversely, 2′-NH_2-MPTP produces serotonin and norepinephrine toxicity in rats at doses comparable to those used in mice. The latter is likely to be associated, at least in part, to differential affinities of MPP^+ versus 2′-NH_2-MPP^+ for VMAT2 in rats and mice. The most important differences between 2′-NH_2-MPTP and MPTP arise from their affinities for plasma monoamine uptake transporters. This mechanistic aspect bestows relative dopamine-selective neurotoxicity to MPTP and 2′-CH_3-MPTP. By contrast, the MAO-catalyzed oxidative metabolite of 2′-NH_2-MPTP is a substrate for serotonin and norepinephrine transporters, conferring 2′-NH_2-MPTP with the ability to produce serotonergic and noradrenergic neurotoxicity largely in the absence of dopaminergic neurotoxicity. Further research in nonhuman primates and with regard to the behavioral consequences of serotonergic and noradrenergic neurodegeneration seems to be warranted. In turn, 2′-NH_2-MPTP animal models could be used to investigate potential treatments for serotonin-related pathologies. Moreover, a clearer understanding of links between serotonin deficiency and behavior may ultimately help to unravel the complex pathophysiology of depression and other neuropsychiatric and neurodegenerative disorders.

Methamphetamine and MDMA Neurotoxicity: Biochemical and Molecular Mechanisms

Verónica Bisagno and Jean Lud Cadet

Contents

Abstract

Methamphetamine (METH) and its analogs, methylenedioxymethamphetamine (MDMA), are psychostimulant drugs with high abuse liability. The two drugs are also very neurotoxic. In the case of METH, the behavioral and neurotoxic effects of the drug occur because it alters dopamine terminal physiology and causes massive release of dopamine (DA) in the synaptic cleft in brain regions that receive dopaminergic projections from

the midbrain. The increase of synaptic DA is compounded by the ability of METH to block DA reuptake into DA terminals. METH toxicity is not only accompanied by terminal dysfunction but also by causing dysfunction of complex networks that subserve cognitive and emotional processes. MDMA is a ring-substituted derivative of phenylisopropylamine which is structurally similar to METH. MDMA is a substrate of the serotonin transporter (SERT) via which it enters monoaminergic neurons and causes release of serotonin (5-HT) from storage vesicles. This is followed by 5-HT release into the synaptic cleft by reversal of normal SERT function. MDMA is selectively neurotoxic to serotonergic nerve terminals in rats, guinea pigs, and nonhuman primates. MDMA users consistently show reduced SERT radionuclide ligand binding across multiple brain regions. There is also evidence that MDMA users can suffer from cognitive deficits. However, the relation of DA and/or 5-HT depletion to cognitive impairments remains to be clarified in METH and MDMA users. Results from these studies are likely to impact the therapeutic approaches to the treatment of patients who suffer from METH and MDMA addiction.

List of Abbreviations

5-HIAA	5-hydroxyindoleacetic acid
5-HT	Serotonin
α-MT	α-methyl-p-tyrosine
CNS	Central nervous system
COMT	Catechol-O-methyltransferase
CuZnSOD	Copper–zinc superoxide dismutase
DA	Dopamine
DAT	Dopamine transporter
ER-	Endoplasmic reticulum-
HHA	3,4-Dihydroxyamphetamine
HHMA	3,4-Dihydroxymethamphetamine
HMA	4-Hydroxy-3-methoxy-amphetamine
L-DOPA	L-3,4-Dihydroxyphenylalanine
MDA	Methylenedioxyamphetamine
MDMA	Methylenedioxymethamphetamine
METH	Methamphetamine
MK-801	Dizocilpine
MTF-1	Metal-responsive transcription factor 1
MTs	Metallothioneins
NET	Norepinephrine transporter
Nrf2	NF-E2-Related factor 2
PARP	Poly(ADP-ribose) polymerase
ROS	Reactive oxygen species
SERT	Serotonin transporter
TH	Tyrosine hydroxylase
TPH	Tryptophan hydroxylase
VMAT2	Vesicular monoamine transporter 2

1 Introduction

Some psychostimulants including methamphetamine (METH) are presently prescribed for weight control, narcolepsy, and attention deficit disorder. These drugs are also used recreationally, with some individuals developing abuse followed by severe addiction. METH addiction is prevalent throughout the world, being second only to marijuana abuse among illicit drugs. During the past two decades, it has become clear that dopamine (DA) plays a critical role in the behavioral pharmacology and addictive properties of abused drugs. DA contributes to incentive salience and is necessary for identifying wanted elements from the environment (Berridge 2007). Drugs of abuse that increase dopaminergic signals alter and sensitize dynamic mesolimbic mechanisms that evolved to attribute incentive salience to rewards (Le Moal and Koob 2007). Such drugs interact with incentive salience integrating Pavlovian associative information with physiological state signals (Berridge 2007). Specific transporters in the synaptic membrane of dopaminergic terminals serve to remove DA from the synaptic cleft to end its action (Sulzer et al. 2005). METH alters dopamine terminal physiology and causes massive release of DA in the synaptic cleft in brain regions that receive dopaminergic projections from the midbrain (Krasnova and Cadet 2009). This is compounded by its ability to block DA reuptake into DA terminals. These mechanisms work together to cause degeneration of monoaminergic terminals in the striatum (O'Callaghan and Miller 1994; Krasnova and Cadet 2009). In the following paragraphs, we describe specific toxic effects and the mechanisms by which METH and its analogs, methylenedioxymethamphetamine (MDMA), induce damage of monoaminergic terminals and non-aminergic cell bodies in the brain.

2 Methamphetamine Toxicity

2.1 Dopamine and Oxidative Stress

Methamphetamine enters DA neurons through the DAT and via passive diffusion. In the cell, it accumulates in vesicles, disrupts the pH gradient required for vesicular DA sequestration, and displaces DA into the cytoplasm (Sulzer and Rayport 1990). METH causes release of monoamines from the neuronal cytosol via plasmalemmal uptake transporters, particularly the DA transporter (DAT), the norepinephrine transporter (NET), and the serotonin (5-HT) transporter (SERT) via a mechanism referred to as reverse transport (Sulzer et al. 2005). METH acts through the vesicular monoamine transporter 2 (VMAT-2) to cause excessive release of dopamine into the cytoplasm followed by DA release into the synaptic cleft through the DAT (Sulzer et al. 2005).

DA accumulates in the cytoplasm which alters the concentration gradient and likely helps to favor the reverse transport of DA via the DAT (see Sulzer et al. 2005).

DA is an important component of the mechanisms that underlie METH neurotoxicity (Sulzer and Rayport 1990).

Neurotoxic effects of METH have been demonstrated in many species including rats, mice, guinea pigs, cats, and monkeys (for detailed reviews see McCann and Ricaurte 2004 and Krasnova and Cadet 2009). Animals given repeated doses of METH suffer significant loss of DA and 5-HT in the striatum, cortex, and olfactory bulb (Deng et al. 2007) and decreases in striatal DAT binding, DAT immunoreactivity and tyrosine hydroxylase (TH) immunoreactivity (Bowyer et al. 2008; Deng et al. 1999), and TH protein levels (O'Callaghan and Miller 1994). Animals that self-administer METH also show deficits in dopaminergic systems (Krasnova et al. 2010). Morphological studies suggest that the reductions in the markers of DA and 5-HT system integrity are related to degeneration of DA and 5-HT axonal terminals (Ricaurte et al. 1982). These neurotoxic consequences can be prevented or attenuated by agents, such as α-methyl-p-tyrosine, that block DA synthesis and decrease DA levels in the striatum (Kuhn et al. 2008). In contrast, treatment with immediate DA precursor, L-3,4-dihydroxyphenylalanine (L-DOPA), that restores cytoplasmic DA levels enhances METH toxicity (Kuhn et al. 2008).

Autoxidation and metabolism of synaptic DA can lead to generation of reactive oxygen species (ROS) including hydrogen peroxide and superoxide radicals, quinones, and semiquinones (Cadet 1988; Cadet and Brannock 1998). The involvement of superoxide radicals in METH toxicity on DA terminals has been tested in transgenic mice that overexpress the human copper–zinc superoxide dismutase (CuZnSOD), a cytosolic enzyme that catalyzes the breakdown of superoxide radicals (Cadet et al. 1994a, b; Jayanthi et al. 1998). These mice that have much higher CuZnSOD enzyme activity in the cytosol than control wild-type animals (Jayanthi et al. 1998) are protected against METH toxicity (Cadet et al. 1994a, b).

METH can also cause neuronal apoptosis in several brain regions, including the striatum, cortex, hippocampus, and olfactory bulb (Deng and Cadet 2000; Deng et al. 2001, 2007; Ladenheim et al. 2000). Because METH administration is associated with ROS production and because ROS can cause apoptosis and DNA damage (Li and Trush 1993), we thought it is likely that METH might induce neuronal apoptosis through ROS-mediated DNA damage. This idea was supported by the observations that METH-induced poly(ADP-ribose) polymerase (PARP) cleavage, increase in caspase-3 activity, and neuronal death were all attenuated in the striata of CuZnSOD transgenic mice (Deng and Cadet 2000). A role for oxidative stress in METH toxicity is supported by data obtained from microarray analyses that have identified changes in the expression of a number of genes that participate in DNA repair, including APEX, PolB, LIG1, and DNA mismatch repair proteins MSH3 and PMS1 after toxic doses of the drug (Cadet et al. 2002).

METH treatment causes alterations in the DAT, including the formation of higher molecular mass DAT-associated complexes (Hadlock et al. 2009). This phenomenon is attenuated by either prevention of METH-induced hyperthermia

or pretreatment with the DA synthesis inhibitor, α-methyl-p-tyrosine (α-MT) (Baucum et al. 2004). Reactive species also are implicated in DAT complex formation because in vitro exposure to the reducing agent, β-mercaptoethanol, reverses this process (Baucum et al. 2004). Concurrent with METH-induced DAT complex formation, METH treatment causes a loss of DAT monomer immunoreactivity and a decrease in DAT function (Baucum et al. 2004).

Another aspect of METH toxicity is the fact that the drug can cause transcription factor NF-E2-related factor 2 (Nrf2) transit cytosolic into nuclear fractions where the protein exerts its regulatory functions (Jayanthi et al. 2009). Nrf2 and metal-responsive transcription factor 1 (MTF-1) are known to play a key role in transcriptional activation of the MT-1/2 genes in response to heavy metals or oxidative stress (Miyazaki et al. 2010), and it has been suggested that astrocytes can act to protect surrounding neurons against excess DA and DA-quinone formation by upregulating quinone-quenching molecules like metallothioneins (MTs) (Miyazaki et al. 2010). Increases in DA might promote nuclear translocation of Nrf2, upregulating MT1/2 expression in astrocytes, suggesting a protective role of Nrf2 against METH toxicity. Accordingly, Granado et al. (2011b) showed that Nrf2 deficiency exacerbated METH-induced damage to dopamine neurons (increase in loss of TH and DAT-containing fibers in striatum) and also potentiated glial activation.

2.2 Role of DAT and VMAT-2 in METH Toxicity

The role of DAT in METH toxicity has been investigated using both pharmacological and genetic means. For example, administration of the DAT inhibitor, methylphenidate, 1 hour after METH treatment, can reverse decreases in vesicular DA uptake, reductions in VMAT-2 ligand binding, and decreases in VMAT-2 immunoreactivity in vesicular subcellular fractions 6 h after injections of the drugs (Sandoval et al. 2003). Modafinil, an anti-narcoleptic drug that has been used off-label to treat psychostimulant addiction, acts as a DAT blocker (Zolkowska et al. 2009) and is neuroprotective against METH toxicity, as documented by attenuation of METH-induced decreases in TH immunoreactivity and DA striatal content (Raineri et al. 2011). Importantly, mice with genetic deletion of DAT are also protected against drug-induced DA depletion, reactive astrocytosis, and ROS production in the striatum (Fumagalli et al. 1998).

A role for VMAT-2 in METH-induced damage to striatal DA terminals is also supported by studies showing that pretreatment with the irreversible inhibitor of vesicular transport, reserpine exacerbates toxicity of the psychostimulant (Kuhn et al. 2008). Additionally, the administration of the alkaloid, lobeline, after injections of METH was able to reverse METH-induced decreases in synaptosomal, membrane-associated, and vesicular VMAT-2 immunoreactivity 24 h after drug treatment while also preventing METH-induced striatal depletion (Eyerman and Yamamoto 2005).

2.3 Role of Dopamine Receptors in METH Toxicity

Several studies have also documented a role for DA receptors in the mediation of METH toxicity (Angulo et al. 2004; Beauvais et al. 2011; Jayanthi et al. 2005; Xu et al. 2005). Specifically, pretreatment with the DA D_1 receptor antagonist, SCH23390 [R-(+)-7-chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine], given before each of 5 METH injections was able to attenuate drug-induced decreases in TH activity and DA levels in the rat striatum and decreases in tryptophan hydroxylase (TPH) activity and 5-HT levels in the striatum and cortex measured 18–20 h after METH treatment (Sonsalla et al. 1986). The DA D_2 receptor antagonist, sulpiride, also blocked METH-induced toxic effects on DA systems without affording any protection to striatal and cortical 5-HT terminals (Sonsalla et al. 1986). In addition, a single injection of the DA D_1 receptor antagonist, SCH23390, prior to a single high-dose METH injection also attenuated long-term decreases in DA levels (Jayanthi et al. 2005), reductions in DAT binding, and depletion in TH protein levels and reactive astrocytosis (Xu et al. 2005). SCH23390 also protected against METH-induced cell death in the striatum (Jayanthi et al. 2005; Xu et al. 2005). The protection afforded by SCH23390 against METH-mediated cell death appears to depend, in part, on the activation of the Fas/FasL death pathway because pretreatment with SCH23390 caused suppression of METH-induced increases in the expression of FasL and caspase-3 in rat striatal cells (Jayanthi et al. 2005). Jayanthi et al. (2009) also measured the expression of several genes that are regulated during ER stress. These include ATF3, HSP27, Hmox1, HSP40, CHOP/Gadd153 and ATF4, ATF6, BiP/GRP78, and GADD34. The DA D_1 receptor antagonist also attenuated or blocked METH-induced increases in the expression of the majority of these genes. METH injections can also cause substantial increases in the expression of proteins that participate in endoplasmic reticulum- (ER-) and mitochondrial-dependent stress responses, and these changes were also blocked by SCH23390 (Beauvais et al. 2011). However, the D_2-like receptor antagonist, raclopride, was found to have only small to moderate effects on ER stress proteins and only small effects on mitochondrial-dependent cellular stress proteins (Beauvais et al. 2011). Both DA D_1 and D_2 receptors appear to be required for METH toxicity since both D_1R (Ares-Santos et al. 2012) and D_2R (Granado et al. 2011a) knockout mice are protected against METH neurotoxicity.

2.4 Role of Microglia on METH-Induced Toxicity

METH toxicity is accompanied by reactive astrocytosis (Bowyer et al. 1994) and microglial activation (Pubill et al. 2002) in various brain regions. In the normal brain, microglial cells exist in a resting state, but, in response to inflammation or brain damage, these cells increase in size, migrate to the site of the injury, and phagocytize dying and dead cells (Raivich 2005). Although microglial activation is

important for immune responses, their overactivation can result in neurotoxic consequences. This process seems to be involved in the case of METH toxicity. For example, METH induces microgliosis in areas of the brain that suffer from neuronal degeneration (Thomas and Kuhn 2005a; Thomas et al. 2004a, b). Reserpine and clorgyline that exacerbate METH toxicity also potentiate in METH-induced microglial activation in the mouse striatum (Thomas et al. 2008). In contrast, attenuation of METH neurotoxicity by dizocilpine (MK-801), dextromethorphan, and α-methyl-p-tyrosine results in inhibition of METH-induced microglial activation (Kuhn et al. 2008; Thomas and Kuhn 2005b). Anti-inflammatory drugs, ketoprofen and indomethacin, and the second-generation tetracycline minocycline afford protection against METH-induced toxicity and microgliosis (Asanuma et al. 2003, 2004; Zhang et al. 2006). Further studies are necessary to identify the specific mechanisms that underlie METH-induced microgliosis and the manner by which these activated microglial cells might cause degeneration of monoaminergic terminals.

3 Preconditioning Doses of METH Protect Against Toxic Doses of METH

Pretreatment with multiple low-dose injections of METH or with gradually escalating doses of the drug has been shown to provide partial protection against the deleterious effects of a high-dose METH challenge (Cadet et al. 2009, 2011; Danaceau et al. 2007; Graham et al. 2008). These investigators use a regimen that involves gradual increases in METH administration to rats in order to mimic progressively larger doses of the drug used by some human METH addicts. METH preconditioning was associated with complete protection against dopamine depletion caused by a METH challenge in the striatum and cortex (Cadet et al. 2009). Hodges et al. (2011) also reported that this regimen resulted in prolonged protection, with a second challenge of METH causing no further decreases in striatal DA or 5-HT levels in comparison to the single METH challenge. Another study has also reported that, although it was associated with some decreases in striatal DAT, METH self-administration attenuated the persistent deficits in dopaminergic neuronal function and increases in GFAP immunoreactivity caused by a subsequent binge METH exposure (McFadden et al. 2012).

These data suggest that repeated injections of low doses of METH might render the brain refractory to the toxic effects of binge injections of the drug, thus providing protection against toxic METH effects in various brain regions. Neuroprotection induced by METH preconditioning might be related to reductions in METH hyperthermia (McFadden et al 2012). Another possible explanation for the neuroprotective effects of METH is the fact that, by reducing striatal DAT and increasing high-molecular DAT complexes that are nonfunctional, the striatum might have become less susceptible to the toxic effects of a METH challenge (Krasnova et al. 2011). This line of reasoning is consistent with the recent report

that a low, sub-toxic dose of METH was able to attenuate 6-OHDA-induced decreases in ATP levels and mitochondrial dehydrogenase activity (El Ayadi and Zigmond 2011).

4 Summary of Discussion of METH Toxicity

Chronic abuse of METH contributes to depression, psychosis, mood disturbances, and psychomotor dysfunctions in humans (Darke et al. 2008; Homer et al. 2008). METH addicts also suffer from deficits in attention, working memory, and decision-making (Gonzalez et al. 2004; Verdejo-García et al. 2006). Withdrawal from the drug is also associated with anhedonia, irritability, and intense craving for the drug (Darke et al. 2008; Homer et al. 2008). Human addicts also suffer persistent decreases in the levels of DAT in the orbitofrontal cortex, dorsolateral prefrontal cortex, and the caudate–putamen (McCann et al. 1998; Sekine et al. 2003; Volkow et al. 2001a, c). METH abusers also show abnormal glucose metabolism in cortical and subcortical brain areas (Volkow et al. 2001b; Wang et al. 2004). In addition, there is prominent microglial activation in the brains of these individuals (Sekine et al. 2008). Alterations in DA tone produced by METH toxicity on dopamine terminals might not only influence the physiology of the brain but might also alter the complex networks that subserve cognitive and emotional processes. It is thus likely that some of the clinical observations in METH abusers might be secondary to METH-induced toxic and neuroinflammatory responses, suggesting that the development of therapeutic agents that address these processes might be necessary to address the basic neurobiology of METH-induced neuropsychiatric manifestations.

5 MDMA Neurotoxicity

MDMA is a ring-substituted derivative of phenylisopropylamine, structurally similar to METH and the hallucinogen, mescaline (Lyles and Cadet 2003). MDMA impacts peripheral and central nervous system (CNS) functions through its actions on the serotonergic system (Baumann and Rothman 2009). MDMA is a substrate of the serotonin transporter via which it enters monoaminergic neurons and causes release of 5-HT from storage vesicles, followed by 5-HT release into the synaptic cleft by reversal of normal SERT function (Baumann and Rothman 2009). Injections of large doses of MDMA cause massive release of 5-HT from presynaptic vesicles, followed by a rapid decrease in 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) levels and decreased TPH activity (Lyles and Cadet 2003). There do not appear to be losses of 5-HT uptake sites at early time points after MDMA administration (Lyles and Cadet 2003). MDMA can also cause dose-dependent DA and NE release in the striatum and hippocampus in rats (Lyles and Cadet 2003). Adverse effects of acute MDMA administration, including cardiovascular stimulation and elevated

body temperature, are thought to involve monoamine release from sympathetic nerves in the periphery or nerve terminals in the CNS (Baumann and Rothman 2009). MDMA is selectively neurotoxic to serotonergic nerve terminals in rats, guinea pigs, and nonhuman primates (Green et al. 1995). In mice, however, MDMA appears to affect mainly the nigrostriatal dopaminergic system (Cadet et al. 1995). MDMA users consistently show reduced SERT radionuclide ligand binding across multiple brain regions (Reneman et al. 2006). Some evidence has suggested that these levels began to recover with increased periods of MDMA abstinence. Recently, Erritzoe et al (2011) reported significantly lower SERT binding potential in the neocortex (−56 %), pallidostriatum (−19 %), and amygdala (−32 %), with the extent of binding correlated with lifetime MDMA usage. Kish et al (2010) compared moderate Ecstasy/MDMA users with nonuser controls and reported that SERT binding was significantly reduced in all the cerebral cortices and hippocampus. The degree of these reductions was significantly associated with the extent of past MDMA usage. An additional molecular structural component of the serotonergic signaling pathway is the 5-HT_{2A} receptor. 5-HT_{2A} receptors are densely distributed in human cortex; 5-HT_{2A} receptor levels were reduced in multiple brain regions in the ongoing/acute MDMA user group, possibly because of ongoing MDMA-mediated increases in 5-HT release (Reneman et al. 2002).

Neurochemical and anatomical studies have reported long-term reductions in markers of 5-HT systems in rats. These include decreased levels of 5-HT and of its major metabolite, 5-HIAA; decreased number of 5-HT transporters; and decreased activity of the rate-limiting enzyme of 5-HT synthesis, TPH (Commins et al. 1987; De Souza et al. 1990). Severe reductions in 5-HT and 5-HIAA levels occurred in the rat neocortex, striatum, and hippocampus (De Souza et al. 1990). These abnormalities are reported to last for months or even years after drug administration (Lyles and Cadet 2003). MDMA also perturbs the function of SERT (Green et al. 2003), a marker of the integrity of serotonin neurons (Blakely et al. 1994). By virtue of its moderating synaptic 5-HT levels, SERT is crucial for the process of 5-HT neurotransmission (Green et al. 2003). MDMA downregulates SERT function without altering SERT mRNA or protein expression, and this rapid downregulation is sustained for at least 90 min and is dose dependent (Kivell et al. 2010).

Histologic studies in animals have shown that large doses of MDMA are associated with neurodegeneration particularly affecting the terminal portions of axons and fibers; raphe cell bodies are spared (reviewed by Lyles and Cadet 2003). In rats, histological studies using the Fink–Heimer staining method have also provided evidence for the degeneration of nerve terminals in the striatum and somatosensory cortex after chronic exposure to MDMA (Commins et al. 1987). Ricaurte et al. (2000) and Callahan et al. (2001) have also provided evidence that MDMA can cause reduction of the anterograde transport of [^{3}H] proline in ascending axons originating in the dorsal raphe nuclei, a subset of which comprise ascending 5-HT axons that project to various forebrain regions. A recent study found microtubular injury in frontal cortex after

MDMA treatment. The most apparent alteration in the ultrastructure of the labeled cortical axons of MDMA treated animals was the widespread disorganization of the microtubular system, suggesting a collapse of axonal microtubular system (with intact mitochondria) that leads to axonal swelling (Adori et al. 2011). These authors also found no signs of damage on dorsal raphe cell bodies. In nonhuman primates, reorganization of 5-HT projections has been reported to occur in the brains of nonhuman primates treated with MDMA (Ricaurte et al. 2000).

Formation of toxic MDMA metabolites which generate free radicals and associated oxidative stress and membrane damage has been proposed as causal agents for the long-term MDMA-induced neurodegeneration (reviewed in Lyles and Cadet 2003). Metabolism of MDMA results in the formation of methylenedioxyamphetamine (MDA) by *N*-demethylation and 3,4-dihydroxymethamphetamine (HHMA), the major metabolite, by *O*-demethylation. *O*-demethylation of MDA subsequently results in 3,4-dihydroxyamphetamine (HHA). HHMA and HHA are metabolized by catechol-*O*-methyltransferase (COMT) to HMMA and to 4-hydroxy-3-methoxyamphetamine (HMA) (reviewed by Green et al. 2003). The metabolites of MDMA might induce reactive species through redox cycling. Also, DA-induced oxidative stress in 5-HT terminals, and 5-HT_{2A} and dopamine D_1 receptor-mediated hyperthermia (Shioda et al. 2008) are all factors associated with MDMA neurotoxicity.

6 Cognition in Human MDMA Subjects

The accumulated evidence suggests that heavy MDMA use is associated with cognitive impairments and mood disturbances, in some cases lasting for months after cessation of drug intake (Baumann and Rothman 2009). Several studies have reported long-term deficits in memory and higher cognition, and other psychobiological functions in these substance abusers (Reneman et al. 2006). It is important to note that not all cognitive skills are affected and that there are also MDMA users who show normal neuropsychological functions (Parrott 2006). The role of other psychiatric disorders needs to be considered when evaluating cognitive functions in MDMA abusers. MDMA can also disrupt neuroendocrine regulation that is influenced by 5-HT levels. For example, MDMA users showed significantly reduced prolactin and cortisol responses to the serotonergic agonist d-fenfluramine in comparison with control subjects (Gerra et al. 2000).

7 Protective Mechanisms Against MDMA-Induced Toxicity

Preconditioning with repeated MDMA dosing appears to exert some neuroprotective effects against larger MDMA doses. For example, Bhide et al. (2009) reported that repeated exposure of adult rats to MDMA provides

neuroprotection against a challenge with large doses of MDMA that were shown to deplete 5-HT and decrease in SERT immunoreactivity. Alterations in MDMA pharmacokinetics or MDMA-induced hyperthermia do not appear to contribute to the neuroprotection provided by preconditioning.

There are other agents that also provide protective effects against MDMA toxicity. Chipana et al. (2008) reported that memantine, an alpha-7 nAChR antagonist used for treatment of Alzheimer's disease, was able to provide complete protection against MDMA-induced reduction in cortical [^{3}H]paroxetine binding sites. Fluoxetine, a SERT blocker, also provided long-lasting protection against MDMA-induced loss of SERT detected in vivo using micro-PET (Li et al. 2010).

8 Conclusion

In conclusion, MDMA users have been reported to suffer from cognitive and biochemical abnormalities. There is a need to correlate the changes of the serotonergic markers and other structural neuroimaging data to neuropsychological performance as well as responses to therapeutic interventions. These studies would help to provide better rationale for the development of pharmacological tools to treat METH- and MDMA-substance abusers.

Glutamate as a Neurotoxin

Gabrielle N. Turski and Chrysanthy Ikonomidou

Contents

Abstract

Glutamate (Glu) is the major excitatory neurotransmitter in the mammalian central nervous system (CNS). Excessive glutamate in the extracellular space can trigger passive and active forms of neuronal death in the CNS via excessive activation of glutamate receptors. This phenomenon has been named excitotoxicity.

DOI 10.1007/978-1-4614-5836-4_84,

Excitotoxicity has been implicated in the pathogenesis of acute and chronic neurodegenerative disorders. However, despite overwhelming preclinical data, human clinical trials in stroke or traumatic brain injury with antiexcitotoxic compounds acting at different levels of the excitotoxic cascade have failed to provide the expected neuroprotective effect. Here we present a focused overview of excitotoxic research including physiology of glutamate receptors and intracellular pathways leading to cell death. We review evidence for involvement of excitotoxicity in human neurodegenerative disorders and the results of several clinical trials. We present the most recent trends in the development of antiexcitotoxic therapies and also briefly refer to the hypothesis that interference with the trophic actions of glutamate in the context of CNS injuries may be one of the reasons why clinical trials with antiexcitotoxic compounds have failed.

1 Introduction

The first hint towards the neurotransmitter role of the amino acid glutamate came in 1935 from work by Krebs, who discovered that glutamate increases metabolism in the isolated retina and that it is concentrated in the cerebral gray matter (Krebs 1935). Hayashi (1952, 1958) discovered the excitatory properties of glutamate on neuronal tissue. Local administration of glutamate on the motor cortex of dogs and primates resulted in motor seizures. Curtis et al. (1959) subsequently demonstrated that glutamate and aspartate, when applied iontophoretically to the cat's spinal cord, depolarized neurons.

Today it is common knowledge that glutamate is the major excitatory neurotransmitter in the nervous system and that it is essential for learning and memory, synaptic plasticity, and neuronal survival and, in early development, for proliferation, migration, and differentiation of neuronal progenitors and immature neurons (Fonnum 1984; Guerrini et al. 1995; Ikonomidou et al. 1999; Komuro and Rakic 1993).

Compartmentalization allows that separate pools within the central nervous system supply glutamate for the metabolic machinery of the cells (metabolic pool) and for intercellular signaling (neurotransmitter pool) (Fonnum 1984). The neurotransmitter pool is located in nerve endings and releases glutamate by a calcium-dependent mechanism. Glutamate is subsequently removed by uptake into the surrounding glial cells and aminated to glutamine.

When released into the synaptic cleft, glutamate acts at the postsynaptic site on receptors (Nakanishi 1992; Hollmann and Heinemann 1994). These include the *N*-methyl-D-aspartate (NMDA), kainate, the 2-amino-3-hydroxy-5-methylisoxazole-propionate (AMPA), and the metabotropic receptors. The first three are coupled to ion

channels and are therefore called ionotropic glutamate receptors. Metabotropic glutamate receptors mediate their actions through G proteins (Hollmann and Heinemann 1994).

Excitotoxicity, a phenomenon discovered in the 1950s and extensively investigated and characterized in the 1970s and 1980s, describes a process in which excess of glutamate and other excitatory amino acid neurotransmitters causes overstimulation of neuronal glutamate receptors leading to degeneration of neurons. Lucas and Newhouse (1957) first described that systemic administration of monosodium glutamate causes degeneration of retinal ganglion cells. Olney and colleagues (Olney 1969, 1971; Olney and Ho 1970; Olney et al. 1972) subsequently observed that excitatory amino acids, when given to infant rodents and primates, cause neurodegeneration in brain areas that lack a blood–brain barrier. The ability of acidic amino acids to destroy neurons correlates with their excitatory potencies (Olney 1969, 1971; Olney and Ho 1970; Olney et al. 1972). This interaction was termed neuroexcitotoxicity. Both ionotropic and metabotropic glutamate receptors can mediate excitotoxicity (McDonald and Schoepp 1992; Schoepp et al. 1995).

2 Glutamate Receptors

2.1 NMDA Receptors

The NMDA receptor (NMDAR) has been named for its affinity for N-methyl-D-aspartate. When activated, the NMDAR allows the influx of cations, most notably calcium. Excessive intracellular calcium concentrations activate intracellular pathways leading to physiological and pathological processes. The NMDAR exhibits a complex gating mechanism, requiring cellular depolarization in addition to the binding of ligands.

NMDA receptors represent tetrameric heteromeric subunit assemblies whose physiological and pharmacological properties depend upon their subunit composition. Three major subunit families, NR1, NR2 (A–D), and NR3 (A and B), have been cloned (Burnashev et al. 1992; Das et al. 1998; Andersen et al. 2001; Chatterton et al. 2002; Matsuda et al. 2002; Monyer et al. 1992). Most NMDA receptors in the CNS are formed from NR1 and NR2 subunits. Alternative splicing results in eight isoforms of NR1. The NR2 subunit family consists of four individual subunits termed NR2A–D (Monyer et al. 1991, 1994; Hollmann and Heinemann 1994). Different NR2 subunits result in different Ca^{2+} permeability of the NMDA receptor channel, different gating properties, and magnesium sensitivity (Monyer et al. 1991, 1994; Ozawa et al. 1998).

Two NR1 subunits can form an ion channel which exhibits all the classical NMDAR properties, i.e., glutamate activation, magnesium block, zinc inactivation, glycine activation, interactions with polyamines, and pH sensitivity. Mayer et al. (1984) showed that depolarization of the NMDAR-expressing neuron is necessary to electrostatically remove a magnesium ion blocking the ion channel pore.

Under physiological conditions, this is accomplished by the activation of other ionotropic glutamate channels. Zinc can inhibit the NMDAR-mediated currents elicited by glutamate (Mayer and Vyklicky 1989). Glycine is a cofactor with glutamate, necessary for NMDAR channel opening (Johnson and Ascher 1987). Glycine shows different affinities at NMDA receptor subtypes. This affinity depends on the NR1 isoform and also the NR2 subunit composition of the receptor complex which allosterically influences the glycine recognition site located on the NR1 subunit (Monyer et al. 1992; Laurie and Seeburg 1994).

Polyamines can potentiate NMDAR currents at low concentrations, increase the frequency of channel opening and glycine affinity, but also reduce currents in a voltage-dependent manner at higher concentrations (Rock and Macdonald 1992; Benveniste and Mayer 1993). The polyamine/NMDAR interaction is dependent upon the subunit composition of the NMDAR channel (Williams 1997).

Protons inhibit NMDAR by interacting with the NR1 subunit on a single lysine residue (Traynelis and Cull-Candy 1990). Thus, alterations in pH can modulate NMDAR function.

NR2 subunits refine NMDAR function and modulate the characteristics of the NR1 ion channel pore. NR2B subunits also bind and link postsynaptic proteins (Sattler et al. 1999) which are parts of postsynaptic densities comprising scaffolding proteins. This allows for the coupling of intracellular enzymes (e.g., neuronal nitric oxide synthase) with ionic second messengers (e.g., Ca^{2+} influx from NMDARs) (Aarts et al. 2002).

A third subunit associated with the NMDA receptor gene family, the NR3 subunit, is expressed in two isoforms: NR3A, which is expressed throughout the CNS, and NR3B, which is expressed primarily in motor neurons (Chatterton et al. 2002). NR1/NR3A and NR1/NR3B complexes are not activated by NMDA or glutamate, but rather elicit an excitatory Ca^{2+} impermeant response via glycine.

2.2 AMPA/Kainate Receptors

AMPA receptors are comprised of four subunits, GluR1–GluR4, and require only glutamate application for activation. They are widely distributed throughout the mammalian central nervous system and mediate fast glutamatergic neurotransmission. The type of subunits within a tetrameric assembly determines biophysical and pharmacological profile of AMPA receptors. GluR1, GluR3, and GluR4 all display strong inwardly rectifying current–voltage and calcium permeability, whereas the GluR2 subunit removes calcium permeability (Hollmann et al. 1991; Burnashev et al. 1995; Geiger et al. 1995). Two splice variants for GluR subunits have been described, flip and flop; these differ in their expression between brain regions and developmental stages. AMPARs are thought to regulate the fast excitation required to remove the magnesium block of nearby NMDARs.

Other non-NMDA receptors are designated GluR5, GluR6, GluR7 (also known as GluK5–7), KA1, and KA2 (also known as GluK1–2). These form high-affinity kainate receptors (Herb et al. 1992, 1996; Hollmann and Heinemann 1994).

The properties of kainate channels are similar to AMPARs, but they are mostly impermeant to calcium ions. Kainate receptors may be localized in both the pre-synapse and post-synapse (Castillo et al. 1997; Vignes and Collingridge 1997), and application of kainate can either stimulate glutamate release (Schmitz et al. 2001) or inhibit presynaptic glutamate release (Frerking et al. 2001). Postsynaptically, kainate channels serve a similar purpose as AMPARs in alleviating magnesium block in NMDARs.

2.3 Metabotropic Glutamate Receptors

Metabotropic glutamate receptors (mGluRs) are single-peptide seven-transmembrane spanning proteins linked to intracellular G proteins. These are built from eight subunits, mGluR1–8. Recent evidence suggests that G-protein-independent signaling can also occur (Heuss et al. 1999). Within the mGluR family, the sequence identity varies. Classification into three subclasses (I–III) has been proposed (Nakanishi 1992; Pin and Duvoisin 1995). Within each class the amino acid sequence identity is 70 % and between classes 45 %. mGluR1 and mGluR5 belong to class I, mGluR2 and mGluR3 to class II, and mGluR4 and mGluR6–8 to class III. Different transduction mechanisms are activated by each class. Class I activates phospholipase C, increases phosphoinositide turnover and Ca^{2+} release from internal stores, and leads to formation of diacylglycerol which then might activate protein kinase C (Abe et al. 1992; Nakanishi 1992). This group of mGluRs also modulates excitatory postsynaptic potentials at hippocampal synapses via tyrosine kinases in a G-protein-independent fashion (Heuss et al. 1999).

Classes II and III are negatively coupled to adenylate cyclase and reduce the intracellular amount of cAMP. Group II mGluRs include mGluR2s and mGluR3s. Group III mGluRs include mGluR4s, mGluR6s, mGluR7s, and mGluR8s. These mGluRs cause downstream inhibition of voltage-dependent calcium channels (Tanabe et al. 1993; Chavis et al. 1994). These receptors are found pre- and postsynaptically (Ozyurt et al. 1988; Bradley et al. 1996). Since presynaptic calcium is integral to neurotransmission, group II and III mGluRs modulate neurotransmission by functioning as autoreceptors and modulating calcium channel influxes. Group I mGluRs potentiate NMDAR-mediated Ca^{2+} influx (Bruno et al. 1995a). mGluR2, 3 and mGluR4, 6, 7, 8 subunits reduce Ca^{2+} influx via NMDARs (Bruno et al. 1995b).

3 The Neurotoxin Glutamate

The mechanisms that mediate excitotoxicity have been extensively studied in the past five decades. The acute component of glutamate toxicity is mediated through a massive influx of sodium and chloride ions into the cell (Rothman 1984, 1985; Choi et al. 1987). A second component of glutamate neurotoxicity is Ca^{2+} dependent and mediated through activation of Ca^{2+}-sensitive proteases (Choi 1987; Frandsen and Schousboe 1991, 1992; Tymianski et al. 1993a).

The concept of slow excitotoxicity arose from observations made by Novelli and coworkers showing that inhibitors of oxidative phosphorylation or of the Na^+/K^+ pump allow glutamate or NMDA to become neurotoxic (Novelli et al. 1988). Subsequently, Zeevalk and Nicklas showed that cyanide triggers excitotoxic lesions sensitive to NMDA antagonists in the chick embryo retina (Zeevalk and Nicklas 1991). Toxicity induced by metabolic inhibition can be mimicked by membrane depolarization with potassium or by relieving the Mg^{2+} block of the NMDA receptor (Zeevalk and Nicklas 1991). These observations were extended by findings in in vivo models showing that mitochondrial toxins (aminooxyacetic acid, an inhibitor of the maleate–aspartate shunt; 1-methyl-pyridine, a mitochondrial complex I toxin; 3-nitropropionic acid and malonic acid, inhibitors of mitochondrial complex II; the nicotinamide antagonist 3-acetylpyridine) produce axon-sparing, excitotoxic lesions in the mammalian central nervous system which can be blocked by NMDA and AMPA antagonists, glutamate release inhibitors, and prior decortication (Beal et al. 1991, 1993a, b; Greene et al. 1993; Henshaw et al. 1994; McMaster et al. 1991; Urbanska et al. 1991; Srivastava et al. 1993; Schulz et al. 1994; Wüllner et al. 1994). These observations led to the hypothesis that energy impairment at the postsynaptic site of glutamatergic synapses causes membrane depolarization, alleviation of the Mg^{2+} block of the NMDA receptors, and heightened neuronal vulnerability towards physiological concentrations of glutamate (Beal 1992a, b; Ikonomidou and Turski 1996).

4 Mechanisms of Excitotoxicity

In neuronal cultures and in vivo, both active (apoptosis-like) and passive (necrosis-like) forms of cell death are seen depending on the intensity of the excitotoxic insult (Bonfoco et al. 1995; Portera-Cailliau et al. 1997). Heterogenous forms of cell death are also observed in animal models of stroke (Snider et al. 1999), hypoxia/ischemia (Fig. 1), and traumatic brain injury (Singleton and Povlishock 2004; Fig. 1). At one end of the spectrum, neurons displaying necrotic morphology are seen following intense glutamatergic insult (Bonfoco et al. 1995). The mechanisms underlying neuronal necrosis include loss of cellular homeostasis with acute mitochondrial dysfunction leading to massive energy failure. Various cell death pathways which include cysteine proteases, mitochondrial endonucleases, peroxynitrite, PARP-1, and GAPDH eventually accomplish cell death following milder glutamatergic insults. These cell death pathways operate in parallel or in sequence to orchestrate neuronal degeneration, and none of them appears to be dominant.

4.1 Calcium

In neuronal cultures, glutamate neurotoxicity can be separated into two components distinguishable on the basis of differences in time course and ionic dependence. The first component, marked by neuronal swelling, occurs early, is dependent on

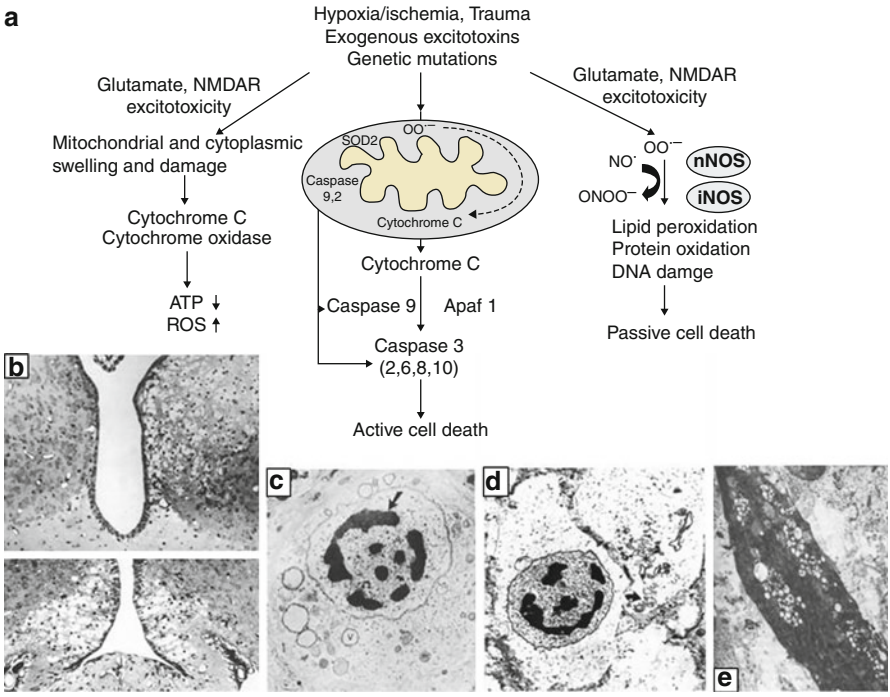

Fig. 1 Pathophysiology of cell death in the context of neurodegenerative disorders. (**a**) Injury generates excessive release of glutamate in the extracellular space which leads to activation of NMDA receptors and massive influx of ions into the cells. Injury also leads to generation of reactive oxygen species (ROS) within the mitochondria, which then signal the release of cytochrome c. Cytochrome c binds to Apaf-1 followed by caspase-9 to form a complex that activates caspase-3 and other caspases. The activation of the *N*-methyl-D-aspartate (*NMDA*) receptor and formation of O_2- and nitric oxide (*NO*) by neuronal nitric oxide (*nNOS*) may lead to release of cytochrome c from the mitochondria or formation of peroxynitrite (*ONOO–*). Resulting hydroxyl radicals can damage lipids, proteins, and DNA and lead to passive cell death. (**b–e**) Examples of types of neuronal degeneration seen in the brain following hypoxia/ischemia or traumatic brain injury (*TBI*) are shown; (**b**) shows neurons undergoing degeneration following hypoxia/ischemia (*upper panel*) in 7-day-old rats or systemic administration of monosodium glutamate in infant mice (*lower panel*). The pattern of degeneration in the two conditions is indistinguishable. (**c**) Electron micrographs depict a neuron undergoing excitotoxic death in the P7 rat brain at 4 h after hypoxia/ischemia and (**d**) after traumatic brain injury. Both cells display disrupted nuclear and cytoplasmic membranes, swollen mitochondria, and cytoplasmic debris. In (**e**) a neuron displaying dark cytoplasm filled with vacuoles is shown 4 h following traumatic brain injury in a 7-day-old rat brain. This neuron is degenerating in a more delayed fashion than shown in (**b**) and (**c**) (Adapted and modified with permission from Liebert Publications from Ikonomidou and Kaindl 2011)

extracellular Na and Cl, and is thus possibly "excitotoxic." The second component, marked by gradual neuronal disintegration, occurs late, is dependent on extracellular Ca^{2+}, and is thus mediated by a transmembrane influx of Ca. While either component alone is ultimately capable of producing irreversible neuronal injury, the Ca-dependent mechanism predominates at lower exposures to glutamate.

Glutamate exposure likely leads to a Ca influx both through glutamate-activated cation channels and through voltage-dependent Ca channels activated by membrane depolarization (Choi 1985, 1987).

Subsequent studies by Choi (1987) suggested that NMDARs may be primarily responsible for this calcium entry. Tymianski et al. (1993a) demonstrated that the path of calcium influx, and not the calcium load, was important in the NMDAR-mediated neurodegenerative process. Indeed, higher lethality can be achieved with lower calcium influxes via NMDARs compared to higher calcium influxes via other calcium-permeant channels (Sattler et al. 1998). Further work showed that NMDARs are spatially linked to neuronal nitric oxide synthase (nNOS) which can produce toxic levels of nitric oxide (NO) (Sattler et al. 1999).

The majority of intracellular calcium is sequestered into the mitochondria (Thayer and Wang 1995; Wang and Thayer 1996). Three phases of intracellular calcium concentration changes in cultured hippocampal neurons exposed to glutamate have been described: an initial phase of increased intracellular calcium lasting 5–10 min, a 2-h latent phase with normal calcium concentrations, and a gradual sustained rise in intracellular calcium associated with cell death (Randall and Thayer 1992).

Calcium activates several mechanisms to orchestrate cell death, including activation of nitric oxide synthase, proteases, and mitochondrial injury.

4.2 Nitric Oxide, Peroxynitrite, and Free Radicals

The findings by Dawson et al. (1991) that nitric oxide synthase (NOS) inhibitors prevent excitotoxic neuronal death in vitro provided first evidence for the role of NO in glutamate-mediated neurodegeneration. Neuronal NOS (nNOS) is the isoform causing excitotoxic injury (Dawson et al. 1996). The postsynaptic density protein of 95 kDa (PSD-95) structurally links nNOS and NMDARs (Sattler et al. 1999). The postsynaptic density protein PSD-95 binds to the C-terminus of the NR2B subunit via a PDZ1 domain and the N-terminus of nNOS via a PDZ2 domain. In addition to targeting multiple intracellular molecules (Stamler et al. 1992), NO also reacts with superoxide to form peroxynitrite, which causes cell death via protein and lipid peroxidation, protein nitration, and DNA injury (Radi et al. 1991a, b) or direct interaction with GAPDH (Hara et al. 2005). GAPDH is a ubiquitous housekeeping enzyme that participates in glycolysis. NO can nitrosylate GAPDH and bind Siah1, an ubiquitin ligase. The formed heterodimer translocates to the nucleus via Siah1 nuclear translocation domain and enhances p300/CBP-associated acetylation of nuclear proteins (Sen et al. 2009). As GAPDH is an active participant in glycolysis, it is possible that the interaction of GAPDH with nitric oxide also causes a functional loss (Molina et al. 1992) which can result in neuronal death via energy failure.

During normal cellular respiration, superoxide is produced and converted by superoxide dismutase into oxygen and hydrogen peroxide. Peroxynitrite, formed from NO and superoxide via a diffusion limited reaction (Huie and Padmaja 1993),

can cause protein nitrosylation (van der Vliet et al. 1998; Schrammel et al. 2003), lipid peroxidation (Radi et al. 1991a, b), direct DNA damage, and protein dysfunction. Peroxynitrite can also inhibit the mitochondrial electron transport chain at complex I and complex II (Radi et al. 1994), the normal function of cytochrome c (Nakagawa et al. 2001) as well as manganese and iron superoxide dismutase in scavenging superoxide (Ischiropoulos et al. 1992) via protein nitration (Yamakura et al. 1998). Peroxynitrite-mediated DNA damage can cause overactivation of the nuclear repairing enzyme poly(ADP)-ribose polymerase (PARP-1) (Zhang et al. 1994; Zingarelli et al. 1996). Evidence that free radicals play a role in glutamate excitotoxicity came from studies showing that superoxide dismutate and antioxidant compounds such as nitrone-based scavengers, free radical spin traps, and 21-aminosteroids/lazaroids confer neuroprotection (Dykens 1994; Gonzalez-Zulueta et al. 1998). Using paramagnetic resonance imaging, Lafon-Cazal et al. (1993) demonstrated a dose-dependent increase in superoxide production following increasing concentrations of NMDA. Further work in different in vitro systems demonstrated that free radical production in the context of excitotoxicity is secondary to calcium influx via NMDAR (Dykens 1994; Dugan et al. 1995; Reynolds and Hastings 1995).

4.3 Zinc

Zinc is present in glutamatergic neurons in a vesicle-associated pool (Martinez-Guijarro et al. 1991), which can contain up to 300 μM concentrations of zinc (Yokoyama et al. 1986). Initial in vivo observations in kainate-treated rodents (Frederickson et al. 1989) that depletion of zinc at presynaptic terminals and simultaneous zinc accumulation in degenerating neurons occurred link zinc to glutamate neurotoxicity. Presynaptic zinc depletion, postsynaptic zinc accumulation, and neuroprotection with zinc chelation have been observed in models of cerebral ischemia (Tonder et al. 1990; Koh et al. 1996) and traumatic brain injury (Suh et al. 2000).

Zinc entry into neurons has been linked to voltage-gated calcium channels, sodium exchangers, NMDARs and AMPA/kainate receptors (Sensi et al. 1997), and TRMP7 channels (Inoue et al. 2010). Increasing intracellular zinc levels result in glycolytic dysfunction as a result of GAPDH inhibition (Sheline et al. 2000), interference with the mitochondrial electron transport chain (Nicholls and Malviya 1968), inhibition of the citric acid cycle (Brown et al. 2000), and increasing levels of reactive oxygen species (Sensi et al. 1999) via overactivation of superoxide-generating enzymes (Noh and Koh 2000) or LOX-12 (Zhang et al. 2004). Increasing levels of zinc also lead to p38 phosphorylation and ERK 1/2 activation which can trigger cell death (McLaughlin et al. 2001; Du et al. 2002).

Although the role of zinc in excitotoxic injury in animal and cell culture models is well documented, it is unclear whether modulating zinc pathways has any potential for treating human diseases.

4.4 Caspases and Calpains

Caspase inhibition prevents NMDA-mediated neuronal death in cerebrocortical (Tenneti et al. 1998) and cerebellar cultures (Du et al. 1997). Tenneti and Lipton (2000) described cytosolic activation of caspases at 20 min post-NMDA application with caspase activity in the nucleus at 18–24 h post-insult. Nuclear caspase activity is indicative of cleaved ICAD, a protein inhibiting the activity of caspase-3-activated DNase (CAD) and results in DNA fragmentation and cell death (Enari et al. 1998).

Brorson et al. (1995b) demonstrated modest neuroprotection in hippocampal cell cultures from NMDA insults with calpain inhibitors. The role of calpains remains less clear and may actually play a reparative role in axons with low, sublethal doses of NMDA (Faddis et al. 1997). Mu-calpain proteolytic activity is necessary in the cleavage and release of apoptosis-inducing factor (AIF) from mitochondria in a cell-free system (Polster et al. 2005). Further, calpain inhibition prevented AIF translocation and subsequent neuronal death in neuronal cultures subjected to oxygen–glucose deprivation (Cao et al. 2007), whereas other studies revealed opposite findings (Wang et al. 2009).

The existing evidence suggests that overactivation of PARP-1 secondary to an excitotoxic stimulus releases PAR polymers into the cytoplasm, which in turn activate calpains by an unclear mechanism. This, in some neuronal systems, leads to AIF release from mitochondria and subsequent cell death.

5 Excitotoxicity in Ischemia and Trauma

Jorgensen and Diemer (1982) first recognized a similar pattern of neuroanatomical degeneration in rats exposed to cerebral hypoxia/ischemia compared to rats treated systemically with monosodium glutamate (Olney 1969). Increased extracellular glutamate concentrations in response to ischemia were measured by microdialysis (Globus et al. 1988). In developing rats, sensitivity to NMDA neurotoxicity was found to parallel developmental vulnerability to hypoxic/ischemic injury (Ikonomidou et al. 1989), and hypoxia/ischemia was described to cause acute neuronal loss in the developing brain with ultrastructural characteristics identical to those caused by glutamate in infant rodent (Ikonomidou et al. 1989; Fig. 1). In adult global ischemia models, increases in glutamate concentrations were observed in the striatum, hippocampus, cortex, and thalamus (Globus et al. 1990). Focal ischemic models demonstrated similar patterns of elevated extracellular glutamate (Hillered et al. 1989).

Glutamate receptor antagonists were found to protect from ischemic injury. Both competitive and noncompetitive NMDA antagonists are effective in focal models of ischemia, and non-NMDA antagonists appear more effective in global cerebral ischemia models. Group I metabotropic glutamate receptor antagonists and group II agonists have been shown to be neuroprotective in gerbils subjected to transient global ischemia (Kingston et al. 1999).

Traumatic brain injury was also shown to result in marked increases in extracellular glutamate concentrations in animals (Faden et al. 1989; Nilsson et al. 1990) and in humans (Baker et al. 1993; Koura et al. 1998) and produce neuropathological changes similar to those induced by glutamate (Fig. 1). Glutamate receptor antagonists can confer neuroprotection in the context of traumatic injuries. NMDAR channel blockers reduced edema following fluid percussion brain injury in rats (McIntosh et al. 1989), whereas riluzole, a sodium channel blocker and glutamate release inhibitor, also provided histological neuroprotection (Zhang et al. 1998). Kynurenate and indole-2-carboxylic acid reduced cerebral edema and improved cognitive and motor dysfunction induced by trauma while protecting against hippocampal cell loss induced by fluid percussion injury (Hicks et al. 1994).

6 Excitotoxicity and Chronic Neurodegenerative Diseases

Morphological changes produced by excitotoxic compounds in the brain and spinal cord resemble in many aspects those observed in the context of chronic neurodegenerative diseases, such as Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis. Therefore, it has been suggested that excitotoxic mechanisms may partly mediate these disorders (Beal 1992b). Especially slow excitotoxicity, triggered by the impairment of mitochondrial energy metabolism, has been implicated.

Although the genetic basis for some of these diseases has been defined, the actual mechanism(s) leading to neurodegeneration are still not understood. Slow excitotoxicity may indeed constitute a contributing factor that could be amenable to pharmacological treatment.

Parkinson's disease (PD) is associated with degeneration of dopaminergic neurons in the ventral mesencephalon. Clinical symptoms consist of tremor, rigidity, bradykinesia, postural deficits, and impaired gait. A gradual decline in the number of dopaminergic neurons of the substantia nigra pars compacta and dopamine content with age is common in the general population. In PD there may be an accelerated rate of cell death, so that a critical level of dopaminergic cell loss (50–70 % of neurons) is reached during normal life span and neurological symptoms of PD become obvious (Bernheimer et al. 1973; McGeer et al. 1989; Fearnley and Lees 1991). It is also possible that an exogenous insult, such as an environmental toxin, may cause a partial loss of substantia nigra dopaminergic neurons which will be followed by further "physiological" decline with age (Calne and Langston 1983). Careful neuropathological studies, serial positron emission tomography (PET), and single photon emission spectroscopy (SPECT) demonstrate a more rapid decline of dopaminergic neurons in the substantia nigra of Parkinson patients as compared to control aging subjects (McGeer et al. 1989; Fearnley and Lees 1991; Brooks 1998).

Initial observations linking excitotoxicity to PD were made by Spencer and colleagues (Spencer 1987). They reported that the excitatory amino acid α-amino-beta-methylaminopropionic acid (BMAA) is linked to Guam ALS–parkinsonism dementia syndrome.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) and its metabolite MPP^+ (1-methyl-4-phenylpyridinium ion) have been used to model PD, since it was discovered that MPTP can cause PD in man (Davis et al. 1979; Langston et al. 1983). The first report suggesting that excitotoxicity may play a role in the pathogenesis of MPTP-induced Parkinson's disease was made by Turski and colleagues (1991), who demonstrated that neurotoxicity of MPP^+, the active metabolite of MPTP, can be blocked in the substantia nigra with both competitive and noncompetitive NMDA receptor antagonists. Such results could be reproduced by other groups (Santiago et al. 1992; Brouillet and Beal 1993; Chan et al. 1993; Srivastava et al. 1993; Jones-Humble et al. 1994). Subsequent studies in primates confirmed that NMDA antagonists attenuated MPTP-induced depletion of substantia nigra dopaminergic neurons (Zuddas et al. 1992; Lange et al. 1993). Glutamate receptor blockers and neuronal NOS inhibitors have been reported to attenuate degeneration of dopamine neurons in MPTP-treated primates (Blum et al. 2001).

Considerable evidence implicates mitochondrial dysfunction in PD. Studies of the electron transport enzymes have been carried out in lymphocytes, platelets, muscle tissue, and postmortem brain tissue from PD patients (Schapira et al. 1990a, b; Di Monte et al. 1991; Hattori et al. 1991; Mann et al. 1992; Nakagawa-Hattori et al. 1992; DiDonato et al. 1993; Janetzky et al. 1994). Decrease in complex I activity was found in the brain, muscle tissue, and platelets of PD patients compared to control subjects. A nuclear magnetic resonance spectroscopy study to measure occipital lobe lactate concentration revealed a highly significant increase of lactate concentrations in PD patients with the largest increases in PD patients with dementia (Bowen et al. 1994). Similar findings indicating increased lactate levels were reported from the striatum of PD patients (Chen et al. 1994; Taylor et al. 1994).

Impaired mitochondrial function may increase vulnerability of affected neurons towards physiological concentrations of glutamate (slow excitotoxicity). Given the fact that the substantia nigra receives rich glutamatergic inputs from the neocortex and the subthalamic nucleus, contribution of slow excitotoxicity to the pathogenesis of this disease in the context of energy failure becomes a very attractive hypothesis.

Antiparkinsonian activity was observed with the noncompetitive NMDA antagonist dextromethorphan (Saez and Tanner, 1993) and in initial trials with the glutamate release inhibitor lamotrigine (Zipp et al. 1993), but these findings could not be confirmed in subsequent studies (Zipp et al. 1995; Montastruc et al. 1997). So far, the only compounds with antiglutamatergic properties that are used for the treatment of patients with PD are amantadine, memantine, and budipine (Schwab et al. 1969; Rabey et al. 1992; Adler et al. 1997). They are used to ameliorate clinical symptoms, but there is no clinical evidence indicating that they influence the course of the disease.

