2nd edition

🐴 Springer

Springer Handbook
of Acoustics

Springer Handbook provides
a concise compilation of approved
key information on methods of
research, general principles, and
functional relationships in physical
and applied sciences. The world's
leading experts in the fields of
physics and engineering will be as-
signed by one or several renowned
editors to write the chapters com-
prising each volume. The content
is selected by these experts from
Springer sources (books, journals,
online content) and other systematic
and approved recent publications of
scientific and technical information.

The volumes are designed to be
useful as readable desk reference
book to give a fast and comprehen-
sive overview and easy retrieval of
essential reliable key information,
including tables, graphs, and bibli-
ographies. References to extensive
sources are provided.

Springer Handbook
of Acoustics

Thomas D. Rossing (Ed.)

2nd edition
With 960 Figures and 90 Tables

Springer

Editor

Center for Computer Research in Music and Acoustics
Stanford, CA 94305, USA

Preface

A handbook, according to the dictionary, *is a book capable of being conveniently carried as a ready reference*. Springer has created the Springer series of handbooks on important scientific and technical subjects, and we are happy that they have included acoustics in this category.

We published the *Springer Handbook of Acoustics* in 2007, and it has had good acceptance and is widely used and referenced. But in the intervening years, much research has occurred in the field of acoustics, and it is time for a second edition. Several authors have revised their chapters to include new material, and we have added two new chapters on Microphone Arrays and on Acoustic Emission.

Acoustics, the science of sound, is a rather broad subject to be covered in a single handbook. It embodies many different academic disciplines, such as physics, mechanical and electrical engineering, mathematics, speech and hearing sciences, music, and architecture. There are many technical areas in acoustics; the Acoustical Society of America, for example, includes 14 technical committees representing different areas of acoustics. It is impossible to cover all of these areas in a single handbook. We have tried to include as many as possible of the *hot* topics in this interdisciplinary field, including basic science and technological applications. We apologize to the reader whose favorite topics are not included.

We have grouped the 30 chapters in the book into seven parts: Propagation of Sound; Physical and Nonlinear Acoustics; Architectural Acoustics; Hearing and Signal Processing; Music, Speech, and Electroacoustics; Biological and Medical Acoustics; Structural Acoustics and Noise; and Engineering Acoustics. The chapters are of varying length. They also reflect the individual writing styles of the various authors, all of whom are authorities in their fields. Although an attempt was made to keep the mathematical level of the chapters as even as possible, readers will note that some chapters are more mathematical than others; this is unavoidable and in fact lends some degree of richness to the book.

We are indebted to many persons, especially Werner Skolaut, the manager of the Springer Handbooks, and to the editorial board for their advice, and especially to Fan Ho Ying and the staff at Springer for handling the revised manuscripts. Each chapter was reviewed by authoritative reviewers, and we are grateful to them for their services. But most of all we thank the authors, all of whom are busy people but devoted much time to carefully preparing their chapters.

Stanford, November 2013   Thomas D. Rossing

Contents

Part E Music, Speech, Electroacoustics

Part F Biological and Medical Acoustics

List of Abbreviations

1-D	one-dimensional
2-D	two-dimensional
2AFC	two-alternative forced choice
3-D	three-dimensional

A

A/D	analog to digital
ABR	auditory brainstem responses
AC	alternating current
AC	articulation class
ACF	autocorrelation function
ADC	analog-to-digital converter
ADCP	acoustic Doppler current profiler
ADP	ammonium dihydrogen phosphate
ADSR	attack time, decay time, sustain level, and release time
AE	acoustic emission
AF	audio frequency
AFSUMB	Asian Federation for Societies of Ultrasound in Medicine and Biology
AG	array gain
AI	articulation index
AIUM	American Institute of Ultrasound in Medicine
ALARA	as low as reasonably achievable
AM	amplitude modulation
AMD	air moving device
AN	auditory nerve
ANSI	American National Standards Institute
AR	assisted resonance
AR	autoregressive
ARMA	autoregressive moving average
ARP	acoustic recording package
ASA	Acoustical Society of America
ASHRAE	American Society of Heating, Refrigerating and Air-Conditioning Engineers
ASTM	American Society for Testing and Materials
ASUM	Australasian Society for Ultrasound in Medicine
ASW	antisubmarine warfare
ASW	apparent source width
ATOC	acoustic thermometry of ocean climate
ATP	adenosine triphosphate
AUV	automated underwater vehicle

B

BB	bite block
BBN	Bolt, Beranek, and Newman
BCC	body-centered cubic
BEM	boundary-element method
BER	bit error rate
BF	beam-former
BF	best frequency
BH	Bridge-Hill
BM	basilar membrane
BMUS	British Medical Ultrasound Society
BNR	beam nonuniformity ratio
BoSSA	bowed sensor speaker array
BR	bass ratio
BS	beam splitter

C

CAATI	computed angle-of-arrival transient imaging
CAC	ceiling attenuation class
CAD	computer-aided design
CCD	charge-coupled device
CD	compact disc
CDF	cumulative distribution function
CDMA	code division multiple access
CF	characteristic frequency
CFD	computational fluid dynamics
CMU	concrete masonry unit
CN	cochlear nucleus
CND	cumulative normal distribution
CNG	compressed natural gas
CNMAT	Center for New Music and Audio Technologies
CONCAWE	CONservation of Clean Air and Water in Europe
COPV	composite overwrapped pressure vessel
CPA	carotid phono-angiography
CPT	current procedural terminology
CSDM	cross-spectral density matrix
CW	continuous wave

D

D/A	digital-to-analog
DAC	digital-to-analog converter
DAFX	digital audio effects
DAT	digital audio tape
DAW	digital audio workstation

DC	direct current
DFT	discrete Fourier transform
DGC	depth gain compensation
DL	difference limen
DLF	difference limen for frequency
DLS	downloadable sounds
DNL	day–night average sound level
DOA	direction of arrival
DOF	degree of freedom
DP	data processing
DRS	directed reflection sequence
DSC	deep sound channel
DSI	digital speckle interferometry
DSL	deep scattering layer
DSP	digital signal processing
DSP	digital speckle photography
DSPI	digital speckle-pattern interferometry
DT	detection threshold
DVT	deep venous thrombosis

E

EARP	equal-amplitude random-phase
EC	European Commission
ECG	electro-cardiograph
ECMA	European Computer Manufacturers' Association
ECMUS	European Committee for Medical Ultrasound Safety
EDT	early decay time
EDV	end diastolic velocity
EEG	electroencephalography
EFSUMB	European Federation of Societies for Ultrasound in Medicine and Biology
EMI	experiments in musical intelligence
EN	European standard
EOF	empirical orthogonal function
EOH	electro-optic holography
EPA	US Environmental Protection Agency
EPNL	effective perceived noise level
ERB	equivalent rectangular bandwidth
ESPI	electronic speckle-pattern interferometry
EU	European Union

F

FCC	face-centered cubic
FCC	Federal Communications Commission
FDA	Food and Drug Administration
FDTD	finite difference time domain
FEA	finite-element analysis
FEM	finite-element method
FERC	Federal Energy Regulatory Commission
FET	field-effect transistor
FFLAGS	fast field program for air–ground system
FFP	fast field program

FFT	fast Fourier transform
FGI	Facility Guidelines Institute
FHWA	US Federal Highway Administration
FIR	finite impulse response
FLAUS	Latin American Federation of Ultrasound in Medicine and Biology
FM	frequency modulation
FMDL	frequency modulation detection limen
FOF	formes d'onde formantiques
FOM	figure of merit
FR	felicity ratios
FRF	frequency response function
FSK	frequency shift keying

G

GA	genetic algorithm
GA	geometrical acoustics
GCC	generalized cross-correlation
GISD	generalized internal source density
GPS	global positioning system

H

HELS	Helmholtz equation least squares
HI-FI	high fidelity
HIFU	high-intensity focused ultrasound
HL	hearing level
HTL	hearing threshold level
HUD	Housing and Urban Development
HVAC	heating, ventilating, and air conditioning

I

I-INCE	International Institute of Noise Control Engineering
IACC	interaural cross-correlation coefficient
IACF	interaural cross-correlation function
IAD	interaural amplitude difference
ICAO	International Civil Aviation Organization
ICMC	International Computer Music Conference
IDFT	inverse DFT
IEC	International Electrotechnical Commission
IEQ	indoor environmental quality
IF	intermediate frequency
IFFT	inverse fast Fourier transform
IHC	inner hair cell
IIC	impact insulation class
IIR	infinite impulse response
IM	intermodulation
IMAC	International Modal Analysis Conference
IMT	intima-media thickness

INCE/USA	Institute of Noise Control Engineering
IP	internet protocol
IRF	impulse response function
ISI	intersymbol interference
ISO	International Organization for Standardization
ITD	interaural time difference
ITDG	initial time delay gap
IVP	intravenous pyelogram
IW	internal gravity wave

J

JND	just noticeable difference

K

KDP	potassium dihydrogen phosphate
KLOrk	Kalamazoo Laptop Orchestra

L

L2Ork	Linux Laptop Orchestra of Virginia Tech
LCMV	linear constraint minimum variance
LDA	laser Doppler anemometry
LDEN	day–evening–night level
LDV	laser Doppler vibrometer
LEED	Leadership in Energy and Environmental Design
LEF	lateral energy fraction
LEMUR	League of Electronic Musical Urban Robots
LEV	listener envelopment
LF	Liljencrants–Fant
LG	late lateral strength
LL	listening level
LNG	liquefied natural gas
LOC	lateral olivocochlear system
LOL	Laptop Orchestra of Louisiana
LORkAS	Laptop Orchestra of Arizona State
LP	lens–pinhole system
LP	long-play vinyl record
LPC	linear predictive coding
LS	laboratory standard
LTAS	long-term-average spectrum
LTI	linear and time invariant

M

M/S	mid/side
MA	moving average
MAA	minimum audible angle
MAC	modal assurance criterion
MAF	minimum audible field

MAP	minimum audible pressure
MASU	Mediterranean and African Society of Ultrasound
MBP	model-based processor
MCR	multichannel reverberation
MDOF	multiple degree of freedom
MEG	magnetoencephalography
MEM	maximum entropy method
MEMS	microelectromechanical system
MFDR	maximum flow declination rate
MFP	matched field processing
MI	mechanical index
MIDI	musical instrument digital interface
MIMO	multiple-input multiple-output
MIR	music information retrieval
MIREX	music information retrieval evaluation exchange
MLD	masking level difference
MLM	maximum-likelihood method
MLS	maximum length sequence
MOC	medial olivocochlear system
MPEG4	moving-picture experts group 4
MRA	main response axis
MRI	magnetic resonance imaging
MSE	mean square error
MSHA	US Mine Safety and Health Administration
MoPho	Mobile Phone Orchestra
MTF	modulation transfer function
MTS	multichannel television sound
MUSIC	multiple signal classification
MV	minimum variance
MVDR	minimum variance distortionless response

N

NC	noise criterion
NCB	balanced noise criterion
NCEJ	Noise Control Engineering Journal
NDE	nondestructive evaluation
NDRC	National Defense Research Council
NDT	nondestructive testing
NEMA	National Electronic Manufacturers Association
NIC	noise isolation class
NIME	new interfaces for musical expression
NIPTS	noise-induced permanent threshold shift

OSHA	Occupational Safety and Health Administration

P

PA	public address
PA	pulse average
PC	personal computer
PC	phase conjugation
PCM	pulse code modulation
PD	probability of detection
PD	pure data
PDF	probability density function
PE	parabolic equation
PFA	probability of false alarm
PFO	patent foramen ovale
PhISEM	physically informed stochastic event modeling
PI	privacy index
PIV	particle image velocimetry
PL	propagation loss
PL	pressure level
PLIF	planar laser-induced fluorescent
PLOrk	Princeton Laptop Orchestra
PLZT	lead lanthanum zirconate titanate
PM	phase modulation
PMA	pre-market approval
PMF	probability mass function
PR	pseudo random
PRI	pulse repetition interval
PRF	pulse repetition frequency
PS	peak systolic
PS	phase stepping
PS	probe source
PSD	power spectral density
PSK	phase shift keying
PTC	psychophysical tuning curve
PVC	premature ventricular contraction
PVDF	polyvinylidene fluoride
PZT	lead zirconate titanate

Q

QAM	quadrature amplitude modulation
QCPA	quantitative phono-angiography

R

RAL	German Institute for Quality Assurance and Certification
RASTI	rapid speech transmission index
RC	room criterion
RCA	Radio Corporation of America
REL	resting expiratory level
RF	radio frequency
RIAA	Recording Industry Association of America
rms	root mean square
RMS	root mean square
ROC	receiver operating characteristics
RPM	revolutions per minute
RT	reverberation time
RUS	resonant ultrasound spectroscopy

S

s.c.	supporting cell
S/N	signal-to-noise ratio
S0 mode	zeroth order symmetric Lamb mode
SA	spatial average
SAA	sound absorption average
SAC	spatial audio coding
SAM	speckle average mechanism
SAOL	structured audio orchestra language
SARA	simple analytic recombinant algorithm
SAW	surface acoustic wave
SB	spectral broadening
SBSL	single-bubble sonoluminescence
SCBA	self contained breathing apparatus
SDIF	sound description interchange format
SDIF	spectral description interchange file
SDOF	single-degree-of-freedom
SDoT	State Department of Transportation
SE	signal excess
SE	source energy
SEA	statistical energy analysis
SG	spiral ganglion
SI	speckle interferometry
SII	speech intelligibility index
SIL	sound intensity level
SIL	speech interference level
SISO	single input single output
SL	sensation level
SL	source level
SLOrk	Stanford Laptop Orchestra

SM	scala media
SMA	stone mastic asphalt
SNR	signal-to-noise ratio
SNR	signal-to-quantization-noise ratio
SOC	superior olivary complex
SOFAR	sound fixing and ranging
SONAR	sound navigation and ranging
SOSUS	sound ocean surveillance system
SP	sound power
SP	spatial peak
SP	speckle photography
SPL	sound pressure level
SPTP	spatial peak temporal peak
SR	spontaneous discharge rate
SRA	source–receive array
SRATE	sampling rate
ST	scala tympani
ST	support
STC	sound transmission class
STFT	short-time Fourier transform
STI	speech transmission index
SV	scala vestibuli
SVR	slow vertex response
SWAT2000	shallow-water acoustic technology experiment

T

TA	temporal average
TAO	thermoacoustic oscillator
TCP	transmission control protocol
TDAC	time-domain alias cancellation
TDGF	time-domain Green's function
TEE	trans-esophageal
TG	temperature gradient
TGC	time gain compensation
THD	total harmonic distortion
TI	thermal index
TIA	transient ischemic attacks
TIB	bone near the focus

TIC	cranial bone near the skin
TIS	soft tissue
TL	transmission loss
TLC	total lung capacity
TMTF	temporal modulation transfer function
TNM	traffic noise model
TP	temporal peak
TR	time-resolved
TR	time reversal
TR	treble ratio
TRM	time-reversal mirror
TS	target strength
TTS	temporary threshold shift
TV	television
TVG	time-varied gain

U

UMM	unit modal mass

V

VBR	variable bitrate
VC	vital capacity
VCA	voltage-controlled variable-gain amplifier

W

WASPAA	IEEE Workshop on Applications of Signal Processing to Audio and Acoustics
WFUMB	World Federation for Ultrasound in Medicine and Biology
WS	working standard
WWII	World War II

X

XMF	extensible music file
XOR	exclusive or

1. Introduction to Acoustics

Thomas D. Rossing

This brief introduction may help to persuade the reader that acoustics covers a wide range of interesting topics. It is impossible to cover all these topics in a single handbook, but we have attempted to include a sampling of hot topics that represent current acoustical research, both fundamental and applied.

Acoustics is the science of sound. It deals with the production of sound, the propagation of sound from the source to the receiver, and the detection and perception of sound. The word *sound* is often used to describe two different things: an auditory sensation in the ear, and the disturbance in a medium that can cause this sensation. By making this distinction, the age-old question *If a tree falls in a forest and no one is there to hear it, does it make a sound?* can be answered.

1.1 Acoustics: The Science of Sound

Acoustics has become a broad interdisciplinary field encompassing the academic disciplines of physics, engineering, psychology, speech, audiology, music, architecture, physiology, neuroscience, and others. Among the branches of acoustics are architectural acoustics, physical acoustics, musical acoustics, psychoacoustics, electroacoustics, noise control, shock and vibration, underwater acoustics, speech, physiological acoustics, etc.

Sound can be produced by a number of different processes, which include the following.

Vibrating bodies: when a drumhead or a noisy machine vibrates, it displaces air and causes the local air pressure to fluctuate.

Changing airflow: when we speak or sing, our vocal folds open and close to let through puffs of air. In a siren, holes on a rapidly rotating plate alternately pass and block air, resulting in a loud sound.

Time-dependent heat sources: an electrical spark produces a crackle; an explosion produces a bang due to the expansion of air caused by rapid heating. Thunder results from rapid heating by a bolt of lightning.

Supersonic flow: shock waves result when a supersonic airplane or a speeding bullet forces air to flow faster than the speed of sound.

1.2 Sounds We Hear

The range of sound intensity and the range of frequency to which the human auditory system responds is quite remarkable. The intensity ratio between the sounds that bring pain to our ears and the weakest

sounds we can hear is more than 10^{12}. The frequency ratio between the highest and lowest frequencies we can hear is nearly 10^3, or more than nine octaves (each octave representing a doubling of frequency). Human vision is also quite remarkable, but the frequency range does not begin to compare to that of human hearing. The frequency range of vision is a little less than one octave (about $4 \times 10^{14} - 7 \times 10^{14}$ Hz). Within this one octave range we can identify more than 7 million colors. Given that the frequency range of the ear is nine times greater, one can imagine how many sound *colors* might be possible.

Humans and other animals use sound to communicate, and so it is not surprising that human hearing is most sensitive over the frequency range covered by human speech. This is no doubt a logical outcome of natural selection. This same match is found throughout much of the animal kingdom. Simple observations show that small animals generally use high frequencies for communication while large animals use low frequencies. In Chap. 19, it is shown that song frequency f scales with animal mass M roughly as $f \propto M^{-1/3}$.

The least amount of sound energy we can hear is of the order of 10^{-20} J (cf. sensitivity of the eye: about one quantum of light in the middle of the visible spectrum $\approx 4 \times 10^{-19}$ J). The upper limit of the sound pressure that can be generated is set approximately by atmospheric pressure. Such an ultimate sound wave would have a sound pressure level of about 191 dB. In practice, of course, nonlinear effects set in well below this level and limit the maximum pressure. A large-amplitude sound wave will change waveform and finally break into a shock, approaching a sawtooth waveform. Nonlinear effects are discussed in Chap. 8.

1.3 Sounds We Cannot Hear: Ultrasound and Infrasound

Sound waves below the frequency of human hearing are called *infrasound*, while sound waves with frequency above the range of human hearing are called *ultrasound*. These sounds have many interesting properties, and are being widely studied. Ultrasound is very important in medical and industrial imaging. It also forms the basis of a growing number of medical procedures, both diagnostic and therapeutic (Chap. 21). Ultrasound has many applications in scientific research, especially in the study of solids and fluids (Chap. 6).

Frequencies as high as 500 MHz have been generated, with a wavelength of about 0.6 μm in air. This is on the order of the wavelength of light and within an order of magnitude of the mean free path of air molecules. A gas ceases to behave like a continuum when the wavelength of sound becomes of the order of the mean free path, and this sets an upper limit on the frequency of sound that can propagate. In solids the assumption of continuum extends down to the intermolecular spacing of approximately 0.1 nm, with a limiting frequency of about 10^{12} Hz. The ultimate limit is actually reached when the wavelength is twice the spacing of the unit cell of a crystal, where the propagation of multiply scattered sound resembles the diffusion of heat [1.1].

Natural phenomena are prodigious generators of infrasound. When Krakatoa exploded, windows were shattered hundreds of miles away by the infrasonic wave. The ringing of both the Earth and the atmosphere continued for hours. The sudden shock wave of an explosion propels a complex infrasonic signal far beyond the shattered perimeter. Earthquakes generate intense infrasonic waves. The faster moving P (primary) waves arrive at distant locations tens of seconds before the destructive S (secondary) waves. (The P waves carry information; the S waves carry energy.) Certain animals and fish can sense these infrasonic precursors and react with fear and anxiety.

A growing amount of astronomical evidence indicates that primordial sound waves at exceedingly low frequency propagated in the universe during its first 380 000 years while it was a plasma of charged particles and thus opaque to electromagnetic radiation. Sound is therefore older than light.

1.4 Sounds We Would Rather Not Hear: Environmental Noise Control

Noise has been receiving increasing recognition as one of our critical environmental pollution problems. Like air and water pollution, noise pollution increases with population density; in our urban areas, it is a serious

threat to our quality of life. Noise-induced hearing loss is a major health problem for millions of people employed in noisy environments. Besides actual hearing loss, humans are affected in many other ways by high levels of noise. Interference with speech, interruption of sleep, and other physiological and psychological effects of noise have been the subject of considerable study. Noise control is discussed in Chap. 23. The propagation of sound in air in Chap. 4, and building acoustics is the subject of Chap. 11.

Fortunately for the environment, even the noisiest machines convert only a small part of their total energy into sound. A jet aircraft, for example, may produce a kilowatt of acoustic power, but this is less than 0.02% of its mechanical output. Automobiles emit approximately 0.001% of their power as sound. Nevertheless, the shear number of machines operating in our society makes it crucial that we minimize their sound output and take measures to prevent the sound from propagating throughout our environment. Although reducing the emitted noise is best done at the source, it is possible, to some extent, to block the transmission of this noise from the source to the receiver. Reduction of classroom noise, which impedes learning in so many schools, is receiving increased attention from government officials as well as from acousticians [1.2].

1.5 Aesthetic Sound: Music

Music may be defined as an art form using sequences and clusters of sounds. Music is carried to the listener by sound waves. The science of musical sound is often called musical acoustics and is discussed in Chap. 15.

Musical acoustics deals with the production of sound by musical instruments, the transmission of music from the performer to the listener, and the perception and cognition of sound by the listener. Understanding the production of sound by musical instruments requires understanding how they vibrate and how they radiate sound. Transmission of sound from the performer to the listener involves a study of concert hall acoustics (covered in Chaps. 9 and 10) and the recording and reproduction of musical sound (covered in Chap. 15). Perception of musical sound is based on psychoacoustics, which is discussed in Chap. 13.

Electronic musical instruments have become increasingly important in contemporary music. Computers have made possible artificial musical intelligence, the synthesis of new musical sounds and the accurate and flexible re-creation of traditional musical sounds by artificial means. Not only do computers talk and sing and play music, they listen to us doing the same, and our interactions with computers are becoming more like our interactions with each other. Electronic and computer music is discussed in Chap. 17.

1.6 Sound of the Human Voice: Speech and Singing

It is difficult to overstate the importance of the human voice. Of all the members of the animal kingdom, we alone have the power of articulate speech. Speech is our chief means of communication. In addition, the human voice is our oldest musical instrument. Speech and singing, the closely related functions of the human voice, are discussed in a unified way in Chap. 16.

In the simplest model of speech production, the vocal folds act as the source and the vocal tract as a filter of the source sound. According to this model, the spectrum envelope of speech sound can be thought of as the product of two components:

Speech sound = source spectrum × filter function.

The nearly triangular waveform of the air flow from the glottis has a spectrum of harmonics that diminish in amplitude roughly as $1/n^2$ (i.e., at a rate of $-12\,\mathrm{dB/octave}$). The formants or resonances of the vocal tract create the various vowel sounds. The vocal tract can be shaped by movements of the tongue, the lips, and the soft palate to tune the formants and articulate the various speech sounds.

Sung vowels are fundamentally the same as spoken vowels, although singers do make vowel modifications in order to improve the musical tone, especially in their high range. In order to produce tones over a wide range of pitch, singers use muscular action in the larynx, which leads to different registers.

Much research has been directed at computer recognition and synthesis of speech. Goals of such research include voice-controlled word processors, voice control of computers and other machines, data entry by voice, etc. In general it is more difficult for a computer to understand language than to speak it.

1.7 How We Hear: Physiological and Psychological Acoustics

The human auditory system is complex in structure and remarkable in function. Not only does it respond to a wide range of stimuli, but it precisely identifies the pitch, timbre, and direction of a sound. Some of the hearing function is done in the organ we call the ear; some of it is done in the central nervous system as well.

Physiological acoustics, which is discussed in Chap. 12, focuses its attention mainly on the peripheral auditory system, especially the cochlea. The dynamic behavior of the cochlea is a subject of great interest. It is now known that the maximum response along the basilar membrane of the cochlea has a sharper peak in a living ear than in a dead one.

Resting on the basilar membrane is the delicate and complex organ of Corti, which contains several rows of hair cells to which are attached auditory nerve fibers. The inner hair cells are mainly responsible for transmitting signals to the auditory nerve fibers, while the more-numerous outer hair cells act as biological amplifiers. It is estimated that the outer hair cells add about 40 dB of amplification to very weak signals, so that hearing sensitivity decreases by a considerable amount when these delicate cells are destroyed by overexposure to noise.

Our knowledge of the cochlea has now progressed to a point where it is possible to construct and implant electronic devices in the cochlea that stimulate the auditory nerve. A cochlear implant is an electronic device that restores partial hearing in many deaf people [1.3]. It is surgically implanted in the inner ear and activated by a device worn outside the ear. An implant has four basic parts: a microphone, a speech processor and transmitter, a receiver inside the ear, and electrodes that transmit impulses to the auditory nerve and thence to the brain.

Psychoacoustics (psychological acoustics), the subject of Chap. 13, deals with the relationships between the physical characteristics of sounds and their perceptual attributes, such as loudness, pitch, and timbre.

The threshold of hearing depends upon frequency, the lowest being around 3–4 kHz, where the ear canal has a resonance, and rising considerably at low frequency. Temporal resolution, such as the ability to detect brief gaps between stimuli or to detect modulation of a sound, is a subject of considerable interest, as is the ability to localize the sound source. Sound localization depends upon detecting differences in arrival time and differences in intensity at our two ears, as well as spectral cues that help us to localize a source in the median plane.

Most sound that reaches our ears comes from several different sources. The extent to which we can perceive each source separately is sometimes called segregation. One important cue for perceptual separation of nearly simultaneous sounds is onset and offset disparity. Another is spectrum change with time. When we listen to rapid sequence of sounds, they may be grouped together (fusion) or they may be perceived as different streams (fission). It is difficult to judge the temporal order of sounds that are perceived in different streams.

1.8 Architectural Acoustics

To many lay people, an acoustician is a person who designs concert halls. That is an important part of architectural acoustics, to be sure, but this field incorporates much more. Architectural acousticians seek to understand and to optimize the sound environment in rooms and buildings of all types, including those used for work, residential living, education, and leisure. In fact, some of the earliest attempts to optimize sound transmission were practised in the design of ancient am-phitheaters, and the acoustical design of outdoor spaces for concerts and drama still challenge architects.

In a room, most of the sound waves that reach the listener's ear have been reflected by one or more surfaces of the room or by objects in the room. In a typical room, sound waves undergo dozens of reflections before they become inaudible. It is not surprising, therefore, that the acoustical properties of rooms play an important role in determining the nature of the sound

heard by a listener. Minimizing extraneous noise is an important part of the acoustical design of rooms and buildings of all kinds. Chapter 9 presents the principles of room acoustics and applies them to performance and assembly halls, including theaters and lecture halls, opera halls, concert halls, worship halls, and auditoria.

The subject of concert hall acoustics is almost certain to provoke a lively discussion by both performers and serious listeners. Musicians recognize the importance of the concert hall in communication between performer and listener. Opinions of new halls tend to polarize toward extremes of very good or very bad. In considering concert and opera halls, it is important to seek a common language for musicians and acousticians in order to understand how objective measurements relate to subjective qualities [1.4, 5]. Chapter 10 discusses

subjective preference theory and how it relates to concert hall design.

Two acoustical concerns in buildings are providing the occupants with privacy and with a quiet environment, which means dealing with noise sources within the building as well as noise transmitted from outside. The most common noise sources in buildings, other than the inhabitants, are related to heating, ventilating, and air conditioning (HVAC) systems, plumbing systems, and electrical systems. Quieting can best be done at the source, but transmission of noise throughout the building must also be prevented. The most common external noise sources that affect buildings are those associated with transportation, such as motor vehicles, trains, and airplanes. There is no substitute for massive walls, although doors and windows must receive attention as well. Building acoustics is discussed in Chap. 11.

1.9 Harnessing Sound: Physical and Engineering Acoustics

It is sometimes said that physicists study nature, engineers attempt to improve it. Physical acoustics and engineering acoustics are two very important areas of acoustics. Physical acousticians investigate a wide range of scientific phenomena, including the propagation of sound in solids, liquids, and gases, and the way sound interacts with the media through which it propagates. The study of ultrasound and infrasound are especially interesting. Physical acoustics is discussed in Chap. 6.

Acoustic techniques have been widely used to study the structural and thermodynamic properties of materials at very low temperatures. Studying the propagation of ultrasound in metals, dielectric crystals, amorphous solids, and magnetic materials has yielded valuable information about their elastic, structural and other properties. Especially interesting has been the propagation of sound in superfluid helium. Second sound, an unusual type of temperature wave, was discovered in 1944, and since that time so-called third sound, fourth sound, and fifth sound have been described [1.6].

Nonlinear effects in sound are an important part of physical acoustics. Nonlinear effects of interest include waveform distortion, shock-wave formation, interactions of sound with sound, acoustic streaming, cavitation, and acoustic levitation. Nonlinearity leads to distortion of the sinusoidal waveform of a sound wave so that it becomes nearly triangular as the

shock wave forms. On the other hand, local disturbances, called *solitons*, retain their shape over large distances.

The study of the interaction of sound and light, called acoustooptics, is an interesting field in physical acoustics that has led to several practical devices. In an acoustooptic modulator, for example, sound waves form a sort of moving optical diffraction grating that diffracts and modulates a laser beam.

Sonoluminescence is the name given to a process by which intense sound waves can generate light. The light is emitted by bubbles in a liquid excited by sound. The observed spectra of emitted light seem to indicate temperatures hotter than the surface of the sun. Some experimental evidence indicates that nuclear fusion may take place in bubbles in deuterated acetone irradiated with intense ultrasound.

Topics of interest in engineering acoustics cover a wide range and include: transducers and arrays, underwater acoustic systems, acoustical instrumentation, audio engineering, acoustical holography and acoustical imaging, ultrasound, and infrasound. Several of these topics are covered in Chaps. 22–27. Much effort has been directed into engineering increasingly small transducers to produce and detect sound. Microphones are being fabricated on silicon chips as parts of integrated circuits. Chapter 29 discusses different types of microphone arrays, such as plane arrays, spherical arrays, and scanning arrays. Chapter 30 discusses acoustic emis-

sion, a nondestructive inspection method and a valuable tool in materials research.

The interaction of sound and heat, called thermoacoustics, is an interesting field that applies principles of physical acoustics to engineering systems. The thermoacoustic effect is the conversion of sound energy to heat or visa versa. In thermoacoustic processes, acoustic power can pump heat from a region of low temperature to a region of higher temperature. This can be used to construct heat engines or refrigerators with no moving parts. Thermoacoustics is discussed in Chap. 7.

1.10 Medical Acoustics

Two uses of sound that physicians have employed for many years are *auscultation*, listening to the body with a stethoscope, and *percussion*, sound generation by the striking the chest or abdomen to assess transmission or resonance. The most exciting new developments in medical acoustics, however, involve the use of ultrasound, both diagnostic imaging and therapeutic applications.

There has been a steady improvement in the quality of diagnostic ultrasound imaging. Two important commercial developments have been the advent of real-time three-dimensional (3-D) imaging and the development of hand-held scanners. Surgeons can now carry out procedures without requiring optical access. Although measurements on isolated tissue samples show that acoustic attenuation and backscatter correlate with pathology, implementing algorithms to obtain this information on a clinical scanner is challenging at the present time.

The therapeutic use of ultrasound has blossomed in recent years. Shock-wave lithotripsy is the predominant surgical operation for the treatment of kidney stones. Shock waves also appear to be effective at helping heal broken bones. High-intensity focused ultrasound is used to heat tissue selectivity so that cells can be destroyed in a local region. Ultrasonic devices appear to hold promise for treating glaucoma, fighting cancer, and controlling internal bleeding. Advanced therapies, such as puncturing holes in the heart, promoting localized drug delivery, and even carrying out brain surgery through an intact skull appear to be feasible with ultrasound [1.7].

Other applications of medical ultrasound are included in Chap. 21.

1.11 Sounds of the Sea

Oceans cover more than 70% of the Earth's surface. Sound waves are widely used to explore the oceans, because they travel much better in sea water than light waves. Likewise, sound waves are used, by humans and dolphins alike, to communicate under water, because they travel much better than radio waves. Acoustical oceanography has many military, as well as commercial applications. Much of our understanding of underwater sound propagation is a result of research conducted during and following World War II. Underwater acoustics is discussed in Chap. 5.