There have been reports that the AMPA receptor antagonist NBQX (2,3-dihydroxy-6-nitro-7-sulfonyl-benzo[f]quinoxaline) improves symptoms and enhances the effect of L-3,4-dihydroxyphenylalanine (L-DOPA) in MPTP-treated monkeys (Klockgether et al. 1991; Wachtel et al. 1992), but these findings could not

be replicated (Luquin et al. 1993; Papa et al. 1993; Zadow et al. 1994; Gossel et al. 1995). Due to such inconsistencies, AMPA receptor antagonists have not made their way into the clinical treatment of PD.

Huntington's disease (HD) is an autosomal dominant disease that gives rise to progressive, selective (localized) neural cell death associated with choreic movements and dementia. The disease is associated with increases in the length of a CAG triplet repeat present in a gene called "huntingtin" located on chromosome 4p16.3. The classic signs of Huntington's disease are progressive chorea, rigidity, and dementia, frequently associated with seizures. A characteristic atrophy of the caudate nucleus is seen radiographically. There is a prodromal phase of mild psychotic and behavioral symptoms which precedes frank chorea by up to 10 years.

The disease was initially modeled by injecting quinolinic acid (an NMDA agonist) into the striatum, leading to loss of GABAergic (GABA, γ-aminobutyric acid) output neurons and sparing interneurons containing somatostatin-NPY (Schwarcz and Kohler 1983; Schwarcz et al. 1983). This neuropathological pattern resembles that seen in Huntington's disease brains (Schwarcz et al. 1983; Beal et al. 1986). Based on these findings, an excitotoxicity hypothesis for the pathogenesis of Huntington's disease was formulated.

Administration of the mitochondrial toxin 3-nitropropionic acid (3-NP) to rodents produces pathology resembling Huntington's disease (Brouillet et al. 1995; Palfi et al. 1996; Borlongan et al. 1997). Interestingly, striatal toxicity of 3-NP can be ameliorated by NMDA receptor antagonists, such as memantine (Wenk et al. 1996), and glutamate release inhibitors, such as riluzole (Guyot et al. 1997). Similarly, striatal toxicity of malonate, a complex II–III inhibitor, was prevented by NMDA receptor antagonists MK-801 and memantine and by the glutamate release inhibitor lamotrigine (Greene and Greenamyre 1995). Thus, it has been postulated that mitochondrial dysfunction in Huntington's patients may be a trigger that constitutes striatal neurons prone to excitotoxicity.

The mechanism through which the widely expressed mutant HD gene mediates slowly progressing striatal neurotoxicity is unknown. Glutamate receptor-mediated excitotoxicity has been hypothesized to contribute to HD pathogenesis. However, inconsistent with this hypothesis, Hansson et al. (1999) showed that transgenic HD mice expressing exon 1 of the human HD gene with an expanded number of CAG repeats are strongly protected from acute striatal excitotoxic lesions. Intrastriatal infusions of quinolinic acid, the agonist of the NMDAR, caused massive striatal neuronal death in wild-type mice, but no damage in transgenic HD littermates. The remarkable neuroprotection in transgenic HD mice occurred at the stage when they had not developed any neurologic symptoms caused by the mutant HD gene. At this stage, there was no change in the number of striatal neurons and astrocytes in untreated transgenic mice, although the striatal volume was decreased by 17 %. Hansson et al. (1999) proposed that the presence of exon 1 of the mutant HD gene induces profound changes in striatal neurons that render these cells resistant to excessive NMDA receptor activation.

The antiglutamatergic compound remacemide, tested in a double-blind placebo-controlled study in HD patients, showed only a trend towards symptomatological

improvement (Kieburtz et al. 1996). Ketamine failed to show any symptomatological improvement (Murman et al. 1997). Thus, there is so far no evidence that symptomatological improvements should be expected by the use of antiglutamatergic compounds in HD patients.

Alzheimer's disease (AD) is by far the most common cause of dementia. Terry and Davies (1980) recommended the term senile dementia of the Alzheimer type (SDAT). Senile (neuritic) plaques and neurofibrillary tangles comprise the major neuropathological lesions in AD brains. Neuritic plaques are spherical lesions and are found in moderate or large numbers in limbic structures and association neocortex. They contain extracellular deposits of amyloid-β protein. Degenerating axons and dendrites are present within and around the amyloid deposits (Terry and Davies 1980; Selkoe 1999).

There are some indications that glutamate and the mechanism of excitotoxicity may be involved in pathogenesis and progression of AD. Constituents of senile plaques stimulate production by microglia of an unknown NMDA agonist (Giulian et al. 1995) as well as production of nitric oxide (NO), known to enhance glutamate release and inhibit its uptake (Lees 1993; Goodwin et al. 1995). β-Amyloid enhances glutamate toxicity (Brorson et al. 1995a; Mattson and Goodman 1995), enhances depolarization dependent glutamate release (Arias et al. 1995), and inhibits its glial uptake (Harris et al. 1996).

There is a decrease in astroglial glutamate EAA2 carrier in the frontal cortex of AD patients. Colocalization of glutamate neurons and neurofibrillary tangles was reported in AD brains (Braak et al. 1993; Francis et al. 1992). Finally, intracerebroventricular administration of β-amyloid produced long-lasting depression of EPSP that was prevented by the NMDA antagonist CPP (Cullen et al. 1996), whereas subcutaneous administration of memantine prevented pathological alterations in the hippocampus produced by direct injection of β-amyloid.

Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease in adults. It is characterized by selective degeneration of upper and lower motor neurons, progressive weakness and paralysis of all muscles, and spasticity (Cleveland and Rothstein 2001). Over 90 % of cases occur sporadically; in 5–10 % of cases the disease is inherited in a dominant mode (familial ALS).

Several pathogenetic mechanisms have been suggested. These include oxidative damage, neurofilament disorganization and subsequent axonal damage, toxicity from intracellular aggregates, and excitotoxicity (Cleveland and Rothstein 2001).

There is unquestionable and landmark evidence that familial ALS and some forms of sporadic ALS are caused by mutations in the Cu/Zn superoxide dismutase (SOD1) gene (Gaudette et al. 2000; Andersen 2001; Andersen et al. 2001). Multiple mutations have been identified so far and almost all provoke a dominantly inherited disease.

Debate on the involvement of excitotoxicity in ALS is based on studies suggesting that the metabolism of glutamate is abnormal in patients with ALS. Rothstein et al. (1992) postulated that the high-affinity glutamate transporter is the site of the defect at least in some forms of the disease. The inhibition of glutamate transport is toxic to neurons, due to persistent elevation of extracellular

glutamate. A possible mechanism for the elevated cerebrospinal fluid concentrations of glutamate and aspartate in patients with ALS could be deficient transport into cells. Studying synaptosomes from neural tissue obtained from 13 patients with ALS as well as from controls, Rothstein et al. (1992) found that ALS patients showed a marked diminution in the maximal velocity of transport for high-affinity glutamate uptake in synaptosomes from the spinal cord, motor cortex, and somatosensory cortex, but not in those from visual cortex, striatum, or hippocampus. This diminution was the result of a pronounced loss of the astroglial EAAT2 protein (Rothstein et al. 1995). Transport of other molecules (gamma-aminobutyric acid and phenylalanine) was normal in patients with ALS.

The fact is that in about one third of ALS patients, glutamate concentrations are increased in the cerebrospinal fluid (CSF) (Shaw et al. 1995), whereas intracellular glutamate concentrations are decreased (Perry et al. 1987; Young 1990; Ludolph et al. 1988). CSF from ALS patients is toxic to hippocampal neurons via stimulation of AMPA receptors (Couratier et al. 1993). The glutamate release inhibitor riluzole attenuated damage induced by ALS CSF (Couratier et al. 1994; Terro et al. 1996). These findings, along with experimental evidence implicating selective vulnerability of spinal motoneurons to AMPA/kainate-receptor agonists (Hugon et al. 1989; Ikonomidou et al. 1996; Williams et al. 1997), implicate that glutamate acting on AMPA/kainate receptors may be pathogenetically involved in motor neuron degeneration in ALS.

Excitotoxicity has been implicated in two other neurological disorders that resemble ALS, the Guam ALS–parkinsonism dementia syndrome and a disease described in the Kii peninsula of Japan. These two disorders have been linked to food excitotoxins (Spencer et al. 1986, 1993).

Along with the finding that SOD1 mutants, when expressed in mice, lead to functional loss of EAAT2 (Nagano et al. 1996), it seems likely that deficient glutamate uptake may contribute to the pathogenesis of some forms of ALS. Riluzole, a glutamate release inhibitor, achieved a modest effect at increasing survival in two independent trials (Bensimon et al. 1994; Lacomblez et al. 1996) and has been approved for the treatment of ALS, although patients do not experience slowing in disease progression.

7 Clinical Experience with Drugs Targeting Excitotoxicity in Stroke and Traumatic Brain Injury

Overall clinical experience has been extremely disappointing. Even though animal models demonstrate dramatic histological and behavioral neuroprotection, no pharmacological intervention targeting excitotoxicity has yet been shown to provide benefit in humans (Muir 2006).

Noncompetitive NMDAR antagonists have been shown in animal models to provide histological and behavioral neuroprotection following focal ischemia (Block and Schwarz 1996; Ozyurt et al. 1988; Seif et al. 1990; Steinberg et al. 1988). Cerestat (CNS 1102) was tested in a multicenter trial in 628 stroke patients

with low-dose, high-dose, and placebo treatments. The trial was stopped because of lack of effect and a trend towards higher mortality with high-dose Cerestat compared to placebo (Albers et al. 2001). Memantine has shown a much better side effect profile in humans (Areosa et al. 2005) and is currently approved for use only in moderate to severe Alzheimer's disease (Reisberg et al. 2003). No stroke trials with memantine have been performed.

The competitive NMDA antagonist Selfotel (CGS 19755) was shown to reduce hippocampal damage in gerbil models of ischemia (Boast et al. 1988). Phase III trials in stroke and in severe head injury were abandoned due to concerns about higher mortality in the treatment arms (Davis et al. 2000; Morris et al. 1999).

The glycine antagonist Gavestinel reached phase III clinical trials, but no difference in morbidity or mortality rates following treatment in stroke was evident (Lees et al. 2000). Ifenprodil and eliprodil, drugs binding at the NMDAR polyamine site, underwent phase III clinical trials but showed no efficacy.

AMPA receptor antagonists initially appeared more effective and showed a longer time-window in preventing neuronal loss in animal models of global ischemia (Sheardown et al. 1990; Buchan et al. 1991). YM872 demonstrated substantial neuroprotective effects in animal models of focal ischemia (Takahashi et al. 1998) and traumatic brain injury models (Furukawa et al. 2003), but phase III trials in ischemic stroke showed no efficacy in 2006.

Lamotrigine inhibits presynaptic voltage-dependent sodium channels and reduces overall excitability and neurotransmitter release (Leach et al. 1986). In animal models, lamotrigine failed to provide neuroprotection in focal ischemia (Tymianski et al. 1993a, b) but showed a reduction of CA1 hippocampal loss of 50 % following global ischemia (Crumrine et al. 1997). BW619C89, a derivative of lamotrigine, underwent phase II trials in 16 of 21 stroke patients (Muir et al. 2000). Clinical development was halted in 2001. Riluzole has also been shown to reduce infarct volumes and improve behavioral outcomes in ischemic (Malgouris et al. 1989; Wahl et al. 1993) and traumatic brain injury (Wahl et al. 1997; Zhang et al. 1998), but no clinical trials for stroke or traumatic brain injury have been performed. Riluzole is licensed for use in ALS (Miller et al. 2007).

8 Clinical Trials with Free Radical Scavengers

The nitrone-based antioxidant NXY-059 was tested in stroke. While the SAINT1 trial examining the efficacy of NXY-059 in clinical stroke was promising (Lees et al. 2000), the SAINT2 trial showed no clinical benefit with treatment (Shuaib et al. 2007). Human clinical trials with the 21-aminosteroid Tirilazad® in head injury resulted in decreased mortality only in males with severe head injury patients and subarachnoid hemorrhages (Marshall et al. 1998). Subsequent trials with Tirilazad in the treatment of subarachnoid hemorrhages (Lanzino and Kassell 1999; Lanzino et al. 1999) showed a reduction in mortality only with the highest grades on arrival, but meta-analysis of Tirilazad in the treatment of subarachnoid aneurysmal hemorrhage demonstrated no clinical outcome differences, but reduced

symptomatic vasospasm (Jang et al. 2009). A Cochrane Review demonstrated increased death or disability in stroke victims treated with Tirilazad compared to placebo in a review of six clinical trials without any statistically significant difference in overall mortality (Bath et al. 2001). Studies in ischemic stroke using Tirilazad have since been abandoned.

In a large multicenter stroke trial, the free radical trapping agent NXY-059, when given within 6 h after the onset of acute ischemic stroke, significantly improved the primary outcome (reduced disability at 90 days), but it did not significantly improve other outcome measures, including neurologic functioning as measured by the NIHSS score (Lees et al. 2006).

Ebselen is a glutathione peroxidase which can interact with peroxynitrite and inhibit enzymes involved in inflammation (Schewe 1995). Clinical trials in Japan demonstrated no significant differences in a 3-month clinical outcome in patients with complete middle cerebral artery occlusion (Yamaguchi et al. 1998) and no significant improvement in clinical outcome despite a reduction in infarct size (Ogawa et al. 1999).

A novel class of drugs named membrane-associated guanylate kinase (MAGUK) inhibitors are currently undergoing phase II clinical trials. The MAGUK inhibitor NA1 uncouples nNOS and NMDARs and has demonstrated neuroprotection in various animal models of stroke (Aarts et al. 2002; Sun et al. 2008).

9 Conclusion

Despite the overwhelming evidence that a variety of neurotoxic mechanisms triggered by excessive glutamate concentrations mediate brain injury in human neurological disorders, all treatment attempts with antiglutamatergic agents in humans have failed. One hypothesis for this failure is that glutamate has a dual function in the injured brain, a toxic one and a trophic one, and that the latter has been ignored.

Synaptic transmission mediated by NMDA receptors is essential for neuronal survival. Blockade of NMDA receptors for only a few hours triggers apoptosis in the developing brain (Ikonomidou et al. 1999; Pohl et al. 1999). NMDA antagonists, when administered during a critical period following traumatic brain injury or in the context of slowly ongoing neurodegeneration, markedly exacerbate damage in adult brain (Ikonomidou et al. 2000).

The Ca^{2+} pool in the immediate vicinity of synaptic NMDA receptors is the on switch for extracellular signal-regulated kinase (ERK1/2)-mediated synapse-to-nucleus signaling (Hardingham et al. 2001). One important function of this Ca^{2+} microdomain near NMDA receptors is to prolong phosphorylation of the transcription factor cyclic AMP response element-binding protein (CREB) induced by synaptic stimuli, thereby enhancing CREB-mediated gene expression. CREB controls transcription of prosurvival genes such as brain-derived neurotrophic factor (BDNF), vasoactive intestinal peptide (VIP), bcl-2, and mcl-1 (Fink et al. 1991; Tao et al. 1998; Riccio et al. 1999). It is therefore postulated that survival-promoting properties of

NMDAR activation derive from the transcription of such prosurvival genes. Neurons surviving ischemic insults (penumbra) demonstrate elevated concentrations of BDNF, bcl-2, and activated CREB, suggesting sustained induction of prosurvival signals (Chen et al. 1995; Tanaka et al. 1999, 2000; Walton and Dragunow 2000). From these findings the logical conclusion is that suppression of NMDA receptor-initiated survival-promoting signals with NMDA antagonists may facilitate death of such cells. Blockade of NMDA-mediated synaptic transmission must therefore be detrimental in situations, in which support by endogenous measures is required, as it happens after stroke or traumatic brain injury or in chronic neurodegenerative disorders (Ikonomidou and Turski 2002).

The long-term elevation of glutamate concentration in humans (days to weeks) after traumatic brain injury has been considered neurotoxic and interpreted as an opportunity for delayed therapy with NMDA antagonists (long time-window for therapy initiation). However, this interpretation may be wrong and such mild elevations of glutamate concentration may represent a self-defense mechanism of the injured brain.

Glutamate may indeed be involved in the initial acute neurodestructive phase after traumatic or ischemic injury, but after this period, it assumes its normal physiological functions, which include promotion of neuronal survival. The hypothesis was that mild increases of glutamate concentrations starting shortly after brain injury are necessary for supporting survival of neurons endangered to die after the insult and for maintaining their physiological functions. Conforming with this hypothesis, it was possible to demonstrate that NMDA antagonists are detrimental to neurons subjected to traumatic brain injury when administration starts after the initial profound elevation of extracellular glutamate concentrations has subsided, that is, 1–7 h after trauma (Ikonomidou et al. 2000). Antecedent treatment with NMDA antagonists in this same setting prevented traumatic neuronal death. These findings strongly argue for the hypothesis that glutamate indeed kills neurons over a brief period after injuries but starts to facilitate repair immediately thereafter. In contrast to its killer function, repair mediated by glutamate appears to be a long-lasting phenomenon. This is in obvious agreement with physiological function of glutamate in the nervous system during development.

Thus, to be successful in preventing excitotoxic brain injury, we would need to specifically target the neurodestructive pathways activated by glutamate while preserving the ones that promote survival. One promising strategy is in the horizon. PSD-95 inhibitors have been shown to confer neuroprotection in stroke models in rodents (Aarts et al. 2002; Sun et al. 2008). The 20-mer peptide Tat-NR2B9c, which acts by perturbing the protein–protein interactions of PSD-95, a synaptic protein that links NMDA receptors to neurotoxic signaling pathways, was most recently shown to confer histological and behavioral neuroprotection in gyrencephalic primates (Cook et al. 2012). This work rejuvenates hopes that more sophisticated and exclusive blockade of neurotoxic but not trophic mechanisms triggered by glutamate may one day provide a mode of treatment that will enable us to limit brain injuries in human patients.

Domoic Acid as a Neurotoxin

Anabel Pérez-Gómez and R. Andrew Tasker

Contents

Abstract

Domoic acid (DOM) is a naturally occurring excitatory amino acid with structural similarity, and similar but not identical pharmacological profile, to kainic acid. DOM is most commonly associated with toxic blooms of marine phytoplankton resulting in contamination of shellfish as well as other species. This brief review summarizes the known toxicological properties of DOM both in vitro and in vivo in a variety of model systems. This chapter also summarizes information on clinical cases of intoxication in both wildlife and humans, as well as highlighting the growing evidence that DOM is a potent neurodevelopmental toxin with relevance to both food safety issues and the etiology of neurological diseases.

1 Chemistry, Physicochemical Properties, and Pharmacology

Domoic acid is a naturally occurring excitatory amino acid (EAA) that has been linked to numerous outbreaks of toxicity in humans (Teitelbaum et al. 1990; Cendes et al. 1995) as well as a variety of other species (for review see Doucette and Tasker 2008; Lefebvre and Robertson 2010). The parent compound is a tricarboxylic amino acid produced by certain marine organisms, the best characterized of which are the red alga *Chondria armata* and the planktonic diatoms of *Nitzschia spp*. (for review see Bates and Horner 1998; Bates and Trainer 2006).

Chemically domoic acid is (2S,3S,4S)-2-carboxy-4-1-methyl-5(R)-carboxyl-l (Z)-3(E)-hexadienyl pyrrolidine-3-acetic acid ($C_{15}H_{21}NO_6$) and has an anhydrous molecular weight of 311.14, a melting point of 215–216 °C (dihydrate), and a UV (ethanol) absorption spectrum with a maximum of 242 nm although this is pH dependent. Structurally domoic acid is very similar to another known toxin, kainic acid, and both are analogues of the amino acids glutamate and proline. The structures of domoic and kainic acid are shown in Fig. 1.

In addition to the parent compound, a number of isomers of domoic acid have been identified. Isodomoic acids A, B, and C are present in small amounts in the red alga *Chondria armata* (Maeda et al. 1986) as are isodomoic acids G and H (Zaman et al. 1997). The isomers isodomoic acids D, E, and F as well as the 5′ epimer have been identified in small amounts from both plankton cells and shellfish tissue (Wright et al. 1990; Walter et al. 1994) although it seems likely that these isomers form on exposure to UV light rather than being metabolic products produced by the plankton (Quilliam 2003). Although the binding of domoic acid isomers in vitro to kainate receptors (Rs) was reported a number of years ago (Hampson et al. 1992), there have been few investigations to date of the pharmacology and toxicology of domoate isomers, with the exception of four publications out of New Zealand (Sawant et al. 2007, 2008; Munday et al. 2008; Sawant et al. 2010).

Both DOM and its analogue kainic acid are excitotoxic and mediate their toxic effects through activation of glutamate receptors (GluRs) with the participation and co-activation of both *N*-methyl-D-aspartate (NMDA) receptors and non-NMDA-R subtypes (AMPA [alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid]/kainate) (Novelli et al. 1992; Larm et al. 1997; Berman and Murray 1997; Berman et al. 2002; Hampson and Manalo 1998; Clements et al. 1998; Tasker and Strain 1998; Tasker et al. 2005). While DOM stimulates AMPA/kainate-Rs (AMPA/KA-Rs) directly, NMDA-R activation appears to be a consequence of either AMPA/KA-R-mediated stimulation of EAA efflux (Novelli et al. 1992; Berman and Murray 1997; Clements et al. 1998; Berman et al. 2002) and/or to reduce tonic

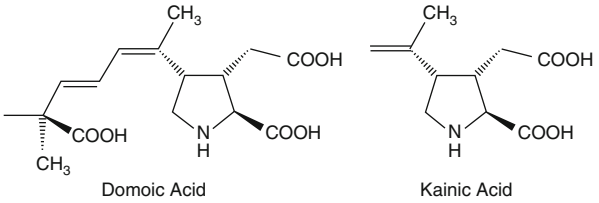

Fig. 1 Structures of domoic acid and kainic acid

inhibition by gamma-aminobutyric acid (GABA) as a result of activation of presynaptic kainate-Rs (KA-Rs) on GABAergic interneurons (Duran et al. 1995; Cunha et al. 1997; Rodriguez-Moreno et al. 2000). Although similar in many respects, DOM and kainic acid are pharmacologically dissociable in some systems because DOM interacts preferentially with the so-called low-affinity kainate subunits designated GluK1 and GluK2 (previously referred to as GluR5 and GluR6) (Verdoorn et al. 1994; Tasker et al. 1996). The complexity of DOM pharmacology combined with the relative lack of knowledge about the physiological properties of KA-Rs probably explains some of the discrepancies reported in the literature, particularly between in vitro and in vivo preparations (see below).

2 DOM Toxicity In Vitro

DOM-induced neurotoxicity has been evaluated in a variety of in vitro systems including immature and mature primary cultures of neurons from cerebellum, cortex, and hippocampus, organotypic hippocampal cultures, and neuroblastoma cell lines. DOM-induced neuronal death is dependent on both exposure duration and concentration, with an EC_{50} reported to range from 3 to 10 μM after 24 h exposure in cerebellar granule cell cultures from both rat and mouse (Novelli et al. 1992; Fernandez-Sanchez and Novelli 1993; Larm et al. 1997; Giordano et al. 2006; Perez-Gomez et al. 2010). The EC_{50} values in cortical neurons range from 4.2 μM in rat (Qiu et al. 2006) to higher than 20 μM in mouse (Jensen et al. 1999) after 24 h treatment, and in mixed hippocampal cultures, an EC_{50} of 7.5 μM has been reported (Roy and Sapolsky 2003). An EC_{50} of 3 μM was obtained for the NG108-15 neuroblastoma cell line (Canete and Diogene 2008), and finally, the treatment of organotypic hippocampal cell cultures (OHSCs) with DOM resulted in selective but not specific toxicity to CA1 pyramidal neurons with an EC_{50} of 3.5 μM after 24 h of exposure (Perez-Gomez and Tasker 2012) and 6 μM after 48 h exposure (Jakobsen et al. 2002). DOM effects in vitro confirm results obtained in vivo showing that DOM is 3–20-fold more potent than KA itself (Stewart et al. 1990; Tasker et al. 1991).

The mechanism of action responsible for DOM toxicity in vitro appears to be more complex than would be predicted from the compound's pharmacological profile as an AMPA/KA-R agonist. DOM in vitro elicits a non-desensitizing response via activation of low-affinity AMPA-Rs (Diaz-Trelles et al. 2003), while activation of KA-Rs does not seem to play a crucial role (Berman and Murray 1997;

Jakobsen et al. 2002; Diaz-Trelles et al. 2003; Gressens et al. 2005). DOM has also been shown to evoke the release of both glutamate and aspartate in cerebellar granule cells (CGCs) (Berman and Murray 1997) as well as in isolated chick retina explants (Nduaka et al. 1999). This appears to occur via a non-vesicular mechanism that is dependent upon reversal of the high-affinity glutamate transporter and cell swelling and, therefore, synergistically potentiates glutamate-/aspartate-mediated neurotoxicity (Berman and Murray 1997). Pharmacologically, both NMDA-R and non-NMDA-R have been implicated in the toxic actions of DOM, in that DOM-induced injury seems to be mediated in part by NMDA-Rs that are activated secondarily as a consequence of AMPA-R-mediated stimulation of EAA release (Berman and Murray 1997). Accordingly, DOM has been shown to act synergistically with NMDA in producing acute cytotoxicity in CGCs (Novelli et al. 1992; Berman and Murray 1996).

In vitro studies have shown increased DOM toxicity with increasing maturation of the central nervous system (Qiu et al. 2006; Hogberg and Bal-Price 2011). This could be due to lower functional expression of the GluRs in the younger cultures. It has also been proposed that more calcium-permeable AMPA-Rs or AMPA-R isoforms could be activated in the mature cultures in comparison to the younger cultures (Qiu et al. 2006), causing glutamate release that subsequently could activate the NMDA-R, promoting neurotoxicity (Berman and Murray 1997; Berman et al. 2002).

Application of DOM produces a rapid and concentration-dependent increase in intracellular calcium in a variety of neuronal preparations, including embryonic brain stem cells (Konig et al. 1994), dorsal root ganglion neurons (Joseph et al. 2011), cultured neurons of chick embryonic retina (Duran et al. 1995), and primary cultures of cortical (Beani et al. 2000), hippocampal (Xi and Ramsdell 1996), cerebellar granule (Perez-Gomez et al. 2010), and Purkinje neurons (Gruol et al. 1997). Vale-Gonzalez et al. (2006) described a prominent intracellular acidification resulting from a rise in intracellular calcium. Some studies have proven that DOM-stimulated increases in cytosolic-free calcium are dependent upon the activation of L-type voltage-sensitive calcium channels (VSCC) following activation of non-NMDA-R (Xi and Ramsdell. 1996; Berman et al. 2002). However, the contribution of a calcium increase through VSCC to DOM toxicity remains controversial as some data suggested that calcium may reduce rather than potentiate the non-desensitizing AMPA-R response to DOM in CGCs, thereby decreasing neurotoxicity as well as the generation of reactive oxygen species (Fernandez-Sanchez and Novelli 1993; Diaz-Trelles et al. 2003; Perez-Gomez et al. 2010).

In some in vitro preparations, DOM-induced neuronal cell death appears to be primarily necrotic in nature. No signs of the classical caspase-dependent apoptotic pathway were detected in organotypic hippocampal slices using different concentrations and time of exposures to DOM (Perez-Gomez and Tasker. 2012) (Fig. 2). In mixed hippocampal cell cultures, DOM neurotoxicity was also found to be necrotic when examined both biochemically and morphologically (Roy and Sapolsky. 2003), and protection afforded by two virally derived caspase inhibitors (p35 and crmA) was ascribed to their ability to sequester free radicals and to stabilize the mitochondrial

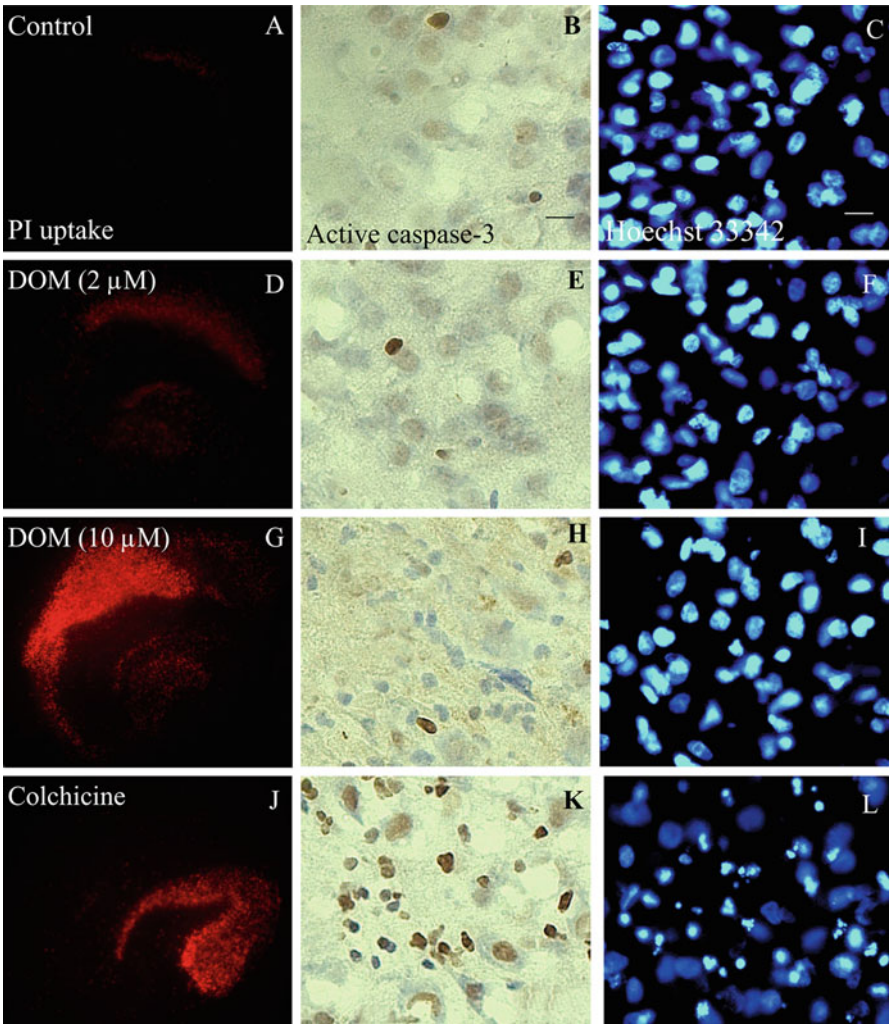

Fig. 2 DOM-induced cell death in organotypic hippocampal slice cultures is primarily necrotic. Propidium iodide exclusion (**a**, **d**, **g**) demonstrates that cell death in OHSCs is concentration dependent but is not accompanied by an increase in the apoptosis marker activated caspase-3 (**e**, **h**) relative to control (**b**) or a change in the intensity of Hoechst 33342 staining for condensed chromatin (**f**, **i**) relative to control (**c**). In contrast administration of colchicine as a positive control results in comparable cell death (**j**) accompanied by changes in both caspase-3 and Hoechst 33342 staining (**k**, **l**)

membrane potential, respectively. However, acute in vitro studies in pure mouse CGCs have shown that DOM can cause either necrotic or apoptotic cell death, depending on its concentration. A high concentration of DOM (1 h, 10 μM) activates both the AMPA/KA-R and NMDA-R which causes a rapid accumulation of intracellular calcium; promotes GSH efflux and a concomitant decrease in

intracellular GSH, inducing an increased lipid peroxidation; and leads to necrotic neuronal death (Giordano et al. 2006). On the other hand, AMPA/KA-Rs (not NMDA-R) have been shown to mediate low-concentration (<0.1 μM) DOM-induced apoptosis (Giordano et al. 2007) with DOM inducing oxidative stress, leading to mitochondrial dysfunction and activation of caspase-3. Similar results were obtained using the motor neuron-like cell line NSC34, where DOM dramatically increased reactive oxygen species production, reduced mitochondrial function and cell viability, and was accompanied by an increase of cell apoptosis (Xu et al. 2008). A moderate increase in degraded α-spectrin concentration was found in organotypic rat brain slices (Erin and Billingsley 2004). The importance of oxidative stress in DOM-induced apoptosis was confirmed in mouse CGCs by the fact that activation of muscarinic receptors provides protection against DOM toxicity in part by an increase in the antioxidant capacity of the cells (Giordano et al. 2009). In addition, and by using the same experimental system (mouse CGCs), Giordano et al. (2008) have shown that DOM also causes an increase in the phosphorylation of p38 and Jun N-terminal (JNK) kinases, which are preferentially activated by cell stress-inducing signals (Raman et al. 2007).

While many reports have described the effects of high concentrations of DOM on neuronal systems in vitro, the effects of low-concentration DOM have also been tested in a variety of in vitro systems, leading to interesting results. Indeed, long-term exposure of primary cortical neurons to low-concentration DOM (50 nM, 4 weeks), which acutely did not induce any effects on electrical activity in the mature cultures, significantly increased the spontaneous activity of neurons when compared to non-treated cultures (Hogberg et al. 2011). The authors concluded that DOM should be recognized as a developmental neurotoxicant as the induced changes in electrical activity could lead to serious disturbance of overall neuronal activity in the developing brain. This conclusion is consistent with the findings of a number of in vivo studies in perinatal animals (see subsequent section) as well as with a recent report by Perez-Gomez and Tasker (2012) in which organotypic hippocampal slice cultures were exposed to concentrations below those required to induce permanent neurotoxicity. In this study, low-concentration DOM produced an increase of proliferation and neurogenesis in the dentate gyrus and CA1 subfields that may contribute to the development of neuroplastic changes and abnormal circuits relevant to disease. Along similar lines, Perez-Gomez et al. (2010) demonstrated that mild, nontoxic exposures to the Na^+/K^+-ATPase inhibitor palytoxin synergistically sensitized the vulnerability of CGCs to normally nontoxic concentrations of DOM, leaving NMDA receptor-mediated excitotoxic response unaltered. The results obtained demonstrate not only a crucial role for Na^+/K^+-ATPase activity in determining neuronal vulnerability to DOM-mediated excitotoxicity, but, as palytoxin and DOM are both seafood contaminants found in geographically overlapping regions, the results raise reasonable concern about possible risks for human health associated to the ingestion of low (i.e., below regulatory limits), subtoxic amounts of these phycotoxins in food.

A few studies have been conducted exploring the possibility that DOM affects not only neurons but also other cells of the central nervous system such as

astrocytes or microglia. It has been shown that exposure of astrocytic cultures to DOM did not induce any cell death (Novelli et al. 1992; Ross et al. 2000; Giordano et al. 2006), but, to a certain extent, it changed some glial functions. Injury to the astrocytes was characterized by ultrastructural changes and altered expression of chemokines/cytokines, tyrosine kinases (Trk), and apoptotic genes (Gill et al. 2008). Changes in the mRNA expression of glial fibrillary acidic protein (GFAP) (downregulation) and S100β (upregulation) (Hogberg and Bal-Price 2011) as well as effects on membrane function of rat glial cells (Liu et al. 2008) and modest increases in intracellular calcium (Giordano et al. 2006) have been reported after DOM treatment. Involvement of glial cells could enhance DOM-induced neurotoxicity as both glutamate uptake and its metabolism to glutamine were significantly inhibited (Ross et al. 2000).

In accordance with the results in astrocytes, DOM does not seem to induce toxicity to microglial cells in vitro (Mayer et al. 2001). The hypothesis that DOM might lead to the activation of microglia has been tested as well, and results seem to depend on the duration of the exposure as well as on the type of culture used. In organotypic hippocampal slice cultures, low-dose DOM insult (2 μM, 24 h) induced a significant increase in the number of reactive microglial cells 7 days after treatment (Perez-Gomez and Tasker 2012). On the other hand, DOM treatment (4–24 h, 1 mM) does not appear to activate neonatal rat microglial cultures and the concomitant expression and release of pro- and anti-inflammatory mediators (Mayer et al. 2007).

3 DOM Toxicity In Vivo

3.1 Absorption, Distribution, and Elimination

DOM is usually administered parenterally (i.p. or s.c.) in most experimental paradigms, but the more common route of exposure for intoxication of wildlife and humans (see Sects. 4.1 and 4.2 below) is by oral ingestion. Surprisingly, however, there have been very few objective studies on the absorption of this toxin following oral administration. Based on these limited observations, it appears that DOM absorption from the GI tract is erratic and bioavailability is approximately 5–10 % whether studied in mice and rats (Iverson et al. 1989, 1990) or in cynomolgus monkeys (Iverson et al. 1990; Tryphonas et al. 1990b; Truelove et al. 1996). Bioavailability following parenteral administration (i.p. or i.v.) on the other hand appears to be complete.

Once absorbed DOM appears to be largely restricted to the vascular compartment with an interpolated apparent steady-state volume of distribution (Vd_{ss}) of approximately 0.20 l/kg in all species studied to date (Suzuki and Hierlihy 1993; Truelove and Iverson 1994). This is consistent with the very hydrophilic nature of the molecule, as is the comparatively poor blood–brain barrier penetration of DOM in normal adult rats, where mean transfer constants ranging from 1.60 to 1.82 ml/g/s $\times$ 10^6 have been reported (Preston and Hynie 1991) (in the same study

sucrose transfer constants ranged from 1.00 to 1.24). These data argue against the existence of a carrier protein and suggest that the highly charged state of DOM at physiological pH results in poor CNS penetration kinetics, which seems at variance with the known CNS toxicity associated with DOM (see below). On closer examination, however, the data suggest that DOM is an extremely potent neurotoxin within the CNS, an assumption that is confirmed by studies reporting extremely low ED_{50} values when DOM is administered directly into the CNS via intracerebroventricular (i.c.v.) injection (Sawant et al. 2008; Vranyac-Tramoundanas et al. 2011) or is administered to very young rats prior to blood–brain barrier closure (Xi et al. 1997; Doucette et al. 2000).

DOM appears to be eliminated almost exclusively by renal excretion. Preston and Hynie (1991) reported that a single i.v. dose of radiolabelled DOM was almost completely eliminated from the serum of intact rats within 30 min, but that nephrectomy resulted in a significantly reduced clearance, such that detectable serum concentrations of DOM were still present at 60 min postinjection (the last time point studied). In a more robust study of renal pharmacokinetics, Suzuki and Hierlihy (1993) reported that serum clearance of DOM was almost entirely due to renal excretion, with similar kinetics over a wide range of dosages (0.5 ng/kg–2.0 mg/kg i.v.). Analysis of serum concentration-time curves produced elimination rate constants (k) of 0.025–0.035 min^{-1} (equivalent to an elimination half-life of approximately 13 min). These authors also reported total body clearance values of 7.75–10.82 ml/min/kg and renal clearance values ranging from 8.80 to 12.20 ml/min/kg. Renal excretion in this study appeared to be mainly by glomerular filtration because kinetics were not altered by the presence of probenecid. Interestingly, these data in rats may help to explain why comparatively few of the humans who ate contaminated shellfish in 1987 presented with symptoms of toxicity (see Sect. 4.2 below).

3.2 Acute Behavioral Toxicity

Following the 1987 outbreak of human toxicity following consumption of shellfish contaminated with DOM (see Sect. 4.2 below), a number of studies were published describing the acute toxicity of DOM in mice, rats, and, to a lesser extent, nonhuman primates. A complete review of these studies is beyond the scope of this chapter, but the reader is referred to Doucette and Tasker (2008) and Tasker et al. (2011) for greater detail. One important thing to note when reviewing the early (pre-1995) literature is that it was intended to describe toxicity resulting from contaminated shellfish. Consequently, most of these investigators did not have access to purified DOM, and/or the precise nature of the toxin(s) causing amnesic shellfish poisoning (see Sect. 4.2) was unknown. For these reasons toxicity data are derived largely from intraperitoneal (i.p.) injections of crude homogenates of toxic mussels (Wright et al. 1990) or of toxin-containing methanol/water extracts of whole mussels (Iverson et al. 1989, 1990; Glavin et al. 1989, 1990; Grimmelt et al. 1990; Bose et al. 1990; Tasker et al. 1991; Strain and Tasker 1991) or mussel

hepatopancreas (Bose et al. 1990; Glavin et al. 1990). Variability in sample preparation probably accounts for some of the variability in dose–response data in these chapters. In fact, Novelli et al. (1992) reported that domoic acid toxicity in mussel extracts could be altered by the presence of other amino acids, implying that even identically prepared extracts could have small differences in toxicity if different batches of shellfish are used. This is consistent with detailed dose–response data compiled by Tasker et al. (1991) in which these authors reported differences in the dose–response curves generated using DOM from extracts of toxic mussels (concentrations confirmed by HPLC) and extracts of "clean" mussels that were "spiked" with known concentrations of purified DOM.

Despite the above-mentioned limitations in early studies, subsequently confirmed in later studies using chemically purified DOM, the acute behavioral toxicity elicited by DOM is remarkably consistent both within and between species. Systemic injections of DOM elicit a graded series of behavioral changes prior to seizure onset whether studied in mice (Iverson et al. 1989; Tasker et al. 1991), rats (Tryphonas and Iverson 1990; Scallet et al. 2004), or nonhuman primates (Tryphonas et al. 1990a, b; Scallet et al. 1993; Schmued et al. 1995; Slikker et al. 1998). The sequence of events is both highly reproducible and predictably dose-related. Following injection, animals will initially demonstrate hypoactivity and sedation (accompanied by gagging and vomiting in nonhuman primates, but not seen in rodents) followed by akinesia, rigidity, stereotypies (repetitive scapular scratching in rodents), loss of postural control, convulsions (forelimb only, progressing to full tonic-clonic), and death. Both the extent to which the animal progresses through this sequence and the speed of progression are dose dependent (Tasker et al. 1991). Further, the profile of acute behavioral toxicity does not appear to be appreciably different in male or female animals, although it has been suggested that different strains of mice may demonstrate altered sensitivity to DOM (Peng et al. 1997).

Predictably, behavioral toxicity following acute injections of DOM correlates with abnormal hippocampal discharges and limbic seizures as recorded electroencephalographically (Nakajima and Potvin 1992; Fujita et al. 1996; Scallet et al. 2004). Moreover, and consistent with the effects observed in human intoxication (see Sect. 4.2), acute injections of DOM in rats have also been reported to alter neurobehavioral performance in tests of passive avoidance, auditory startle, or conditioned avoidance response (Sobotka et al. 1996) or of learning and memory (Sutherland et al. 1990; Petrie et al. 1992; Nakajima and Potvin 1992; Clayton et al. 1999).

3.3 Histopathology

Despite the differences in study protocol, there is an overall agreement regarding the histopathology of the acute brain lesions associated with DOM toxicity. DOM induces neurodegenerative changes consisting of neuronal shrinkage, vacuolization of the cytoplasm, cell drop out, edema, and microvacuolation of the neuropil. Light

and electron microscopic observations in animal studies show two types of neuronal degeneration associated with DOM toxicity: swollen, vacuolated neurons are described intermingled with some shrunken and darkly stained electron dense neurons (Tryphonas et al. 1990a, b; Strain and Tasker 1991; Ananth et al. 2001; Pulido 2008). These findings are consistent with the view that the neuronal degeneration induced by DOM is mostly necrotic, at least in the short term. Studies using markers of cell injury and apoptosis also support this view (Ananth et al. 2001) as do studies in organotypic hippocampal slice cultures (see Sect. 2 above). These changes have preferential distribution within structures of the limbic system (Tryphonas et al. 1990a, b; Tryphonas and Iverson 1990; Strain and Tasker,1991), and the hippocampus among other brain regions appears to be a specific target site having high sensitivity to DOM toxicity, particularly the pyramidal neurons in the CA3 region, followed by the dentate gyrus and CA1 region (Tryphonas, et al. 1990a, b; Sutherland et al. 1990; Strain and Tasker 1991). With some exception, the CA2 region is reported as the least affected (Slikker et al. 1998). Other regions affected include the piriform and entorhinal cortices, olfactory bulbs, nucleus accumbens, arcuate nucleus, area postrema, and the retina (Iverson et al. 1989; Tryphonas et al. 1990a, b; Tryphonas and Iverson 1990; Schmued et al. 1995). The anatomical extent of brain lesions induced by DOM has also been identified by magnetic resonance imaging microscopy in both human (Cendes et al. 1995) and rats (Lester et al. 1999) and is consistent with the histopathology data.

In addition to neuronal degeneration, there is also evidence suggesting involvement and injury of glial cells, including astrocytes and microglia (Mayer 2000; Mayer et al. 2001; Gill et al. 2008; Pulido 2008) which is also consistent with results obtained in organotypic slice cultures (see Sect. 2 above).

3.4 DOM as a Developmental Neurotoxin

Although much of the early DOM literature dealt with acute, and to a lesser extent chronic, toxicity in adult animals (see Sects. 3.2 and 3.3 above), evidence and interest in the effects of DOM on the developing nervous system and DOM's potential role as a developmental neurotoxin have been appearing at an escalating pace over the past several years (for review see Costa et al. 2010). Despite an early report of negative consequences to DOM exposure in utero (Dakshinamurti et al. 1993), the issue of gestational toxicity lays somewhat dormant for many years but has recently been explored in greater detail with publications on maternal-fetal transfer rates (Maucher and Ramsdell 2007) and fetal kinetics (Maucher-Fuquay et al. 2012) as well as reports of toxicity following exposure in utero in rats (Tanemura et al. 2009) and sea lions (Ramsdell and Zabka 2008).

Because rat brain development is delayed relative to humans, early postnatal life in the rat corresponds roughly to late third-trimester brain development in humans, a particularly sensitive period of brain development. Pioneering studies by Xi et al. (1997) and Doucette et al. (2000) demonstrated convincingly that the neonatal rat brain was exquisitely sensitive to the toxic effects of DOM. Further, this difference

in potency relative to adult rats changes throughout early life, with dose–response relationships for DOM toxicity shifting progressively to the right between 0 and 22 days of age (Doucette et al. 2000), an effect that is presumed to be due to maturation of the blood–brain barrier. During the second postnatal week of life in the rat (i.e., the middle of the brain growth spurt; Dobbing and Smart 1974), doses of DOM as low as 20 μg/kg can alter neurobehavioral development (Doucette et al. 2003). Of particular interest, and concern, are an ever-increasing number of publications showing that exposure of rat pups to low doses of DOM during early development can result in later-onset symptoms of disease in the resulting adult animal. Best characterized to date are the effects of low-dose neonatal DOM in producing a neurodevelopmental model of temporal lobe epilepsy characterized by changes in behavior (Doucette et al. 2004), hippocampal morphology (Doucette et al. 2004; Bernard et al. 2007; Gill et al. 2010b), seizure threshold (Gill et al. 2010a), and cognition (Gill et al. 2012). More recently, low doses of DOM during development have also been shown to produce apparently permanent changes in both sleep patterns (Gill et al. 2009) and attentional processing performance (e.g., prepulse inhibition, latent inhibition) (Adams et al. 2008; Marriott et al. 2012) that are commonly seen in schizophrenia and related neuropsychiatric disorders. These observations and the resulting slowly developing disease models can prove useful in dissecting the complex sequence of changes that underlies neurological diseases, but given that current regulatory limits on DOM are based on acute toxicity in adult animals, they also raise serious questions about the potential of low concentrations of DOM in the environment or in food being a developmental neurotoxin that may warrant additional scrutiny (Stewart 2010).

4 Clinical Toxicity

4.1 Toxicity in Wildlife

DOM and to some extent DOM isomers have been found in oceans worldwide, so it is not surprising that there have been many reports of DOM toxicity in wildlife species. Reviews of much of this data can be found in Doucette and Tasker (2008) and Lefebvre and Robertson (2010) as well as other sources. While production of DOM in the aquatic environment has historically been associated with the red alga *Chondria armata* (Takemoto and Daigo 1960), the source of DOM as an environmental toxicant is through blooms of planktonic species including *Pseudo-nitzschia multiseries* and *Pseudo-nitzschia australis* as well as many others. For further detail, the reader is directed to any of several excellent reviews including Bates and Horner (1998) and Bates and Trainer (2006). Plankton species are a food source for many aquatic invertebrates particularly bivalve molluscs (e.g., mussels, clams, oysters) as well as planktivorous fish (e.g., anchovies, sardines) and mammals (e.g., filter-feeding whales). While toxicity has been reported in all of these species, it is also clear that DOM toxicity extends higher up to the food chain and affects invertebrates that consume contaminated shellfish (e.g., crabs) as well as piscivorous birds

(e.g., cormorants, pelicans) and marine mammals that eat fish and/or shellfish (e.g., sea lions, sea otters, piscivorous whales) (Lefebvre et al. 1999, 2000, 2001, 2002).

The symptoms associated with DOM toxicity in these species vary, but it is generally believed that most invertebrate species are unaffected (presumably due to their rudimentary nervous system), whereas fish, birds, and mammals display classic signs of neurotoxicity. Indeed it is believed, although not confirmed, that seabirds intoxicated with DOM in California were the inspiration for Alfred Hitchcock's famous movie The Birds (© Universal Pictures, 1963). Less romantic, but far better documented, accounts of DOM intoxication in wildlife have been reported by a number of groups, including an excellent series of reports on intoxication of California sea lions (*Zalophus californianus*) by both US west coast and east coast scientists (e.g., Scholin et al. 2000; Ch'ng et al. 2002; Gulland et al. 2002; Silvagni et al. 2005; Goldstein et al. 2008).

4.2 Toxicity in Humans

Late in 1987, an outbreak of a newly recognized acute illness caused by eating blue mussels and characterized by gastrointestinal and unusual neurological symptoms occurred in Canada. More than 107 people (47 men and 60 women) were affected, most from Quebec. A case was defined as the presence of gastrointestinal symptoms (vomiting, abdominal cramps, diarrhea) within 24 h and neurological symptoms within 48 h (severe headache and memory loss). The etiologic agent was found to be DOM, an excitatory neurotransmitter amino acid, produced by *Nitzschia pungens f. multiseries*. Both *N. pungens* and DOM were present in the digestive glands of the causative cultivated mussels, harvested from the eastern coast of Prince Edward Island, and shipped to other parts of Canada (Perl et al. 1990; Teitelbaum et al. 1990).

Of the 107 persons that met the case definition, 19 were hospitalized from 4 to 101 days, 12 of these were admitted to intensive care, and 3 died in hospital at 12–18 days after admission. Another patient died after 3 months. Ninety nine of the patients answered a questionnaire, in which they provided information on the symptoms and on the amount of mussels consumed. Of these patients, 49 were between 40 and 59 years old and 38 patients were 60 years or older. Symptoms of illness included nausea (77 %), vomiting (76 %), abdominal cramps (51 %), diarrhea (42 %), headache (43 %), and memory loss (25 %). None of the younger patients (20–39 yrs) suffered memory loss, and their only symptoms were of a gastrointestinal nature. Hospital charts were available for 16 of the 19 hospitalized patients, indicating that all severely ill patients less than 65 years old had preexisting illnesses, including diabetes (3), chronic renal disease (2), and hypertension with a history of transient ischemic attacks (1) considered to be predisposing factors. All patients admitted to intensive care had serious neurologic dysfunction, including coma (9), mutism (11), and seizures (8). Seven patients had unstable blood pressure or cardiac arrhythmias. For nine patients and one person who did not become ill, analytical information on the unconsumed portion of the

Table 1 Estimated exposure and clinical course of patients who ingested DOM in contaminated mussels during the 1987 outbreak of amnesic shellfish poisoning in Canada

Patient	Age	Estimated DOM consumed (mg)	Clinical symptoms and treatment			
			GI	Memory loss	Hospitalized	ICU
1	72	60	Y	-	-	-
2	62	70	Y	Y	-	-
3	70	80	Y	-	-	-
4	61	90	Y	-	-	-
5	67	110	Y	-	-	-
6	71	110	Y	-	-	-
7	74	270	Y	Y	Y	-
8	68	290	Y	Y	Y	Y
9	84	290	Y	Y	Y	Y

Data adapted from Perl et al. (1990)
GI refers to gastrointestinal symptoms; *ICU* refers to intensive care unit

mussels and recall information on portion size were available, and this was used to estimate exposure. The concentration of DOM in these mussels was determined by mouse bioassay (characteristic hind leg scratching) and ranged between 31 and 128 mg/100 g. Increasing exposure correlated with the clinical course of events (Table 1). All patients reported gastrointestinal illness, but only one of six patients who consumed between 60 and 110 mg DOM suffered memory loss and none required hospitalization. All three patients who had consumed 270–290 mg DOM suffered neurological symptoms and were hospitalized. One person who consumed only 20 mg DOM did not become ill. The cognitive impairment observed in this new disease, attributed to DOM, appeared to be persistent and led to the term "amnesic shellfish poisoning" (Perl et al. 1990; Todd 1990). For a detailed description of neurologic and neuropsychiatric profiles of patients subsequent to the initial event, the reader is referred to reports by Gjedde and Evens (1990) and Cendes et al. (1995).

Neuropathological examination of the four patients who died indicated neuronal necrosis and astrocytosis particularly in the hippocampus and the amygdaloid nucleus. All four victims also had lesions in the claustrum, secondary olfactory areas, the septal area, and the nucleus accumbens septi. Two had prominent thalamic damage, especially in the dorsal medial nucleus. The subfrontal cortex was also damaged in three of the patients. The authors noted that the pattern of damage in the hippocampus appeared to parallel that seen in animals which suffered neurotoxic reactions after administration of kainic acid. Cerebrovascular disease was evident in two patients: an acute hemorrhagic infarct in the left posterior perisylvian cerebral in one victim and, in the other, cerebellar infarcts likely related to a myocardial infarct 3 days prior to death. Neurofibrillary tangles, and senile plaques, typical features of Alzheimer's disease, were not observed in these patients (Teitelbaum et al. 1990).

Although the 1987 incident in Montreal is the only confirmed case of human intoxication with DOM, an outbreak of DOM poisoning may have occurred in

October/November 1991 in Washington State, USA. Approximately two-dozen people became ill after ingesting razor clams harvested along the Washington and Oregon coasts. Although gastrointestinal or neurological symptoms were observed within 36 h of ingestion, no other symptoms consistent with DOM intoxication were reported. A total of 21 possible DOM victims and 43 non-victims were interviewed. Based on the concentrations of DOM measured in razor clams, the mean total DOM consumption by the 21 victims would have been 17 mg (estimated to be 0.28 mg/kg b.w.) and 8 mg by the unaffected individuals (0.13 mg/kg b.w.). A total of 13 patients developed neurological symptoms, but all recovered. Unfortunately the incident was not well reported and was unsubstantiated (Todd 1993; Jeffrey et. al. 2004).

5 Conclusion

Revived from relative obscurity into the limelight as a result of the 1987 incident of human intoxication, DOM has become an environmental and experimental toxin of considerable importance worldwide. As an environmental contaminant affecting both the food supply and wildlife species, DOM and DOM isomers are now routinely monitored in many jurisdictions. As an experimental tool in neurotoxicology and neuroscience, DOM has a unique place as a slowly desensitizing AMPA/KA-R agonist that shows high potency and efficacy in a wide variety of experimental systems. Perhaps the most interesting thing, and of great potential concern, however, is the emerging evidence of DOM as a neurodevelopmental toxin and a precipitating factor in the onset and progression of various forms of neurological disease. Whether these properties can be exploited in the form of disease models and/or warrant improved vigilance on the part of global regulatory bodies, continued study of the many fascinating properties of DOM and isomers is warranted.

Abstract

Tryptophan metabolism along kynurenine pathway yields a number of compounds affecting brain function. Among kynurenine derivatives, neuroprotective kynurenic acid (KYNA) and neurotoxic quinolinic acid and 3-hydroxykynurenine have stimulated the greatest scientific interest. KYNA, initially considered merely a side-product of tryptophan degradation, was discovered in 1982 to act as excitatory amino acid receptor antagonist. Since then, a number of novel KYNA targets emerged. KYNA was suggested to play a role as antagonist of α7 nicotinic receptors and ligand of G protein-coupled GPR35 and human aryl hydrocarbon (AHR) receptors. In here, research data is reviewed supporting the idea that produced by astrocytes KYNA serves as an endogenous neuroprotectant. Mechanisms controlling brain levels of KYNA are discussed in the context of neurodegenerative disorders, brain ischemia, and seizures. Available data concerning changes of brain KYNA in respective animal models and in human diseases, together with an overview of effects following the application of KYNA, KYNA analogues or compounds influencing the activity of enzymes along kynurenine pathway are presented. Emerging therapies designed to increase the level of neuroprotective KYNA may become an important avenue in the treatment of brain disorders accompanied by neuronal loss.

1 Introduction

The history of kynurenic acid (KYNA; see Fig. 1) dates to year 1853, when German chemist Baron Justus von Liebig determined its presence in canine urine (Liebig 1853). Half a century later, the discovery of tryptophan was followed by the observation that KYNA is one of its metabolites (Hopkins and Cole 1901; Ellinger 1904). For almost eight decades, the compound was considered merely a side-product of *tryptophan* degradation. In early 1980s, KYNA was reported to antagonize amino acid-induced excitation of central neurons (Perkins and Stone 1982) and to block neurotoxicity and seizures evoked by another tryptophan metabolite, quinolinic acid (Foster et al. 1984). Soon, the presence of KYNA within the brain of mammals and rodents was confirmed (Moroni et al. 1988a, b; Turski et al. 1988). Subsequently, numerous basic and clinical investigations addressed the role of KYNA in brain function, and the potential ways to modulate KYNA central levels were elucidated.

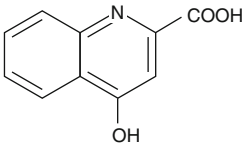

Fig. 1 Structure of kynurenic acid

2 KYNA Synthesis and Brain Levels

Tryptophan, after entering the brain in a free form, is utilized along various metabolic pathways yielding structural and enzymatic proteins or centrally active substances such as serotonin and kynurenines. In mammals, approx. 95–99 % of dietary tryptophan not bound into proteins is converted to kynurenine along the so-called *kynurenine* pathway (Stone and Darlington 2002); see Fig. 2.

Brain kynurenine derives from production in situ (40–50 %) and from peripheral pool. Kynurenine enters the brain via large neutral amino acid transporter (Fukui et al. 1991; Németh et al. 2006). KYNA itself penetrates across the blood-brain barrier to a lesser degree (Scharfman and Goodman 1998; Salvati et al. 1999). However, peripheral application of KYNA prior to ischemia may dramatically increase brain concentrations of compound (Salvati et al. 1999). Transport occurs mostly via passive diffusion (Fukui et al. 1991). Notably, human organic anion transporter hOT3 might play a role in the uptake of KYNA from the brain into brain capillary endothelial cells (Uwai et al. 2012).

Within the brain, kynurenine can be either transaminated to KYNA or hydroxylated to *3-hydroxykynurenine*, which is further converted to *quinolinic acid*, and finally to nicotinamide adenine dinucleotide (NAD) (Moroni 1999; Németh et al. 2005, 2006). 3-Hydroxykynurenine generates large quantities of free radicals, whereas quinolinic acid is an *N*-methyl-D-aspartate receptor agonist with potent excitotoxic properties (Stone 2001). Of many kynurenine derivatives, neuroinhibitory KYNA and neurotoxic quinolinic acid and 3-hydroxykynurenine have stimulated the greatest scientific interest.

The brain level of KYNA depends directly on the activity of kynurenine aminotransferases (KATs), but, indirectly, it is also strongly associated with the action of enzymes contributing to the production and degradation of its precursor, kynurenine. The synthesis of kynurenine is regulated by two separate enzymes, tryptophan 2,3-dioxygenase (TDO) and indoleamine 2,3-dioxygenase (IDO). TDO and IDO are expressed in the brain but their activities are rather low. Therefore, as mentioned above, more than 50 % of brain kynurenine is regarded to originate from peripheral sources.

Increasing scientific interest has focused recently on *kynurenine 3-monooxygenase* (KMO), which converts kynurenine to 3-hydroxykynurenine. As KMO displays lower K_m for kynurenine than KATs (Bender and McCreanor 1985), it is considered a key enzyme controlling the availability of kynurenine for KYNA synthesis. The process of irreversible transamination of kynurenine to

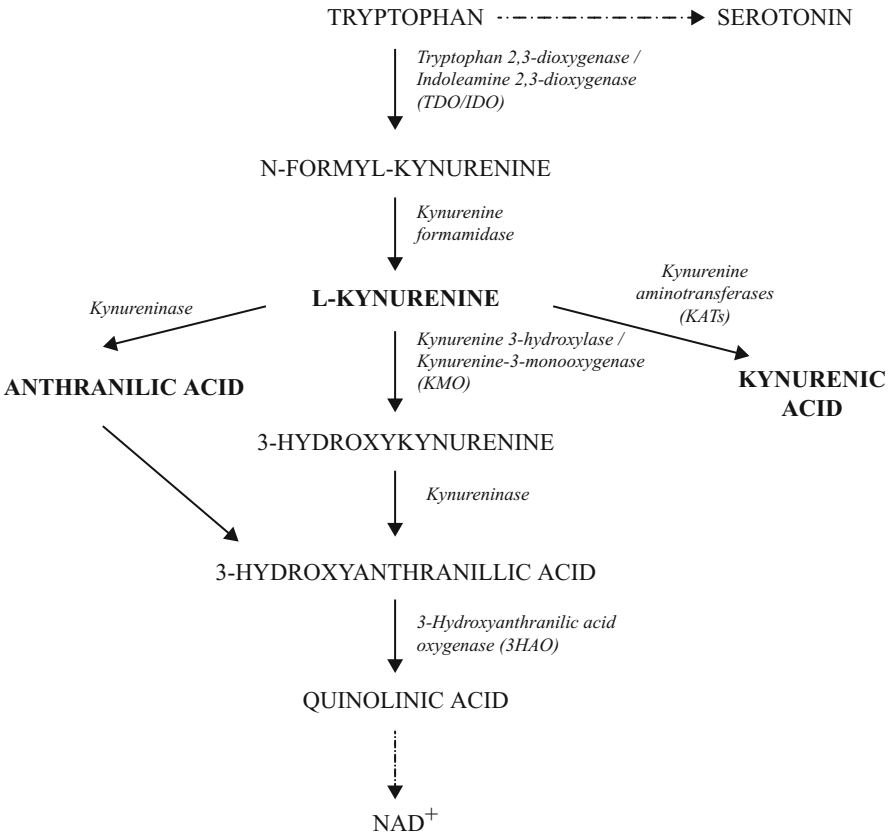

Fig. 2 Scheme of kynurenine pathway

KYNA is catalyzed by four distinct kynurenine aminotransferases I–IV (KATs) (Okuno et al. 1991a; Guidetti et al. 2007; Bellocchi et al. 2009) considered nowadays as potential targets for regulating brain KYNA levels. KAT I [glutamine transaminase K (GTK)/cysteine conjugate beta-lyase (CCBL) 1], KAT II [aminoadipate aminotransferase (AADAT)], KAT III (CCBL2), and KAT IV [glutamic-oxaloacetic transaminase (GOT) 2/mitochondrial aspartate aminotransferase (mASPAT)] have been identified in mouse, rat, and human brains (Han et al. 2010). KATs are expressed primarily in the *astrocytes* (Roberts et al. 1992; Guidetti et al. 1997), but neurons are also able to produce KYNA (Du et al. 1992; Roberts et al. 1992; Rzeski et al. 2005). KATs display diverse optimal pH range and different levels of specific activity in specific brain regions and, although sharing a number of amino acid and α-ketoacid substrates, have distinct substrate profile (Okuno et al. 1991b; Guidetti et al. 2007; Bellocchi et al. 2009).

Concentrations of KYNA in the central nervous system (CNS) vary depending on the analyzed species, age, and CNS area. In brain structures, KYNA levels range

from 0.014 to 3.38 pmol/mg of tissue (Carlá et al. 1988; Turski et al. 1988; Swartz et al. 1990; Beal et al. 1992; Jauch et al. 1995). The lowest concentrations of KYNA in the human brain were detected in cerebellum and medulla (approx. 0.1–0.3 pmol/mg). In cortical areas and substantia nigra, KYNA reaches approx. 0.2–0.6 pmol/mg, whereas the highest concentrations occur in globus pallidus and putamen (0.7–1.4 pmol/mg) (Turski et al. 1988; Swartz et al. 1990; Jauch et al. 1995; Baran et al. 1996). The content of KYNA in *cerebrospinal fluid* (CSF) ranges from 1 to 5 nM (Swartz et al. 1990; Erhardt et al. 2001; Rejdak et al. 2002; Iłżecka et al. 2003).

The level of KYNA in the CNS increases with age. In humans aged <50 years, KYNA content in CSF is lower in comparison with elderly individuals (2.8 vs. 4.1 fmol/μl) (Kepplinger et al. 2005). In rats between 1st week and 18th month of age, KYNA increases over 50-fold, from approx. 15 to 750 pmol/g of protein (Moroni et al. 1988a). Others reported rise of brain KYNA by 80 % up to 350 %, between 3rd and 24th month of age, from approx. 20 to approx. 70 pmol/g of tissue (Gramsbergen et al. 1992; Braidy et al. 2011).

In periphery, the presence of KYNA was demonstrated in various animal and human tissues such as kidneys, liver, or heart (Carlá et al. 1988). Large quantities of KYNA are released by vascular *endothelium*, as demonstrated in rat aortic rings and endothelial cell cultures (Stazka et al. 2002; 2005). In humans, serum levels of KYNA range between 4 and 30 nM (Swan et al. 1983; Urbanska et al. 2006; Hartai et al. 2007; Baran et al. 2010). In rats, the concentrations are slightly higher and reach 20–90 nM (Stazka et al. 2005; Fukushima et al. 2009; Baran et al. 2010).

Interestingly, KYNA is not only synthesized de novo by mammalian tissues but also produced by saprophytic bacteria in the intestinal tract and exogenously delivered with food (Kuc et al. 2008; Turski et al. 2009). High concentration of KYNA was found in food, e.g., in herbs, bee products, broccoli, and potatoes (Turski et al. 2009).

3 Regulation of KYNA Synthesis

Brain level of KYNA may be regulated in various ways, including the availability of direct precursor and the activity of biosynthetic enzymes. Accumulating data identified also a number of other modulatory factors, of either endo- or exogenous origin.

Extracellular milieu, including ionic composition, pH, glucose, and oxygen availability, can affect KYNA production, as shown in vitro in brain cortical slices (Turski et al. 1989; Gramsbergen et al. 1991, 1997). Low concentrations of Cl^- and K^+ as well as depolarizing concentrations of K^+ (50 mM) reduce, whereas high Na^+ increases KYNA production. Hypoxia, anoxia, and hypoglycemia inhibit KYNA synthesis, while hyperglycemia remains without effect (Turski et al. 1989; Chmiel-Perzyńska et al. 2007). It has also been shown that β-hydroxybutyrate, one of the ketone bodies rising in the serum during diabetic ketoacidosis or *ketogenic diet*, stimulates brain KYNA synthesis in cortical slices and glial cultures (Chmiel-Perzyńska et al. 2011). *β-hydroxybutyrate* did not affect directly the activity of semi-purified preparation of KYNA biosynthetic enzymes in vitro. However, in

glial cultures β-hydroxybutyrate stimulated the de novo expression of KAT I and II. These data suggest that during fasting or ketogenic diet, high level of β-hydroxybutyrate may not only protect brain from the reduction of KYNA elicited by hypoglycemia and/or acidosis but actually enhance its synthesis above control values (Chmiel-Perzyńska et al. 2011).

Endogenous agonists of ionotropic glutamate receptors, such as *L-cysteine sulfinate*, L-aspartate, L-glutamate, L-cysteate, L-homocysteine sulfinate, and L-homocysteate, reduce the production of KYNA in cortical slices with IC_{50} values of 0.08, 0.3, 0.79, 1.77, 2.9, and 3.93 mM, respectively (Urbanska et al. 1997, 2000; Kocki et al. 2003). Their action is mediated most probably via inhibition of KAT I/KAT II activity. Among studied agonists, L-cysteine sulfinate appears one of the most potent KAT II inhibitors, displaying the IC_{50}=2 μM (Kocki et al. 2003).

Synthetic *metabotropic receptor agonists* were also shown to reduce KYNA synthesis in cortical slices. Among them, quisqualate was unequivocally the most potent inhibitor, acting in the micromolar range of concentrations, while agonists of group I (DHPG), group I/II (t-ACPD), group II (L-CCG-I), and group III (L-AP4) acted weaker (Urbanska et al. 1997). Interestingly, L-AP4 and t-ACPD were ineffective in spinal cord slices (Urbanska et al. 2000).

The effect of *dopaminergic* ligands on striatal KYNA production was studied in vivo in developing and adult rats (Rassoulpour et al. 1998). D_1 receptor antagonist SCH 23390, but not the D_2 receptor antagonists, raclopride and haloperidol, increased striatal KYNA levels, whereas D_1 and D_2 receptor agonists reduced KYNA levels approximately to the same extent in young animals. D-Amphetamine impaired striatal synthesis of KYNA irrespectively of animals' age (Rassoulpour et al. 1998). Similarly, peripheral application of L-DOPA, precursor of dopamine, decreased extracellular KYNA in rat striatum (Wu et al. 2002). In humans, however, L-DOPA treatment does not seem to affect central KYNA levels (Ogawa et al. 1992; Samadi et al. 2005).

Selective and mixed β_1- and β_2-adrenergic agonists, such as xamoterol, denopamine, albuterol, clenbuterol, or epinephrine, as well as cAMP analogues, enhanced KYNA synthesis in vitro and in vivo (Luchowska et al. 2008, 2009). KT5720, a selective inhibitor of *protein kinase A* (PKA), strongly reduced KYNA formation in cortical slices and in glial cultures. Notably, the effective concentrations were extremely low, ranging between 0.1 and 10 μM. β-adrenergic agonists, cAMP analogues, or KT5720 did not affect directly the activity of KATs measured in vitro, in semi-purified homogenate. However, the exposure of cultured glial cells to cAMP analogues and β-adrenergic agonists stimulated the enzymatic conversion of kynurenine, most probably due to an enhancement of KATs synthesis. The cAMP/PKA-related pathway seems an important factor regulating the endogenous levels of KYNA via expression of KATs (Luchowska et al. 2008, 2009).

Nitric oxide (NO) donors, S-nitroso-N-acetylpenicillamine (SNAP), and 3-morpholinosydnonimine (SIN-1) enhanced KYNA production in cortical slices yet did not affect KATs activity (Luchowski and Urbanska 2007). SNAP is the source of NO and S-nitrosylating agent, whereas SIN-1 is the NO/peroxynitrite (ONOO–) generator with a very weak S-nitrosylating activity. Their stimulatory effects were abolished in the presence of free radicals scavenger, L-ascorbate,

indicating possible involvement of the excessive release of reactive oxygen species in the observed phenomenon (Luchowski and Urbanska 2007).

Mitochondrial toxins compromising the status of mitochondrial respiration, such as aminooxyacetic acid (AOAA), *3-nitropropionic acid (3-NPA)*, or *1-methyl-4-phenylpyridinium (MPP$^+$)*, inhibit KYNA synthesis in vitro and in vivo (Turski et al 1989; Urbanska et al. 1997; Luchowski et al. 2002; Kocki et al. 2003). AOAA disrupts the function of aspartate-malate shuttle across the mitochondrial membrane; 3-NPA is an irreversible inhibitor of succinate dehydrogenase and mitochondrial complex II, whereas MPP$^+$ blocks the activity of complex I and IV (Urbanska 2005). 3-NPA and AOAA inhibit the activity of KAT I and KAT II, whereas MPP$^+$ blocks only KAT II action (Luchowski et al. 2002). Interestingly, mitochondrial toxins exert indirect excitotoxic effects, modeling Parkinson's (MPP$^+$) and Huntington's (AOAA and 3-NPA) diseases upon local or intracerebral application (Urbanska 2005).

D,L-homocysteine, which increased levels are considered a risk factor in atherosclerosis, biphasically affects KYNA production in the endothelium. In micromolar concentrations (approx. 40–100 μM), D,L-homocysteine stimulates, whereas in higher concentrations, it inhibits KYNA formation (Stazka et al. 2005). Similarly, low concentrations of compound stimulated KYNA synthesis, while millimolar concentrations impaired KYNA formation (IC_{50}= approx. 5–6 mM) in the brain (Luchowska et al. 2005; Chmiel-Perzyńska et al. 2007). Metabolic derivative of D,L-homocysteine, *S*-adenosylhomocysteine, displayed similar but more potent activity than parent compound, augmenting KYNA production at 0.03–0.08 mM and reducing it at $\geq$0.5 mM. The stimulatory effect of *S*-adenosylhomocysteine was abolished in the presence of the kynurenine uptake inhibitors, L-leucine and L-phenyloalanine (Luchowska et al. 2005).

Number of clinically effective compounds may exert their therapeutic effects, at least in part, via increase of central KYNA synthesis. *Memantine*, a well-tolerated derivative of amantadine acting predominantly as an open-channel blocker of *N*-methyl-D-aspartate (NMDA) receptors, protects neurons against excitotoxic insults under different experimental paradigms in vitro and in vivo (Danysz and Parsons 2003). The compound is used clinically to ameliorate symptoms of Parkinson's and Alzheimer's diseases. Recently, memantine was found to stimulate KYNA production at low, micromolar concentrations, possibly via PKA-dependent mechanism (Kloc et al. 2008).

Antiepileptic drugs, carbamazepine, felbamate, phenobarbital, phenytoin, and lamotrigine (at 0.5–3.0 mM), were found to increase KYNA synthesis in rat cortical slices and to enhance KAT I activity (Kocki et al. 2004, 2006). On the contrary, vigabatrin, gabapentin, and tiagabine decreased KYNA production, possibly due to the inhibition of KAT I and KAT II. This aspect of their action may be partially involved in the paradoxical exacerbation of absence or myoclonic seizures, as sometimes observed clinically after administration of vigabatrin, gabapentin, and tiagabine (Kocki et al. 2006).

Recently, *antidepressants* fluoxetine, citalopram, amitriptyline, and imipramine (1–10 μM) were demonstrated to increase de novo production of KYNA and

to diminish 3-hydroxykynurenie synthesis (at 24 and 48, but not 2-h incubation). RT-PCR studies revealed that antidepressants did not alter KAT1, KAT2 and kynurenine-3-monooxygenase (Kmo) gene expressions after 2-h exposure. After 48 h, the expression of KAT1 and KAT2 was strongly upregulated, and Kmo expression was downregulated by all antidepressants. These findings indicate that antidepressants may act in part via restoring the beneficial ratio between KYNA and 3-hydroxykynurenine (Kocki et al. 2012).

Notably, also the environmental factors may affect central KYNA production. Pyrethroid *pesticides*, such as deltamethrin and fenpropathrin, were shown to inhibit KYNA production in cortical slices (Zielińska et al. 2005). Tobacco smoking may either increase or decrease central KYNA levels, depending on the exposure time. In rats, short, 4- to 6-day administration of *nicotine* decreased brain KYNA. Withdrawal of nicotine resulted in the return of KYNA concentration to control values (Rassoulpour et al. 2005). In contrast, 10-day exposure to nicotine increased KYNA level in hippocampus, striatum, and cortex, but not in the serum (Rassoulpour et al. 2005). Others confirmed the stimulatory effect of 10-day nicotine application. However, chronic, 30-day exposure to nicotine was reported to increase serum KYNA level and to decrease cortical KYNA content, despite the enhanced KATs activity (Zielińska et al. 2009). Only central, but not the plasma changes of KYNA, were reversed by the use of an antagonist of nicotinic receptors, mecamylamine (Zielińska et al. 2009). Possibly, nicotine application induces distinct mechanisms involved in the regulation of KYNA synthesis, distribution, and elimination (Zielińska et al. 2009).

4 Mechanisms of KYNA Action

Since the initial discovery identifying KYNA as en endogenous antagonist of ionotropic glutamate receptors (Perkins and Stone 1982), a number of novel KYNA targets emerged. Currently, KYNA is also suggested to act as an antagonist of nicotinic receptors and as ligand of G protein-coupled GPR35 and human aryl hydrocarbon (AHR) receptors.

In electrophysiological studies, KYNA was shown to block competitively the activation of ionotropic glutamate receptors of *NMDA*, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (*AMPA*) and kainate type, at relatively high μM concentrations (Perkins and Stone 1982, 1983; Stone 1993). At much lower concentrations (10–30 μM; IC_{50}=8 μM), KYNA acts as an antagonist of the strychnine-insensitive glycine site of NMDA receptor complex (Kessler et al. 1989; Stone 1993). Bearing in mind that extracellular concentration of KYNA is within nM range, initially endogenous KYNA levels were considered too low to modulate excitatory neurotransmission. However, accumulated data leave no doubt that even modest increase of KYNA may alter brain function, e.g., change the neuronal firing in locus coeruleus, reduce the locomotor activity, impair cognition, and prevent seizures or impair excitotoxic neuronal loss (Vécsei and Beal 1991; Russi et al. 1992; Carpenedo et al. 1994, 2002; Pocivavsek et al. 2011).

Moreover, locally applied low nanomolar concentrations of KYNA were shown to reduce the release of glutamate in caudate nucleus and to inhibit the neurotransmitter release in striatal preparations (Carpenedo et al. 2001). Experimental studies confirmed that fluctuations of KYNA level may alter glutamine, acetylcholine, and dopamine release (Wonodi and Schwarcz 2010).

KYNA was also reported to antagonize the α_7 *nicotinic receptors* (nAChRs) in hippocampus, already at low 100 nM concentration, reaching $IC_{50}\sim7$ μM. However, KYNA effect in slices was much less robust than that seen in cultured neurons (Hilmas et al. 2001; Stone 2007). Hippocampal α_7 nAChRs are located on some GABAergic neuronal cell bodies and on glutamatergic dendrites and axon terminals and seem to modulate neurotransmitter release rather than to mediate neurotransmission (Vizi and Lendvai 1999; Dajas-Bailador et al. 2000). Axonal α_7 nAChRs are involved in the modulation of presynaptic NMDAR expression and structural plasticity of glutamatergic presynaptic boutons during early synaptic development (Lin et al. 2010). The role of KYNA in the modulation of α_7 nAChRs in vivo is yet not clear, because three groups failed to detect any effect of KYNA on α_7 nAChRs-mediated events using electrophysiological methods and direct patch-clamp recording in hippocampal cultures and rodent acute brain slices (Arnaiz-Cot et al. 2008; Mok et al. 2009; Dobelis et al. 2012).

In 2006, KYNA was discovered to act as a ligand of *G protein-bound receptor, GPR35* (Wang et al. 2006). The possible role of altered GPR35 function in the development of hypertension, immune modulation, and gastric cancer has been suggested (Okumura et al. 2004; Min et al. 2010). GPR35 is highly expressed in human monocytes, T cells, neutrophils, dendritic cells, and within the gastrointestinal tract (Wang et al. 2006). The potency of KYNA toward GPR35 varies depending on experimental paradigm and effector system. In Chinese hamster ovary cells transfected with GPR35, KYNA elevated intracellular Ca^{2+} with the EC_{50} of approx. 7 μM (rat) and 40 μM (human) (Wang et al. 2006). Using GPR35-β-arrestin-2 interaction assay, KYNA was demonstrated to promote the interaction of GPR35 with β-arrestin-2 and cause internalization of the receptor systems with low potency, at >100 μM (Jenkins et al. 2011). Others, however, have shown that the arrest of human monocytes on human umbilical vein endothelial cells expressing *ICAM-1 (intercellular adhesion molecule 1)*, in the process mediated by β_2-integrins, occurs at low, 300 nM concentration of KYNA (Barth et al. 2009). Thus, stimulation of GPR35 with KYNA may contribute to the development of inflammatory changes. GPR35 presence was also confirmed within CNS, in the spinal cord and dorsal root ganglia, cerebellum, and brain (Wang et al. 2006; Guo et al. 2008; Ohshiro et al. 2008). In mouse glial cell cultures, the expression of GPR35 receptors was confined to the cytosol and the membranes (Cosi et al. 2011). In these cells, KYNA significantly reduced the forskolin-induced cAMP accumulation with EC_{50} of approx. 1 μM (Cosi et al. 2011). Other effects assigned to the activation of GPR35 include voltage-dependent Ca^{2+}-current inhibition (10 μM–1 mM), antinociception, and regulation of neuronal firing (Guo et al. 2008; Zhao et al. 2010). Thus, to date the majority of reports suggest that the interaction of KYNA with GPR35 receptors occurs at concentrations exceeding its

extracellular levels. Further research is needed to clarify whether KYNA indeed plays a physiologically important role as a ligand of GPR35.

The latest discovery indicates that KYNA and kynurenine acts as the agonists of *human aryl hydrocarbon receptor (AHR)* (DiNatale et al. 2010; Opitz et al. 2011). AHR is essential for the toxicity of dioxins and related compounds. Additionally, it plays a role in adaptive metabolism and development, hormonal signaling, hematopoiesis, insulin release, and tumor development. Hyperactivation of AHR may lead to a variety of transcriptional responses (Bradshaw and Bell 2009; Bock and Köhle 2009; Stevens et al. 2009; Esser 2012). Stimulation of AHR by exogenous ligands coupled with inflammatory signals can evoke synergistic induction of *interleukin-6* (IL-6) expressions in tumor cells (DiNatale et al. 2010). KYNA was shown to enhance the expression of IL-6 at low 100 nM concentration and was suggested as a factor involved in the escape of tumors, via IL-6-dependent pathway, from the immune surveillance (DiNatale et al. 2010).

Initially considered to act primarily through the inhibition of glutamate-mediated neurotransmission, KYNA, with new reports emerging, is not regarded an inert metabolite anymore. Accumulating data support the view that this product of kynurenine pathway may be essentially involved in human physiology and pathology.

5 Experimental KYNA Deficiency

In the search for selective tools able to decrease KYNA formation, scientific attention was drawn to *aminooxyacetic acid* (AOAA) (Urbanska et al. 1998). AOAA, originally recognized as a nonselective inhibitor of aminotransferases (Wood and Peesker 1973), was identified as one of the most potent inhibitors of KYNA synthesis in vitro and in vivo (Turski et al. 1989; Speciale et al. 1990). It blocks KATs activity displaying IC_{50} values in very low micromolar range and is only slightly weaker than L-cysteine-sulfinate (Turski et al. 1989; Okuno et al. 1991b; Chmiel-Perzyńska et al. 2007). Using in vivo approach, it was demonstrated that intrastriatally injected AOAA evokes selective excitotoxic quinolinate-like neuronal loss in rats (Urbanska et al. 1989, 1991), what was confirmed by others (Beal et al. 1991). Neurochemical, histological, and behavioral features of striatal neuronal loss closely resembled changes observed in the course of Huntington's disease (HD) (Urbanska et al. 1989, 1991; Beal et al. 1991). Lesions blocked with the use of KYNA and NMDA antagonists did not occur following ablation of *corticostriatal glutamatergic input* and were age dependent (Urbanska et al. 1989, 1991). Bilateral lesions of caudate with AOAA markedly affected cataleptic response of animals, increasing the reaction to arecoline and morphine and reducing the response to haloperidol (Urbanska et al. 1989, 1991), mimicking the behavioral changes characteristic for other HD models (Sanberg 1980; Sanberg et al. 1981). Bearing in mind that AOAA is a nonspecific inhibitor of aminotransferases, AOAA-induced effects could be attributed to the inhibition of enzymes other than KATs. However, neither application of GABA aminotransferase inhibitor nor

L-aspartate aminotransferase inhibitor evoked neuronal degeneration in striatum (Urbanska et al. 1989, 1991). It was also proposed that AOAA-induced indirect excitotoxicity results from mitochondrial dysfunction, as AOAA is known to disrupt the malate-aspartate shuttle across mitochondrial membrane (Beal et al. 1991). However, AOAA affects KYNA synthesis at much lower concentration than required to alter mitochondrial respiration (Hotta 1968). Thus, the diminished formation of KYNA cannot be ruled out as one of the mechanism involved in the AOAA-evoked neuronal loss.

Apart from *excitotoxicity*, AOAA displays potent convulsant properties. The compound evokes clonic seizures in rodents when applied systemically, intracerebroventricularly, or intrahippocampally (McMaster et al. 1991; Turski et al. 1991b, 1992). Diazepam, phenobarbital, and valproate, but not ethosuximide, trimethadione, acetazolamide, diphenylhydantoin, or carbamazepine, prevent convulsions induced by systemic administration of AOAA. Seizures evoked by intracerebroventricular injection of AOAA are blocked with KYNA and selective NMDA antagonists (Turski et al. 1991b, 1992).

Additionally, AOAA was demonstrated to induce seizures when injected into the rat entorhinal cortex (Du and Schwarcz 1992; Eid et al. 1995). In this paradigm, AOAA application resulted in selective neuronal loss within layer III of *entorhinal cortex* (Du and Schwarcz 1992). Notably, in contrast to striatum, the sequel of changes following application of quinolinic acid into the entorhinal cortex was qualitatively different from AOAA-evoked changes. Animals subjected to quinolinate did not display behavioral seizures; however, neuronal loss in layer V of the entorhinal cortex, often accompanied by neurodegeneration in the superficial layers of the dorsal perirhinal cortex, was a constant finding (Eid et al. 1995).

Novel data indicate that AOAA inhibits KYNA synthesis more potently in the milieu mimicking diabetic hyperglycemia. High level of glucose (30 mM) reduced the IC_{50} value of AOAA by approx. 50 % (from 11.6 to 7.1 μM), suggesting that severe hyperglycemia may render the brain more susceptible to the excitotoxic events (Chmiel-Perzyńska et al. 2007).

The above data suggest that AOAA is a valuable tool allowing detailed studies of excitotoxicity associated, at least in part, with deficient synthesis of brain KYNA.

6 KYNA and Brain Disorders

6.1 Parkinson's Disease

Parkinson's disease (PD) is one of the most common progressive neurodegenerative disorders, affecting approx. six million people worldwide. Although clinically heterogenous, PD is primarily characterized by tremor, bradykinesia, and muscle rigidity associated with dopaminergic denervation, primarily due to neuronal loss within substantia nigra pars compacta. Later on, other motor signs such as postural instability and impairment of gait and speech develop due to alterations in

non-dopaminergic transmission. Moreover, autonomic dysfunction and cognitive impairment arise in the course of disease (Lees et al. 2009). Familial forms of PD account for 10–15 % of diagnoses. Pathogenesis of remaining 85–90 % cases of PD is still unclear, and only some of the underlying mechanisms have been clarified so far. Disturbances of *ubiquitin-proteasome system*, dysfunction of mitochondria, and oxidative stress are among the recognized factors (Ali et al. 2011). Accumulating data indicate possible role of altered KYNA metabolism in the pathogenesis of PD (Szabó et al. 2011).

Consistently with neuroprotective as well as antiparkinsonian effect of glutamate receptors antagonists (Klockgether and Turski 1990; Klockgether et al. 1991; Turski et al. 1991a), application of KYNA or approaches aimed to increase its central level were shown to ameliorate neuronal loss and behavioral symptoms in experimental models of PD.

KYNA, injected intracerebrally, reduced akinesia, tremor, and rigidity in a severely parkinsonian monkeys subjected to *1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP*), mitochondrial toxin commonly used to replicate PD-like symptoms in experimental animals (Graham et al. 1990). Parkinsonian symptoms are thought to result partially from the overactivation of neurons in the output areas of basal ganglia, i.e., substantia nigra pars reticulata and the medial segment of globus pallidus. In rat and primate models of PD, the direct injection of KYNA into the medial segment of the globus pallidus reduced behavioral changes (Brotchie et al. 1991). Similarly, in monkeys with hemiparkinsonism evoked by unilateral, intra-arterial MPTP application, the infusion of KYNA into contralateral globus pallidus internus partially alleviated symptoms of disease (Butler et al. 1997).

In rats, intraventricular administration of KMO inhibitor, *nicotinylalanine*, together with intraperitoneal kynurenine and probenecid infusion, evoked up to threefold increase of brain KYNA concentration (Miranda et al. 1997). Immunohistochemical assessment revealed that this rise of KYNA level was sufficient to protect nigrostriatal dopaminergic neurons from neurodegeneration caused by intranigral administration of quinolinic acid and to reverse some behavioral alterations (Miranda et al. 1997, 1999). Intraperitoneal treatment with kynurenine and probenecid prevented also neuronal damage and behavioral alterations induced by intrastriatal injections of *6-hydroxydopamine* (Silva-Adaya et al. 2011).

In primate model of MPTP-induced parkinsonism, orally administered *KMO inhibitor, Ro 61-8048*, increased central kynurenine and KYNA levels. This treatment was shown to improve L-DOPA-induced dyskinesias without alteration of drug antiparkinsonian efficacy (Samadi et al. 2005). Indeed, accumulating data suggest that glutamatergic manipulation of basal ganglia output is a promising approach to treat L-DOPA-induced dyskinesia in PD (Brotchie and Jenner 2011).

KYNA deficiency seems to play an important role in the development and progress of parkinsonian symptoms. An active metabolite of *MPTP*, MPP^+ reduced cortical KYNA synthesis and inhibits KAT activity in vitro (Luchowski et al. 2002; Urbanska 2005). These results were confirmed in vivo, in a study demonstrating

that MPTP treatment decreases the number and optical density of KAT I immunoreactive neurons in substantia nigra of mice (Knyihár-Csillik et al. 2004). Similarly, application of 6-hydroxydopamine induced dose-dependent loss of KAT I immunoreactivity in the middle and lateral areas of substantia nigra pars compacta (Knyihár-Csillik et al. 2006). In human neuroblastoma cell line, pretreatment with KYNA attenuated MPP^+-induced neuronal apoptotic cell death, decreased level of proapoptotic *Bax* protein, reduced MPP^+-evoked mitochondrial dysfunction, and prevented activation of *caspase* 3 and 9 (Lee et al. 2008).

Human studies revealed decline of KYNA and kynurenine in frontal cortex, putamen, and substantia nigra of PD victims (Ogawa et al. 1992). Tryptophan/kynurenine and kynurenine/KYNA ratios remained unchanged, and the therapy with L-DOPA did not seem to influence brain KYNA (Ogawa et al. 1992). In contrast, the level of KYNA in caudate and precentral cortical gyrus did not differ from control values, as shown by another study from the same group aimed to analyze brain KYNA content in Huntington's, Parkinson's, and Alzheimer's diseases (Beal et al. 1992).

In periphery, KYNA content within erythrocytes obtained from PD patients, as well as the activity of KAT II but not of KAT I, are increased (Hartai et al. 2005). Interestingly, the authors have also detected the activity of KAT I and KAT II in the serum of both patients and controls. In PD, the activity of both enzymes was decreased; however, there was no concomitant change in serum KYNA level (Hartai et al. 2005).

In the view of available data, deficient KYNA synthesis seems to be one of the underlying factors contributing to the pathogenesis of PD.

Surprisingly, there is no clinical data assessing potential efficacy of KYNA derivatives or NMDA antagonists in the treatment of dyskinesia in PD. Future research should be aimed to develop compounds acting selectively within basal ganglia. Targeting KYNA synthesis within specific brain areas seems to be one of the attractive therapeutic options.

6.2 Huntington's Disease

Huntington's disease (HD) is an inherited autosomal dominant neurodegenerative disorder associated with progressive loss of neurons, primarily in caudate-putamen. During later stages of disease, the cerebral cortex (particularly layers III, V, and VI), globus pallidus, thalamus, subthalamic nucleus, substantia nigra, white matter, and the cerebellum can also be markedly affected (Zuccato et al. 2010). Clinically, HD is manifested by progressive emotional, motor, and cognitive impairments. The development of HD results from *CAG trinucleotide* repeat expansion in the exon-1 of the gene encoding for huntingtin protein on chromosome 4. The length of CAG repeats correlates with age at onset of motor symptoms; however, HD patients may differ dramatically in disease manifestations, despite similar genetic changes. It is established now that multiple genes distinct from the HD locus itself may modify the course of disease (Zuccato et al 2010; Bano et al. 2011).

As with other human pathologies, proper animal models are invaluable tools that allow detailed studies of pathophysiological mechanisms underlying disease development. Initially, HD animal models were based on the intrastriatal injections of selective *excitotoxins*, such as kainate and quinolinic acid, indirect excitotoxin, AOAA, and peripheral application of mitochondrial toxin, 3-NPA (Coyle and Schwarcz 1976; Schwarcz et al. 1983; Urbanska et al. 1991; Brouillet et al. 1993). In rats, intrastriatal injection of AOAA leads to neuropathological and behavioral sequel mimicking HD (Urbanska et al. 1989, 1991; Beal et al. 1991) (see paragraph 5). Chronic, intraperitoneal administration of low doses of 3-NPA was demonstrated to induce relatively selective neuronal loss within striatum, accompanied by behavioral changes replicating symptoms of HD (Gould and Gustine 1982; Hamilton and Gould 1987; Brouillet et al. 1993).

It seems of interest that both AOAA and 3-NPA inhibit KATs activity, and, notably, AOAA is one of the most potent inhibitors of KATs (Luchowski et al. 2002; Urbanska 2005). 3-NPA was demonstrated to reduce the number of KAT I immunopositive glial cells in rat striatum and temporal cortex (Csillik et al. 2002). Susceptibility to 3-NPA action increases with age of animals (Csillik et al. 2002). Thus, results from chemical models of HD suggest that striatal deficiency of KYNA might be one of the factors contributing to the development of HD.

Following the discovery of genetic base of HD, novel animal models emerged. Disturbed function of kynurenine pathway was reported in heterozygous, symptomatic FVB/N mice transgenic for mutant *huntingtin* (Guidetti et al. 2000). Interestingly, transgenic animals showed large, over tenfold elevations in 3-hydroxykynurenine content in both striatum and cortex accompanied by smaller increases of KYNA levels, resulting in a prominent increase of the 3-hydroxykynurenine/KYNA ratio (Guidetti et al. 2000).

Human studies performed in later stages of disease revealed decline of CSF KYNA levels in HD (Beal et al. 1990; Heyes et al. 1994). In the brain tissue, twofold increase of KYNA in the motor cortex in Brodmann's area 4, but not within caudate, globus pallidus, and prefrontal cortex, was reported (Connick et al. 1988, 1989). Further studies demonstrated, however, that KYNA concentration in *putamen* and cortex of HD patients is decreased (Beal et al. 1990, 1992). Others have also reported approx. 50 % reduction of KYNA content in caudate, but not in hippocampus or cortical areas, in specimens obtained from late stage of HD (Jauch et al. 1995). In putamen, KYNA content reached approx. 67 % of control, however, at the border of statistical significance. Enzymatic analyses revealed decreased activity of KAT I and II (in putamen ~48–55 % of control) (Jauch et al. 1995). Notably, deficiency of KYNA in putamen seems to be associated with an increase of kynurenine/KYNA ratio (Beal et al. 1990), indicating possible activation of the kynurenine pathway arm leading to neurotoxic metabolites.

Indeed, an increase of *3-hydroxykynurenine* in the brain was demonstrated by different groups (Reynolds and Pearson 1989; Pearson and Reynolds 1992; Guidetti et al. 2000, 2004). In specimens of putamen and temporal and frontal cortices, the concentration of 3-hydroxykynurenine was increased by nearly twofold

(Reynolds and Pearson 1989; Pearson and Reynolds 1992). Others reported that neostriatal and neocortical 3-hydroxykynurenine levels are increased by five- to tenfold, whereas KYNA was only slightly elevated in cortical samples obtained from early-stage HD patients (Guidetti et al. 2000). Further analysis of 3-hydroxykynurenine and quinolinic acid levels in the brains of patients with early or late HD has revealed an increase of these toxic kynurenine metabolites in 0/1 stage of disorder, but not during later phases (Guidetti et al. 2004).

Overall, an increased 3-hydroxykynurenine/KYNA ratio in HD patients and transgenic mice modeling the disease indicates the presence of abnormally high level of neurotoxic kynurenine metabolite accompanied by comparatively deficient formation of neuroprotective KYNA (Pearson and Reynolds 1992; Jauch et al. 1995; Guidetti et al. 2000, 2004). Based on accumulated data, it seems that changes in brain KYNA content and kynurenine pathway function are hallmarks of HD. In early stages of disease, both KYNA and 3-hydroxykynurenine levels may be increased. Later on, KYNA production seems to be severely compromised and 3-hydroxykynurenine/KYNA ratio is consistently higher (Pearson and Reynolds 1992; Jauch et al. 1995; Guidetti et al. 2000, 2004). Whether these changes reveal causative association or merely reflect consequences of progressive neuropathology remains to be established. However, accumulated data favor the opinion that disturbed kynurenine pathway function could be a component of pathological sequel contributing to the development of HD (Schwarcz et al. 2010).

Consequently, a number of studies were undertaken to evaluate the potential therapeutic benefits of increasing KYNA and/or decreasing 3-hydroxykynurenine level, via inhibition of KMO. The depletion of *NADPH-diaphorase* positive neurons caused by intrastriatal infusion of quinolinic acid was prevented by the intracerebral injections of nicotylalanine, an inhibitor of kynureninase and KMO, combined with intraperitoneal administration of kynurenine and probenecid, an inhibitor of organic acid transport (Harris et al. 1998). Chronic oral administration of *2-(3,4-dimethoxybenzenesulfonylamino)-4-(3-nitrophenyl)-5-(piperidin-1-yl) methylthiazole (JM6)*, small-molecule prodrug, acting as inhibitor of KMO, extended life span, prevented synaptic loss, and decreased microglial activation in the mouse model of HD (Zwilling et al. 2011). Similarly, in a fruit fly model of HD, KMO inhibition with *UPF 648 [(1S,2S)-2-(3,4-dichlorobenzoyl)-cyclopropane-1-carboxylic acid]* provided neuroprotection against degeneration of photoreceptor neurons (Campesan et al. 2011). In transgenic mkat-2-/- mice, characterized by higher susceptibility to quinolinate-induced excitotoxic neuronal loss, application of UPF 648, KMO inhibitor, reduced quinolinic acid toxicity (Sapko et al. 2006).

Recently, a novel KYNA analogue, *N-(2-N,N-dimethylaminoethyl)-4-oxo-1H-quinoline-2-carboxamide hydrochloride*, administered intraperitoneally, completely prevented the atrophy of the striatal neurons, increased survival time by about 30 %, and ameliorated hypolocomotion in transgenic *N171-82Q mice* (Zádori et al. 2011).

Thus, available data suggest that shift of kynurenine pathway toward KYNA synthesis may be neuroprotective in HD, whereas an excess of

3-hydroxykynurenine can be pathogenic. Moreover, changes in the levels of kynurenine pathway metabolites resulting in decrease of 3-hydroxykynurenine/KYNA ratio seem to be of potential therapeutic value. It would be of great interest to evaluate the efficacy of KMO inhibitors, as well as modulators of other kynurenine pathway enzymes, in early-stage and advanced HD.

6.3 Alzheimer's Disease

Alzheimer's disease (AD) is the most common form of dementia characterized by the progressive memory loss and deterioration of higher cognitive functions. Neuropathological findings include the presence of extracellular senile (neuritic) plaques composed from various proteins, such as β-amyloid, α-synuclein, or presenilins. Another hallmark of AD is the occurrence of intracellular neurofibrillary tangles containing hyperphosphorylated-tau protein and apolipoprotein E (Chintamaneni and Bhaskar 2012). The pathogenic process seems to start earlier than the onset of clinical symptoms, and it is estimated nowadays that neurodegeneration in AD begins decades before episodes of memory loss (Chintamaneni and Bhaskar 2012).

KYNA metabolism in the course of AD has been researched; however, the data are not conclusive. Initially, no change in the concentration of L-kynurenine and KYNA in the brains of AD victims was reported (Beal et al. 1992). In contrast, CSF KYNA was significantly lower in patients suffering from AD (Heyes et al. 1992). Others have demonstrated a significant rise of KYNA level in putamen (192 %) and caudate nucleus (177 %), but not in cortical specimens obtained from 11 patients with advanced form of AD (Baran et al. 1999). A trend for a decrease of kynurenine and 3-hydroxykynurenine in frontal cortex, caudate nucleus, putamen, hippocampus, and cerebellum of AD brain was also noted (Baran et al. 1999). In putamen and caudate, elevated KYNA correlated with an enhanced KAT I activity. A minor increase of KAT II activity was detected only in the caudate nucleus of AD subjects (Baran et al. 1999).

Peripheral KYNA status in AD was subject of two recent studies. Serum and erythrocytic KYNA were decreased by approx. 35 % in patients with AD, whereas kynurenine level and the activities of KAT I and KAT II remained unchanged (Hartai et al. 2007). The peripheral decline of KYNA accompanied by unaltered kynurenine levels was confirmed in study analyzing plasma samples of AD patients. Notably, quinolinic acid concentration was increased, suggesting an activation of kynurenine pathway arm leading to neurotoxic metabolites (Gulaj et al. 2010).

Only few reports analyzed the concentration of another neurotoxic kynurenine derivative, *3-hydroxykynurenine*, in the course of AD. Studies postmortem revealed an increase of 3-hydroxykynurenine content in temporal cortex of AD victims (Pearson and Reynolds 1992). In contrast, patients with AD exhibited decreased 3-hydroxykynurenine levels in CSF (Tohgi et al. 1992). Others found an increased

3-hydroxykynurenine/tryptophan ratio in the serum of AD patients, compared to age-matched and younger control (Widner et al. 2000).

In vitro studies have shown that fragments of amyloid peptide can stimulate IDO, thus activating an early step in kynurenine pathway what leads to an enhanced production of QUIN by human *macrophages* and *microglia* (Guillemin et al. 2003). Thus, existing data implicate the peripheral deficiency of KYNA in earlier stages of AD accompanied by shift of kynurenine pathway toward synthesis of neurotoxic 3-hydroxykynurenine. Considering the fact that most of the current data are based on the analysis performed during late stage of disease, when cerebral neurodegeneration is advanced, it seems that the central changes in kynurenine metabolism require further studies.

So far, potential usefulness of increasing brain KYNA as a possible therapy in early AD has been the subject of one study. Indeed, 4-month oral application of KMO inhibitor, *JM6*, blocked the development of spatial memory deficits in a transgenic mouse model of AD (Zwilling et al. 2011). JM6 also reduced anxiety-related behavior and prevented synaptophysin loss indicating its protective efficacy toward synapses; however, it did not alter the occurrence of Aβ plaques (Zwilling et al. 2011).

On the other hand, reduction of NMDA-mediated transmission by excessive KYNA levels may contribute to the deterioration of cognitive functions and memory in patients with AD (Baran et al. 1999). In fact, plasma levels of KYNA correlate positively with cognitive functions assessment in Mini Mental State Examination and with the result of Hachinski Ischaemic Score (HIS) in AD patients (Gulaj et al. 2010).

In the view of above findings, disturbances of kynurenine pathway seem to be evident in AD; however, the nature of central KYNA changes and their role in AD-related structural and behavioral pathologies require further studies.

6.4 Ischemia

It is estimated that cerebral stroke affects approx. 15 million of people every year and is the second leading cause of mortality worldwide. Rapid occlusion of cerebral artery (ischemic stroke) or rupture of cerebral blood vessel (hemorrhagic stroke) evokes inadequate local supply of oxygen and glucose followed by an increase of extracellular glutamate levels, overactivation of glutamate receptors, and subsequent influx of excessive Ca^{2+} into neurons. Increased *intracellular* Ca^{2+} combined with oxidative stress finally lead to neuronal death (Mattson 2008).

Various experimental data indicated that blockade of NMDA receptors may reduce consequences of ischemia and injury of brain tissue; however, the therapeutic window seems to be very narrow and limited to several minutes post-insult (Ginsberg 2008; McIntosh et al. 1990; Muir and Lees 2003). Consequently, different manipulations increasing the brain level of KYNA have become an interesting alternative and were studied in various models of ischemia/anoxia.

In vitro, KYNA derivative, *7-Cl-KYNA*, reduced neuronal damage in CA1 area of organotypic hippocampal slice cultures deprived of oxygen and glucose

(Newell et al. 1995). Other attempts demonstrated the efficacy of *KMO inhibitors* acting via reduction of 3-hydroxkynurenine and quinolinate synthesis, thus shifting kynurenine metabolism to the formation of KYNA. In organotypic hippocampal slice cultures, KMO inhibitors decreased hypoxia-/hypoglycemia-induced neuronal death in the CA1 region (Carpenedo et al. 2002).

In vivo experiments demonstrated that KYNA attenuates brain edema associated with anoxic-ischemic brain damage in neonatal rats (Simon et al. 1986). In 1-week-old rats subjected to hypoxia combined with ligation of the left carotid artery, peripheral administration of KYNA reduced brain damage (Andiné et al. 1988). Pretreatment with KYNA reduced the size of infarction and improved neurological outcome in the rat model of *focal ischemia* following middle cerebral artery occlusion (Germano et al. 1987). Peripheral administration of high doses of KYNA (1,000 mg/kg) markedly attenuated the hippocampal neurodegeneration in the gerbil model of global ischemia (Salvati et al. 1999). In the model of transient ischemia in gerbils, application of KYNA via microdialysis probe attenuated lactate accumulation and subsequent hippocampal damage (Katayama et al. 1992). KYNA, given systemically (500 mg kg^{-1}, IP) or administered locally through the dialysis probe (10 mM), significantly reduced the forebrain ischemia-evoked release of glutamate and aspartate within rat striatum (Ghribi et al. 1994). In contrast, topical administration of KYNA onto the cortex in a four-vessel occlusion rat model did not reveal any changes in ischemia-evoked release of aspartate or glutamate (Phillis et al. 1999).

KYNA precursor, kynurenine, reduced infarct size in mice subjected to permanent focal cerebral ischemia produced by electrocoagulation of the distal middle cerebral artery and prevented the pyramidal cell loss in the CA1 area of the *hippocampus* in gerbils subjected to transient bilateral carotid artery occlusion (Gigler et al. 2007). Moreover, kynurenine markedly impaired the ischemia-evoked changes of spatial memory (Gigler et al. 2007). In the model of global brain ischemia, kynurenine, applied either pre- or early post-insult, reduced cortical neuronal loss (Robotka et al. 2008).

Neuroprotective properties of KYNA were also confirmed in an animal model of *heatstroke*. Treatment with KYNA (30–100 mg/kg, IV), 4 h prior to the heat stress, attenuated hypothalamic neuronal degeneration and apoptosis in rats. Authors suggest that systemic delivery of KYNA may attenuate not only neuronal degeneration but also multiorgan dysfunction in rats after heatstroke (Hsieh et al. 2011).

Increase of endogenous KYNA in the brain achieved through pharmacological blockade of KMO effectively protects against *excitotoxicity* (Miranda et al. 1997; Harris et al. 1998; Schwarcz and Pellicciari 2002). Administration of KMO inhibitors, causing 200–300 % rise of brain KYNA level, significantly reduced postischemic brain damage induced by bilateral carotid occlusion in gerbils or by middle cerebral artery occlusion in rats (Cozzi et al. 1999).

Alterations in endogenously produced KYNA were assessed in some models of ischemia. In cortical slices, KYNA synthesis was inhibited by hypoxia and glucose deprivation (Turski et al. 1989). Similarly, in *organotypic hippocampal slice cultures*, the lack of oxygen and glucose decreased the amount of KYNA

released into the incubation medium (Carpenedo et al. 2002). Only limited data come from in vivo animal models. In gerbils subjected to transient global ischemia, the endogenous levels of KYNA and the activity of its biosynthetic enzymes, kynurenine aminotransferases I (KAT I) and II (KAT II) in the hippocampus, were not altered 24 and 72 h after ischemic episode (Luchowska et al. 2003).

Interestingly, in patients at early (up to 24 h after infarct) stage of stroke, serum KYNA correlated positively with *D,L-homocysteine* which is considered an independent risk factor of atherosclerosis and an emerging risk factor in cognitive dysfunction and stroke (Urbanska et al. 2006). Following acute ischemic episode, an elevated kynurenine/tryptophan ratio suggested activation of kynurenine pathway (Darlington et al. 2007). Patients who died within first 3 weeks after stroke demonstrated increased serum KYNA level in comparison to subjects who survived (Darlington et al. 2007). Recent clinical study revealed that the kynurenine/tryptophan ratio, measured up to 7 days poststroke, correlated with infarct size and severity of clinical symptoms assessed with NIHSS (Brouns et al. 2010).

Disturbances of kynurenine pathway in the course of acute brain ischemia seem to have potentially important implications. It is not clear yet whether observed alterations reflect reactive, inflammation-linked activation of kynurenine pathway or develop prior to the inflammatory changes. Further studies, evaluating the ratio between neurotoxic kynurenine metabolite 3-hydroxykynurenine and neuroprotective KYNA during early and late phase of stroke, should clarify this issue. Nevertheless, encouraging experimental data suggest that increasing brain KYNA may be an interesting alternative in the therapy of early stroke.

6.5 Seizures and Epilepsy

Among kynurenine pathway metabolites, *quinolinic acid* is a well-described, neurotoxic agent able to evoke seizures in rodents, similarly to kynurenine itself (Lapin 1978, 1983). In contrast, KYNA displays clear anticonvulsant properties, as demonstrated by various experimental approaches in vitro and in vivo.

Pretreatment of brain slices with KYNA precursor, kynurenine, inhibited spontaneous epileptiform activity induced by the lack of Mg^{2+} (Scharfman and Ofer 1997). KYNA suppressed spontaneous epileptiform burst discharges in the *CA3* region of rat hippocampal slices induced by Mg^{2+}-free medium or picrotoxin (Stone 1988) and inhibited penicillin-induced synchronized afterdischarges in hippocampal slices from immature rats (Brady and Swann 1988). KYNA also depressed the amplitude and duration of Mg^{2+}-free bursts and reduced the frequency of penicillin-evoked discharges (Schneiderman and MacDonald 1989).

In vivo, KYNA efficiently blocks convulsions evoked by quinolinate, produced along second arm of kynurenine pathway (Foster et al. 1984; Lapin et al. 1986). An increase of central KYNA levels, due to systemic administration of kynurenine, prevented the development of pentylenetetrazol-evoked seizures (Vécsei et al. 1992; Németh et al. 2004) and convulsions induced by the extract of poisonous

Atlantic coast mussels (Pinsky et al. 1989). Systemic or intracerebroventricular injection of KYNA inhibited seizures caused by the administration of bicuculline (Turski et al. 1990). Infusion of KYNA into the nucleus of the solitary tract reduced the severity of seizures induced by bicuculline or pentylenetetrazol (Walker et al. 1999). KYNA was also demonstrated to block the NMDA-evoked convulsions (Chiamulera et al. 1990). In WAG/Rij rats, genetic model of *absence epilepsy*, spontaneous spike-wave discharges were inhibited by KYNA administration. KYNA blocked also NMDA-induced potentiation of spike-wave discharges in this model (Peeters et al. 1994a, b).

Intracerebroventricularly applied KYNA displays protective effects in electrically kindled seizures (Thompson et al. 1988). Treatment with KYNA prior to the electrical *kindling* stimulus significantly reduced the rate of kindling in prepubescent and adult rats (Thompson et al. 1988). However, systemic administration of kynurenine or tryptophan did not protect rats against seizures induced by hyperbaric oxygen (Dale et al. 2000). KYNA had no effect on nicotine-induced seizures in mice (Kiś et al. 2000).

Interestingly, *antiepileptic drugs* may affect the synthesis of KYNA. Phenobarbital, felbamate, phenytoin, and lamotrigine increased KYNA production and activity of KAT I in vitro (Kocki et al. 2006). Moreover, high-fat and low-protein and low-carbohydrate *ketogenic diet*, leading to depletion of glucose and stimulation of ketone bodies synthesis, may also increase KYNA formation (Chmiel-Perzyńska et al. 2011). Exposure to profound ketosis (15 mM β-hydroxybutyrate) (BHB) with concomitant low glucose level (0.5 mM) increased synthesis of KYNA both in cortical slices and glial cultures. An increased activity of KAT I and II was detected in *glial cultures* but not in cortical slices (Chmiel-Perzyńska et al. 2011). Similar results were observed under in vivo conditions. In rats maintained on ketogenic diet, concentration of KYNA in hippocampus and striatum, but not in cortex, increased about two- to fourfold (Zarnowski et al. 2012).

Brain synthesis of KYNA is altered by a seizure episode, possibly due to the activation of glial cells (Wu et al. 2005). Reactive *astrogliosis* is characteristic for seizure models that are accompanied by neuronal loss in susceptible brain regions. Considering the fact that astrocytes are the main source of KYNA within the brain, increased KYNA level in the areas with prominent gliosis is not unexpected and may constitute defense mechanism.

Indeed, in the model of kainate-induced limbic seizures associated with widespread neuronal brain damage, the extracellular KYNA concentration in piriform cortex was not changed during the first 4 h of status epilepticus, but increased 1 month later, when astrogliosis was prominent (Wu et al. 1991). Various chemically induced seizures seem to increase KYNA level in dorsal hippocampus, starting in the first few hours after seizure development (Wu and Schwarcz 1996). Others have not confirmed hippocampal increase of KYNA during kainate-evoked seizures (Baran et al. 1995). However, 3 h after kainate injection, KYNA levels were raised in other brain areas, e.g., in piriform cortex, frontal cortex, amygdala, caudate, and putamen. The most prominent KYNA increases were observed in animals that developed status epilepticus (Baran et al. 1995).

Contrasting data were obtained in models of kindled seizures, developing over long period and assumed to mimic *epileptogenesis* more adequately. In amygdala-kindled seizures, KYNA level was reported to increase only in nucleus accumbens, but not in hippocampus, cerebral cortex, olfactory bulb, striatum, thalamus, tectum, cerebellum, or pons/medulla, as assessed 50 days after the last kindled seizure (Löscher et al. 1996). Moreover, the development of pentylenetetrazol-induced kindling was shown to be associated with the progressive decrease of KYNA in caudate-putamen, entorhinal cortex, piriform cortex, amygdala, and hippocampus (Maciejak et al. 2009). Changes in KYNA levels correlated with the stage of seizures (Maciejak et al. 2009). Similarly, deficiency of brain KYNA was revealed in a genetic model of absence seizures (WAG/Rij rats). In these rats, the level of KYNA in frontal cortex is lower, comparing to age-matched controls, at the time point when spontaneous seizures develop (Kamiński et al. 2003).

Human studies have also revealed alterations of central KYNA levels in epilepsy. Concentration of KYNA in CSF from epileptic patients was not changed, but serum KYNA in patients with intractable complex *partial seizures* was decreased (Heyes et al. 1994). Others have shown that in children with *West syndrome* or infantile spasm, the level of KYNA in CSF is lower, whereas among patients with grand mal seizures or occipital paroxysm, the CSF KYNA remains unaltered (Yamamoto et al. 1994, 1995). In the group of children with epileptic or febrile seizures, disturbances in circadian rhythm of kynurenine synthesis were found. The production of KYNA, kynurenine, 3-hydroxykynurenine, and xanthurenic acid was elevated during nocturnal hours in comparison to controls. The increase of KYNA and xanthurenic acid was not as high as of other kynurenines during epileptic seizures, whereas during febrile convulsions all kynurenines were increased by the same degree (Muñóz-Hoyos et al. 1997).

7 Conclusion

Systematic evaluation and interpretation of data indicates in general the beneficial effects of increasing central KYNA level in models of neuronal loss and seizures. Current state of research supports the notion that the selective blockade of excessive glutamate-mediated neurotransmission with exogenous compounds may be valuable in terms of neuroprotection; on the other hand, it might hamper processes of neuronal repair.

Promising experimental data indicate that novel, devoid of side-effects methods to manipulate glutamate transmission in humans should be sought. Endogenously produced KYNA is an attractive candidate for such studies. Sophisticated research adopting broader, multifactorial approach such as the development of drugs able to discriminate between brain structures or able to modify kynurenine metabolism selectively, in different cellular and subcellular compartments, is needed. Emerging therapies aimed to increase the level of neuroprotective KYNA or to reduce the brain expression of neurotoxic 3-hydroxykynurenine may become an important avenue in the treatment of neurodegeneration, ischemia, and seizures.

Neurotoxicity in Psychostimulant and Opiate Addiction

Ewa Niedzielska, Bartłomiej Rospond, Lucyna Pomierny-Chamioło, Anna Sadakierska-Chudy, and Małgorzata Filip

Contents

Abstract

Psychostimulants and opioids evoke toxicity within the central nervous system (CNS), primarily linked to action of the substance (e.g., enhancement of synaptic concentrations of dopamine) or by indirect effects (increases in extrasynaptic glutamate levels, toxic metabolites). Associated with the development of drug addiction, the above mechanisms lead to the several pathological processes within the complex network of brain cell-to-cell

Abuse • Addiction • Amphetamine • Animal studies • Cocaine • Dependence • Human studies • Neurotoxicity • Opiate

List of Abbreviations

5-HIAA	5-hydroxyindoleacetic acid
5-HT	Serotonin
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
BDNF	Brain-derived neurotrophic factor
CART	Cocaine- and amphetamine-regulated transcript
CAT	Catalase
CNS	Central nervous system
CpG	Cytosine–guanine dinucleotide
CREB	cAMP response element binding
CYP450	Cytochrome P450
DNMT	DNA methyltransferase
FADD	Fas-associated death domain
FasL	Fas ligand
fMRI	Functional magnetic resonance imaging
GABA	ɣ-aminobutyric acid
GPx	Glutathione peroxidase
GSH	Glutathione
HDAC	Histone deacetylase
HMT	Histone methyltransferase
HSP72	72-kDa heat shock protein
HVA	Homovanillic acid
MAO	Monoamine oxidase
MDA	Malondialdehyde
MDMA	3,4-methylenedioxymethamphetamine ecstasy
miRNA	microRNA
MRI	Magnetic resonance imaging
MRS	Magnetic resonance spectroscopy
NMDA	N-methyl-D-aspartic acid
OPRD	Delta opioid receptor gene
OPRK	kappa opioid receptor gene
OPRM	mu opioid receptor gene
PET	Positron emission tomography
rCBF	Cerebral blood flow

rCMR	Regional cerebral metabolic rate
ROS	Reactive oxygen species
RS	Reactive species
SNP	Single-nucleotide polymorphism
SOD	Superoxide dismutase
SPECT	Single photon emission computed tomography
TH	Tyrosine hydroxylase
TNF	Tumor necrosis factor
VMAT	Vesicular monoamine transporter

1 Introduction

Neurotoxicity can result from exposure to several exogenous factors and drugs of abuse are of such example. Psychostimulant and opiate intake is widespread, and their repeated exposure leads to either physical damage or disruption in the activity of the nervous system.