The speed of sound in water, which is about 1500 m/s, increases with increasing static pressure by about 1 part per million per kilopascal, or about 1% per 1000 m of depth, assuming temperature remains constant. The variation with temperature is an increase of about 2% per °C temperature rise. Refraction of sound, due to these changes in speed, along with reflection at the surface and the bottom, lead to waveguides at various ocean depths. During World War II, a *deep channel* was discovered in which sound waves could travel distances in excess of 3000 km. This phenomenon gave rise to the deep channel or sound fixing and ranging (SOFAR) channel, which could be used to locate, by acoustic means, airmen downed at sea.

One of the most important applications of underwater acoustics is sound navigation and ranging (SONAR). The purpose of most sonar systems is to detect and localize a target, such as submarines, mines, fish, or surface ships. Other SONARs are designed to measure some quantity, such as the ocean depth or the speed of ocean currents.

An interesting phenomenon called cavitation occurs when sound waves of high intensity propagate through water. When the rarefaction tension phase of the sound wave is great enough, the medium ruptures and cavitation bubbles appear. Cavitation bubbles can be produced by the tips of high-speed propellers. Bubbles affect the speed of sound as well as its attenuation [1.7, 8].

2. A Brief History of Acoustics

Thomas D. Rossing

Although there are certainly some good histori-
cal treatments of acoustics in the literature, it still
seems appropriate to begin a handbook of acous-
tics with a brief history of the subject. We begin
by mentioning some important experiments that
took place before the 19th century. Acoustics in
the 19th century is characterized by describing the
work of seven outstanding acousticians: Tyndall,
von Helmholtz, Rayleigh, Stokes, Bell, Edison, and
Koenig. Of course this sampling omits the mention
of many other outstanding investigators.

To represent acoustics during the 20th century,
we have selected eight areas of acoustics, again
not trying to be all-inclusive. We select the eight
areas represented by the first eight technical ar-
eas in the Acoustical Society of America. These are
architectural acoustics, physical acoustics, engi-
neering acoustics, structural acoustics, underwater
acoustics, physiological and psychological acous-
tics, speech, and musical acoustics. We apologize
to readers whose main interest is in another area
of acoustics. It is, after all, a broad interdisciplinary
field.

2.1 Acoustics in Ancient Times

Acoustics is the science of sound. Although sound
waves are nearly as old as the universe, the scientific
study of sound is generally considered to have its ori-
gin in ancient Greece. The word acoustics is derived
from the Greek word *akouein*, to hear, although Sauveur
appears to have been the first person to apply the term
acoustics to the science of sound in 1701 [2.1].

Pythagoras, who established mathematics in Greek
culture during the sixth century BC, studied vibrating
strings and musical sounds. He apparently discovered
that dividing the length of a vibrating string into simple
ratios produced consonant musical intervals. Accord-
ing to legend, he also observed how the pitch of the
string changed with tension and the tones generated

by striking musical glasses, but these are probably just legends [2.2].

Although the Greeks were certainly aware of the importance of good acoustical design in their many fine theaters, the Roman architect Vitruvius was the first to write about it in his monumental *De Architectura*, which includes a remarkable understanding and analysis of theater acoustics:

> *We must choose a site in which the voice may fall smoothly, and not be returned by reflection so as to convey an indistinct meaning to the ear.*

2.2 Early Experiments on Vibrating Strings, Membranes and Plates

Much of early acoustical investigations were closely tied to musical acoustics. Galileo reviewed the relationship of the pitch of a string to its vibrating length, and he related the number of vibrations per unit time to pitch. Joseph Sauveur made more-thorough studies of frequency in relation to pitch. The English mathematician Brook Taylor provided a dynamical solution for the frequency of a vibrating string based on the assumed curve for the shape of the string when vibrating in its fundamental mode. Daniel Bernoulli set up a partial differential equation for the vibrating string and obtained solutions which d'Alembert interpreted as waves traveling in both directions along the string [2.3].

The first solution of the problem of vibrating membranes was apparently the work of S. D. Poisson, and the circular membrane was handled by R. F. A. Clebsch. Vibrating plates are somewhat more complex than vibrating membranes. In 1787 *E. F. F. Chladni* described his method of using sand sprinkled on vibrating plates to show nodal lines [2.4]. He observed that the addition of one nodal circle raised the frequency of a circular plate by about the same amount as adding two nodal diameters, a relationship that Lord Rayleigh called Chladni's law. Sophie Germain wrote a fourth-order equation to describe plate vibrations, and thus won a prize provided by the French emperor Napoleon, although Kirchhoff later gave a more accurate treatment of the boundary conditions. *Rayleigh*, of course, treated both membranes and plates in his celebrated book *Theory of Sound* [2.5].

Chladni generated his vibration patterns by *strewing sand* on the plate, which then collected along the nodal lines. Later he noticed that fine shavings from the hair of his violin bow did not follow the sand to the nodes, but instead collected at the antinodes. *Savart* noted the same behavior for fine lycopodium powder [2.6]. Michael *Faraday* explained this as being due to acoustic streaming [2.7]. Mary *Waller* published several papers and a book on Chladni patterns, in which she noted that particle diameter should exceed $100\,\mu m$ in order to collect at the nodes [2.8]. Chladni figures of some of the many vibrational modes of a circular plate are shown in Fig. 2.1.

Fig. 2.1 Chladni patterns on a circular plate. The first four have two, three, four, and five nodal lines but no nodal circles; the second four have one or two nodal circles

2.3 Speed of Sound in Air

From earliest times, there was agreement that sound is propagated from one place to another by some activity of the air. Aristotle understood that there is actual motion of air, and apparently deduced that air is compressed. The Jesuit priest Athanasius Kircher was one of the first to observe the sound in a vacuum chamber, and since he could hear the bell he concluded that air was not necessary for the propagation of sound.

Robert Boyle, however, repeated the experiment with a much improved pump and noted the much-observed decrease in sound intensity as the air is pumped out. We now know that sound propagates quite well in rarified air, and that the decrease in intensity at low pressure is mainly due to the impedance mismatch between the source and the medium as well as the impedance mismatch at the walls of the container.

As early as 1635, Gassendi measured the speed of sound using firearms and assuming that the light of the flash is transmitted instantaneously. His value came out to be 478 m/s. Gassendi noted that the speed of sound did not depend on the pitch of the sound, contrary to the view of Aristotle, who had taught that high notes are transmitted faster than low notes. In a more careful experiment, Mersenne determined the speed of sound to be 450 m/s [2.9]. In 1650, G. A. Borelli and V. Viviani of the Accademia del Cimento of Florence obtained a value of 350 m/s for the speed of sound [2.10]. Another Italian, G. L. Bianconi, showed that the speed of sound in air increases with temperature [2.11].

The first attempt to calculate the speed of sound through air was apparently made by Sir Isaac Newton.

He assumed that, when a pulse is propagated through a fluid, the particles of the fluid move in simple harmonic motion, and that if this is true for one particle, it must be true for all adjacent ones. The result is that the speed of sound is equal to the square root of the ratio of the atmospheric pressure to the density of the air. This leads to values that are considerably less than those measured by Newton (at Trinity College in Cambridge) and others.

In 1816, Pierre Simon Laplace suggested that in Newton's and Lagrange's calculations an error had been made in using for the volume elasticity of the air the pressure itself, which is equivalent to assuming the elastic motions of the air particles take place at constant temperature. In view of the rapidity of the motions, it seemed more reasonable to assume that the compressions and rarefactions follow the adiabatic law. The adiabatic elasticity is greater than the isothermal elasticity by a factor γ, which is the ratio of the specific heat at constant pressure to that at constant volume. The speed of sound should thus be given by $c = (\gamma p/\rho)^{1/2}$, where p is the pressure and ρ is the density. This gives much better agreement with experimental values [2.3].

2.4 Speed of Sound in Liquids and Solids

The first serious attempt to measure the speed of sound in liquid was probably that of the Swiss physicist Daniel Colladon, who in 1826 conducted studies in Lake Geneva. In 1825, the Academy of Sciences in Paris had announced as the prize competition for 1826 the measurement of the compressibility of the principal liquids. Colladon measured the static compressibility of several liquids, and he decided to check the accuracy of his measurements by measuring the speed of sound, which depends on the compressibility. The compressibility of water computed from the speed of sound turned out to be very close to the statically measured values [2.12]. Oh yes, he won the prize from the Academy.

In 1808, the French physicist *J. B. Biot* measured the speed of sound in a 1000 m long iron water pipe in Paris by direct timing of the sound travel [2.13]. He compared the arrival times of the sound through the metal and through the air and determined that the speed is much greater in the metal. Chladni had earlier studied the speed of sound in solids by noting the pitch emanating from a struck solid bar, just as we do today. He deduced that the speed of sound in tin is about 7.5 times greater than in air, while in copper it was about 12 times greater. Biot's values for the speed in metals agreed well with Chladni's.

2.5 Determining Frequency

Much of the early research on sound was tied to musical sound. Vibrating strings, membranes, plates, and air columns were the bases of various musical instruments. Music emphasized the importance of ratios for the different tones. A string could be divided into halves

or thirds or fourths to give harmonious pitches. It was also known that pitch is related to frequency. Marin Mersenne (1588–1648) was apparently the first to determine the frequency corresponding to a given pitch. By working with a long rope, he was able determine the

frequency of a standing wave on the length, mass, and tension of the rope. He then used a short wire under tension and from his rope formula he was able to compute the frequency of oscillation [2.14]. The relationship between pitch and frequency was later improved by Joseph Sauveur, who counted beats between two low-pitched organ pipes differing in pitch by a semitone. Sauveur [2.1] deduced that

> *the relation between sounds of low and high pitch is exemplified in the ratio of the numbers of vibrations which they both make in the same time.*

He recognized that two sounds differing a musical fifth have frequencies in the ratio of 3 : 2. We have already commented that Sauveur was the first to apply the term *acoustics* to the science of sound [2.1]:

> *I have come then to the opinion that there is a science superior to music, and I call it acoustics; it has for its object sound in general, whereas music has for its objects sounds agreeable to the ear.*

Tuning forks were widely used for determining pitch by the 19th century. Johann Scheibler (1777–1837) developed a tuning-fork *tonometer* which consisted of some 56 tuning forks. One was adjusted to the pitch of A above middle C, and another was adjusted by ear to be one octave lower. The others were then adjusted to differ successively by four vibrations per second above the lower A. Thus, he divided the octave into 55 intervals, each of about four vibrations per second. He then measured the number of beats in each interval, the sum total of such beats giving him the absolute frequency. He determined the frequency of the lower A to be 220 vibrations per second and the upper A to be 440 vibrations per second [2.15].

Felix Savart (1791–1841) used a rapidly rotating toothed wheel with 600 teeth to produce sounds of high frequency. He estimated the upper frequency threshold of hearing to be 24 000 vibrations per second. Charles Wheatstone (1802–1875) pioneered the use of rapidly rotating mirrors to study periodic events. This technique was later used by Rudolph Koenig and others to study speech sounds.

2.6 Acoustics in the 19th Century

Acoustics really blossomed in the 19th century. It is impossible to describe but a fraction of the significant work in acoustics during this century. We will try to provide a skeleton, at least, by mentioning the work of a few scientists. Especially noteworthy is the work of Tyndall, von Helmholtz, and Rayleigh, so we begin with them.

2.6.1 Tyndall

John Tyndall was born in County Carlow, Ireland in 1820. His parents were unable to finance any advanced education. After working at various jobs, he traveled to Marburg, Germany where he obtained a doctorate. He was appointed Professor of Natural Philosophy at the Royal Institution in London, where he displayed his skills in popular lecturing. In 1872 he made a lecture tour in the United States, which was a great success. His first lectures were on heat, and in 1863 these lectures were published under the title *Heat as a Mode of Motion*.

In 1867 he published his book *On Sound* with seven chapters. Later he added chapters on the transmission of sound through the atmosphere and on combinations of musical tones. In two chapters on vibrations of rods, plates, and bells, he notes that longitudinal vibrations produced by rubbing a rod lengthwise with a cloth or leather treated with rosin excited vibrations of higher frequency than the transverse vibrations. He discusses the determination of the waveform of musical sounds. By shining an intense beam of light on a mirror attached to a tuning fork and then to a slowly rotating mirror, as Lissajous had done, he spread out the waveform of the oscillations.

Tyndall is well remembered for his work on the effect of fog on transmission of sound through the atmosphere. He had succeeded Faraday as scientific advisor to the Elder Brethren of Trinity House, which supervised lighthouses and pilots in England. When fog obscures the lights of lighthouses, ships depend on whistles, bells, sirens, and even gunfire for navigation warnings. In 1873 Tyndall began a systematic study of sound propagation over water in various weather conditions in the straits of Dover. He noted great inconsistencies in the propagation.

2.6.2 Helmholtz

Hermann von Helmholtz was educated in medicine. He had wanted to study physics, but his father could not afford to support him, and the Prussian government of-

fered financial support for students of medicine who would sign up for an extended period of service with the military. He was assigned a post in Potsdam, where he was able to set up his own laboratory in physics and physiology. The brilliance of his work led to cancelation of his remaining years of army duty and to his appointment as Professor of Physiology at Königsberg. He gave up the practice of medicine and wrote papers on physiology, color perception, and electricity. His first important paper in acoustics appears to have been his *On Combination Tones*, published in 1856 [2.16].

His book *On Sensations of Tone* (1862) combines his knowledge of both physiology and physics and music as well. He worked with little more than a stringed instrument, tuning forks, his siren, and his famous resonators to show that pitch is due to the fundamental frequency but the quality of a musical sound is due to the presence of upper partials. He showed how the ear can separate out the various components of a complex tone. He concluded that the quality of a tone depends solely on the number and relative strength of its partial tone and not on their relative phase.

In order to study vibrations of violin stings and speech sounds, von Helmholtz invented a vibration microscope, which displayed Lissajous patterns of vibration. One lens of the microscope is attached to the prong of a tuning fork, so a fixed spot appears to move up and down. A spot of luminous paint is then applied to the string, and a bow is drawn horizontally across the vertical string. The point on the horizontally vibrating violin string forms a Lissajous pattern as it moves. By viewing patterns for a bowed violin string, von Helmholtz was able to determine the actual motion of the string, and such motion is still referred to as Helmholtz motion.

Much of Helmholtz's book is devoted to discussion of hearing. Using a double siren, he studied difference tones and combination tones. He determined that beyond about 30 beats per second, the listener no longer hears individual beats but the tone becomes jarring or rough. He postulated that individual nerve fibers acted as vibrating strings, each resonating at a different frequency. Noting that skilled musicians

can distinguish with certainty a difference in pitch arising from half a vibration in a second in the doubly accented octave,

he concluded that some 1000 different pitches might be distinguished in the octave between 50 and 100 cycles per second, and since there are 4500 nerve fibers in the cochlea, this represented about one fiber for each two cents of musical interval. He admitted, however

that we cannot precisely ascertain what parts of the ear actually vibrate sympathetically with individual tones.

2.6.3 Rayleigh

Rayleigh was a giant. He contributed to so many areas of physics, and his contributions to acoustics were monumental. His book *Theory of Sound* still has an honored place on the desk of every acoustician (alongside von Helmholtz's book, perhaps). In addition to his book, he published some 128 papers on acoustics. He anticipated so many interesting things. I have sometimes made the statement that every time I have a good idea about sound Rayleigh steals it and puts it into his book.

John William Strutt, who was to become the third Baron Rayleigh, was born at the family estate in Terling England in 1842. (Milk from the Rayleigh estate has supplied many families in London to this day.) He enrolled at Eton, but illness caused him to drop out, and he completed his schooling at a small academy in Torquay before entering Trinity College, Cambridge. His ill health may have been a blessing for the rest of the world. After nearly dying of rheumatic fever, he took a long cruise up the Nile river, during which he concentrated on writing his *Science of Sound*.

Soon after he returned to England, his father died and he became the third Baron Rayleigh and inherited title to the estate at Terling, where he set up a laboratory. When James Clerk Maxwell died in 1879, Rayleigh was offered the position as Cavendish Professor of Physics at Cambridge. He accepted it, in large measure because there was an agricultural depression at the time and his farm tenants were having difficulties in making rent payments [2.15].

Rayleigh's book and his papers cover such a wide range of topics in acoustics that it would be impractical to attempt to describe them here. His brilliant use of mathematics set the standard for subsequent writings on acoustics. The first volume of his book develops the theory of vibrations and its applications to strings, bars, membranes, and plates, while the second volume begins with aerial vibrations and the propagation of waves in fluids.

Rayleigh combined experimental work with theory in a very skillful way. Needing a way to determine the intensity of a sound source, he noted that a light disk suspended in a beam of sound tended to line up

with its plane perpendicular to the direction of the fluid motion. The torque on the disk is proportional to the sound intensity. By suspending a light mirror in a sound field, the sound intensity could be determined by means of a sensitive optical lever. The arrangement, known as a Rayleigh disk, is still used to measure sound intensity.

Another acoustical phenomenon that bears his name is the propagation of Rayleigh waves on the plane surface of an elastic solid. Rayleigh waves are observed on both large and small scales. Most of the shaking felt from an earthquake is due to Rayleigh waves, which can be much larger than the seismic waves. Surface acoustic wave (SAW) filters and sensors make use of Rayleigh waves.

2.6.4 George Stokes

George Gabriel Stokes was born in County Sligo, Ireland in 1819. His father was a Protestant minister, and all of his brothers became priests. He was educated at Bristol College and Pembroke College, Cambridge. In 1841 he graduated as senior wrangler (the top First Class degree) in the mathematical tripos and he was the first Smith's prize man. He was awarded a Fellowship at Pembroke College and later appointed Lucasian professor of mathematics at Cambridge. The position paid rather poorly, however, so he accepted an additional position as professor of physics at the Government School of Mines in London.

William Hopkins, his Cambridge tutor, advised him to undertake research into hydrodynamics, and in 1842 he published a paper *On the steady motion of incompressible fluids.* In 1845 he published his classic paper *On the theories of the internal friction of fluids in motion*, which presents a three-dimensional equation of motion of a viscous fluid that has come to be known as the Stokes–Navier equation. Although he discovered that Navier, Poisson, and Saint-Venant had also considered the problem, he felt that his results were obtained with sufficiently different assumptions to justify publication. The Stokes–Navier equation of motion of a viscous, compressible fluid is still the starting point for much of the theory of sound propagation in fluids.

2.6.5 Alexander Graham Bell

Alexander Graham Bell was born in Edinburgh, Scotland in 1847. He taught music and elocution in Scotland before moving to Canada with his parents in 1868, and in 1871 he moved to Boston as a teacher of the deaf. In his spare time he worked on the *harmonic telegraph*, a device that would allow two or more electrical signals to be transmitted on the same wire. Throughout his life, Bell had been interested in the education of deaf people, which interest lead him to invent the microphone and, in 1876, his *electrical speech machine*, which we now call a telephone. He was encouraged to work steadily on this invention by Joseph Henry, secretary of the Smithsonian Institution and a highly respected physicist and inventor.

Bell's telephone was a great financial, as well as technical success. Bell set up a laboratory on his estate near Braddock, Nova Scotia and continued to improve the telephone as well as to work on other inventions. The magnetic transmitter was replaced by Thomas Edison's carbon microphone, the rights to which he obtained as a result of mergers and patent lawsuits [2.15].

2.6.6 Thomas Edison

The same year that Bell was born in Scotland (1847), Thomas A. Edison, the great inventor, was born in Milan, Ohio. At the age of 14 he published his own small newspaper, probably the first newspaper to be sold on trains. Also aged 14 he contracted scarlet fever which destroyed most of his hearing. His first invention was an improved stock-ticker for which he was paid $40 000. Shortly after setting up a laboratory in Menlo Park, New Jersey, he invented (in 1877) the first phonograph. This was followed (in 1879) by the incandescent electric light bulb and a few years later by the Vitascope, which led to the first silent motion pictures. Other inventions included the dictaphone, mimeograph and storage battery.

The first published article on the phonograph appeared in *Scientific American* in 1877 after Edition visited the New York offices of the journal and demonstrated his machine. Later he demonstrated his machine in Washington for President Hayes, members of Congress and other notables. Many others made improvements to Edison's talking machine, but the credit still goes to Edison for first showing that the human voice could be recorded for posterity.

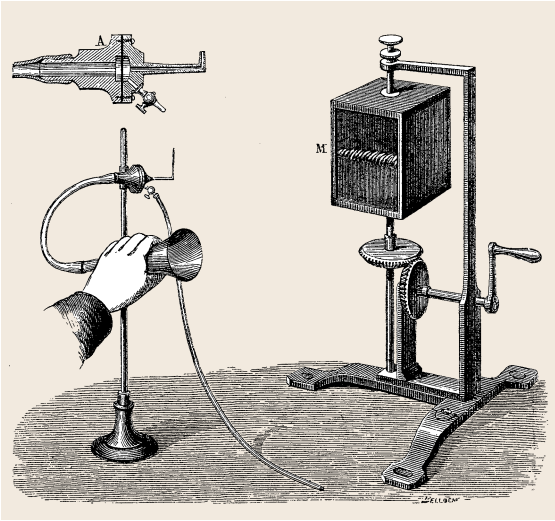
In its founding year (1929), the Acoustical Society of America (ASA) made Thomas Edison an honorary fellow, an honor which was not again bestowed during the 20 years that followed.


Fig. 2.2 Koenig's manometric flame apparatus. The image of the oscillating flame is seen in the rotating mirror (after [2.17])

2.6.7 Rudolph Koenig

Rudolph Koenig was born in Koenigsberg (now Kaliningrad), Russia in 1832 and attended the university there at a time when von Helmholtz was a Professor of Physiology there. A few years after taking his degree, Koenig moved to Paris where he studied violin making under Villaume. He started his own business making acoustical apparatus, which he did with great care and talent. He devoted more than 40 years to making the best acoustical equipment of his day, many items of which are still in working order in museums and acoustics laboratories. Koenig, who never married, lived in the small front room of his Paris apartment, which was also his office and stock room, while the building and testing of instruments was done in the back rooms by Koenig and

a few assistants. We will attempt to describe but a few of his acoustical instruments, but they have been well documented by *Greenslade* [2.17], *Beyer* [2.18], and others. The two largest collections of Koenig apparatus in North America are at the Smithsonian Institution and the University of Toronto.

Koenig made tuning forks of all sizes. A large 64 Hz fork formed the basis for a tuning-fork clock. A set of forks covering a range of frequencies in small steps was called a *tonometer* by Johann Scheibler. For his own use, Koenig made a tonometer consisting of 154 forks ranging in frequency from 16 to 21 845 Hz. Many tuning forks were mounted on hollow wooden resonators. He made both cylindrical and spherical Helmholtz resonators of all sizes.

To his contemporaries, Koenig was probably best known for his invention (1862) of the manometric flame apparatus, shown in Fig. 2.2, which allowed the visualization of acoustic signals. The manometric capsule is divided into two parts by a thin flexible membrane. Sounds waves are collected by a funnel, pass down the rubber tube, and cause the membrane to vibrate. Vibrations of the membrane cause a periodic change in the supply of gas to the burner, so the flame oscillates up and down at the frequency of the sound. The oscillating flame is viewed in the rotating mirror.

Koenig made apparatus for both the Fourier analysis and the synthesis of sound. At the 1876 exhibition, the instrument was used to show eight harmonics of a sung vowel. The Fourier analyzer included eight Helmholtz resonators, tuned to eight harmonics, which fed eight manometric flames. The coefficients of the various sinusoidal terms related to the heights of the eight flame images. The Helmholtz resonators could be tuned to different frequencies. The Fourier synthesizer had 10 electromagnetically-driven tuning forks and 10 Helmholtz resonators. A hole in each resonator could be opened or closed by means of keys [2.17].

2.7 The 20th Century

history of acoustics in the 20th century could be presented in several ways. In his definitive history, *Beyer* [2.15] devotes one chapter to each quarter century, perhaps the most sensible way to organize the subject. One could divide the century at the year 1929, the year the Acoustical Society of America was founded. One of the events in connection with the 75th anniversary of this society was the publication of a snap-

shot history of the Society written by representatives from the 15 technical committees and edited by Henry *Bass* and William *Cavanaugh* [2.19]. Since we make no pretense of covering all areas of acoustics nor of reporting all acoustical developments in the 20th century, we will merely select a few significant areas of acoustics and try to discuss briefly some significant developments in these. For want of other criteria, we have selected

the nine areas of acoustics that correspond to the first eight technical committees in the Acoustical Society of America.

2.7.1 Architectural Acoustics

Wallace Clement Sabine (1868–1919) is generally considered to be the father of architectural acoustics. He was the first to make quantitative measurements on the acoustics of rooms. His discovery that the product of total absorption and the duration of residual sound is a constant still forms the basis of sound control in rooms. His pioneering work was not done entirely by choice, however. As a 27-year old professor at Harvard University, he was assigned by the President to determine corrective measures for the lecture room at Harvard's Fogg Art Museum. As he begins his famous paper on reverberation [2.20]:

> The following investigation was not undertaken at first by choice but devolved on the writer in 1895 through instructions from the Corporation of Harvard University to propose changes for remedying the acoustical difficulties in the lecture-room of the Fogg Art Museum, a building that had just been completed.

Sabine determined the reverberation time in the Fogg lecture room by using an organ pipe and a chronograph. He found the reverberation time in the empty room to be 5.62 seconds. Then he started adding seat cushions from the Sanders Theater and measuring the resulting reverberation times. He developed an empirical formula $T = 0.164\,V/A$, where T is reverberation time, V is volume (in cubic feet) and A is the average absorption coefficient times the total area (in square feet) of the walls, ceiling and floor. This formula is still called the Sabine reverberation formula.

Following his success with the Fogg lecture room, Sabine was asked to come up with acoustical specifications for the New Boston Music Hall, now known as Symphony Hall, which would ensure hearing superb music from every seat. Sabine answered with a shoebox shape for the building to keep out street noise. Then, using his mathematical formula for reverberation time, Sabine carefully adjusted the spacing between the rows of seats, the slant of the walls, the shape of the stage, and materials used in the walls to produce the exquisite sound heard today at Symphony Hall (Fig. 2.3).

Vern Knudsen (1893–1974), physicist at University of California Los Angeles (UCLA) and third president

Fig. 2.3 Interior of Symphony Hall in Boston whose acoustical design by Wallace Clement Sabine set a standard for concert halls

of the Acoustical Society of America, was one of many persons who contributed to architectural acoustics in the first half of the 20th century. His collaboration with Hans Kneser of Germany led to an understanding of molecular relaxation phenomena in gases and liquids. In 1932 he published a book on *Architectural Acoustics* [2.21], and in 1950, a book *Architectural Designing in Acoustics* with *Cyril Harris* [2.22], which summarized most of what was known about the subject by the middle of the century.

In the mid 1940s Richard Bolt, a physicist at the Massachusetts Institute of Technology (MIT), was asked by the United Nations (UN) to design the acoustics for one of the UN's new buildings. Realizing the work that was ahead of him, he asked Leo Beranek to join him. At the same time they hired another MIT professor, Robert Newman, to help with the work with the United Nations; together they formed the firm of Bolt, Beranek, and Newman (BBN), which was to become one of the foremost architectural consulting firms in the world. This firm has provided acoustical consultation for a number of notable concert halls, including Avery Fisher Hall in New York, the Koussevitzky Music Shed at Tanglewood, Davies Symphony Hall in San Francisco, Roy Thompson Hall in Toronto, and the Center for the Performing Arts in Tokyo [2.23]. They are also well known for their efforts in pioneering the Arpanet, forerunner of the Internet.

Recipients of the Wallace Clement Sabine award for accomplishments in architectural acoustics, include Vern Knudsen, Floyd Watson, Leo Beranek, Erwin Meyer, Hale Sabine, Lothar Cremer, Cyril Harris, Thomas Northwood, Richard Waterhouse, Harold Marshall, Russell Johnson, Alfred Warnock, William Cavanaugh, John S. Bradley, and Christopher Jaffe. The silver medal in architectural acoustics was awarded to Theodore Schultz. The work of each of these distinguished acousticians could be a chapter in the history of acoustics but space does not allow it.

2.7.2 Physical Acoustics

Although all of acoustics, the science of sound, incorporates the laws of physics, we usually think of physical acoustics as being concerned with fundamental acoustic wave propagation phenomena, including transmission, reflection, refraction, interference, diffraction, scattering, absorption, dispersion of sound and the use of acoustics to study physical properties of matter and to produce changes in these properties. The foundations for physical acoustics were laid by such 19th century giants as von Helmholtz, Rayleigh, Tyndall, Stokes, Kirchhoff, and others.

Ultrasonic waves, sound waves with frequencies above the range of human hearing, have attracted the attention of many physicists and engineers in the 20th century. An early source of ultrasound was the Galton whistle, used by Francis Galton to study the upper threshold of hearing in animals. More powerful sources of ultrasound followed the discovery of the piezoelectric effect in crystals by Jacques and Pierre Curie. They found that applying an electric field to the plates of certain natural crystals such as quartz produced changes in thickness. Later in the century, highly efficient ceramic piezoelectric transducers were used to produce high-intensity ultrasound in solids, liquids, and gases.

Probably the most important use of ultrasound nowadays is in ultrasonic imaging, in medicine (sonograms) as well as in the ocean (sonar). Ultrasonic waves are used in many medical diagnostic procedures. They are directed toward a patient's body and reflected when they reach boundaries between tissues of different densities. These reflected waves are detected and displayed on a monitor. Ultrasound can also be used to detect malignancies and hemorrhaging in various organs. It is also used to monitor real-time movement of heart valves and large blood vessels. Air, bone, and other calcified tissues absorb most of the ultrasound beam; therefore this technique cannot be used to examine the bones or the lungs.

The father of sonar (sound navigation and ranging) was Paul Langevin, who used active echo ranging sonar at about 45 kHz to detect mines during World War I. Sonar is used to explore the ocean and study marine life in addition to its many military applications [2.24]. New types of sonar include synthetic aperture sonar for high-resolution imaging using a moving hydrophone array and computed angle-of-arrival transient imaging (CAATI).

Infrasonic waves, which have frequencies below the range of human hearing, have been less frequently studied than ultrasonic waves. Natural phenomena are prodigious generators of infrasound. When the volcano Krakatoa exploded, windows were shattered hundreds of miles away by the infrasonic wave. The *ringing* of both earth and atmosphere continued for hours. It is believed that infrasound actually formed the upper pitch of this natural volcanic explosion, tones unmeasurably deep forming the actual central harmonic of the event. Infrasound from large meteoroids that enter our atmosphere have very large amplitudes, even great enough to break glass windows [2.25]. Ultralow-pitch earthquake sounds are keenly felt by animals and sensitive humans. Quakes occur in distinct stages. Long before the final breaking release of built-up earth tensions, there are numerous and succinct precursory shocks. Deep shocks produce strong infrasonic impulses up to the surface, the result of massive heaving ground strata. Certain animals (fish) can actually hear infrasonic precursors.

Aeroacoustics, a branch of physical acoustics, is the study of sound generated by (or in) flowing fluids. The mechanism for sound or noise generation may be due to turbulence in flows, resonant effects in cavities or waveguides, vibration of boundaries of structures etc. A flow may alter the propagation of sound and boundaries can lead to scattering; both features play a significant part in altering the noise received at a particular observation point. A notable pioneer in aeroacoustics was Sir James Lighthill (1924–1998), whose analyses of the sounds generated in a fluid by turbulence have had appreciable importance in the study of nonlinear acoustics. He identified quadrupole sound sources in the inhomogeneities of turbulence as a major source of the noise from jet aircraft engines, for example [2.26].

There are several sources of nonlinearity when sound propagates through gases, liquids, or solids. At least since the time of Stokes, it has been known that in fluids compressions propagate slightly faster than rarefactions, which leads to distortion of the wave front and even to the formation of shock waves. Richard Fay (1891–1964) noted that the waveform takes on the

shape of a sawtooth. In 1935 Eugene Fubini–Ghiron demonstrated that the pressure amplitude in a nondissipative fluid is proportional to an infinite series in the harmonics of the original signal [2.15]. Several books treat nonlinear sound propagation, including those by *Beyer* [2.27] and by *Hamilton* and *Blackstock* [2.28].

Measurements of sound propagation in liquid helium have led to our basic understanding of cryogenics and also to several surprises. The attenuation of sound shows a sharp peak near the so-called lambda point at which helium takes on superfluid properties. This behavior was explained by Lev Landau (1908–1968) and others. Second sound, the propagation of waves consisting of periodic oscillations of temperature and entropy, was discovered in 1944 by V. O. Peshkov. Third sound, a surface wave of the superfluid component was reported in 1958, whereas fourth sound was discovered in 1962 by K. A. Shapiro and Isadore Rudnick. Fifth sound, a thermal wave, has also been reported, as has *zero* sound [2.15].

While there a number of ways in which light can interact with sound, the term *optoacoustics* typically refers to sound produced by high-intensity light from a laser. The optoacoustic (or photoacoustic) effect is characterized by the generation of sound through interaction of electromagnetic radiation with matter. Absorption of single laser pulses in a sample can effectively generate optoacoustic waves through the thermoelastic effect. After absorption of a short pulse the heated region thermally expands, creating a mechanical disturbance that propagates into the surrounding medium as a sound wave. The waves are recorded at the surface of the sample with broadband ultrasound transducers.