2 Psychostimulants and Opiates

Psychostimulants (e.g., cocaine and amphetamines, like methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA=ecstasy)) are drugs that temporarily enhance the activity of the CNS and can induce the feeling of euphoria in humans, while in laboratory animals locomotor overstimulation, reinforcement/reward, as well as subjective effects in a drug discrimination task are produced. The most prominent pharmacological mechanism of psychostimulants is the facilitation of dopaminergic neurotransmission; however, these drugs also enhance noradrenaline and/or serotonin (5-HT) activity (for a review, see Fleckenstein et al. 2007; Sulzer 2011). Psychostimulants can be characterized as "releasers" (amphetamines) and "uptake blockers" (cocaine) based on the mechanism of their acute effect on neurotransmitter flux through the monoamine transporter.

The direct actions of amphetamine and methamphetamine include the reversal of transport across the dopamine transporter (in lower extracellular concentrations; Sitte et al. 1998), diffusion into the cell due to its lipophilicity at higher extracellular concentrations (Sulzer et al. 1995; Kahlig et al. 2005), inhibition of the dopamine transporter, and inhibition of the vesicular monoamine transporter (VMAT)2 function; together, these actions induce stimulation-independent dopamine release (Sitte et al. 1998; Riddle et al. 2002). Amphetamine also enhances dopamine synthesis (Kuczenski 1975) and impairs dopamine metabolism by inhibiting monoamine oxidase (MAO) (Ramsay and Hunter 2002). In high concentrations or with repeated treatment, amphetamine inhibits tyrosine hydroxylase (TH) and/or TH protein levels (Ellison et al. 1978; Bowyer et al. 1998).

In contrast to amphetamine and methamphetamine, MDMA's mechanism depends on the animal species (Green et al. 2003). In nonhuman primates MDMA acts as a 5-HT neurotoxin; in rats, MDMA depletes 5-HT terminal markers due to enhanced 5-HT release (reviewed by Green et al. 2003); in mice MDMA releases dopamine (Rothman and Baumann 2003).

The primary mechanism of cocaine is linked to its ability to bind to the dopamine transporter, inhibit dopamine reuptake, and elevate synaptic and extrasynaptic dopamine levels (Brown et al. 2001), whereas it was more recently established that cocaine binding sites also contain both high- and low-affinity binding components (i.e., dopamine D_2 receptors) (Marcellino et al. 2010), indicating a novel allosteric agonist action of cocaine in low (1–10 nM) concentrations on dopamine receptors (Ferraro et al. 2010). Apart from being a dopamine transporter blocker, cocaine also inhibits the noradrenaline and 5-HT transporters (Gatley et al. 1998). Of less significance is cocaine's action on the VMAT-2; cocaine enhances the storage of cytoplasmic catecholamines into synaptic vesicles, acting on the VMAT-2 which further allows for massive synaptic neurotransmitter release in response to depolarization (Brown et al. 2001).

It should be noted that metabolism of psychostimulants generates active substances that have their own toxic effects on nerves, including the brain. Thus, metabolites of amphetamine and methamphetamine include norephedrine, hydroxyamphetamine, hydroxynorephedrine N-hydroxymethylamphetamine, and possibly N-formylamphetamine (Jenkins and Cone 1998; Soloway and Patil 2011), by virtue of an action of cytochrome P450 (CYP450) on the parent drug. Metabolism of MDMA starts with O- or N-demethylation resulting in α-methyldopamine, N-methyl-α-methyldopamine, or 6-hydroxy-α-methyldopamine, while during further biotransformation, conjugation with thiols or glutathione (GSH) leads to thioether derivatives or 5-(glutathion-S-yl)-α-methyldopamine; all the above metabolites are toxic to neurons (Milhazes et al. 2006; Capela et al. 2006, 2007; Cunha-Oliveira et al. 2008; Barbosa et al. 2012; Martinez et al. 2012).

Neurotoxic cocaine metabolites are benzoylecgonine, norcocaine, and cocaethylene (Nassogne et al. 1998; Bunney et al. 2001).

Opiates are any of the narcotics derived from the opium poppy plant. Together with other psychoactive drugs called "opioids," they share mechanisms of action, i.e., they bind to opioid receptors (see below). Opiates (e.g., morphine, heroin) and opioids (oxycodone, methadone, pentanyl, tramadol, pethidine, dextropropoxyphene, etc.) induce a feeling of well-being and a relief of pain, while their long-term repeated use leads to addiction and tolerance. This group of addictive drugs is characterized by a strong withdrawal syndrome that includes both somatic and affective components. In laboratory animals, opioids produce a biphasic locomotor response, consisting of an initial reduction followed by an increase in locomotor activity, discriminative stimulus, and reinforcement, whereas withdrawal syndrome includes a constellation of jumping, wet-dog shakes, teeth chattering, forepaw treading, forepaw tremors, and diarrhea.

Opiates/opioids exert their actions by binding to three opioid receptors, μ, δ, and κ, and the former two are involved in drug pleasurable effects due to the stimulation of dopaminergic neurons. Following opiates/opioids, enhanced dopamine extrasynaptic levels result from two points: at the level of the dopamine synapse and at the level of the afferents to the dopamine cell bodies (reviewed in Wise 1987; Sulzer 2011). The enhancement of dopamine release in the striatum may result from an indirect effect of opioids leading to the disinhibition of tegmental dopaminergic neurons by inhibiting γ-aminobutyric acid (GABA) interneurons or GABA terminals containing opioid receptors in the ventral tegmental area or by the direct activation of opioid receptors on accumbal cholinergic or GABAergic neurons (Sulzer 2011).

Opiates undergo several metabolic changes leading to assorted derivatives possessing toxic potential. Morphine is converted mainly by glucuronidation into morphine-3-glucoronide and morphine-6-glucoronide. However, oxidative demethylation and further oxidation via CYT450-dependent processes (principally via CYP3A4 and CYP2D6) may lead to N-hydroxymethylnormorphine, normorphine, and hydromorphone (Coller et al. 2009). Of note, morphine-3-glucoronide shows rewarding efficacy in mice (Vindenes et al. 2006).

Heroin (diacetylmorphine) undergoes rapid deacetylation to 6-monoacetylmorphine, which is approximately six times more potent than morphine, and further deacetylation to morphine (Sawynok 1986).

Pethidine is converted via CYT450 to a neurotoxic norpethidine, while dextropropoxyphene undergoes biotransformation into nordextropropoxyphene, a cardiotoxic agent.

A hallmark of psychostimulants and opioids (as well as other abused drugs), even having different mechanisms of action, is that they all impinge and increase dopamine neurotransmission within the mesolimbic circuitry of the brain (the so-called reward system); these effects are seen after acute (above) or chronic drug exposure (Filip et al. 2010; Sulzer 2011). The reward pathway is composed of dopaminergic neurons that project from the ventral tegmental area to several cortical and subcortical structures. The key structure that executes reward processes and is implicated in the addictive effects of the drugs is the nucleus accumbens, the terminus of the mesolimbic dopaminergic pathway. The nucleus accumbens is a regulator of motivation and learning processes (Di Chiara et al. 1999). It should be underlined that although impairment evoked by abuse of addictive drugs starts in the brain areas processing reward, the long-term drug intake disrupts the whole brain and leads to dysfunctions of emotions, motivations, learning, memory, executive control, and cognitive awareness. These functions are executed by the amygdala and hippocampus (memory and learning), the insula (conscious emotions), the dorsal striatum (habit forming learning), the orbitofrontal cortex (motivation/drive, salience attribution, motivation, and compulsive behaviors), the prefrontal cortex (executive control), and the cingulate gyrus (inhibitory control, attention, and impulsivity) (Volkow et al. 2003). Interestingly, in drug addiction there are recognized strong feedback mechanisms within the above brain structures with a special significance for the prefrontal cortex. In fact, in drug addicts, dysregulation of

prefrontal cortex activity impairs its inhibitory coordination of other brain circuits, fixing the maintenance of drug habit. The above impairment behaviors are under control of glutamatergic neurotransmission (reviewed by Tzschentke and Schmidt 2003; Volkow et al. 2003; Kalivas 2004). Glutamategic neurotransmission is a cellular mediator of synaptic plasticity as well as learning and memory processes, and the current notion of addiction indicates that aberrant forms of drug-induced synaptic plasticity and learning in the brain drive compulsive and relapsing behaviors (Dacher and Nugent 2011).

3 In Vivo Evidences of Neurotoxicity

3.1 Human Studies

3.1.1 Psychostimulants

Neurological and Psychiatric Impairments

As reported in vivo, chronic use with amphetamines or cocaine has been implicated in cognitive deficits and psychological and anatomical impairments in human addicts. Among chronic drug users, methamphetamine abuse is associated with impairment of episodic memory, executive functions (e.g., novel problem solving), complex information processing speed, and decision-making abilities (impulsivity and risky decision-making) (Bechara and Martin 2004; Scott et al. 2007). Smaller impairments are present in motor skills (e.g., coordination) and language abilities (Caligiuri and Buitenhuys 2005; Scott et al. 2007). Other studies report a high level of psychiatric symptoms such as auditory/visual hallucinations, suspiciousness, and delusional thoughts in methamphetamine users (McKetin et al. 2006); such symptoms typically last only hours or diminish within a week of withdrawal, but prolonged symptom episodes have also been reported (McKetin et al. 2006). Abstinent methamphetamine abusers suffer also from mood disturbances like depression and anxiety (London et al. 2004) that may occur after the use episode, but may last for many months thereafter (Zweben et al. 2004).

Literature findings about influence of chronic MDMA use on neurocognition are equivocal. Some studies point out that only a "heavy" MDMA use can cause primary memory dysfunction (Gouzoulis-Mayfrank and Daumann 2006), while a low dose of MDMA (one or two tablets containing the usual amount of MDMA) has no relevant effects on human cognitive brain function (de Win et al. 2006; Jager et al. 2007). Moreover, there is a concern that memory deficits in MDMA users, although subtle, might be a risk factor for earlier onset and/or more severe decline of age-related memory deficits in later years, possibly due to hippocampal dysfunction (Gouzoulis-Mayfrank and Daumann 2009). Moreover, chronic MDMA users reported significantly increased levels of emotional instability, depressive mood, anxiety, aggression, impulsive features, and paranoid ideation (O'Leary et al. 2001; Gouzoulis-Mayfrank and Daumann 2009). It should be added that several factors like polydrug use, genetic factors (Gouzoulis-Mayfrank and Daumann 2009), or positive family history of psychiatric problems

(O'Leary et al. 2001) have been recognized within MDMA abusers, making a linkage between MDMA abuse and the drug-induced psychological problems to be established in further studies. Disturbances in working memory were reported also for cocaine-dependent subjects in which functional magnetic resonance imaging (fMRI) analyses during a working memory task showed impaired activation in the frontal, striatal, and thalamic brain regions (Cowan 2007; Moeller et al. 2010).

Chronic cocaine users suffer from diminished decision-making capacity, disrupted perception of motivational drive, and impairments in self-control (Goldstein et al. 2007a). Some researchers indicate that cocaine use by mothers during pregnancy increases the risk of significant cognitive (e.g., lower IQ, poorer language development, impaired attention), emotional (impulsivity), and motor deficits in the offspring (Arendt et al. 1999; Smith et al. 2001; Harvey 2004; Jones et al. 2004). Of note, some researchers do not report noticeable neurological or psychiatric abnormalities in children born of mothers who abused cocaine during pregnancy (Eyler et al. 2001; Rose-Jacobs et al. 2002).

Morphological Changes

Amphetamine users, apart from functional manifestation of drug-induced neurotoxicity (above), show prominent morphological brain changes. In fact, a loss of gray matter in the cingulate, paralimbic, and limbic cortices; noticeable smaller hippocampus volume; and hypertrophy of white matter were found in chronic methamphetamine users (Thompson et al. 2004). Additionally, MDMA users reveal reduction of multiple gray matter regions in the neocortical, bilateral cerebellum, and midline brain stem brain regions, potentially involved in some previously reported neuropsychiatric impairments (Cowan et al. 2003).

There are also morphological abnormalities in cocaine abusers seen as decreases in gray matter in the orbitofrontal cortex, age-related hyperintense areas of white matter regions in the cerebral and insular subcortex in fMRI scans (Franklin et al. 2002). Apart from the above brain regions, magnetic resonance imaging (MRI) tests performed on cocaine-dependent subjects ($N = 40$) showed also lower gray matter volumes in cerebellar hemispheres and thalamus (Sim et al. 2007). The authors suggest that cerebellar deficits may contribute to neuropsychological deficits and motor dysfunction frequently observed in cocaine-dependent subjects. Long-term consumption of cocaine may also influence white matter connections in the brain (Lane et al. 2010); deficits in white matter integrity have an inverse relationship with the length of abstinence from cocaine abuse in cocaine-dependent patients (Xu et al. 2010). Cocaine was also found to upregulate heat shock protein expression, leading to blood–brain barrier breakdown and brain edema formation (Sharma et al. 2009).

Recently reviewed by Derauf et al. 2009, infants, children, and young adults display some morphological abnormalities on MR-based imaging scans as cortical infarcts, pachygyria, schizencephaly, paraventricular hemorrhage, subependymal and periventricular cysts, as well as decreases in the volume of the corpus callosum, caudate–putamen or thalamus, and in cortical gray matter in both cocaine and methamphetamine abusers or their offspring.

Microglia Changes

Chronic methamphetamine users showed an increased level of glial activation marker myoinositol in the frontal gray and left frontal white matter (Ernst et al. 2000; Chang et al. 2007; Sung et al. 2007; Krasnova and Cadet 2009). With use of positron emission tomography (PET), Sekine et al. (2008) indicated that methamphetamine-dependent individuals present a remarkable level of microgliosis in several brain regions (the midbrain, thalamus, striatum, insular, and orbitofrontal cortices); these changes were correlated inversely with the duration of the drug abstinence. Because the above observation contrasts with the findings in autopsied methamphetamine users' brains (see 4.1.1.2), further correlation analyses between the time needed for induction and progression of microglia activation are required.

Metabolic Changes

Human amphetamine addicts have serious brain metabolism impairments that are significantly altered in cortical and striatal areas (Volkow et al. 2001a; Wang et al. 2004). Recent papers reported reduced concentrations of N-acetylaspartate, being a marker of neuronal activity linked with attention control (Ernst et al. 2000; Sung et al. 2007; Licata and Renshaw 2010), and of creatine that serves as a metabolic integrity marker (Sekine et al. 2002) in the basal ganglia of methamphetamine abusers. Moreover, chronic methamphetamine users display raised striatal volumes and altered brain glucose metabolism in the orbitofrontal and limbic regions in the frontal gray and left frontal white matter (Ernst et al. 2000; Sung et al. 2007; Chang et al. 2007; Krasnova and Cadet 2009) as well as a higher glucose activity in the parietal cortex and lower activity in the thalamus and striatum (Volkow et al. 2001a).

Similarly to chronic methamphetamine, MDMA users showed decreased ratios of N-acetylaspartate to creatine which were associated with memory deficits (Reneman et al. 2001); however, other authors have not reported such differences (Daumann et al. 2004).

In vivo imaging findings on human cocaine users showed acute cocaine-evoked activation of the anterior cingulate (Daglish and Nutt 2003; Romero et al. 2010), while presentation of cocaine-associated cues resulted in the significant activation of metabolic activity of the anterior cingulate cortex region (Goldstein et al. 2007b). Local perfusion deficits were confirmed by PET and single photon emission computed tomography (SPECT) imaging in active cocaine abusers in the orbitofrontal cortex where the glucose metabolism was elevated and linked closely to changes in cerebral metabolism (Holman et al. 1991, 1993; Levin and Kaufman 1995; Levin et al. 1995; Volkow et al. 1991, 2004; Martinez et al. 2009), and this hypermetabolic response correlated with intense craving in cocaine abusers (Volkow and Fowler 2000) and persisted after months of detoxification (Volkow et al. 1988). PET studies confirmed MRI analyses about decreased metabolic activity in the orbitofrontal cortex and cingulate gyrus in the detoxified cocaine abusers (Volkow et al. 2004); such decreases were associated with reductions in striatal dopamine D_2 receptors (see below). In another study in active cocaine

abusers in both genders, PET and 2-deoxy-2[^{18}F]fluoro-D-glucose indicated a reduction in whole brain glucose metabolism in female and a trend to increase in male subjects during cocaine-cues video (Volkow et al. 2011). Children with prenatal cocaine exposure showed increased striatal creatine levels in magnetic resonance spectroscopy (MRS) study what suggested an impairment of energy metabolism in the brain of children exposed to this drug in utero (Fowler et al. 2007). The findings observed in stimulant abusers document brain metabolic changes in areas involved in reward circuitry and dopamine systems.

Changes in Neurotransmission

PET and MRI imaging studies have revealed that amphetamines can lead to neurodegenerative changes in the brains of human addicts; these abnormalities include persistent decreases in the levels of dopamine transporters in the orbitofrontal cortex, dorsolateral prefrontal cortex, and caudate–putamen (McCann et al. 1998a; Volkow et al. 2001b, c; Sekine et al. 2003; McCann et al. 2008) and the lower density of 5-HT transporters in global brain regions (Sekine et al. 2006) in methamphetamine addicts. PET imaging identified also partial recovery of dopamine transporter binding in methamphetamine abusers during abstinence (Volkow et al. 2001c). The dopamine transporter reduction paralleled slower motor function and impaired episodic memory functioning, enhanced severity of psychiatric symptoms, and longer duration of methamphetamine use, while the reduction of 5-HT transporter may have a connection with increased aggressive behavior in methamphetamine abusers (Scott et al. 2007). It should be added that deleterious effects of methamphetamine such as N-acetylaspartate, creatine decrease, and microglial overactivity are enhanced in HIV-positive methamphetamine abusers (Chang et al. 2005), which indicate additive detrimental effect of coexisting HIV infection and methamphetamine abuse on human brain function.

Studies in MDMA users have reported enduring decrements in global brain 5-HT transporter binding (Ricaurte et al. 2000); however, neither a significant correlation between reductions in 5-HT transporter availability and extent of MDMA abuse nor improvements in markers for transporter during periods of drug abstinence have been demonstrated (Buchert et al. 2006; Thomasius et al. 2006). Of note, a separate SPECT imaging study in MDMA recreational users reported reduced striatal dopamine transporter binding (Reneman et al. 2002).

A growing number of evidence indicate enhanced glutamate transmission in many limbic brain areas in the development of amphetamine neurotoxicity (Abekawa et al. 1994; Stephans and Yamamoto 1994; Rocher and Gardier 2001; Cunha-Oliveira et al. 2008). Thus, reduction in glutamate and glutamine transporter systems has been described in the frontal gray matter of abstinent chronic methamphetamine abusers but not in active drug addicts (Ernst and Chang 2008) as an adaptation leading possibly due to reduced methamphetamine excitotoxicity (Ramonet et al. 2004). Since downregulation of glutamate and/or glutamine transporter levels is lowest at the beginning of abstinence ($\leq$1 month), they may serve as a factor involved in methamphetamine craving (cf. Ernst and Chang 2008).

Another amphetamine-derived psychostimulant, MDMA, evokes reduction in the metabolite of 5-HT, 5-hydroxyindoleacetic acid (5-HIAA), levels in cerebrospinal fluid in human abusers (Ricaurte et al. 1990; McCann et al. 1994, 1999; Bolla et al. 1998), and such change is regarded as a marker of the drug-induced toxicity. Confirmed by PET studies showing significant and dose-dependent depletion of 5-HT transporter levels in most cortical and subcortical brain regions of chronic MDMA users (McCann et al. 1998b; Semple et al. 1999; Reneman et al. 2001), the latter depletion was negatively correlated with the extent of abuse (McCann et al. 1998b; Ricaurte et al. 2000) and paralleled memory and learning impairment (Cowan et al. 2003).

PET studies have been also performed to reveal cocaine-induced abnormalities in brain dopamine neurotransmission, including long-lasting decreases in D_2 receptor density in cocaine abusers (Volkow and Fowler 2000). These observations concerning D_2 receptor level could be linked to reduced sensitivity of reward circuits to stimulation by natural rewards and increased risk for drug taking (Volkow et al. 2004). Moreover, detoxified cocaine abusers had still a marked decrease in dopamine release as measured by methylphenidate-induced decreases in striatal [^{11}C] raclopride binding (Volkow et al. 1997), while the dopamine transporter density – elevated shortly after cocaine abstinence – was normalized with long-term detoxification (Malison et al. 1998). Interestingly, no difference in D_1 receptor density was observed between cocaine-dependent subjects and matched controls (Martinez et al. 2009). Another PET scan report showed the low VMAT-2 availability in the striatum of cocaine abusers which the authors link to a compensatory downregulation of the dopamine storage vesicles in response to chronic drug abuse and/or a loss of dopamine terminals (Narendran et al. 2012).

Manifestations of Genomic Mechanisms

The areas of the genome underlying amphetamine-type (cocaine and methamphetamine) substance use disorders are coming into light. In an American Indian community at high risk for substance dependence, analyses of multipoint variance component LOD scores failed to yield evidence of linkage for stimulant dependence for a panel of 791 microsatellite polymorphisms. However, the importance of "craving" as an important addiction phenotype was associated with regions on chromosomes 12, 15, and 18 in this user population. In more detail, the "craving" phenotype and "heavy stimulant use" were associated with a locus found on chromosomes 15q25.3–26.1 near the nicotinic receptor gene cluster while a loci for stimulant "craving" on chromosomes 12p13.33–13.32 and 18q22.3 (Ehlers et al. 2011). The single-nucleotide polymorphism (SNP) 118A>G in the mu opioid receptor gene (OPRM1) coding sequence was associated with methamphetamine psychosis, having latency less than 3 years from first drug intake in Japanese subjects (Ide et al. 2004). In cocaine addicts, an association with drug intake was shown with three promoter SNPs (−1793T>A, −1699insT, and −2044C>A) of OPRM1 gene (Hoehe et al. 2000), while a very recent large study identified association between the 17TT genotype and a cocaine addiction in HIV-positive and HIV-negative African addicts (Crystal et al. 2012). In a study of

methamphetamine dependence/psychosis, an association was found with SNP rs2075572 (IVS2+691G>C) of the latter gene in Japanese subjects (Ide et al. 2004, 2006), but not with the SNP rs2234918 (921T>C) in exon 3 of the delta opioid receptor gene (OPRD1) (Kobayashi et al. 2006).

3.1.2 Opiates

Neurological and Psychiatric Impairments

It is well-established that chronic exposure to heroin often results in cognitive deficits such as poorer performance in learning, cognition, and memory in human addicts (Cipolli and Galliani 1987; Guerra et al. 1987; Spain and Newsom 1991; Eisch et al. 2000). Other findings showed that methadone itself may contribute to cognitive impairment. In fact, greater impairment on verbal fluency, processing speed, response inhibition, visuospatial attention, cognitive flexibility, and set shifting was found in methadone-maintained patients than in abstinent groups. Also, in direct comparison of the methadone-maintained patients to former heroin users, similar impairment in executive function, visual memory, and impulsivity was found (cf. Martin et al. 2007). Methadone-maintained subjects rated the subjective value of a monetary reinforcement lower than the healthy comparison group, too (Martin-Soelch et al. 2001). Acquired brain injury (e.g., head trauma, nonfatal overdose) following long-term heroin use may contribute to variability in cognitive impairment. Interestingly, buprenorphine, another opioid used for maintenance treatment of former heroin abusers, was found to cause less psychomotor and cognitive impairment than methadone (Curran et al. 2001).

Morphological Changes

In heroin addicts neuroimaging studies indicate morphological changes within the posterior limb of the internal capsule and sparing of subcortical U fibers (cf. Martin et al. 2007). Another study (Lyoo et al. 2006) reported gray matter reductions in prefrontal, insular, and temporal cortices in patients on methadone maintenance compared with age- and sex-matched healthy subjects.

Metabolic Changes

Two studies have reported disturbances in frontal gray matter of patients maintained on methadone, buprenorphine, or heroin as the patients had lower concentration of N-acetylaspartate, as measured by MRS (Haselhorst et al. 2002; Yücel et al. 2007). MRI scans revealed diffuse white matter changes which paralleled widespread confluent vacuolar degeneration of the deep white matter, sparing of the brain stem and cerebellar white matter and extensive axonal injury in two patients with fatal drug-associated leukoencephalopathy (Ryan et al. 2005). Another in vivo functional assay indicates acute left-sided sensorimotor hemiplegia occurring acutely after a first inhaled dose of heroin by a 16-year-old male (Vella et al. 2003). The latter authors detected disturbances predominantly in parieto-occipital subcortical white matter and both ventral globus pallidus in MRS data and postulate defects in mitochondrial function as well as hypoxic injury in specific and limited areas of white matter due to acute heroin.

In SPECT scans conducted on opiate-dependent (methadone-maintained or heroin-using) subjects, a decrease in regional (the frontal and temporal cortex) cerebral blood flow (rCBF) was shown (Danos et al. 1998). A similar pattern of rCBF reduction has also been reported during the first week (Rose et al. 1996; Danos et al. 1998) or 10 weeks (Botelho et al. 2006) of detoxification, while Rose et al. (1996) have reported improved rCBF in the frontal cortex in patients rescanned at 3 weeks of withdrawal. Long-lasting neurobiological abnormalities in the regional cerebral metabolic rate (rCMR) in the anterior cingulate cortex were detected following a 6-month abstinence period in opiate addicts using fluorodeoxyglucose PET (FDG-PET) (Galynker et al. 2000).

Manifestation of Oxidative Stress

In heroin addicts ($N = 34$) chronic opioid use evokes significant growth of oxidative stress (Kovatsi et al. 2010).

Manifestations of Genomic and Epigenetic Mechanisms

There is a strong association between major genes of the opioid system and addiction to opiates. The most widely studied are mu, kappa, and delta receptors encoded by OPRM1, OPRK1, and OPRD1 genes (cf. Levran et al. 2012). Within two important SNPs (i.e., 17C>T (Ala6Val) and 118A>G (Asp40Asn)) out of the variants described in dbSNP in the OPRM1 gene coding sequence, only the SNP 118A>G has been linked with opioid addiction, and such observations come from Swedish (Bart et al. 2005), Chinese, European American (Drakenberg et al. 2006), and Indian patients (Deb et al. 2010). Other studies did not detect the above association (Franke et al. 2001; Glatt et al. 2007; Levran et al. 2009) nor association between the17T allele and opioid dependence in Indian (Kapur et al. 2007) and African (Crowley et al. 2003) addicts. Similarly, no association with opioid addiction has been reported in African and European American subjects analyzing SNPs −1793T>A, −1699insT, −1320A>G, 17C>T, 118A>G, as well as SNPs 540825 and 562859 (Crowley et al. 2003; Smith et al. 2005).

There are some evidences for association of OPRK1 SNPs 1051660 (Yuferov et al. 2004; Gerra et al. 2007) and of OPRK1 SNP rs6473797 (Levran et al. 2008) with opioid addiction. Recently, some papers indicated other polymorphism SNPs (e.g., rs2236861, rs2236857, rs3766951, rs204055, rs2236857, and rs2298896) for the OPRD1 gene in human addicts; associations with heroin addiction strongly depend on ethnic groups (cf. Levran et al. 2012).

Being a multifactorial and polygenic disorder, drug addiction does not conform to a simple Mendelian transmission pattern. Thus, epidemiological studies conducted on family, twin, and adoption suggest involvement in both genetic variance and environmental factors to increase susceptibility to addiction that neither act in isolation (Dick and Foroud 2003). Recent studies from the last 10 years demonstrated that posttranscriptional regulation of gene expression plays a key role in neurogenesis and synaptic plasticity (Puckett and Lubin 2011) and supports the role of epigenetic processes to control drug addiction (Robison and

Nestler 2011; Wong et al. 2011). A separate study indicated also the occurrence of epigenetic mechanisms (i.e., an increase in OPRM1 DNA methylation) in lymphocytes of methadone-maintained former heroin addicts (Nielsen et al. 2009). Another recent study demonstrates that overall methylation in human blood DNA from opioid addicts was increased and cytosine–guanine dinucleotide (CpG) islands located in *OPRM1* promoter were hypermethylated (Chorbov et al. 2011). Additionally, in sperm-derived DNA the methylation was increased at CpG sites, but global methylation was not affected (Chorbov et al. 2011). Hypermethylation of *OPRM1* promoter can cause gene silencing, while methylation in sperm may suggest heritability of dependence phenotypes.

3.2 Animal Studies

3.2.1 Psychostimulants

Behavioral Manifestation of Neurotoxicity

Methamphetamine was shown to induce only subtle to moderate functional manifestation of neurotoxic-like alterations in behavior of laboratory animals (cf. Gouzoulis-Mayfrank and Daumann 2009). Thus, only up to 3 days after a neurotoxic methamphetamine administration (4 times × 10 mg/kg, every 2 h) is there a decrease in spontaneous locomotor activity in rodents (Timar et al. 2003). In more subtle motor tests, i.e., active avoidance performance and balance beam performance, residual deficiency was reported in rats after methamphetamine neurotoxic treatment (Walsh and Wagner 1992). The most affected by methamphetamine intake were learning and memory behaviors. Neurotoxic methamphetamine exposure, under regimens of 4 × 10 mg/kg, every 2 h, or 24 × 1.67 mg/kg once every 15 min, impaired novel object recognition and impaired learning in a multiple T water maze test, with no differences on spatial navigation or reference memory in the Morris water maze in rats (Herring et al. 2008). Disturbances in consolidation of learned place preference and impairments on a radial maze sequential learning task and on a novelty preference object recognition were reported after neurotoxic methamphetamine doses in rodents (Chat-Mendes et al. 2007; Gouzoulis-Mayfrank and Daumann 2009). Interestingly, in nonhuman primates, gradual rise in methamphetamine doses in an escalating dose regimen diminished social behavior on "injection" days, with aggression declining during the study; such effects disappeared after 3 weeks of drug abstinence (Melega et al. 2008).

More conflicting findings concern functional manifestation of MDMA neurotoxicity. Some studies reported enhanced anxiety or weak memory performance in rodents and monkeys exposed to MDMA (Winsauer et al. 2002; Melega et al. 2008) but normal or return-to-normal task execution after 2–3 weeks abstinence even with previous 33-week MDMA escalated doses (Melega et al. 2008). Other findings indicate no assessment of functional impairments like risk-taking behavior or anxiety after MDMA administration (Gouzoulis-Mayfrank and Daumann 2009);

according to the latter studies, MDMA-treated animals do not present functional abnormalities despite persistent neurotoxicity reported postmortem.

Prolonged exposure to cocaine (sometimes even an acute drug injection) resulted in cognitive impairment and/or a decrease in social contacts in animals (Daza-Losada et al. 2009; Murnane and Howell 2011). Monkeys exposed to self-administered cocaine showed attentional impairments with a more specific cognitive control impairment, implicating orbitofrontal cortex dysfunction (Porter et al. 2011).

Changes in Neurotransmission

Several neuroimaging and microdialysis findings reveal abnormalities within brain neurotransmission due to chronic psychostimulant exposure. Thus, imaging studies (PET, SPECT, or fMRI) indicate neurotoxic effects regarding dopamine and 5-HT brain systems due to long-term psychostimulant exposure to animals (for a review, see Howell and Murnane 2011; Murnane and Howell 2011). Neurotoxic effects toward dopamine system alterations include decreases in dopamine synthesis (lower DOPA level) (Melega et al. 1997) and a drop in dopamine transporter densities (Villemagne et al. 1998; Melega et al. 2000; Hashimoto et al. 2007) in the striatum of monkeys after two i.m. injections with methamphetamine/amphetamine or following 3–4 i.m. injections with methamphetamine to nonhuman primate (Villemagne et al. 1998; Hashimoto et al. 2007).

Neuroimaging reports showed neurotoxic results of MDMA action on 5-HT brain system during noncontingent drug administration. In fact, an early PET imaging study in a baboon characterized the effects of MDMA on in vivo 5-HT transporter availability using MDMA (5 mg/kg s.c., once or twice a day for 4 days) that caused diminished 5-HT transporter density in the caudate–putamen and cortical regions (Scheffel et al. 1998; Szabo et al. 2002). Such decreases in 5-HT transporter availability, however, were not evidenced during contingent MDMA administration in rhesus monkeys (self-administration model) even during higher MDMA dosage (100–140 mg/kg/day) and repeated drug treatment (12 months) (Banks et al. 2008). Long-term (18 months) self-administered MDMA to rhesus monkeys evoked also no significant change in the VMAT availability following at least 2 months of drug abstinence, as assessed with PET neuroimaging, despite an evidence of attenuation of reinforcing properties of MDMA perhaps through neurotoxic effects of MDMA (Fantegrossi et al. 2004).

PET imaging studies in monkeys showed that chronic exposure to self-administered cocaine resulted in a significant reduction in dopamine D_2 receptor levels (Czoty et al. 2004; Nader et al. 2006) that persisted for up to 1 year of abstinence in some monkeys (Nader et al. 2006). These studies demonstrate that monkeys with long-term histories of cocaine use reliably display lower dopamine D_2 receptor densities in ways that correlate with cocaine dose and duration of exposure (Moore et al. 1998; Nader et al. 2002).

Data from in vivo microdialysis in rodents indicated long-lasting reductions in dopamine and 5-HT brain levels following amphetamine derivatives, including

methamphetamine (Herring et al. 2008) and MDMA (Gudelsky and Yamamoto 2008). Apart from enhanced release of monoamines in the striatum, nucleus accumbens, and prefrontal cortex, MDMA also evoked the release of acetylcholine in the striatum, hippocampus, and prefrontal cortex and increased the extracellular concentration of energy substrates, e.g., glucose and lactate, in the rat brain. In contrast to the acute stimulatory actions of MDMA on the release of monoamines and acetylcholine, repeated MDMA administration in high doses resulted in a neurotoxicity to 5-HT axon terminals in the rat (for a review, see Gudelsky and Yamamoto 2008).

Repeated cocaine self-administration evokes significant alterations in extracellular monoamine and amino acid levels in rodents' brain. Many in vivo microdialysis studies (Pettit and Justice 1989; Pontieri et al. 1996; Lecca et al. 2007; Saddoris et al. 2011) including a very recent paper by Wydra et al. (2013) indicated that self-administered cocaine evoked extracellular accumbal dopamine and that its level was much higher in comparison to yoked rats given passive *i.v.* cocaine injections. Ferris et al. (2011), using a combination of cocaine self-administration and microdialysis in freely moving rats, showed a decrease in dopamine transporter sensitivity to cocaine in the nucleus accumbens core. Such a significant decrease in the ability of cocaine to inhibit the dopamine transporter was apparent after a single day of self-administration, lasting for several days following cessation of cocaine intake (Ferris et al. 2011); the latter finding confirms PET imaging studies showing that acute cocaine administration decreases the availability of the plasma membrane transporter for binding, even after cocaine is no longer blocking dopamine uptake as evidenced by a return of dopamine to its basal levels (Kimmel et al. 2012).

A few other reports demonstrated increases in extracellular GABA derived from neuronal sources after 3 weeks of withdrawal from repeated passive cocaine administration (Xi et al. 2003), but no changes in GABA levels during cocaine self-administration (Sizemore et al. 2000). Moreover, in animals extinguished from cocaine self-administration, a reduction in basal extracellular GABA levels was observed in the ventral pallidum, while the reinstatement of cocaine seeking was associated with an augmentation of such effects (Tang et al. 2005). Changes in dopamine and GABA neurotransmission during the maintenance phase mirror the motivational aspects of cocaine intake. Apart from dopamine and GABA, cocaine also regulates glutamate extracellular levels with small increases at a few isolated time points during the self-administration sessions (Sizemore et al. 2000; McFarland et al. 2003; Madayag et al. 2007; Miguéns et al. 2008) as well as decreases in basal extracellular levels of nucleus accumbens glutamate (Wydra et al. 2013). Such glutamatergic inputs are believed to be critical for the learning and maintenance of goal-directed responding, including drug-seeking behavior (cf. Koob and Swerdlow 1988).

Metabolic Changes

In vivo studies on animals confirm human PET imaging data (see above) that amphetamines evoke serious functional alterations in glucose metabolism.

Thus, methamphetamine repeated treatment (1 mg/kg, every other day for 5 days) decreased 18-FDG uptake in the hippocampus and in the insular cortex in rats conditioned to receive methamphetamine in a distinct environment. Hypoactivation of glucose metabolism in the hippocampus, amygdala, and auditory cortex was also seen after acute MDMA (20 mg/kg or 40 mg/kg) to rats (Soto-Montenegro et al. 2007). On the other hand, another PET study indicated that rats showing strong drug-associated place preference displayed large increases in 18-FDG uptake in the dorsal and ventral striatum, cingulate cortex, and retrosplenial cortex which proves their involvement in the conditioned effects of amphetamines (Carrion et al. 2009).

Chronic use of cocaine is also associated with lasting alterations in brain metabolism. A recent study documents cocaine-induced changes in brain metabolic activity as a function of history of drug voluntary intake (Henry et al. 2010). The latter authors showed that acute *i.v.* cocaine treatment resulted in increases in glucose metabolism in the anterior cingulate and medial prefrontal cortex. Similar metabolic decrements were found by Lyons et al. (1996) who reported that an *i.v.* infusion of cocaine (1 mg/kg) markedly decreased glucose utilization in the orbitofrontal cortex, entorhinal cortex, nucleus accumbens, and parts of the hippocampal formation in monkeys; smaller decrements were observed in the caudate and anterior putamen, too. The progressive involvement of cortical and striatal areas as a function of extensive cocaine exposure has also been demonstrated in monkeys with [^{14}C]2-deoxyglucose and PET method (Lyons et al. 1996; Porrino et al. 2004). Initial exposures to cocaine resulted in metabolic effects of cocaine contained primarily in the ventromedial regions of the prefrontal cortex, while following chronic exposure to cocaine self-administration, glucose metabolism expanded mainly within the striatum.

Interestingly, changes in brain metabolism lasted even after long-term drug abstinence, as evidenced in the study with 28-day cocaine withdrawal in rats trained to self-administer cocaine where significant increases in the cerebral blood volume in the medial prefrontal cortex, caudate–putamen, motor cortex, and the pedunculopontine tegmental nucleus were detected (Chen et al. 2011).

Manifestation of Oxidative Stress

Supporting the role of oxidative stress in toxicity of amphetamines, several antioxidants (e.g., N-acetylcysteine, vitamin E) or overexpression of antioxidant enzymes (e.g., superoxide dismutase (SOD)) attenuates the neurotoxic action of amphetamines (Colado et al. 1997; Imam et al. 2001, 2000; Wan et al. 2006; Wu et al. 2007).

Manifestations of Epigenetic Mechanisms

Separate studies conducted on transgenic animals indicated that overexpression of histone deacetylase (HDAC)4 or HDAC5 decreases behavioral responses to cocaine (Kumar et al. 2005; Renthal et al. 2007), whereas genetic deletion of *Hdac5* enhanced mouse responses to the chronic effects of cocaine (Renthal et al. 2007).

3.2.2 Opiates

Behavioral Manifestation of Neurotoxicity

As evidenced in many papers, chronic exposure to opioids can lead to disturbances in cognitive functions and evoke anxiety in rodents. Impairments in learning and memory processes were detected in long-term memory consolidation in mice when heroin was administered after the learning sessions (Castellano 1975, 1980; Florian and Roullet 2004). Similar results were shown in discriminative avoidance paradigms – radial-, Y-, and plus-mazes and in the Morris water maze after chronic administration of morphine (Spain and Newsom 1991; Pu et al. 2002) and also in the Morris water maze following a single methadone dose administered 15 min before training to rats (Hepner et al. 2002) or chronic methadone in mice (Tramullas et al. 2007). Such memory impairment effects have been linked with opioid-induced neurotoxicity through activation of apoptotic pathways (see below).

Changes in Neurotransmission

With neuromolecular imaging it was documented that rats given passive single (10 mg/kg) or repeated (10 mg/kg) doses of morphine had significantly increased extracellular dopamine and 5-HT levels in the nucleus accumbens; the increases above 90 % in monoamine levels were seen already after a second dose of morphine. Decreases in dopamine neurotransmission after acute or repeated dosing of morphine, and still significantly lower on the 5th day of morphine abstinence, were detected in SPECT scans in monkeys (Xiao et al. 2006). Another effective toxic target related to morphine abuse is glutamatergic neurotransmission. Thus, in rodents chronic morphine use modifies extracellular concentrations of glutamate in the nucleus accumbens (Sepúlveda et al. 2004), prefrontal cortex, and hippocampus (Guo et al. 2005). Recently, spectroscopic analysis in rats showed that morphine administration (10 mg/kg) twice a day for one, six, or ten consecutive days resulted in a reduction in glutamate, with no statistically proven changes in glutamine, myoinositol, taurine, or N-acetylaspartate in the prefrontal cortex (i.e., 10 days of consecutive morphine treatment), while glutamate and myoinositol levels were elevated in the hippocampus (Gao et al. 2007). Other in vivo findings demonstrate short-lasting adaptations in neuronal glutamate relief (Nicol et al. 1996), synaptic glutamate uptake (Xu et al. 2003), expression of glutamate transporters (Mao et al. 2002), and neuronal activities of glutamate dehydrogenase and GABA transaminase (Kaur and Kaur 2001) following consecutive morphine administration.

4 Postmortem Evidences of Neurotoxicity

4.1 Human Studies

4.1.1 Psychostimulants

Changes in Neurotransmission

In humans several evidences of pathological changes have been observed in brain monoaminergic systems following abuse of amphetamines. Thus, postmortem

analyses in chronic methamphetamine users have shown a reduction in levels of dopamine nerve terminal markers in the caudate–putamen (Wilson et al. 1996; Moszczynska et al. 2004; Kitamura 2009) and reductions in 5-HT transporter levels in the orbitofrontal and occipital cortices (Kish et al. 2009). Moreover, VMAT-2 levels were remarkably reduced in some methamphetamine users, which may indicate a neurotoxic action of the drug resulting from disturbances in striatal dopamine terminal integrity (Kitamura 2009).

Regarding MDMA neurotoxicity in human addicts, there are some proof showing that MDMA led to the severe reduction of striatal 5-HT and 5-HIAA, assessed shortly (21-h) postmortem in the brain of an MDMA user who had taken MDMA regularly for 9 years (Kish et al. 2000), while another high-dose MDMA user had diminished 5-HT transporter level and TH activity in the brain (Kish et al. 2010).

For the development of amphetamine neurotoxicity to dopamine and 5-HT terminals, the occurrence of hyperthermia seems to be important. Physical activity, like dancing in the clubs or even staying in a warm environment which prevents proper heat dissipation, contributes significantly to the general morbidity and mortality in MDMA (Milroy et al. 1996; Armenian et al. 2012; Parrott 2012) or methamphetamine (Ishigami et al. 2003; Ago et al. 2006) users. Disruption of blood–brain barrier permeability and brain edema development in autopsy cases after acute fatal intoxication of methamphetamine (Ago et al. 2006; Inoue et al. 2006) or MDMA (Milroy et al. 1996) were found. Findings from forensic autopsy cases indicate that intake of a lethal dose of methamphetamine ($N = 11$) with the occurrence of hyperthermia immediately before death resulted in the 72-kDa heat shock protein (HSP72) expression in the microvessels and ependymal cells in the hippocampus (Kitamura 2009).

Long-term cocaine exposure in human addicts leads to neurotoxic effects on dopamine neurons seen as reductions in the total number of striatal dopamine D_2 receptors (Little et al. 2009). Other necropsy findings on cocaine abusers revealed serious dysfunction of monoaminergic systems, seen as decreases in the levels of VMAT-2 (Little et al. 2003) or an elevation of α-synuclein expression in midbrain dopamine neurons together with an increase of the 5-HT transporter in the striatum and the limbic system (for a review, see Büttner 2011). Elevation in α-synuclein expression may indicate increases in synaptic vesicle trafficking or pools, or enhancement in neuronal plasticity, or even selective loss of dopamine neurons (reviewed in Trexler and Rhoades 2012).

Activation of Microglia

Some postmortem studies in active methamphetamine users point to a significant increase in the number of microglia throughout the caudate–putamen, although such an increase neither paralleled immunohistochemical evidence for reactive microgliosis (Kitamura 2009) nor proliferation of the marker of reactive microglia CR3.43 (human complement receptor 3) (Kitamura et al. 2010). Also, long-term cocaine exposure by human addicts evokes infiltration of phagocytic cells (activated macrophages and activated microglia) within the caudate–putamen (Little et al. 2009). Of note, cocaine-evoked activation of microglial cells releasing

proinflammatory cytokines in the white matter and subcortical regions seems to be related to damage of neuronal cells (cf. Büttner 2011).

Manifestation of Oxidative Stress

The formation of reactive species (RS) and the resulting oxidative and/or nitrosative stress is a common toxicological pathway of amphetamines, and this plays an important role in the neurotoxicity observed in the brain after chronic exposure to the psychostimulants in human addicts (Mirecki et al. 2004; Fitzmaurice et al. 2006; Carvalho et al. 2012). Thus, a significant increase in levels of 4-hydroxynonenal and malondialdehyde (MDA), being products generated from lipid peroxidation, was found in the caudate nucleus and to a smaller extent in the frontal cortex in autopsied brains of chronic methamphetamine users (Fitzmaurice et al. 2006). Such increases in lipid peroxidation products were linked with a depletion in GSH concentration and with an enhancement in the levels of Cu, Zn-SOD activity in the caudate of methamphetamine users (Mirecki et al. 2004). These data suggest that methamphetamine exposure in humans leads to above-normal formation of potentially toxic lipid peroxidation products in the brain, while increased Cu,Zn-SOD activity seems to reflect possible compensatory response to oxidative stress due to amphetamine administration.

Manifestations of Apoptosis

Up to now, there is no definitive proof that apoptosis accounts for psychostimulant neurotoxicity in human addicts. Thus, a necropsy analysis on the striatum of chronic METH users ($N = 11$) showed a lack of caspase-3 activation (Kitamura et al. 2007). Another very recent postmortem human brain report by Alvaro-Bartolome et al. (2011) on cocaine abusers ($N = 10$) demonstrated also no activation of extrinsic and intrinsic apoptotic pathways in the prefrontal cortex and lack of activation of caspase 3 while the Fas-associated death domain (FADD) receptor complex and cytochrome c were downregulated. These authors showed also enhanced degradation of nuclear PARP-1, a hallmark of apoptosis, which was postulated to result from the formation of reactive oxygen species (ROS) by cocaine metabolites due to the induction of contraregulatory adaptations or non-apoptotic (neuroplastic) actions by the psychostimulant.

Manifestations of Genomic and Epigenetic Mechanisms

An early report on brains from humans with a history of cocaine abuse showed marked reductions in the levels of enkephalin mRNA and mu opiate receptor binding within the caudate and putamen, while levels of dynorphin mRNA and kappa opiate receptor binding in the putamen and caudate were elevated (Hurd and Herkenham 1993). As suggested by the latter authors, an imbalance between euphoric (enkephalin and mu opiate receptors) and dysphoric (dynorphin and kappa opiate receptors) markers may be linked with craving phenomenon detected in the human cocaine addict brain.

More recent microarray analysis showed alterations in brain gene expression in the postmortem anterior prefrontal cortex from human cocaine abusers

(Lehrmann et al. 2006). Thus, the drug-specific changes included reduction in calmodulin-related transcripts (CALM1, CALM2, CAMK2B), while transcripts related to cholesterol biosynthesis and trafficking (FDFT1, apolipoprotein L = APOL2, SCARB1) and Golgi/endoplasmic reticulum functions (semaphorin 3B = SEMA3B, GCC1) were increased. As these changes represent common molecular features of drug abuse, they may underlie changes in synaptic function and plasticity that could have important ramifications for decision-making capabilities in drug abusers (cf. Lehrmann et al. 2006). Another gene array analysis in brains from cocaine abusers detected altered expression of some myelin-related genes in the nucleus accumbens, while in situ hybridization to quantify transcript expression of these genes showed only decreased expression of the transcript encoding PLP1. PLP1 is expressed at very high levels in oligodendrocytes and is essential in maintaining stability of myelin sheets, thus implicating adaptive changes following chronic cocaine abuse. Of note, postmortem expression of claudin-11 and transferrin was decreased in the caudate and internal capsule, respectively, in cocaine addicts (Kristiansen et al. 2009).

There are some early evidences about the epigenetic mechanisms due to psychostimulant intake. Chronic cocaine abuse induces alterations in gene expression in the nucleus accumbens of humans (Albertson et al. 2004). Microarray analysis revealed further that expression of cocaine- and amphetamine-regulated transcript (CART) was increased, but some myelin-related genes were decreased. Another study on human postmortem brain revealed transcription and epigenetic changes in the hippocampus (Zhou et al. 2011) with suppression of more than one third of genes responsible for ATP synthesis and increases of the transcript level of DNA methyltransferase (DNMT)3a, cAMP response element binding (CREB)1, HDAC2, and HDAC4. In addition, changes in H3K4me3 distribution were noted near promoters of active genes and away from promoters of protein-coding genes.

4.1.2 Opiates

Changes in Neurotransmission

Chronic opiate exposure impairs brain monoaminergic neurotransmission in human addicts. As evidenced in postmortem nucleus accumbens of 9 chronic heroin users, levels of TH protein and dopamine were reduced. On the other hand, striatal levels of the VMAT and 5-HT were normal (Kish et al. 2001).

Changes in Protein Levels

A recent postmortem report indicated that in the hippocampi of 29 lethally intoxicated heroin addicts, there was a significant increase in polysialic acid neural cell adhesion molecule, being one of the key players involved in plasticity and regeneration, of neural-tissue-positive neurons and glial cells, possibly reflective of an attempt to repair cell damage due to long-term heroin neurotoxicity and impaired plasticity (Weber et al. 2006). This may account for cognitive deficits seen in human addicts (see above).

In the brain of young opiate abusers ($N = 34$, all <40 years age), an excess of AT 8-positive neurofibrillary tangles was found in the subiculum, temporal neocortex,

nucleus basalis of Meynert, and the locus coeruleus, while beta-amyloid precursor protein is increased in the brain stem and temporal lobe (Ramage et al. 2005). The above changes may be risk factors for poorer performance in cognition and memory in opiate addicts; however, the direct proof is still lacking.

Another study performed on brains of chronic opiate addicts ($N = 17$) who had died of a heroin or methadone overdose showed a marked (47 %) reduction in levels of immunoreactive NF-L proteins in the frontal cortex (García-Sevilla et al. 1997); this change was considered as a specific damage of axonal transport resulting from long-term opiate-evoked neuronal damage.

Manifestation of Oxidative Stress

A study performed on samples of 17 human brains obtained 2–4 days after heroin users' death indicates high protein oxidation levels in all lobes of the cortex, brain stem, hippocampus, and white matter and lower peroxyl radical-trapping capacity – a marker reflective of the relationship between ROS amount and antioxidant efficiency (Gutowicz et al. 2006). The latter authors found an elevation of MDA levels, a lipid peroxidation product, in all parts of the brain except the hippocampal formation. Despite the above evidence for neurotoxicity, there was no reduction in the activity of antioxidant enzymes such as SOD or catalase (CAT) (Gutowicz et al. 2006).

Manifestations of Epigenetic Mechanisms

A significant change in the expression of numerous genes encoding proteins involved in presynaptic release of neurotransmitter was reported by Albertson et al. (2006) in heroin abusers. Thus, the transcript encoding the endogenous opioid peptide prodynorphin (*PDYN*) was decreased, while the neurotrophin receptor *NTRK2* (also known as *TrkB*) was significantly upregulated in heroin abusers. In addition, alterations in many genes involved in processes related to neurotransmitter release and recycling, including SNARE proteins, vesicular proteins, and recycling proteins, imply synaptic dysfunction in the brains of human heroin abusers. A very recent report by Michelhaugh et al. (2011) identified alterations of long noncoding RNA (lncRNA)s (such as MIAT, MEG3, NEAT1, and NEAT2) in heroin abusers compared to control subjects.

4.2 Animal Studies

4.2.1 Psychostimulants

Changes in Neurotransmission

Amphetamines produce long-term decreases in markers of biogenic amine neurotransmission (mainly dopamine and 5-HT), and these neurotoxic effects include the decrease in monoamine levels and their major metabolites, reduced level of monoamine transporter binding sites, diminished expression and/or activity of enzymes involved in the metabolism, and synthesis of brain monoamine neurotransmitters – evident in rodents and nonhuman primates

(Yamamoto et al. 2010; Carvalho et al. 2012). Thus, dopamine brain system impairments relate to decreased level of the neurotransmitter (Wagner et al. 1980; Quinton and Yamamoto 2006), the dopamine metabolite, homovanillic acid HVA (Preston et al. 1985), reduced TH activity (Ellison et al. 1978; Hotchkiss and Gibb 1980), and a lower density of the dopamine transporter (Wagner et al. 1980; Krasnova et al. 2001) following high (usually 5–15 mg/kg in rats) doses and/or longitude methamphetamine/amphetamine administration in rodents (Morgan and Gibb 1980; Ricaurte et al. 1982; Gouzoulis-Mayfrank and Daumann 2009) or nonhuman primates (Preston et al. 1985; Woolverton et al. 1989). In a model of a prevalent human methamphetamine exposure, produced by daily multiple doses in monkeys (escalation dosing of methamphetamine over 33 weeks, with final dosages resulting in estimated peak plasma methamphetamine concentrations of 1–3 μM), postmortem analysis of brains showed persistent reductions in striatal dopamine levels and dopamine transporter binding associated with neurotoxicity in presynaptic dopamine system integrity (Melega et al. 2008). Similar long-term reductions in brain dopamine axonal markers were observed in baboons treated with methamphetamine (0.5–2 mg/kg, *i.m.*, 4 times at 2 h intervals) (Villemagne et al. 1998).

On the other hand, the long-term (1.5 years) exposure to self-administered cocaine in monkeys evokes significant increases in dopamine transporter binding sites at the caudal level of the subcortical areas (the ventral caudate, ventral putamen, and nucleus accumbens) (Letchworth et al. 2001). The latter finding – showing similarity to studies in human cocaine addicts – suggests importance of this biomarker to the neurobiological effects of cocaine. Other studies on monkey i.v. self-administered cocaine for 18–22 months showed lowered dopamine D_2 binding site density in the striatum (Moore et al. 1998); these data parallel studies on rodents and humans (see above).

The neurotoxic effects of amphetamines also apply to 5-HT-ergic nerves in the brain. Methamphetamine, although more toxic to DA neurons, leads also to 5-HT system impairments including (1) depletion of 5-HT and its metabolite 5-HIAA levels, (2) diminished tryptophan hydroxylase activity in the striatum and hippocampus, and (3) lower 5-HT transporter densities in rat frontal cortex, amygdala, and striatum (Hotchkiss and Gibb 1980; Ricaurte et al. 1980; Gouzoulis-Mayfrank and Daumann 2009). Another amphetamine derivate, MDMA, causes mainly 5-HT system impairments in rats or nonhuman primates (Quinton and Yamamoto 2006; Gouzoulis-Mayfrank and Daumann 2009; Carvalho et al. 2012) with reduction of 5-HT and 5-HIAA levels, decreased activity of tryptophan hydroxylase, and a diminished density of 5-HT transporter in rat cortical and subcortical brain areas (Battaglia et al. 1987; Itzhak and Achat-Mendes 2004; Cadet et al. 2007; Carvalho et al. 2012). Nevertheless, in mice, MDMA causes primarily dopaminergic neurotoxicity (Green et al. 2003), which demonstrates that not every species has the same sensitivity to amphetamines' actions. According to many studies, nonhuman primates seem to be more sensitive to the neurotoxic effects of MDMA than rodents, resulting in higher rates of 5-HT depletion with smaller doses of MDMA, and persisting hypoinnervation patterns in most neocortical

regions and the hippocampus examined even 7 years posttreatment (Ricaurte et al. 1992; Gouzoulis-Mayfrank and Daumann 2009). In fact, 18 months of MDMA self-administration in primates produced 40–50 % depletion in 5-HT levels in the frontal, parietal, and temporal cortex, while lesser evoked downward trends in 5-HT depletions (approximately 25 %) were apparent in the occipital cortex, thalamus, and hypothalamus (Fantegrossi et al. 2004).

Methamphetamine was found to increase extracellular glutamate level followed by *N*-methyl-D-aspartic acid (NMDA) receptor activation and subsequent increase in intracellular Ca^{2+} concentration (Cunha-Oliveira et al. 2008). As described earlier, a rise in the Ca^{2+} concentration leads to the massive production of nitric oxide that in reaction with O_2 forms $ONOO^-$ (Capela et al. 2009); both NO and $ONOO^-$ lead to nitration of proteins including biosynthetic enzymes of dopamine and 5-HT (Kuhn and Arthur 1997; Kuhn et al. 1999; Carvalho et al. 2012). As hypothesized by Yamamoto et al. (2010), the oxidation and nitration of proteins associated with dopamine and 5-HT terminals appear to be the main mechanisms by which the amphetamine-evoked neurotoxicity arises.

Several studies have addressed the influence of hyperthermia following administration of amphetamines on neurotoxicity in animals. As found, methamphetamine-induced hyperthermia may be a factor increasing the drug-induced neurotoxicity, but it is not a necessary and sufficient condition in neurotoxicity induced by methamphetamine (Kita et al. 2003). Furthermore, hyperthermia might interact with other known mediators of methamphetamine neurotoxicity, such as increased glutamate neurotransmission, to enhance toxicity (see above).

Metabolic Changes

Some changes have been found in brain energy metabolism in rodents after amphetamine treatment. For example, subchronic amphetamine treatment (12–15 mg/kg/day for 7 days followed by 7-daily injections with 6–7 mg/kg/day) in rats caused enhanced local cerebral glucose utilization in the nucleus accumbens (Orzi et al. 1983). Increases in glucose metabolism were reported also after acute amphetamine administration (1–5 mg/kg) in extrapyramidal motor systems in rats (Wechsler et al. 1979; Porrino et al. 1984). Conversely, methamphetamine administration (4 × 12.5 mg/kg, every 2 h) decreased local cerebral glucose utilization in the extrapyramidal system, also in the hippocampus and dorsal raphe nucleus in rats (Huang et al. 1999). These findings clearly demonstrate that amphetamines lead to regional, drug-dependent, and regimen-dependent alterations in brain metabolism.

Morphological Changes

There are several proofs that chronic treatment with psychostimulant drugs of abuse results in neuronal degeneration. Thus, in rats treated continuously with amphetamine (e.g., pellets implanted *s.c.* releasing amphetamine for 10 days) or methamphetamine (e.g., 10 mg/kg × 4 times with 2 h intervals or 15 mg/kg *s.c.* every 6 h for 24 h), anatomical alterations in the form of swollen, dystrophic, or fragmented dopamine axons in the striatum have been found (Ellison et al. 1978; Hanspeter 1981; Ricaurte et al. 1982; Broening et al. 1997). Degenerations of presynaptic

5-HT axon terminals induced by high and/or repeated doses of methamphetamine (Axt and Molliver 1991; Cadet et al. 2003; McCann and Ricaurte 2004) were found throughout the forebrain of rats (O'Hearn et al. 1988), while in squirrel monkeys a reduction in 5-HT innervation was seen 7 years after exposure to the drug (Hatzidimitriou et al. 1999).

Glia and Microglia Activation

As a consequence of amphetamine intake, damage of striatal axonal terminals was accompanied by reactive astrocytosis (Bowyer et al. 1994) and microglial activation (Pubill et al. 2002) via an increase in the expression of proinflammatory molecules (e.g., proinflammatory cytokines, interleukins). Interestingly, even an acute exposure to methamphetamine increased mRNA levels of IL-6, IL-1α, and tumor necrosis factor (TNF)-α in mouse striatum (Sriram et al. 2006; Gonçalves et al. 2008). Neurotoxic methamphetamine exposure (4 times × 10 mg/kg, every 2 h, or 24 times × 1.67 mg/kg once every 15 min) resulted in an increase in glial fibrillary acidic protein level 3 days posttreatment (Herring et al. 2008). Methamphetamine alone or its metabolites might activate glial cells by virtue of elevated cellular dopamine auto-oxidation, resulting in profound formation of dopamine o-quinones, strong microglial activators (Kuhn et al. 2006; Yamamoto et al. 2010; Carvalho et al. 2012).

The ability of MDMA to induce microglial activation is more ambiguous. Thus, microgliosis induced by MDMA administration was found in the male (but not female) mouse striatum and was absent in the rat cortex or striatum. MDMA injections increased also production of the proinflammatory cytokine IL-1β in rat frontal cortex (Orio et al. 2004), while the *i.c.v.* administration of IL-1β intensified MDMA-induced 5-HT toxicity in the cortex. On the other hand, MDMA has been shown to have an immunosuppressive power that involves an increase in IL-10 production, an anti-inflammatory cytokine (Yamamoto et al. 2010).

Manifestations of Oxidative Stress

There is reliable evidence of oxidative damage in animal brain after repeated exposure to amphetamines (see Table 1). Thus, amphetamine, methamphetamine, or MDMA do increase lipid peroxidation (Jayanthi et al. 1998; Gluck et al. 2001; Alves et al. 2007; Miranda et al. 2007) and induce various changes in the levels of GSH (Harold et al. 2000; Carvalho et al. 2001; Frenzilli et al. 2007; Miranda et al. 2007) or activity of several antioxidant enzymes (Jayanthi et al. 1998; Frey et al. 2006; Frenzilli et al. 2007; Miranda et al. 2007), providing evidences for the importance of RS in amphetamine-induced toxicity.

Interestingly, the bidirectional changes in brain SOD activity were demonstrated after amphetamine or its derivatives. For example, subchronic amphetamine administration caused a rise in the SOD activity in rat hippocampus (Frey et al. 2006), while MDMA led to the drop in SOD activity in mouse hippocampus (Frenzilli et al. 2007). The stronger oxidative potential following MDMA derives from its highly reactive quinone intermediate metabolites (cf. Capela et al. 2007). Production of RS appears to be linked in large part with amphetamine-induced thermal instability

Table 1 Preclinical evidence of oxidative stress after amphetamines exposure

Model treatment	Animal	Dose and treatment regimen	Biomarker	Change (brain structure)	Reference
D-Amph, chronic passive administration	Rat	1 mg/kg, 2 mg/kg or 4 mg/kg (*i.p.*) for 7 days	SOD	↑(HIP), ↓(STR) for 1 mg/kg	Frey et al. (2006)

(Krasnova et al. 2001) in animals and in humans, as hyperthermia – particularly if ambient temperature is high – promotes greater RS formation and associated neurotoxicity (Green et al. 2003; Quinton and Yamamoto 2006; Parrott 2012).

Cocaine likewise was found to promote oxidative stress in the brain of experimental animals (see Table 2), and it was recorded as a significant elevation in SOD, glutathione peroxidase (GPx), and CAT activity in the rat cortex and striatum (Dietrich et al. 2005; Macedo et al. 2005, 2010); however, changes in brain CAT were not validated in other studies (Macedo et al. 2005; Muriach et al. 2010). In the hippocampus GSH concentration and GPx activity were reduced in repeatedly cocaine-treated rats; such changes were not evident in the frontal cortex (Muriach et al. 2010). Cocaine intoxication led also to an increase in lipid peroxidation in several brain structures linked to dopamine synthesis and release

(Dietrich et al. 2005; Bashkatova et al. 2006). A very recent report indicates that voluntary cocaine intake (by *i.v.* drug self-administration) evokes a significant reduction in MDA level together with increases in SOD activity in the hippocampus and frontal cortex, while an enhancement in the SOD activity was not seen in yoked cocaine animals (Pomierny-Chamiolo et al. 2012). As suggested, enhanced RS production and oxidative cell status may occur via cocaine or its oxidized metabolites (e.g., norcocaine derivatives; Kovacic 2005).

As stated above, psychostimulants prompt an increase in RS level via enhanced synaptic dopamine concentration or by its oxidation by nonenzymatic or enzymatic pathways (see above). In the mechanisms of drug dependence and neurotoxicity, glutamatergic neurotransmission is strongly involved. In cocaine addiction an increased level of extracellular glutamate concentration in dopamine-innervated areas (Cunha-Oliveira et al. 2008) could be associated with excitotoxic processes through increased activation of NMDA receptors and subsequent increase in intracellular Ca^{2+} level (Rego and Oliveira 2003), leading to the formation of mitochondrial RS and lipid peroxidation (Maciel et al. 2001).

Antioxidant status after chronic exposure may be different than effects of acute exposure due to maladaptations seen in neurotransmitter levels and in antioxidant defense mechanisms that maintain cellular homeostasis (see Table 1 for specific changes in a brain region, drug type, and dosage regimen).

Manifestation of Apoptosis

Several preclinical studies have reported apoptotic features after chronic or even acute exposure to psychostimulants, especially amphetamine derivatives (Cunha-Oliveira et al. 2008). For example, repeated amphetamine administration in mice (4 × 10 mg/kg, every 2 h) caused an increase in p53 protein levels in medium spiny striatal projection neurons with a secondary increase in Bax (proapoptotic gen) and decrease in Bcl-2 (anti-death gene) levels in mouse striatum (Krasnova et al. 2005). Neurotoxicity due to activation of apoptotic pathways has been shown with acute drug treatments. Thus, acute methamphetamine (40 mg/kg, *i.p.*) resulted in an activation proapoptotic Bcl-2 family genes (Bax, Bad and Bid) in mice that was accompanied by a decrease in anti-death genes Bcl-2 and Bcl-X in the frontal cortex (Jayanthi et al. 2001). The same methamphetamine treatment resulted in the release of AIF and smac/DIABLO from the mitochondria in mouse striatum (Jayanthi et al. 2004), followed by activation of the caspase cascade (caspase 9 and 3) (Deng et al. 2002; Jayanthi et al. 2004). Similarly to methamphetamine, acute MDMA exposure caused upregulation of Bax and downregulation of Bcl-2 in the rat hippocampus and cerebellum and respective changes in genes relating to those proteins (Soleimani Asl et al. 2011, 2012). The latter findings suggest that MDMA neurotoxicity can be linked to stimulation of the intrinsic apoptosis pathway. Of note, apoptotic biomarkers were evident also in rat cortical neurons following MDMA (Capela et al. 2006).

In addition to the above mitochondrial apoptosis pathway, acute high-dose (40 mg/kg, *i.p.*) methamphetamine was found to activate cell death via

dysregulation of calcium homeostasis in mice (Jayanthi et al. 2004), initiating calcium-dependent apoptosis via the permeabilization of the outer mitochondrial membrane (Kroemer et al. 2007). Furthermore, acute methamphetamine injection with 20–40 mg/kg to rodents caused activation of calpain – a calcium responsive cytosolic cysteine protease (Jayanthi et al. 2004; Samantaray et al. 2006). In line with the latter observations, proteolysis of the cytoskeletal scaffolding protein spectrin, consequent to calpain activation, has been shown in many studies in rat brain limbic and subcortical structures following methamphetamine exposure (Warren et al. 2005; Staszewski and Yamamoto 2006). Finally, toxic doses of acute methamphetamine (40 mg/kg, *i.p.*) have been shown, in rat striatum, to induce the transcription factors AP-1, Egr, and Nur77 (Jayanthi et al. 2005), which regulate Fas ligand (FasL) expression (Droin et al. 2003; Tóth et al. 2001). Altogether, the literature findings indicate several factors in the amphetamine-related cell death in rodent brain, including activation of either the mitochondria-dependent apoptotic pathway or activation of calpain, or Fas death pathway, or p53 death pathway.

On the other hand, morphological changes of apoptosis induced by cocaine have not been evident (Cunha-Oliveira et al. 2008). As recently reported, chronic cocaine, including its 3-day withdrawal, altered neither Fas–FADD receptor complex, cytochrome c, caspase 3, AIF, and PARP-1 cleavage nor associated signaling in the cerebral cortex. However, some discrete changes (a 28 % decrease in the content of antiapoptotic truncated isoform of dopamine- and cAMP-regulated phosphoprotein of 32 kDa) in rat brain cortex appeared (Alvaro-Bartolomé et al. 2011).

Manifestations of Genomic and Epigenomic Actions

The regulation of changes in gene expression evoked by psychostimulant drugs of abuse is an area of intensive research (Cadet and Krasnova 2009; Piechota et al. 2012). Altered gene expression [e.g., brain-derived neurotrophic factor (BDNF), G-protein signaling 3] in drug addiction is reported in the prefrontal cortex, ventral tegmental area, and striatum (including the nucleus accumbens) (Wong et al. 2011). Another long-term molecular effect relates to upregulation of the cAMP pathway in the nucleus accumbens and dorsal striatum – partially mediated by CREB. Dopamine D_1 receptor stimulation during chronic cocaine administration induces activation of transcription factor CREB, which has many gene targets including BDNF, c-Fos, adenylyl cyclase, corticotropin-releasing factor, dynorphin, and enkephalins (Cunha-Oliveira et al. 2008). A recent study in mice, using whole-genome microarray profiling to evaluate the detailed time course of transcriptional alterations, identified 27 genes (i.e., circadian genes Per1, Per2, and Nr1d1; the glucocorticoid-dependent genes Fkbp5, Sult1a1, and Plin4; the drug-regulated group of transcripts enriched in the nucleus accumbens Pdyn, Cartpt, and Rgs2; as well as new genes Fam40b and Inmt) under regulation by chronic methamphetamine administration (Piechota et al. 2012). As suggested, the above transient gene expression alterations during drug treatment – seen also in the early period of withdrawal – may be contributors to persistent neuroplastic alterations responsible for the development of drug addiction.

A number of findings suggest that epigenetic changes may mediate neuroplasticity in psychostimulant addiction (Kumar et al. 2005; Levine et al. 2005; Romieu et al. 2008; Im et al. 2010; Maze et al. 2010). A recent study has demonstrated that amphetamine induced phosphorylation of methyl CpG binging protein (MeCP2) at Ser421 in mouse accumbal areas, leading to increases in protein activity and enhanced repressive function (Deng et al. 2010). Findings by Renthal and Nestler 2008 show that acute exposure to amphetamine results in ΔFosB binding to the *c-fos* promoter and in repression of its expression through recruitment of HDAC1 and histone methyltransferase (HMT) around the promoter site, leading to downregulation of the gene expression. The same authors showed that chronic amphetamine abuse increases histone H3K9me2 on the *c-fos* promoter, further substantiating its transcriptional silencing (Renthal and Nestler 2008). As suggested, interaction between ΔFosB and *c-fos* may serve as a homeostatic mechanism for the regulation of sensitivity to repeated drug treatment. Other studies indicated global increase in histone H4 acetylation and specific *fosB* promoter-associated H4 hyperacetylation in mouse striatum after repeated amphetamine treatment (Shen et al. 2008). Moreover, co-treatment of amphetamine and HDAC inhibitors (butyric acid and valproic acid) had additive effects on the increase in histone H4 acetylation (Shen et al. 2008; Adachi and Monteggia 2009). The latter study seems to support the notion that amphetamine functions as an HDAC inhibitor, suggesting that HDACs could be used therapeutically for the modulation of psychostimulant action. Acute amphetamine administration provokes an increase in the number of neurons positive for phosphorylation of histone H3 in serine 10 (pH3S10) in a few telencephalic and diencephalic rat brain regions (Rottlant and Armario 2012).

Acute methamphetamine exposure decreased DNMT1 and DNMT2 in the rat hippocampus (Numachi et al. 2004), while bidirectional changes for DNMT1 were observed in the nucleus accumbens in two rat strains (Numachi et al. 2007) following subchronic methamphetamine exposure. The fact that Lewis rats are more susceptible than Fisher rats to methamphetamine sensitization may be reflective of different DNA methylation patterns (Numachi et al. 2007; Kovatsi et al. 2011). Interestingly, a single methamphetamine injection (20 mg/kg) induced time-dependent modifications in the acetylation of histone H3 and H4 as well as increases in AFT2 (enzymes that have HAT activity for histone H4) and HDAC2 expression in rat nucleus accumbens (Martin et al. 2012). Martin and coworkers demonstrated methamphetamine-induced increases of histone H4K5 and H4K8 acetylation as well as decreases in the acetylation of histone H3K9, H3K16, and H3K18. These results suggest that the psychostimulant effect mediated by increased AFT2 and HDAC2 expression may relate to effects on histone acetylation and hypoacetylation. The most recent study has indicated that repeated methamphetamine injections significantly decreased acetylation of histone H4 at lysine 5 (H4K5), lysine 12 (H4K12), and lysine 16 (H4K16) in rat dorsal striatum, at *GluA1* and *GluA2* DNA sequences encoded α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor subunits (Cadet and Jayanthi 2013). Because these changes were seen with the enrichment of methyl CpG binding

protein 2 (MeCP2) at the promoters of both *GluA1* and *GluA2*, the results indicate that methamphetamine induced downregulation of *GluA1* and *GluA2* mRNA levels and did affect glutamatergic function.

Some limited data indicate amphetamines affect expression patterns of microRNAs (miRNA)s. Thus, Lippi and colleagues (2011) have shown that chronic treatment with amphetamine increases the level of *miR-29a/b* in mouse hippocampus. The *miR-29a/b* family directly targets the transcript of *Arpc3*, a subunit of the ARP2/3 actin nucleation complex involved in dendritic spine morphogenesis (Lippi et al. 2011). Current bioinformatic analysis has revealed that amphetamine increases levels of *miR-181a* in a mouse model of chronic drug treatment (Saba et al. 2012), linking epigenetic modification with synaptic plasticity. In fact, *miR-181a* is a negative posttranscriptional regulator of GluA2 expression, and thus it would be an essential regulator of mammalian AMPA-type glutamate receptors, a key determinant of synaptic plasticity.

There are some links between DNA methylation and cocaine addiction. First, cocaine self-administration increased MeCP2 expression in rat ventral and dorsal striatum (Cassel et al. 2006), while lentiviral knockdown of MeCP2 in dorsal striatum decreased drug intake under extended drug conditions (Im et al. 2010). Repeated cocaine administration altered DNMT3a, an enzyme linked to CpG methylation, expression in the mouse nucleus accumbens, with decreases seen during very early phases of withdrawal and sustained increases seen at later time points (LaPlant et al. 2010). Of note, prenatal cocaine exposure alters DNA methylation and gene expression in hippocampal neurons of neonatal and adolescent mice (Novikova et al. 2008).

A few reports point also to interaction between histone acetylation and cocaine. Thus, acute or chronic exposure to this psychostimulant increased cellular levels of H3 and H4 acetylation in the nucleus accumbens (Kumar et al. 2005; McQuown and Wood 2010), while repeated passive cocaine treatment downregulated dimethylation of histone 3 lysine 9 (H3K9me2), a marker of heterochromatin in the same brain area (Maze et al. 2010); this later effect paralleled a decrease in the total amount of heterochromatin and an increase in the volume of these nuclei. Increased H3 acetylation was also observed during cocaine self-administration and conditional place preference, while pharmacological inhibition of sirtuins (their induction is associated with H3 acetylation) reduced cocaine rewarding effects seen in conditioned place preference and self-administration (Renthal et al. 2009).

Findings from the past 3 years indicate that chronic cocaine regulates numerous miRNAs in mouse striatum (Schaefer et al. 2010; Eipper-Mains et al. 2011) as well miRNA-linked proteins that are strongly linked to drug addiction (Li and van der Vaart 2011). For example, cocaine self-administration in rats increased *miR-212* expression in the striatum that was suggested to be – at least partially – responsible for cocaine overconsumption through CREB, MeCP2, and BDNF signaling (Im et al. 2010). Another report identified induction of *miR-212* and *miR-132* in the dorsal striatum after 7 days of cocaine self-administration in rats (Hollander et al. 2010). On the other hand, chronic passive cocaine administration decreased *miR-124*

and increased *miR-181a* in rat brain (Chandrasekar and Dreyer 2009). *miR-124* overexpression in the nucleus accumbens reduced cocaine place conditioning, whereas overexpression of *miR-181a* had the opposite effect (Chandrasekar and Dreyer 2011). Recently, it was found that cocaine mediates the changes of miR-8 family expression in brain and basing on the biostatistical analyses, a suggestion of novel mechanisms for drug-induced alterations in the neuronal cytoskeletal and synaptic structure has been raised (Eipper-Mains et al. 2011). Interestingly, Schaefer et al. (2010) identified an overlapping subset of cocaine-induced miRNAs (*miR-324* and *miR-369*) in dopamine D_2 receptor-expressing neurons of the nucleus accumbens together with reduction in cocaine self-administration.

4.2.2 Opiates

Metabolic Changes

An early report on a single dose of morphine (20 mg/kg) demonstrated increases in glucose concentration (42 %) in rat brain (Miller et al. 1972). The same enhancement in local cerebral metabolic rate for glucose was shown for morphine repeated treatment in 95 brain regions of rats; the most significant changes were seen in the nucleus accumbens and prefrontal cortex (Kraus et al. 1997).

Morphological Changes

Chronic treatment of morphine (from 20 mg/kg to 140 mg/kg twice a day over 14 days at escalating doses) in rats, followed by drug withdrawal, resulted in a dramatic reduction of spine density in second-order dendritic trunks in the accumbens shell (Spiga et al. 2005). Chu et al. (2008) using the same treatment protocol with morphine showed that rough endoplasmic reticulum swelled, membrane configuration of the nucleus and mitochondria were blurred, and structure of myelin sheath changed in the rat ventral tegmental area. These findings support the linkage between opioid-induced abuse and structural functional plasticity of dendritic spines in the brain.

Glia and Microglia Activation

Opioid-induced proinflammatory glial activation (increases in microglial and astrocytic activation markers and release of proinflammatory cytokinesis) was suggested to be involved in the development of opioid dependence and reward (Watkins et al. 2005; Hutchinson et al. 2007). Recently, the glial markers have been implicated also in drug-induced craving. Thus, Lin et al. (2011) showed that repeated exposures to morphine decreased glial fibrillary acidic protein in rat amygdala tissue in the stage of extinction. Another report indicates that heroin self-administration and withdrawal regulate in a time-dependent manner tegmental and accumbal glial cell line-derived neurotrophic factor mRNA expression (Airavaara et al. 2011).

Manifestation of Oxidative Stress

There is evidence that repeated opioid treatments induce oxidative stress in the brain (see Table 3). Heroin injected continuously in increasing dosage

Table 3 Preclinical evidence of oxidative stress after opioid exposure

Model treatment	Animal	Dose and treatment regimen	Biomarker	Change (brain structure)	Reference
Morphine, chronic passive administration	Mouse	5 mg/kg (*s.c.*) for 7 days	GSH	↓Brain homogenate	Abdel-Zaher et al. (2010)
			GPx	↓Brain homogenate	
			MDA	↑Brain homogenate	
Tramadol, chronic passive administration	Mouse	50 mg/kg (*s.c.*) for 7 and 15 days	GSH	↓Brain homogenate	Abdel-Zaher et al. (2011)
			GSH-Px	↓Brain homogenate	
			MDA	↑Brain homogenate	

Abbreviations: ↑ increase, ↓ decrease, *GPx* glutathione peroxidase, *GSH* gluthatione, *MDA* malondialdehyde

(1–35 mg/kg) to mice caused increasingly greater numbers of DNA-damaged cells, protein carbonyl groups, and MDA levels (Qiusheng et al. 2005). Prooxidant status was also marked by decreased activity of antioxidant enzymes (SOD, CAT, GSH) (Qiusheng et al. 2005). It should be stressed that even a single morphine dose can produce oxidative damage in the brain (e.g., decreased GSH levels); however, its manifestation depends on the dose of morphine and age of the animal. Another opioid, tramadol at a 50 mg/kg (*i.p.*) dose, decreased nonenzymatic antioxidants such as intracellular GSH and enzymatic antioxidants such as GPx in mouse brain; repeated tramadol treatments resulted in an increase in the MDA level in the brain (Abdel-Zaher et al. 2011).

Manifestation of Apoptosis

Several studies performed on rodents have shown that sustained exposure to opioids produced cell death in many areas of the brain (Mao et al. 2002; Emeterio et al. 2006), together with increases in the brain expression of proapoptotic factors belonging to both the mitochondrial and the Fas-receptor apoptotic pathways (Boronat et al. 2001; Mao et al. 2002; Emeterio et al. 2006; Tramullas et al. 2007). For example, prolonged (34 days) heroin (5 mg/kg, *s.c.*) administration to mice evoked upregulation of proapoptotic proteins such as Fas, FasL, and Bad, in the cortex and hippocampus, indicating the activation of both the death receptor and the mitochondrial apoptotic pathways. In parallel, the presence of TUNEL (terminal deoxyribonucleotidyl transferase-mediated dUTP nick and labeling method)-positive cells scattered throughout the brain evidenced another indicator of apoptosis linked to DNA fragmentation (Tramullas et al. 2008). The signs of apoptosis were reported even after a single injection of heroin (5 mg/kg), which increased the expression level of Bad in the cortex and FasL in the hippocampus.

These biochemical indices in heroin-treated mice were accompanied by impaired cognitive ability in the Morris water maze and cognitive flexibility-related performance, raising the possibility that chronic exposure to opioid drugs in the brain would interfere with learning and memory through a neurotoxic effect related to activation of apoptotic pathways. Interestingly, heroin-induced apoptosis (caspase 2 and 9 activation) in neuronal-like PC12 cells was associated by increased mitochondrial membrane permeability and decreased mitochondrial potential (Oliveira et al. 2002, 2003).

Similarly to heroin, other opioid drugs can lead to apoptosis in neuronal cells. Thus, tramadol and morphine given to rats in progressive doses of (20, 40, and 80 mg/kg/day of tramadol; 4, 8, and 12 mg/kg/day of morphine) significantly enhanced the presence of red neurons (a histologic marker of apoptosis) as compared with control group (Atici et al. 2004). Chronic morphine or tramadol use in increasing doses caused red neuron degeneration in the rat brain, which probably contributes to cerebral dysfunction. Interestingly, the numbers of red neurons were significantly higher in the temporal and occipital regions in the tramadol group as compared with the morphine group, and these findings are of importance when prolonged opioid treatment is necessary (Atici et al. 2004).

Manifestation of Genetic and Epigenetic Actions

Genetic and epigenetic changes are another area of molecular interactions that could explain the mechanism of opioid neurotoxicity, addiction, and abstinence syndrome. In numerous studies altered adenyl cyclase activity and enhanced intracellular levels of cAMP have been observed during manifestations of opioid withdrawal syndromes (Sharma et al. 1977; Law et al. 1982; Koob and Bloom 1988; Piñeyro and Archer-Lahlou 2007). Recently reported by Piechota et al. (2012), chronic treatment with heroin regulates several genes in mouse striatum, with the most substantial impact for circadian genes (Per1, Per2, and Nr1d1) and glucocorticoid-dependent genes (Fkbp5, Sult1a1, and Plin4), a drug-regulated group of transcripts (Pdyn, Cartpt, and Rgs2, as well as Fam40b and Inmt). The appearance of opioid receptor downregulation and their desensitization were suggested to be the result of histone-deacetylase-mediated epigenetic control of genes (Hu et al. 2001; Hwang et al. 2007). Another paper by Zhou et al. (2006) revealed that morphine-withdrawal-related stress condition increased *oprm1* expression in the rat hypothalamus and striatum as well as lateral hypothalamic orexin mRNA level; this finding supports the hypothesis that orexin activity plays a role in morphine-withdrawal-related behaviors. There is also a finding showing that morphine decreased acetylation of histones H3 and H4, trimethylation of lysine 4 of H3 (H3K4me3) at the promoters of *KCNAB2* and *KCNF1* genes (both encoded subunits of potassium channel), which in turn decreased their transcription in rat ventral tegmental area (Mazei-Robison et al. 2011). Parallel reduction of trimethylation of H4K4me3 at the promoter of *GIRK3* gene (encoded potassium subunit channel) may suggest that morphine downregulates the K^+ channel via epigenetic changes and enhanced excitability of dopamine cell bodies within the mesencephalon.

There are implications for the significance of noncoding RNA, primarily miRNAs, in opioid-based addictive behaviors. Morphine has been implicated in the regulation of *miR-23b* and *let-7* expression that regulates posttranscriptional levels of mu opioid receptor (Wu et al. 2009; He et al. 2010). In the rat hippocampus, morphine activates ERK1/2 and decreases the expression level of *miR-190* (Zheng et al. 2010), which regulates the expression of neurogenic differentiation 1, thereby affecting the morphology of dendrites and adult neurogenesis. In addition, *miR-190* interacts with *pax6* gene-encoded transcription factor regulating neurogenesis (Zheng et al. 2012).

5 Conclusion

Psychostimulants and opioids evoke toxicity within the CNS, which in human research is detected after a particular cumulative drug exposure, while in preclinical studies neurotoxicities are recorded even after acute drug administration. Mechanisms leading to neurotoxicity linked to psychostimulants and opioids are due primarily to the action of the substance (e.g., enhancement of synaptic concentrations of dopamine) or by indirect effects (increases in extrasynaptic glutamate levels, toxic metabolites). Associated with the development of drug addiction, these mechanisms lead to the several pathological processes within the complex network of brain cell-to-cell interactions, such as alteration in neurotransmitter systems, dysregulation of energy metabolism, changes in structure of cellular membrane, apoptosis, generation of RS, glial/microglial cell overactivation, excitotoxicity and prominent deficits in brain morphology (neuronal loss, axonal damage), alterations of transcription factors, immediate early genes and epigenetic mechanisms, as well as neurocognitive and neuropsychological impairments (e.g., risk of Parkinson's disease). The extent of neurotoxic variations depends on drug type, drug dosage (chronic vs acute treatment), species (human vs nonhuman primates or rodents), external factors (environmental temperature), and brain region.

Molecular Mechanism and Effects of Clostridial Neurotoxins

Bal Ram Singh, Raj Kumar, and Shuowei Cai

Contents

Abstract

The genus Clostridia, gram-positive anaerobic bacteria, produce two of the deadliest toxins known to mankind: tetanus and botulinum. Toxicity of these molecules comes from their action on very specific substrates, SNARE proteins, in the neuronal cells. They cleave SNAREs, which are the crucial components of neuroexocytosis, causing inhibition of release of neurotransmitters at the synapses. Botulinum neurotoxin molecule has evolved itself to have high stability, specificity, and selectivity. It maneuvers and exploits itself in each step of intoxication and preserves its active structure to achieve an exquisite toxicity. The mechanisms of action and biological functions of clostridial neurotoxins

still have several unresolved questions. Several unique characteristics of these neurotoxins attract scientists to understand the mysteries of neurotoxin molecules. Despite high toxicity, botulinum neurotoxin has a wide range of medicinal applications. In the last few decades, toxin transformed itself from life-threatening disease to a wonder drug. Therapeutic use of botulinum neurotoxin is based on three unique features: specificity, potency, and duration of action. Active research is underway to transform botulinum neurotoxins into the most versatile and useful drugs for neuromuscular disorders, and as cosmeceuticals. This chapter summarizes current knowledge on its structure and mechanism of intoxication. It also describes basic understanding of the evolution of this molecule to achieve this extremely high biological activity in terms of toxicity or therapeutics. Understanding the true nature and function of its dynamic structure still remains a work in progress.

1 Toxins

In general toxins can be small molecules, peptides, or proteins. These molecules are toxic because they are capable to evade protection mechanisms of the infected host cells and affect important cellular processes such as protein synthesis, inhibition of other cellular processes, and promotion of hemolysis. Toxins can be generally grouped according to their source (e.g., bacterial toxins), their purpose (e.g., phototoxins), and their site of action or affected organs (e.g., hepatotoxins, neurotoxins). Among these the most complex and deadly toxins are the bacterial toxins. Pathogenic bacteria use many ways to interact with target tissues or cells. Toxins produced by bacteria can act locally or at a distant location from the sites of infection, leading to various diseases in human and animals. Bacterial toxins are classified as two types: exotoxins, which are secreted by the bacteria in the environment, and endotoxins, which may be released after the lysis of bacterial cell wall. Clostridial neurotoxins produced by anaerobic *Clostridium botulinum* and *Clostridium tetani* are exotoxins, which can be produced in infected tissues, such as wounds or infant guts. These neurotoxins are the most toxic substances currently known to mankind. There are many unique features associated with these neurotoxins and also with the bacteria which produce them, all of which together play a role in the mechanism of pathogenicity, making this class of pathogens highly unique.

2 Clostridium Family

The genus *Clostridium* represents gram-positive, ubiquitous, anaerobic, and endospore-forming bacteria. Clostridium has about 100 species consisting of ubiquitous bacteria and pathogens. Members of this group of bacteria exhibit large straight or slightly curve-shaped bacterial cells. Members of this genus produce some of the

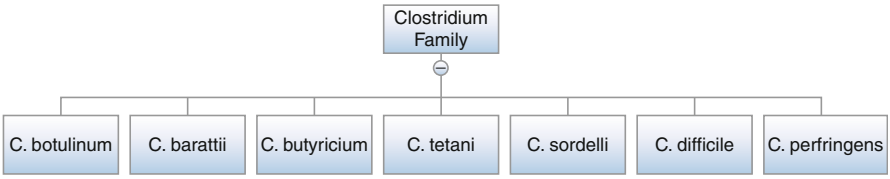

Fig. 1 Members of *Clostridium* family, known for producing toxins

most potent toxins discovered so far. Dormant cells are highly resistant to heat, desiccation, toxic chemicals, and detergents. Spores do not germinate normally unless they have suitable environment to grow. Most of clostridial species are saprophytes, but a few are pathogenic to humans and animals, for example, *C. difficile*, *C. botulinum*, *C. tetani*, and *C. perfringens* (Fig. 1). The pathogens are primarily saprophytes in nature. *C. tetani* and *C. botulinum* produce the most potent biological toxins known to mankind. In their active form they secrete exotoxins which cause various diseases, such as tetanus and botulism.

3 The *Clostridium botulinum*

Clostridium botulinum, which was first isolated from a contaminated ham and from the spleen of a patient by van Ermengem in Belgium in 1895 (Van Ermengem 1979; Foster 1993) grows anaerobically at 37 °C or 30 °C under pH 6.5–7.0 conditions. Most of *C. botulinum* as well as some isolates of *C. butyricum* and *C. baratii* can produce botulinum neurotoxins (BoNTs). The strains of *C. botulinum* are traditionally classified into seven serotypes, A to G, according to the antigenic properties of neurotoxins they produce. Generally, one strain of *C. botulinum* can only produce one type of neurotoxin, but several strains that produce more than one type of neurotoxin have been identified over the years. One type C strain (C6813) was found to produce the mosaic neurotoxin in which one-third of the C-terminal region was similar to that of type D neurotoxin (Moriishi et al. 1996). One type A strain, called type AB now, was shown to produce both type A and type B neurotoxins (Fujinaga et al. 1995). *C. botulinum* type G organism differs phenotypically from other *C. botulinum* types and is now designated as *C. argentinense* (Gimenez and Ciccarelli 1970; Campbell et al. 1993b). *Clostridium butyricum* and *Clostridium baratii* were found producing type E (BoNT/E) and type F (BoNT/F) neurotoxins, respectively (Fuji and Kimura 1993; Thompson et al. 1993).

BoNT is synthesized as a single and relatively inactive polypeptide chain, which undergoes a proteolytic cleavage at its nicking site to form a biologically active dichain structure linked by a disulfide bond. The proteolytic strains of *C. botulinum* produce endogenous proteases and secrete the neurotoxin as an active dichain form by cleaving it with endogenous protease, but non-proteolytic strains of *C. botulinum* require exogenous proteases, such as trypsin in the intestinal tract of hosts, to cleave the progenitor toxin to activate it (Call et al. 1995, Fig. 2).

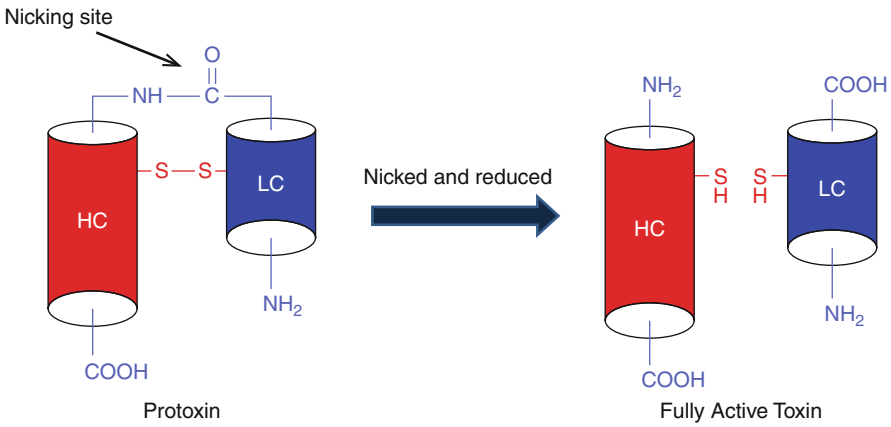

Fig. 2 Botulinum neurotoxin: BoNTs are produced as a single chain (progenitor or protoxin) which is processed exogenously or endogenously as a dichain. Reduction of disulfide bond makes fully active toxin

Strains of *C. botulinum* can also be divided into four phylogenetically and physiologically distinct groups (I to IV) based on biochemical properties and nucleic acid hybridization studies. Group I includes type A, proteolytic strains of types B and F. Group II includes type E, non-proteolytic strains of types B and F. Group III consists of types C and D, and group IV consists of type G (Campbell et al. 1993a). Rainey and Stackebrandt (1993) and Campbell et al. (1993b) used a very high level of 23S rRNA sequence similarity to show that groups I, II, III, and IV *C. botulinum* represent a single genetic unit phylogenetically remote from each other and that the marked genotypic variation within the species does not correlate with the neurotoxins produced. *C. baratii* that produces type F neurotoxin belongs to a new added group, group V, and *Clostridium butyricum* that produces type E neurotoxin belonged to the latest group, group VI (see Table 1; Chang 2011). The same conclusions were also drawn from 16S rRNA sequence similarities (Hutson et al. 1993). However, the genetic relationship inferred from the BoNT sequences differs markedly from above conclusions and it is clearly established now that all three types of BoNT/F (proteolytic, non-proteolytic, and *C. baratii* type F) are genealogically highly related.

The spores of proteolytic *C. botulinum* are heat resistant and do not grow at temperatures below 10 °C, but the spores of non-proteolytic *C. botulinum*, which are less heat resistant, can germinate relatively rapidly at temperatures in the range of 2–10 °C (Lund and Peck 1994). Type A *C. botulinum* has 0.39 h generation time and reaches its exponential growth after 5 h of anaerobic incubation of spores (Call et al. 1995). The bacterial growth curve of type A *C. botulinum* (strain Hall) shows a lag period of 4 h and log phase at 10 h before reaching the stationary phase (Roberts and Hobbs 1968; Billon et al. 1997; Shukla and Singh 1999, 2009; Stringer et al. 2009).

Table 1 Summarized characteristics of six physiologically distinct Clostridia that produce the botulinum neurotoxin (BoNT)[a]

	Group I			Group II			Group III		Group IV	Group V	Group VI
Endogenous Protease Activity	Proteolytic			Non Proteolytic			Non Proteolytic		Proteolytic	Non Proteolytic	Non Proteolytic
Clostridial Neurotoxin Serotype	A	B	F	B	F	E	C	D	G	F	E

	means all strians ; +/– means some strains are positive while others are negative; – means all strains negative.										
	Spore Heat Resistance is determined in phosphate buffer (pH 7.0) without lysozyme										
	Group II could be separated into 2 major groups in the future, one containing E the other containing B & F.										
	The genome of a phage contains BoNT/C gene cluster has been sequenced. It is a linear dsDNA of 186 kb with a low %G+C (26.2%)										
	Type G neurotoxin gene cluster is located at a 123 kB Plasmid.										

* Modified table from Chang (2011) PhD thesis dissertation

The studies with a monoclonal antitoxin conjugated with colloidal gold demonstrated that the type A BoNT is synthesized in the cell cytoplasm at late-exponential phase (17 h) and reaches its maximum concentration at stationary phase (24–25 h). The BoNT is translocated across the cytoplasmic membrane and then exported to the extracellular medium via cell wall exfoliation. The greatest proportion of BoNT is located within the cell wall at 45 h (Call et al. 1995).

The spores of *C. botulinum* are widely distributed in soil, mud, and surface waters over much of the globe, but different types of *C. botulinum* prevail in different geographical locations. In the western United States, Brazil, Argentina, and China, type A spores predominate, while proteolytic type B spores tend to predominate in soils of the eastern United States and non-proteolytic type B in Britain and Europe. Type E is often associated with freshwater and marine sediments, and northern regions such as northern Canada and Japan (McClure et al. 1994). Initially, the strains of *C. botulinum* type A were divided into two groups, infant type A and type A, based on the cases of infant botulism in Japan and the classical food-borne botulism (Sakaguchi et al. 1990). But several studies (Collins et al. 1994; Cordoba and Collins 1995; Aranda et al. 1997) have revealed that the strains of *C. botulinum* type A could be divided into two groups (subtypes), A1 and A2, based on different geographical locations isolated and did not correlate with their origins as the cases of both infant botulism and food-borne botulism. Strains isolated from infant botulism in Japan and several strains isolated from classical food-borne botulism in United Kingdom and in Mauritius fell into group A2, while all strains examined from the USA and two strains from UK, from both infant and food-borne botulism fell, into group A1. Group A1 is typical *C. botulinum* type A containing hemagglutinin genes and shows hemagglutinin activity. Several group A1 strains contain an unexpressed type B neurotoxin gene (Ab type). Group A2 lacks the hemagglutinin gene and possesses no hemagglutinin activity. Along with the increasing number of sequenced type A strains, we can now identify more subtypes based on the criteria of sequence variations between 2.6 % and 32 % at the amino acid level, while compared to up to 70 % between different main serotypes of neurotoxin (Marks 2004; Smith et al. 2005; Arndt et al. 2006). Currently there are five subtypes of type A neurotoxin (termed A1, A2, A3, A4, A5), five type B subtypes, six type E subtypes (Arndt et al. 2006; Chen et al. 2007a; Hill et al. 2007; Smith and Hill 2007; Carter et al. 2009), and seven type F subtypes (Raphael et al. 2010) have been classified (see details in Table 1, Chang 2011). Interestingly all five type A subtypes belong to the same group (group I), while the other subtypes belong to more than one groups. Overall, the subtypes A1 $\sim$ A5, B1 $\sim$ B3, and F1 $\sim$ F5 belong to group I. The subtypes B4 $\sim$ B5, F6, E1 $\sim$ E3, and E6 belong to group II. The subtypes E4 $\sim$ E5 belong to group VI, and only subtype F7 belongs to group V. The existence of these subtypes is a manifestation of host adaption and divergent evolution of neurotoxin gene, and it will be important more and more in the development of neurotoxin antiserum and antidotes.

3.1 Botulism

Historically, botulism – derived from botulinus meaning sausage – was discovered long before the name appeared in the literature. Earliest reference to possible botulism-related disease is found in an edict by Emperor Leo VI of Byzantium (886–911) in which manufacturing of blood sausages was forbidden (Erbguth 2004). However, the first systematic study of "sausage poisoning" was carried out in 1815 by a health officer in the town of Herrenberg of Württemberg (Germany) by the name of J. G. Steinbuch and later independently by Justinus Kerner, another medical officer in the town of Welzheim in Württemberg (Erbguth 2004). Kerner's work was published in journals and monographs in early 1800s. In 1822, Kerner described his observations and experiments with sausage toxin, also referred as fat poison, in a monograph. Kerner wrote "The nerve conduction is brought by the toxin into a condition in which its influence on the chemical process of life is interrupted. The capacity of nerve conduction is interrupted by the toxin in the same way as in an electrical conductor by rust." Interestingly, Kerner had also hypothesized on the idea of sausage toxin being used as a therapeutic agent (Erbguth 1996, 1998).

Botulism is a severe disease characterized by flaccid paralysis and caused by botulism neurotoxins, extremely potent food poisons with a mouse lethal dose of 0.1 ng/kg (Montecucco and Schiavo 1993). Three types of botulism have been observed, so far. Classical food-borne botulism is caused by ingestion of food where the bacteria have produced the neurotoxin. Infant botulism result due to the production of neurotoxin in the intestine after germination and outgrowth of ingested spores. Wound botulism maybe due to the outgrowth of bacteria in the wound or due to unknown origin (Cordoba and Collins 1995; Hatheway and Ferreira 1996). Classical food-borne botulism in humans is caused mainly by *C. botulinum* types A, B, E, and rarely by type F neurotoxins. Classical food-borne botulism in animals is always caused by *C. botulinum* types C1 and D neurotoxins (Fach et al. 1993; Cordoba and Collins 1995). In contrast, the causative agents for infant botulism can be *C. botulinum* types A or B neurotoxins or *Clostridium butyricum* type E and *Clostridium baratii* type F neurotoxins. The wound botulism is rare in humans, and the causative agents are either type A or type B from group I (Hatheway 1993), but is increasingly significantly in recent years among drug users (Merrison et al. 2002). Neurotoxins can also be used in the therapy of a variety of human muscle disorders such as strabismus, hemifacial spasm, and blepherospasm (Schantz and Johnson 1992; Eleopra et al. 2004).

Epidemiologically, different serotypes of BoNT are known to selectively cause the disease in different animals. For example, BoNT/C is mostly associated with avian botulism; BoNT/C and BoNT/D with cattle, sheep, and horse; and BoNT/A, BoNT/B, and BoNT/E are associated with human, cattle, and horse botulism, while BoNT/E is particularly associated with fish botulism (Huss and Eskildsen 1974; Burns and Williams 1975; Ala-Huikku et al. 1977; Fernandez et al. 1989; Baldassi et al. 1991; Haagsma 1991; Jeffrey et al. 1994; Ashie et al. 1996;

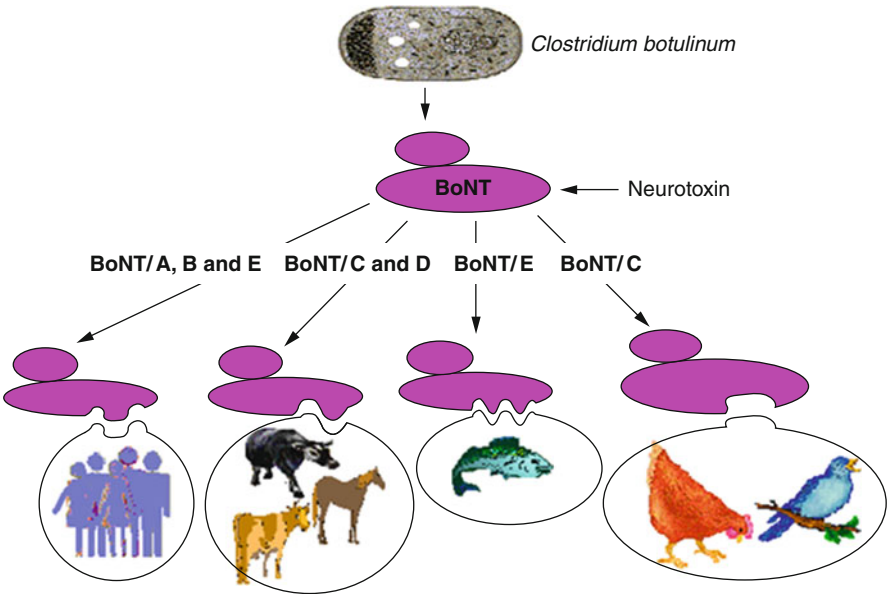

Fig. 3 Schematic representation of different binding topography of various serotypes of BoNT for their interactions with unique protein receptors in different species (Adapted from Singh 1999)

Ortolani et al. 1997). It is believed that botulism by a selective serotype of BoNT in a given animal is in part related to the presence of a high-affinity receptor for that serotype in the host animal system (Fig. 3). The true case number of food-borne botulism is probably underreported in the world. First, botulism is not a reportable disease in all countries (Therre 1999), and secondly the efficiency of investigating potential outbreaks varies from country to country (Peck 2009). It is estimated that the botulism case reporting efficiency in the USA is about 50 % only (Mead et al. 1999).

4 Clostridium Neurotoxins

Clostridial bacteria produce two of the deadliest neurotoxins known: tetanus and botulinum. Tetanus neurotoxin is produced by *C. tetani* and *C. botulinum* produces botulinum toxin. *C. tetani* produces a single toxic species, whereas strains of *Clostridium botulinum* produce at least seven serologically distinct neurotoxins: A–G. BoNTs are food poisons, whereas TeNT is not, and this has been attributed in part to the existence of the complex form of BoNT, consisting of toxin as well as neurotoxin-associated proteins (NAPs). There is no protein associated with tetanus toxin (Singh et al. 1995; Innoue et al. 1996; Minton 1995). NAPs are supposed to protect and enhance the activity of neurotoxin (Sharma and Singh 2004;

Kukreja and Singh 2007). However, Maksymowych et al. (1999) showed that there is no role of NAPs in enhancing the toxin activity. The extreme potency of these toxins lies in their specificity to the neuronal cells.

Clostridial neurotoxins belong to a group of bacterial toxins known as A-B type toxins consisting of at least two separate functional domains: one is responsible for binding and internalization and other is responsible for the intercellular action of the toxins. Both BoNT and TeNT are known to exert neuroparalytic effect in vertebrates (Humeau et al. 2000). Tetanus is structurally similar to BoNT but produces different symptoms upon intoxication. The action site is also different: BoNTs act on peripheral nervous system, while TeNTs act on central nervous system (Caleo and Schiavo 2009). Tetanus toxin induces spastic paralysis, while botulinum toxin induces flaccid paralysis. BoNTs inhibit the release of acetylcholine at the neuromuscular junctions (Simpson 1986, 2004), whereas TeNT inhibits the release of glycine and γ-amino butyric acid in the central nervous system (Schiavo et al. 2000). However, BoNT/A suppresses the release of acetylcholine, glutamate, noradrenaline, glycine, serotonin, GABA, and dopamine (Bozzi et al. 2006; Ashton and Dolly 1988; Verderio et al. 2004, 2007; Sutton et al. 2004; Costantin et al. 2005; Antonucci et al. 2008) in neuronal cells and synaptosomes. The differential site of BoNT and TeNT action may be due to differences in the binding affinity of the BoNT and TeNT for peripheral nerves vs. central nerves and also due to differential retrograde action of the toxins once internalized into nerve cells (Schiavo et al. 1993b, 1994b, 2000; Wang et al. 2012).

Clostridial neurotoxins are Zn-metalloprotease having very high specificity for its substrate: SNARE proteins involved in neurotransmitter release in the neuronal cells. The toxins selectively cleave the SNARE proteins; syntaxin, synaptobrevin (also known as vesicle-associated membrane protein or VAMP) and SNAP-25, but the final results are same – the hydrolysis of the target protein, blockage of neurotransmitter release, and a resultant paralysis. While BoNTs remain in the nerve terminal, the tetanus toxin is transported retrograde axonal transport into the cell body. Tetanus and botulinum toxins affect both somatic and autonomic nervous systems, but autonomic features are more common in tetanus.

All seven serotypes of BoNT are structurally similar. They are synthesized as a single-polypeptide chain of 150 kDa each which is processed by endogenous or exogenous proteases into an activated dichain form (Dekleva and Das Gupta 1989; Krieglstein et al. 1994; Singh and DasGupta 1989, Fig. 2). In each case, the dichain neurotoxin is composed of 100 kDa heavy chain (HC) and a 50 kDa light chain (LC), which is linked through a disulfide bond. Heavy chain consists of two domains of 50 kDa each: H_C and H_N; H_C is binding domain and H_N is the translocation domain. Structurally each toxin molecule has all three domains: binding domain (H_C), translocation domain (H_N), and catalytic domain (LC). Hc comprises two subdomains – a β-sheets domain (H_{CN}) and a β-tree-foil (H_{CC}).

The three domains of BoNTs appear to be naturally designed for toxin delivery system, as binding domain (BD) acts a targeting unit, the translocation domain (TD)

can deliver cargo into a cell, and the catalytic domain acts as the cargo (Foster 2009; Bade et al. 2004; Chaddock and Marks 2006; Chaddock and Acharya 2011). The arrangement and the function of subunit in BoNTs are analogy to those in diphtheria toxin and anthrax toxin complex (Humeau et al. 2000; Monteccuco and Schiavo 1994; Montecucco et al. 1994; Montecucco and Schiavo 1995; Schiavo et al. 1994a, b; Singh 2000). In BoNT structure, in addition to the disulfide link between HC and LC, there is a belt, a loop from the HC that wraps around LC to hold the two chains together (Lacy and Stevens 1999; Chen et al. 2007b). The active site of LC is partially occluded by the belt in unreduced toxin (Simpson et al. 2004; Ahmed and Smith 2000), and the belt is predicted to be intermolecular chaperone for the light chain (Brunger et al. 2007). All the domains work together with high precision and accuracy. That is perhaps part of the reason why BoNTs are highly effective biologics, making them the most toxic substances.

The BD of HC binds to nerve cells, and after internalization of the BoNT through endocytosis, the TD forms a pore in the endosomal membrane, through which the LC domain crosses into the cytosol. This leads to intracellular blocking of neurotransmitters release by proteolysis of one of the three proteins of SNARE complex by Zn-endopeptidase activity of the LC. Isolated LC cleaves SNARE protein but it cannot readily internalize on its own, and therefore remain nontoxic. Also, isolated H_C or H_N cannot cleave SNARE proteins, so remain nontoxic. So only when three domains come together they create most the toxic substance known. It is notable that this unique assembly allows us to explore the possibility of combinatorial profiling of multidomain assemblies, for example, LC-TD for retargeting LC function (Darios et al. 2010).

The crystal structure of BoNT/A (PDB: 3BTA), BoNT/B (PDB: 1EPW), and BoNT/E (PDB: 3FFZ) supports the hypothesis of modular assembly of BoNT (Fig. 4). Crystal structure of TeNT is not available. BoNT/A and BoNT/B show similar structural organization, whereas BoNT/E has some significant differences. Nevertheless, BoNT/E also has all the three domains, and while all other serotypes are made of two chains endogenously, BoNT/E is produced entirely as a single-chain protein. However, BoNT/B and BoNT/F are also produced as a single chain by non-proteolytic strains of the *Clostridium botulinum* (East et al. 1998). All the three domains are working together to achieve intoxication and act as a chaperone for the others (Brunger et al. 2007; Montal 2010). BoNT's functional complexities emerge from its modular design and tight interplay of individual component actions. Above-described design helps BoNT in using a very vital neuronal cell process, endocytosis, to reach to its targets. Exquisite toxicity of BoNTs is achieved by its unique structure which this molecule exploits very well. BoNT is considered an astonishing nanomachine that unites recognition, trafficking, unfolding, translocation, refolding, and catalysis in a single entity.

As stated earlier, TeNT is also synthesized by bacteria as a single-chain polypeptide, and because of the presence of bacterial protease, the toxin is isolated in a nicked form like botulinum toxin. Like A-B toxin, both separated heavy

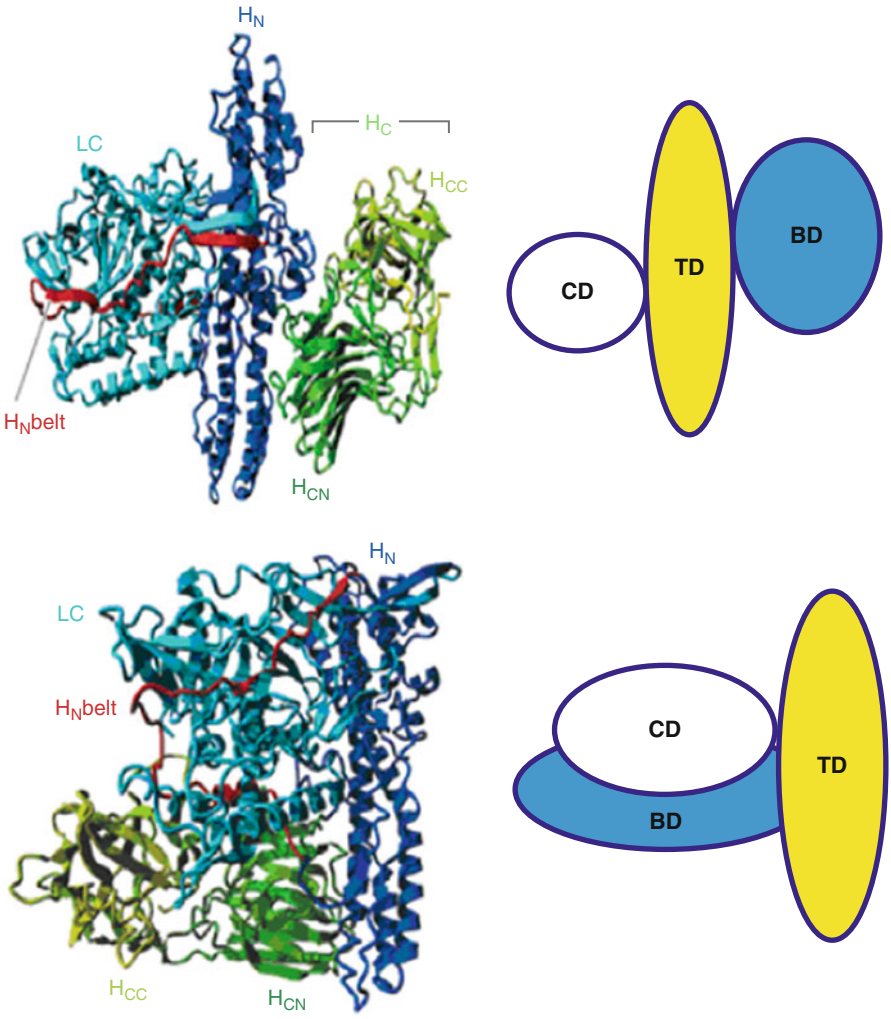

Fig. 4 Crystal structure of BoNT/A (3BTA) and BoNT/E (3FFZ). Hc is depicted in *green*, H_N is in *blue*, and LC is in *gray* color. Hc belt is depicted in *red*. BoNT/B (1EPW) is similar to BoNT/A. In case of BoNT/E LC (CD) and HC (BD) are on the same side of translocation domain (*TD*), whereas in BoNT/A CD and BD are on the opposite side of translocation domain (Kumaran et al. 2009)

chain and light chain of TeNT are nontoxic. But there is a second protease-sensitive site in heavy chain which splits the heavy chain approximately in half. In nonreducing condition, two chains can be isolated: one consists of 50 kDa heavy chain linked to 50 kDa light chain (referred to as fragment B), and other contains rest of heavy chain (50 kDa, fragment C). Fragment B is toxic to animal, and like botulinum toxin, it induces flaccid paralysis (Monteccuco and Schiavo 1994).

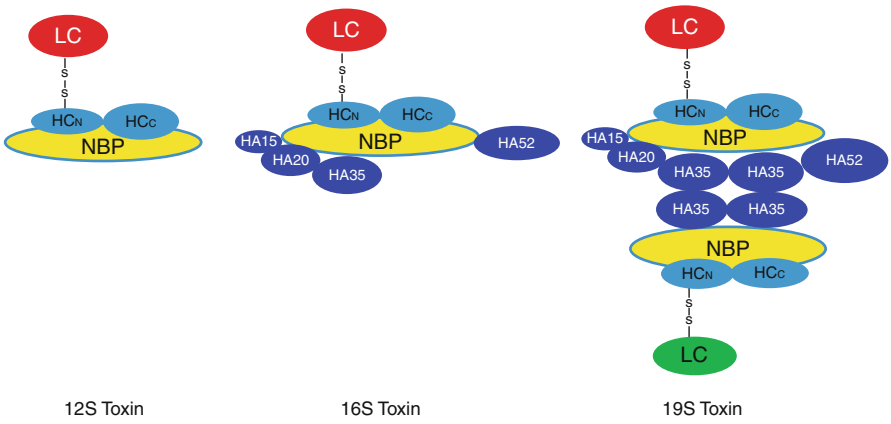

Fig. 5 Structure of botulinum neurotoxin complex. The toxins are produced by bacteria as progenitor toxins, composed of toxin molecule associated with NBP and other NAPs (hemagglutinins or HAs). Based on the organization of these proteins, botulinum toxins are termed as LL (19S), L (16S), and M (12S) toxin. HA35 has the highest molar ratio in complex compared to toxin. According to Innoue et al. (1996), molar ratio of toxin to HA35 is 1.00:3.99 and 1.00:7.76 in 16S and 19S toxin, respectively

4.1 Neurotoxin-Associated Proteins

In bacterial cultures, BoNTs are released in the form of multimeric complexes, with the set of nontoxic neurotoxin-associated proteins (NAPs) coded by genes adjacent to neurotoxin gene. These complexes are termed progenitor toxins (Innoue et al. 1996; Minton 1995). Some BoNT-associated proteins have hemagglutinating activity (Fujita et al. 1995). A large nontoxic non-hemagglutinating protein of 139 kDa coded for the gene by a gene upstream to the BoNT gene is present in all seven serotypes of BoNTs called neurotoxin binding protein (NBP) (Innoue et al. 1996; Minton 1995; Fujita et al. 1995; Singh et al. 1995). One of the interesting facts about the NBP is that it has similar structural domains as BoNT (Gu et al. 2012). Three forms of progenitor toxins have been characterized: extra-large size (LL complex, sediments at 19 S, about 900 kDa), large size (L Complex, sediments at 16 S, about 500 kDa), and medium size (M complex, sediments at 12 S, about 300 kDa). The M complex is BoNT-NBP complex; L Complex of BoNT-NBP, and several components of NAPs with hemagglutinin activity, and the LL complex are believed to be a dimer of L complex associated with each other (Innoue et al. 1996). The four hemagglutinin (HA) proteins found in BoNT/A complex are HA15/17(15 or 17 kDa), HA33/35 (33 or 35 kDa), HA19/20 (19 or 20 kDa), and HA70 (70 kDa). Notably, HA52 and HA15/17 are fractions of HA70 (Fig. 5). Innoue et al. (1996) determined the molar composition of different protein in complex. HA33/35 has been purified from BoNT/A complex (Fu et al. 1998), and also has been expressed as a recombinant protein.