Sonoluminescence uses sound to produce light. Sonoluminescence, the emission of light by bubbles in a liquid excited by sound, was discovered by H. Frenzel and H. Schultes in 1934, but was not considered very interesting at the time. A major breakthrough occurred when Felipe Gaitan and his colleagues were able to produce single-bubble sonoluminescence, in which a single bubble, trapped in a standing acoustic wave, emits light with each pulsation [2.29].

The wavelength of the emitted light is very short, with the spectrum extending well into the ultraviolet. The observed spectrum of emitted light seems to indicate a temperature in the bubble of at least $10\,000\,°C$, and possibly a temperature in excess of one million degrees C. Such a high temperature makes the study of sonoluminescence especially interesting for the possibility that it might be a means to achieve thermonuclear fusion. If the bubble is hot enough, and the pressures in

it high enough, fusion reactions like those that occur in the Sun could be produced within these tiny bubbles.

When sound travels in small channels, oscillating heat also flows to and from the channel walls, leading to a rich variety of *thermoacoustic* effects. In 1980, Nicholas *Rott* developed the mathematics describing acoustic oscillations in a gas in a channel with an axial temperature gradient, a problem investigated by Rayleigh and Kirchhoff without much success [2.30]. Applying Rott's mathematics, *Hofler* et al. invented a standing-wave thermoacoustic refrigerator in which the coupled oscillations of gas motion, temperature, and heat transfer in the sound wave are phased so that heat is absorbed at low temperature and waste heat is rejected at higher temperature [2.31].

Recipients of the ASA silver medal in physical acoustics since it was first awarded in 1975 have included Isadore Rudnick, Martin Greenspan, Herbert McSkimin, David Blackstock, Mack Breazeale, Allan Pierce, Julian Maynard, Robert Apfel, Gregory Swift, Philip Marston, Henry Bass, Peter Westervelt, and Andrea Prosperetti.

2.7.3 Engineering Acoustics

It is virtually impossible to amplify sound waves. Electrical signals, on the other hand, are relatively easy to amplify. Thus a practical system for amplifying sound includes input and output *transducers*, together with the electronic amplifier. Transducers have occupied a central role in engineering acoustics during the 20th century.

The transducers in a sound amplifying system are microphones and loudspeakers. The first microphones were Bell's magnetic transmitter and the loosely packed carbon microphones of Edison and Berliner. A great step forward in 1917 was the invention of the condenser microphone by Edward Wente (1889–1972). In 1962, James West and Gerhard Sessler invented the foil electret or electret condenser microphone, which has become the most ubiquitous microphone in use. It can be found in everything from telephones to children's toys to medical devices. Nearly 90% of the approximately one billion microphones manufactured annually are electret designs.

Ernst W. Siemens was the first to describe the *dynamic* or moving-coil loudspeaker, with a circular coil of wire in a magnetic field and supported so that it could move axially. John Stroh first described the conical paper diaphragm that terminated at the rim of the speaker in a section that was flat except for corruga-

tions. In 1925, Chester W. Rice and Edward W. Kellogg at General Electric established the basic principle of the direct-radiator loudspeaker with a small coil-driven mass-controlled diaphragm in a baffle with a broad mid-frequency range of uniform response. In 1926, Radio Corporation of America (RCA) used this design in the *Radiola* line of alternating current (AC)-powered radios. In 1943 James Lansing introduced the Altec-Lansing 604 duplex radiator which combined an efficient 15 inch woofer with a high-frequency compression driver and horn [2.32].

In 1946, Paul Klipsch introduced the Klipschorn, a corner-folded horn that made use of the room boundaries themselves to achieve efficient radiation at low frequency. In the early 1940s, the Jensen company popularized the vented box or bass reflex loudspeaker enclosure. In 1951, specific loudspeaker driver parameters and appropriate enclosure alignments were described by Neville Thiele and later refined by Richard Small. Thiele–Small parameters are now routinely published by loudspeaker manufacturers and used by professionals and amateurs alike to design vented enclosures [2.33].

The Audio Engineering Society was formed in 1948, the same year the microgroove 33 1/3 rpm long-play vinyl record (LP) was introduced by Columbia Records. The founding of this new society had the unfortunate effect of distancing engineers primarily interested in audio from the rest of the acoustics engineering community.

Natural piezoelectric crystals were used to generate sound waves for underwater signaling and for ultrasonic research. In 1917 Paul Langevin obtained a large crystal of natural quartz from which $10 \times 10 \times 1.6$ cm slices could be cut. He constructed a transmitter that sent out a beam powerful enough to kill fish in its near field [2.15]. After World Wart II, materials, such as potassium dihydrogen phosphate (KDP), ammonium dihydrogen phosphate (ADP) and barium titanate replaced natural quartz in transducers. There are several piezoelectric ceramic compositions in common use today: barium titanate, lead zirconate titanate (PZT) and modified iterations such as lead lanthanum zirconate titanate (PLZT), lead metaniobate and lead magnesium niobate (PMN, including electrostrictive formulations). The PZT compositions are the most widely used in applications involving light shutters, micro-positioning devices, speakers and medical array transducers.

Recipients of the ASA silver medal in engineering acoustics have included Harry Olson, Hugh Knowles, Benjamin Bauer, Per Bruel, Vincent Salmon, Albert Bodine, Joshua Greenspon, Alan Powell, James West, Richard Lyon, John Bouyoucos, Allan Zuckerwar, and Gary Elko. Interdisciplinary medals have gone to Victor Anderson, Steven Garrett, and Gerhard Sessler.

2.7.4 Structural Acoustics

The vibrations of solid structures was discussed at some length by Rayleigh, Love, Timoshenko, Clebsch, Airey, Lamb, and others during the 19th and early 20th centuries. Nonlinear vibrations were considered by G. Duffing in 1918. R. N. Arnold and G. B. Warburton solved the complete boundary-value problem of the free vibration of a finite cylindrical shell. Significant advances have been made in our understanding of the radiation, scattering, and response of fluid-loaded elastic plates by G. Maidanik, E. Kerwin, M. Junger, and D. Feit.

Statistical energy analysis (SEA), championed by Richard Lyon and Gideon Maidanik, had its beginnings in the early 1960s. In the 1980s, Christian Soize developed the fuzzy structure theory to predict the mid-frequency dynamic response of a master structure coupled with a large number of complex secondary subsystems. The structural and geometric details of the latter are not well defined and therefore labeled as *fuzzy*.

A number of good books have been written on the vibrations of simple and complex structures. Especially noteworthy, in my opinion, are books by *Cremer* et al. [2.34], *Junger* and *Feit* [2.35], *Leissa* [2.36], [2.37], and *Skudrzyk* [2.38]. Statistical energy analysis is described by *Lyon* [2.39]. Near-field acoustic holography, developed by Jay Maynard and Earl Williams, use pressure measurements in the near field of a vibrating object to determine its source distribution on the vibrating surface [2.40]. A near-field acoustic hologram of a rectangular plate driven at a point is shown in Fig. 2.4.
Fig. 2.4 Near-field hologram of pressure near a rectangular plate driven at 1858 Hz at a point (courtesy of Earl Williams)

The ASA has awarded its Trent–Crede medal, which recognizes accomplishment in shock and vibration, to Carl Vigness, Raymond Mindlin, Elias Klein, J. P. Den Hartog, Stephen Crandall, John Snowdon, Eric Ungar, Miguel Junger, Gideon Maidanik, Preston Smith, David Feit, Sabih Hayek, Jerry Ginsberg, and Peter Stepanishen.

2.7.5 Underwater Acoustics

The science of underwater technology in the 20th century is based on the remarkable tools of transduction that the 19th century gave us. It was partly motivated by the two world wars and the cold war and the threats raised by submarines and underwater mines. Two nonmilitary commercial fields that have been important driving forces in underwater acoustics are geophysical prospecting and fishing. The extraction of oil from the seafloor now supplies 25% of our total supply [2.41].

Essential to understanding underwater sound propagation is detailed knowledge about the speed of sound in the sea. In 1924, *Heck* and *Service* published tables on the dependence of sound speed on temperature, salinity, and pressure [2.42]. Summer conditions, with strong solar heating and a warm atmosphere, give rise to sound speeds that are higher near the surface and decrease with depth, while winter conditions, with cooling of the surface, reverses the temperature gradient. Thus, sound waves will bend downward under summer conditions and upward in the winter.

Submarine detection can be either passive (listening to the sounds made by the submarine) or active (transmiting a signal and listen for the echo). Well into the 1950s, both the United States and United Kingdom chose active high-frequency systems since passive systems at that time were limited by the ship's radiated noise and the self noise of the arrays. During World War II, underwater acoustics research results were secret, but at the end of the war, the National Defense Research Council (NDRC) published the results. The Sub-Surface Warfare Division alone produced 22 volumes [2.41]. Later the NDRC was disbanded and projects were transferred to the Navy (some reports have been published by IEEE).

The absorption in seawater was found to be much higher than predicted by classical theory. O. B. Wilson and R. W. Leonard concluded that this was due to the relaxation frequency of magnesium sulfate, which is present in low concentration in the sea [2.43]. Ernest Yeager and Fred Fisher found that boric acid in small concentrations exhibits a relaxation frequency near 1 kHz. In 1950 the papers of Tolstoy and Clay discussed propagation in shallow water. At the Scripps Institution of Oceanography Fred Fisher and Vernon Simmons made resonance measurements of seawater in a 2001 glass sphere over a wide range of frequencies and temperature, confirming the earlier results and improving the empirical absorption equation [2.41].

Ambient noise in the sea is due to a variety of causes, such as ships, marine mammals, snapping shrimp, and dynamic processes in the sea itself. Early measurements of ambient noise, made under Vern Knudsen, came to be known as the Knudsen curves. Wittenborn made measurements with two hydrophones, one in the sound channel and the other below it. A comparison of the noise levels showed about a 20 dB difference over the low-frequency band but little difference at high frequency. It has been suggested that a source of low-frequency noise is the collective oscillation of bubble clouds.

The ASA pioneers medal in underwater acoustics has been awarded to Harvey Hayes, Albert Wood, Warren Horton, Frederick Hunt, Harold Saxton, Carl Eckart, Claude Horton, Arthur Williams, Fred Spiess, Robert Urick, Ivan Tolstoy, Homer Bucker, William Kuperman, Darrell Jackson, Frederick Tappert, Henrik Schmidt, William Carey, and George Frisk.

2.7.6 Physiological and Psychological Acoustics

Physiological acoustics deals with the peripheral auditory system, including the cochlear mechanism, stimulus encoding in the auditory nerve, and models of auditory discrimination.

This field of acoustics probably owes more to Georg von Békésy (1899–1972) than any other person. Born in Budapest, he worked for the Hungarian Telephone Co., the University of Budapest, the Karolinska Institute in Stockholm, Harvard University, and the University of Hawaii. In 1962 he was awarded the Nobel prize in physiology and medicine for his research on the ear. He determined the static and dynamic properties of the basilar membrane, and he built a mechanical model of the cochlea. He was probably the first person to observe eddy currents in the fluid of the cochlea. Josef Zwislocki (1922–) reasoned that the existence of such fluid motions would inevitably lead to nonlinearities, although Helmholtz had pretty much assumed that the inner ear was a linear system [2.44].

In 1971 William Rhode succeeded in making measurements on a live cochlea for the first time. Using the

Mössbauer effect to measure the velocity of the basilar membrane, he made a significant discovery. The frequency tuning was far sharper than that reported for dead cochleae. Moreover, the response was highly nonlinear, with the gain increasing by orders of magnitude at low sound levels. There is an active amplifier in the cochlea that boosts faint sounds, leading to a strongly compressive response of the basilar membrane. The work of Peter Dallos, Bill Brownell, and others identified the outer hair cells as the cochlear amplifiers [2.45].

It is possible, by inserting a tiny electrode into the auditory nerve, to pick up the electrical signals traveling in a single fiber of the auditory nerve from the cochlea to the brain. Each auditory nerve fiber responds over a certain range of frequency and pressure. Nelson Kiang and others have determined that tuning curves of each fiber show a maximum in sensitivity. Within several hours after death, the basilar membrane response decreases, the frequency of maximum response shifts down, and the response curve broadens.

Psychological acoustics or *psychoacoustics* deals with subjective attributes of sound, such as loudness, pitch, and timbre and how they relate to physically measurable quantities such as the sound level, frequency, and spectrum of the stimulus.

At the Bell Telephone laboratories, Harvey Fletcher, first president of the Acoustical Society of America, and W. A. Munson determined contours of equal loudness by having listeners compare a large number of tones to pure tones of 1000 Hz. These contours of equal loudness came to be labeled by an appropriate number of *phon*s. S. S. Stevens is responsible for the loudness scale of *sone*s and for ways to calculate the loudness in *sone*s. His proposal to express pitch in *mels* did not become as widely adopted, however, probably because musicians and others prefer to express pitch in terms of the musical scale.

The threshold for detecting pure tones is mostly determined by the sound transmission through the outer and middle ear; to a first approximation the inner ear (the cochlea) is equally sensitive to all frequencies, except the very highest and lowest. In 1951, J. C. R. *Licklider* (1915–1990), who is well known for his work on developing the Internet, put the results of several hearing surveys together [2.46]. Masking of one tone by another was discussed in a classic paper by *Wegel* and *Lane* who showed that low-frequency tones can mask higher-frequency tones better than the reverse [2.47].

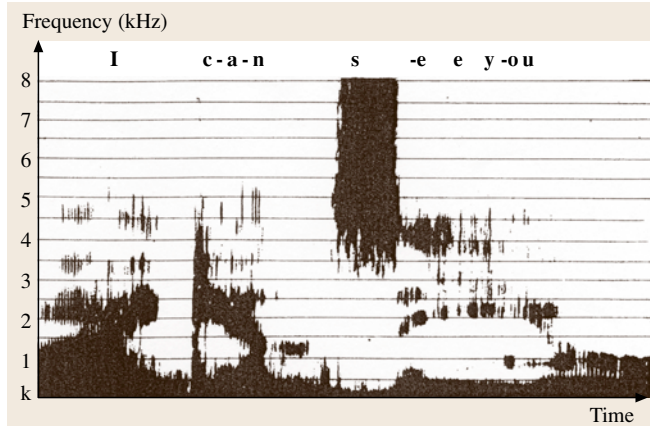
Two major theories of pitch perception gradually developed on the basis of experiments in many labo-


Fig. 2.5 Speech spectrogram of a simple sentence (*I can see you*) recorded on a sound spectrograph

ratories. They are usually referred to as the place (or frequency) theory and the periodicity (or time) theory. By observing wavelike motions of the basilar membrane caused by sound stimulation, Békésy provided support for the place theory. In the late 1930s, however, J. F. Schouten and his colleagues performed pitch-shift experiments that provided support for the periodicity theory of pitch. Modern theories of pitch perception often combine elements of both of these [2.48].

Recipients of the ASA von Békésy medal have been Jozef Zwislocki, Peter Dallos, Murray Sachs, William Rhode, and Charles Liberman, while the silver medal in psychological and physiological acoustics has been awarded to Lloyd Jeffress, Ernest Wever, Eberhard Zwicker, David Green, Nathaniel Durlach, Neal Viemeister, Brian Moore, Steven Colburn, and William Yost.

2.7.7 Speech

The production, transmission, and perception of speech have always played an important role in acoustics. Harvey Fletcher published his book *Speech and Hearing* in 1929, the same year as the first meeting of the Acoustical Society of America. The first issue of the *Journal of the Acoustical Society of America* included papers on speech by G. Oscar Russell, Vern Knudsen, Norman French and Walter Koenig, Jr.

In 1939, Homer Dudley invented the vocoder, a system in which speech was analyzed into component parts consisting of the pitch fundamental frequency of the voice, the noise, and the intensities of the speech in a series of band-pass filters. This machine, which was

demonstrated at New York World's Fair, could speak simple phrases.

An instrument that is particularly useful for speech analysis is the *sound spectrograph*, originally developed at the Bell Telephone laboratories around 1945. This instrument records a sound-level frequency–time plot for a brief sample of speech on which the sound level is represent by the degree of blackness in a two-dimensional time–frequency graph, as shown in Fig. 2.5. Digital versions of the sound spectrograph are used these days, but the display format is similar to the original machine.

Phonetic aspects of speech research blossomed at the Bell Telephone laboratories and elsewhere in the 1950s. Gordon Peterson and his colleagues produced several studies of vowels. Gunnar Fant published a complete survey of the field in *Acoustic Theory of Speech Production* [2.49]. The pattern playback, developed at Haskins Laboratories, dominated early research using synthetic speech in the United States. James Flanagan (1925–) demonstrated the significance of the use of our understanding of fluid dynamics in analyzing the behavior of the glottis. Kenneth Stevens and Arthur House noted that the bursts of air from the glottis had a triangular waveform that led to a rich spectrum of harmonics.

Speech synthesis and automatic recognition of speech have been important topics in speech research. Dennis Klatt (1938–1988) developed a system for synthesizing speech, and shortly before his death he gave the first completely intelligible synthesized speech paper presented to the ASA [2.50]. *Fry* and *Denes* [2.51] constructed a system in which speech was fed into an acoustic recognizer that compares

> *the changing spectrum of the speech wave with certain reference patterns and indicates the occurrence of the phoneme whose reference pattern best matches that of the incoming wave.*

Recipients of the ASA silver medal in speech communication have included Franklin Cooper, Gunnar Fant, Kenneth Stevens, Dennis Klatt, Arthur House, Peter Ladefoged, Patricia Kuhl, Katherine Harris, Ingo Titze, Winifred Strange, David Pisone.

2.7.8 Musical Acoustics

Musical acoustics deals with the production of musical sound, its transmission to the listener, and its perception. Thus this interdisciplinary field overlaps architectural acoustics, engineering acoustics, and psy-choacoustics. The study of the singing voice also overlaps the study of speech. In recent years, the scientific study of musical performance has also been included in musical acoustics.

Because the transmission and perception of sound have already been discussed, we will concentrate on the production of musical sound by musical instruments, including the human voice. It is convenient to classify musical instruments into families in accordance with the way they produce sound: string, wind, percussion, and electronic.

Bowed string instruments were probably the first to attract the attention of scientific researchers. The modern violin was developed largely in Italy in the 16th century by Gaspara da Salo and the Amati family. In the 18th century, Antonio Stradivari, a pupil of Nicolo Amati, and Guiseppi Guarneri created instruments with great brilliance that have set the standard for violin makers since that time. Outstanding contributions to our understanding of violin acoustics have been made by Felix Savart, Hermann von Helmholtz, Lord Rayleigh, C. V. Raman, Frederick Saunders, and Lothar Cremer, all of whom also distinguished themselves in fields other than violin acoustics. In more recent times, the work of Professor Saunders has been continued by members of the Catgut Acoustical Society, led by Carleen Hutchins. This work has made good use of modern tools such as computers, holographic interferometers, and fast Fourier transform (FFT) analyzers. One noteworthy product of modern violin research has been the development of an octet of scaled violins, covering the full range of musical performance.

The piano, invented by Bartolomeo Cristofori in 1709, is one of the most versatile of all musical instruments. One of the foremost piano researcher of our time is Harold Conklin. After he retired from the Baldwin Piano Co, he published a series of three papers in *JASA* (J. Acoustical Society of America) that could serve as a textbook for piano researchers [2.52]. Gabriel Weinreich explained the behavior of coupled piano strings and the aftersound which results from this coupling. Others who have contributed substantially to our understanding of piano acoustics are Anders Askenfelt, Eric Jansson, Juergen Meyer, Klaus Wogram, Ingolf Bork, Donald Hall, Isao Nakamura, Hideo Suzuki, and Nicholas Giordano. Many other string instruments have been studied scientifically, but space does not allow a discussion of their history here.

Pioneers in the study of wind instruments included Arthur Benade (1925–1987), John Backus (1911–

1988), and John Coltman (1915–). Backus, a research physicist, studied both brass and woodwind instruments, especially the nonlinear flow control properties of woodwind reeds. He improved the capillary method for measuring input impedance of air columns, and he developed synthetic reeds for woodwind instruments. Benade's extensive work led to greater understanding of mode conversion in flared horns, a model of woodwind instrument bores based on the acoustics of a lattice of tone holes, characterization of wind instruments in terms of cutoff frequencies, and radiation from brass and woodwind instruments. His two books *Horns, Strings and Harmony* and *Fundamentals of Musical Acoustics* have both been reprinted by Dover Books. Coltman, a physicist and executive at the Westinghouse Electric Corporation, devoted much of his spare time to the study of the musical, historical, and acoustical aspects of the flute and organ pipes. He collected more than 200 instruments of the flute family, which he used in his studies. More recently, flutes, organ pipes, and other wind instruments have been studied by Neville Fletcher and his colleagues in Australia.

The human voice is our oldest musical instrument, and its acoustics has been extensively studied by Johan Sundberg and colleagues in Stockholm. A unified discussion of speech and the singing voice appears in this handbook.

The acoustics of percussion instruments from many different countries have been studied by Thomas *Rossing* and his students, and many of them are described in his book *Science of Percussion Instruments* [2.53] as well as in his published papers.

Electronic music technology was made possible with the invention of the vacuum tube early in the 20th century. In 1919 Leon Theremin invented the aetherophone (later called the Theremin), an instrument whose vacuum-tube oscillators can be controlled by the proximity of the player's hands to two antennae. In 1928, Maurice Martenot built the Ondes Martenot. In 1935 Laurens Hammond used magnetic tone-wheel generators as the basis for his electromechanical organ, which became a very popular instrument. Analog music synthesizers became popular around the middle of the 20th century. In the mid 1960s, Robert Moog and Donald Buchla built successful voltage-controlled music synthesizers which gave way to a revolution in the way composers could easily synthesize new sounds. Gradually, however, analog music synthesizers gave way to digital techniques making use of digital computers. Although many people contributed to the development of computer music, Max Mathews is often called the father of computer music, since he developed the MUSIC I program that begat many successful music synthesis programs and blossomed into a rich resource for musical expression [2.54].

The ASA has awarded its silver medal in musical acoustics to Carleen Hutchins, Arthur Benade, John Backus, Max Mathews, Thomas Rossing, Neville Fletcher, Johan Sundberg, Gabriel Weinreich, William Strong.

2.8 Conclusion

This brief summary of acoustics history has only scratched the surface. Many fine books on the subject appear in the list of references, and readers are urged to explore the subject further. The science of sound is a fascinating subject that draws from many different disciplines.

3. Basic Linear Acoustics

Alan D. Pierce

This chapter deals with the physical and mathematical aspects of sound when the disturbances are, in some sense, small. Acoustics is usually concerned with small-amplitude phenomena, and consequently a linear description is usually applicable. Disturbances are governed by the properties of the medium in which they occur, and the governing equations are the equations of continuum mechanics, which apply equally to gases, liquids, and solids. These include the mass, momentum, and energy equations, as well as thermodynamic principles. The viscosity and thermal conduction enter into the versions of these equations that apply to fluids. Fluids of typical great interest are air and sea water, and consequently this chapter includes a summary of their relevant acoustic properties. The foundation is also laid for the consideration of acoustic waves in elastic solids, suspensions, bubbly liquids, and porous media.

This is a long chapter, and a great number of what one might term classical acoustics topics are included, especially topics that one might encounter in an introductory course in acoustics: the wave theory of sound, the wave equation, reflection of sound, transmission from one media to another, propagation through ducts, radiation from various types of sources, and the diffraction of sound.

List of symbols

B_V	bulk modulus at constant entropy
c	speed of sound
c_p	specific heat at constant pressure
c_v	specific heat at constant volume
D/Dt	convective time derivative
$\mathfrak{D}$	rate of energy dissipation per unit volume
$\boldsymbol{e}_i$	unit vector in the direction of increasing x_i
f	frequency, cycles per second
$\boldsymbol{f}$	force per unit volume
$f_1,\ f_2$	volume fractions
$\boldsymbol{g}$	acceleration associated with gravity
h	absolute humidity, fraction of molecules that are water
$H(\omega)$	transfer function
$\boldsymbol{I}$	acoustic intensity (energy flux)
k	wavenumber
$\mathfrak{L}$	Lagrangian density

M	average molecular weight	∂	partial differentiation operator
$\boldsymbol{n}$	unit vector normal to a surface	ϵ	expansion parameter
p	pressure	ϵ_{ij}	component of the strain tensor
$\hat{p}(\omega)$	Fourier transform of $p(t)$, complex amplitude	ζ	location of pole in the complex plane
		η	loss factor
$\boldsymbol{q}$	heat flux vector	θ_{I}	angle of incidence
Q	quality factor	κ	coefficient of thermal conduction
R_0	universal gas constant	λ	wavelength
Re	real part	λ_{L}	Lamè constant for a solid
s	entropy per unit mass	μ	(shear) viscosity
S	surface, surface area	μ_{B}	bulk viscosity
$\boldsymbol{t}$	traction vector, force per unit area	μ_{L}	Lamè constant for a solid
T	absolute temperature	ν	Poisson's ratio
$\mathfrak{T}$	kinetic energy per unit volume	ξ	internal variable in irreversible thermodynamics
u	internal energy per unit mass		
$\boldsymbol{u}$	locally averaged displacement field of solid matter	ξ_j	component of the displacement field
		π	ratio of circle circumference to diameter
$\boldsymbol{U}$	locally averaged displacement field of fluid matter	ρ	density, mass per unit volume
		σ_{ij}	component of the stress tensor
$\mathfrak{U}$	strain energy per unit volume	τ_{B}	characteristic time in the Biot model
$\boldsymbol{v}$	fluid velocity	τ_ν	relaxation time associated with ν-th process
V	volume		
w	acoustic energy density	ϕ	phase constant
α	attenuation coefficient	Φ	scalar potential
β	coefficient of thermal expansion	$\chi(x)$	nominal phase change in propagation distance x
γ	specific heat ratio		
δ_{ij}	Kronecker delta	$\boldsymbol{\Psi}$	vector potential
$\delta(t)$	delta function	ω	angular frequency, radians per second

3.1 Overview

Small-amplitude phenomena can be described to a good approximation in terms of linear algebraic and linear differential equations. Because acoustic phenomenon are typically of small amplitude, the analysis that accompanies most applications of acoustics consequently draws upon a linearized theory, briefly referred to as linear acoustics.

One reason why one chooses to view acoustics as a linear phenomenon, unless there are strong indications of the importance of nonlinear behavior, is the intrinsic conceptual simplicity brought about by the principle of superposition, which can be loosely described by the relation

$$\mathfrak{L}(af_1 + bf_2) = a\mathfrak{L}(f_1) + b\mathfrak{L}(f_2) , \tag{3.1}$$

where f_1 and f_2 are two *causes* and $\mathfrak{L}(f)$ is the set of possible mathematical or computational steps that predicts the *effect* of the cause f, such steps being de-

scribable so that they are the same for any such cause. The quantities a and b are arbitrary numbers. Doubling a cause doubles the effect, and the effect of a sum of two causes is the sum of the effects of each of the separate causes.

Thus, for example, a complicated sound field caused by several sources can be regarded as a sum of fields, each of which is caused by an individual source. Moreover, if there is assurance that the governing equations have time-independent coefficients, then the concept of frequency has great utility. Waves of each frequency propagate independently, so one can analyze the generation and propagation of each frequency separately, and then combine the results.

Nevertheless, linear acoustics should always be regarded as an approximation, and the understanding of nonlinear aspects of acoustics is of increasing importance in modern applications. Consequently, part of

the task of the present chapter is to explain in what sense linear acoustics is an approximation. An extensive discussion of the extent to which the linearization approximation is valid is not attempted, but a discussion is given of the manner in which the linear equations result from nonlinear equations that are regarded as more nearly exact.

The historical origins [3.1] of linear acoustics reach back to antiquity, to *Pythagoras* and *Aristotle* [3.2], both of whom are associated with ancient Greece, and also to persons associated with other ancient civilizations. The mathematical theory began with Mersenne, Galileo, and Newton, and developed into its more familiar form during the time of *Euler* and *Lagrange* [3.3]. Prominent contributors during the 19-th century include Poisson, Laplace, Cauchy, Green, Stokes, Helmholtz, Kirchhoff, and Rayleigh. The latter's book [3.4], *The Theory of Sound*, is still widely read and quoted today.

3.2 Equations of Continuum Mechanics

Sound can propagate through liquids, gases, and solids. It can also propagate through composite media such as suspensions, mixtures, and porous media. In any portion of a medium that is of uniform composition, the general equations that are assumed to apply are those that are associated with the theory of continuum mechanics.

3.2.1 Mass, Momentum, and Energy Equations

The primary equations governing sound are those that account for the conservation of mass and energy, and for changes in momentum. These may be written in the form of either partial differential equations or integral equations. The former is the customary starting point for the derivation of approximate equations for linear acoustics. Extensive discussions of the equations of continuum mechanics can be found in texts by *Thompson* [3.5], *Fung* [3.6], *Shapiro* [3.7], *Batchelor* [3.8], *Truesdell* [3.9]), and *Landau* and *Lifshitz* [3.10], and in the encyclopedia article by *Truesdell* and *Toupin* [3.11].

The conservation of mass is described by the partial differential equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0 , \tag{3.2}$$

where ρ is the (possibly position- and time-dependent) mass density (mass per unit volume of the material), and $\boldsymbol{v}$ is the local and instantaneous particle velocity, defined so that $\rho \boldsymbol{v} \cdot \boldsymbol{n}$ is the net mass flowing per unit time per unit area across an arbitrary stationary surface within the material whose local unit outward normal vector is $\boldsymbol{n}$.

The generalization of Newton's second law to a continuum is described by Cauchy's equation of motion, which is written in Cartesian coordinates as

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \sum_{ij} \boldsymbol{e}_i \frac{\partial \sigma_{ij}}{\partial x_j} + \boldsymbol{g}\rho . \tag{3.3}$$

Here the Eulerian description is used, with each field variable regarded as a function of actual spatial position coordinates and time. (The alternate description is the Lagrangian description, where the field variables are regarded as functions of the coordinates that the material being described would have in some reference configuration.) The σ_{ij} are the Cartesian components of the stress tensor. The quantities $\boldsymbol{e}_i$ are the unit vectors in a Cartesian coordinate system. These stress tensor components are such that

$$\boldsymbol{t} = \sum_{i,j} \boldsymbol{e}_i \sigma_{ij} n_j \tag{3.4}$$

is the traction vector, the *surface* force per unit area on any given surface with local unit outward normal $\boldsymbol{n}$.

The second term on the right of (3.3) is a body-force term associated with gravity, with $\boldsymbol{g}$ representing the vector acceleration due to gravity. In some instances, it may be appropriate (as in the case of analyses of transduction) to include body-force terms associated with external electromagnetic fields, but such are excluded from consideration in the present chapter.

The time derivative operator on the left side of (3.3) is Stokes' total time derivative operator [3.12],

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v} \cdot \nabla , \tag{3.5}$$

with the two terms corresponding to: (i) the time derivative as would be seen by an observer at rest, and (ii) the convective time derivative. This total time derivative applied to the particle velocity field yields the particle acceleration field, so the right side of (3.3) is the apparent force per unit volume on an element of the continuum.

The stress tensor's Cartesian component σ_{ij} is, in accordance with (3.4), the i-th component of the surface force per unit area on a segment of the (internal and hypothetical) surface of a small element of the continuum, when the unit outward normal to the surface is

a)

b)
Fig. 3.1 Sketches supporting the identification of $\rho\boldsymbol{v}\cdot\boldsymbol{n}$ as mass flowing per unit area and per unit time through a surface whose unit outward normal is $\boldsymbol{n}$. All the matter in the slanted cylinder's volume flows through the area ΔS in time Δt

Fig. 3.2 Traction vector on a surface whose unit normal $\boldsymbol{n}$ is in the $+x$-direction
Fig. 3.3 Two-dimensional sketch supporting the identification of the force per unit volume associated with stress in terms of partial derivatives of the stress components

in the j-th direction. This surface force is caused by interactions with the neighboring particles just outside the surface or by the transfer of momentum due to diffusion of molecules across the surface.

The stress-force term on the right side of (3.3) results from the surface-force definition of the stress components and from a version of the divergence theorem, so that the stress-related force per unit volume is

$$\boldsymbol{f}_{\text{stress}} \to \frac{1}{V}\int_S \boldsymbol{t}(\boldsymbol{n})\,\mathrm{d}S \to \frac{1}{V}\int_S \sum_{ij}\boldsymbol{e}_i\sigma_{ij}n_j\,\mathrm{d}S$$

$$\to \frac{1}{V}\int_V \sum_{ij}\boldsymbol{e}_i\frac{\partial\sigma_{ij}}{\partial x_j}\,\mathrm{d}V \to \sum_{ij}\boldsymbol{e}_i\frac{\partial\sigma_{ij}}{\partial x_j}\ . \quad (3.6)$$

Here V is an arbitrary but small volume enclosing the point of interest, and S is the surface enclosing that volume; the quantity $\boldsymbol{n}$ is the unit outward normal vector to the surface.