While BoNT/A exists in three complex forms, M, L, or LL, types B, C, and D BoNTs exist in two forms, L and M. Type E BoNT is now known to exist in L and

M forms, although NAPs composition of the L form is different (Singh and Zhang 2004; Kukreja and Singh 2007). Type F BoNTs are reported only in M form, and type G exists only in L form (Fujita et al. 1995, Fig. 5).

Since every BoNT serotype is associated with one or more NAPs, it is also important to examine biological role, if any, of these proteins. BoNTs in complex forms are more stable than in purified form. NAPs protect BoNTs against proteolysis and denaturation (Chen et al. 1998; Sakaguchi 1983; Kukreja and Singh 2007). Survival of the complex in harsh GI-tract conditions is believed to be a major reason for BoNTs to be food poison. Oral toxicity of BoNTs is more in complex form than their purified forms (Sakaguchi 1983). At least one of the NAPs has been shown to exhibit a series of biological functions. It has been shown to possess heat-shock protein characteristics (Shukla and Singh 1999, 2009) and is believed to act as molecular chaperone (Shukla et al. 1997). HA33 is also known to block neuronal apoptosis (Kumar et al. 2012). Furthermore, HA33 is known to assist in the translocation of BoNT across the gut wall after ingestion of the BoNT complex (Matsumura et al. 2008; Fujinaga et al. 2009). These results indicate that associated protein play an important role in the toxico-infection process of botulism.

5 Mechanism of Action of Clostridial Neurotoxin

It has been proposed (Simpson 1986, 2004; Hilger and Bigalke 1995) that the biological action of clostridial neurotoxins involves three steps: (a) binding and internalization of the neurotoxin via the HC through receptor-mediated endocytosis (cellular process by which cell absorbs and engulfing external molecule), (b) membrane translocation of LC into the cytosol purportedly through a pH-induced membrane channel formed by the HC, and (c) intracellular blocking of neurotransmitter release by proteolysis of one of the three SNARE proteins of by Zn-endopeptidase activity of the LC (Fig. 6). Isolated LC cleaves SNARE protein but it cannot readily internalize on its own and therefore remains nontoxic. Also, isolated H_C or H_N cannot cleave SNARE proteins, so remain nontoxic. So only when three domains are together they create the most toxic substance known to humanity. Interestingly, this unique assembly allows us to explore the possibility of combinatorial profiling of multidomain assemblies, for example, LC-TD for targeting LC function (Darios et al. 2010).

5.1 Receptor Binding and Internalization

As described above, BoNTs have trimodular architecture, and this unique architecture has a physiological meaning. This unique structural organization helps it to achieve its goal in harsh cellular environment of host. Its mechanism of action starts with the high-affinity interaction with a surface protein receptor, via ganglioside co-receptor. So far, protein receptors identified are SV2A for BoNT/A (Dong et al. 2006; Mahrhold et al. 2006); glycosylated SV2A and SV2B for BoNT/E

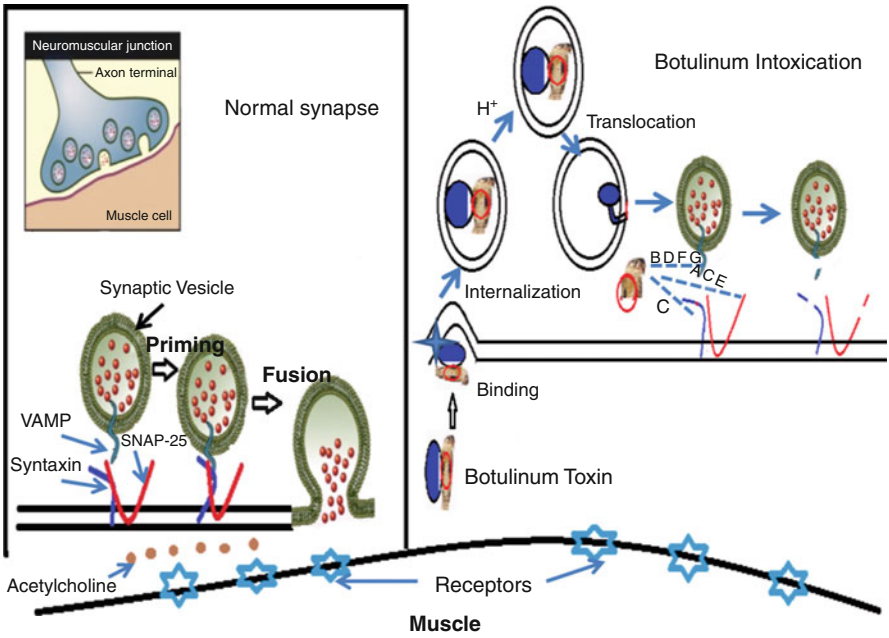

Fig. 6 Mode of action of botulinum neurotoxin. *Left*, pre and postsynaptic events in normal neuronal cells. *Right*, steps involved in botulinum intoxication; binding, internalization, translocation

(Dong et al. 2008); glycosylated SV2A, SV2B, and SV2C for BoNT/F (Fu et al. 2009; Rummel et al. 2009); and synaptotagmin I and II for BoNT/B (Dong et al. 2003; Nishiki et al. 1994, 1996) and BoNT/G (Rummel et al. 2004a). Interestingly, the BoNT serotypes which exhibit highest sequence similarity in binding region share the same protein receptor, i.e., A, E, and F bind to SV2 and B and G bind to SytI and SytII. The protein receptor(s) for BoNT/C and BoNT/D remain unknown. Binding of BoNTs to the peripheral neuromuscular junction is the initial step of intoxication. Apart from these receptors BoNTs have high-affinity (with nM dissociation constants) binding with ganglioside co-receptor (Binz and Rummel 2009). BoNT types A, B, C, and F bind GT1b, GD1a, and GD1b, respectively. BoNT/E binds GT1b and GD1a, whereas BoNT/G recognizes all gangliosides with similar affinity. BoNT/D binds phosphatidylethanolamine (PE). The ganglioside binding pockets lie in the Hcc domain. Crystal structure of Hcc fold is highly conserved for all BoNTs (~60 % homology). GT1b binds on a crevice formed by Trp1266 and Tyr1267 on one face and Glu1203, His1253, and Phe1252 on the other face. Generally, lactose-binding motif has all these key residues (H...SXWY...G) (Rummel et al. 2004b), and this is conserved among all BoNT serotypes (Stenmark et al. 2008). This particular motif provides hydrophobic character to the binding cavity. In contrast, BoNT/D, which interacts with PE, (phosphatidylethanolamine) lacks the key residues and shows a dependency on Lys1117 and Lys1135 for PE

binding. Study of Hcc structure in the presence and absence of the SytII peptide (Jin et al. 2006; Rummel et al. 2004b) is similar. Also in the presence and absence of GT1b, no change in conformation was inferred (Stenmark et al. 2008), which implies not only the Hcc fold is rigid but that the binding sites for GT1b and SytII are nonoverlapping. This still needs to be looked at carefully as there is no structure available for a BoNT/A-SV2 complex or of a BoNT/B-GT1b complex. Nevertheless, we have BoNT/A Hcc-GT1b complex (PDB 2VU9) and BoNT/B Hcc-SytII peptide complex (PDB 2NM1), which allow us to understand the lipid and receptor binding. It is also believed that solvent accessible surface of each BoNT serotype is unique. Each ternary complex (BoNT/A-SV2-GT1b or BoNT/E-glycosylated SV2A-GT1b) may expose distinct charge groups. PIPs (phosphatidylinositol 4,5-bisphsophate) are minor phospholipids in cell membrane and involve in recruitment/regulation of protein in membrane and in signaling. PIP binding site is identified in BoNT/A H_{CN}. Existence of two lipid binding sites, PIP and GT1b, suggests a dual anchorage mechanism for binding and internalization of this toxin (Muraro et al. 2009). Together with phospholipids, toxin acquires a new surface that confers a propensity for novel interaction which assisted in membrane insertion. Evidences suggest that after binding toxin does not enter the cell directly through plasma membrane, but is endocytosed into endosomes (enter into a lumen vesicular structure) in a temperature- and energy-dependent process (Dolly et al. 1984; Critchley et al. 1985; Black and Dolly 1986; Schiavo et al. 2000). The Hc domain of toxin plays an important role in internalization.

5.2 Pore Formation and Translocation

Second step after receptor-mediated endocytosis and internalization is the translocation of LC into the cytosol. LC must cross the hydrophobic barrier to reach cytosol. It is important to note that internalization and translocation both are distinct steps of cell intoxication. Translocation is a crucial step in the neurotoxicity of BoNTs. It is believed that H_N is translocation domain. H_N exhibits high-sequence conservation among all the serotypes with exception of the belt region that diverges significantly (Lacy and Stevens 1999). H_N helps in making pore in the endosomal membrane to facilitate LC translocation. LC translocation by HC stringently depends on the following conditions: (a) a pH gradient, acidic on the inside and neutral in the cytosol; (b) a redox gradient, oxidizing on the inside and reducing on the cytosolic side; and (c) a transmembrane potential (Montal 2010; Koriazova and Montal 2003; Fischer and Montal 2006, 2007).

There is no general consensus on how the translocation of LC occurs. According to one hypothesis, the LC unfolds at low pH and permeates through the transmembrane pore formed by H_N. After exposure to the neutral pH of the cytosol, the LC refolds, and it is released from the vesicle by reduction of the interchain disulfide bond. This is known as "tunnel" model (Boquet et al. 1976; Montecucco and Schiavo 1995), and formation of transmembrane ion-conducting pore is the prerequisite for this model. This model has some problems: (1) the light chains of toxin

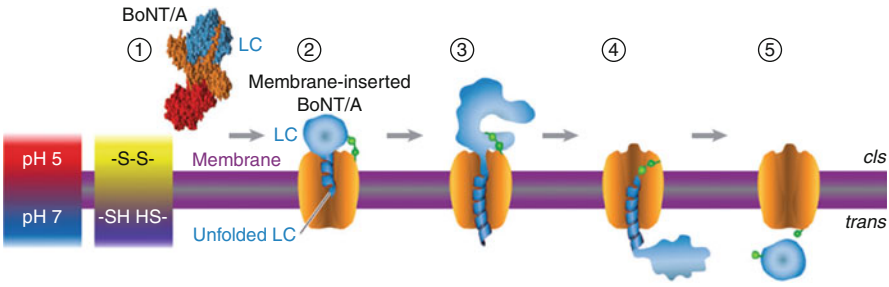

Fig. 7 Schematic representation of BoNT/A LC translocation. BoNT/A prior to insertion (*1*), membrane inserted BoNT/(*2*), partial unfolding of light chain and translocation (*3*) and (*4*), and exit to cytosol (*5*) (Copyright (2007) © National Academy of Science, USA)

may be exposed to the fatty acid chains of lipids, and (2) channel activity values of the order of a few tens of picoseconds do not account for the dimensions expected for a protein channel that has to accommodate a polypeptide chain with lateral groups of different volume, charge, and hydrophilicity.

A second model, proposed by Beise et al. (1994) suggests a decrease in the internal pH of endocytotic vehicle carrying toxin by ATPase proton pump, followed by neurotoxin insertion into the lipid bilayer. Electrochemical gradients and osmotic lysis cause destabilization of the lipid bilayers, breaking the membrane barrier, and the cargo of toxin molecules are released into the cytosol. This model explains the translocation of toxins fairly well, but some experimental findings are inconsistent with it. It is already shown that TeNT does not lyse the plasmalemma of neuronal cell at pH 5.0 and also diphtheria toxin forms channel without lysing the cell (Beaumelle et al. 1992).

Third model is the cleft model (Humeau et al. 2000; Simpson 2004) in which there is conformational change at low pH in both HC and LC in such a way that they expose their hydrophobic surfaces and enter into lipid bilayer by getting in contact with its hydrophobic core. The HC forms a transmembrane hydrophilic cleft that nests the passage of the partially unfolded LC with its hydrophobic segments facing the lipids. This process may be driven by electrochemical gradient, such as pH gradient across endosomal membrane. Neutral pH of cytosol and/or cytosolic chaperones help LC to fold and regain its water-soluble neutral conformation after reduction of the interchain disulfide bond. In the cleft model, the ion channel is a consequence of membrane translocation rather than a prerequisite.

A recent study by Montal (2010) suggests a very interesting mechanism of translocation, suggesting the role of interchain disulfide bond. This explanation suggests occlusion of heavy chain channel by light chain, if disulfide bond is reduced prior to translocation. Also, disulfide bond reduction within the bilayers aborts translocation. Translocation is only complete when disulfide bridge and the C-terminus of the LC enter the cytosol. According to this observation, it may be suggested that channel formation and translocation are two different events and not associated with each other (Montal 2010, Fig. 7).

Examination of BoNT crystal structure also reveals a transmembrane region (548–872) and a loop (561–568; completely disordered) connecting translocation belt (492–545 in BoNT/A and 481–532 in BoNT/B) and HN, which may change its conformation at low pH. The translocation domain appeared to be sensitive to environment variables, as the pH of this region is 4.66 (as compared to 9.1 for the binding domain and 6.0 for the whole toxin). There are several clusters of negative charges as well as proximal flexible structures in HN which can assist the pore formation (Lacy and Stevens 1999).

Evidences show that there are similarities in the action of botulinum and tetanus neurotoxins. TeNT, like BoNT, is a 150 kDa single-polypeptide protein with a heavy chain (100 kDa) and a light chain (50 kDa) region held together by a disulfide bridge and by noncovalent protein-protein interactions; TeNT also binds to peripheral nerve terminals, internalizes through endocytosis, and retrogrades to central nerves, where the light chain translocates into cytosol, leading to biochemical action that blocks neurotransmitter release.

The carboxyl terminal of TeNT heavy chain binds to cholinergic receptors of the presynaptic membranes of the central and peripheral nervous system, and possibly to sympathetic adrenergic fibers. Polysialogangliosides are an example of cholinergic receptors. TeNT binds tightly to such receptors because of the protein's multiple interactions with sugar and protein binding sites. It is retrogradely transported within the axon to the cell body. TeNT is released from the postsynaptic dendrites and taken up by the presynaptic nerve terminals. The entire journey of TeNT from peripheral neurons to its ultimate site of action, inhibitory neurons of central nervous system, involves binding, internalization, and transport within a cell. Transport of the toxin seems to occur within smooth vesicles, cisternae, and tubules. The toxin acts specifically on the interneurons of the spinal cord that inhibit voluntary muscle action. The N-terminus of the heavy chain is the translocation domain because it forms pores or toxin channels in the vesicle lipid bilayers of spinal cord neurons. The light (50 kDa) chain of TeNT is the toxic part of the protein. This portion is a specific protease that cleaves synaptobrevin, a vesicle-associated membrane protein (VAMP), at a single site. VAMPs help mediate membrane fusion, vesicle transport, and neurotransmitter release. Cleavage of synaptobrevin would not only denature the protein, but it would also prevent the exocytosis of the glycine and γ-aminobutyric acid neurotransmitters that control muscle contraction. With such actions inhibited, the nerve cells that control voluntary muscle action fire constantly and lead to the characteristic unopposed muscle spasm leading to spastic paralysis.

5.3 Blockage of Neurotransmitter Release

5.3.1 SNAREs and Neurotransmission

To understand the intracellular mechanism of action of clostridium neurotoxins, we first need to understand its substrate SNARE proteins and its role in neurotransmitter release. SNAREs are set of three proteins: synaptic vesicle protein, VAMP

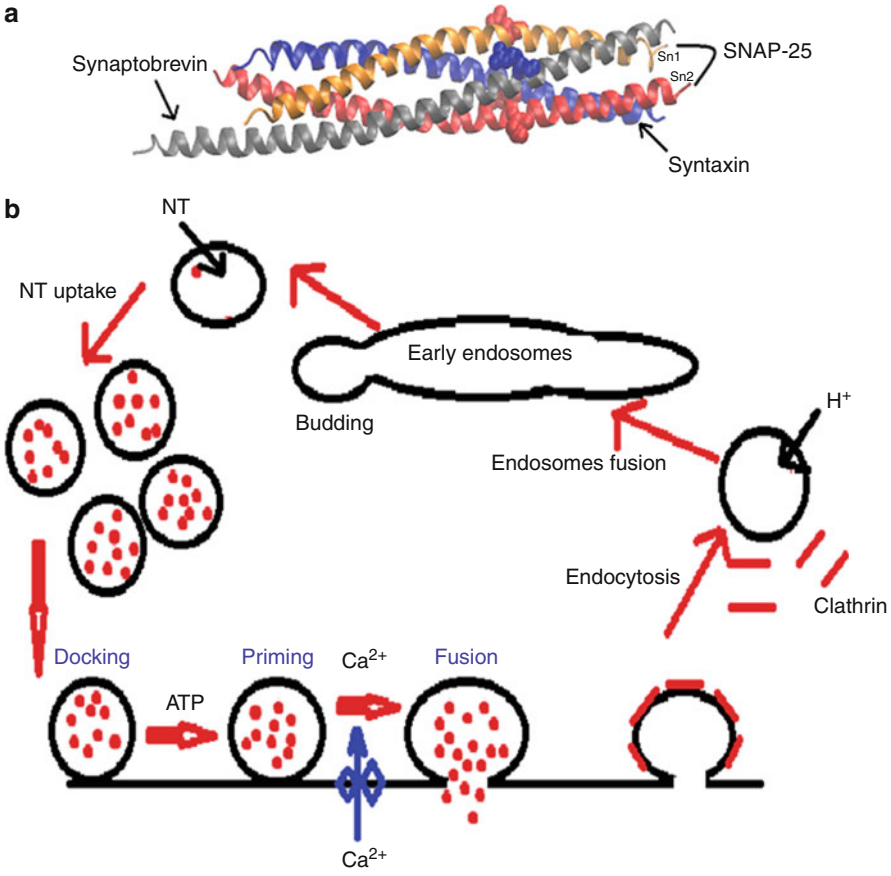

Fig. 8 (**a**) Tetrahelical assembly structure of SNARE complex, (**b**) schematic representation of the processes of endocytosis and exocytosis. Docking, priming, and fusion of exocytosis are represented in this figure. SNARE proteins (syntaxin, SNAP-25, and synaptobrevin) are critically involved in different steps of the exocytosis process. Synaptic vesicles loaded with neurotransmitter dock near the plasma membrane. Partial SNARE complex formation occurs in the priming step. Primed vesicles fuse very rapidly with the plasma membrane after calcium influx upon the arrival of the action potential. Energy for the fusion comes from SNARE assembly

(vesicle-associated membrane protein also called as synaptobrevin), and plasma membrane proteins, syntaxin, and SNAP-25 (synaptosome-associated protein of 25 kDa) (Fig. 8a). These three proteins are membrane receptors for NSF (*N*-ethylamide-sensitive factors) and SNAPs (soluble NSF attachment proteins and are named as SNARE (SNAP receptors) proteins. SNAREs can be divided into two categories based on their localization inside the cells: v-SNAREs, localized in vesicle membrane, and t-SNAREs, localized in target membrane or plasma membrane. They are also sometimes termed as R-SNARE (middle group arginine) and Q-SNARE (middle group glutamines). SNARE proteins are characterized by

a conserved 60–70 amino acid motif. In addition to this motif SNAREs also have sequences that anchor them to the membrane. Syntaxin and synaptobrevin are anchored through their respective transmembrane domains, whereas SNAP-25 associates with the plasma membrane via the palmitoylation of cysteine residues in the linker region. These proteins play a very important role in the membrane fusion and neuronal exocytosis, one of the important physiological processes in neuronal cells. SNAP-25 and syntaxin are highly conserved in their isoforms. SNAP-25 is also needed for axonal growth and regeneration (Osen et al. 1993). One of the unique characteristic features of SNARE proteins is their assembly in 1:1:1 stoichiometry to form a very stable ternary complex, which is resistant to dissociation by sodium dodecyl sulfate (SDS). During the ternary complex formation, carboxy-terminal domain of syntaxin (amino acids 199–243; H-3 helix) binds to SNAP-25. Complex of SNAP-25 and syntaxin binds to the central part of the synaptobrevin (amino acids 27–96). All of SNAP-25 is required for binding with synaptobrevin (VAMP2, 29–60) and amino- and carboxy-terminal domains participate in binding to syntaxin (syntaxin 1, 199–243). Assembly of SNARE complex brings the two opposing membrane bilayers of synaptic vesicle and plasma membrane closure and acts as a bridge. The arrival of action potential triggers inflow of Ca^{2+} ion, allowing the vesicle to dock at the active zone. After docking, second Ca^{2+} influx in the active zone creates a fusion pore involving two other proteins: synaptophysin and physophillin. Other vital components in this process are synaptotagmin and complexin. Complexin interacts with tetrahelical strands (Fig. 8a) of SNARE complex and prevents neurotransmitter release until an action potential arrives at synapse to facilitate quantal release (Kummel et al. 2012). Synaptotagmin binds to Ca^{2+} ion and acts as a sensor for vesicle fusion and quantal neurotransmitter release (Kummel et al. 2012). Formation of initial pore leads to complete fusion of vesicle membrane to plasma membrane, and the content of vesicle (neurotransmitter) is released into the synaptic cleft. The whole process is called exocytosis (Fig. 8a and b).

5.3.2 Motifs and Conformations Involved in Unique Substrate Recognition of BoNT Endopeptidase

All the light chains are Zn-metalloprotease of thermolysin family but are unique among Zn proteases due to their stringent specificity for substrates or at least long peptide segments containing highly selective cleavage sites. BoNT LCs require 16 to >50 residue long substrates whereas other Zn proteases can hydrolyze as short as two residue peptides (Shone et al. 1993; Cornille et al. 1997; Shone and Roberts 1994). The known substrate for BoNTs is SNARE proteins with stringent substrate specificity. TeNT and BoNTs target and peptide bond specificity is displayed in Table 2.

Each of the clostridial toxins cleaves their targets at distinct sites, except BoNT/B and TeNT which cleave the same peptide bond on the same substrate. This exquisite selectivity is believed to be due to the presence of highly conserved motifs in SNARE proteins. These motifs are termed as S1 to S4 in SNAP-25; V1 and V2 in VAMP; and X1 and X2 in syntaxin. Although BoNT/B and TeNT attack the same

Table 2 TeNT and BoNT target and peptide bond specificities. Cleavage site is at P1–P1'

BoNT/F	VAMP	E- R- D-Q- K-L- S- E
BoNT/G	VAMP	E- T- S- A- A-K- L-K

Gln-Phe peptide bond, these toxins display distinct affinities for V1 and V2. For efficient cleavage, BoNT/A and BoNT/E require C-terminal region of SNAP-25 which has S4 motifs. However, S1 (leu20-Arg30), S2 (leu36-Ile45), and S3 (Met50-Glu59) motives partially substitute for S4 (Glu145-Ser154) motif (Washbourne et al. 1997). SNARE proteins are protected from proteolytic attack if they are bound to ternary complex (Poulain et al. 2008). This is probably due to masking of the cleavage site or recognition motifs.

Several evidences suggest that neurotoxins recognize tertiary structure of their substrates:

(a) Clostridial neurotoxins require long substrates compared to other Zn-metalloprotease.
(b) They cleave their substrates exclusively at single-specific site out of several identical peptide bonds present in their respective target proteins.
(c) Synthetic peptides of same cleavage segments are not hydrolyzed by the neurotoxins; they are shown to be good inhibitors of proteolytic activity of the toxins. This means although they can bind, they are not cleaved by toxins (Schiavo et al. 1992a, b, 1993a, b; Dayanithi et al. 1994).
(d) Light chains of these toxins cleave very specific bonds even if the same bonds are present in other part of the substrate sequence (Gln15-Arg16 of SNAP-25 in case of BoNT/A and Arg59-Ile60 and Arg191-Ile192 in case of BoNT/E).

Apart from SNARE, several homologues of these proteins are known as a substrate for BoNT, which can be cleaved to different degrees. Murine SNAP-23 can be cleaved by BoNT/E and to some extent by BoNT/A, but human SNAP-23 is resistant to both because of mutation Lys185Asp and Pro185Arg (Washbourne et al. 1997; Vaidyanathan et al. 1999; Pickett and Perrow 2011). Mutations in amino acid sequences of the toxin targets make them resistant to proteolysis and can account for almost all cases of species insensitivity to BoNT or TeNT.

LC of BoNT is a compact globular structure composed of a combination of β-sheets and α-helices (PDB ID 1XTG; 1 F82; 1T3A; 2ISE). All the crystal structures reported so far are derived from a truncated version of the LCs.

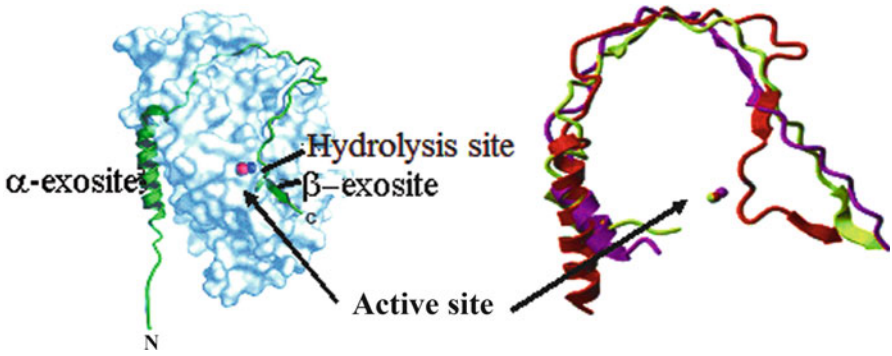

Fig. 10 Structure of BoNT/A LC in complex with truncated SNAP-25 (Sn2, *left*), showing interaction of SNAP-25 (Sn2 segment) with α- and β-exosites and active site. *Right* figure shows overlapped structure of SNAP-25 (Sn2 segment, *red*) and HC belt of BoNT/A (*magenta*) and BoNT B (*lime*) (Adapted from Brunger et al. 2007)

The central part of this enzyme is Zn^{2+} binding motif, HEXXH + E, and is conserved among all BoNTs. The finding is that all the clostridial neurotoxins have similar active site motifs, suggesting common evolutionary origin of these proteins (Fig. 9).

It is notable that the active site of BoNT is located in a very deep and narrow crevice, whereas in thermolysin active site is broad and very near to the surface (Fig. 10). In case of BoNT/A LC, active site crevice travels through half of the enzyme structure (20 Å deep) and is negatively charged (Brunger et al. 2007). Interestingly, translocation domain has a belt, a unique loop in extended conformation (residues 492–545 for BoNT/A and 481–532 for BoNT/B). This belt has a remarkable similarity with residues 141–205 (the Sn2 segment) of SNAP-25 in spite of low sequence similarity of the belts among all the clostridial toxins (BoNT and TeNT; Lacy and Stevens 1999; Chen et al. 2007b, Fig. 10). For BoNT/A, the catalytic Zn^{2+} is bound to the active site by interaction with imidazole ring of His223 and His227 and with the carboxyl side chain of Glu262. The Zn^{2+} is also coordinated by a water molecule, which is activated by Glu224, and believed to

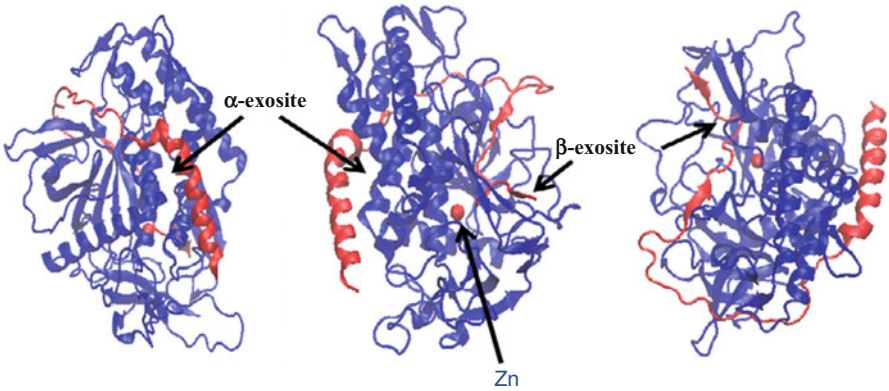

Fig. 11 Crystal structure of BoNT/A LC with its substrate SNAP-25 (Sn2). α-exosite and β-exosite are shown as a primary substrate recognition point. 250 and 370 loops are also interacting with substrate (Breidenbach and Brunger, Nature 2004)

play a critical role in proteolysis. However, Glu262, which is directly coordinating to active site Zn, also plays a pivotal role in the stability of active site (Kukreja et al. 2007). Furthermore, four flexible loops, 50/60 loop, 170 loop, 370 loop, and 250 loop, form the rim of active site cleft and are believed to take part in substrate binding. Rest of the protein is a mixture of α-helix and β-sheets.

A topographical model for the interaction of BoNT with its substrate has been described by Breidenbach and Brunger (2004, Fig. 11) who used enzymatically inactive version of BoNT/A LC (created by two point mutations, E224Q and Y366F) and carboxy-terminal SNARE domain of SNAP-25, residues 141–204 (Sn2), to obtain crystal structure of enzyme-substrate complex. The crystal structure of the complex revealed that apart from active site, this molecule has two exosites: α-exosite and β-exosite. α-exosite is a hydrophobic patch formed at the interface of four light chain-α-helices, residues 102–113 (α-helix 1), 310–321 (α-helix 2), 335–348 (α-helix 3), and 351–358 (α-helix 4). β-exosite is a distorted two strand in the 250 loop of the LC, a peptide segment with residues 242–249. The amino-terminal helical region of Sn2 interacts with the endopeptidase α-exosite, whereas C-terminal of Sn2 interacts with β-exosite. The hydrophilic face of the amphipathic Sn2 helix is oriented towards the solvent, while the hydrophobic side chain buried against the α-exosite. Interaction with β-exosite is primarily mediated by backbone interactions, but Met 202 of Sn2 is also very critical for this interaction. Substrate shorter than residues prior to Met 202 cannot be cleaved by BoNT at a measurable rate (Schmidt and Bostian 1995). β-exosite is very critical for the recognition of BoNT. Notably, residues 183–190 of Sn2 detach from the surface of LC and rejoin the LC at Arg191. There are series of anchoring points that could serve as additional determinants of substrate specificity. Substrate residues 170–172 and 192–193 are two anchoring points, and individual side chains from Arg176, Ile178, Ile181, and Glu183 are also recognized by the endopeptidase. This may be one of the reasons for the requirement of long substrate. The largest

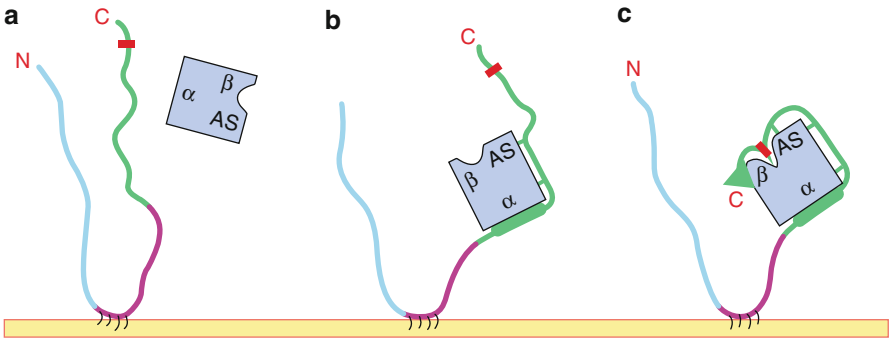

Fig. 12 Schematic model of BoNT/A LC substrate recognition and cleavage (Adapted from Breidenbach and Brunger 2004). (**a**) Sn1 (*cyan*) and Sn2 (*green*) domains of SNAP-25 are attached to presynaptic membrane by palmitoylation (*black*) of cysteine residues of SNAP-25. (**b**) Binding of BoNT/A is initiated by recognition of Sn2 domain of SNAP-25 by α-exosite of protein and few anchoring points (*green* notches). (**c**) After these interaction SNAP-25 binds to β-exosite, inducing conformation change in 370 loop, which leads to cleavage of SNAP-25 by BoNT/A LC

structural changes that are related to substrate binding occur in 250 loop (β-exosite) and 370 loop In BoNT/A; the 250 loop adopts an open conformation which contracts and folds over the 370 loop upon substrate binding at the β-exosite.

The model of active site and exosites of BoNT/A endopeptidase explains the mechanism of SNAP-25 substrate cleavage as follows. SNAP-25 is attached to presynaptic membrane through palmitoylation of cysteine residues. C-terminus and N-terminus are unstructured or flexible in the uncomplexed SNAP-25. SNAP-25 upon binding to BoNT/A probably initiates helix formation which is recognized by α-exosite and anchored points and finally by β-exosite (Figs. 11 and 12).

A major point against this model is that the BoNT/A L chain and SNAP-25 co-crystal structure do not show any significant direct interaction of the α-exosite of the light chain with the S4 motif of SNARE, not considered critical for binding of SNAP-25 (Breidenbach and Brunger 2004), but are critical for the endopeptidase activity (Washbourne et al. 1997). Thus, while the crystal structures provide useful information on the folding patterns of BoNTs, and on the interaction between BoNT/A light chain and SNAP-25, these do not take into consideration the role of dynamic structures in the functioning of the molecule. Nevertheless, this co-crystal structure provides a very good model to understand the behavior of this molecule with its substrate. The crystal structure explains why clostridium neurotoxins can cleave free SNAREs but not the SNARE complex because when SNARE complex is formed, then the residues of SNAP-25 involved in recognition/bindings are not accessible for these interactions. Notably, C-terminus of BoNT/A LC plays important role in catalysis. Finding by Baldwin et al. (2004) suggests that minimum residue needed for optimal catalysis is 1–425. Deletion of C-terminal region beyond 425 has a small effect on substrate binding but drastically reduced the catalytic efficiency. It has been speculated that there is extensive H-bond network in the

C-terminal region which stabilizes the structure of C-terminal loop region as well as active site core (Baldwin et al. 2004).

5.3.3 Static Versus Dynamic Structure: Role of PRIME Conformation

The static crystal structure of botulinum endopeptidase determined by x-ray diffraction studies (Segelke et al. 2004; Breidenbach and Brunger 2004) does not adequately describe the dynamic properties of the enzyme in solution where it represents a manifold of conformational substates. Indeed, crystal packing forces might lead to structural arrangements, which might not be relevant to solution conditions. Conformational fluctuations resulting from collective modes of motion, which involve concerted displacements of many atoms, can push the unbound states of enzymes into conformations closely resembling the bound states, thereby priming them to form complexes with the substrate. Hence, every conformational state of the enzyme that is populated along the reaction pathway presents a unique opportunity for interactions with substrate or drug molecules.

We have recently discovered biologically active molten globule structure of the BoNT/A (Cai and Singh 2001). The catalytic domain of BoNT/A also possesses a novel conformation at the physiological temperature of 37 °C and is named as PRIME (pre-imminent molten globule enzyme) state (Kukreja and Singh 2005). The PRIME state is dynamically flexible and is likely to facilitate specific interactions with its substrate, SNAP-25 for its optimum and selective enzymatic activity. Thus, we suspect that the PRIME conformational state provides a flexible structure which plays a very critical role in the biological function of BoNT/A, especially in its intracellular toxic action.

The schematic model of the temperature-induced PRIME conformational and molten globule states of BoNT/A light chain, as represented in Fig. 13, reflects how these states in BoNT/A light chain may facilitate binding and cleavage of SNAP-25. The intramolecular mobility of PRIME state is significantly higher than that of the native state which can be attributed to increased dynamics and expansion of the protein core, facilitating a maximum specific binding of SNAP-25, leading to its cleavage. The molten globule conformation observed at 50 °C, on the other hand, has a considerably intact secondary structure, loose packing of side chains in the protein core, and partial unfolding of loops. This structure also binds to SNAP-25, although to a lesser degree than the PRIME state, thus showing only about 61 % of the optimum enzymatic activity (Fig. 13).

Our observation of the PRIME conformation of BoNT/A LC with optimum enzymatic activity is the first observation of enzymatically active molten globule or molten globule-like structure (Kukreja and Singh 2005). The role of such a dynamic structure is more significant in view of the extreme specificity of the endopeptidase towards its substrate, SNAP-25, and its tremendous utility in designing specific antidotes against botulism threats. This structure of BoNT/A light chain seems to play a major role in its endopeptidase activity and particularly as it interacts with potential inhibitor candidates. Currently, BoNT/A light chain used in most

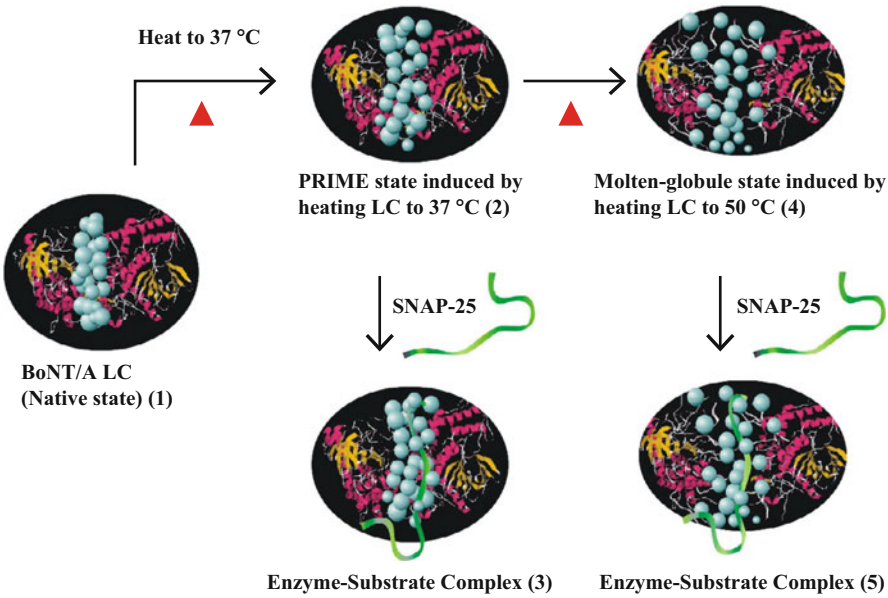

Fig. 13 Schematic model representing the PRIME state and the molten globule state in BoNT/A LC facilitating binding of substrate SNAP-25. The *blue*-colored balls represent the nonpolar side chains which are tightly packed in the native conformation (1). Upon heating to 37 °C, there are significant alterations in the polypeptide folding and the protein core becomes slightly loosened compared to the native state and forms the PRIME state (2), facilitating binding of SNAP-25 to form the enzyme-substrate complex (3). BoNT/A LC exhibits optimum activity in the PRIME state. Further heating of BoNT/A LC to 50 °C leads to the formation of the molten globule (4), facilitating binding of SNAP-25 to form the enzyme-substrate complex (5) although to a lesser degree than the PRIME state, thus exhibiting only about 61 % of the optimum enzyme activity (Kukreja and Singh 2005)

laboratories working on structure and inhibitor development is a truncated form of the 448 residue full-length polypeptide. The forms being used are LC-444, LC-438, LC-425, and LC-424. Although all these truncated forms have enzyme activity, their interactions with potential inhibitors as well as their substrates (peptide substrate and whole protein substrate, SNAP-25) were peculiarly different (Baldwin et al. 2004; Fredenburg et al. 2007), and a dynamic conformational variability could explain these differences. Silvaggi et al. (2008) have in fact observed limited flexibility of active site, although those changes would not necessarily explain differential interaction of BoNT endopeptidases with their respective substrates, because of the involvement of exosites in substrate binding (Breidenbach and Brunger 2004). Burnett et al. (2007) have observed that "Our inability to identify an acceptable binding mode for mpp-RATKML led to a pivotal question: is it possible that the conformation of the x-ray determined BoNT/A LC may not be the bioactive conformation, at least with respect to inhibitor binding?"

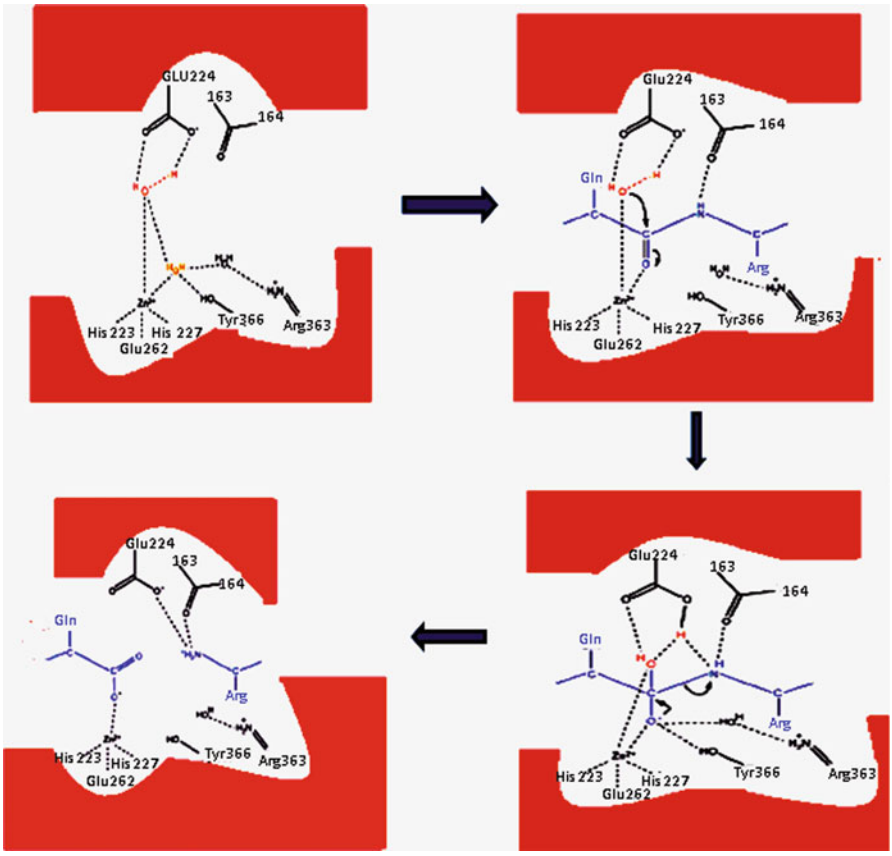

Fig. 14 Schematic representation of proposed BoNT/A LC mechanism. A polarized water molecule, by Glu223 and Zn^{2+} (*top left*), nucleophilically attacks the carbonyl carbon of the scissile bond to form an oxyanion (*top right*). This oxyanion is stabilized by Tyr366 (*bottom right*). Peptide bond of the substrate is cleaved by two proton transfer for activated water molecule mediated by Glu223. This process resulted in a protonated amine (*bottom left*)

Mechanistic details of a flexible structure interacting with its whole substrate have yet to be worked out, but when that is resolved it could reveal transformative role of protein dynamics in the protein-protein interactions involved in such a high specificity in BoNT/A endopeptidase-SNAP-25 interactions.

5.3.4 Chemical Mechanism of Substrate Cleavage

Proposed mechanism of substrate cleavage is depicted in Fig. 14. In the first step water molecule is polarized by Glu224 and Zn^{2+}. Activated oxygen of water mounts a nucleophilic attack on the carbonyl carbon of P1 of scissile bond. Side chain of Tyr366 is responsible for stabilization of the resulting oxyanion, which develops at

P1 carbonyl oxygen atoms. Oxyanion is also stabilized by Arg363 through a water molecule. Peptide bond cleavage is likely achieved by two proton transfer from the attacking water molecule mediated by Glu224 and results in the protonated amine of P1'. Proposed mechanism is slightly different from the mechanism of another Zn-metalloprotease, thermolysin. In thermolysin, Tyr157 and His231 have been proposed to stabilize the transition state (Matthews 1988). No residues have been identified to involve in the stabilization of the transition state of ES (enzyme-substrate) complex of BoNT-catalyzed proteolysis. In fact, the space occupied by these two residues in thermolysin is occupied by Sn2 residues in the case of BoNT/A. This leads to two hypothesis: either there are no residues in the case of BoNT/A to stabilize the evolving oxyanion or that BoNT/A might involve substrate-assisted catalysis.

His223, Glu224, His227, and Glu262 are the important residues in BoNT/A active site, and they are conserved in the other serotypes. Mutation of Glu224 to Asp leads to almost total loss of activity, and removal of His227 abolishes the catalytic activity of BoNT/A. Analysis of TeNT neurotoxin has confirmed that these key residues are identical to BoNT/A. Other residues, such as Glu271 and Tyr375 (in TeNT) and Arg 363 and Tyr365 (in BoNT/A), have been shown to be involved in catalysis, and it has been proposed that these residues may be involved in transition state stabilization.

6 Effects and Consequences of Botulinum Neurotoxin Exposure

As mentioned earlier, botulinum toxins are the most poisonous substance known. The LD50, dose of these toxins in mouse when administered intravenously, subcutaneously, or intraperitoneally, is estimated 1 ng/kg. Tetanus toxin LD50 is 2 ng/kg. All the botulinum toxins are less toxic when exposure is through pulmonary route. Human LD50 is 3 ng/kg (McNally et al. 1994). The effect of botulinum toxin may affect areas away from the injection site and cause serious symptoms including loss of strength and all-over muscle weakness, double vision, blurred vision and drooping eyelids, hoarseness or change or loss of voice (dysphonia), trouble saying words clearly (dysarthria), loss of bladder control, trouble breathing, and trouble swallowing. While all the seven serotypes have similar domain organization and function, and show only immunological distinction (Simpson et al. 2004), duration of their intracellular action (longevity) and potency varies substantially. BoNT/A, BoNT/B, and BoNT/E intoxication is persistent for about 180 days, 90 days, and 30 days, respectively (Adler et al. 2001; Dolly and Aoki 2006; Pickett and Perrow 2011).

Persistence of BoNT/A intoxication is because of stability of its catalytic domain, light chain, inside the neuronal cells. This is supported by intoxication of BoNT/A in spinal cord neurons (Keller et al. 1999) and muscle paralysis experiments (Adler et al. 1996). Notably, neurons and neuroendocrine cells have high level of tyrosine kinases (Brugge et al. 1985; Maher 1988). Therefore, it has been

speculated that intercellular phosphorylation of light chain may contribute to latter's longevity (Montiel et al. 1996). Recently, it has also been proposed that differential ubiquitination of different BoNT light chains may be responsible for differential intercellular stability of BoNT proteins (Tsai et al. 2010). Because of the longevity of BoNT intoxication, and that too due to the survival of toxin inside the cell, an inadvertent consequence is the possibility of the host cellular response to the long-term presence of the toxin.

Microarray analysis reveals that 169 genes were upregulated, while 60 genes were downregulated in epithelial cell (HT-29), whereas 223 genes were upregulated and 18 genes were downregulated in neuronal cell model (SH-SY5Y) exposed to toxin for just 96 h. These modulated genes are associated with neuroinflammatory, ubiquitin-protease degradation, phosphatidylinositol, and calcium signaling in SH-SY5Y pathways (Thirunavukkarasu et al. 2011). Interestingly, these modulated genes are different from those observed upon exposure of HT-29 cells, which are model for gut epithelial cells. Are there gene expression responses related to survival of BoNT intracellularly? Further research work of cells to different serotypes of BoNT will shed more light on the genomic host response and BoNT longevity inside the neuronal cells.

As BoNTs are associated with NAPs, and in most cases of botulism cases or even BoNT as a therapeutic drug, patients are exposed to the BoNT complex, it is important to consider the effect of NAPs as well on biochemical and physiological host response. Immunogenicity of BoNT/A complex is more than that of pure BoNT/A itself. Interestingly, NAPs are more immunogenic than the toxin (Kukreja et al. 2009). HA33, molecule major component of BoNT/A NAPs, exhibits maximum immunogenicity. HA33 is also shown to inhibit apoptosis (Kumar et al. 2012). Apoptosis is also inhibited by BoNT/A in SH-SY5Y cells (Kumar et al. 2012), although BoNT/C is shown to enhance apoptosis in cerebral granular cells (Berliocchi et al. 2005). While these studies indicate that BoNT and NAPs significantly affect cell metabolism and physiology, there are many questions, including variations in responses to different BoNT types, variation in responses of different cell and tissue types, and variation in responses due to different states of cellular physiology, that remain to be addressed with further experiments.

Effect of botulinum toxin on nerve impulse activity and muscle contractions resumes over time as a result of sprouting near to nerve ending, thus renewing the ability of the nerve to cause muscle contraction. Eventually, the new nerve retracts and original nerve ending regains its function (Jankowic 2004; De Paiva et al. 1999, Fig. 15).

Release of neurotransmitter is affected by botulinum neurotoxins due to the cleavage of SNARE proteins, but that is not the only process affected by BoNT. Neuropeptide P, or substance P, involved in neurogenic inflammation and pain disorders is also affected by BoNT (Aoki 2004). There is lack of evidence of direct effect of BoNT on central nervous system. Because of its size, 150 kDa, BoNT cannot penetrate blood–brain barrier (Dressler et al. 2005). Possibility of retrograde transport has been suggested previously; however, no transsynaptic transport has

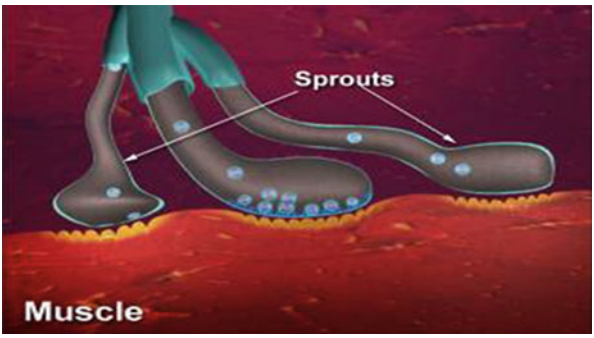

Fig. 15 Nerve sprouting induced by botulinum toxin (http://www.allergan.com/assets/pdf/botox_mechanism_of_action.pdf)

been observed. In vitro studies suggest that BoNT can affect central nervous system (Antonucci et al. 2009; Caleo and Schiavo 2009). BoNT/E has been shown to affect glutamate release and block spikes activity of pyramidal neurons in vivo (Bozzi et al. 2006). A recent study finds that BoNT spreads in CNS tissues (Jamie 2008); however, the injected dose was way too high compared to the doses used in therapeutic application.

7 Medical Applications of Clostridial Neurotoxins

Despite being highly toxic, clostridial neurotoxins are highly effective therapeutic agents. BoNT-based therapeutic products are approved by USFDA which include Botox®, Dysport® (BoNT/A complex), Myobloc®, Neurobloc® (BoNT/B complex), and Xeomin® (purified BoNT/A). These products are very popular cosmetic drugs in the world. USFDA also approved BoNT/A for the treatment of strabismus, blepharospasm, and hemifacial spasm. Since BoNT affects autonomous nervous system, it has been shown for effective treatments in hyperhidrosis, migraine, and myofascial pain. However, like other medical drug, BoNT treatment has some side effects too. Since these therapeutic agents are proteins, they have potential for antibody formation leading to a decrease in effectiveness of treatment. Since cholinergic neurons are important part of cognitive systems, BoNT can have potential role there as well and can have long-term effect on cognition (Lackovic et al. 2009; Ney and Joseph 2007). But this has been observed in relatively low number of patients.

8 Potential Future Applications

Each domain of clostridial toxins has very unique characteristics which can be used for some other medical applications. Retargeting of the endopeptidase domain of clostridial neurotoxin neuronal and nonneuronal cells is successfully performed. Retargeted LH_N (light chain fused with N-terminus of heavy chain) with nerve growth factor (NGF) and wheat germ agglutinin (WGA) has already been reported

(Chaddock et al. 2000a, b). BoNT usefulness in alleviating pain is still under investigation. Mechanism is not very clear and there is no clear dose–response relationship. Retargeting technology has been exemplified using a variety of targeting ligands in a diverse range of cell types (Yeh et al. 2011; Pickett 2010; Somm et al. 2012; e.g., HEK (human embryonic kidney) 293 cells and BMDMs (bone marrow-derived macrophages). Additionally, the ability of BoNT and TeNT to transport large polypeptide makes them a good delivery vehicle. TeNT has been shown to transport DNA and enzymes in neurons (Toivonen et al. 2010; Wang et al. 2012). BoNT/A and BoNT/B have been tested for treatment of Parkinson's, rabies, and Tuorette's disease. One thing for sure is that anticholinergic effect of BoNT can be exploited for medicinal applications associated with physiological system employing cholinergic neurons. Above observations suggest that clostridial neurotoxins have become a valuable research and medicinal tool. Also it seems more uses of BoNT and its derivatives are in the offing. In conclusion, Mother Nature has provided a unique molecule with unique characteristics which can be exploited for other beneficial uses.

Botulinum Neurotoxins as Therapeutics

Raja Mehanna and Joseph Jankovic

Contents

Abstract

Since first recognized as the cause of food-borne botulism in the early nineteenth century, botulinum toxin was suggested as a potential treatment for involuntary spasms and movements. Multiple double-blind, placebo-controlled, and open-label studies provided evidence that botulinum toxin is a powerful therapeutic tool in a variety of neurologic and other disorders including ophthalmologic, gastrointestinal, urologic, orthopedic, dermatologic, secretory, painful, and cosmetic disorders. We here review the basic mechanisms of botulinum toxin action at the neuromuscular junction and discuss some of its main clinical applications.

SNARE	Soluble *N*-ethylmaleimide sensitive factor attachment protein receptor
TTA	Therapeutics and Technology Assessment
UBI	Unilateral brow injection
VAMP	Vesicle-associated membrane protein

1 Introduction

Since first recognized in 1817 by Christian Andreas Justinus Kerner as the cause of food-borne botulism, botulinum toxin (BoNT) was suggested as a potential treatment for involuntary spasms and movements. However, it was not until 1973 when Alan Scott, M.D., pediatric ophthalmologist and researcher in San Francisco, demonstrated that BoNT injections into the extraocular muscles improved strabismus in monkeys. The first report of clinical application of BoNT was published in 1984, when it was demonstrated to be safe and effective in the treatment of blepharospasm (Frueh et al. 1984). Subsequent multiple double-blind, placebo-controlled, and open-label studies provided evidence that BoNT was a powerful therapeutic tool in a variety of neurologic and other disorders including ophthalmologic, gastrointestinal, urologic, orthopedic, dermatologic, secretory, painful, and cosmetic disorders (Truong and Jost 2006; Jankovic 2009b; Hallett et al. 2013; Naumann et al. 2013) (Table 1).

We will first review the basic mechanisms of BoNT action at the neuromuscular junction and then discuss some of its main clinical applications.

Table 1 Clinical applications of botulinum toxin

Neurologic disorders
Blepharospasm (lid "apraxia")
Oromandibular–facial–lingual dystonia
Laryngeal dystonia (spasmodic dysphonia)
Cervical dystonia (torticollis)
Limb dystonia
Task-specific dystonia (e.g., writer's cramp)
Other axial/focal/segmental dystonias (primary, secondary)
Hemifacial spasm
Limb, head, voice, jaw tremor
Motor and phonic tics
Palatal myoclonus
Nystagmus and oscillopsia
Myokymia
Spasticity (stroke, cerebral palsy, head injury, multiple sclerosis)
Stuttering
Ophthalmologic disorders
Strabismus
Protective ptosis
Pain disorders
Headaches – chronic migraine especially
Tennis elbow and other sports injuries
Chronic anterior knee pain
Lumbosacral strain and back spasms
Radiculopathy with secondary muscle spasm
Myofascial pain syndromes
Gastrointestinal disorders
Sialorrhea
Spasm of the inferior constrictor of the pharynx (cricopharyngeal muscle)
Achalasia (lower esophageal sphincter spasm)
Obesity (distal stomach)
Spasm of the sphincter of Oddi
Anal fissure
Constipation
Anismus
Genito-urologic disorders
Spastic bladder
Detrusor-sphincter dyssynergia
Overactive bladder
Prostatic hypertrophy
Vaginismus

Table 1 (continued)

Secretory disorders
Hyperlacrimation
Drooling (sialorrhea)
Hyperhidrosis
Gustatory sweating
Cosmetic
Glabellar wrinkles
Brow furrows
Frown lines
"Crow's feet"
Platysma lines
Facial asymmetry
Acne
Others
Diabetic foot ulcers
Pruritus

2 Mechanism of Action of BoNT

2.1 Different and Unique Properties of Various Serotypes of BoNT

The therapeutic value of BoNT is due to its ability to produce local paralysis when injected into a muscle by preventing the release of acetylcholine (Ach) from the presynaptic nerve terminal, also referred to as chemodenervation. There are seven immunologically distinct BoNTs (A–G), with type A being the most studied and most widely used. Synthesized as single-chain polypeptide (molecular weight of 150 kD), each toxin molecule has relatively little potency until it is cleaved by trypsin or bacterial enzymes into a heavy chain (100 kD) and a light chain (50 kD). BoNT exerts its action in a three-step process that involves binding to the receptor to the presynaptic membrane through its heavy chain, internalization of the whole toxin by endocytosis, and enzymatic action of the light chain after it has been cleaved from the heavy chain. The light chain acts as a zinc-dependent protease that selectively cleaves proteins, known as the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) proteins, which are critical for fusion of intraneuronal presynaptic vesicle with the presynaptic membrane, thus preventing the release of Ach. The SNARE target proteins are different for different immunotypes of BoNT. The light chains of both BoNT-A and BoNT-E cleave SNAP-25, but at different sites. The light chains of BoNT-B, -D, and -F cleave synaptobrevin-2, also known as VAMP (vesicle-associated membrane protein), an integral protein of the synaptic vesicle membrane. BoNT-C cleaves both SNAP-25 and syntaxin, another plasma membrane-associated protein. Only types A and B are used clinically.

Table 2 Available types of BoNT in the USA

Generic name	Brand name(manufacturer)	Target
Onabotulinumtoxin A	Botox® (Allergan, Inc., Irvine, CA, USA) or Prosigne® (China)	SNAP 25
Abobotulinumtoxin A	Dysport® (Beaufour Ipsen, France-UK)	SNAP 25
Incobotulinumtoxin A	Xeomin® (Merz Pharmaceuticals GmbH, Frankfurt, Germany)	SNAP 25
Rimabotulinumtoxin B	Myobloc® (US) (WorldMeds, Louisville, KY, USA) or Neurobloc® (Europe)	VAMP (synaptobrevin)

Legend: *BoNT* botulinum toxin, *SNAP* soluble N-ethylmaleimide-sensitive factor attachment protein receptor, *VAMP* vesicle-associated membrane protein

There is considerable evidence that BoNT injected peripherally also influences central nervous system function. By blocking gamma as well as alpha motor neurons, there is denervation of intrafusal muscle fibers. This reduces muscle spindle afferent input to the central nervous system and thereby modifies sensorimotor and proprioceptive pathways (Giladi 1997; Hallett 2000; Rosales and Dressler 2010). These mechanisms may contribute to the therapeutic effects of BoNT in focal dystonias beyond the effects anticipated on the basis of muscle relaxation alone. There is also evidence that BoNT spreads not only to adjacent muscles but also to muscles on the contralateral side of the body (Frick et al. 2012). This is based on a study in which botulinum toxin (2.5 U) was injected into the tibialis muscle of anesthetized rats ($n = 26$) whereas control animals ($n = 25$) received a saline injection. Neuromuscular function, pharmacology, and expression of acetylcholine receptors (nAChRs) were evaluated in the tibialis at 0, 4, and 16 days after injection on the opposite side and in saline-injected controls. Although the mechanism of spread to the contralateral sides is not clear, the investigators demonstrated a decrease in specific twitch tension on the contralateral side and an increased sensitivity to atracurium on the toxin-injected side, despite upregulation of expression of acetylcholine receptors.

The original commercial preparation of BoNT was onabotulinumtoxin A, marketed as Botox® (Allergan, Inc., Irvine, CA, USA). Other forms of BoNT-A clinically available in the USA are abobotulinumtoxin A or Dysport® (Beaufour Ipsen, France-UK) and incobotulinumtoxin A or Xeomin® (Merz Pharmaceuticals GmbH, Frankfurt, Germany) (Albanese 2011). Another type of BoNT-A currently in clinical trials is PureTox® (Johnson & Johnson, USA). In addition, there is a Chinese form of BoNT-A (Prosigne or CBTX-A, Lanzhou Biological Products Institute, China), a Korean preparation (Meditoxin®/Neuronox®, Medy-Tox, South Korea), and many other formulations in experimental clinical trials and in development (Table 2).

Currently, the only preparation of BoNT-B is rimabotulinumtoxin B, known by the brand name Myobloc® (USA) or Neurobloc® (Europe) (US WorldMeds, Louisville, KY, USA). BoNT-B is an antigenically distinct form of BoNT and has unique physical and clinical properties that distinguish it from BoNT-A (Sadick 2003).

It is important to note that the biologic activity, measured in units, is different for the different products. Each preparation should be considered unique in its potency and properties and is measured with proprietary units that are considered to be non-interchangeable (Albanese 2009, 2011). However, through clinical practice when switching from one to another product, also supported by numerous comparison studies, many clinicians have used the following conversion ratios: Dysport® versus Botox® as 2.5 to 1 (Marchetti et al. 2005) and Myobloc/Neurobloc® versus Botox® as 50:1 (Pathak et al. 2006), whereas Xeomin® and Botox® seem to be equivalent in their potency (Jost et al. 2007; Frevert 2010; Dressler et al. 2011).

In Botox® and Dysport®, the BoNT component is formed by botulinum neurotoxin and by nontoxic proteins known as complexing proteins (Dressler and Benecke 2007), whereas the purification and manufacturing process for Xeomin® removes the complexing proteins (Frevert 2009b) giving it the highest specific neurotoxin activity (Frevert 2010).

2.2 Antigenicity and Immunoresistance

In addition to the biologically active toxin, many products include various amounts of nontoxin proteins like hemagglutinins and other proteins that are not required to stabilize the toxin but can have some immune-stimulating activity (Frevert 2009a). Xeomin® and PureTox® are free of such complexing proteins (Frevert 2009b). Some patients stop responding to BoNT injections after sometimes years of benefit. This seems to be secondary to the production of blocking antibodies directed against the heavy chain of the BoNT molecule (Jankovic and Schwartz 1995). Methods used to detect blocking antibodies include the mouse protection assay, the mouse phrenic nerve hemidiaphragm test, and many other tests (Hanna et al. 1999). The most commonly available test is the Western blot assay, but because of its lack of sensitivity and specificity, this test does not reliably predict true immunoresistance (Hanna and Jankovic 1998). A unilateral brow injection (UBI) is a useful clinical test, as inability to frown on the injected side due to weakness of the procerus and corrugator muscles confirms the absence of clinically meaningful immunoresistance (Hanna et al. 1999). The original preparation of Botox® contained 25 ng of neurotoxin complex protein per 100 U, but in 1997, the Food and Drug Administration (FDA) approved a new preparation that contains only 5 ng per 100 U, which has been associated with lower antigenicity (Jankovic et al. 2003). Depending on the technique used to detect blocking antibodies, the risk of antibodies to Botox® has markedly decreased (Mejia et al. 2005) and is now estimated to be about as low as 1.2 % of patients receiving the product repeatedly for up to 4 years (Brin et al. 2008). BoNT-B may be a useful alternative for patients who develop resistance to BoNT-A (Berman et al. 2005), but this preparation may be associated with higher risk of antigenicity (Jankovic et al. 2006). In one study, the effect of BoNT-B was sustained for up to 2.5 years in type A-resistant patients, but the magnitude of response diminished over time (Factor et al. 2005). Although the various neurotoxins are antigenically different, they contain a common subunit structure, and cross-reactive

epitopes may cause cross-neutralization of antibodies (Atassi et al. 2008). Most patients who develop blocking antibodies to one type of BoNT thus have an increased risk of developing blocking antibodies to a different type of BoNT despite a possible initial good response to the new BoNT. While low antigenicity has been predicted with formulations of BoNT without complexing proteins (e.g., Xeomin® and PureTox®), no long-term data are yet available to support this notion.

Although frequently suggested, an association between a large cumulative dose of BoNT and long treatment duration with the development of anti-BoNT antibodies could not be confirmed (Bakheit et al. 2011).

2.3 Adverse Effects

Most of the adverse effects of BoNT are not preventable, but some are clearly associated with wrong dosage, inappropriate selection of muscles, and faulty injection techniques. Clinicians inexperienced with BoNT treatment should consider referral to a specialist experienced with proper use of BoNT. There are many controversies related to BoNT techniques, including the role of electromyography (EMG) in guiding injections, particularly to reach certain muscles (Comella et al. 1992). Although EMG guidance may be appropriate for BoNT treatment of limb dystonia, this does not mean that placement with EMG guidance correlates with better results, since the selection of the muscle involved in the hand dystonia is based on clinical examination and not on EMG (Jankovic 2001). Two class II methodological studies compared EMG versus muscle stimulation for needle localization; one of these studies showed enhanced accuracy of needle placement under EMG guidance (Molloy et al. 2002) while the other was inconclusive (Geenen et al. 1996). A more recent simple blind randomized control study showed that EMG guidance was associated with slightly better clinical outcome and a lower dose of BoNT in the treatment of cervical dystonia (CD), but the control group had a duration of symptoms twice as long as the EMG-guided group, so the results are difficult to interpret (Werdelin et al. 2011).

Side effects of BoNT injection usually result from an excessive weakness in the injected muscles. Local reactions include pain, edema, erythema, ecchymosis, headache, and short-term hyperesthesia (Lu and Lippitz 2009). The toxin can also diffuse to adjacent muscles and result in unwanted weakness. A number of factors seem to influence diffusion of BoNT including injection technique, concentration, and volume (Ramirez-Castaneda et al. 2013). Rarely, the toxin spreads systemically to distant sites resulting in mild generalized muscle weakness, malaise, nausea, fatigue, rash, or flu-like symptoms (Naumann et al. 2006; Baizabal-Carvallo et al. 2011; Dressler 2010a). It has been proposed that systemic distribution may be mediated by capillary or venous uptake and the volume of fluid used for BoNT reconstitution may increase systematic spread (Crowner et al. 2010).

The most common adverse effects encountered when using BoNT for CD include injection-site pain, muscle weakness, dysphagia, dry mouth, and flu-like symptoms (Poewe et al. 1998; Mejia et al. 2005; Naumann et al. 2006). Flu-like

symptoms occur in 1.7–20 % of BoNT-A injections (Baizabal-Carvallo et al. 2011) without marked differences between various serotypes of formulations although head-to-head comparisons are lacking. This side effect, however, seems to be more frequent with BoNT-B, observed in 5–55 % of injections (Baumann et al. 2003; Baumann et al. 2005a, b). The BoNT-related flu-like symptoms are typically mild, develop within 10 days of the injection, and last an average of 2–3 days, but may last up to 14 days and in rare cases render the patient bedridden. The symptom can be usually relieved with over-the-counter antipyretics and analgesics (Baizabal-Carvallo et al. 2011).

Results of a meta-analysis of 36 randomized controlled studies comprised of 1,425 subjects who received treatment with Botox® for various indications reported a rate of mild-to-moderate adverse effects of approximately 25 % in the Botox®-treated group compared with 15 % in the control group ($p < 0.001$). No severe adverse events, however, have been reported (Naumann and Jankovic 2004). In February 2008 the FDA expressed concern about potential severe adverse effects (respiratory compromise and death) associated with the use of onabotulinumtoxin A, based on submitted reports of children treated for cerebral palsy-associated limb spasticity. According to evidence-based clinical guidelines published by the American Academy of Neurology (AAN) in 2010, BoNT is considered to be an effective treatment for spasticity in children and adolescent with cerebral palsy (Delgado et al. 2010). In the 17 studies they reviewed, the most common adverse effects were localized pain, unsteadiness and increased falls, and fatigue. Although excessive weakness was noted in some cases, no deaths were reported.

The Cervical Dystonia Patient Registry for the Observation of Botulinum Toxin Type A Efficacy Study (CD-PROBE) is an ongoing registry aimed at understanding the use of Botox® in the treatment of CD (Jankovic et al. 2011a). Preliminary results from CD-PROBE suggest that repeated injections of Botox® have a low rate of adverse effects and are associated with meaningful and sustained relief of CD pain and improvement in quality of life (Charles et al. 2010). This has been confirmed by other retrospective series (Camargo et al. 2011), and there are other longitudinal observational studies currently under way designed to provide data on long-term clinical use of BoNT (Fernandez et al. 2013a, b).

Patients with post-polio syndrome and Eaton–Lambert syndrome, however, have been reported to have generalized weakness after local BoNT (Erbguth et al. 1993). Other contraindications to the use of BoNT include myasthenia gravis, motor neuron disease, concurrent use of aminoglycoside antibiotics, and pregnancy, although women, inadvertently injected during pregnancy, reported no untoward side effects to the fetus (Jankovic 2010a).

3 Clinical Application

BoNT is currently used in a wide variety of disorders, a few of which have been approved by the FDA (Table 3) or recommended by medical organizations (Table 4).

Table 3 FDA-approved botulinum toxin products

Trade name	Drug name	FDA-approved indications
Botox®	Onabotulinumtoxin A	Cervical dystonia, severe primary axillary hyperhidrosis, strabismus in patients ≥12 years old, blepharospasm in patients ≥12 years of age. Upper limb spasticity in adult patients. Temporary improvement in the appearance of moderate to severe glabellar lines
Dysport®	Abobotulinumtoxin A	Cervical dystonia, temporary improvement in the appearance of moderate to severe glabellar lines
Xeomin®	Incobotulinumtoxin A	Cervical dystonia, blepharospasm
Myobloc®	Rimabotulinumtoxin B	Cervical dystonia

Table 4 Level of evidence for clinical use of BoNT

Level A (established effective)	Blepharospasm Cervical dystonia Spasticity in adults Equinus varus deformity in children with cerebral palsy Axillar hyperhidrosis Anal fissure Idiopathic detrusor overactivity
Level B (possibly effective)	Hemifacial spasm Adductor laryngeal dystonia Adductor spasticity in children with cerebral palsy Focal upper extremity dystonia Upper extremity essential tremor Palmar hyperhidrosis Pain control in children with cerebral palsy and upper extremity spasticity Allergic rhinitis Sialorrhea.
Level C (probably effective)	Gustatory sweating Oromandibular dystonia Laryngeal dystonia.

3.1 Neurological Disorders

Since the first placebo-controlled trials of BoNT in the treatment of CD (Tsui et al. 1985, 1986) and cranial dystonia, including blepharospasm (Jankovic and Orman 1987), hundreds of other studies have been published confirming the efficacy and safety of BoNT in a variety of movement disorders and other neurologic and non-neurologic disorders.

The Therapeutics and Technology Assessment (TTA) Subcommittee of the American Academy of Neurology, in their 2008 evidence-based review (currently being revised), assigned level A recommendation for the use of

BoNT for the treatment of CD and a level B recommendation for blepharospasm (Simpson et al. 2008a, b). This evidence-based review was recently updated by a panel of experts (Hallett et al. 2013). The panel evaluated published data on the four individual commercially available formulations: abobotulinumtoxinA (A/Abo), onabotulinumtoxinA (A/Ona), incobotulinumtoxinA (A/Inco), and rimabotulinumtoxinB (B/Rima) and made the following recommendations: "For the treatment of blepharospasm, the evidence supported a Level A recommendation for BoNT-A, A/Inco, and A/Ona; a Level B recommendation for A/Abo; and a Level U recommendation for B/Rima. For hemifacial spasm, the evidence supported a Level B recommendation for BoNT-A and A/Ona, a Level C recommendation for A/Abo, and a Level U recommendation for A/Inco and B/Rima. For the treatment of oromandibular dystonia, the evidence supported a Level C recommendation for BoNT-A, A/Abo, and A/Ona, and a Level U recommendation for A/Inco and B/Rima. For the treatment of cervical dystonia, the published evidence supported a Level A recommendation for all four BoNT formulations. For limb dystonia, the available evidence supported a Level B recommendation for both A/Abo and A/Ona, but no published studies were identified for A/Inco or B/Rima, resulting in a Level U recommendation for these two formulations. For adductor laryngeal dystonia, evidence supported a Level C recommendation for the use of A/Ona, but a Level U recommendation was warranted for B/Rima, A/Abo, and A/Inco. For the treatment of focal tics, a Level U recommendation was warranted at this time for all four formulations. For the treatment of tremor, the published evidence supported a level B recommendation for A/Ona, but no published studies were identified for A/Abo, A/Inco, or B/Rima, warranting a Level U recommendation for these three formulations".

3.1.1 Blepharospasm

In 1987, Jankovic and Orman reported the results of a double-blind, placebo-controlled trial of onabotulinumtoxin A (Botox®) in 28 patients with cranial-cervical dystonia, including blepharospasm, oromandibular dystonia, and CD, the results of which were in part used by the FDA to approve Botox® in 1989 as a therapeutic agent in patients with strabismus, blepharospasm, and hemifacial spasm (Jankovic and Orman 1987). Subsequently there have been many other studies confirming the safety and efficacy of BoNT-A in the treatment of blepharospasm (Elston 1987; Mejia et al. 2005; Jankovic 2004; Kenney and Jankovic 2008; Gil Polo et al. 2013). Because of the paucity of double-blind, placebo-controlled trials (Roggenkämper et al. 2006), the TTA Subcommittee of the American Academy of Neurology concluded that there is only level B (probably effective) evidence for the efficacy of BoNT-A for the treatment of blepharospasm (Simpson et al. 2008b). This recommendation will likely be changed to level A as a result of more recent, well-designed, controlled trials with various BoNT products.

The onset of the Botox® effect occurs within 24–72 h, peaks at 2–4 weeks, and lasts 3–6 months (Tan 2005). While about a third of all treatment sessions are followed by some side effects (ptosis, blurring of vision or diplopia, tearing, and local hematoma), only 1–2 % affect patient's functioning, and complications

usually improve spontaneously in less than 3 weeks (Elston 1987; Roggenkämper et al. 2006). The relationship between blepharospasm, BoNT, and occurrence of dry eyes in some patients is not well understood.

In a small prospective, randomized, double-blind study on 21 patients with blepharospasm, Prosigne® was found to have similar efficacy, safety, and tolerability than Botox® with a 1:1 dose equivalence (Quagliato et al. 2010a).

Dysport® has also showed sustained efficacy and favorable safety profile with 80 U/eye (Truong et al. 2008a; Truong 2012). The onset of action occurs within 2 weeks of treatment, peaks at 4–8 weeks, and lasts 10–16 weeks (Odergren et al. 1998). In an early double-blind study in patients with blepharospasm who received one injection of Botox® and one injection of Dysport® in two separate treatment sessions, there was similar efficacy and no significant difference in the duration of the treatment effect between the two preparations, although there were significantly ($p < 0.05$) fewer side effects with Botox® (particularly ptosis; $p < 0.01$) (Nüssgens and Roggenkämper 1997). A more recent study however noted that the mean duration of improvement of blepharospasm was significantly longer for Dysport® (Bentivoglio et al. 2009), but confirmed Dysport® had a higher rate of adverse effects. Finally, another study that evaluated the effect of Botox® after switching from Dysport® showed that Botox® was more effective and had a longer duration of effect than Dysport® (Bihari 2005).

The efficacy and safety of Xeomin® in the treatment of blepharospasm was demonstrated by a prospective, double-blind, placebo-controlled, randomized, multicenter study involving 109 patients (Jankovic et al. 2011b). An open-label extension of that study demonstrated maintained efficacy and good tolerability of Xeomin® at 48 weeks, after an average of five injections (Grafe and Hanschmann 2010; Grafe et al. 2010). In that study, the most commonly reported adverse effects were eyelid ptosis, dry eye, and dry mouth. Xeomin® was found to be clinically non-inferior to Botox® in head-to-head studies (Roggenkämper et al. 2006) (Jankovic 2009a; Wabbels et al. 2011). There is no difference between the two preparations in efficacy, safety profile, onset of action, duration, and waning of effect (Jost et al. 2007; Grafe et al. 2009a). Xeomin® is FDA approved for the treatment of blepharospasm (Barnes et al. 2010).

Myobloc® has also been used successfully in the treatment of blepharospasm, especially in Botox®-resistant patients (Dutton et al. 2006), although double-blind controlled studies in these disorders are lacking (Colosimo et al. 2003). However, side effects are more common than typically expected of BoNT-A, particularly pain on injection, ptosis, dry mouth, and dry eyes (Dutton et al. 2006).

Apraxia of eyelid opening, especially when associated with blepharospasm, seems to improve with injection of the pretarsal orbicularis oculi and injection of the pretarsal portion of the eyelid, or pars ciliaris at the lid margin seems critical for the treatment to be effective in that condition (Inoue and Rogers 2007).

3.1.2 Other Cranial Dystonias

Oromandibular dystonia (OMD) is among the most challenging forms of focal dystonia to treat as it rarely improves with medications (Jankovic and Orman 1988;

Klawans and Tanner 1988; Sankhla et al. 1998). Also, there are no surgical treatments, and BoNT therapy can be complicated by swallowing problems. Clenching, trismus, and bruxism are frequent manifestations of oromandibular dystonia. Although most of the data on BoNT in the management of oromandibular dystonia (OMD) come from open-label studies, these provide compelling evidence on the efficacy of both BoNT-A and BoNT-B in patients with OMD (Wan et al. 2005; Jankovic and Orman 1987; Tan and Jankovic 2000; Laskawi and Rohrbach 2001; Alonso-Navarro et al. 2011). Patients with dystonic jaw closure, treated with injections into the masseter and temporalis muscles, generally respond better than those with jaw-opening dystonia. Although most patients with jaw-opening dystonia benefit from injections into the submentalis muscle complex, some may also require injections into the lateral pterygoid muscles (Evidente and Adler 2010). As with blepharospasm, the improvement is usually noted within the first 5 days and persists for about 3–4 months. Early BoNT treatment of oromandibular dystonia, particularly when associated with trismus and bruxism, may prevent dental and other complications, including the temporomandibular joint syndrome.

Frowning without blepharospasm, as a manifestation of upper facial dystonia, often seen in parkinsonian patients, particularly those with progressive supranuclear palsy, can be also effectively treated with BoNT (Hirota et al. 2008).

3.1.3 Laryngeal Dystonia (Spasmodic Dysphonia)

Several studies have established the efficacy and safety of Botox®, Dysport®, and Myobloc® in the treatment of adductor laryngeal dystonia, produced by involuntary contraction of the thyroarytenoid muscle, and this approach is now considered by most to be the treatment of choice for spasmodic dysphonia (Adler et al. 2004b; Wan et al. 2005; Upile et al. 2009). Adverse effects include transient breathy hypophonia, hoarseness, and rarely dysphagia with aspiration (Wan et al. 2005). This approach usually requires a multidisciplinary team, consisting of an otolaryngologist experienced in laryngeal injections and a neurologist knowledgeable about motor disorders of speech and voice. There are three approaches currently used in the BoNT treatment of spasmodic dysphonia: (1) unilateral EMG-guided injection; (2) bilateral approach, injecting with EMG guidance in each vocal fold; and (3) an injection via indirect laryngoscopy without EMG. Irrespective of the technique, most investigators report about 75–95 % improvement in voice symptoms (Jankovic 2010a). However, when Dysport® is used, it seems that unilateral injections are safer than, and as effective as, bilateral injections (Troung et al. 1991; Upile et al. 2009). BoNT produces less consistent benefits when spasmodic dysphonia is accompanied by voice tremor. As for abductor spasmodic dysphonia, one class III prospective, randomized, crossover treatment study involving 15 patients showed no objective benefit of Botox®, whether injected percutaneously or transnasally into the posterior cricoarytenoid muscle (Bielamowicz et al. 2001). However, anecdotal experience from centers that frequently treat patients with spasmodic dysphonia indicates that BoNT-A is an effective treatment even in the abductor form, although the effects are more consistent in patients with adductor form of spasmodic dysphonia (Evidente and Adler 2010).

3.1.4 Cervical Dystonia (CD)

The introduction of BoNT in the treatment of CD has changed the natural history of this disease in that cervical contractures are now much less frequent than they were prior to BoNT (Ramirez-Castaneda and Jankovic 2013). The efficacy and safety of BoNT in the treatment of CD have been demonstrated in several controlled and open trials (Brashear et al. 1999; Brin et al. 1999; Truong et al. 2005, 2010), and the TTA Subcommittee of the American Academy of Neurology concluded that there is level A (effective) evidence for the efficacy of Botox® for the treatment of CD (Simpson et al. 2008b). The most common treatment-related adverse events of BoNT in CD are mild-to-moderate weakness, dysphagia, dry mouth, neck pain, and injection-site pain.

In one of the first clinical trials to evaluate the efficacy of BoNT for the treatment of CD, treatment with Botox® produced significant improvement including reduction in pain. Side effects were few and no significant systemic adverse reactions were noted (Tsui et al. 1986). These results have since been confirmed in numerous short-term (Brin et al. 1987; Gelb et al. 1989; Greene et al. 1990) and long-term studies (Jankovic and Schwartz 1990; Ramirez-Castaneda and Jankovic 2013).

In a small prospective, randomized, double-blind study on 24 patients with CD, Prosigne® was found to have similar efficacy, safety, and tolerability than Botox® with a 1:1 dose equivalence (Quagliato et al. 2010b).

Dysport® was also shown to be significantly more efficacious than placebo at weeks 4, 8, and 12 in a multicenter, double-blind, randomized, placebo-controlled trial on 80 patients with blurred vision and weakness as the only side effects to occur significantly more often with Dysport® (Truong et al. 2005). These results were confirmed by multiple other randomized, double-blind, placebo-controlled trials (Truong et al. 2008b, 2010; Wissel et al. 2001; Truong and Jost 2006). Dysport® has also been shown to be more effective and better tolerated than trihexyphenidyl in the treatment of CD (Brans et al. 1996).

A recent study that evaluated the safety, efficacy, and duration of effect of Botox® after switching from Dysport® in patients with CD showed that Botox® had more efficacy and a longer duration of effect than Dysport® (Bihari 2005). However, another study showed Dysport® to be more effective than Botox® with higher adverse effects, although none of these required withdrawal of therapy or specific management (Ranoux et al. 2002). Finally, a systematic review showed Dysport® to cause more dysphagia than Botox®, possibly as a result of a greater diffusion (Chapman et al. 2007).

Myobloc® has been shown to be more effective than placebo in both type A-responsive and type A-resistant CD (Brashear et al. 1999; Brin et al. 1999; Lew et al. 1997) and may be an alternative in patients who have developed resistance to BoNT-A (Brin et al. 1999). Botox® and Myobloc® were directly compared at 1:40 dose ratio in 139 patients with CD, with no difference in improvement at 4 weeks following injection, but with more frequent dysphagia and dry mouth with Myobloc® (Comella et al. 2005). Another study on 111 patients with CD randomized to receive either Botox® or Myobloc/Neurobloc® at a dosing ratio of 66.7 showed no significant differences in the efficacy or occurrence of

injection-site pain and dysphagia. Dry mouth however was consistently found to be more frequent with Myobloc/Neurobloc® than with Botox® (Pappert et al. 2008). A report of a 44 % of BoNT-B antibody-induced therapy failure in toxin-naïve CD patients after a relatively short exposure may however limit its use (Dressler and Bigalke 2005).

The risk of immunoresistance seems to be higher with Myobloc® than with Botox®. In a prospective, open-label, multicenter study of 333 BoNT-naïve patients with CD, after a median of 9 of Botox® treatments over a mean of 2.5 years (range: 3.2 months to 4.2 years), only 1.2 % tested positive for blocking antibodies (Brin et al. 2008). In one study of 100 patients with CD followed for 42 months over a mean of 5 (up to 12) visits, a third of the patients who were negative for BoNT-B antibodies at baseline became positive for such antibodies at the last visit (Jankovic et al. 2006). Thus, although BoNT-B offers a useful alternative to patients with immunoresistance to BoNT-A, long-term efficacy is limited by the development of blocking antibodies, probably as a result of the cross-reactivity between the two serotypes.

Xeomin® was shown to be an effective and safe treatment of CD in a double-blind, placebo-controlled study of 233 patients, 39 % of which were BoNT naïve (Comella et al. 2011). It was found to be as effective and safe as Botox® in three different clinical trials totaling 816 patients with a 1:1 dose ratio (Jost et al. 2007) and in several other series (Benecke et al. 2005; Dressler 2009). Xeomin® seems to have similar efficacy and safety among treatment-naïve and previously treated patients (Grafe et al. 2009a, b, c; Fernandez et al. 2013a). Repeated treatments with Xeomin® seem effective and well tolerated (Grafe and Hanschmann 2010; Evidente et al. 2013). The clinical effect of Xeomin® begins within 1 week, peaks at approximately 4–6 weeks, and is sustained for about 110 days (Jost et al. 2007). The most frequently reported adverse effects of Xeomin® are mild dysphagia, neck pain, and muscle weakness (Comella et al. 2011). Xeomin® is FDA approved for the treatment of CD (Barnes et al. 2010).

3.1.5 Writer's Cramp, Other Limb Dystonias, and Axial Dystonia

The treatment of hand dystonia with BoNT is more challenging than the other dystonias, because there are more muscles involved in finely coordinated motor function required in the act of writing, dressing, and in various demanding tasks such as playing musical instruments and sport activities. Several open and double-blind controlled trials have concluded that BoNT injections into selected hand and forearm muscles probably provide the most effective relief in patients with various task-specific and occupational dystonias. BoNT stands as the first-line treatment of choice for the majority of focal dystonias (Albanese et al. 2006; Benecke and Dressler 2007; Albanese et al. 2011) and seems to retain its efficacy a decade after initiation of treatment (Lungu et al. 2011). BoNT has also been used to effectively correct abnormal limb postures seen in other movement disorders such as foot dystonia and striatal hand in Parkinson's disease patients (Giladi et al. 1994; Pacchetti et al. 1995), progressive supranuclear palsy, and corticobasal degeneration (Cordivari et al. 2001; Vanek and Jankovic 2001).

A marked improvement in the severity and disability was achieved with EMG-guided injection of BoNT-A in 93 patients with writer's cramp, whereas primary writing tremor was little improved (Marion et al. 2003). In one study, 69 % of 84 musicians reported improvement with EMG-guided Dysport® injections, but only 36 % reported long-term benefit (Schuele et al. 2005). Dysport® was also shown to be effective in a class I randomized, double-blind, placebo-controlled trial in 40 patients with writers' cramp (Kruisdijk et al. 2007) as well as in a class II study (Contarino et al. 2007). On the other hand, Botox® improved focal hand dystonia in 80 % of patients in a class II double-blind, placebo-controlled, crossover study (Cole et al. 1995), with similar results found in another class II study (Tsui et al. 1993).

BoNT has also been used in the treatment of axial postural abnormalities secondary to axial dystonia, with variable success (Jankovic 2010b). One study reported improvement of six of nine patients with lateral axial dystonia (scoliosis) after EMG-guided injection of 500 U of Dysport® into paraspinal muscles at the level of L2–L5 on the side of the trunk flexion (Bonanni et al. 2007). Another study reported improvement of camptocormia in 9 of 11 patients who received 300–600 U of Botox® into the rectus abdominis (Azher and Jankovic 2005). In contrast, ultrasound-guided injection of the iliopsoas muscle with BoNT is not effective in camptocormia (von Coelln et al. 2008).

3.1.6 Hemifacial Spasm

Hemifacial spasm is defined as a neurologic disorder manifested by involuntary, recurrent twitches of the eyelids and other muscles of only one side of the face (Yaltho and Jankovic 2011). The muscular contractions result from an irritative lesion of the ipsilateral facial nerve, most commonly from compression by a vascular loop. While microvascular decompression of the facial nerve has a high success rate, this surgical treatment is associated with certain risks, such as permanent facial paralysis, deafness, stroke, and even death. Therefore, local injections of BoNT into involved facial muscles offer a useful alternative to surgical therapy. Nearly all patients improve; the complications are minimal and transient, and the approach can be individualized by injecting only those muscles – the contractions of which are most disturbing to the patient. Along with blepharospasm, the FDA approved onabotulinumtoxin A injections for hemifacial spasm in 1989.

The average latency from injection to the onset of benefit is 5.4 days, and the total duration of benefit averages 18.4 weeks. Side effects include facial weakness, lid weakness, ptosis, teary or dry eyes, diplopia, and hematoma. The average duration of improvement in hemifacial spasm, 5 months, is longer than in any of the dystonic disorders, and rare patients have achieved long-lasting remissions. Facial myoclonus associated with Rasmussen encephalitis, similar to hemifacial spasm, but pathophysiologically related to focal cortical seizure, has been also reported to improve with BoNT (Jankovic 2010a).

The frequent use of Botox® and Dysport® in the treatment of hemifacial spasm stems mainly from extensive open-label and clinical experience (Gil Polo et al. 2013)

rather than from controlled trials (Jankovic et al. 1990; Jost and Kohl 2001; Kenney and Jankovic 2008). In one class II prospective, blinded study, Botox® was showed to be safe and effective (Yoshimura et al. 1992).

One study that evaluated the effect of Botox® after switching from Dysport® showed that Botox® was more efficacious in treating hemifacial spasm dystonia or hemifacial spasm and had a longer duration of effect than Dysport® (Bihari 2005). However, a class II single-blind, randomized, parallel-design study comparing Botox® and Dysport® at a dose ratio of 1:4 in 91 patients with hemifacial spasm or blepharospasm showed similar clinical efficacy and tolerability of both products (Sampaio et al. 1997). Xeomin® has been shown to be as effective and as safe as Botox®, with a ratio of 1:1 in 17 patients with hemifacial spasm (Dressler 2009). Prosigne® was found to have similar efficacy, safety, and tolerability than Botox® with 1:1 dose equivalence on 36 patients with hemifacial spasm (Quagliato et al. 2010a).

Myobloc® has also been used successfully in the treatment of hemifacial spasm, although double-blind controlled studies in this disorder are lacking (Colosimo et al. 2003; Trosch et al. 2007).

3.1.7 Tremor

Tremor accompanies dystonia in about half of all dystonic patients, and dystonic tremor improves in some patients treated for focal dystonia with BoNT. Chemodenervation with Botox® may ameliorate not only dystonic tremor but also essential tremor involving the hands, as demonstrated by at least two double-blind, placebo-controlled studies (Jankovic et al. 1996; Brin et al. 2001). When wrist extensor injections are avoided, weakness of finger extensors, noted in the initial studies, can be prevented. BoNT can also be considered for rest tremor associated with Parkinson's disease (PD) when antiparkinsonian treatments fail to insure satisfactory relief (Jankovic and Schwartz 1991; Diamond and Jankovic 2006a, b). In an open-label pilot study, Dysport® injection in the masseters markedly improved jaw tremor in 3 PD patients (Schneider et al. 2006).

However, essential tremor and dystonic tremor seem to respond better to BoNT than rest tremors related to PD, and further studies are needed to demonstrate efficacy of BoNT for the latter and to provide insights on how to improve the treatment protocol (Jankovic 2009b).

Although Botox® is clearly a useful treatment in patients with hand tremor, it has also been found effective in the treatment of voice tremor (Adler et al. 2004a) and head tremor (Pahwa et al. 1995). In a small, randomized, crossover trial of onabotulinumtoxin A in 23 patients with disabling tremor in 33 upper limbs related to MS, there was a significant improvement after active treatment compared with that after placebo at 6 and 12 weeks after injection in the Bain score for tremor, writing, Archimedes spiral drawing, drinking from a cup, and in the 9-hole peg test (Van Der Walt et al. 2012). There was, however, no improvement in the quality of life as measured by the Quality of Life in ET Questionnaire (QUEST). Treatment was complicated by transient weakness, noted in 42.2 % of patients treated with BTX, compared to 6.1 % of patients treated with placebo ($p = 0.0005$).

3.1.8 Tics

Motor and phonic tics associated with Tourette syndrome typically improve with antidopaminergic drugs, but when these drugs do not adequately control the tics or are associated with troublesome side effects, BoNT injections into the affected body parts not only may provide satisfactory control of the tics but also may eliminate the premonitory urge. BoNT treatment is particularly useful in the treatment of focal motor tics and phonic tics, including coprolalia. In a placebo-controlled class II study of 18 patients with simple motor tics (Marras et al. 2001), Botox® treatment was associated with a 39 % reduction in the number of tics per minute within 2 weeks after injection against a 6 % increase in the placebo group ($p = 0.004$). In addition, there was a 0.46 reduction in "urge scores" with BoNT, against a 0.49 increase in the placebo group ($p = 0.02$). This preliminary study, however, lacked the power to show significant differences in other measured variables, such as severity score, tic suppression, pain, and patient global impression. However, it measured the results at 2 weeks, when the full effects of Botox® may have not yet been appreciated, and measured the effect of one treatment only, whereas several adjustments in doses and sites of injections over several treatment visits are usually needed in clinical practice. Another class IV open-label study of 15 patients with simple motor tics showed long-term efficacy of Botox® (Rath et al. 2010), with a permanent remission of the treated tic in three patients at 10 years' follow-up. The premonitory urge was similarly reduced.

3.1.9 Spasticity and Other Hypertonic Disorders

In addition to involuntary movement disorders, BoNT has been used effectively to treat spasticity associated with cerebral palsy, multiple sclerosis, or following stroke.

There is extensive data from clinical trials indicating that Botox® is well tolerated and effective in reducing focal upper limb hypertonia following stroke (Childers et al. 2004; Gordon et al. 2004; Turkel et al. 2006; Elia et al. 2009; Simpson et al. 2009). A meta-analysis of seven multicenter, randomized, double-blind, placebo-controlled, parallel-group trials totaling 544 poststroke patients showed that Botox® decreased poststroke spasticity in upper limb-injected muscles proportionally to the dose of BoNT used. Injected muscles included the flexor carpi ulnaris (FCU), flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), flexor digitorum profundus (FDP), and biceps brachii (BB) (Yablon et al. 2011). A multicenter, randomized, double-blind, placebo-controlled study of 120 poststroke patients with lower limb spasticity showed that a onetime Botox® injection yielded significant improvement at 4, 5, and 8 weeks (Kaji et al. 2010). Experienced injectors have recommended the following doses of Botox in the treatment of spasticity: for the lower limb, 3–6 U/kg per muscle; for the upper limb above the elbow, 2–3 U/kg per muscle; and for the upper limb below the elbow and posterior tibialis, 0.5–2 U/kg per muscle (Jankovic 2010a).

A double-blind, placebo-controlled, crossover study also demonstrated improvement in spasticity of thigh adductors in patients with multiple sclerosis after receiving Botox® with subsequent functional gain, specifically easier nursing care, and better comfort when sitting in a wheelchair (Snow et al. 1990).

Dysport® also seems to improve upper limb and, to a lesser extent, lower limb spasticity secondary to stroke (Keam et al. 2011).

Xeomin® was also shown to be effective in reducing poststroke upper limb spasticity in a recent open-label study of 145 patients (Kanovsky et al. 2011).

Based on the review of 11 class I trials for adult upper extremity spasticity, one of them using BoNT-B, and three class I trials for lower limb spasticity, the AAN recommends that BoNT should be offered as a treatment option to reduce muscle tone and improve passive function in adults with spasticity (Simpson et al. 2008a).

Several reviews have assessed the therapeutic effect of BoNT-A, Botox® and Dysport® confounded, for spasticity of the upper or lower limbs secondary to cerebral palsy and the consequent impact on quality of life (Lannin et al. 2006; Naumann et al. 2006; Park and Rha 2006; Coutinho et al. 2011). A meta-analysis of 20 randomized controlled trials of Botox® and/or Dysport® versus placebo or rehabilitation, totaling 882 patients, showed that BoNT-A has a good safety profile during the first months of use, with however more systemic side effects. BoNT-A use was related to respiratory tract infection, bronchitis, pharyngitis, asthma, muscle weakness, urinary incontinence, falls, seizures, fever, and unspecified pain (Albavera-Hernández et al. 2009). Since a dose–response relationship has been observed in the frequency and severity of adverse events of BoNT-A (Naumann et al. 2006), it is possible that children with cerebral palsy have a higher probability of occurrence since they require high doses of toxin relative to their body mass.

In children with cerebral palsy, Botox® (2–8, up to 16 U per kg body weight per muscle) is often found effective when injected in calf muscles to correct equinus deformity and toe walking and in the hamstring muscles to correct crouch and scissor gait, improve sitting and hygiene care, and reduce pain. In a double-blind, controlled study, patients with cerebral palsy receiving 40–80 U of Botox® per muscle experienced a significantly greater improvement in Ashworth score and gait measures than the "low-dose" group (20–40 U per muscle) (Wissel et al. 1999). Multiple studies of Botox® or Dysport® injections into the gastrocnemius showed gait improvement over 1–3 months (Simpson et al. 2008a). One randomized, double-blind, placebo-controlled study injecting Dysport® into the thigh adductors and medial hamstrings of children with adductor spasticity showed significant improvement in knee-to-knee distance as well as adductor muscle tone (Mall et al. 2006). The results of many of the studies are difficult to interpret and compare, because patients with various forms and etiologies of spasticity were enrolled and different methodologies were used to inject and rate the patients. Although some double-blind trials have demonstrated meaningful functional improvement in patients with spasticity, other controlled studies have failed to demonstrate improvement. Many of the published studies suffer methodological problems, particularly in selecting the appropriate outcome measures that may or may not capture the functional goals of the patients. The AAN granted BoNT injections a level A of evidence for the treatment of equinovarus deformity in children with cerebral palsy and a level B for treatment of adductor spasticity and for pain control and in children with cerebral palsy and upper extremity spasticity (Level B) (Simpson et al. 2008a).

Xeomin® was reported useful in treating acquired brain injury-induced upper limb spasticity in a series of 192 patients (Barnes et al. 2010) and lower limb spasticity in one case report (Lippert-Gruner and Svestkova 2011). It has been shown to be as effective and as safe as Botox, with a ratio of 1:1 in a series of 94 patients with spasticity (Dressler 2009).

3.2 Painful Disorders

3.2.1 Headache

No significant difference between Botox® and placebo could be demonstrated in four different studies on patients suffering from episodic migraines, defined as less than 15 days of headache per month (Silberstein et al. 2000; Elkind et al. 2006; Relja et al. 2007; Saper et al. 2007; Naumann et al. 2008). Similarly, out of 4 studies of Botox® for chronic daily headache, none demonstrated a significant effect of Botox® on the primary outcome measure (Mathew et al. 2005). Botox® was also ineffective in treating chronic tension headaches in four randomized, placebo-controlled studies (Naumann et al. 2008). Another study reported that imploding headaches (head seems to be crushed, clamped, or stubbed by external forces) and ocular headaches (eye-popping pain) were more likely to respond to Botox® than exploding headaches (buildup of pressure inside the head) (Jakubowski et al. 2006).

One controlled study demonstrated the effectiveness of fixed-site administration of 100 U of Botox® in the treatment of patients with chronic migraine who specifically did not overuse pain medication (Freitag et al. 2008). However, 150 U of Botox would be needed in patients with chronic migraine and medication overuse (Grazzi, 2013). Chronic migraine is defined as headache occurring $\geq$15 days per month for $\geq$3 months, with headaches occurring on $\geq$8 days being classified as migraine headaches or headaches that respond to migraine-specific medications (Olesen et al. 2006). More recently, pivotal results from the Phase III Research Evaluating Migraine Prophylaxis Therapy (PREEMPT) clinical program involving two double-blinded, placebo-controlled studies established Botox® as a safe, well-tolerated, and effective headache prophylactic treatment for chronic migraine using a combination of fixed-site administration and follow-the-pain approach, at doses ranging from 155 to 195 U administered across seven head and neck muscles every 12 weeks for up to five treatment cycles (Aurora et al. 2010; Blumenfeld et al. 2010; Diener et al. 2010; Dodick et al. 2010). However, these results were not replicated with Dysport® (Chankrachang et al. 2011).

The antinociceptive effect of BoNT in headache was initially thought to be a result of relief of muscle spasms, but in vitro studies have shown that BoNT blocks the peripheral release of pain and inflammatory neurotransmitters such as glutamate, substance P, and calcitonin gene-related peptide (Aoki 2003, 2005; Gazerani et al. 2009). Moreover, it has been inferred from animal studies that BoNT-A exerts its antinociceptive effects through retrograde transport and involvement of the central nervous system (Bach-Rojecky and Lacković 2009).

3.2.2 Chronic Knee Pain

In one randomized, double-blind, placebo-controlled, crossover trial on 24 patients with chronic anterior knee pain associated with quadriceps muscle imbalance, one 500 U injection of Dysport® in the vastus lateralis associated with retraining of the vastus medialis provided marked pain improvement compared to placebo. This intervention permitted patients to restore a more balanced knee extensor control during functional activity (Singer et al. 2011).

3.2.3 Painful Limbs/Moving Extremities

The syndrome of painful limbs/moving extremities describes a clinical condition characterized by involuntary toe or finger movement associated with pain in the affected hand/arm or foot/leg. Botox® injections in the involved muscles have been shown to improve pain and movement in some case reports (Singer and Papapetropoulos 2007; Eisa et al. 2008).

3.2.4 Other Pain Syndromes

BoNT-A seems effective in controlling musculoskeletal pain, such as myofascial pain, low back pain, trigeminal neuralgia, and other chronic pain syndromes (Reilich et al. 2004; Sycha et al. 2004; Bhidayasiri and Truong 2005; Bohluli et al. 2011). However, these conditions represent a diverse group, and the results with BoNT-A have not been universally positive (Waseem et al. 2011; Zhang et al. 2011). A recent meta-analysis failed to confirm any significant improvement of neck pain after BoNT-A injection (Langevin et al. 2011a, b).

3.3 Hyperhidrosis

Several well-designed trials have demonstrated efficacy of intradermal injection of Botox® and Dysport® in axillar (Heckmann et al. 2001; Naumann and Lowe 2001; Doft et al. 2011; Dressler and Adib Saberi 2013) and palmar hyperhidrosis (Lowe et al. 2002; Solish et al. 2007; Ito et al. 2011). A within-subject comparison showed similar effectiveness and tolerance but longer duration of action of Dysport® compared to Botox® (Simonetta et al. 2003). Xeomin® has been shown to be as effective and as safe as Botox®, with a ratio of 1:1 in 64 patients with hyperhidrosis (Dressler 2009). This was confirmed by a double-blinded study on 46 patients complaining of axillar hyperhidrosis with injection of Botox® under one arm and Xeomin® under the other (Dressler 2010b).

Myobloc® has also been shown to improve axillary as well as palmar hyperhidrosis (Baumann et al. 2005a, b) and appears to be as effective as Botox® in the treatment of axillary hyperhidrosis at a conversion factor of 20:1, with however more discomfort on injection (Dressler et al. 2002). In a recent within-subject comparison of 10 patients, Myobloc® was significantly more effective and had a longer duration than Botox®, at a conversion ratio of 50:1 (Frasson et al. 2011). Xeomin® has also been used successfully for the treatment of axillar hyperhidrosis (Dressler 2012). The TTA Subcommittee of the AAN concluded that there is level

A evidence for the recommendation that BoNT should be offered as a treatment option for axillary hyperhidrosis and level B for palmar hyperhidrosis (Naumann et al. 2008).

Gustatory sweating is a unique entity characterized by profuse sweating of the face, scalp, and neck during or immediately after ingestion of food or drink (Naumann et al. 1997). It most often occurs as a complication of surgery to the area of the face near the parotid glands (Nolte et al. 2004). The effect of Botox® on gustatory sweating has been evaluated in one class II and three class III studies totaling 131 patients, with an effect lasting up to a year (Naumann et al. 1997; Laccourreye et al. 1999; Eckardt and Kuettner 2003; Nolte et al. 2004). At present available evidence supports a Level C recommendation for BoNT for the treatment of gustatory sweating.

3.4 Gastrointestinal Conditions

3.4.1 Sialorrhea

Several studies, including randomized placebo-controlled trials (Ondo et al. 2004; Lagalla et al. 2006; Jackson et al. 2009), have provided evidence that Botox®, Dysport®, or Myobloc® injections in the parotid glands with or without injection in the submandibular glands may be the treatment of choice for sialorrhea and drooling associated with PD and other disorders with bulbar dysfunction, such as amyotrophic lateral sclerosis, cerebral palsy, posttraumatic encephalopathy, and bilateral strokes (Nóbrega et al. 2007; Santamato et al. 2008; Molloy 2007; Basciani et al. 2011; Chinnapongse et al. 2011; Moller et al. 2011). Ultrasound-guided injection may improve the efficacy of BoNT treatment for sialorrhea (Dogu et al. 2004). Xeomin® has been shown to be as effective and as safe as Botox®, with a ratio of 1:1 in a small series of patients with sialorrhea (Dressler 2009).

An open-label study of 30 children with neurological disorders and sialorrhea showed no difference in efficacy or side effects between BoNT-A and BoNT-B (Wilken et al. 2008). Other studies provided evidence that BoNT-B may be more effective than BoNT-A in treating sialorrhea as dry mouth is significantly more frequently noted in patients treated for CD with BoNT-B as compared to BoNT-A (Tintner et al. 2005; Jankovic 2009b; Guidubaldi et al. 2011). However, a recent randomized double-blind crossover trial demonstrated similar efficacy but shorter latency and lower cost of Myobloc® compared to Dysport® (Guidubaldi et al. 2011).

The potential adverse effects of using BoNT for sialorrhea include transient dysphagia and xerostomia although dysphagia has not been reported in any study. In fact, a study of oropharyngeal swallowing dynamics, based on swallowing videofluoroscopy, showed no difference before or 30 days after injections of BoNT-A into the parotids in patients with PD (Nóbrega et al. 2009).

3.4.2 Achalasia

Achalasia is manifested by spontaneous and repetitive contractions of the proximal esophagus with failure of the lower esophageal sphincter to relax during swallowing. This leads to dysphagia. Several small studies have demonstrated the beneficial effects of Botox® injections into the lower esophageal sphincter in the treatment of

achalasia, particularly in patients who are not candidates for surgery or balloon dilatation (Pohl and Tutuian 2007; Barnes et al. 2011; Lakhtakia et al. 2011).

3.4.3 Constipation and Fecal Incontinence

Anismus (constipation due to functional obstruction at the pelvic outlet by paradoxical contraction of the striated sphincter muscles during defecation straining) has been suggested to represent a form of focal dystonia and has been considered as a possible etiology of constipation in some patients (Mathers et al. 1988). Several small open-label studies demonstrated the beneficial effects of Botox® anal injections in the treatment of the subtype of constipation secondary to anismus (Albanese et al. 2003; Cadeddu et al. 2005; Hompes et al. 2012). The puborectalis muscle is usually injected under transrectal ultrasonographic guidance.

On the other hand, rectal hypercontractility can lead to fecal incontinence. Intrarectal Dysport® injections have shown some improvements in fecal incontinence in a small series (Bridoux et al. 2011).

3.4.4 Anal Fissure

Botox® and Dysport® injections into the internal anal sphincter seem effective in treating chronic anal fissure with a low rate of transient incontinence secondary to diffusion to the external anal sphincter and without permanent complications. However, the therapeutic response is heterogenous (Brisinda et al. 2002; Maria et al. 2000; Yiannakopoulou 2012).

3.5 Overactive Bladder and Other Urologic Problems

An increasing number of reports provide evidence that Botox® injections into the bladder wall is an effective treatment in increasing the bladder capacity and improving urge and incontinence in patients with overactive bladder associated with neurogenic and idiopathic detrusor overactivity (Patel et al. 2006; Chen and Liao 2011; Deffontaines-Rufin et al. 2011). However, the rate of treatment discontinuation may be as high as 61.3 % at 3 years, secondary the need to intermittent self-catheterization or urinary tract infections (Mohee et al. 2013). A randomized controlled trial comparing anticholinergic versus BoNT for urinary urge incontinence has recently started (Visco et al. 2012). The TTA Subcommittee of the AAN concluded that there is level A evidence for the recommendation that BoNT should be offered as a treatment option for this urinary disorder (Naumann et al. 2008).

Other genitourinary indications for Botox® treatment include voiding dysfunction due to benign prostatic hypertrophy (Chuang and Chancellor 2006; Marchal et al. 2011).

3.6 Allergic Rhinitis

Two class II placebo-controlled studies with a total of 73 patients demonstrated the efficacy of 20–30 units of Botox® in each nasal cavity to manage the symptoms of

allergic rhinitis (Unal et al. 2003; Yang et al. 2008). Botox® was also superior when compared to intranasal triamcinolone (Yang et al. 2008). However, the follow-up was only for 8 weeks, so the durability of effectiveness is unclear.

3.7 Cosmetic

It is beyond the scope of this review to discuss the vast literature on cosmetic use of BoNT, which represents about half of all the uses of BoNT. Botox® and Myobloc® have been used in brow lifts and for treating glabellar lines, horizontal forehead lines, crow's feet, hypertrophic orbicularis, upper nasalis (bunny) lines, repeated nasal flares, melomental folds, perioral rhytides or smoker's lines, mouth frown, peau d'orange skin, mental crease, facial asymmetry with both hyper- and hypofunctional muscle imbalance, necklace lines, and platysmal bands (Glogau 2002; Baumann et al. 2003; Choi et al. 2013a, b; Dessy et al. 2011). Overly aggressive or imprecise treatment in the cervical area can lead to incompetent mouth, weakness of the neck flexors, and dysphagia (Klein 2001). The duration of effect of BoNT for cosmetic indications ranges from 3 to 4 months and up to 6–8 months, depending on the treatment site and injection technique (Carruthers and Carruthers 2001). Myobloc® seems to have a faster onset of action by 1–2 days for all these muscle groups, but a shorter duration and lesser potency of action when compared to Botox® at a conversion factor of 1:20 to 1:100. In addition, intradermal injections with Myobloc® are more painful than with Botox® (Yamauchi and Lowe 2004).

Botox® injected peri-nasally at a dose of 20–25 units for facial tics also improved acne in two patients despite previous failure of several anti-acne agents. Clearing of peri-nasal acne began 1–2 weeks after each treatment and lasted 4–5 months (Diamond and Jankovic 2006a, b). Xeomin® and Dysport® have recently demonstrated efficacy in the treatment of crow's feet (Prager et al. 2011).

4 Conclusion

Since first recognized as the cause of food-borne botulism in the early nineteenth century, BoNT was suggested as a potential treatment for involuntary spasms and movements. Almost 200 years later, its known clinical applications span across numerous neurological and other diseases. The Neurotoxin Institute was established in 2002 as an umbrella organization providing unbiased educational programs and other information about the broad use of BoNT in different specialties (www.neurotoxininstitute.com).

Neurotoxic Effects, Mechanisms, and Outcome of 192-IgG Saporin

Laura Petrosini, P. De Bartolo, and D. Cutuli

Contents

Abstract

The first type-selective anti-neuronal active in vivo immunotoxin is 192 IgG-saporin. 192 IgG-saporin selectively destroys cholinergic neurons of basal forebrain that provide cholinergic input to the hippocampus, entire cortical mantle, amygdala, and olfactory bulb. Immunotoxic lesions by 192 IgG-saporin represent a valid animal model of Alzheimer's disease, given the degeneration of basal cholinergic system present in this pathology.

Selective lesioning of cholinergic innervation by means of intracerebroventricular (i.c.v.) or intraparenchymal (i.pr.) 192 IgG-saporin is able to interfere with experience-dependent plasticity. A number of studies have demonstrated alteration of several structural and biochemical parameters related with neuroplasticity (dendritic spines and branching of pyramidal neurons, adult neurogenesis, levels of neurotrophic factors) in both cortical mantle and hippocampus.

Furthermore, lesions of the cholinergic basal forebrain affect cognitive functions, such as learning, memory, and attention, as well as sleep-waking cycle. The effects of selective immunotoxic lesions have been examined in a variety of behavioral paradigms of learning and memory. The general framework has to take into account the route of injection (i.c.v. or i.pr.), lesion extent, age of lesioning, and kind of behavior analyzed. Namely, cholinergic depletion can elicit specific learning and memory impairments as well as deficits in attentional and discriminative abilities. However, 192 IgG-saporin lesions result in overt behavioral deficits only using high demanding tasks and following high-grade CBF lesions, indicating that the relationship between CBF lesion extent and cognitive impairment is a threshold relationship in which a high degree of neuronal loss can be tolerated without detectable consequences.

1 Introduction

The cholinergic basal forebrain (CBF) is one of the diffusely projecting systems of the brain. It provides cholinergic input to the hippocampus, entire cortical mantle, amygdala, and olfactory bulb. The physiological function of the CBF is thought to modulate the excitability of cortical and hippocampal neurons. Anatomical and physiological data on the CBF encourage the notion that it modulates some cognitive functions, as learning, memory, and attention, as well as sleep-waking cycle. The evidence for this hypothesis has come from observations that muscarinic antagonists generally impair cognitive function in humans and animals, and cholinomimetics can reverse such impairments or enhance cognition when given alone (Hagan and Morris 1988). Although the precise site within the CNS for the cholinergic drug effects on behavior is uncertain, the CBF is regarded as the probable anatomical substrate for the cognitive effects of cholinergic drugs (Markowska et al. 1995). The discovery that the CBF degenerates in Alzheimer's disease (AD) and that its degree of degeneration correlates with the degree of dementia (Perry et al. 1978) has strongly encouraged interest on the role of the CBF in cognition. Degeneration of the CBF in AD has motivated investigators to attempt to model these pathological features through a variety of experimental lesioning techniques. The approaches employed have included fimbria-fornix transaction (Matsuoka et al. 1991), injection of the toxin aziridinium ion of ethylcholine mustard (AF64A) into the basal forebrain or target areas of cholinergic neurons (Walsh and Opello 1994), and intracerebral injections of excitotoxins (selective toxins for excitatory neurons, such as kainic, ibotenic, *N*-methyl-D-aspartate (NMDA), and quisqualic acids) (Dunnett et al. 1991). The major shortcoming of these works is that each of these techniques lacks selectivity. For example, excitotoxins are able to destroy cell soma without damaging crossing fibers. Yet, their selectivity depends on the injection site: there is great selectivity where the neurons are organized in distinct groups, as for *locus coeruleus*. Differently, since cholinergic neurons of basal forebrain are highly widespread among other cell types, the excitotoxic lesions induce unwanted loss of non-cholinergic neighboring neurons (Dunnett et al. 1991) rendering thus difficult to ascribe the eventual resulting deficits specifically to destruction of the CBF.

In the 1990s, the problem of selective lesions of the CBF has been addressed through the development of the new lesioning techniques that have proved very significant for functional neuroscience research. The power and validity of this approach reside in the nature of the lesion.

2 Immunolesioning Techniques

Immunolesions use monoclonal anti-neuronal antibodies to deliver similar cytotoxin selectivity to only those neurons bearing surface moieties recognized by the antibodies. Immunolesioning can destroy a specific type of neuron locally, or after axonal suicide transport from the injection site, thus combining selectivity for both anatomical region and cell type.

Immunotoxins are composed of monoclonal antibodies conjugated to various ribosome-inactivating proteins (RIPs). The monoclonal antibody component of an immunotoxin binds to specific cell surface molecules to result in endocytosis of the antibody and its coupled RIP. Once internalized, the RIP component inhibits protein synthesis, catalytically inactivating ribosomes and resulting in cell death. If immunotoxin binds to nerve terminals or axons, it is internalized by receptor-mediated endocytosis and then travels by retrograde axonal transport to neuronal cell bodies, where the RIP acts to inhibit protein synthesis. If antigen-bearing soma is present at the injection site, then axonal transport is obviously not necessary to deliver the toxin. However, high local toxin concentrations at the injection site may produce nonspecific cytotoxicity with necrosis of all cell type.

The first immunotoxin that was reported to be effective in making neuronal lesions is OX7-saporin that consisted of the monoclonal antibody OX7 coupled to saporin. Saporin is one RIP often used; derived from the plant *Saponaria officinalis* (soapwort). OX7 recognizes Thy-1, an abundant surface molecule present on all neurons, so the resulting immunotoxin is not selective for any one type of neuron. For a review see Wiley (1992).

3 192 IgG-Saporin

The first type-selective anti-neuronal active in vivo immunotoxin is the 192 IgG-saporin. 192 IgG-saporin consists of the monoclonal antibody 192 IgG which is disulfide coupled to saporin. The antibody component is directed against low-affinity rat nerve growth factor (NGF) receptor ($p75^{NGFFR}$). Targeting p75 serves as an ideal way to selectively lesion the CBF neurons because in the adult rat basal forebrain, only the cholinergic neurons express p75. They possess p75 NGF receptors while neurons containing other neurotransmitters in the region, and even the nearby striatal cholinergic interneurons, do not express detectable levels of same receptors. NGF plays a role in the maintenance of function of the magnocellular CBF neurons, which have NGF receptors (Thomas et al. 1991). When injected, 192 IgG-saporin binds to the surface of p75-bearing neurons and is internalized by

endocytosis. Once in the cytoplasm, the saporin moiety escapes endosomes and enzymatically inactivates the large ribosomal subunit halting protein synthesis and leading ultimately to cell death. For a review see Wiley (1992).