Considerations of the net torque that such surface forces would exert on a small element, and the requirement that the angular acceleration of the element be finite in the limit of very small element dimensions, leads to the conclusion,

$$\sigma_{ij} = \sigma_{ji}\ , \quad (3.7)$$

so the stress tensor is symmetric.

The equations described above are supplemented by an energy conservation relation,

$$\rho\frac{\mathrm{D}}{\mathrm{D}t}\left(\tfrac{1}{2}v^2 + u\right) = \sum_{ij}\frac{\partial}{\partial x_j}\left(\sigma_{ij}v_i\right) + \rho\boldsymbol{g}\cdot\boldsymbol{v} - \nabla\cdot\boldsymbol{q}\ ,$$

$$(3.8)$$

which involves the internal energy u per unit mass and the heat flux vector $\boldsymbol{q}$. The latter has the interpretation that its dot product with any unit normal vector represents the heat energy flowing per unit time and per unit area across any internal surface with the corresponding unit normal. An alternate version,

$$\rho \frac{\mathrm{D}u}{\mathrm{D}t} = \sum_{ij} \sigma_{ij} \frac{\partial v_i}{\partial x_j} - \nabla \cdot \boldsymbol{q} \,, \tag{3.9}$$

of the energy equation results when the vector dot product of $\boldsymbol{v}$ with (3.3) is subtracted from (3.8). (In carrying through the derivation, one recognizes that $\boldsymbol{v} \cdot (\rho \mathrm{D}\boldsymbol{v}/\mathrm{D}t)$ is $(1/2)\rho \mathrm{D}v^2/\mathrm{D}t$.)

3.2.2 Newtonian Fluids and the Shear Viscosity

The above equations apply to both fluids and solids. Additional equations needed to complete the set must take into account the properties of the material that make up the continuum. Air and water, for example, are fluids, and their viscous behavior corresponds to that for newtonian fluids, so that the stress tensor is given by

$$\sigma_{ij} = \sigma_n \delta_{ij} + \mu \phi_{ij} \,, \tag{3.10}$$

which involves the rate-of-shear tensor,

$$\phi_{ij} = \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} - \frac{2}{3} \nabla \cdot \boldsymbol{v} \delta_{ij} \,, \tag{3.11}$$

which is defined so that the sum of its diagonal elements is zero. The quantity σ_n that appears in (3.10) is the average normal stress component, and μ is the shear viscosity, while δ_{ij} is the Kronecker delta, equal to unity if the two indices are equal and otherwise equal to zero.

3.2.3 Equilibrium Thermodynamics

Further specification of the equations governing sound requires some assumptions concerning the extent to which equilibrium or near-equilibrium thermodynamics applies to acoustic disturbances. In the simplest idealization, which neglects relaxation processes, one assumes that the thermodynamic variables describing the perturbations are related just as for quasi-equilibrium processes, so one can use an equation of state of the form

$$s = s(u, \rho^{-1}) \,, \tag{3.12}$$

which has the corresponding differential relation [3.13],

$$T \, \mathrm{d}s = \mathrm{d}u + p \, \mathrm{d}\rho^{-1} \,, \tag{3.13}$$

in accordance with the second law of thermodynamics. Here s is the entropy per unit mass, T is the absolute temperature, and p is the absolute pressure. The reciprocal of the density, which appears in the above relations, is recognized as the specific volume. (Here the adjective specific means per unit mass.)

For the case of an ideal gas with temperature-independent specific heats, which is a common idealization for air, the function in (3.12) is given by

$$s = \frac{R_0}{M} \ln \left(u^{1/(\gamma-1)} \rho^{-1} \right) + s_0 \,. \tag{3.14}$$

Here s_0 is independent of u and ρ^{-1}, while M is the average molecular weight (average molecular mass in atomic mass units), and R_0 is the universal gas constant (equal to Boltzmann's constant divided by the mass in an atomic mass unit), equal to 8314 J/kg K. The quantity γ is the specific heat ratio, equal to approximately 7/5 for diatomic gases, to 5/3 for monatomic gases, and to 9/7 for polyatomic gases whose molecules are not collinear. For air (which is primarily a mixture of diatomic oxygen, diatomic nitrogen, with approximately 1% monatomic argon), γ is 1.4 and M is 29.0. (The expression given here for entropy neglects the contribution of internal vibrations of diatomic molecules, which cause the specific heats and γ to depend slightly on temperature. When one seeks to explain the absorption of sound in air, a nonequilibrium entropy [3.14] is used which depends on the fractions of O_2 and N_2 molecules that are in their first excited vibrational states, in addition to the quantities u and ρ^{-1}.)

For other substances, a knowledge of the first and second derivatives of s, evaluated at some representative thermodynamic state, is sufficient for most linear acoustics applications.

3.2.4 Bulk Viscosity and Thermal Conductivity

The average normal stress must equal the negative of the thermodynamic pressure that enters into (3.13), when the fluid is in equilibrium. Consideration of the requirement that the equations be the same regardless of the choice of directions of the coordinate axes, plus the assumption of a newtonian fluid, lead to the relation [3.12],

$$\sigma_n = -p + \mu_\mathrm{B} \nabla \cdot \boldsymbol{v} \,, \tag{3.15}$$

which involves the bulk viscosity μ_B. Also, the Fourier model for heat conduction [3.15] requires that the heat

flux vector $\boldsymbol{q}$ be proportional to the gradient of the temperature,

$$q = -\kappa \nabla T \,, \tag{3.16}$$

where κ is the coefficient of thermal conduction.

Transport Properties of Air

Regarding the values of the viscosities and the thermal conductivity that enter into the above expressions, the values for air are approximated [3.16–18] by

$$\mu_S = \mu_0 \left(\frac{T}{T_0}\right)^{3/2} \frac{T_0 + T_S}{T + T_S} \,, \tag{3.17}$$

$$\mu_B = 0.6\mu_S \,, \tag{3.18}$$

$$\kappa = \kappa_0 \left(\frac{T}{T_0}\right)^{3/2} \frac{T_0 + T_A \, e^{-T_B/T_0}}{T + T_A \, e^{-T_B/T}} \,. \tag{3.19}$$

Here T_S is 110.4 K, T_A is 245.4 K, T_B is 27.6 K, T_0 is 300 K, μ_0 is 1.846×10^{-5} kg/(ms), and κ_0 is 2.624×10^{-2} W/(mK).

Transport Properties of Water

The corresponding values of the viscosities and the thermal conductivity of water depend only on temperature and are given by [3.19, 20]

$$\mu_S = 1.002 \times 10^{-3} \, e^{-0.0248\Delta T} \,, \tag{3.20}$$

$$\mu_B = 3\mu_S \,, \tag{3.21}$$

$$\kappa = 0.597 + 0.0017\Delta T - 7.5 \times 10^{-6}(\Delta T)^2 \,. \tag{3.22}$$

The quantities that appear in these equations are understood to be in MKS units, and ΔT is the temperature relative to 283.16 K (10 °C).

3.2.5 Navier–Stokes–Fourier Equations

The assumptions represented by (3.12, 13, 15), and (3.16) cause the governing continuum mechanics equations for a fluid to reduce to

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0 \,, \tag{3.23}$$

$$\rho \frac{D\boldsymbol{v}}{Dt} = -\nabla p + \nabla (\mu_B \nabla \cdot \boldsymbol{v})$$
$$+ \sum_{ij} \boldsymbol{e}_i \frac{\partial}{\partial x_j}(\mu \phi_{ij}) + \boldsymbol{g}\rho \,, \tag{3.24}$$

$$\rho T \frac{Ds}{Dt} = \tfrac{1}{2}\mu \sum_{ij} \phi_{ij}^2 + \mu_B (\nabla \cdot \boldsymbol{v})^2 + \nabla \cdot (\kappa \nabla T) \,, \tag{3.25}$$

which are known as the Navier–Stokes–Fourier equations for compressible flow.

3.2.6 Thermodynamic Coefficients

An implication of the existence of an equation of state of the form of (3.12) is that any thermodynamic variable can be regarded as a function of any other two (independent) thermodynamic variables. The pressure p, for example, can be regarded as a function of ρ and T, or of s and ρ. In the expression of differential relations, such as that which gives dp as a linear combination of ds and $d\rho$, it is helpful to express the coefficients in terms of a relatively small number of commonly tabulated quantities. A standard set of such includes:

1. The square of the sound speed,

$$c^2 = \left(\frac{\partial p}{\partial \rho}\right)_s \,, \tag{3.26}$$

2. The bulk modulus at constant entropy,

$$B_V = \rho c^2 = \rho \left(\frac{\partial p}{\partial \rho}\right)_s \,, \tag{3.27}$$

3. The specific heat at constant pressure,

$$c_p = T \left(\frac{\partial s}{\partial T}\right)_p \,, \tag{3.28}$$

4. The specific heat at constant volume,

$$c_v = T \left(\frac{\partial s}{\partial T}\right)_\rho \,, \tag{3.29}$$

5. The coefficient of thermal expansion,

$$\beta = \rho \left(\frac{\partial (1/\rho)}{\partial T}\right)_p \,. \tag{3.30}$$

(The subscripts on the partial derivatives indicate the independent thermodynamic quantity that is kept fixed during the differentiation.) The subscript V on B_V is included here to remind one that the modulus is associated with changes in volume. For a fixed mass of fluid the decrease in volume per unit volume per unit increase in pressure is the bulk compressibility, and the reciprocal of this is the bulk modulus.

The coefficients that are given here are related by the thermodynamic identity,

$$\gamma - 1 = T\beta^2 c^2/c_p \,, \tag{3.31}$$

where γ is the specific heat ratio,

$$\gamma = \frac{c_p}{c_v} \,. \tag{3.32}$$

In terms of the thermodynamic coefficients defined above, the differential relations of principal interest in acoustics are

$$d\rho = \frac{1}{c^2} dp - \left(\frac{\rho\beta T}{c_p}\right) ds , \tag{3.33}$$

$$dT = \left(\frac{T\beta}{\rho c_p}\right) dp + \left(\frac{T}{c_p}\right) ds . \tag{3.34}$$

Thermodynamic Coefficients for an Ideal Gas

For an ideal gas, which is the common idealization for air, it follows from (3.12) and (3.13) (with the abbreviation R for R_0/M) that the thermodynamic coefficients are given by

$$c^2 = \gamma R T = \frac{\gamma p}{\rho} , \tag{3.35}$$

$$c_p = \frac{\gamma R}{\gamma - 1} , \tag{3.36}$$

$$c_v = \frac{R}{\gamma - 1} , \tag{3.37}$$

$$\beta = \frac{1}{T} . \tag{3.38}$$

For air, R is 287 J/kg K and γ is 1.4, so c_p and c_v are 1005 J/kg K and 718 J/kg K. A temperature of 293.16 K and a pressure of 10^5 Pa yield a sound speed of 343 m/s and a density ρ of 1.19 kg/m^3.

Thermodynamic Properties of Water

For pure water [3.21], the sound speed is approximately given in MKS units by

$$c = 1447 + 4.0\Delta T + 1.6 \times 10^{-6} p . \tag{3.39}$$

Here c is in meters per second, ΔT is temperature relative to 283.16 K (10 °C), and p is absolute pressure in pascals. The pressure and temperature dependence of the density [3.19] is approximately given by

$$\rho \approx 999.7 + 0.048 \times 10^{-5} p$$
$$- 0.088\Delta T - 0.007(\Delta T)^2 . \tag{3.40}$$

The coefficient of thermal expansion is given by

$$\beta \approx (8.8 + 0.022 \times 10^{-5} p + 1.4\Delta T) \times 10^{-5} , \tag{3.41}$$

and the coefficient of specific heat at constant pressure is approximately given by

$$c_p \approx 4192 - 0.40 \times 10^{-5} p - 1.6\Delta T . \tag{3.42}$$

The specific heat ratio is very close to unity, the deviation being described by

$$\frac{\gamma - 1}{\gamma} \approx 0.0011 \left(1 + \frac{\Delta T}{6} + 0.0024 \times 10^{-5} p\right)^2 . \tag{3.43}$$

The values for sea water are somewhat different, because of the presence of dissolved salts. An approximate expression for the speed of sound in sea water [3.22] is given by

$$c \approx 1490 + 3.6\Delta T + 1.6 \times 10^{-6} p + 1.3\Delta S . \tag{3.44}$$

Here ΔS is the deviation of the salinity in parts per thousand from a nominal value of 35.

3.2.7 Ideal Compressible Fluids

If viscosity and thermal conductivity are neglected at the outset, then the Navier–Stokes equation (3.24) reduces to

$$\rho \frac{Dv}{Dt} = -\nabla p + g\rho , \tag{3.45}$$

which is known as the Euler equation. The energy equation (3.25) reduces to the isentropic flow condition

$$\frac{Ds}{Dt} = 0 . \tag{3.46}$$

Moreover, the latter in conjunction with the differential equation of state (3.33) yields

$$\frac{Dp}{Dt} = c^2 \frac{D\rho}{Dt} . \tag{3.47}$$

The latter combines with the conservation of mass relation (3.2) to yield

$$\frac{Dp}{Dt} + \rho c^2 \nabla \cdot v = 0 , \tag{3.48}$$

where ρc^2 is recognized as the bulk modulus B_V.

In many applications of acoustics, it is these equations that are used as a starting point.

3.2.8 Suspensions and Bubbly Liquids

Approximate equations of the same general form as those for an ideal fluid result for fluids that have small particles of a different material suspended in them. Let the fluid itself have ambient density ρ_1 and let the material of the suspended particles have ambient density ρ_2.

The fractions of the overall volume that are occupied by the two materials are denoted by f_1 and f_2, so that $f_1 + f_2 = 1$. Thus, a volume V contains a mass

$$M = \rho_1 f_1 V + \rho_2 f_2 V . \tag{3.49}$$

The equivalent density M/V is consequently

$$\rho_{eq} = \rho_1 f_1 + \rho_2 f_2 . \tag{3.50}$$

The equivalent bulk modulus is deduced by considering the decrease $-\Delta V$ of such a volume due to an increment Δp of pressure with the assumption that the pressure is uniform throughout the volume, so that

$$-\Delta V = V_1 \frac{\Delta p}{B_{V,1}} + V_2 \frac{\Delta p}{B_{V,2}} , \tag{3.51}$$

where $V_1 = f_1 V$ and $V_2 = f_2 V$ are the volumes occupied by the two materials. The equivalent bulk modulus consequently satisfies the relation

$$\frac{1}{B_{V,eq}} = \frac{f_1}{B_{V,1}} + \frac{f_2}{B_{V,2}} . \tag{3.52}$$

The bulk modulus for any material is the density times the sound speed squared, so the effective sound speed for the mixture satisfies the relation

$$\frac{1}{\rho_{eq} c_{eq}^2} = \frac{f_1}{\rho_1 c_1^2} + \frac{f_2}{\rho_2 c_2^2} , \tag{3.53}$$

whereby

$$\frac{1}{c_{eq}^2} = \left(\frac{f_1}{\rho_1 c_1^2} + \frac{f_2}{\rho_2 c_2^2} \right) (\rho_1 f_1 + \rho_2 f_2) . \tag{3.54}$$

The latter relation, rewritten in an equivalent form, is sometimes referred to as *Wood's* equation [3.23], and can be traced back to a paper by *Mallock* [3.24].
Fig. 3.4 Sketch of a fluid with embedded particles suspended within it

3.2.9 Elastic Solids

For analyses of acoustic wave propagation in solids (including crystals), the idealization of a linear elastic solid [3.6, 25–28] is often used. The solid particle displacements are regarded as sufficiently small that convective time derivatives can be neglected, so the Cauchy equation, given previously by (3.3), reduces, with the omission of the invariably negligible gravity term, to an equation, whose i-th Cartesian component is

$$\rho \frac{\partial^2 \xi_i}{\partial t^2} = \sum_{j=1}^3 \frac{\partial \sigma_{ij}}{\partial x_j} . \tag{3.55}$$

Here ρ is the density; $\xi_i(\boldsymbol{x}, t)$ is the i-th Cartesian component of the displacement of the particle nominally at $\boldsymbol{x}$. This displacement is measured relative to the particle's ambient position. Also, the ambient stress is presumed sufficiently small or slowly varying with position that it is sufficient to take the stress components that appear in Cauchy's equation as being those associated with the disturbance. These should vanish when there is no strain associated with the disturbance.

The stress tensor components σ_{ij} are ordinarily taken to be linearly dependent on the (linear) strain components,

$$\epsilon_{ij} = \frac{1}{2} \left(\frac{\partial \xi_i}{\partial x_j} + \frac{\partial \xi_j}{\partial x_i} \right) , \tag{3.56}$$

so that

$$\sigma_{ij} = \sum_{kl} K_{ijkl} \epsilon_{kl} . \tag{3.57}$$

The number of required distinct elastic coefficients is limited for various reasons. One is that the stress tensor is symmetric and another is that the strain tensor is symmetric. Also, if the quasistatic work required to achieve a given state of deformation is independent of the detailed history of the deformation, then there must be a strain-energy density function $\mathfrak{U}$ that, in the limit of small deformations, is a bilinear function of the strains. There are only six different strain components and the number of their distinct products is $6 + 5 + 4 + 3 + 2 + 1 = 21$, and such is the maximum number of coefficients that one might need. Any intrinsic symmetry, such as exists in various types of crystals, will reduce this number further [3.29].

Strain Energy

The increment of work done during a deformation by stress components on a small element of a solid that is

initially a small box (Δx by Δy by Δz) is

$$\delta[\text{Work}] = \sum_i \sigma_{ii} \left(\frac{\partial}{\partial x_i} \delta\xi_i \right) \Delta x \Delta y \Delta z$$

$$+ \sum_{i \neq j} \sigma_{ij} \left(\frac{\partial}{\partial x_j} \delta\xi_i \right) \Delta x \Delta y \Delta z , \quad (3.58)$$

where here σ_{ij} is interpreted as the i-th component of the force per unit area on a surface whose outward normal is in the direction of increasing x_j. With use of the symmetry of the stress tensor and of the definition of the strain tensor components, one obtains the incremental strain energy per unit volume as

$$\delta\mathfrak{U} = \sum_{ij} \sigma_{ij} \delta\epsilon_{ij} . \quad (3.59)$$

If the reference state, where $\mathfrak{U} = 0$, is taken as that in which the strain is zero, and given that each stress component is a linear combination of the strain components, then the above integrates to

$$\mathfrak{U} = \sum_{ij} \frac{1}{2} \sigma_{ij} \epsilon_{ij} . \quad (3.60)$$

Here the stresses are understood to be given in terms of the strains by an appropriate stress–strain relation of the general form of (3.57).

Because of the symmetry of both the stress tensor and the strain tensor, the internal energy $\mathfrak{U}$ per unit can be regarded as a function of only the six distinct strain components: ϵ_{xx}, ϵ_{yy}, ϵ_{zz}, ϵ_{xy}, ϵ_{yz}, and ϵ_{xz}. Consequently, with such an understanding, it follows from the differential relation (3.59) that

$$\frac{\partial\mathfrak{U}}{\partial\epsilon_{xx}} = \sigma_{xx} ; \qquad \frac{\partial\mathfrak{U}}{\partial\epsilon_{xy}} = 2\sigma_{xy} , \quad (3.61)$$

with analogous relations for derivatives with respect to the other distinct strain components.

Isotropic Solids

If the properties of the solid are such that they are independent of the orientation of the axes of the Cartesian coordinate system, then the solid is said to be isotropic. This idealization is usually regarded as good if the solid is made up of a random assemblage of many small grains. The tiny grains are possibly crystalline with directional properties, but the orientation of the grains is random, so that an element composed of a large number of grains has no directional orientation. For such an isotropic solid the number of
Fig. 3.5 Displacement field vector ξ in a solid. A material point normally at x is displaced to $x + \xi(x)$

different coefficients in the stress–strain relation (3.57) is only two, and the relation can be taken in the general form

$$\sigma_{ij} = 2\mu_{\text{L}}\epsilon_{ij} + \lambda_{\text{L}}\delta_{ij} \sum_{k=1}^{3} \epsilon_{kk} . \quad (3.62)$$

This involves two material constants, termed the Lamè constants, and here denoted by λ_{L} and μ_{L} (the latter being the same as the shear modulus G).

Equivalently, one can express the strain components in terms of the stress components by the inverse of the above set of relations. The generic form is sometimes written

$$\epsilon_{ij} = \frac{1+\nu}{E}\sigma_{ij} - \frac{\nu}{E} \sum_k \sigma_{kk}\delta_{ij} , \quad (3.63)$$

where E is the elastic modulus and ν is Poisson's ratio. The relation of these two constants to the Lamè constants is such that

$$\lambda_{\text{L}} = \frac{\nu E}{(1+\nu)(1-2\nu)} , \quad (3.64)$$

$$\mu_{\text{L}} = G = \frac{E}{2(1+\nu)} . \quad (3.65)$$

In undergraduate texts on the mechanics of materials, the relations (3.63) are often written out separately for the diagonal and off-diagonal strain elements, so

Table 3.1 Representative numbers for the elastic properties of various materials. (A comprehensive data set, giving values appropriate to specific details concerning the circumstances and the nature of the specimens, can be found at the web site for MatWeb, Material Property Data)

Material	E (Pa)	ν	λ_L (Pa)	μ_L (Pa)	ρ (kg/m³)
Aluminum	7.0×10^{10}	0.33	5.1×10^{10}	2.6×10^{10}	2.8×10^{3}
Brass	10.5×10^{10}	0.34	8.3×10^{10}	3.9×10^{10}	8.4×10^{3}
Copper	12.0×10^{10}	0.34	9.5×10^{10}	4.5×10^{10}	8.9×10^{3}
Iron	12.0×10^{10}	0.25	4.8×10^{10}	4.8×10^{10}	7.2×10^{3}
Lead	1.4×10^{10}	0.43	3.2×10^{10}	0.5×10^{10}	11.3×10^{3}
Steel	20.0×10^{10}	0.28	9.9×10^{10}	7.8×10^{10}	7.8×10^{3}
Titanium	11.0×10^{10}	0.34	8.7×10^{10}	4.1×10^{10}	4.5×10^{3}

that,

$$\epsilon_{xx} = \frac{1}{E}[\sigma_{xx} - \nu(\sigma_{yy} + \sigma_{zz})] , \tag{3.66}$$

$$\gamma_{xy} = 2\epsilon_{xy} = \frac{1}{G}\sigma_{xy} , \tag{3.67}$$

with analogous relations for the other strain components. The nomenclature γ_{xy} is used for what is often termed the shear strain, this being twice as large as that shear strain that is defined as a component of a strain tensor.

The strain energy density $\mathfrak{U}$ of an isotropic solid results from (3.60) and (3.62), the result being

$$\mathfrak{U} = \mu_L \sum_{ij} \epsilon_{ij}^2 + \frac{1}{2}\lambda_L \left(\sum_k \epsilon_{kk}\right)^2 . \tag{3.68}$$

In the idealized and simplified model of acoustic propagation in solids, the conservation of mass and energy is not explicitly invoked. The density that appears on the right side of (3.55) is regarded as time independent, and as that appropriate for the undisturbed state of the solid.

3.3 Equations of Linear Acoustics

The equations that one ordinarily deals with in acoustics are linear in the field amplitudes, where the fields of interest are quantities that depend on position and time. The basic governing equations are partial differential equations.

3.3.1 The Linearization Process

Sound results from a time-varying perturbation of the dynamic and thermodynamic variables that describe the medium. For sound in fluids (liquids and gases), the quantities appropriate to the ambient medium (i. e., the medium in the absence of a disturbance) are customarily represented [3.30] by the subscript 0, and the perturbations are represented by a prime on the corresponding symbol. Thus one expresses the total pressure as

$$p = p_0 + p' , \tag{3.69}$$

with corresponding expressions for fluctuations in specific entropy, fluid velocity, and density. The linear equations that govern acoustical disturbances are then determined by the first-order terms in the expansion of the governing nonlinear equations in the primed variables. The zeroth-order terms cancel out completely because the ambient variables should themselves correspond to a valid state of motion of the medium. Thus, for example, the linearized version of the conservation of mass relation in (3.2) is

$$\frac{\partial \rho'}{\partial t} + \nabla \cdot (\boldsymbol{v}_0 \rho' + \boldsymbol{v}' \rho_0) = 0 . \tag{3.70}$$

The possible forms of the linear equations differ in complexity according to what is assumed about the medium's ambient state and according to what dissipative terms are included in the original governing equations. In the establishment of a rationale for using simplified models, it is helpful to think in terms of the order of magnitudes and characteristic scales of the coefficients in more nearly comprehensive models. If the

spatial region of interest has bounding dimensions that are smaller than any scale length over which the ambient variables vary by a respectable fraction, then it may be appropriate to idealize the coefficients in the governing equations as if the ambient medium were spatially uniform or homogeneous. Similarly, if the characteristic wave periods or propagation times are much less than characteristic time scales for the ambient medium, then it may be appropriate to idealize the coefficients as being time independent. Examination of orders of magnitudes of terms suggests that the ambient velocity may be neglected if it is much less than the sound speed c. The first-order perturbation to the gravitational force term can ordinarily be neglected [3.31] if the previously stated conditions are met and if the quantity g/c is sufficiently smaller than any characteristic frequency of the disturbance. Analogous inferences can be made about the thermal conductivity and viscosity. However, the latter may be important [3.32] in the interaction of acoustic waves in fluids with adjacent solid bodies.

A discussion of the restrictions on using linear equations and of neglecting second- and higher-order terms in the primed variables is outside the scope of the present chapter, but it should be noted that one regards p' as small [3.30] if it is substantially less than $\rho_0 c^2$, and $|\boldsymbol{v}'|$ as small if it is much less than c, where c is the sound speed defined via (3.26). It is not necessary that p' be much less than p_0, and it is certainly not necessary that $|\boldsymbol{v}'|$ be less than $|\boldsymbol{v}_0|$.

3.3.2 Linearized Equations for an Ideal Fluid

The customary equations for linear acoustics neglect dissipation processes and consequently can be derived from the equations for flow of a compressible ideal fluid, given in (3.45) through (3.48). If one neglects gravity at the outset, and assumes the ambient fluid velocity is zero, then the ambient pressure is constant. In such a case, (3.48) leads after linearization to

$$\frac{\partial p}{\partial t} + \rho c^2 \nabla \cdot \boldsymbol{v} = 0 \,, \tag{3.71}$$

and the Euler equation (3.45) leads to

$$\rho \frac{\partial \boldsymbol{v}}{\partial t} = -\nabla p \,. \tag{3.72}$$

Here a common notational convention is used to delete primes and subscripts. The density ρ here is understood to be the ambient density ρ_0, while p and $\boldsymbol{v}$ are under-

stood to be the acoustically induced perturbations to the pressure and fluid velocity.

These two coupled equations for p and $\boldsymbol{v}$ remain applicable when the ambient density and sound speed vary with position.

3.3.3 The Wave Equation

A single partial differential equation for the acoustic part of the pressure results when one takes the time derivative of (3.71) and then uses (3.72) to reexpress the time derivative of the fluid velocity in terms of pressure. The resulting equation, as derived by *Bergmann* [3.31] for the case when the density varies with position, is

$$\nabla \cdot \left(\frac{1}{\rho} \nabla p \right) - \frac{1}{\rho c^2} \frac{\partial^2 p}{\partial t^2} = 0 \,. \tag{3.73}$$

If the ambient density is independent of position, then this reduces to

$$\nabla^2 p - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \,, \tag{3.74}$$

which dates back to Euler and which is what is ordinarily termed the wave equation of linear acoustics. Often this is written as

$$\Box^2 p = 0 \,, \tag{3.75}$$

in terms of the d'Alembertian operator defined by

$$\Box^2 = \nabla^2 - c^{-2} \partial^2 / \partial t^2 \,. \tag{3.76}$$

3.3.4 Wave Equations for Isotropic Elastic Solids

When the ambient density and the Lamé constants are independent of position, the Cauchy equation and the stress–strain relations described by (3.55, 56), and (3.62) can be combined to the single vector equation,

$$\frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = \left(c_1^2 - c_2^2 \right) \nabla (\nabla \cdot \boldsymbol{\xi}) + c_2^2 \nabla^2 \boldsymbol{\xi} \,, \tag{3.77}$$

which is equivalently written as

$$\frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = c_1^2 \nabla (\nabla \cdot \boldsymbol{\xi}) - c_2^2 \nabla \times (\nabla \times \boldsymbol{\xi}) \,. \tag{3.78}$$

Here the quantities c_1 and c_2 are defined by

$$c_1^2 = \frac{\lambda_{\mathrm{L}} + 2\mu_{\mathrm{L}}}{\rho} \,, \tag{3.79}$$

$$c_2^2 = \frac{\mu_{\mathrm{L}}}{\rho} \,. \tag{3.80}$$

Because any vector field may be decomposed into a sum of two fields, one with zero curl and the other with zero divergence, one can set the displacement vector $\boldsymbol{\xi}$ to

$$\boldsymbol{\xi} = \nabla \Phi + \nabla \times \boldsymbol{\Psi} \tag{3.81}$$

in terms of a scalar and a vector potential. This expression will satisfy (3.77) identically, provided the two potentials separately satisfy

$$\nabla^2 \Phi - \frac{1}{c_1^2} \frac{\partial^2 \Phi}{\partial t^2} = 0 , \tag{3.82}$$

$$\nabla^2 \boldsymbol{\Psi} - \frac{1}{c_2^2} \frac{\partial^2 \boldsymbol{\Psi}}{\partial t^2} = 0 . \tag{3.83}$$

Both of these equations are of the form of the simple wave equation of (3.74). The first corresponds to longitudinal wave propagation, and the second corresponds to shear wave propagation. The quantities c_1 and c_2 are referred to as the dilatational and shear wave speeds, respectively.

If the displacement field is irrotational, so that the curl of the displacement vector is zero (as is so for sound in fluids), then each component of the displacement field satisfies (3.82). If the displacement field is solenoidal, so that its divergence is zero, then each component of the displacement satisfies (3.83).

3.3.5 Linearized Equations for a Viscous Fluid

For the restricted but relatively widely applicable case when the Navier–Stokes–Fourier equations are presumed to hold and the characteristic scales of the ambient medium and the disturbance are such that the ambient flow is negligible, and the coefficients are idealizable as constants, the linear equations have the form appropriate for a disturbance in a homogeneous, time-independent, non-moving medium, these equations being

$$\frac{\partial \rho'}{\partial t} + \rho_0 \nabla \cdot \boldsymbol{v}' = 0 , \tag{3.84}$$

$$\rho_0 \frac{\partial \boldsymbol{v}'}{\partial t} = -\nabla p' + \left(\frac{1}{3}\mu + \mu_{\mathrm{B}} \right) \nabla \left(\nabla \cdot \boldsymbol{v}' \right)$$
$$+ \mu \nabla^2 \boldsymbol{v}' , \tag{3.85}$$

$$\rho_0 T_0 \frac{\partial s'}{\partial t} = \kappa \nabla^2 T' , \tag{3.86}$$

$$\rho' = \frac{1}{c^2} p' - \left(\frac{\rho \beta T}{c_{\mathrm{p}}} \right)_0 s' , \tag{3.87}$$

$$T' = \left(\frac{T\beta}{\rho c_{\mathrm{p}}} \right)_0 p' + \left(\frac{T}{c_{\mathrm{p}}} \right)_0 s' . \tag{3.88}$$

The primes on the perturbation field variables are needed here to distinguish them from the corresponding ambient quantities.

3.3.6 Acoustic, Entropy, and Vorticity Modes

In general, any solution of the linearized equations for a fluid with viscosity and thermal conductivity can be regarded [3.30, 32–34] as a sum of three basic types of solutions. The common terminology for these is: (i) the acoustic mode, (ii) the entropy mode, and (iii) the vorticity mode. Thus, with appropriate subscripts denoting the various fundamental mode types, one writes the fluid velocity perturbation in the form,

$$\boldsymbol{v}' = \boldsymbol{v}_{\mathrm{ac}} + \boldsymbol{v}_{\mathrm{ent}} + \boldsymbol{v}_{\mathrm{vor}} , \tag{3.89}$$

with similar decompositions for the other field variables. The decomposition is intended to be such that, for waves of constant frequency, each field variable's contribution from any given mode satisfies a partial differential equation that is second order (rather than of some higher order as might be derived from (3.84)–(3.88)) in the spatial derivatives. That such a decomposition is possible follows from a theorem [3.35, 36] that any solution of a partial differential equation of, for example, the form,

$$\left(\nabla^2 + \lambda_1 \right)\left(\nabla^2 + \lambda_2 \right)\left(\nabla^2 + \lambda_3 \right)\psi = 0 , \tag{3.90}$$

can be written as a sum,

$$\psi = \psi_1 + \psi_2 + \psi_3 , \tag{3.91}$$

where the individual terms each satisfy second-order differential equations of the form,

$$\left(\nabla^2 + \lambda_i \right)\psi_i = 0 . \tag{3.92}$$

This decomposition is possible providing no two of the λ_i are equal. (In regard to (3.90), one should note that each of the three operator factors is a second-order differential operator, so the overall equation is a sixth-order partial differential equation. One significance of the theorem is that one has replaced the seemingly formidable problem of solving a sixth-order partial differential equation by that of solving three second-order partial differential equations.)

Linear acoustics is primarily concerned with solutions of the equations that govern the acoustic mode,

while conduction heat transfer is primarily concerned with solutions of the equations that govern the entropy mode. However, the simultaneous consideration of all three solutions is often necessary when one seeks to satisfy boundary conditions at solid surfaces. The decomposition becomes relatively simple when the characteristic angular frequency is sufficiently small that

$$\omega \ll \frac{\rho c^2}{(4/3)\mu + \mu_B} \,, \tag{3.93}$$

$$\omega \ll \frac{\rho c^2 c_p}{\kappa} \,. \tag{3.94}$$

These conditions are invariably well met in all applications of interest. For air the right sides of the two inequalities correspond to frequencies of the order of 10^9 Hz, while for water they correspond to frequencies of the order of 10^{12} Hz. If the inequalities are not satisfied, it is also possible that the Navier–Stokes–Fourier model is not appropriate, since the latter presumes that the variations are sufficiently slow that the medium can be regarded as being in quasi-thermodynamic equilibrium.

The acoustic mode and the entropy mode are both characterized by the vorticity (curl of the fluid velocity) being identically zero. (This characterization is consistent with the theorem that any vector field can be decomposed into a sum of a field with zero divergence and a field with zero curl.) In the limit of zero viscosity and zero thermal conductivity (which is a limit consistent with (3.93) and (3.94)), the acoustic mode is characterized by zero entropy perturbations, while the entropy mode is a time-independent entropy perturbation, with zero pressure perturbation. These identifications allow the approximate equations governing the various modes to be developed in the limit for which the inequalities are valid. In carrying out the development, it is convenient to use an expansion parameter defined by,

$$\epsilon = \frac{\omega\mu}{\rho_0 c^2} \,, \tag{3.95}$$

where ω is a characteristic angular frequency, or equivalently, the reciprocal of a characteristic time for the perturbation. In the ordering, ϵ is regarded as small, μ_B/μ and $\kappa/\mu c_p$ are regarded as of order unity, and all time derivative operators are regarded as of order ω.

Acoustic Mode

To zeroth order in ϵ, the acoustic mode is what results when the thermal conductivity and the viscosities are identically zero and the entropy perturbation is also zero. In such a case, the relations (3.71) and (3.72) are valid and one obtains the wave equation of (3.74). All of the field variables in the acoustic mode satisfy this wave equation to zeroth order in ϵ. This is so because the governing equations have constant coefficients.

When one wishes to take into account the corrections that result to first order in ϵ, the entropy perturbation is no longer regarded as identically zero, but its magnitude can be deduced by replacing the T' that appears in (3.86) by only the first term in the sum of (3.88), the substitution being represented by

$$T_{ac} = \frac{T_0 \beta}{\rho_0 c_p} p_{ac} \,. \tag{3.96}$$

To the same order of approximation one may use the zeroth-order wave equation (3.74) to express the right side of (3.86) in terms of a second-order time derivative of the acoustic-mode pressure. The resulting equation can then be integrated once in time with the constant of integration set to zero because the acoustic mode's entropy perturbation must vanish when the corresponding pressure perturbation is identically zero. Thus one obtains the acoustic-mode entropy as

$$s_{ac} \approx \frac{\kappa\beta}{\rho_0^2 c^2 c_p} \frac{\partial p_{ac}}{\partial t} \,, \tag{3.97}$$

correct to first order in ϵ.

This expression for the entropy perturbation is substituted into (3.87) and the resulting expression for ρ_{ac} is substituted into the conservation of mass relation, represented by (3.84), so that one obtains

$$\frac{\partial p_{ac}}{\partial t} - \frac{(\gamma-1)\kappa}{\rho_0 c^2 c_p} \frac{\partial^2 p_{ac}}{\partial t^2} + \rho_0 c^2 \nabla \cdot \boldsymbol{v}_{ac} = 0 \,. \tag{3.98}$$

The vorticity in the acoustic mode is zero,

$$\nabla \times \boldsymbol{v}_{ac} = 0 \,, \tag{3.99}$$

so the momentum balance equation (3.85) simplifies to one where the right side is a gradient. Then with an appropriate substitution for the divergence of the fluid velocity from (3.84), one finds that the momentum balance equation to first order in ϵ takes the form

$$\rho_0 \frac{\partial \boldsymbol{v}_{ac}}{\partial t} = -\nabla \left\{ p_{ac} + \frac{1}{\rho_0 c^2}[(4/3)\mu + \mu_B]\frac{\partial p_{ac}}{\partial t} \right\} \,. \tag{3.100}$$

The latter and (3.84), in a manner similar to that in which the wave equation of (3.73) is derived, yield the dissipative wave equation represented by

$$\nabla^2 p_{ac} - \frac{1}{c^2}\frac{\partial^2 p_{ac}}{\partial t^2} + \frac{2\delta_{cl}}{c^4}\frac{\partial^3 p_{ac}}{\partial t^3} = 0 \,. \qquad (3.101)$$

The quantity δ_{cl}, defined by

$$\delta_{cl} = \frac{1}{2\rho_0}\left[(4/3)\mu + \mu_B + (\gamma - 1)(\kappa/c_p)\right], \quad (3.102)$$

is a constant that characterizes the classical dissipation in the acoustic mode.

Entropy Mode

For the entropy mode, the pressure perturbation vanishes to zeroth order in ϵ, while the entropy perturbation does not. Thus for this mode, (3.87) and (3.88) approximate in zeroth order to

$$\rho_{ent} = -\left(\frac{\rho\beta T}{c_p}\right)_0 s_{ent} \,, \qquad (3.103)$$

$$T_{ent} = \left(\frac{T}{c_p}\right)_0 s_{ent} \,. \qquad (3.104)$$

The latter when substituted into the energy equation (3.86) yields the diffusion equation of conduction heat transfer,

$$\frac{\partial s_{ent}}{\partial t} = \frac{\kappa}{\rho_0 c_p}\nabla^2 s_{ent} \,. \qquad (3.105)$$

All of the entropy-mode field variables, including T_{ent}, satisfy this diffusion equation to lowest order in ϵ.

The mass conservation equation, with an analogous substitution from (3.103) and another substitution from (3.88), integrates to

$$v_{ent} = \frac{\beta T_0 \kappa}{\rho_0 c_p^2}\nabla s_{ent} \,, \qquad (3.106)$$

so there is a weak fluid flow caused by entropy or temperature gradients in the entropy mode. The substitution of this expression for the fluid velocity into the linearized Navier–Stokes equation (3.85) subsequently yields a lowest-order expression for the entropy-mode contribution to the pressure perturbation, this being

$$p_{ent} = \frac{\beta T_0}{c_p}[(4/3)\mu + \mu_B - (\kappa/c_p)]\frac{\partial s_{ent}}{\partial t} \,. \qquad (3.107)$$

Vorticity Mode

For the vorticity mode, the divergence of the fluid velocity is identically zero,

$$\nabla \cdot v_{vor} = 0 \,. \qquad (3.108)$$

The mass conservation equation (3.84) and the thermodynamic relations, (3.87) and (3.88), consequently require that all of the thermodynamic field quantities with subscript 'vor' are zero. The Navier–Stokes equation (3.85) accordingly requires that each component of the fluid velocity associated with this mode satisfy the vorticity diffusion equation

$$\rho_0 \frac{\partial v_{vor}}{\partial t} = \mu\nabla^2 v_{vor} \,. \qquad (3.109)$$

3.3.7 Boundary Conditions at Interfaces

For the model of a fluid without viscosity or thermal conduction, such as is governed by (3.71)–(3.75), the appropriate boundary conditions at an interface are that the normal component of the fluid velocity be continuous and that the pressure be continuous;

$$v_1 \cdot n_{12} = v_2 \cdot n_{12} \,; \qquad p_1 = p_2 \,. \qquad (3.110)$$

At a rigid nonmoving surface, the normal component must consequently vanish,

$$v \cdot n = 0 \,, \qquad (3.111)$$

but no restrictions are placed on the tangential component of the velocity. The model also places no requirements on the value of the temperature at a solid surface.

When viscosity is taken into account, no matter how small it may be, the model demands additional boundary conditions. An additional condition invariably imposed is that the tangential components of the velocity also be continuous, the rationale [3.37] being that a fluid should not slip any more freely with respect to an interface than it does with itself; this lack of slip is invariably observed [3.38] when the motion is examined sufficiently close to an interface. Similarly, when thermal conduction is taken into account, the rational interpretation of the model requires that the temperature be continuous at an interface. Newton's third law requires that the shear stresses exerted across an interface be continuous, and the conservation of energy requires that the normal component of the heat flux be continuous.

Fig. 3.6 Graphical proof that the normal component of fluid velocity should be continuous at any interface. The interface surface is denoted by $S(t)$, and $x_S(t)$ is the location of any material particle on either side of the interface, but located just at the interface. Both it and the particle on the other side of the interface that neighbors it at time t will continue to stay on the interface, although they may be displaced tangentially ◄

and normal velocity component, but have temperature and tangential velocity components, respectively, that are comparable to those of the acoustic mode. The boundary and continuity conditions can be satisfied by the sum of the three mode fields, but not by the acoustic mode field alone. However, the entropy and vorticity mode fields typically die out rapidly with distance from an interface. The characteristic decay lengths [3.30] when the disturbance has an angular frequency ω are

$$\ell_{\text{vor}} = \left(\frac{2\mu}{\omega\rho} \right)^{1/2} , \tag{3.112}$$

$$\ell_{\text{ent}} = \left(\frac{2\kappa}{\omega\rho c_{\text{p}}} \right)^{1/2} . \tag{3.113}$$

Given that the parameter ϵ in (3.95) is much less than unity, these lengths are much shorter than a characteristic wavelength. If they are, in addition, much shorter than the dimensions of the space to which the acoustic field is confined, then the acoustic boundary layer has a minor effect on the acoustic field outside the boundary layer. However, because dissipation of energy can occur within such boundary layers, the existence of a boundary layer can have a long-term accumulative effect. This can be manifested by the larger attenuation of sound waves propagating in pipes [3.39] and in the finite Q (quality factors) of resonators.

The apparent paradox, that tiny but nonzero values of the viscosity and thermal conductivity should drastically alter the basic nature of the boundary conditions at an interface, is resolved by acoustic boundary-layer theory. Under normal circumstances, disturbances associated with sound are almost entirely in the acoustic mode except in oscillating acoustic boundary layers near interfaces. In these boundary layers, a portion of the disturbance is in the entropy and vorticity modes. These modes make insignificant contributions to the total perturbation pressure

3.4 Variational Formulations

Occasionally, the starting point for acoustical analysis is not a set of partial differential equations, such as those described in the previous section, but instead a variational principle. The attraction of such an alternate approach is that it is a convenient departure point for making approximations. The most fundamental of the variational principles is the ver-

sion of Hamilton's principle [3.40, 41] that applies to a continuum.

3.4.1 Hamilton's Principle

The standard version is that where the displacement field $\xi(x, t)$ is taken as the field variable. The medium is

assumed to have no ambient motion, and viscosity and thermal conduction are ignored.

At any given instant and near any given point there is a kinetic energy density taken as

$$\mathfrak{T} = \frac{1}{2}\rho \sum_i \left(\frac{\partial \xi_i}{\partial t}\right)^2 . \tag{3.114}$$

This is the kinetic energy per unit volume; the quantity ρ is understood to be the ambient density, this being an appropriate approximation given that the principle should be consistent with a linear formulation.

The second density of interest is the strain energy density, $\mathfrak{U}$, which is presumed to be a bilinear function of the displacement field components and of their spatial derivatives. For an isotropic linear elastic solid, this is given by (3.68), which can be equivalently written, making use of the definition of the strain components, as

$$\mathfrak{U} = \frac{1}{4}\mu_L \sum_{ij} \left(\frac{\partial \xi_i}{\partial x_j} + \frac{\partial \xi_j}{\partial x_i}\right)^2 + \frac{1}{2}\lambda_L \left(\nabla \cdot \boldsymbol{\xi}\right)^2 . \tag{3.115}$$

For the case of a compressible fluid, the stress tensor is given by

$$\sigma_{ij} = -p\delta_{ij} = \rho c^2 \nabla \cdot \boldsymbol{\xi} \delta_{ij} . \tag{3.116}$$

Here p is the pressure associated with the disturbance, and the second version follows from the time integration of (3.71). The general expression (3.60) consequently yields

$$\mathfrak{U} = \frac{1}{2}\rho c^2 \left(\nabla \cdot \boldsymbol{\xi}\right)^2 \tag{3.117}$$

for the strain energy density in a fluid.

There are other examples that can be considered for which there are different expressions for the strain energy density.

Given the kinetic and strain energy densities, one constructs a Lagrangian density,

$$\mathcal{L} = \mathfrak{T} - \mathfrak{U} . \tag{3.118}$$

Hamilton's principle then takes the form

$$\delta \iiiint \mathcal{L} \, dx \, dy \, dz \, dt = 0 . \tag{3.119}$$

Here the integration is over an arbitrary volume and arbitrary time interval. The symbol δ implies a variation from the exact solution of the problem of interest. In such a variation, the local and instantaneous value

$\boldsymbol{\xi}(x, t)$ is considered to deviate by an infinitesimal amount $\delta\boldsymbol{\xi}(x, t)$.

The variation of the Lagrangian is calculated in the same manner as one determines differentials using the chain rule of differentiation. One subsequently uses the fact that a variation of a derivative is the derivative of a variation. One then integrates by parts, whenever necessary, so that one eventually obtains, an equation of the form

$$\iiiint \sum_i [\text{expression}]_i \delta\xi_i \, dx \, dy \, dz \, dt$$
$$+ [\text{boundary terms}] = 0 . \tag{3.120}$$

Here the boundary terms result from the integrations by parts, and they involve values of the variations at the boundaries (integration limits) of the fourfold integration domain. If one takes the variations to be zero at these boundaries, but otherwise arbitrary within the domain, one concludes that the coefficient expressions of the $\delta\xi_i$ within the integrand must be identically zero when the displacement field is the correct solution. Consequently, one infers that the displacement field components must satisfy

$$[\text{expression}]_i = 0 . \tag{3.121}$$

The detailed derivation yields the above with the form

$$\frac{\partial \mathcal{L}}{\partial \xi_i} - \frac{\partial}{\partial t}\left(\frac{\partial \mathcal{L}}{\partial(\partial\xi_i/\partial t)}\right) - \sum_j \frac{\partial}{\partial x_j}\left(\frac{\partial \mathcal{L}}{\partial(\partial\xi_i/\partial x_j)}\right)$$
$$+ \sum_{jk} \frac{\partial^2}{\partial x_j \partial x_k}\left(\frac{\partial \mathcal{L}}{\partial(\partial^2\xi_i/\partial x_j \partial x_k)}\right) - \ldots = 0 . \tag{3.122}$$

This, along with its counterparts for the other displacement components, is sometimes referred to as the Lagrange–Euler equation(s). The terms that are required correspond to those spatial derivatives on which the strain energy density $\mathfrak{U}$ depends.

For the case of an isotropic solid, the Lagrange–Euler equations correspond to those of (3.77), which is equivalently written, given that the Lamé coefficients are independent of position, as

$$\rho \frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = \rho\left(c_1^2 - c_2^2\right)\nabla\left(\nabla \cdot \boldsymbol{\xi}\right) + \rho c_2^2 \nabla^2 \boldsymbol{\xi} . \tag{3.123}$$

For a fluid, the analogous result is

$$\rho \frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = \nabla(\rho c^2 \nabla \cdot \boldsymbol{\xi}) . \tag{3.124}$$

The more familiar Bergmann version (3.73) of the wave equation results from this if one divides both sides by ρ, then takes the divergence, and subsequently sets

$$p = -\rho c^2 \nabla \cdot \boldsymbol{\xi} \, . \tag{3.125}$$

Here the variational principle automatically yields a wave equation that is suitable for inhomogeneous media, where ρ and c vary with position.

3.4.2 Biot's Formulation for Porous Media

A commonly used model for waves in porous media follows from a formulation developed by *Biot* [3.42], with a version of Hamilton's principle used in the formulation. The medium consists of a solid matrix that is connected, so that it can resist shear stresses, and within which are small pores filled with a compressible fluid.

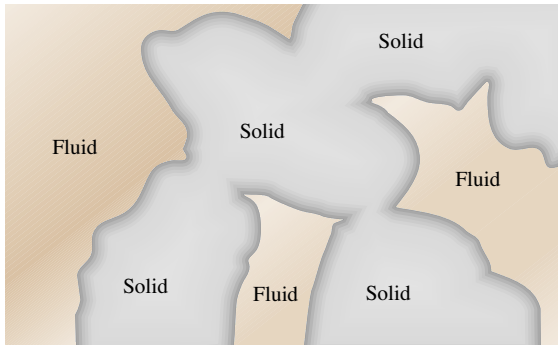
Two displacement fields are envisioned, one associated with the local average displacement $\boldsymbol{U}$ of the fluid matter, the other associated with the average displacement $\boldsymbol{u}$ of the solid matter. The average here is understood to be an average over scales large compared to representative pore sizes or grain sizes, but yet small compared to whatever lengths are of dominant interest. Because nonlinear effects are believed minor, the kinetic and strain energies per unit volume, again averaged over such length scales, are taken to be quadratic in the displacement fields and their derivatives. The overall medium is presumed to be isotropic, so the two energy densities must be unchanged under coordinate rotations. These innocuous assumptions lead to the general ex-


Fig. 3.7 Sketch of a portion of a porous medium in which a compressible fluid fills the pores within a solid matrix. Grains that touch each other are in welded contact, insofar as small-amplitude disturbances are concerned

pressions

$$\mathfrak{T} = \frac{1}{2}\rho_{11}\frac{\partial \boldsymbol{u}}{\partial t} \cdot \frac{\partial \boldsymbol{u}}{\partial t} + \rho_{12}\frac{\partial \boldsymbol{U}}{\partial t} \cdot \frac{\partial \boldsymbol{u}}{\partial t} + \frac{1}{2}\rho_{22}\frac{\partial \boldsymbol{U}}{\partial t} \cdot \frac{\partial \boldsymbol{U}}{\partial t} \, ,$$
$$\tag{3.126}$$

$$\mathfrak{U} = \frac{1}{4}N\sum_{ij}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)^2 + \frac{1}{2}A\left(\nabla \cdot \boldsymbol{u}\right)^2$$
$$+ Q\left(\nabla \cdot \boldsymbol{u}\right)\left(\nabla \cdot \boldsymbol{U}\right) + \frac{1}{2}R\left(\nabla \cdot \boldsymbol{U}\right)^2 \, . \tag{3.127}$$

where there are seven, possibly position-dependent, constants. The above form assumes that there is no potential energy associated with shear deformation in the fluid and that there is no potential energy associated with the relative displacements of the solid and the fluid. The quantities $\boldsymbol{U}$ and $\boldsymbol{u}$ here, which are displacements, should not be confused with velocities, although these symbols are used for velocities in much of the literature. They are used here for displacements, because they were used as such by Biot in his original paper.

Because the two energy densities must be nonnegative, the constants that appear here are constrained so that

$$\rho_{11} \geq 0 \, ; \quad \rho_{22} \geq 0 \, ; \quad \rho_{11}\rho_{22} - \rho_{12}^2 \geq 0 \, , \tag{3.128}$$

$$N \geq 0 \, ; \quad A + 2N \geq 0 \, ; \quad R \geq 0 \, ;$$
$$(A + 2N)R - Q^2 \geq 0 \, . \tag{3.129}$$

The coupling constants, ρ_{12} and Q, can in principle be either positive or negative, but their magnitudes are constrained by the equations above.

It is presumed that this idealization for the energy densities will apply best at low frequencies, and one can conceive of a possible low-frequency disturbance where the solid and the fluid move locally together, with the locking being caused by the viscosity in the fluid and by the boundary condition that displacements at interfaces must be continuous. In such circumstances the considerations that lead to the composite density of (3.50) should apply, so one should have

$$\rho_{11} + 2\rho_{12} + \rho_{22} = \rho_{eq} = f_s\rho_s + f_f\rho_f \, . \tag{3.130}$$

Here f_s and f_f are the volume fractions of the material that are solid and fluid, respectively. The latter is referred to as the porosity.

In general, the various constants have to be inferred from experiment, and it is difficult to deduce them from first principles. An extensive discussion of these constants with some representative values can be found in the monograph by *Stoll* [3.43].

Because the friction associated with the motion of the fluid with respect to the solid matrix is inherently nonconservative (i. e., energy is lost), the original version (3.119) of Hamilton's principle does not apply. The applicable extension includes a term that represents the time integral of the virtual work done by nonconservative forces during a variation. If such nonconservative forces are taken to be distributed over the volume, with the forces per unit volume on the fluid denoted by $\mathfrak{F}$ and those on the solid denoted by $\mathfrak{f}$, then the modified version of Hamilton's principle is

$$\iiiint (\delta\mathfrak{L} + \mathfrak{F} \cdot \delta\boldsymbol{U} + \mathfrak{f}\cdot\delta\boldsymbol{u}) \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z \, \mathrm{d}t = 0. \tag{3.131}$$

Moreover, one infers that

$$\mathfrak{F} = -\mathfrak{f} \,, \tag{3.132}$$

since the virtual work associated with friction between the solid matrix and the fluid must vanish if the two are moved together.

The Lagrange–Euler equations that result from the above variational principle are

$$\frac{\partial}{\partial t}\left(\frac{\partial\mathfrak{L}}{\partial\left(\partial U_i/\partial t\right)}\right) + \sum_j \frac{\partial}{\partial x_j}\left(\frac{\partial\mathfrak{L}}{\partial\left(\partial U_i/\partial x_j\right)}\right) = \mathfrak{F}_i \,, \tag{3.133}$$

$$\frac{\partial}{\partial t}\left(\frac{\partial\mathfrak{L}}{\partial\left(\partial u_i/\partial t\right)}\right) + \sum_j \frac{\partial}{\partial x_j}\left(\frac{\partial\mathfrak{L}}{\partial\left(\partial u_i/\partial x_j\right)}\right) = \mathfrak{f}_i \,. \tag{3.134}$$

Biot, in his original exposition, took the internal distributed forces to be proportional to the relative velocities, reminiscent of dashpots, so that

$$\mathfrak{F}_i = -\mathfrak{f}_i = -b\left(\frac{\partial U_i}{\partial t} - \frac{\partial u_i}{\partial t}\right) \,. \tag{3.135}$$

Here the quantity b can be regarded as the apparent dashpot constant per unit volume. This form is such that the derived equations, in the limit of vanishingly small frequencies, are consistent with Darcy's law [3.44] for steady fluid flow through a porous medium.

The equations that result from this formulation, when written out explicitly, are

$$\frac{\partial^2}{\partial t^2}(\rho_{11}\boldsymbol{u} + \rho_{12}\boldsymbol{U}) - \nabla(A'\nabla\cdot\boldsymbol{u} + Q\nabla\cdot\boldsymbol{U})$$
$$+ \nabla\times[N\,(\nabla\times\boldsymbol{u})] = b\frac{\partial}{\partial t}\,(\boldsymbol{U} - \boldsymbol{u}) \,, \tag{3.136}$$

$$\frac{\partial^2}{\partial t^2}(\rho_{12}\boldsymbol{u} + \rho_{22}\boldsymbol{U}) - \nabla(Q\nabla\cdot\boldsymbol{u} + R\nabla\cdot\boldsymbol{U})$$
$$= -b\frac{\partial}{\partial t}\,(\boldsymbol{U} - \boldsymbol{u}) \,, \tag{3.137}$$

with the abbreviation $A' = A + 2N$. Here, and in what follows, it is assumed that the various material constants are independent of position, although some of the derived equations may be valid to a good approximation even when this is not the case.

3.4.3 Disturbance Modes in a Biot Medium

Disturbances that satisfy the equations derived in the previous section can be represented as a superposition of three basic modal disturbances. These are here denoted as the acoustic mode, the Darcy mode, and the shear mode, and one writes

$$\boldsymbol{u} = \boldsymbol{u}_{\mathrm{ac}} + \boldsymbol{u}_{\mathrm{D}} + \boldsymbol{u}_{\mathrm{sh}} \,, \tag{3.138}$$

$$\boldsymbol{U} = \boldsymbol{U}_{\mathrm{ac}} + \boldsymbol{U}_{\mathrm{D}} + \boldsymbol{U}_{\mathrm{sh}} \,. \tag{3.139}$$

At low frequencies, the motion in the acoustic mode and in the shear mode is nearly such that the fluid and solid displacements are the same,

$$\boldsymbol{U}_{\mathrm{ac}} \approx \boldsymbol{u}_{\mathrm{ac}} \,; \qquad \boldsymbol{U}_{\mathrm{sh}} \approx \boldsymbol{u}_{\mathrm{sh}} \,. \tag{3.140}$$

The lowest-order (in frequency divided by the dashpot parameter b) approximation results from taking the sum of (3.136) and (3.137) and then setting $\boldsymbol{u} = \boldsymbol{U}$, yielding

$$\rho_{\mathrm{eq}}\frac{\partial^2}{\partial t^2}\boldsymbol{U} - \nabla(B_{\mathrm{V,B}}\nabla\cdot\boldsymbol{U}) + \nabla\times[G_{\mathrm{B}}\,(\nabla\times\boldsymbol{U})] = 0 \,, \tag{3.141}$$

with the abbreviations

$$\rho_{\mathrm{eq}} = \rho_{11} + 2\rho_{12} + \rho_{22} \,, \tag{3.142}$$

$$B_{\mathrm{V,B}} = A + 2N + 2Q + R \,, \tag{3.143}$$

$$G_{\mathrm{B}} = N \,, \tag{3.144}$$

for the apparent density, bulk modulus, and shear modulus of the Biot medium. The same equation results for the solid displacement field $\boldsymbol{u}$ in this approximation.

Acoustic Mode

For the acoustic mode, the curl of each displacement field is zero, so

$$\rho_{\mathrm{eq}}\frac{\partial^2}{\partial t^2}\boldsymbol{U} - \nabla\left(B_{\mathrm{V,B}}\nabla\cdot\boldsymbol{U}\right) = 0 \,. \tag{3.145}$$

One can identify an apparent pressure disturbance associated with this mode, so that

$$p_{\mathrm{ac}} \approx -B_{\mathrm{V,B}}\nabla\cdot\boldsymbol{U} \,, \tag{3.146}$$

and this will satisfy the wave equation

$$\nabla^2 p_{ac} - \frac{1}{c_{ac}^2} \frac{\partial^2 p_{ac}}{\partial t^2} = 0 , \tag{3.147}$$

where

$$c_{ac}^2 = \frac{B_{V,B}}{\rho_{eq}} \tag{3.148}$$

is the square of the apparent sound speed for disturbances carried by the acoustic mode.

The equations just derived can be improved by an iteration procedure to take into account that the dashpot constant has a finite (rather than an infinite) value. To the next order of approximation, one obtains

$$\nabla^2 U_{ac} - \frac{1}{c_{ac}^2} \frac{\partial^2}{\partial t^2} U_{ac} = -\frac{\tau_B}{c_{ac}^2} \frac{\partial^3}{\partial t^3} U_{ac} . \tag{3.149}$$

This wave equation with an added (dissipative) term holds for each component of U_{ac} and of u_{ac}, as well as for the pressure p_{ac}. The time constant τ_B which appears here is given by

$$\tau_B = \frac{D^2}{b B_{V,B}^2 \rho_{eq}} , \tag{3.150}$$

where

$$D = (\rho_{11} + \rho_{12})(R + Q) \\ - (\rho_{22} + \rho_{12})(A + 2N + Q) \tag{3.151}$$

is a parameter that characterizes the mismatch between the material properties of the fluid and the solid. The appearance of the dissipative term in the wave equation is associated with the imperfect locking of the two displacement fields, so that

$$U_{ac} - u_{ac} \approx \frac{D}{b B_{V,B}} \frac{\partial u_{ac}}{\partial t} . \tag{3.152}$$

One should note that (3.149) is of the same general mathematical form as the dissipative wave equation (3.101).

Shear mode

For the shear mode, the divergence of each displacement field is zero, so (3.141) reduces to

$$\rho_{eq} \frac{\partial^2}{\partial t^2} U + \nabla \times [G_B (\nabla \times U)] = 0 , \tag{3.153}$$

where this holds to lowest order for both U_{sh} and u_{sh}, these being equal in this approximation. A mathematical identity for the curl of a curl reduces this to

$$\nabla^2 u_{sh} - \frac{1}{c_{sh}^2} \frac{\partial^2 u_{sh}}{\partial t^2} = 0 , \tag{3.154}$$

where

$$c_{sh}^2 = \frac{G_B}{\rho_{eq}} . \tag{3.155}$$

An iteration process that takes into account that the two displacement fields are not exactly the same yields

$$u_{sh} - U_{sh} \approx \frac{\rho_{22} + \rho_{12}}{b} \frac{\partial U_{sh}}{\partial t} , \tag{3.156}$$

with the result that the wave equation above is replaced by a dissipative wave equation

$$\nabla^2 u_{sh} - \frac{1}{c_{sh}^2} \frac{\partial^2 u_{sh}}{\partial t^2} = -\frac{(\rho_{22} + \rho_{12})^2}{G_B b} \frac{\partial^3 u_{sh}}{\partial t^3} . \tag{3.157}$$

Darcy Mode

For the Darcy mode, the curl of both displacement fields is zero,

$$\nabla \times U_D = 0 ; \qquad \nabla \times u_D = 0 . \tag{3.158}$$

The inertia term in both (3.136) and (3.137) is negligible to a lowest approximation, and the compatibility of the two equations requires

$$(A' + Q)u_D = -(R + Q)U_D , \tag{3.159}$$

so that the fluid and the solid move in opposite directions.

Given the above observation and the neglect of the inertia terms, either of (3.136) and (3.137) reduces to the diffusion equation

$$\nabla^2 U_D = \kappa_D \frac{\partial U_D}{\partial t} , \tag{3.160}$$

with the same equation also being satisfied by u_D. Here

$$\kappa_D = \frac{b B_{V,B}}{A' R - Q^2} \tag{3.161}$$

is a constant whose reciprocal characterizes the tendency of the medium to allow diffusion of fluid through the solid matrix. This is independent of any of the inertial densities, and it is always positive.

3.5 Waves of Constant Frequency

One of the principal terms used in describing sound is that of frequency. Although certainly not all acoustic disturbances are purely sinusoidal oscillations of a quantity (such as pressure or displacement) that oscillates with constant frequency about a mean value, it is usually possible to characterize (at least to an order of magnitude) any such disturbance by one or a limited number of representative frequencies, these being the reciprocals of the characteristic time scales. Such a description is highly useful, because it gives one some insight into what detailed physical effects are relevant and of what instrumentation is applicable. The simplest sort of acoustic signal would be one where a quantity such as the fluctuating part p of the pressure is oscillating with time t as

$$p = A \cos(\omega t - \phi) . \tag{3.162}$$

Here the amplitude A and phase constant ϕ are independent of t (but possibly dependent on position). The quantity ω is called the angular frequency and has the units of radians divided by time (for example, rad/s or simply s^{-1}, when the unit of time is the second). The number f of repetitions per unit time is what one normally refers to as the frequency (without a modifier), such that $\omega = 2\pi f$. The value of f in hertz (abbreviated to Hz) is the frequency in cycles (repetitions) per second. The period $T = 1/f$ is the time interval between repetitions.

The human ear responds [3.45] almost exclusively to frequencies between roughly 20 Hz and 20 kHz. Consequently, sounds composed of frequencies below 20 Hz are said to be infrasonic; those composed of frequencies above 20 kHz are said to be ultrasonic. The scope of acoustics, given its general definition as a physical phenomenon, is not limited to audible frequencies.

3.5.1 Spectral Density

The term frequency spectrum is often used in relation to sound. Often the use is somewhat loose, but there are circumstances for which the terminology can be made precise. If the fluctuating physical quantity p associated with the acoustic disturbance is a sum of sinusoidal disturbances, the n-th being $p_n = A_n \cos(2\pi f_n t - \phi_n)$ and having frequency f_n, no two frequencies being the same, then the set of mean squared amplitudes can be taken as a description of the spectrum of the signal. Also, if the sound is made up of many different frequencies, then one can use the time-averaged sum of the p_n^2

that correspond to those frequencies within a given specified frequency band as a measure of the strength of the signal within that frequency band. This sum divided by the width of the frequency band often approaches a quasi-limit as the bandwidth becomes small, but with the number of included terms still being moderately large, and with this quasi-limit being a definite smooth function of the center frequency of the band. This quasi-limit is called the spectral density p_f^2 of the signal. Although an idealized quantity, it can often be repetitively measured to relatively high accuracy; instrumentation for the measurement of spectral densities or of integrals of spectral densities over specified (such as octaves) frequency bands is widely available commercially.