4 Organization of the Basal Forebrain Cholinergic System

Neurons in the basal forebrain provide the major source of cholinergic innervation for the entire neocortex, hippocampus, amygdala, and olfactory bulb. CBF is a continuum of several overlapping nuclei with divergent efferent pathways, such that a single projection field is not exclusive of a particular nucleus. The forebrain and upper brainstem of the rat contain six groups of cholinergic projection neurons designated by Mesulam as Ch1–Ch6 on the basis of cytoarchitectonic criteria and connectivity patterns. The Ch terminology was originally described on the monkey brain and later proposed in extended form in the rat. The Ch1–Ch2 sectors are contained within the medial septal (MS) nucleus and the vertical limb nucleus of the diagonal band of Broca (DBBv), respectively. They provide the major cholinergic projection to the hippocampal formation. The Ch3 sector is mostly contained within the lateral part of the horizontal limb nucleus of the diagonal band and provides the primary cholinergic projection to the olfactory bulb. The Ch4 sector contains the cholinergic neurons of the nucleus basalis magnocellularis (NBM), the substantia innominata (SI), and probably also laterally situated neurons of the vertical limb nucleus as well as medially situated cells of the horizontal limb nucleus. One unifying feature of Ch4 is that its components provide the major cholinergic projection to neocortical targets, as well as to the amygdala. The Ch5–Ch6 regions are located in the pontomesencephalic reticular formation and provide the major cholinergic innervation to the thalamus. For a review see Mesulam et al. (1983).

Developmental studies using biochemical, histochemical, and immunocytochemical techniques have shown that cholinergic neurons in the rodent basal forebrain are generated prenatally according to a distinct spatiotemporal pattern and undergo extensive maturation during the first postnatal month. Cholinergic fibers from Ch1–2 or Ch4 sectors, which start growing as early as embryonic day 15, reach the appropriate target fields in the hippocampus or neocortex at about the time of birth and establish adult-like patterns of innervation in either region within the fourth postnatal week, when the postnatal maturation of cholinergic markers is fairly complete (Leanza et al. 1996).

Several studies addressing the role of cholinergic neurotransmission investigated how to use 192 IgG-saporin, evaluating extent, time course, specificity, and mechanism of action of intraparenchymal or intraventricular injections in the adult CNS.

5 Selectivity and Effectiveness of 192 IgG-Saporin

The selectivity and effectiveness of 192 IgG-saporin for producing lesions of the CBF has now been shown by several research groups. Both intracerebroventricular (i.c.v.)

administration of the 192 IgG-saporin and direct injection into distinctive basal forebrain nuclei induce nearly complete and specific lesions of cholinergic cells but sparing other neuronal systems in the basal forebrain.

192 IgG-saporin i.c.v. injection affects CBF as well as Purkinje cells of the cerebellum (Berger-Sweeney et al. 1994; Heckers et al. 1994) because a subset of these cells starts expressing p75 receptors of NGF during development and continues during adulthood (Pioro and Cuello 1988). Differently, 192 IgG-saporin i.c.v. injections spare the cholinergic neurons of other brain regions, the gamma-aminobutyric acidergic (GABAergic) neurons expressing parvalbumin that are intermingled within the CBF, the calbindin D-28K expressing neurons of the NBM, and the NADPH diaphorase-expressing neurons of the NBM (Heckers et al. 1994; Wiley et al. 1995). 192 IgG-saporin i.c.v. injections also result in loss of cholinergic markers such as choline acetyltransferase (ChAT) activity, acetylcholine esterase (AChE) positive fibers, and high-affinity choline transport (HAChT) in the target fields of the CBF (Wrenn and Wiley 1998). 192 IgG-saporin i.c.v. injections at different time points of neonatal age (from 0 to 30 postnatal day) are used for studying the development of the central cholinergic system (Berger-Sweeney 1998; Leanza et al. 1996).

When injected intraparenchymally (i.pr.) into basal forebrain, 192 IgG-saporin effects are present mainly in the proximity of the injection site, sparing interspersed non-cholinergic neurons (Berger-Sweeney et al. 1994). Notably, i.pr. injections induce a more pronounced gliosis than i.c.v. injections. Delayed loss of cholinergic striatal interneurons after injection into the Ch4 sector has been described (Heckers et al. 1994); however this finding has not been replicated. Striatal cholinergic neurons express the p75 NGF receptor in early development phases, but this expression decreases drastically during adulthood (Pioro and Cuello 1988). The described loss of striatal cholinergic neurons might be due to the lesion-induced re-expression of p75 NGF receptors in the striatum (Heckers et al. 1994). The sphere of CBF-killed cells that results from i.pr. injections can be expanded by increasing the dose. However, at high dose, nonselectivity may become a problem (Wrenn and Wiley, unpublished observation). 192 IgG-saporin i.pr. injections can also be performed in the target fields (hippocampus, cortex) of the CBF. Injections into the hippocampus result in a mainly ipsilateral loss of the Ch1–Ch2 sector cholinergic neurons, an effect blocked by simultaneous injections of colchicines. Similarly, intracortical injections cause a loss of cholinergic fiber density in the cortex and a loss of Ch4 cholinergic neurons (Ohtake et al. 1997).

The selectivity and lethality of 192 IgG-saporin for CBF neurons were further demonstrated by Book et al. (1994) by using a double-labeling approach. In this study, the persistent retrograde tracer Fluoro-Gold was cortically injected 1 week before the i.c.v. injections of 192 IgG-saporin or saline. The Fluoro-Gold pre-labeled both cholinergic and non-cholinergic basal forebrain neurons. After depleting the cholinergic neurons, Ch4 was stained immunohistochemically for ChAT. These authors found that only the neurons that were double-labeled for both Fluoro-Gold and ChAT were lost in the 192 IgG-saporin-treated rats. Thus, 192 IgG-saporin selectively killed the cholinergic neurons of the Ch4 sectors, leaving intact non-cholinergic neurons.

It is important to emphasize that much of the CBF projection to amygdala is not lesioned by i.c.v or i.pr. injections of 192 IgG-saporin. Most cholinergic neurons projecting to the amygdala do not express p75 receptors; therefore, they are unaffected by 192 IgG-saporin (Heckers et al. 1994). The sparing of the cholinergic innervation to the amygdala renders the experimental immunotoxic model significantly different from the AD pathology, representing a methodological limit that has to be taken into account.

In summary, 192 IgG-saporin is the most effective and selective means for producing lesions of the rat CBF. Its advantage over previous techniques is in its ability to selectively kill cholinergic neurons of the basal forebrain and to leave intact intermingled non-cholinergic neurons. Significant drawbacks of 192 IgG-saporin include sparing of the cholinergic innervations to amygdala and destruction of some cerebellar Purkinje neurons.

6 Structural and Biochemical Effects of 192 IgG-Saporin

One of the most interesting functional correlates of cortical cholinergic input is its role in mediating neuroplasticity. Neuroplasticity is a lifelong process that mediates the structural and functional reaction of dendrites, axons, and synapses to experience, aging, and injury.

The selective lesioning of cortical cholinergic innervation by means of 192 IgG-saporin interferes with experience-dependent plasticity in the barrel fields. When all whiskers except for D2 and D3 were trimmed, a pairing between the D2 and D3 barrel fields occurred so the D2 neurons in the cerebral cortex started to show a greater responsivity to the stimulation of D3 than to stimulation of adjacent D1, which had been trimmed. This pairing, indicative of experience-induced synaptic plasticity, is not obtained in rats with selective immunotoxic lesions in the Ch4 (Baskerville et al. 1997). In newborn rat pups, barrel representing intact whiskers failed to show the expected expansion into the territory representing trimmed whiskers in animals with Ch4 lesions (Kilgard and Merzenich 1998). Furthermore, pairing auditory stimuli with electrical stimulation of the Ch4 in adult rats caused a long-lasting reorganization of primary auditory cortex so that the area optimally responsive to the paired tone expanded substantially. This plasticity was not observed following the selective immunotoxic destruction of cholinergic Ch4 neurons. Thus, it appears that cortical cholinergic denervation can undermine the learning-dependent reorganization of cortical representations and perhaps also the ability of the brain to keep itself in good repair in response to injury (Conner et al. 2003).

Several studies have investigated structural modifications of neocortical pyramidal neurons following selective CBF lesions. Injections of 192 IgG-saporin (i.c.v. or i.pr.) induce an increase of apical and basal dendritic spines related to an unaltered dendritic branching in parietal (De Bartolo et al. 2009; Mandolesi et al. 2008) as well as in frontal (Harmon and Wellman 2003; Wellman and Sengelaub 1995) pyramidal neurons during the middle adulthood. The same pattern of changes was found when the selective cholinergic lesion occurred in neonatal age

(De Bartolo et al. 2010). Furthermore, in frontal pyramidal neurons, the lesion-induced increment of dendritic spines has been related to an increased expression of GluR1 subunit of the aminomethylphosphonate (AMPA) receptors (Garret et al. 2006; Kim et al. 2005), suggesting the spines as the morphological substrate for the increase of AMPA receptors induced by the cholinergic lesion. The hypothesis has been advanced that neocortical neurons upregulate AMPA receptors and spine number as a compensatory response to the lesion-induced decreased innervation (Fiala et al. 2002). In fact, the increase in spines would execute a "mechanical" function and prevent lesion-induced atrophy of dendritic branching (Harmon and Wellman 2003). The hypothesis that the spines might provide protection against dendritic atrophy is supported by evidence that in frontal pyramidal neurons of aged rats with forebrain cholinergic lesions, spines did not increase (Harmon and Wellman 2003) and dendritic branching decreased (Works et al. 2004). Nevertheless, an increase in spines does not necessarily imply an increase in functional synapses. A study of slice preparations of hippocampal neurons showed that new spines form even when synapses are inactivated and persist for many hours in the absence of any functional activity (Kirov and Harris 1999). A recent in vivo study (Arellano et al. 2007) reported the existence of non-synaptic spines in the mouse neocortex, indicating that dendritic spines might not be used to form synaptic contacts. A recent review reported that most new spines which appear in adult animals are transient, and only a small percentage of them will ultimately form functional synapses (Alvarez and Sabatini 2007). Moreover, the presence of spatial deficits following forebrain lesions (for details see below) seems to suggest that the newly formed spines of parietal pyramidal neurons are functionally inactive and thus do not directly influence behavior.

The reduced neuroplasticity following CBF-selective lesions is confirmed by many studies investigating the effects of 192 IgG-saporin injections on adult neurogenesis. It has been demonstrated that, 5 weeks after lesion, neurogenesis declined significantly in the granule cell layers of dentate gyrus in hippocampal formation as well as in olfactory bulb. Furthermore, immunotoxic lesions led to increased numbers of apoptotic cells specifically in the subgranular zone, the progenitor regions of dentate gyrus, and within the periglomerular layer of olfactory bulb. So, it has been advanced that the cholinergic system plays a survival-promoting role for neuronal progenitors and immature neurons within regions of adult neurogenesis, similar to effects observed during brain development (Cooper-Kuhn et al. 2004). Moreover, it has been demonstrated that i.c.v. 192 IgG-saporin injections on pnd 7 accelerate the death of newborn cells in the dentate gyrus, but does not change their overall survival rate or phenotypic differentiation (Rennie et al. 2011).

Many effects of selective CBF lesions confirming the reduced neuroplasticity have been described about metabolic markers and are consistent with the view of cholinergic influence over metabolism and amyloid precursor protein (APP) processing in the neocortex and hippocampus. For example, it has been demonstrated that i.c.v. 192 IgG-saporin injections during adulthood causes sustained reductions in glucose utilization in brain regions impacted by cholinergic synapse loss, including frontal cortical and hippocampal regions, relative to glucose use levels (Browne et al. 2001).

Also, neurotrophic factors strongly implicated in neuroplasticity display alterations following selective cholinergic depletion. In consequence of i.c.v. 192 IgG-saporin injections, NGF levels increased in the frontal cortex and hippocampus at 3 and 7 days and decreased in the serum at 7 days from lesion, suggesting that opposite changes in brain and serum occur at early stages of cholinergic depletion (Gelfo et al. 2011). 192 IgG-saporin i.c.v. injections induce a reduction of neurotrophin brain-derived neurotrophic factor (BDNF) levels in the parietal cortex as well as in the serum at later stages (15 days from lesion) (Angelucci et al. 2011). It appears interesting, since BDNF has an important role in survival, differentiation and functionality of neurons undergoing degeneration in pathological conditions such as cholinergic neurons in AD.

7 Behavioral and Cognitive Outcomes of 192 IgG-Saporin Lesions

The effects of selective immunotoxic lesions have been examined in a variety of behavioral paradigms of learning and memory. However, behavioral studies after 192 IgG-saporin lesions provide a quite unexpected picture: massive cholinergic depletion results in little or no impairment in commonly used spatial and not spatial learning and memory tests (Baxter and Chiba 1999; Everitt and Robbins 1997; McGaughy et al. 2000). Differently, deficits have been noted after cholinergic depletion on tasks that focus on attentional and discriminative abilities (Burk et al. 2002; McGaughy et al. 2002; Ricceri 2003). This general framework is further complicated by route of injection (i.c.v. or i.pr.), lesion extent, age of lesioning, and kind of behavior analyzed.

7.1 Mnesic Functions

The i.c.v. injection method has most consistently produced learning and memory deficits, and the most informative studies have used a range of immunotoxin doses which has allowed analyzing correlations between lesion extent and behavioral deficit.

High-dose (4–10 μg) i.c.v. injections of 192 IgG-saporin result in impairment in the acquisition of navigational learning in Morris Water Maze (MWM) and retention memory deficits in passive avoidance (PA) (Berger-Sweeney et al. 1994; Garcia-Alloza et al. 2006; Leanza et al. 1996; Nilsson et al. 1992; Steckler et al. 1995; Traissard et al. 2007; Waite & Thal 1995; Waite et al. 1995, 1999; Walsh et al. 1995; Zhang et al. 1996). Impaired performance in cued versions of MWM task has been also reported (Berger-Sweeney et al. 1994; Walsh et al. 1995). The behavioral changes are paralleled by a greater than 90 % reduction in CBF neurons that result in 80–90 % reduction in ChAT in the hippocampal and cortical target fields. Conversely, rats with less-extensive CBF lesions following i.c.v. (≈55–75 % cholinergic loss) (Cutuli et al. 2009; De Bartolo et al. 2010; Lehmann et al. 2000, 2002; Mandolesi et al. 2008; Nilsson et al. 1988; Waite et al. 1999) or i.pr.

(MS, DBB and/or NBM) immunotoxic injections (≈15–78 % cholinergic loss) were only slightly or not at all behaviorally affected in tasks, as MWM, PA, active avoidance, fear conditioning, and T-maze (Baxter et al. 1995, 1996; Dornan et al. 1996; Frick et al. 2004; Garcia-Alloza et al. 2006; Mandolesi et al. 2008; Torres et al. 1994; Wenk et al. 1994).

192 IgG-saporin i.c.v. lesions also impair spatial learning and working memory. A significant correlation between working memory impairment and lesion extent was observed (Wrenn and Wiley 1998; Wrenn et al. 1999), and this dose-dependent impairment was present only in rats that harbored total CBF lesions greater than 75 % (threshold effect). Several studies reported deficient performances in radial arm maze (RAM) (Cutuli et al. 2009; De Bartolo et al. 2010; Lehmann et al. 2003; Traissard et al. 2007) and in a water version of RAM (Antonini et al. 2009) following 192 IgG-saporin i.c.v. injections. Working memory deficits observed in RAM following CBF depletions are consistent with findings obtained by using T-maze alternation test and delayed matching to position/sample (DMTP/DMTS) and delayed nonmatching to position (DNMTP) tasks (Leanza et al. 1996; Lehmann et al. 2000, 2002; McDonald et al. 1997; Paban et al. 2005a, b; Steckler et al. 1995; Wrenn and Wiley 2001). Once again, i.pr. injections producing small, circumscribed cholinergic depletion (<75 %) did not evoke dramatic working memory deficits (McMahan et al. 1997; Pang et al. 2001) or effect in DNMTP task (Steckler et al. 1995). Galani et al. (2002) observed minor impairments only during initial phases of MWM and RAM tests after NBM injection. Perry et al. (2001) found RAM and MWM long-term (11 months) deficits after NBM and MS 192 IgG-saporin lesion, but not short-term deficits (5 months). The few studies considering perseverative behaviors and procedural strategies put into action during RAM demonstrated pervasive deficits of spatial exploration and cognitive planning following i.c.v. (Cutuli et al. 2009; De Bartolo et al. 2010) and NBM (Mandolesi et al. 2008) 192 IgG-saporin lesions.

The role of damage of cerebellar Purkinje cells has been addressed by including additional control groups with selective cerebellar lesions produced by means of OX7-saporin. Injections of 192 IgG-saporin or OX7-saporin (i.c.v.) result in sensory-motor deficits, compatible with the role of Purkinje cells in hyperactivity, motor coordination, and balance (Gandhi et al. 2000; Waite et al. 1995, 1999). Waite et al. (1999) demonstrated that OX7-saporin lesions mimic the effects on MWM acquisition shown after 192 IgG-saporin i.c.v. injections. Reference memory deficits selectively induced by OX7-saporin injections were also found in MWM and RAM (Gandhi et al. 2000; Traissard et al. 2007), confirming the critical importance of cerebellar damage in the i.c.v. lesioning effects. Deficits in the MWM-cued version are addressed to a non-cholinergic cerebellar Purkinje cell damage (Berger-Sweeney et al. 1994; Walsh et al. 1995). On the contrary, Purkinje cell loss is not responsible for PA retention memory and RAM working memory deficits seen after 192 IgG-saporin i.c.v. injections (Wiley et al. 1995; Wrenn et al. 1999). Namely, a threshold relationship between CBF lesion extent and working memory consequences has been demonstrated, indicating that moderate (about 32 %) Purkinje cell loss alone is insufficient to impair RAM performances (Wrenn and Wiley 2001).

As final notation, whether or not a behavioral deficit is observed depends upon an interplay between lesion extent and task demands. For example, recalling a single platform location in the MWM is less demanding than recalling a list of locations in the RAM. Consequently, when lesion extent was high and tasks were demanding, not all 192 IgG-saporin i.pr. studies have yielded negative results in learning and memory paradigms. In fact, Torres et al. (1994) and Rispoli et al. (2006) found impaired PA retention after injection into the NBM. Working memory deficits were reported in MWM (Baxter et al. 1995) and RAM after injections into the MS and/or NBM (Dornan et al. 1996; Mandolesi et al. 2008; Shen et al. 1996; Walsh et al. 1996). Impaired DNMTP performances were found after injection into the MS and the cingulate cortex (Torres et al. 1994; Walsh et al. 1996). Selective removal of the cholinergic projections to the cortical mantle by NBM injections of 192 IgG-saporin led to impaired social interaction reducing the duration of active social contact (Savage et al. 2011).

7.2 Spatial/Object Novelty Discrimination

Many studies assessed the effects of 192 IgG-saporin lesions on spatial/object recognition. Unlike the MWM, analysis of the open field (OF) with object performances revealed that i.c.v. 192 IgG-saporin lesions significantly affect spatial discrimination, since lesioned rats did not show selective renewed interest in the displaced objects (Cutuli et al. 2009; De Bartolo et al. 2010; Paban et al. 2005a, b). Conversely, after 192 IgG-saporin i.c.v. and i.pr. injections, the lesioned rats detected the presence of a novel object (Cutuli et al. 2009; De Bartolo et al. 2010; Savage et al. 2011; Vnek et al. 1996). A severe object recognition deficit in rats was observed only after injecting 192 IgG-saporin directly into perirhinal cortex (Winters and Bussey 2005).

The lesion-induced absence of spatial change detection is apparently inconsistent with the tuned MWM performances displayed by the 192 IgG-saporin-lesioned animals. It is possible that the MWM task is more affected by stress levels associated with the forced swimming to search for the escape platform (Cutuli et al. 2009; De Bartolo et al. 2010; Ricceri 2003). The stress responses induced by immersion in water might trigger neuromodulatory compensation that masks mild spatial working memory deficits (Everitt and Robbins 1997; McMahan et al. 1997). In fact, tasks involving high levels of stress may lead to stress-related increases of ACh release in the hippocampus (Gilad 1987; Mizoguchi et al. 2001; Mizuno and Kimura 1997). This could compensate for the greater loss of cholinergic functions in relatively stressful (MWM) than in less stressful (spatial/object novelty) tasks.

7.3 Attentional Functions

Many attentional functions have been found to be sensitive to selective cholinergic depletion, and the robustness of these effects varies with the kind of attentional

demands (McGaughy et al. 2000). Tasks requiring decremental attentional processing, such as latent inhibition, have been found to be unaffected by i.pr. cholinergic depletions (Chiba et al. 1995; Doughtery et al. 1996). However, following NBM or posterior parietal cortex 192 IgG-saporin infusions, subjects were impaired in serial conditioning tasks (Bucci et al. 1998; Chiba et al. 1995). 192 IgG-saporin i.c.v.-lesioned rats were impaired in a 5-Choice Serial Reaction Time test with increasing variability of the delay and visual search demands (Waite et al. 1999). Also the cognitive flexibility consisting in efficiently switching between spatially changing response rules was affected by 192 IgG-saporin i.c.v. lesions, as demonstrated by Cutuli et al. (2009) by using a serial learning task in which rats had to reach a food reward, finding out a sequence of correct open doors daily changed.

The extent of neocortical cholinergic depletion steadily correlates with performance in a sustained attention test (McGaughy et al. 1996, 1999; McGaughy and Sarter 1998, 1999). NBM infusions of 192 IgG-saporin produced dramatic, persistent impairment in the ability to detect unpredictably occurring signals, but not in their correct identification of non-signals in a sustained attentional task. The ability to discriminate signals from non-signals early declined with the additional cognitive demand provided by prolonged time on task. Dose-dependent cholinergic cortical denervation after NMB or i.c.v. lesions resulted in consequent behavioral impairments. Similar sensitivity to cortical cholinergic denervation was found when divided attention was tested. In conditional discrimination tests, lesioned animals showed increased response latencies in conditions requiring the simultaneous maintenance of two sets of conditional response rules (Turchi and Sarter 1997; Waite et al. 1999).

7.4 Neonatal Lesions

Selective cholinergic lesions by means of 192 IgG-saporin have been performed also in developing rats. Neonatal 192 IgG-saporin i.c.v. lesions produce a permanent loss in CBF, without inducing the cerebellar damage shown following i.c.v. infusion in adults.

While on the first postnatal day (pnd 1) single 192 IgG-saporin i.c.v. injections induce a very mild cholinergic loss in the cortex (17 % reduction in cortical ChAT activity) accompanied by no reduction in hippocampal ChAT activity and no behavioral alteration (Ricceri 2003; Ricceri et al. 1997, 1999), combined pnd 1 and 3 192 IgG-saporin injections lead to a dramatic reduction of ascending cholinergic projections to both the hippocampus and neocortex and impaired PA learning and MWM (Leanza et al. 1996; Ricceri et al. 2002). After 192 IgG-saporin i.c.v. injections at pnd 4, ChAT activity was markedly reduced in the hippocampus and cortical regions (73–84 %), but rats were unimpaired in MWM (Leanza et al. 1996). At pnd 7 192 IgG-saporin injections provoked consistent reductions in ChAT activity (78–84 % hippocampus, 52–64 % neocortex) accompanied by early and long-term behavioral impairments (Ricceri 2003; Wrenn and Wiley 1998).

In fact, pnd 7-lesioned rats displayed altered ultrasonic vocalizations in maternal separation and fear conditioning paradigms (Ricceri 2003; Ricceri et al. 2007; Scattoni et al. 2005), learning deficits in PA, and reduced exploratory behavior (Ricceri et al. 1997). At adulthood pnd 7-lesioned rats showed no deficits in MWM and delayed spatial alternation T-maze (De Bartolo et al. 2010; Pappas et al. 1996; Ricceri et al. 1999) but altered reactions to spatial novelty (De Bartolo et al. 2010; Ricceri et al. 1999), deficits in social transmission of food preferences (Ricceri et al. 2004), impaired working memory performances in RAM, and impulsive behaviors (De Bartolo et al. 2010; Pappas et al. 2005; Scattoni et al. 2006). In summary, as in adult animals, neonatal 192 IgG-saporin i.c.v. injections result in behavioral impairment only when the resultant CBF lesion is extensive and tasks are highly demanding.

8 Conclusion

The immunotoxin 192 IgG-saporin causes a selective, long-lasting loss of the cholinergic neurons within the CBF and is able to interfere with experience-dependent plasticity. A number of studies have demonstrated alterations of several structural and biochemical parameters related with neuroplasticity (dendritic spines and branching of pyramidal neurons, adult neurogenesis, levels of neurotrophic factors) in both cortical mantle and hippocampus.

The introduction of immunotoxic lesioning methods has proved to be a valuable tool in the investigation of the role of ascending cholinergic systems in cognition. The effects of selective immunotoxic lesions have been examined in a variety of behavioral paradigms. The general framework has to take into account the route of injection (i.c.v. or i.pr.), lesion extent, age of lesioning, and kind of behavior analyzed in the different studies. Overall, cholinergic depletion has been demonstrated to provoke selective learning and memory impairments as well as deficits in attentional and discriminative abilities. However, as demonstrated by the literature reviewed in this chapter, the specificity of the neurotoxic lesioning method is strictly linked to the validity and sensitivity of behavioral methods. Furthermore, 192 IgG-saporin lesions result in overt behavioral deficits only with high-grade CBF lesions, indicating a threshold relationship between CBF lesion extent and cognitive impairment.

TRPV1 Activators ("Vanilloids") as Neurotoxins

Contents

Abstract

A distinct subset of primary sensory neurons is distinguished by their unique sensitivity to capsaicin, the pungent ingredient in hot chili peppers. The initial excitation by capsaicin of these neurons is followed by a long-lasting, but fully reversible, refractory state (traditionally termed as desensitization) or under certain conditions, like neonatal treatment, frank neurotoxicity. This neurotoxic action was extensively used to identify capsaicin-sensitive neuronal pathways and to explore their physiological function. In 1997, a specific receptor for capsaicin and related compounds (collectively referred to as vanilloids) was identified as transient receptor potential cation

Authors Ashutosh Kumar and Rakesh Kumar Majhi have equally contributed.

channel subfamily V member 1 (TRPV1), a multifunctional channel involved in thermosensation (heat) and taste perception (e.g., peppers and vinegar). Importantly, TRPV1 also functions as a molecular integrator for a broad range of seemingly unrelated noxious stimuli including venoms from spiders and jellyfish. Indeed, TRPV1 is thought to be a major transducer of the thermal hyperalgesia that follows inflammation and/or tissue injury. Ablation of sensory neurons by vanilloids is, however, not only a research tool but also has a clear therapeutic potential. Currently, site-specific resiniferatoxin (an ultrapotent capsaicin analog) injections are being evaluated as "molecular scalpels" to achieve permanent analgesia in cancer patients with chronic, intractable pain. In this chapter, we review our knowledge of the molecular mechanisms underlying vanilloid-induced neurotoxicity, which includes both TRPV1-mediated and independent signalling pathways.

Keywords

Capsaicin • Resiniferatoxin • The capsaicin (vanilloid) receptor TRPV1 • Vanilloids

List of Abbreviations

CCK-B	Cholecystokinin receptor-B
CGRP	Calcitonin gene-related peptide
CNS	Central nervous system
CTB	Cholera toxin subunit B
DRG neuron	Dorsal root ganglion neuron
ETC1	Electron transport chain complex 1
ETC3	Electron transport chain complex 3
ICK-peptides	Inhibitory cystine knot peptides
ISH	In situ hybridization
MPT	Membrane permeability transition
NADA	*N*-arachidonoyl-dopamine
NNOS	Neuronal nitric oxide synthase
OLDA	*N*-oleoyldopamine
PALDA	*N*-palmitoyldopamine
PCR	Polymerase chain reaction
PKC	Protein kinase C
PMOR	Plasma membrane NADH oxidoreductase
ROPA	Resiniferonol 9,13,14-orthophenylacetate
ROS	Reactive oxygen species
RTX	Resiniferatoxin
SP	Substance P
STEARDA	*N*-stearoyldopamine
TG-neurons	Trigeminal ganglion neurons

TiTX	Tinyatoxin
TRPV1	Transient receptor potential cation channel subfamily V member 1

1 Introduction

Natural products provide a window of opportunity to identify new targets for pharmacological intervention. Capsaicin, the active principle in hot chili peppers (*Capsicum annum*), is a prime example. Connoisseurs of hot spicy food are intimately familiar with the predominant pharmacological actions of capsaicin from personal experience: it induces profuse perspiration (known as gustatory sweating) as well as a hot, burning sensation that dissipates upon repeated challenge (desensitization). Evolutionary selective pressure seems to have maximized the pungency of capsaicin. It was speculated that the compound's pungency is able to deter ambulatory animals from eating chili pepper fruits, favoring those plants whose seeds were dispersed widely by birds. Indeed, the avian TRPV1 receptor is not activated by capsaicin, and hence birds are undeterred from ingesting chili pepper fruits and can excrete the pepper seeds large distances away. This forms the basis of the development of hot pepper-flavored "squirrel-free" bird feed. It is still a mystery, however, why the same pungency that repels squirrels is perceived as pleasurable by many human beings.

Although topical capsaicin has been used in folk medicine to relieve pain for centuries, it took the genius of the late Miklós (Nicholas) Jancsó to ask the obvious question: how can an irritant molecule paradoxically cause analgesia? Jancsó noticed that the initial transient irritation by capsaicin was followed by a long-lasting refractory state in which the neurons not only did not respond to a repeated capsaicin challenge but were also insensitive to various unrelated stimuli, and he termed this state as "desensitization" (Jancsó and Jancsó 1949; Jancsó-Gábor et al. 1970). Per definition, capsaicin-mediated desensitization is reversible. However, following neonatal treatment or when sufficiently high doses are used in adult animals, capsaicin induces neuronal death and causes permanent analgesia (Jancsó et al. 1984). This forms the experimental foundation for the use of site-specific resiniferatoxin (an ultrapotent capsaicin analog) injections to achieve permanent relief of otherwise intractable pain in cancer patients. Furthermore, chemical ablation of sensitive neurons by capsaicin turned out to be an invaluable tool to dissect capsaicin-sensitive pathways and to explore their physiological function. Generally speaking, these neurons comprise a functional subset of peptidergic primary sensory neurons with unmyelinated (C-type) fibers that respond to noxious stimuli and initiate the cascade of neurogenic inflammation.

The molecular mechanisms underlying capsaicin-mediated desensitization are poorly understood, and the line between desensitization and neurotoxicity is most likely ill defined and arbitrary. The sensitization of TRPV1 by different kinases and involvement of different pathways also remain unclear (Vellani et al. 2006;

Otten et al. 1983; Negri et al. 2006). The cloned capsaicin (vanilloid) receptor TRPV1 is an inwardly rectifying cation channel with limited selectivity for Ca^{2+}, and Ca^{2+}-overload is a well-established cause of neurotoxicity (Chard et al. 1995; Caterina et al. 1997; Sugimoto et al. 1998; Czaja et al. 2008). Indeed, neurochemical calcium and other ions such as cobalt stains were historically used to visualize sensitive neurons in capsaicin-treated animals (Winter 1987). At the ultrastructural level, neuronal calcium staining is coupled to swollen mitochondria, but it is still hotly debated if this reflects a buffering of cytoplasmic Ca^{2+} by the mitochondria (a direct TRPV1-mediated effect) or an indirect, TRPV1-independent interference of capsaicin with the mitochondrial electron transport chains (ETCs) (Szolcsányi et al. 1971).

The first vanilloids to be identified were pungent phytochemical compounds that typically contain a vanillyl (4-hydroxy-3-methoxybenzyl) moiety essential for bioactivity (hence the name "vanilloid") and are present in nature, mainly as plant resources (Table 1). Prime examples include capsaicin (the pungent ingredient in chili peppers), piperine (responsible for the piquancy of black pepper), resiniferatoxin (isolated from the latex of the cactus-like plant *Euphorbia resinifera*), curcumin (from *Curcuma longa*), eugenol (in clove), and zingerone (from ginger). Subsequently, vanilloids (so-called endovanilloids) were isolated from animal tissues (e.g., *N*-arachidonoyl-dopamine, NADA, isolated from rat brain) or were obtained via chemical synthesis to explore structure-activity relations (Huang et al. 2002). Few more examples are *N*-oleoyldopamine (OLDA), *N*-palmitoyldopamine (PALDA), and *N*-stearoyldopamine (STEARDA) (Chu et al. 2003). Indeed, the existence of a specific capsaicin receptor was first postulated based on the fairly strict structural requirements for capsaicin-like bioactivity.

2 Capsaicin-Sensitive Neurons

In culture, capsaicin kills ~35 % of dorsal root ganglion (DRG) neurons. It was postulated that capsaicin destroys these neurons due to influx of excess Ca^{2+} (Chard et al. 1995). Indeed, capsaicin causes a drastic increase in basal intracellular Ca^{2+} concentration when applied to the cultured DRG neuron. This in vitro toxicity correlates with the observation that application of capsaicin in vivo for prolonged periods can cause irreversible toxic effect leading to loss of pain-sensing neurons (Holzer 1991; Maggi 1991). The DRG neurons abolished by capsaicin are small in size, possess either unmyelinated C- or thinly myelinated Aδ–fibers, and show large inward intracellular Ca^{2+} currents in response to capsaicin. Both Ca^{2+} current and the neurotoxic effect of capsaicin were prevented by pre-treating the cells with ruthenium red, currently recognized as a general, nonspecific blocker of TRP channels. The neurotoxic action of capsaicin can also be prevented by chelating extracellular Ca^{2+} and/or by blocking Ca^{2+}-activated proteases like calcineurin (Docherty et al. 1996). Taken together, these results imply that capsaicin exerts its neurotoxic effects predominantly due to

Table 1 Example of some vanilloids

Vanilloids	Chemical structure	Molecular formula	Origin	Properties and action	Reference
Capsaicin		$C_{18}H_{27}NO_3$	*Capsicum* genus	Analgesic, anticancer, antiobesity, anti-inflammatory, antioxidant activates TRPV1 at 10–8 to 10–6 M	Caterina et al. 1997; Luo et al. 2011; Knotkova et al. 2008.
Resiniferatoxin		$C_{37}H_{40}O_9$	*Euphorbia resinifera*	Inhibits inflammatory hyperalgesia, activates TRPV1 at 10–10 to 10–8 M	Neubert et al. 2008; Caterina et al. 1997.
Paradol		$C_{17}H_{26}O_3$	*Aframomum melegueta*	Antioxidative, antitumor, activates TRPA1 and TRPV1	Chung et al. 2001; Riera et al. 2009.

(*continued*)

Table 1 (continued)

Vanilloids	Chemical structure	Molecular formula	Origin	Properties and action	Reference
Curcumin		$C_{21}H_{20}O_6$	*Zingiberaceae* family	Used for pain relief, anticarcinogenic and food additive	Kuptniratsaikul et al. 2009; Aggarwal and Shishodia 2004.
Rotenone		$C_{23}H_{22}O_6$	*Lonchocarpus nicou*	Used as pesticide, insecticide, piscicide, and neurotoxin	Swarnkar et al. 2012; Cabeza-Arvelaiz and Schiestl 2012
Coenzyme Q		$C_{59}H_{90}O_4$	Most eukaryotic cells	Antioxidant	Littarru and Tiano 2007; Hoppe et al. 1999

consequences of both increased Ca^{2+} concentration inside the cell and cascades of cellular signalling events (Chard et al. 1995).

Capsaicin-sensitive sensory neurons are bipolar neurons with somata in dorsal root and trigeminal ganglia. The peripheral fibers innervate the skin as well as the viscera, whereas the central axons enter the central nervous system (CNS) where they form synapse at second-order neurons in the dorsal horn of the spinal cord and the spinal nucleus of the trigeminal tract, respectively. The vagal nerve also supplies capsaicin-sensitive innervations to some visceral organs: the cell bodies of these neurons are in the nodose ganglia, and they centrally project to the area postrema. The presence of TRPV1 in these neuronal pathways is firmly established by a combination of [^{3}H]-labeled resiniferatoxin (RTX) autoradiography, TRPV1 immunostaining, and other molecular methods (Szallasi and Blumberg 1999). The existence of TRPV1-expressing brain nuclei is, however, controversial.

In 1988, using a silver impregnation method, Ritter and Dinh described unexpected neuronal degeneration in several discrete forebrain and hindbrain areas of adult rats following i.p. capsaicin administration (50 or 90 mg/kg) (Ritter and Dinh. 1988). Subsequently, the presence of TRPV1 receptors was reported in corresponding (and also in additional) rat brain nuclei (and also in other parts) and the cortex in [^{3}H]RTX-binding experiments as well as by polymerase chain reaction (PCR), in situ hybridization (ISH), Western blot analysis, and immunostaining studies targeting to detect TRPV1 at RNA and protein level (Acs et al. 1996; Tóth et al. 2005; Doyle et al. 2002; Valtschanoff et al. 2001; Caterina et al. 1997; Goswami et al. 2010; Sasamura et al. 1998). Recordings obtained from rat brain slices implied that these TRPV1 receptors were functional and might be involved in learning and memory formation. Indeed, TRPV1 has been linked to the pathogenesis of Alzheimer disease (Micale et al. 2010; Pákáski et al. 2009). An additional important role for brain TRPV1 in anxiety and fear was postulated based on studies in TRPV1 knockout animals (Marsch et al. 2007). Most recently, however, only weak and minimal TRPV1 expression was found in rodent brain using a sensitive and selective reporter-mouse model (Tóth et al. 2005). This discrepancy is puzzling. Furthermore, relevant to the topic of this review, it clearly questions the value of capsaicin-induced toxicity to dissect "capsaicin sensitive" (i.e., TRPV1-expressing) pathways.

3 Plant-Derived Vanilloid Toxins

Though there are handful examples of vanilloids from plant origin, in this chapter, only vanilloids, namely, capsinoid and resiniferanoids, will be discussed in details.

Capsinoids: Capsaicin, the archetypal vanilloid, is responsible for the piquancy of hot chili peppers (Buck and Burks 1986). Capsaicin and related compounds are collectively called capsinoids. Naturally occurring capsinoids include capsiate, dihydrocapsiate, and nordihydrocapsiate. Like capsaicin, capsinoids activate TRPV1 (Iida et al. 2003), yet, they were reported to be sweet-tasting. Of synthetic capsinoids,

in the past olvanil and nuvanil had attracted attention as "improved" (candidate molecules that can be given per os to achieve desensitization) in preclinical models of chronic pain. The synthetic capsaicin, civamide (*cis*-capsaicin), is under clinical development by Winston Pharmaceuticals for indications like cluster headache.

Resiniferanoids: Resiniferatoxin (RTX) is a naturally occurring ultrapotent capsaicin analog isolated from the dried latex of the cactus-like perennial *Euphorbia resinifera*, a native of the Anti-Atlas Mountains in Morocco (Appendino and Szallasi 1997). The closely related tinyatoxin (TiTX) is present in the soap of *Euphorbia poissonii*, a succulent plant in Nigeria, which is traditionally used as a pesticide. TiTX is somewhat (approximately threefold) less potent than RTX. Although a method for the full synthesis of RTX is available, the molecule is still isolated from its natural host or obtained semi-synthetically from its parent diterpene, resiniferonol 9,13,14-orthophenylacetate (ROPA). Attempts to recapitulate the ultra potency of RTX by synthesizing phorbol-based vanilloids (phorbol is inexpensive and its chemistry is well known) met limited success. Of note, ROPA is a potent activator of protein kinase C (PKC) and acts as a tumor promoter (Frey et al. 2004). At nanomolar concentrations RTX activates TRPV1, but does not activate PKC, and does not promote the formation of tumor either in the mouse skin model of two-stage carcinogenesis (Driedger and Blumberg 1980). RTX, however, did show unexpected activity against various cancer cell lines in a most likely TRPV1-independent manner (discussed later in details).

4 Venoms as Toxins for Vanilloid Receptors

Venomous creatures such as spiders, scorpions, snakes, and snails contain a wealth of peptide toxins which can activate or block different ion channels including vanilloid receptors and produce shock, paralysis, or death (Escoubas and Rash 2004; Miller 1995; Terlau and Olivera 2004). Often such venoms and toxins and their activity on ion channels define the pray-predator relationship and exert selection pressure of certain species in specific environmental niches (Fry et al. 2006). Some venoms contain toxins which act on somatosensory neurons and provoke a noxious sensation, primarily in mammals (Siemens et al. 2006; Bohlen and Julius 2012). Somewhat unexpectedly, bites or stings by such venomous creatures were shown to activate the TRPV1 receptor and produce inflammatory pain (Siemens et al. 2006; Cuypers et al. 2006).

Venom from a *Tarantula* sp., *Psalmopoeus cambridgei*, commonly found in the West Indies, has three inhibitory cystine knot (ICK) peptides present in one peptide (Siemens et al. 2006). Previously, it was shown that venoms and toxins from spiders, snakes, and scorpions mainly target three members of the TRP channel family, namely, TRPV1, TRPA1, and TRPM8 (Siemens et al. 2006). By reverse phase chromatographic technique, the *Tarantula* venom was purified and fractionated further. When testing the bioactive fractions on HEK-293 cells heterogeneously expressing different TRP channels, it was demonstrated that the toxin was selective to TRPV1 (Siemens et al. 2006). Edman sequencing revealed the

presence of three closely related peptides named vanillotoxin 1, vanillotoxin 2, and vanillotoxin 3, all of which can act as agonists for TRPV1. Similar to the ICK peptide, these vanillotoxins have six cysteine residues in each toxin sequence (Zhu et al. 2003). Recently, another tarantula, namely, *Ornithoctonus huwena*, from China has been reported to produce a toxin that functions as a TRPV1 agonist (Bohlen et al. 2010). Interestingly, this toxin is similar to the vanillotoxin 1–3. This toxin is named double knot toxin because it has two ISK motifs repeated in tandem (Bohlen et al. 2010).

For the sake of completeness, it should be mentioned that there are venoms which contain inhibitory components against TRPV1. For example, extract from a nematocyte (sea anemone *Heteractis crispa*) contains a peptide, named APHC1, which blocks TRPV1 (Andreev et al. 2008). Furthermore, venom from a funnel web spider (*Agelenopsis aperta*) has two toxin components (AG489 and AG505) which inhibit TRPV1 (Kitaguchi and Swartz 2005).

5 The Diversity of Vanilloid Actions

The spectrum of vanilloid actions depends not only on the pharmacophore but also on the species and the route of administration. One has to carefully consider all these factors before selecting the appropriate compound for the studies.

Pharmacophore: RTX functions as an ultrapotent capsaicin analog with a peculiar spectrum of pharmacological activities. For example, in the rat, RTX is several thousandfold more potent than capsaicin in inhibiting the xylene-induced neurogenic inflammatory response or in causing twitch inhibition in the vas deferens (Wardle et al. 1996). By contrast, RTX is only similar in potency to capsaicin in evoking the eye-wiping response upon intraocular instillation. RTX also has unique actions: unlike capsaicin which repeatedly evokes the pulmonary chemo-reflex with no evidence of desensitization, RTX desensitizes this reflex without causing any detectable prior activation. Interestingly, RTX and capsaicin congeners showed distinct structure-activity relations for receptor binding and Ca^{2+} uptake, respectively. Resiniferanoids displayed high affinity in the binding assay and low activity in the Ca^{2+} uptake assay, whereas capsinoids showed the opposite pattern. Based on these observations, the existence of two types of vanilloid receptor was postulated, an R-type (presumably metabotropic) vanilloid receptor responsible for desensitization and a C-type (most likely) ionotropic receptor mediating irritation. This hypothesis, however, turned out to be not true: following the cloning of TRPV1, it was recognized that the same receptor mediates both R-type binding and C-type calcium responses (Caterina et al. 1997). Pharmacokinetics appears to play an important role in determining RTX-like and capsaicin-like activities. In most cases, capsaicin-evoked Ca^{2+} current is rapid in onset, large in magnitude, and short in duration. By contrast, RTX induces sustained, slowly developing and long-lasting currents. This observation might explain why RTX treatment shows a better desensitization-to-excitation ratio than capsaicin for most end-points examined.

Species Differences: Evolutionary, heat, and capsaicin sensitivity seems to have developed over a time in different species. However, different species reveal differences in responsiveness against heat and capsaicin (Nagy and Rang 2000; Phillips et al. 2004; Jordt and Julius 2002; Sardar et al. 2012). Even mammalian species show striking differences in the way they react to capsaicin challenge (Gavva et al. 2004). Reptiles, such as snakes, seem to be insensitive to capsaicin as trigeminal ganglion (TG) neurons from snakes do not respond to capsaicin (Gracheva et al. 2010). Birds do not respond to capsaicin. In keeping with this, chicken DRG neurons lack specific [^{3}H]RTX-binding sites, and the treatment of DRG neurons from chicken with capsaicin does not results in Ca^{2+} influx (Jordt and Julius 2002; Goswami et al. 2007). Chicken, however, do possess TRPV1 but it is resistant to capsaicin due to a point mutation at the position of S512 which confers capsaicin sensitivity in mammals (Jordt and Julius 2002). Within mammals, rats and rabbits are a good example for species-related differences in capsaicin sensitivity (Gavva et al. 2004). In rats, application of 1 % capsaicin to the saphenous nerve resulted in a 35 % decrease in the C:Aδ fiber ratio (Pini et al. 1990), while the same concentration of capsaicin administration to saphenous nerve of rabbits did not change the C: Aδ fiber ratio (Lynn and Shakhanbeh 1988). This implies the existence of low density and/or low capsaicin-affinity TRPV1 receptors in the rabbit. Indeed, no high-affinity RTX binding was detected in rabbit DRG neuron membranes (Gavva et al. 2004). An intriguing species-related difference in RTX actions was reported in the cat. Unlike in rats where, as described above, RTX desensitizes the pulmonary chemoreflex without prior activation, in the cat, RTX evokes the full reflex triad (Pórszász and Szolcsányi 1991–1992; Sculptoreanu et al. 2005). Bat has two isoforms of TRPV1 of which one is responsive to infrared (Gracheva et al. 2011). However, both isoforms are responsive to capsaicin and high temperature.

Routes of Administration: The site of administration of vanilloids can be an important factor in determining neurotoxicity. This is due to the fact that intrathecal, perineural, intraganglionic, subcutaneous, intraperitoneal, and topical application of vanilloids exposes different parts of sensory neurons to differential vanilloid concentrations. For example, intraganglionic injections expose the cell bodies of sensitive neurons to high vanilloid concentrations, leaving the peripheral terminals intact. By contrast, topical vanilloid administration mainly targets the peripheral nerve terminals with no detectable effect on perikarya. As an added complication, different parts of the primary afferent neurons (central terminals, cell bodies, axons, and peripheral terminals) have their own range of sensitivity to vanilloid agonists. For example, peripheral sensory axons have different sensitivity to capsaicin, with the most vulnerable part being the subepidermal part of the axon (Chung et al. 1990). Intrathecal or intraganglionic administration of RTX selectively deletes TRPV1-expressing neurons and confers irreversible thermal, inflammatory, and cancer pain relief (Brown et al. 2005; Karai et al. 2004; Tender et al. 2005). By contrast, peripheral administration of a single dose of RTX produces a long-lasting but reversible analgesia by ablating nociceptive nerve terminals (Karai et al. 2004; Kissin 2008; Neubert et al. 2003; Goswami et al. 2007). This effect could

last from few days to few weeks and is preceded by a rapid loss of specific [^{3}H]RTX-binding sites which is already apparent 1 h after RTX treatment. Similarly, a long-lasting (up to 1 month) but fully reversible loss of TRPV1-like immunoreactivity was observed in skin biopsies taken from volunteers following exposure to a high-concentration capsaicin patch (Qutenza) (Inoue et al. 2002). Taken together, these results imply that it is impossible to extrapolate vanilloid actions from one species to another, especially if the route of administration is also changed.

6 Vanilloid Interaction with Receptors

Among all TRPV channels, TRPV1 represents the best characterized channel in terms of the vanilloid-mediated activation. It has been demonstrated that the temperature gating of TRPV1 is actually a voltage-dependent process (Voets et al. 2005). In a similar manner, vanilloids also modulate the voltage dependency of the TRP channel in ambient temperature and thus eliminates the requirement for high temperatures. In a simplified manner, it can be said that at molecular level, interaction of vanilloids with TRPV1 results in a conformational change which reduces the requirements for high temperature and thus is suitable for channel opening. However, information regarding the species-specific interaction of vanilloids to TRPV1 remains insufficient and discrepancies in the vanilloid-binding sites remain ambiguous.

Initially, it was demonstrated that capsaicin and capsazepine are competitive inhibitors of RTX binding on membrane fraction suggesting that these compounds probably bind at the same region (Szallasi et al. 1993). Capsaicin was originally believed to activate TRPV1 by binding to its extracellular loops. However, use of a membrane impermeable analog of capsaicin, i.e., DA-5018.HCl, reveals opposite effect on the TRPV1 present in the inside-out patched membrane. This compound activates TRPV1 when applied outside of the pipet, but failed to activate TRPV1 when applied from inside of the patch. This result confirms that capsaicin, being lipophilic in nature, can cross the plasma membrane and thus can bind to an intracellular/intramembranous region of TRPV1 (Jung et al. 1999). Indeed, it was demonstrated that capsaicin binds to the TM regions of TRPV1. The capsaicin-binding region was mapped down to a critical residue (Y511) located at the region between the 1st intracellular loop joining TM2 and TM3 regions of rat TRPV1 (Jordt and Julius 2002). The same position is responsible for capsaicin sensitivity too. In agreement with the involvement of that residues in capsaicin sensitivity, two mutants, namely, TRPV1-Y511A and TRPV1-S512Y (rat TRPV1), abolished capsaicin-mediated activation, while TRPV1-Y511A mutant failed to respond to anandamide also (an endogenous vanilloid that activates TRPV1) (Jordt and Julius 2002). Functional studies with the capsaicin-insensitive orthologs of TRPV1 (avian and rabbit) have demonstrated that capsaicin-mediated gating requires a small region of the TRPV1 which includes residues at positions 511 and 512 (Jordt and Julius 2002; Gavva et al. 2004). Interestingly, the mutant, namely, TRPV1-S512Y, converted the activity of the antagonist 5'I-RTX into an intrinsic agonist, albeit

with a lower potency than its parent compound, RTX (Sutton et al. 2005). Notably, these two residues are present between transmembrane domain 3 (TM3) and the first intracellular loop region. Based on these observations, it was proposed that gating of this channel may involve a sequential movement of a paddle structure. According to this concept, the TM3 and TM4 region of the channel is predicted to form a gating paddle (Chou et al. 2004), with residues such as M547 (Rat) and L547 (human) forming a part of the key agonist-binding site which is accessible from the intracellular interface (Johnson et al. 2006). However, this suggests that the critical agonist-binding region is not buried deep within the transmembrane region as suggested by the traditional homology models (Jordt and Julius 2002; Gavva et al. 2004; Phillips et al. 2004). This concept is also supported by the recent observation made in voltage-dependent potassium channel KvAP where X-ray crystal structure confirmed that amino acids at position 512 and 547 are located in close proximity (Jiang et al. 2003). In agreement with the joint action of TM3 and TM4 in agonist recognition, residue M/L547 located at the TM4 mediates significant species differences in resiniferatoxin (RTX) sensitivity, and the S512 is critical for discriminating between pH and capsaicin gating of TRPV1 (Jordt and Julius 2002).

However, a number of studies indicated the involvement of additional residues located within TM4, the putative S5–S6 pore region, and also at the N- and C-termini of TRPV1 on vanilloid-mediated activities and capsaicin responsiveness (Welch et al. 2000; Vlachova et al. 2003; Gavva et al. 2004; Phillips et al. 2004; Jung et al. 2002). For example, involvement of residues (R114 and E761) located in the N- and C-cytosolic tails of rat TRPV1 respectively has influence on the RTX-binding and RTX-mediated response to TRPV1 (Jung et al. 2002). Similarly, a number of critical residues located within the TM3 and TM4 (also considered as voltage sensor) regions have been shown to be responsible for major species-specific differences in vanilloid activity (Chou et al. 2004; Gavva et al. 2004; Phillips et al. 2004). In agreement with the involvement of TM3 and TM4 in the capsaicin activity in different species, M547 and T550 located in TM3 and TM4 region of TRPV1 (rat as well as human) confer vanilloid sensitivity, [^{3}H]RTX-binding and capsazepine-binding, parameters which are different in rabbit TRPV1 (Gavva et al. 2004). Changing the single residue at 550 in rabbit TRPV1 to the corresponding residue found in rat and human TRPV1 (I550T) was sufficient to confer gain of function for activation by capsaicin (Gavva et al. 2004). Furthermore, TRPV1 (rat as well as in human) mutants, namely, TRPV1-T550I and TRPV1-Y511A, demonstrate a loss of sensitivity to capsaicin (Gavva et al. 2004). A single mutation embedded in the TM4 region of TRPV1 (human), namely, TRPV1-L547M, produced a 30-fold increase in sensitivity to [^{3}H]RTX, whereas the reverse mutation in the rat isoform caused a decrease in sensitivity of equal amplitude (Chou et al. 2004). These critical residues affect ligand recognition to some extent and also affect channel function in response to ligand binding (Gavva et al. 2004).

Three amino acid residues located near the pore region of the rat TRPV1 are also involved in the capsaicin responsiveness. This is confirmed by the TRPV1 mutants,

namely, TRPV1-E636Q, TRPV1-D646N, and TRPV1-E648Q mutants, which affects capsaicin-mediated gating but not the heat or proton-mediated activation of TRPV1 (Welch et al. 2000). In addition, mutation of three residues located in TM6 (NML676FAP) also abolished capsaicin-mediated activation with little effect on ligand binding to rat TRPV1 (Kuzhikandathil et al. 2001). Similarly, another mutant, namely, TRPV1-L547M (Human) located at the 4th TM region, causes a decrease in capsaicin potency (Johnson et al. 2006).

7 Vanilloid-Induced Messenger Plasticity

It was postulated that vanilloids do not affect non-nociceptive neurons and/or mechanosensitive nociceptive neurons (Karai et al. 2004). This is important because, unlike local anaesthetics which target ubiquitous sodium channels in all axons, vanilloids selectively block heat-sensitive TRPV1-positive nociceptors and thus leave other sensory modalities intact, rendering these molecules a better choice for pain relief. In the rat spinal cord, RTX treatment ameliorated the so-called "wind-up" phenomenon after repeated peripheral C-fiber stimulation that is believed to correspond to central sensitization (Xu et al. 1997). This effect on the "wind-up" response correlated to the time course of the thermal hypoalgesia in the hot plate test (Xu et al. 1997). Unexpectedly, RTX treatment also resulted in reduced sensitivity to mechanical stimulation (Pan et al. 2003). The mechanical hypoalgesia was, however, transient (a few days) compared to the thermal hypoalgesia (several weeks). Since TRPV1-expressing C-fiber neurons do not respond to mechanical stimuli (and mechanosensitive A neurons do not express TRPV1), it is unclear how RTX treatment elevates the threshold for mechanical stimulation. One might wonder, however, if this is somehow part of the "messenger plasticity" that follows vanilloid administration.

Paradoxically, RTX treatment can cause mechanical allodynia. Pan et al. injected 200 μg/kg RTX i.p. to rats and observed rapid increase in the paw withdrawal latency to a heat stimulus, while profound tactile allodynia developed in 3 weeks (Pan et al. 2003). This unexpected increase in mechanical sensitivity lasted for at least 6 weeks (Pan et al. 2003). In the RTX-treated rats, IB4-labeled unmyelinated C-fiber terminals in the dorsal horn were significantly reduced, and cholera toxin subunit B (CTB)-labeled myelinated fiber terminals appeared to sprout into lamina II of the spinal dorsal horn (Pan et al. 2003). Electron microscopic examination of the sciatic nerve also revealed significant loss of unmyelinated fibers and extensive ultrastructural damage of myelinated fibers in RTX-treated rats (Pan et al. 2003). Immunofluorescence labeling showed diminished TRPV1-like immunoreactivity in DRG neurons and the spinal dorsal horn following RTX administration. This study suggests that systemic (i.p.) RTX administration diminishes the thermal pain sensitivity by depletion of unmyelinated afferent fibers. At the same time, RTX damages the myelinated afferent fibers and causes their abnormal sprouting in lamina II of the spinal dorsal horn. The latter anatomical change might be the reason behind delayed tactile allodynia (Pan et al. 2003).

As discussed above, desensitization to vanilloids is reversible and thus contrasts to irreversible neurotoxicity. For example, it has been reported that a single topical application of RTX to the rat cornea reduces the capsaicin-evoked eye-wiping response in a dose-dependent manner for 3–5 days, while the normal nociceptive responses return by 5–7 days (Bates et al. 2010). Importantly, RTX administration did not impair epithelial wound healing and blink reflex or cause detectable histological damage to the cornea (Bates et al. 2010). Immunohistochemistry experiments revealed that RTX treatment caused a temporary loss of calcitonin gene-related peptide (CGRP) expressing nociceptive fibers: the majority of fibers reappeared within 12 days and full recovery was attained within 4 months (Bates et al. 2010). Systemic (s.c.) RTX treatment also inhibits the capsaicin-induced eye-wiping response and depletes CGRP-like immuoreactivity in the dorsal horn of the spinal cord: these effects last much longer (months) than those observed after topical administration (less than 2 weeks) but are fully reversible. Subcutaneous RTX, however, causes skin ulcerations (that can be severe in some animals) in the head (mostly in the facial skin and around the ears), the cause of which is unclear. It was suggested that RTX may cause paradoxical itch and the ulcers are secondary to the scratching behavior of the animals. This effect of RTX is somewhat different than other vanilloids such as capsaicin and curcumin which reveal anticarcinogenic and antitumor activity (Surh et al. 1995; Park and Surh 1997; Limtrakul et al. 1997; Jang et al. 1989; Huang et al. 1997; Tanaka et al. 2002). Also, high-concentration RTX (leaking from the injection site) may damage the epithelium, either directly (there are reports that keratinocytes may express functional TRPV1 receptors) or indirectly (Li et al. 2007). Finally, intraganglionic RTX injection (into the trigeminal ganglion) was reported to abolish eye wiping in response to capsaicin in an irreversible fashion; this was associated with a loss of TRPV1/CGRP-positive neurons (Karai et al. 2004).

The effect of RTX-induced denervation on TRPV1 expression in surrounding tissues has been recently examined. Surgical removal of both the sciatic and saphenous nerves from rat right hind legs and a parallel setup administration of RTX to the rat leg subcutaneously were performed (Kun et al. 2012). Two weeks after administration, the dorsal and plantar paw skin samples of hind legs, as well as the oral mucosa, were excised. Neither chemical nor surgical denervation influenced the level of TRPV1 receptor mRNA and protein expression in non-neural cells of either skin regions or mucosa (Kun et al. 2012). This indicates that RTX pretreatment is cytotoxic only to TRPV1-positive neurons and does not affect surrounding non-neural tissues.

As discussed above, vanilloid treatment depletes the proinflammatory neuropeptides substance-P (SP) and CGRP from capsaicin-sensitive sensory neurons. It was proposed that capsaicin blocks centripetal intra-axonal transport and thereby starves the cell bodies of nerve growth factor (NGF) which is produced in the periphery and is important for neuropeptide synthesis. Indeed, RTX treatment causes a marked decrease in pre-protachykinin mRNA levels encoding SP (Szallasi et al. 1999). Subsequently, it was discovered that vanilloid-induced changes in neuropeptide levels are, in fact, bidirectional: while SP and CGRP are