The utility of the spectral density concept rests on the principle of superposition and on a version of Parseval's theorem, which states that, when the signal is a sum of discrete frequency components, then if averages are taken over a sufficiently long time interval,

$$(p^2)_{av} = \sum_n \left(p_n^2 \right)_{av} . \tag{3.163}$$

Consequently, in the quasi-limit corresponding to the spectral density description, one has the mean squared pressure expressed as an integral over spectral density,

$$(p^2)_{av} = \int_0^\infty p_f^2(f) \, df . \tag{3.164}$$

The spectral density at a given frequency times a narrow bandwidth centered at that frequency is interpreted as the contribution to the mean squared acoustic pressure from that frequency band.

If the signal is a linear response to a source (or excitation) characterized by some time variation $s(t)$ with spectral density $s_f^2(f)$, then the spectral density of the response is

$$p_f^2(f) = |H_{ps}(2\pi f)|^2 s_f^2(f) , \tag{3.165}$$

where the proportionality factor $|H_{ps}(2\pi f)|^2$ is the square of the absolute magnitude of a transfer function that is independent of the excitation, but which does depend on frequency. For any given frequency, this transfer function can be determined from the response to a known sinusoidal excitation with the same frequency. Thus the analysis for constant-frequency excitation is fundamental, even when the situation of interest may involve broadband excitation.

3.5.2 Fourier Transforms

Analogous arguments can be made for transient excitation and transient signals, where time-dependent quantities are represented by integrals over Fourier transforms, so that

$$p(t) = \int_{-\infty}^{\infty} \hat{p}(\omega) e^{-i\omega t} d\omega \,, \qquad (3.166)$$

with

$$\hat{p}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} p(t) e^{i\omega t} dt \,. \qquad (3.167)$$

Here $\hat{p}(\omega)$ is termed the Fourier transform of $p(t)$, and $p(t)$ is conversely termed the inverse Fourier transform of $\hat{p}(\omega)$. Definitions of the Fourier transform vary in the acoustics literature. What is used here is what is commonly used for analyses of wave propagation problems. Whatever definition is used must be accompanied by a definition of the inverse Fourier transform, so that the inverse Fourier transform produces the original function. In all such cases, given that $p(t)$ and ω are real, one has

$$\hat{p}(-\omega) = \hat{p}(\omega)^* \,, \qquad (3.168)$$

where the asterisk denotes the complex conjugate. Thus, the magnitude of the Fourier transform need only be known for positive frequencies. The phase changes sign when one changes the sign of the frequency.

Parseval's theorem for Fourier transforms is

$$\int_{-\infty}^{\infty} p^2(t) dt = 4\pi \int_{0}^{\infty} |\hat{p}(\omega)|^2 d\omega \,, \qquad (3.169)$$

so that $4\pi |\hat{p}(\omega)|^2 \Delta\omega$ can be regarded as to the contribution to the time integral of $p^2(t)$ from a narrow band of (positive) frequencies of width $\Delta\omega$.

3.5.3 Complex Number Representation

Insofar as the governing equations are linear with coefficients independent of time, disturbances that vary sinusoidally with time can propagate without change of frequency. Such sinusoidally varying disturbances of constant frequency have the same repetition period (the reciprocal of the frequency) at every point, but the phase will in general vary from point to point.

When one considers a disturbance of fixed frequency or one frequency component of a multifrequency disturbance, it is convenient to use a complex number representation, such that each field amplitude is written [3.4, 46]

$$p = \mathrm{Re}(\hat{p} e^{-i\omega t}) \,. \qquad (3.170)$$

Here $\hat{p}$ is called the complex amplitude of the acoustic pressure and in general varies with position. (The use of the $e^{-i\omega t}$ time dependence is traditional among acoustics professionals who are primarily concerned with the wave aspects of acoustics. In the vibrations literature, one often finds instead a postulated $e^{j\omega t}$ time dependence. The use of j as the square root of -1 instead of i is a carryover from the analysis of oscillations in electrical circuits, where i is reserved for electrical current.)

If one inserts expressions such as (3.170) into a homogeneous linear ordinary or partial differential equation with real time-independent coefficients, the result can always be written in the form

$$\mathrm{Re}\left(\Phi e^{-i\omega t}\right) = 0 \,, \qquad (3.171)$$

where the quantity Φ is an expression depending on the complex amplitudes and their spatial derivatives, but not depending on time. The requirement that (3.171) should hold for all values of time consequently can be satisfied if and only if

$$\Phi = 0 \,. \qquad (3.172)$$

Moreover, the form of the expression Φ can be readily obtained from the original equation with a simple prescription: replace all field variables by their complex amplitudes and replace all time derivatives using the substitution

$$\frac{\partial}{\partial t} \to -i\omega \,. \qquad (3.173)$$

Thus, for example, the linear acoustic equations given by (3.71) and (3.72) reduce to

$$-i\omega\hat{p} + \rho c^2 \nabla \cdot \hat{\boldsymbol{v}} = 0 \,, \qquad (3.174)$$
$$-i\omega\rho\hat{\boldsymbol{v}} = -\nabla\hat{p} \,. \qquad (3.175)$$

The wave equation in (3.74) reduces (with $k = \omega/c$ denoting the wavenumber) to

$$\nabla^2\hat{p} + k^2\hat{p} = 0 \,, \qquad (3.176)$$

which is the Helmholtz equation [3.47] for the complex pressure amplitude.

3.5.4 Time Averages of Products

When dealing with waves of constant frequency, one often makes use of averages over a wave period of the product of two quantities that oscillate with the same frequency. Let

$$p = \mathrm{Re}\left(\hat{p}\,e^{-i\omega t}\right) ; \qquad v = \mathrm{Re}\left(\hat{v}\,e^{-i\omega t}\right) \qquad (3.177)$$

be two such quantities. Then the time average of their product is

$$[p(t)v(t)]_{\mathrm{av}} = |\hat{p}||\hat{v}|[\cos(\omega t - \phi_p)\cos(\omega t - \phi_v)]_{\mathrm{av}} , \qquad (3.178)$$

where ϕ_p and ϕ_v are the phases of $\hat{p}$ and $\hat{v}$.

The trigonometric identity

$$\cos(A)\cos(B) = \frac{1}{2}\left[\cos(A+B) + \cos(A-B)\right] , \qquad (3.179)$$

with appropriate identifications for A and B, yields a term which averages out to zero and a term which is independent of time. Thus one has

$$[p(t)v(t)]_{\mathrm{av}} = \frac{1}{2}|\hat{p}||\hat{v}|\cos(\phi_p - \phi_v) , \qquad (3.180)$$

or, equivalently

$$[p(t)v(t)]_{\mathrm{av}} = \frac{1}{2}|\hat{p}||\hat{v}|\mathrm{Re}(e^{i(\phi_p - \phi_v)}) , \qquad (3.181)$$

which in turn can be written

$$[p(t)v(t)]_{\mathrm{av}} = \frac{1}{2}\mathrm{Re}(\hat{p}\hat{v}^*) . \qquad (3.182)$$

The asterisk here denotes the complex conjugate. Because the real part of a complex conjugate is the same as the real part of the original complex number, it is immaterial whether one takes the complex conjugate of $\hat{p}$ or $\hat{v}$, but one takes the complex conjugate of only one.

3.6 Plane Waves

A solution of the wave equation that plays a central role in many acoustical concepts is that of a plane traveling wave.

3.6.1 Plane Waves in Fluids

The mathematical representation of a plane wave is such that all acoustic field quantities vary with time and with one Cartesian coordinate. That coordinate is taken here as x; consequently, all the acoustic quantities are independent of y and z. The Laplacian reduces to a second partial derivative with respect to x and the d'Alembertian can be expressed as the product of two first-order operators, so that the wave equation takes the form

$$\left(\frac{\partial}{\partial x} - \frac{1}{c}\frac{\partial}{\partial t}\right)\left(\frac{\partial}{\partial x} + \frac{1}{c}\frac{\partial}{\partial t}\right) p = 0 . \qquad (3.183)$$

The solution of this equation is a sum of two expressions, each of which is such that operation by one or the other of the two factors in (3.183) yields zero. Such a solution is represented by

$$p(x,t) = f(x - ct) + g(x + ct) , \qquad (3.184)$$

where f and g are two arbitrary functions. The argument combination $x - ct$ of the first term is such that the function f with that argument represents a plane wave traveling forward in the $+x$-direction at a velocity c. The

second term in (3.184) similarly represents a plane wave traveling backwards in the $-x$-direction, also at a velocity c. For a traveling plane wave, not only the shape, but also the amplitude is conserved during propagation. A typical situation for which wave propagation can be adequately described by traveling plane waves is that of low-frequency sound propagation in a duct. Diverging or converging (focused) waves can often be approximately regarded as planar within regions of restricted extent.

The fluid velocity that corresponds to the plane wave solution above has y and z components that are identically zero, but the x-component, in accordance with (3.71) and (3.72), is

$$v_x = \frac{1}{\rho c}f(x - ct) - \frac{1}{\rho c}g(x + ct) . \qquad (3.185)$$
Fig. 3.8 Waveform propagating in the $+s$-direction with constant speed c. Shown are plots of the function $f(s - ct)$ versus s at two successive values of the time t
Fig. 3.9 Plane wave propagating in the direction of the unit vector $\boldsymbol{n}$

The general rule that emerges from this is that, for a plane wave propagating in the direction corresponding to unit vector $\boldsymbol{n}$, the acoustic part of the pressure is

$$p = f(\boldsymbol{n} \cdot \boldsymbol{x} - ct) \tag{3.186}$$

for some generic function f of the indicated argument, while the acoustically induced fluid velocity is

$$\boldsymbol{v} = \frac{\boldsymbol{n}}{\rho c} p \ . \tag{3.187}$$

Because the fluid velocity is in the same direction as that of the wave propagation, such waves are said to be longitudinal. (Electromagnetic plane waves in free space, in contrast, are transverse. Both the electric field vector and the magnetic field vector are perpendicular to the direction of propagation.)

For a plane wave traveling along the $+x$-axis at a velocity c, the form of (3.186) implies that one can represent a constant-frequency acoustic pressure disturbance by the expression

$$p = |P| \cos\left[k(x - ct) + \phi_0\right] = \text{Re}(P\,\mathrm{e}^{\mathrm{i}k(x-ct)}) \ , \tag{3.188}$$

with the angular frequency identified as

$$\omega = ck \ . \tag{3.189}$$

Alternately, if the complex amplitude representation of (3.170) is used, one writes the complex amplitude of the acoustic pressure as

$$\hat{p} = P\,\mathrm{e}^{\mathrm{i}kx} \ , \tag{3.190}$$

where P is a complex number related to the constants that appear in (3.188) as

$$P = |P|\,\mathrm{e}^{\mathrm{i}\phi_0} \ . \tag{3.191}$$
Fig. 3.10 Fluid velocity and pressure in a one-cycle sinusoidal pulse propagating in the $+x$-direction

Here $|P|$ is the amplitude of the disturbance, ϕ_0 is a phase constant, and k is a constant termed the wavenumber. The wavelength λ is the increment in propagation distance x required to change the argument of the cosine by 2π radians, so

$$k = \frac{2\pi}{\lambda} \ . \tag{3.192}$$

Also, the increment in t required to change the argument by 2π is the period T, which is the reciprocal of the frequency f, so one has

$$\lambda = \frac{c}{f} \ . \tag{3.193}$$

3.6.2 Plane Waves in Solids

Plane acoustic waves in isotropic elastic solids [3.26] have properties similar to those of waves in fluids. Dilatational (or longitudinal) plane waves are such that the curl of the displacement field vanishes, so the displacement vector must be parallel to the direction of propagation. (Dilation means expansion and is the antonym of compression. Dilatational plane waves could equally well be termed compressional plane waves. Seismologists refer to dilational waves as P-waves, where the letter P stands for primary. They refer to shear waves as S-waves, where the letter S stands for secondary.) A comparison of (3.82) with the wave equation (3.74) indicates that such a wave must propagate with a speed c_1 determined by (3.79). Thus, a wave propagating in the $+x$-direction has no y and z components of displacement, and has an x-component described by

$$\xi_x = F(x - c_1 t) \ , \tag{3.194}$$

where F is an arbitrary function. The stress components can be deduced from (3.56, 57, 79, 80). These equations,

as well as symmetry considerations, require for a dilatational wave propagating in the x-direction, that the off-diagonal elements of the stress tensor vanish. The diagonal elements are given by

$$\sigma_{xx} = \rho c_1^2 F'(x - c_1 t) , \tag{3.195}$$

$$\sigma_{yy} = \sigma_{zz} = \rho(c_1^2 - 2c_2^2) F'(x - c_1 t) . \tag{3.196}$$

Here the primes denote derivatives with respect to the total argument.

The divergence of the displacement field in a shear wave is zero, so a plane shear wave must cause a displacement perpendicular to the direction of propagation.

Shear waves are therefore transverse waves. Equation (3.83), when considered in a manner similar to that described above for the wave equation for waves in fluids, leads to the conclusion that plane shear waves must propagate with a speed c_2. A plane shear wave polarized in the y-direction and propagating in the x-direction will have only a y-component of displacement, given by

$$\xi_y = F(x - c_2 t) . \tag{3.197}$$

The only nonzero stress components are the shear stresses

$$\sigma_{yx} = \rho c_2^2 F'(x - c_2 t) = \sigma_{xy} . \tag{3.198}$$

3.7 Attenuation of Sound

Plane waves of constant frequency propagating through bulk materials have amplitudes that typically decrease exponentially with increasing propagation distance, such that the magnitude of the complex pressure amplitude varies as

$$|\hat{p}(x)| = |\hat{p}(0)| e^{-\alpha x} . \tag{3.199}$$

The quantity α is the plane wave attenuation coefficient and has units of nepers per meter (Np/m); it is an intrinsic frequency-dependent property of the material. This exponential decrease of amplitude is called attenuation or absorption of sound and is associated with the transfer of acoustic energy to the internal energy of the material. (If $|\hat{p}|^2$ decreases to a tenth of its original value, it is said to have decreased by 10 decibels (dB), so an attenuation constant of α nepers per meter is equivalent to an attenuation constant of $[20/(\ln 10)]\alpha$ decibels per meter, or 8.6859α decibels per meter.)

3.7.1 Classical Absorption

The attenuation of sound due to the classical processes of viscous energy absorption and thermal conduction is derivable [3.33] from the dissipative wave equation (3.101) given previously for the acoustics mode. Dissipative processes enter into this equation through a parameter δ_{cl}, which is defined by (3.102). To determine the attenuation of waves governed by such a dissipative wave equation, one sets the perturbation pressure equal to

$$p_{ac} = P e^{-i\omega t} e^{ikx} , \tag{3.200}$$

where P is independent of position and k is a complex number. Such a substitution, with reasoning such as that which leads from (3.171) to (3.172), yields an algebraic equation that can be nontrivially (amplitude not identically zero) satisfied only if k satisfies the relation

$$k^2 = \frac{\omega^2}{c^2} + i \frac{2\delta_{cl}\omega^3}{c^3} . \tag{3.201}$$

The root that corresponds to waves propagating in the $+x$-direction is that which evolves to (3.189) in the limit of no absorption, and for which the real part of k is positive. Thus to first order in δ_{cl}, one has the complex wavenumber

$$k = \frac{\omega}{c} + i \frac{\delta_{cl}\omega^2}{c^3} . \tag{3.202}$$

The attenuation coefficient is the imaginary part of this, in accordance with (3.199), so

$$\alpha_{cl} = \frac{\delta_{cl}\omega^2}{c^3} . \tag{3.203}$$

This is termed the classical attenuation coefficient for acoustic waves in fluids and is designated by the subscript "cl". The distinguishing characteristic of this classical attenuation coefficient is its quadratic increase with increasing frequency.

The same type of frequency dependence is obeyed by the acoustic and shear wave modes for the Biot model of porous media in the limit of low frequencies. From (3.149) one derives

$$\alpha_{ac} = \frac{\tau_B}{2c_{ac}}\omega^2 , \tag{3.204}$$

and, from (3.157), one derives

$$\alpha_{\text{sh}} = \frac{c_{\text{sh}}(\rho_{22} + \rho_{12})^2}{2G_{\text{B}}b} \omega^2 . \tag{3.205}$$

3.7.2 Relaxation Processes

For many substances, including air, sea water, biological tissues, marine sediments, and rocks, the variation of the absorption coefficient with frequency is not quadratic [3.48–50], and the classical model is insufficient to predict the magnitude of the absorption coefficient. The substitution of a different value of the bulk viscosity is insufficient to remove the discrepancy, because this would still yield the quadratic frequency dependence. The successful theory to account for such discrepancies in air and sea water and other fluids is in terms of relaxation processes. The physical nature of the relaxation processes vary from fluid to fluid, but a general theory in terms of irreversible thermodynamics [3.51–53] yields appropriate equations.

The equation of state for the instantaneous (rather than equilibrium) entropy is written as

$$s = s(u, \rho^{-1}, \xi) , \tag{3.206}$$

where ξ represents one or more internal variables. The differential relation of (3.13) is replaced by

$$T\,\mathrm{d}s = \mathrm{d}u + p\,\mathrm{d}\rho^{-1} + \sum_\nu A_\nu\,\mathrm{d}\xi_\nu , \tag{3.207}$$

where the affinities A_ν are defined by this equation. These vanish when the fluid is in equilibrium with a given specified internal energy and density. The pressure p here is the same as enters into the expression (3.15) for the average normal stress, and the T is the same as enters into the Fourier law (3.16) of heat conduction. The mass conservation law (3.2) and the Navier–Stokes equation (3.24) remain unchanged, but the energy equation, expressed in (3.25) in terms of entropy, is replaced by the entropy balance equation

$$\rho\frac{\mathrm{D}s}{\mathrm{D}t} + \nabla\cdot\frac{\boldsymbol{q}}{T} = \sigma_{\text{s}} . \tag{3.208}$$

Here the quantity σ_{s}, which indicates the rate of irreversible entropy production per unit volume, is given by

$$T\sigma_{\text{s}} = \mu_{\text{B}}(\nabla\cdot\boldsymbol{v})^2 + \tfrac{1}{2}\mu\sum_{ij}\phi_{ij}^2 + \frac{\kappa}{T}(\nabla T)^2$$
$$+ \rho\sum_\nu A_\nu\frac{\mathrm{D}\xi_\nu}{\mathrm{D}t} . \tag{3.209}$$

One needs in addition relations that specify how the internal variables ξ_ν relax to their equilibrium values. The simplest assumption, and one which is substantiated for air and sea water, is that these relax independently according to the rule [3.54]

$$\frac{\mathrm{D}\xi_\nu}{\mathrm{D}t} = -\frac{1}{\tau_\nu}\left(\xi_\nu - \xi_{\nu,\text{eq}}\right) . \tag{3.210}$$

The relaxation times τ_ν that appear here are positive and independent of the internal variables.

When the linearization process is applied to the nonlinear equations for the model just described of a fluid with internal relaxation, one obtains the set of equations

$$\frac{\partial\rho'}{\partial t} + \rho_0\nabla\cdot\boldsymbol{v}' = 0 , \tag{3.211}$$

$$\rho_0\frac{\partial\boldsymbol{v}'}{\partial t} = -\nabla p' + (1/3\mu + \mu_{\text{B}})$$
$$\times\nabla(\nabla\cdot\boldsymbol{v}') + \mu\nabla^2\boldsymbol{v}' , \tag{3.212}$$

$$\rho_0 T_0\frac{\partial s'}{\partial t} = \kappa\nabla^2 T' , \tag{3.213}$$

$$\rho' = \frac{1}{c^2}p' - \left(\frac{\rho\beta T}{c_{\text{p}}}\right)_0 s'$$
$$+ \sum_\nu\left(\xi_\nu' - \xi_{\nu,\text{eq}}'\right)a_\nu , \tag{3.214}$$

$$T' = \left(\frac{T\beta}{\rho c_{\text{p}}}\right)_0 p' + \left(\frac{T}{c_{\text{p}}}\right)_0 s'$$
$$+ \sum_\nu\left(\xi_\nu' - \xi_{\nu,\text{eq}}'\right)b_\nu , \tag{3.215}$$

$$\frac{\partial\xi_\nu'}{\partial t} = -\frac{1}{\tau_\nu}\left(\xi_\nu' - \xi_{\nu,\text{eq}}'\right) , \tag{3.216}$$

$$\xi_{\nu,\text{eq}}' = m_\nu s' + n_\nu p' . \tag{3.217}$$

Here a_ν, b_ν, m_ν, and n_ν are constants whose values depend on the ambient equilibrium state.

For absorption of sound, the interest is in the acoustic mode, and so approximations corresponding to those discussed in the context of (3.93) through (3.101) can also be made here. The quantities a_ν and b_ν are treated as small, so that one obtains, to first order in ϵ and in these quantities, a wave equation of the form

$$\nabla^2 p_{\text{ac}} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\left(p_{\text{ac}} - \frac{2\delta_{\text{cl}}}{c^2}\frac{\partial p_{\text{ac}}}{\partial t}\right.$$
$$\left. - 2\sum_\nu\frac{(\Delta c)_\nu}{c}\tau_\nu\frac{\partial p_\nu}{\partial t}\right) = 0 . \tag{3.218}$$

The auxiliary internal variables that enter here satisfy the supplemental relaxation equations

$$\frac{\partial p_\nu}{\partial t} = -\frac{1}{\tau_\nu}(p_\nu - p_{ac}) \ . \qquad (3.219)$$

Here the notation is such that the p_ν are given in terms of previously introduced quantities by

$$p_\nu = \xi'_\nu / n_\nu \ . \qquad (3.220)$$

The sound speed increments that appear in (3.218) represent the combinations

$$(\Delta c)_\nu = 1/2 a_\nu n_\nu c^2 \ . \qquad (3.221)$$

Equations (3.218) and (3.219) are independent of the explicit physical interpretation of the relaxation processes. Insofar as acoustic propagation is concerned, any relaxation process is characterized by two parameters, the relaxation time τ_ν and the sound speed increment $(\Delta c)_\nu$. The various parameters that enter into the irreversible thermodynamics formulation of (3.214) through (3.216) affect the propagation of sound only as they enter into the values of the relaxation times and of the sound speed increments. The replacement of internal variables by quantities p_ν with the units of pressure implies no assumption as to the precise nature of the relaxation process. (An alternate formulation for a parallel class of relaxation processes concerns structural relaxation [3.55]. The substance can locally have more than one state, each of which has a different compressibility. The internal variables are associated with the deviations of the probabilities of the system being in each of the states from the probabilities that would exist were the system in quasistatic equilibrium. The equations that result are mathematically the same as (3.218) and (3.219).)

The attenuation of plane waves governed by (3.218) and (3.219) is determined when one inserts substitutions of the form of (3.200) for p_{ac} and the p_ν. The relaxation equations yield the relations

$$\hat{p}_\nu = \frac{1}{1 - i\omega\tau_\nu}\hat{p}_{ac} \ . \qquad (3.222)$$

These, when inserted into the complex amplitude version of (3.218), yield the dispersion relation

$$k^2 = \frac{\omega^2}{c^2}\left(1 + i\frac{2\omega\delta_{cl}}{c^2} + \sum_\nu \frac{2(\Delta c)_\nu}{c}\frac{i\omega\tau_\nu}{1 - i\omega\tau_\nu}\right) \ . \qquad (3.223)$$

To first order in the small parameters, δ_{cl} and $(\Delta c)_\nu$, this yields the complex wavenumber

$$k = \frac{\omega}{c}\left(1 + i\frac{\omega\delta_{cl}}{c^2} + \sum_\nu \frac{(\Delta c)_\nu}{c}\frac{i\omega\tau_\nu}{1 - i\omega\tau_\nu}\right) \ , \qquad (3.224)$$
Fig. 3.11 Attenuation per wavelength (in terms of characteristic parameters) for propagation in a medium with a single relaxation process. Here the wavelength λ is $2\pi c/\omega$, and the ratio f/f_ν of frequency to relaxation frequency is $\omega\tau_\nu$. The curve as constructed is independent of c and $(\Delta c)_\nu$

which corresponds to waves propagating in the $+x$-direction. The attenuation coefficient, determined by the imaginary part of (3.224), can be written

$$\alpha = \alpha_{cl} + \sum_\nu \alpha_\nu \ . \qquad (3.225)$$

The first term is the classical attenuation determined by (3.203). The remaining terms correspond to the incremental attenuations produced by the separate relaxation processes, these being

$$\alpha_\nu = \frac{(\Delta c)_\nu}{c^2}\frac{\omega^2\tau_\nu}{1 + (\omega\tau_\nu)^2} \ . \qquad (3.226)$$

Any such term increases quadratically with frequency at low frequencies, as would be the case for classical absorption (with an increased bulk viscosity), but it approaches a constant value at high frequencies.

The labeling of the quantities $(\Delta c)_\nu$ as sound speed increments follows from an examination of the real part of the complex wavenumber, given by

$$k_R = \frac{\omega}{c}\left(1 - \sum_\nu \frac{(\Delta c)_\nu}{c}\frac{(\omega\tau_\nu)^2}{1 + (\omega\tau_\nu)^2}\right) . \qquad (3.227)$$

The ratio of ω to k_R is identified as the phase velocity v_{ph} of the wave. In the limit of low frequencies, the phase velocity predicted by (3.227) is the quantity c, which is the sound speed for a quasi-equilibrium process. In the limit of high frequencies, however, to first order in the $(\Delta c)_\nu$, the phase velocity approaches the limit

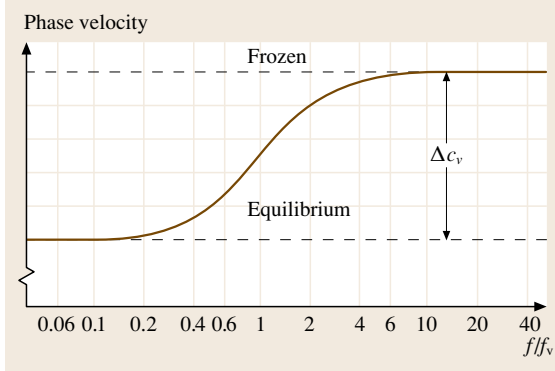
$$v_{ph} \to c + \sum_\nu (\Delta c)_\nu \ . \qquad (3.228)$$


Fig. 3.12 Change in phase velocity as a function of frequency for propagation in a medium with a single relaxation process. The asymptote at zero frequency is the equilibrium sound speed c, and that in the limit of infinite frequency is the frozen sound speed $c + \Delta c_v$

Consequently, each $(\Delta c)_v$ corresponds to the net increase in phase velocity of the sound wave that occurs when the frequency is increased from a value small compared to the relaxation frequency to one large compared to the relaxation frequency. Here the term relaxation frequency is used to denote the reciprocal of the product of 2π with the relaxation time.

3.7.3 Continuously Distributed Relaxations

It is sometimes argued that, for heterogeneous media such as biological tissue and rocks, the attenuation is due to a statistical distribution of relaxation times, so that the sum in (3.224) should be replaced by an integral, yielding

$$k = \frac{\omega}{c}\left(1 + i\frac{\omega\delta_{cl}}{c^2} + \frac{1}{c}\int_0^\infty \frac{d(\Delta c)}{d\tau}\frac{i\omega\tau}{1 - i\omega\tau}\,d\tau\right),$$

(3.229)

and so that the attenuation constant due to the relaxation processes becomes

$$\sum_v \alpha_v \rightarrow \frac{1}{c^2}\int_0^\infty \frac{d(\Delta c)}{d\tau}\frac{\omega^2\tau}{1 + (\omega\tau)^2}\,d\tau .$$

(3.230)

Here, the quantity

$$\frac{d(\Delta c)}{d\tau}\Delta\tau$$

(3.231)

is interpreted as the additional increment in phase velocity at high frequencies due to all the relaxation processes whose relaxation times are in the interval $\Delta\tau$.

Such a continuous distribution of relaxation processes is intrinsically capable of explaining a variety of experimentally observed frequency dependencies of $\alpha(\omega)$. A simple example is that where

$$\frac{d(\Delta c)}{d\tau} = \frac{K}{\tau^q} ,$$

(3.232)

with K being a constant independent of τ, and with q being a specified exponent, with $0 < q < 2$. In such a case the integral in (3.230) becomes

$$\frac{1}{c^2}\int_0^\infty \frac{d(\Delta c)}{d\tau}\frac{\omega^2\tau}{1 + (\omega\tau)^2}\,d\tau = \frac{K}{c^2}\omega^q\int_0^\infty \frac{u^{1-q}}{1 + u^2}\,du$$

(3.233)

giving a power-law dependence on ω that varies as ω^q. Although the hypothesis of (3.232) is probably unrealistic over all ranges of relaxation time τ, its being nearly satisfied over an extensive range of such times could yield predictions that would explain a power-law dependence. (The integral that appears here is just a numerical constant, which is finite provided $0 < q < 2$. The integral emerges when one changes the integration variable from τ to $u = \omega\tau$.)

The corresponding increment in the reciprocal $1/v_{ph} = k_R/\omega$ of the phase velocity v_{ph} is

$$\Delta\left(\frac{1}{v_{ph}}\right) = -\frac{1}{c^2}\int_0^\infty \frac{d(\Delta c)}{d\tau}\frac{\omega^2\tau^2}{1 + (\omega\tau)^2}\,d\tau .$$

(3.234)

Insertion of (3.232) into this yields

$$\Delta\left(\frac{1}{v_{ph}}\right) = -\frac{K}{c^2}\omega^{q-1}\int_0^\infty \frac{u^{2-q}}{1 + u^2}\,du ,$$

(3.235)

which varies with ω as ω^{q-1}. In this case, however, the integral exists only if $1 < q < 3$, so the overall analysis has credibility only if $1 < q < 2$.

3.7.4 Kramers–Krönig Relations

In attempts to explain or predict the frequency dependence of attenuation and phase velocity in materials, some help is found from the principle of causality [3.56]. Suppose one has a plane wave traveling in the $+x$-direction and that, at $x = 0$, the acoustic pressure is a transient given by

$$p(0, t) = \int_{-\infty}^\infty \hat{p}(\omega)e^{-i\omega t}\,d\omega = 2\text{Re}\int_0^\infty \hat{p}(\omega)e^{-i\omega t}\,d\omega .$$

(3.236)

Then the transient at a distant positive value of x is given by

$$p(x, t) = 2\text{Re} \int_0^\infty \hat{p}(\omega) \text{e}^{-\text{i}\omega t}\, \text{e}^{\text{i}kx}\, \text{d}\omega, \qquad (3.237)$$

where $k = k(\omega)$ is the complex wavenumber, the imaginary part of which is the attenuation coefficient.

The causality argument is now made that, if $p(0, t)$ vanishes at all times before some time t_0 in the past, then so should $p(x, t)$. One defines $k(\omega)$ for negative values of frequency so that

$$k(-\omega) = -k^*(\omega). \qquad (3.238)$$

This requires that the real and imaginary parts of the complex wavenumber be such that

$$k_R(-\omega) = -k_R(\omega); \qquad k_I(-\omega) = k_I(\omega), \qquad (3.239)$$

so that the real part is odd, and the imaginary part is even in ω. This extension to negative frequencies allows one to write (3.237) in the form

$$p(x, t) = \int_{-\infty}^\infty \hat{p}(\omega) \text{e}^{-\text{i}\omega t}\, \text{e}^{\text{i}kx}\, \text{d}\omega. \qquad (3.240)$$

The theory of complex variables assures one that this integral will indeed vanish for sufficiently early times if: (i) one can regard the integrand as being defined for complex values of ω, and (ii) one can regard the integrand as having certain general properties in the upper half of the complex ω plane. In particular, it must be analytic (no poles, no branch cuts, no points where a power series does not exist) in this upper half of the comp;ex plane. Another condition is that, when t has a sufficiently negative value, the integrand goes to zero as $|\omega| \to \infty$ in the upper half-plane. The possibility of the latter can be tested with the question of whether

$$\text{Re}\,[-\text{i}\omega t + \text{i}kx] \to -\infty \qquad \text{as} \quad \omega \to \text{i}\infty, \qquad (3.241)$$

with $t < 0$ and $x > 0$. In any event, for all these conditions to be met, the complex wavenumber $k(\omega)$, considered as a complex function of the complex variable ω, has to be analytic in the upper half-plane. One cannot say at the outset, without having a well-defined causal mathematical model, just how it behaves at infinity, but various experimental data suggests it approaches a polynomial with a leading exponent of not more than two. Also, analysis on specific cases suggests it is always such that k/ω is analytic and, moreover, finite at $\omega = 0$.

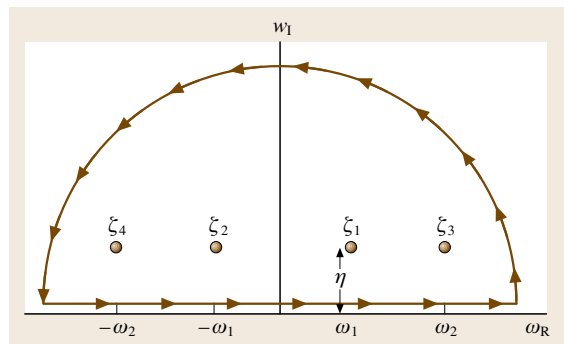
Contour Integral Identity

Given these general properties of the complex wavenumber, one considers the contour integral

$$I_A(\zeta_1, \zeta_2, \zeta_3, \zeta_4)$$
$$= \oint \frac{k/\omega}{(\omega - \zeta_1)(\omega - \zeta_2)(\omega - \zeta_3)(\omega - \zeta_4)}\, \text{d}\omega, \qquad (3.242)$$

where the contour is closed, the integration proceeds in the counterclockwise sense, the contour is entirely in the upper half plane, and where the contour encloses the four poles at ζ_1, ζ_2, etc., all of which are in the upper half-plane.

(The number of poles that one includes is somewhat arbitrary, and four is a judicious compromise for the present chapter. The original [3.57, 58] analysis directed toward acoustical applications included only two, but this led to divergent integrals when the result was applied to certain experimental laws that had been extrapolated to high frequencies. The more poles one includes, the less dependent is the prediction on details of extrapolations to frequencies outside the range of experimental data.)

The integral can be deformed to one which proceeds along the real axis from $-\infty$ to ∞ and which is then completed by a semicircle of infinite radius that encloses the upper half-plane. Because of the supposed behavior of k at ∞ in the upper half-plane, the latter integral is zero and one has


$$I_A(\zeta_1, \zeta_2, \zeta_3, \zeta_4)$$
$$= \int_{-\infty}^\infty \frac{k/\omega}{(\omega - \zeta_1)(\omega - \zeta_2)(\omega - \zeta_3)(\omega - \zeta_4)}\, \text{d}\omega. \qquad (3.243)$$

Fig. 3.13 Contour integral in the complex frequency plane used in the derivation of one version of the Kramers–Krönig relations

Furthermore, the residue theorem yields

$$
\begin{aligned}
&I_A(\zeta_1, \zeta_2, \zeta_3, \zeta_4) \\
&= \frac{2\pi i (k/\omega)_1}{(\zeta_1 - \zeta_2)(\zeta_1 - \zeta_3)(\zeta_1 - \zeta_4)} \\
&\quad + \frac{2\pi i (k/\omega)_2}{(\zeta_2 - \zeta_1)(\zeta_2 - \zeta_3)(\zeta_2 - \zeta_4)} \\
&\quad + \frac{2\pi i (k/\omega)_3}{(\zeta_3 - \zeta_1)(\zeta_3 - \zeta_2)(\zeta_3 - \zeta_4)} \\
&\quad + \frac{2\pi i (k/\omega)_4}{(\zeta_4 - \zeta_1)(\zeta_4 - \zeta_2)(\zeta_4 - \zeta_3)} \,,
\end{aligned}
\tag{3.244}
$$

where $(k/\omega)_1$ is k/ω evaluated at $\omega = \zeta_1$, etc.

To take advantage of the symmetry properties (3.239), one sets

$$
\zeta_1 = \omega_1 + i\eta \,, \qquad \zeta_3 = -\omega_1 + i\eta \,;
$$
$$
\zeta_2 = \omega_2 + i\eta \,; \qquad \zeta_4 = -\omega_2 + i\eta \,,
\tag{3.245}
$$

so that the poles occur in pairs, symmetric about the imaginary axis. One next lets the small positive parameter η go to zero, and recognizes that

$$
\lim_{\epsilon \to 0} \lim_{\eta \to 0} \int_{\omega_1 - \epsilon}^{\omega_1 + \epsilon} \frac{f(\omega)}{\omega - \omega_1 - i\eta} \, d\omega = \pi i f(\omega_1) \,.
\tag{3.246}
$$

Thus in this limit, the integral (3.243) becomes represented as a principal value plus a set of four *narrow gap* terms that that are recognized as one half of the right side of (3.244). The resulting mathematical identity is

$$
\begin{aligned}
&\mathrm{Pr} \int_{-\infty}^{\infty} \frac{k/\omega}{(\omega^2 - \omega_1^2)(\omega^2 - \omega_2^2)} \, d\omega = \frac{i\pi}{\omega_1^2 - \omega_2^2} \\
&\times \left(\frac{k(\omega_1) + k(-\omega_1)}{2\omega_1^2} - \frac{k(\omega_2) + k(-\omega_2)}{2\omega_2^2} \right) \,.
\end{aligned}
\tag{3.247}
$$

Real Part Within the Integrand

When one uses the symmetry properties (3.239), the above reduces to

$$
\begin{aligned}
&2\,\mathrm{Pr} \int_{0}^{\infty} \frac{k_R(\omega)}{\omega(\omega^2 - \omega_1^2)(\omega^2 - \omega_2^2)} \, d\omega \\
&= -\frac{\pi}{\omega_1^2 - \omega_2^2} \left(\frac{k_I(\omega_1)}{\omega_1^2} - \frac{k_I(\omega_2)}{\omega_2^2} \right) \,.
\end{aligned}
\tag{3.248}
$$

The significant thing about this result and the key to its potential usefulness is that the left side involves only the real part of $k(\omega)$ and the right side only the imaginary. Thus if one knew the real part completely and

knew the imaginary part for only one frequency, one could find the imaginary part for any other frequency with the relation

$$
\begin{aligned}
\frac{k_I(\omega)}{\omega^2} &= \frac{k_I(\omega_1)}{\omega_1^2} + \frac{2(\omega_1^2 - \omega^2)}{\pi} \\
&\times \mathrm{Pr} \int_{0}^{\infty} \frac{k_R(\omega')}{\omega'(\omega'^2 - \omega_1^2)(\omega'^2 - \omega^2)} \, d\omega' \,.
\end{aligned}
\tag{3.249}
$$

Here the notation is slightly altered: ω' is the dummy variable of integration, ω_1 is the value of the angular frequency at which one presumably already knows k_I, and ω is that angular frequency for which the value is predicted by the right side. Relations such as this which allow predictions of one part of $k(\omega)$ from another part are known as Kramers–Krönig relations.

Other Kramers–Krönig relations can be obtained from (3.247) with a suitable replacement for k/ω in the integrand and/or taking limits with ω_1 or ω_2 approaching either 0 or ∞. One can also add or subtract simple functions to the integrand where the resulting extra integrals are known. For example, if one sets k/ω to unity in (3.247) one obtains the identity

$$
\mathrm{Pr} \int_{0}^{\infty} \frac{d\omega'}{(\omega'^2 - \omega_1^2)(\omega'^2 - \omega^2)} = 0 \,.
\tag{3.250}
$$

Thus, (3.249) can be equivalently written

$$
\begin{aligned}
\frac{k_I(\omega)}{\omega^2} &= \frac{k_I(\omega_1)}{\omega_1^2} + \frac{2(\omega_1^2 - \omega^2)}{\pi} \\
&\times \mathrm{Pr} \int_{0}^{\infty} \frac{[k_R(\omega')/\omega'] - [k_R(\omega')/\omega']_0}{(\omega'^2 - \omega_1^2)(\omega'^2 - \omega^2)} \, d\omega' \,,
\end{aligned}
\tag{3.251}
$$

where the subscript 0 indicates that the quantity is evaluated in the limit of zero frequency. A further step is to take the limit as $\omega_1 \to 0$, so that one obtains

$$
\begin{aligned}
\frac{k_I(\omega)}{\omega^2} &= \left[\frac{k_I(\omega)}{\omega^2} \right]_0 - \frac{2\omega^2}{\pi} \\
&\times \mathrm{Pr} \int_{0}^{\infty} \frac{[k_R(\omega')/\omega'] - [k_R(\omega')/\omega']_0}{\omega'^2(\omega'^2 - \omega^2)} \, d\omega' \,.
\end{aligned}
\tag{3.252}
$$

The numerator in the integrand is recognized as the difference in the reciprocals of the phase velocities, at

$\omega = \omega'$ and at $\omega = 0$. The validity of the equality requires the integrand to be sufficiently well behaved near $\omega' = 0$, and this is consistent with k_R being odd in ω and representable locally as a power series. Validity also requires that k_I/ω^2 be finite at $\omega = 0$, which is consistent with the relaxation models mentioned in the section below. The existence of the integral also places a restriction on the asymptotic dependence of k_R as $\omega \to \infty$.

A possible consequence of the last relation is that

$$\lim_{\omega \to \infty} \left(\frac{k_I(\omega)}{\omega^2} \right)$$
$$= \left(\frac{k_I(\omega)}{\omega^2} \right)_0$$
$$+ \frac{2}{\pi} \int_0^\infty \frac{[k_R(\omega')/\omega'] - [k_R(\omega')/\omega']_0}{\omega'^2} \, d\omega' . \quad (3.253)$$

The validity of this requires that the integral exists, which is so if the phase velocity approaches a constant at high frequency. An implication is that the attenuation must approach a constant multiplied by ω^2 at high frequency, where the constant is smaller than that at low frequency if the phase velocity at high frequency is higher than that at low frequency.

Imaginary Part Within the Integrand

Analogous results, only with the integration over the imaginary part of k, result when k/ω is replaced by k in (3.247). Doing so yields

$$2 \Pr \int_0^\infty \frac{k_I(\omega)}{(\omega^2 - \omega_1^2)(\omega^2 - \omega_2^2)} \, d\omega$$
$$= \frac{\pi}{\omega_1^2 - \omega_2^2} \left(\frac{k_R(\omega_1)}{\omega_1} - \frac{k_R(\omega_2)}{\omega_2} \right) , \quad (3.254)$$

which in turn yields

$$\frac{k_R(\omega)}{\omega} = \frac{k_R(\omega_1)}{\omega_1} - \frac{2(\omega_1^2 - \omega^2)}{\pi}$$
$$\times \Pr \int_0^\infty \frac{k_I(\omega')}{(\omega'^2 - \omega_1^2)(\omega'^2 - \omega^2)} \, d\omega' . \quad (3.255)$$

Then, taking of the limit $\omega_1 \to 0$, one obtains

$$\frac{k_R(\omega)}{\omega}$$
$$= \left(\frac{k_R(\omega)}{\omega} \right)_0 + \frac{2\omega^2}{\pi} \Pr \int_0^\infty \frac{k_I(\omega')}{\omega'^2(\omega'^2 - \omega^2)} \, d\omega' .$$
$$\quad (3.256)$$

This latter expression requires that k_I/ω^2 be integrable near $\omega = 0$.

Attenuation Proportional to Frequency

Some experimental data for various materials suggest that, for those materials, k_I is directly proportional to ω over a wide range of frequencies. The relation (3.256) is inapplicable if one seeks the corresponding expression for phase velocity. Instead, one uses (3.255), treating ω_1 as a parameter. If one inserts

$$k_I(\omega) = K\omega \quad (3.257)$$

into (3.255), the resulting integral can be performed analytically, with the result

$$\frac{k_R(\omega)}{\omega} = \frac{k_R(\omega_1)}{\omega_1} - \frac{2}{\pi} K \ln \left(\frac{\omega}{\omega_1} \right) . \quad (3.258)$$

(The simplest procedure for deriving this is to replace the infinite upper limit by a large finite number and then separate the integrand using the method of partial fractions. After evaluation of the individual terms, one takes the limit as the upper limit goes to infinity, and discovers appropriate cancelations.) The properties of the logarithm are such that the above indicates that the quantity

$$\frac{k_R(\omega)}{\omega} + \frac{2}{\pi} K \ln(\omega) = \text{constant} \quad (3.259)$$

is independent of ω. This deduction is independent of the choice of ω_1, but the analysis does not tell one what the constant should be. A concise restating of the result is that there is some positive number ω_0, such that

$$\frac{k_R(\omega)}{\omega} = \frac{2}{\pi} K \ln \left(\frac{\omega_0}{\omega} \right) . \quad (3.260)$$

The result is presumably valid at best only over the range of frequencies for which (3.257) is valid. Since negative phase velocities are unlikely, it must also be such that the parameter ω_0 is above this range. This approximate result also predicts a zero phase velocity in the limit of zero frequency, and this is also likely to be unrealistic. But there may nevertheless be some range of frequencies for which both (3.257) and (3.260) would give a good fit to experimental data.

3.7.5 Attenuation of Sound in Air

In air, the relaxation processes that affect sound attenuation are those associated with the (quantized) internal vibrations of the diatomic molecules O_2 and N_2. The ratio of the numbers of molecules in the ground and

first excited vibrational states is a function of temperature when the gas is in thermodynamic equilibrium, but during an acoustic disturbance the redistribution of molecules to what is appropriate to the concurrent gas temperature is not instantaneous. The knowledge that the relaxation processes are vibrational relaxation processes and that only the ground and first excited states are appreciably involved allows the sound speed increments to be determined from first principles. One need only determine the difference in sound speeds resulting from the two assumptions: (i) that the distribution of vibrational energy is frozen, and (ii) that the vibrational energy is always distributed as for a gas in total thermodynamic equilibrium. The resulting sound speed increments [3.14] are

$$\frac{(\Delta c)_v}{c} = \frac{(\gamma - 1)^2}{2\gamma} \frac{n_v}{n} \left(\frac{T_v^*}{T}\right)^2 e^{-T_v^*/T} , \qquad (3.261)$$

where n is the total number of molecules per unit volume and n_v is the number of molecules of the type corresponding to the designation parameter v. The quantity T is the absolute temperature, and T_v^* is a characteristic temperature, equal to the energy jump ΔE between the two vibrational states divided by Boltzmann's constant. The value of T_1^* (corresponding to O_2 relaxation) is 2239 K, and the value of T_2^* (corresponding to N_2 relaxation) is 3352 K. For air the fraction n_1/n of molecules that are O_2 is 0.21, while the fraction n_2/n of molecules that are N_2 is 0.78. At a representative temperature of 20 °C, the calculated value of $(\Delta c)_1$ is 0.11 m/s, while that for $(\Delta c)_2$ is 0.023 m/s.

Because relaxation in a gas is caused by two-body collisions, the relaxation times at a given absolute temperature must vary inversely with the absolute pressure. The relatively small (and highly variable) number of water-vapor molecules in the air has a significant effect on the relaxation times because collisions of diatomic molecules with H_2O molecules are much more likely to cause a transition between one internal vibrational quantum state and another. Semi-empirical expressions for the two relaxation times for air are given [3.59, 60] by

$$\frac{p_{\text{ref}}}{p} \frac{1}{2\pi\tau_1} = 24 + 4.04 \times 10^6 h \left(\frac{0.02 + 100h}{0.391 + 100h}\right) , \qquad (3.262)$$

$$\frac{p_{\text{ref}}}{p} \frac{1}{2\pi\tau_2} = \left(\frac{T_{\text{ref}}}{T}\right)^{1/2} (9 + 2.8 \times 10^4 h \, e^{-F}) \qquad (3.263)$$

$$F = 4.17 \left[\left(\frac{T_{\text{ref}}}{T}\right)^{1/3} - 1\right] . \qquad (3.264)$$

The subscript 1 corresponds to O_2 relaxation, and the subscript 2 corresponds to N_2 relaxation. The quantity h here is the fraction of the air molecules that are H_2O molecules; the reference temperature is 293.16 K; and the reference pressure is 10^5 Pa. The value of h can be determined from the commonly reported relative humidity (RH, expressed as a percentage) and the vapor pressure of water at the local temperature according to the defining relation

$$h = 10^{-2}(\text{RH})\frac{p_{\text{vp}}(T)}{p} . \qquad (3.265)$$

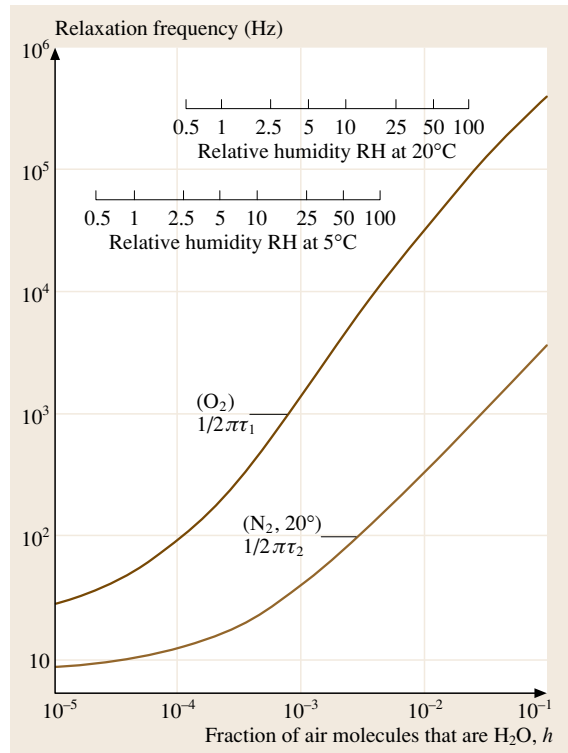
However, as indicated in (3.262) and (3.263), the physics of the relaxation process depends on the absolute humidity and has no direct involvement with the value of the vapor pressure of water. A table of the vapor pressure of water may be found in various references; some representative values in pascals are 872,


Fig. 3.14 Relaxation frequencies of air as a function of absolute humidity. The pressure is 1.0 atmosphere
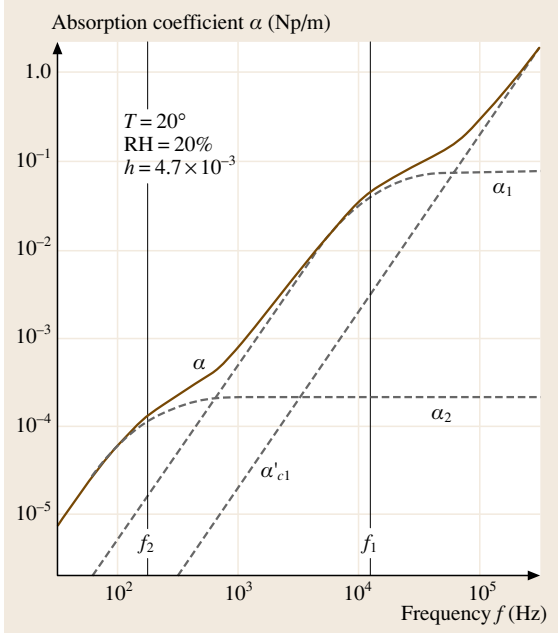

Fig. 3.15 Attenuation of sound in air as a function of frequency (log–log plot). The slopes of the initial portions of the dashed lines correspond to a quadratic dependence on frequency

1228, 1705, 2338, 4243, and 7376 Pa at temperatures of 5, 10, 15, 20, 30, and 40 °C, respectively.

Because of the two relaxation frequencies, the frequency dependence of the attenuation coefficient for sound in air has three distinct regions. At very low frequencies, where the frequency is much lower than that associated with molecular nitrogen, the attenuation associated with vibrational relaxation of nitrogen molecules dominates. The dependence is nearly quadratic in frequency, with an apparent bulk viscosity that is associated with the nitrogen relaxation. In an intermediate region, where the frequency is substantially larger than that associated with nitrogen relaxation, but still substantially less than that associated with oxygen relaxation, the dependence is again quadratic in frequency, but the coefficient is smaller, and the apparent bulk viscosity is that associated with oxygen relaxation. Then in the higher-frequency range, substantially above both relaxation frequencies, the quadratic frequency dependence is again evident, but with an even smaller

coefficient, the attenuation being the same as that corresponding to classical processes, and with the intrinsic bulk viscosity associated with molecular rotation. Nevertheless, even through the coefficient of the square of the frequency drops over two intervals, the overall trend is that the attenuation constant always increases with increasing frequency.

3.7.6 Attenuation of Sound in Sea Water

The relaxation processes contributing to the attenuation of sound are associated with dissolved boric acid $B(OH)_3$ (subscript 1) and magnesium sulfate $MgSO_4$ (subscript 2). From approximate formulas derived by *Fisher* and *Simmons* [3.61] from a combination of experiment and theory one extracts the identifications

$$\frac{\delta_{cl}}{c^3} = 1.42 \times 10^{-15} F(T_C) G(P_{atm}) , \qquad (3.266)$$

with

$$F(T_C) = 1 - 4.24 \times 10^{-2} T_C + 8.53 \times 10^{-4} T_C^2 \\ - 6.23 \times 10^{-6} T_C^3 , \qquad (3.267)$$

$$G(P_{atm}) = 1 - 3.84 \times 10^{-4} P_{atm} + 7.57 \times 10^{-8} P_{atm}^2 , \qquad (3.268)$$

$$\frac{(\Delta c)_1}{c^2} = 1.64 \times 10^{-9} \left(1 + 2.29 \times 10^{-2} T_C \\ - 5.07 \times 10^{-4} T_C^2\right) \frac{S}{35} , \qquad (3.269)$$

$$\frac{(\Delta c)_2}{c^2} = 8.94 \times 10^{-9} \left(1 + 0.0134 T_C\right) \\ \times \left(1 - 10.3 \times 10^{-4} P_{atm} \\ + 3.7 \times 10^{-7} P_{atm}^2\right) \frac{S}{35} , \qquad (3.270)$$

$$\frac{1}{2\pi\tau_1} = 1320\, T\, e^{-1700/T} , \qquad (3.271)$$

$$\frac{1}{2\pi\tau_2} = 15.5 \times 10^6\, T\, e^{-3052/T} . \qquad (3.272)$$

Here T_C is temperature in °C, T is absolute temperature, while P_{atm} is the absolute pressure in atmospheres; S is the salinity in parts per thousand (which is typically of the order of 35 for sea water). All of the quantities on the left sides of these equations are in MKS units.

3.8 Acoustic Intensity and Power

A complete set of linear acoustic equations, regardless of the idealization incorporated into its formulation, usually yields a corollary [3.30, 62]

$$\frac{\partial w}{\partial t} + \nabla \cdot \boldsymbol{I} = -\mathfrak{D} \, , \tag{3.273}$$

where the terms are quadratic in the acoustic field amplitudes, the quantity w contains one term that is identifiable as a kinetic energy of fluid motion per unit volume, and the quantity $\mathfrak{D}$ is either zero or positive.

3.8.1 Energy Conservation Interpretation

The relation (3.273) is interpreted as a statement of energy conservation. The quantity w is the energy density, or energy per unit volume associated with the wave disturbance, while the vector quantity $\boldsymbol{I}$ is an intensity vector or energy flux vector. Its interpretation is such that its dot product with any unit vector represents the energy flowing per unit area and time across a surface whose normal is in that designated direction. The quantity $\mathfrak{D}$ is interpreted as the energy that is dissipated per unit time and volume.

This interpretation of an equation such as (3.273) as a conservation law follows when one integrates both sides over an arbitrary fixed volume V within the fluid and reexpresses the volume integral of the divergence of $\boldsymbol{I}$ by a surface integral by means of the divergence theorem (alternately referred to as Gauss's theorem). Doing this yields

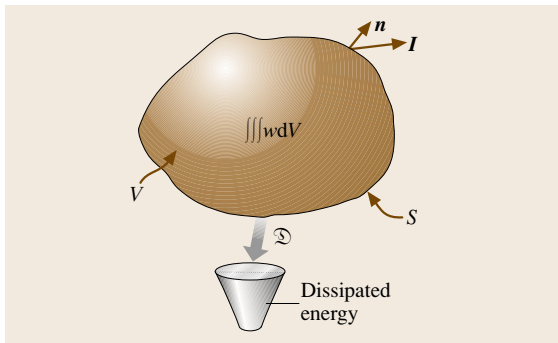
$$\frac{\partial}{\partial t} \iiint\limits_{V} w \, dV + \iint\limits_{S} \boldsymbol{I} \cdot \boldsymbol{n} \, dS = - \iiint\limits_{V} \mathfrak{D} \, dV \, , \tag{3.274}$$


Fig. 3.16 Hypothetical volume inside a fluid, within which the acoustic energy is being dissipated and out of which acoustic energy is flowing

where $\boldsymbol{n}$ is the unit normal vector pointing out of the surface S enclosing V. This relation states that the net rate of increase of *acoustical energy* within the volume must equal the *acoustic power* flowing into the volume across its confining surface minus the energy that is being dissipated per unit time within the volume.

3.8.2 Acoustic Energy Density and Intensity

For the ideal case, when there is no ambient velocity and when viscosity and thermal conduction are neglected, the energy corollary results from (3.71) and (3.72). The derivation begins with one's taking the dot product of the fluid velocity $\boldsymbol{v}$ with (3.72), and then using vector identities and (3.71) to reexpress the right side as the sum of a divergence and a time derivative. The result yields the identification of the energy density as

$$w = \frac{1}{2}\rho v^2 + \frac{1}{2}\frac{1}{\rho c^2}p^2 \, , \tag{3.275}$$

and yields the identification of the acoustic intensity as

$$\boldsymbol{I} = p\boldsymbol{v} \, . \tag{3.276}$$

For this ideal case, there is no dissipative term on the right side. The corollary of (3.273) remains valid even if the ambient density and sound speed vary from point to point.

The first term in the expression for w is recognized as the acoustic kinetic energy per unit volume, and the second term is identified as the potential energy per unit volume due to compression of the fluid.

Intensity Carried by Plane Waves
For a plane wave, it follows from (3.186) and (3.187) that the kinetic and potential energies are the same [3.63], and that the energy density is given by

$$w = \frac{1}{\rho c^2}p^2 \, . \tag{3.277}$$

The intensity becomes

$$\boldsymbol{I} = \boldsymbol{n}\frac{p^2}{\rho c} \, . \tag{3.278}$$

For such a case, the intensity and the energy density are related by

$$\boldsymbol{I} = c\boldsymbol{n}w \, . \tag{3.279}$$

This yields the interpretation that the energy in a sound wave is moving in the direction of propagation with the

sound speed. Consequently, the sound speed can be regarded as an energy propagation velocity. (This is in accord with the fact that sound waves in this idealization are nondispersive, so the group and phase velocities are the same.)

3.8.3 Acoustic Power

Many sound fields can be idealized as being steady, such that long-time averages are insensitive to the duration and the center time of the averaging interval. Constant-frequency sounds and continuous noises fall into this category.

In the special case of constant-frequency sounds, when complex amplitudes are used to described the acoustic field, the general theorem (3.182) for averaging over products of quantities oscillating with the same frequency applies, and one finds

$$w_{\mathrm{av}} = \frac{1}{4}\rho\hat{\boldsymbol{v}}\cdot\hat{\boldsymbol{v}}^* + \frac{1}{4}\frac{1}{\rho c^2}\left|\hat{p}\right|^2 , \tag{3.280}$$

$$\boldsymbol{I}_{\mathrm{av}} = \frac{1}{2}\mathrm{Re}\left\{\hat{p}^*\hat{\boldsymbol{v}}\right\} . \tag{3.281}$$

For steady sounds, the time derivative of the acoustic energy density will average to zero over a sufficiently long time period, so the acoustic energy corollary of (3.273), in the absence of dissipation, yields the time-averaged relation

$$\nabla\cdot\boldsymbol{I}_{\mathrm{av}} = 0 . \tag{3.282}$$

This implies that the time-averaged vector intensity field is solenoidal (zero divergence) in regions that do not contain acoustic sources. This same relation holds for any frequency component of the acoustic field or for the net contribution to the field from any given frequency band. In the following discussion, the intensity $\boldsymbol{I}_{\mathrm{av}}$ is understood to refer to such a time average for some specified frequency band.

The relation (3.282) yields the integral relation

$$\int_S \boldsymbol{I}_{\mathrm{av}}\cdot\boldsymbol{n}\,\mathrm{d}S = 0 , \tag{3.283}$$

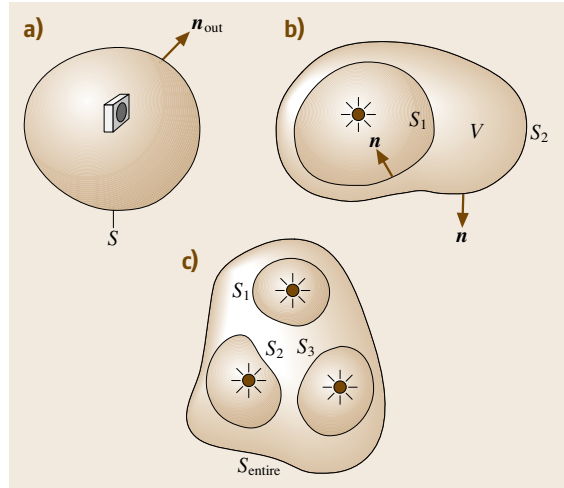
which is interpreted as a statement that the net acoustic power flowing out of any region not containing sources must be zero when averaged over time and for any given frequency band.


Fig. 3.17 Surfaces enclosing one or more sources. The integration of the time-averaged acoustic intensity component in the direction of the unit outward normal over any such surface yields the time average of the total power generated with the volume enclosed by the surface

For a closed surface that encloses one or more sources, such that the governing linear acoustic equations do not apply at every point within the volume, the reasoning above allows one to define the time-averaged net acoustic power of these sources as

$$\mathfrak{P}_{\mathrm{av}} = \int_S \boldsymbol{I}_{\mathrm{av}}\cdot\boldsymbol{n}\,\mathrm{d}S , \tag{3.284}$$

where the surface S encloses the sources. It follows from (3.283) that the acoustic power of a source computed in such a manner will be the same for any two choices of the surface S, provided that both surfaces enclose the same source and no other sources. The value of the integral is independent of the size and of the shape of S. This result is of fundamental importance for the measurement of source power. Instrumentation to measure the time-averaged intensity directly has become widely available in recent years and is often used in determining the principal noise sources in complicated environments.

3.8.4 Rate of Energy Dissipation

Under circumstances in which viscosity, thermal conduction, and internal relaxation are to be taken into account, the linear acoustic equations for the acoustic mode, which yield the dissipative wave equation of (3.218) and the relaxation equations described by

(3.219), yield [3.14] an energy corollary of the form of (3.273). To a satisfactory approximation the energy density and intensity remain as given by (3.275) and (3.276). The energy dissipation per unit volume is no longer zero, but is instead

$$\mathfrak{D}_{av} = 2\frac{\delta_{cl}}{\rho c^4}\left(\frac{\partial p}{\partial t}\right)^2 + 2\sum_{\nu}\frac{(\Delta c)_{\nu}}{\rho c^3}\tau_{\nu}\left(\frac{\partial p_{\nu}}{\partial t}\right)^2 .$$

(3.285)

For constant-frequency plane waves propagating in the x-direction, the time average of the time derivative of the energy density is zero, and the time averages of I and $\mathfrak{D}$ will both be quadratic in the wave amplitude $|\hat{p}|$. The identification of the attenuation coefficient α must then be such that

$$\mathfrak{D}_{av} = 2\alpha I_{av} .$$

(3.286)

3.9 Impedance

Complex ratios of acoustic variables are often intrinsic quantities independent of the detailed nature of the acoustic disturbance.

3.9.1 Mechanical Impedance

The ratio of the complex amplitude of a sinusoidally varying force to the complex amplitude of the resulting velocity at a point on a vibrating object is called the mechanical impedance at that point. It is a complex number and usually a function of frequency. Other definitions [3.64] of impedance are also in widespread use in acoustics.

3.9.2 Specific Acoustic Impedance

The specific acoustic impedance or unit-area acoustic impedance $Z_S(\omega)$ for a surface is defined as

$$Z_S(\omega) = \frac{\hat{p}}{\hat{v}_{in}} ,$$

(3.290)

where $\hat{v}_{in}$ is the component of the fluid velocity directed into the surface under consideration. Typically, the specific acoustic impedance, often referred to briefly as the impedance without any adjective, is used to describe the acoustic properties of materials. In many cases, surfaces of materials abutting fluids can be characterized as locally reacting, so that Z_S is independent of the detailed nature of the acoustic pressure field. In particular, the

The magnitude of the acoustic intensity decreases with propagation distance x as

$$I_{av}(x) = I_{av}(0)e^{-2\alpha x} .$$

(3.287)

This identification of the attenuation coefficient is consistent with that given in (3.225).

3.8.5 Energy Corollary for Elastic Waves

An energy conservation corollary of the form of (3.273) also holds for sound in solids. The appropriate identifications for the energy density w and the components I_i of the intensity are

$$w = \frac{1}{2}\rho\sum_i\left(\frac{\partial\xi_i}{\partial t}\right)^2 + \frac{1}{2}\sum_{i,j}\epsilon_{ij}\sigma_{ij}$$

(3.288)

$$I_i = -\sum_j\sigma_{ij}\frac{\partial\xi_j}{\partial t} .$$

(3.289)

locally reacting hypothesis implies that the velocity of the material at the surface is unaffected by pressures other than in the immediate vicinity of the point of interest. At a nominally motionless and passively responding surface, and when the hypothesis is valid, the appropriate boundary condition on the complex amplitude $\hat{p}$ that satisfies the Helmholtz equation is given by

$$i\omega\rho\hat{p} = -Z_S\nabla\hat{p}\cdot\boldsymbol{n} ,$$

(3.291)

where $\boldsymbol{n}$ is the unit normal vector pointing out of the material into the fluid. A surface that is perfectly rigid has $|Z_S| = \infty$. The other extreme, where $Z_S = 0$, corresponds to the ideal case of a pressure release surface. This is, for example, what is normally assumed for the upper surface of the ocean in underwater sound. Since a passive surface absorbs energy from the sound field, the time-averaged intensity component into the surface should be positive or zero. This observation leads to the requirement that the real part (specific acoustic resistance) of the impedance should always be nonnegative. The imaginary part (specific acoustic reactance) may be either positive or negative.

3.9.3 Characteristic Impedance

For extended substances, a related definition is that of characteristic impedance Z_{char}, defined as the ratio of $\hat{p}$ to the complex amplitude $\hat{v}$ of the fluid velocity in the direction of propagation when a plane wave is propagat-

ing through the substance. As indicated by (3.187), this characteristic impedance, when the fluid is lossless, is ρc, regardless of frequency and position in the field. In the general case when the propagation is dispersive and there is a plane wave attenuation, one has

$$Z_{\text{char}} = \frac{\rho \omega}{k} , \tag{3.292}$$

where $k(\omega)$ is the complex wavenumber.

The MKS units $[(\text{kg/m}^{-3})(\text{m/s})]$ of specific acoustic impedance are referred to as MKS rayl (after Rayleigh). The characteristic impedance of air under standard conditions is approximately $400\,\text{MKS rayls}$, and that of water is approximately $1.5 \times 10^6\,\text{MKS rayl}$.

3.9.4 Radiation Impedance

The radiation impedance Z_{rad} is defined as $\hat{p}/\hat{v}_{\text{n}}$, where $\hat{v}_{\text{n}}$ corresponds to the outward normal component of velocity at a vibrating surface. (Specific examples involving spherical waves are given in a subsequent section of this chapter.)

Given the definition of the radiation impedance, the time-averaged power flow per unit area of surface out of the surface is

$$\begin{aligned} I_{\text{rad}} &= \frac{1}{2}\text{Re}\big(\hat{p}\hat{v}_{\text{n}}^*\big) = \frac{1}{2}|\hat{v}_{\text{n}}|^2 \text{Re}\big(Z_{\text{rad}}\big) \\ &= \frac{1}{2}|\hat{p}|^2 \text{Re}\left(\frac{1}{Z_{\text{rad}}}\right) . \end{aligned} \tag{3.293}$$

The total power radiated is the integral of this over the surface of the body.

3.9.5 Acoustic Impedance

The term acoustic impedance Z_{A} is reserved [3.64] for the ratio of $\hat{p}$ to the volume velocity complex amplitude. Here volume velocity is the net volume of fluid flowing past a specified surface element per unit time in a specified directional sense. One may speak, for example, of the acoustic impedance of an orifice in a wall, of the acoustic impedance at the mouth of a Helmholtz resonator, and of the acoustic impedance at the end of a pipe.

3.10 Reflection and Transmission

When sound impinges on a surface, some sound is reflected and some is transmitted and possibly absorbed within or on the the other side of the surface. To understand the processes that occur, it is often an appropriate idealization to take the incident wave as a plane wave and to consider the surface as flat.

3.10.1 Reflection at a Plane Surface

When a plane wave reflects at a surface with finite specific acoustic impedance Z_{S}, a reflected wave is formed such that the angle of incidence θ_{I} equals the angle of reflection (law of mirrors). Here both angles are reckoned from the line normal to the surface and correspond to the directions of the two waves. If one takes the y-axis as pointing out of the surface and the surface as coinciding with the $y = 0$ plane, then an incident plane wave propagating obliquely in the $+x$-direction will have a complex pressure amplitude

$$\hat{p}_{\text{in}} = \hat{f}\,e^{ik_x x}\,e^{-ik_y y} , \tag{3.294}$$

where $\hat{f}$ is a constant. (For transient reflection, the quantity $\hat{f}$ can be taken as the Fourier transform of the incident pressure pulse at the origin.) The two in-

dicated wavenumber components are $k_x = k \sin \theta_{\text{I}}$ and $k_y = k \cos \theta_{\text{I}}$.

The reflected wave has a complex pressure amplitude given by

$$\hat{p}_{\text{re}\Lambda} = \Re(\theta_{\text{I}}, \omega)\hat{f}\,e^{ik_x x}\,e^{ik_y y} , \tag{3.295}$$

where the quantity $\Re(\theta_{\text{I}}, \omega)$ is the pressure amplitude reflection coefficient.

Fig. 3.18 Reflection of a plane wave at a planar surface

Analysis that makes use of the boundary condition (3.291) leads to the identification

$$\mathfrak{R}(\theta_{\mathrm{I}}, \omega) = \frac{\xi(\omega)\cos\theta_{\mathrm{I}} - 1}{\xi(\omega)\cos\theta_{\mathrm{I}} + 1} \tag{3.296}$$

for the reflection coefficient, with the abbreviation

$$\xi(\omega) = \frac{Z_{\mathrm{S}}}{\rho c} , \tag{3.297}$$

which represents the ratio of the specific acoustic impedance of the surface to the characteristic impedance of the medium.

3.10.2 Reflection at an Interface

The above relations also apply, with an appropriate identification of the quantity Z_{S}, to sound reflection [3.65] at an interface between two fluids with different sound speeds and densities. Translational symmetry requires that the disturbance in the second fluid have the same apparent phase velocity (ω/k_x) (trace velocity) along the x-axis as does the disturbance in the first fluid. This requirement is known as the trace velocity matching principle [3.4, 30] and leads to the observation that k_x is the same in both fluids. One distinguishes two possibilities: the trace velocity is higher than the sound speed c_2 or lower than c_2.

For the first possibility, one has the inequality

$$c_2 < \frac{c_1}{\sin\theta_{\mathrm{I}}} , \tag{3.298}$$

and a propagating plane wave (transmitted wave) is excited in the second fluid, with complex pressure am-

Fig. 3.19 Reflection of a plane wave at an interface between two fluids

plitude

$$\hat{p}_{\mathrm{trans}} = \mathfrak{T}(\omega, \theta_{\mathrm{I}}) \hat{f} \, \mathrm{e}^{\mathrm{i}k_x x} \, \mathrm{e}^{\mathrm{i}k_2 y \cos\theta_{\mathrm{II}}} , \tag{3.299}$$

where $k_2 = \omega/c_2$ is the wavenumber in the second fluid and θ_{II} (angle of refraction) is the angle at which the transmitted wave is propagating. The trace velocity matching principle leads to Snell's law,

$$\frac{\sin\theta_{\mathrm{I}}}{c_1} = \frac{\sin\theta_{\mathrm{II}}}{c_2} . \tag{3.300}$$

The change in propagation direction from θ_{I} to θ_{II} is the phenomenon of refraction.

The requirement that the pressure be continuous across the interface yields the relation

$$1 + \mathfrak{R} = \mathfrak{T} , \tag{3.301}$$

while the continuity of the normal component of the fluid velocity yields

$$\frac{\cos\theta_{\mathrm{I}}}{\rho_1 c_1} (1 - \mathfrak{R}) = \frac{\cos\theta_{\mathrm{II}}}{\rho_2 c_2} \mathfrak{T} . \tag{3.302}$$

From these one derives the reflection coefficient

$$\mathfrak{R} = \frac{Z_{\mathrm{II}} - Z_{\mathrm{I}}}{Z_{\mathrm{II}} + Z_{\mathrm{I}}} , \tag{3.303}$$

which involves the two impedances defined by

$$Z_{\mathrm{I}} = \frac{\rho_1 c_1}{\cos\theta_{\mathrm{I}}} , \tag{3.304}$$

$$Z_{\mathrm{II}} = \frac{\rho_2 c_2}{\cos\theta_{\mathrm{II}}} . \tag{3.305}$$

The other possibility, which is the opposite of that in (3.298), can only occur when $c_2 > c_1$ and, moreover, only if θ_{I} is greater than the critical angle

$$\theta_{\mathrm{cr}} = \arcsin(c_1/c_2) . \tag{3.306}$$

In this circumstance, an inhomogeneous plane wave, propagating in the x-direction, but dying out exponentially in the $+y$-direction, is excited in the second medium. Instead of (3.299), one has the transmitted pressure given by

$$\hat{p}_{\mathrm{trans}} = \mathfrak{T}(\omega, \theta_{\mathrm{I}}) \hat{f} \, \mathrm{e}^{\mathrm{i}k_x x} \, \mathrm{e}^{-\beta k_2 y} , \tag{3.307}$$

with

$$\beta = [(c_2/c_1)^2 \sin^2\theta_{\mathrm{I}} - 1]^{1/2} . \tag{3.308}$$

The previously stated equations governing the reflection and transmission coefficients are still applicable, provided one replaces $\cos\theta_{\mathrm{II}}$ by $\mathrm{i}\beta$. This causes the magnitude of the reflection coefficient $\mathfrak{R}$ to become

unity, so the time-averaged incident energy is totally reflected. Acoustic energy is present in the second fluid, but its time average over a wave period stays constant once the steady state is reached.

3.10.3 Theory of the Impedance Tube

Impedance tubes are commonly used in the measurement of specific acoustic impedances; the underlying theory [3.66, 67] is based for the most part on (3.295), (3.296), and (3.297) above. The incident and the reflected waves propagate along the axis of a cylindrical tube with the sample surface at one end. A loudspeaker at the other end creates a sinusoidal pressure disturbance that propagates down the tube. Reflections from the end covered with the test material create an incomplete standing-wave pattern inside the tube.

The wavelength of the sound emitted by the source can be adjusted, but it should be kept substantially larger than the pipe diameter, so that the plane wave assumption holds. With k_x identified as being 0, the complex amplitude that corresponds to the sum of the incident and reflected waves has an absolute magnitude given by

$$|\hat{p}| = |\hat{f}||1 + \Re e^{2iky}|, \qquad (3.309)$$

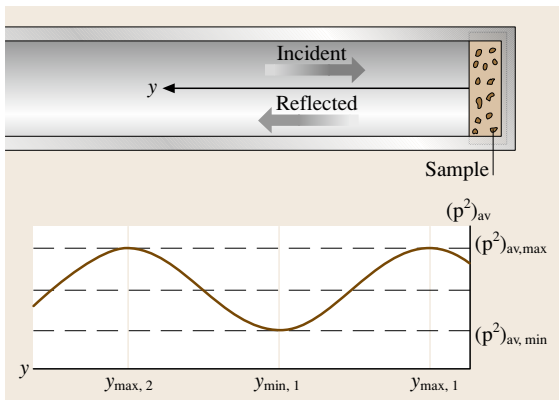
where y is now the distance in front of the sample. The second factor varies with y and repeats at intervals of a half-wavelength, and varies from a minimum value of $1 - |\Re|$ to a maximum value of $1 + |\Re|$. Consequently,


Fig. 3.20 Incident and reflected waves inside an impedance tube. The time-averaged pressure within the tube has minimum and maximum values whose ratio depends on the impedance of the sample at the end. Another measured parameter is the distance back from the sample at which the first maximum occurs

the ratio of the peak acoustic pressure amplitude $|\hat{p}|_{\max}$ (which occurs at one y-position) to the minimum acoustic pressure amplitude $|\hat{p}|_{\min}$ (which occurs at a position a quarter-wavelength away) determines the magnitude of the reflection coefficient via the relation

$$\frac{|\hat{p}|_{\min}}{|\hat{p}|_{\max}} = \frac{1 - |\Re|}{1 + |\Re|} . \qquad (3.310)$$

The phase δ of the reflection coefficient can be determined with use of the observation that the peak amplitudes occur at y-values where $\delta + 2ky$ is an integer multiple of 2π, while the minimum amplitudes occur where it is π plus an integer multiple of 2π. Once the magnitude and phase of the reflection coefficient are determined, the specific acoustic impedance can be found from (3.296) and (3.297).

3.10.4 Transmission Through Walls and Slabs

The analysis of transmission of sound through a wall or a partition [3.68] is often based on the idealization that the wall is of unlimited extent.

If the incoming plane wave has an angle of incidence θ_I and if the fluid on the opposite side of the wall has the same sound speed, then the trace velocity matching principle requires that the transmitted wave be propagating in the same direction.

A common assumption when the fluid is air is that the compression in the wall is negligible, so the wall is treated as a slab that has a uniform velocity v_{sl} throughout its thickness. The slab moves under the influence of the incident, reflected, and transmitted sound fields according to the relation (corresponding to Newton's
Fig. 3.21 Transmission of an incident plane wave through a thin flexible slab

second law) given by

$$m_{sl}\frac{\partial v_{sl}}{\partial t} = p_{front} - p_{back} + \text{bending term} , \quad (3.311)$$

where m_{sl} is the mass per unit surface area of the slab.

The front side is here taken as the side facing the incident wave; the transmitted wave propagates away from the back side. The bending term (discussed further below) accounts for any tendency of the slab to resist bending. If the slab is regarded as nonporous then the normal component of the fluid velocity both at the front and the back is regarded the same as the slab velocity itself. If it is taken as porous [3.69, 70] then these continuity equations are replaced by the relations

$$v_{front} - v_{sl} = v_{back} - v_{sl} = \frac{1}{R_f}(p_{front} - p_{back}) ,$$
$$(3.312)$$

where R_f is the specific flow resistance. The latter can be measured in steady flow for specific materials. For a homogeneous material, it is given by the product of the slab thickness h and the flow resistivity, the latter being a commonly tabulated property of porous materials. (The law represented by (3.312) is the thin slab, or blanket, counterpart of the Darcy's law mentioned in a preceding section, where Biot's model of porous media is discussed.)

In general, when one considers the reflection at and transmission through a slab, one can define a slab specific impedance Z_{sl} such that, with regard to complex amplitudes,

$$\hat{p}_{front} - \hat{p}_{back} = Z_{sl}\hat{v}_{front} = Z_{sl}\hat{v}_{back} , \quad (3.313)$$

where Z_{sl} depends on the angular frequency ω and the trace velocity $v_{tr} = c/\sin\theta_I$ of the incident wave over the surface of the slab. The value of the slab specific impedance can be derived using considerations such as those that correspond to (3.312) and (3.313). In terms of the slab specific impedance, the transmission coefficient $\mathfrak{T}$ is

$$\mathfrak{T} = \left(1 + \frac{1}{2}\frac{Z_{sl}}{\rho c}\cos\theta_I\right)^{-1} . \quad (3.314)$$

The fraction τ of incident power that is transmitted is $|\mathfrak{T}|^2$.

3.10.5 Transmission Through Limp Plates

If the slab can be idealized as a limp plate (no resistance to bending) and not porous, the slab specific impedance

Z_{sl} is $-i\omega m_{sl}$ and one obtains

$$\tau = \left[1 + \left(\frac{\omega m_{sl}}{2\rho c}\right)^2 \cos^2\theta_I\right]^{-1} \approx \left(\frac{2\rho c}{\omega m_{sl}\cos\theta_I}\right)^2$$
$$(3.315)$$

for the fraction of incident power that is transmitted. The latter version, which typically holds at moderate to high audible frequencies, predicts that τ decreases by a factor of 4 when the slab mass m_{sl} per unit area is increased by a factor of 2. In the noise control literature, this behavior is sometimes referred to as the mass law.

3.10.6 Transmission Through Porous Blankets

For a porous blanket that has a specific flow resistance R_f the specific slab impedance becomes

$$Z_{sl} = \left(\frac{1}{R_f} - \frac{1}{i\omega m_{sl}}\right)^{-1} , \quad (3.316)$$

and the resulting fraction of incident power that is transmitted can be found with a substitution into (3.314), with τ equated to $|\mathfrak{T}|^2$.

3.10.7 Transmission Through Elastic Plates

If the slab is idealized as a Bernoulli–Euler plate with elastic modulus E, Poisson's ratio ν, and thickness h, the bending term in (3.311) has a complex amplitude given by

$$\text{bending term} = -\frac{B_{pl}k_x^4\hat{v}_{sl}}{(-i\omega)} , \quad (3.317)$$

where

$$B_{pl} = \frac{1}{12}\frac{Eh^3}{(1 - \nu^2)} \quad (3.318)$$

is the plate bending modulus. The slab specific impedance is consequently given by

$$Z_{sl} = -i\omega m_{sl}\left[1 - \left(\frac{f}{f_c}\right)^2\sin^4\theta_I\right] , \quad (3.319)$$

where

$$f_c = \frac{c^2}{2\pi}\left(\frac{m_{sl}}{B_{pl}}\right)^{1/2} \quad (3.320)$$

gives the coincidence frequency, the frequency at which the phase velocity of freely propagating bending waves in the plate equals the speed of sound in the fluid.

Although the simple result of (3.319) predicts that the fraction of incident power transmitted is unity at a frequency of $f_c/\sin^2\theta_I$, the presence of damping processes in the plate causes the fraction of incident power transmitted always to be less than unity. A simple way of taking this into account makes use of a loss factor η (assumed to be much less than unity) for the plate, which corresponds to the fraction of stored elastic energy that is dissipated through damping processes during one radian (a cycle period divided by 2π). Because twice the loss factor times the natural frequency is the time coefficient for exponential time decay of the amplitude when the system is vibrating in any natural mode, the former can be regarded as the negative of the imaginary part of a complex frequency. Then, because the natural frequency squared is always proportional to the elastic modulus, and because the loss factor is invariably small, the loss factor can be formally introduced

into the mathematical model by the replacement of the real elastic modulus by the complex number $(1-i\eta)E$. When this is done, one finds

$$Z_{sl} = \omega\eta m_{pl}\left(\frac{f}{f_c}\right)^2\sin^4\theta_I - i\omega m_{sl}$$
$$\times\left[1-\left(\frac{f}{f_c}\right)^2\sin^4\theta_I\right] \qquad (3.321)$$

for the slab impedance that is to be inserted into (3.314). The extra term ordinarily has very little effect on the fraction of incident power that is transmitted except when the (normally dominant) imaginary term is close to zero. When the frequency f is $f_c/\sin^2\theta_I$, one finds the value of τ to be

$$\tau = \left(1+\frac{1}{2}\frac{\omega\eta m_{pl}}{\rho c}\cos\theta_I\right)^{-2}, \qquad (3.322)$$

rather than identically unity.

3.11 Spherical Waves

In many circumstances of interest, applicable idealizations are waves that locally resemble waves spreading out radially from sources or from scatterers. The mathematical description of such waves has some similarities to plane waves, but important distinctions arise. The present section is concerned with a number of important situations where the appropriate coordinates are spherical coordinates.

3.11.1 Spherically Symmetric Outgoing Waves

For a spherically symmetric wave spreading out radially from a source in an unbounded medium, the symmetry implies that the acoustic field variables are a function of only the radial coordinate r and of time t. The Laplacian reduces then to

$$\nabla^2 p = \frac{\partial^2 p}{\partial r^2} + \frac{2}{r}\frac{\partial p}{\partial r} = \frac{1}{r}\frac{\partial^2(rp)}{\partial r^2}, \qquad (3.323)$$

so the wave equation of (3.74) takes the form

$$\frac{\partial^2(rp)}{\partial r^2} - \frac{1}{c^2}\frac{\partial^2(rp)}{\partial t^2} = 0. \qquad (3.324)$$

The solution of this is

$$p(r,t) = \frac{f(r-ct)}{r} + \frac{g(r+ct)}{r}. \qquad (3.325)$$

Causality considerations (no sound before the source is turned on) lead to the conclusion that the

second term on the right side of (3.325) is not an appropriate solution of the wave equation when the source is concentrated near the origin. The expression

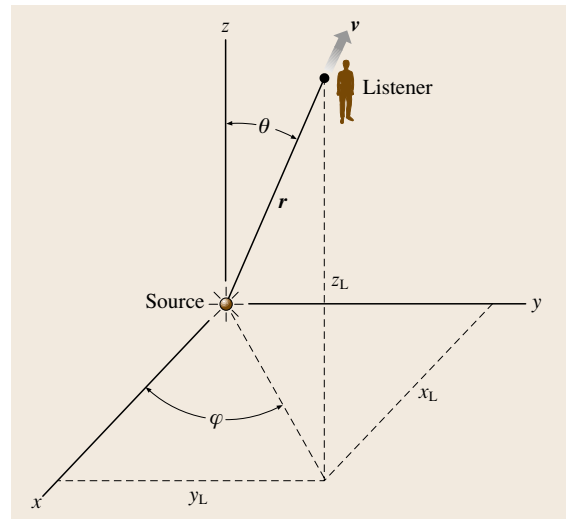
$$p(r,t) = \frac{f(r-ct)}{r}, \qquad (3.326)$$


Fig. 3.22 Spherical coordinates. The common situation is when the source is at the origin and the listener (sound receiver) has coordinates (r,θ,ϕ)

which describes the acoustic pressure in an outgoing spherically symmetric wave, has the property that listeners at different radii will receive (with a time shift corresponding to the propagation time) waveforms of the same shape, but of different amplitudes. The factor of $1/r$ is characteristic of spherical spreading and implies that the peak waveform amplitudes in a spherical wave decrease with radial distance as $1/r$.

Spherical waves of constant frequency have complex amplitudes governed by the Helmholtz equation (3.176), with the Laplacian given as stated in (3.323). The complex pressure amplitude corresponding to (3.326) has the form

$$p = A \frac{e^{ikr}}{r} . \tag{3.327}$$

The fluid velocity associated with an outgoing spherical wave is purely radial and has the form

$$v_r = \frac{1}{\rho c} \left[-r^{-2} F(r - ct) + r^{-1} f(r - ct) \right] . \tag{3.328}$$

Here the function F is such that its derivative is the function f that appears in (3.326). Because the first term (a near-field term) decreases as the square rather than the first power of the reciprocal of the radial distance, the fluid velocity asymptotically approaches

$$v_r \to \frac{p}{\rho c} , \tag{3.329}$$

which is the same as the plane wave relation of (3.187). For outgoing spherical waves of constant frequency, the complex amplitude of the fluid velocity is

$$\hat{v}_r = \frac{1}{\rho c} \left(1 - \frac{1}{ikr} \right) \hat{p} . \tag{3.330}$$

In this expression, there is a term that is in phase with the pressure and another term that is $90°$ ($\pi/2$) out of phase with it.

The time-averaged intensity for spherical waves, in accord with (3.281), is

$$I_{av} = \frac{1}{2} \mathrm{Re}\left(\hat{p} \hat{v}_r^* \right) . \tag{3.331}$$

The expression for v_r given above allows this to be simplified to

$$I_{av} = \frac{1}{2} \frac{1}{\rho c} |\hat{p}|^2 . \tag{3.332}$$

Then, with the expression (3.327) inserted for $\hat{p}$, one obtains

$$I_{av} = \frac{1}{2} \frac{1}{\rho c} \frac{|A|^2}{r^2} . \tag{3.333}$$

The result confirms that the time-averaged intensity falls off as the square of the radial distance. This behavior is what is termed spherical spreading.

The spherical spreading law also follows from energy conservation considerations. The time-averaged power flowing through a spherical surface of radius r is the area $4\pi r^2$ of the surface times the time-averaged intensity. This power should be independent of the radius r since there is no external energy input or attenuation that is included in the considered model, so the intensity must fall off as $1/r^2$.

3.11.2 Radially Oscillating Sphere

The classic example of a source that generates outgoing spherical waves is an impenetrable sphere whose radius $r_{sp}(t)$ oscillates with time with some given velocity amplitude v_o, so that

$$r_{sp}(t) = a + \frac{v_o}{\omega} \sin(\omega t) . \tag{3.334}$$

Here a is the nominal radius of the sphere, and v_o/ω is the amplitude of the deviations of the actual radius from that value. For the linear acoustics idealization to be valid, it is required that this deviation be substantially less than a, so that

$$v_o \ll \omega a . \tag{3.335}$$

The boundary condition on the fluid dynamic equations should ideally be

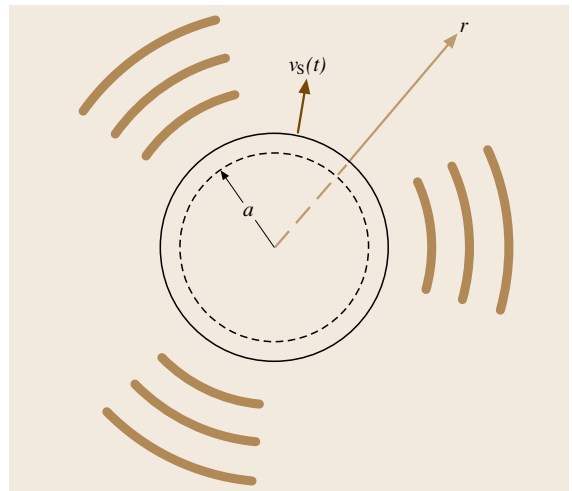
$$v_r = v_o \cos(\omega t) \qquad \text{at} \quad r = r_{sp}(t) , \tag{3.336}$$


Fig. 3.23 Parameters used for the discussion of constant frequency sound radiated by a radially oscillating sphere

but, also in keeping with the linear acoustics idealization, it is replaced by

$$v_r = v_o \cos(\omega t) \qquad \text{at} \quad r = a. \tag{3.337}$$

The corresponding boundary condition on the complex amplitude is

$$\hat{v}_r = v_o \qquad \text{at} \quad r = a. \tag{3.338}$$

If the complex amplitude of the acoustic part of the pressure is taken of the general form of (3.327) then the radial fluid velocity, in accord with (3.330), has the complex amplitude

$$\hat{v}_r = \frac{1}{\rho c} \left(1 - \frac{1}{ikr}\right) A \frac{e^{ikr}}{r}. \tag{3.339}$$

The approximate boundary condition (3.338) consequently allows one to identify the constant A as

$$A = v_o \left(\frac{ika^2 \rho c}{ika - 1}\right) e^{-ika}, \tag{3.340}$$

so that the acoustical part of the pressure has the complex amplitude

$$\hat{p} = v_o \left(\frac{ika \rho c}{ika - 1}\right) \left(\frac{a}{r}\right) e^{-ik[r-a]}. \tag{3.341}$$

Radiation Impedance

The ratio of the complex amplitude of the pressure to that of the fluid velocity in the outward direction at a point on a vibrating surface is termed the specific radiation impedance (specific here meaning per unit area), so that

$$Z_{\text{rad}} = \frac{\hat{p}}{\hat{v}_n}, \tag{3.342}$$

where $\hat{v}_n$ is the component of the complex amplitude of the fluid velocity in the outward normal direction. For the case of the radially oscillating sphere of nominal radius a, the analysis above yields

$$Z_{\text{rad}} = \rho c \left(\frac{ika}{ika - 1}\right). \tag{3.343}$$

Usually, this is referred to simply as the radiation impedance, without the qualifying adjective *specific*.

The time-averaged power radiated by an oscillating body, in accord with (3.281), is

$$\mathfrak{P}_{\text{av}} = \frac{1}{2} \int \text{Re} \left(\hat{p}^* \hat{v}_n\right) \, dS, \tag{3.344}$$

where the integral extends over the surface. Given the definition of the radiation impedance, this can be written in either of the equivalent forms

$$\mathfrak{P}_{\text{av}} = \frac{1}{2} \int |\hat{p}|^2 \text{Re} \left(\frac{1}{Z_{\text{rad}}}\right) dS$$
$$= \frac{1}{2} \int |\hat{v}_n|^2 \text{Re} \left(Z_{\text{rad}}\right) dS. \tag{3.345}$$

For the case of the radially oscillating sphere, the quantity $\hat{v}_n$ is v_o, and

$$\text{Re} \left(Z_{\text{rad}}\right) = \rho c \left(\frac{k^2 a^2}{1 + k^2 a^2}\right). \tag{3.346}$$

The latter increases monotonically from 0 to 1 as the frequency increases from 0 to ∞. The surface area of the sphere is $4\pi a^2$, so the time-averaged acoustic power is

$$\mathfrak{P}_{\text{av}} = (2\pi a^2)(\rho c) v_o^2 \left(\frac{k^2 a^2}{1 + k^2 a^2}\right). \tag{3.347}$$

3.11.3 Transversely Oscillating Sphere

Another basic example for which the natural description is in terms of spherical coordinates is that of a rigid sphere oscillating back and forth in the z-direction about the origin.

The velocity of an arbitrary point on the surface of the sphere can be taken as $v_c \mathbf{e}_z \cos(\omega t)$, where v_c is the velocity amplitude of the oscillation and $\mathbf{e}_z$ is the unit vector in the direction of increasing z. Consistent with
Fig. 3.24 Parameters used for the discussion of constant-frequency sound radiated by a transversely oscillating sphere

the desire to use a linear approximation, one approximates the unit normal vector for a given point on the surface of the sphere to be the same as when the sphere is centered at the origin, so that $\boldsymbol{n} \approx \boldsymbol{e}_r$, where the latter is the unit vector in the radial direction. The normal component of the fluid velocity is then approximately

$$v_n = v_c \left(\boldsymbol{e}_z \cdot \boldsymbol{e}_r \right) \cos(\omega t) \, . \tag{3.348}$$

The dot product is $\cos\theta$, where θ is the polar angle.

One also makes the approximation that the boundary condition is to be imposed, not at the actual (moving) location of the point on the surface, but at the place in space where that point is when the sphere is centered at the origin. All these considerations lead to the linear acoustics boundary condition

$$\hat{v}_r = v_c \cos\theta \qquad \text{at} \quad r = a \tag{3.349}$$

for the complex amplitude of the fluid velocity.

The feature distinguishing this boundary condition from that for the radially oscillating sphere is the factor $\cos\theta$. The plausible conjecture that both $\hat{v}_r$ and $\hat{p}$ continue to have the same θ dependence for all values of r is correct in this case, and one can look for a solution of the Helmholtz equation that has such a dependence, such as

$$\hat{p} = B \frac{\partial}{\partial z} \left(\frac{\mathrm{e}^{\mathrm{i}kr}}{r} \right) = B \cos\theta \frac{\mathrm{d}}{\mathrm{d}r} \left(\frac{\mathrm{e}^{\mathrm{i}kr}}{r} \right) \, . \tag{3.350}$$

The first part of this relation follows because a derivative of a solution with respect to any Cartesian coordinate is also a solution and because, as demonstrated in a previous part of this section, $\mathrm{e}^{\mathrm{i}kr}/r$ is a solution. The second part follows because $r^2 = z^2 + x^2 + y^2$, so $\partial r/\partial z = z/r = \cos\theta$. The quantity B is a complex numerical constant that remains to be determined.

The radial component of Euler's equation (3.175) for the constant-frequency case requires that

$$-\mathrm{i}\omega\rho\hat{v}_r = -\frac{\partial\hat{p}}{\partial r} \, , \tag{3.351}$$

where on the right side the differentiation is to be carried out at constant θ. Given the expression (3.350), the corresponding relation for the radial component of the fluid velocity is consequently

$$\hat{v}_r = \frac{B}{\mathrm{i}\omega\rho} \cos\theta \frac{\mathrm{d}^2}{\mathrm{d}r^2} \left(\frac{\mathrm{e}^{\mathrm{i}kr}}{r} \right) \, . \tag{3.352}$$

The boundary condition at $r = a$ is satisfied if one takes B to have a value such that

$$v_c = \frac{B}{\mathrm{i}\omega\rho} \left[\frac{\mathrm{d}^2}{\mathrm{d}r^2} \left(\frac{\mathrm{e}^{\mathrm{i}kr}}{r} \right) \right]_{r=a} \, . \tag{3.353}$$

The indicated algebra yields

$$B = -\left(\frac{\mathrm{i}\omega\rho a^3 v_c}{2 + 2\mathrm{i}ka + k^2 a^2} \right) \mathrm{e}^{-\mathrm{i}ka} \, , \tag{3.354}$$

so the complex amplitude of the acoustic part of the pressure becomes

$$\hat{p} = \rho c v_c \frac{k^2 a^2}{2 + 2\mathrm{i}ka + k^2 a^2} \left(1 - \frac{1}{\mathrm{i}kr} \right) \left(\frac{a}{r} \right)$$
$$\times \mathrm{e}^{-\mathrm{i}k[r-a]} \cos\theta \, , \tag{3.355}$$

while the radial component of the fluid velocity is

$$\hat{v}_r = v_c \left(\frac{2 + 2\mathrm{i}kr + k^2 r^2}{2 + 2\mathrm{i}ka + k^2 a^2} \right) \left(\frac{a^3}{r^3} \right) \mathrm{e}^{-\mathrm{i}k[r-a]} \cos\theta \, . \tag{3.356}$$

The radiation impedance is

$$Z_{\mathrm{rad}} = \rho c \left(\frac{k^2 a^2 + \mathrm{i}ka}{2 + 2\mathrm{i}ka + k^2 a^2} \right) \, . \tag{3.357}$$

Various simplifications result when considers limiting cases for the values of kr and ka. A case of common interest is when $ka \ll 1$ (small sphere) and $kr \gg 1$ (far field), so that

$$\hat{p} = \left(\frac{\omega^2 \rho v_c a^3}{c} \right) \frac{\mathrm{e}^{\mathrm{i}kr}}{r} \cos\theta \, . \tag{3.358}$$

3.11.4 Axially Symmetric Solutions

The example discussed in the previous subsection of radiation from a transversely oscillating sphere is one of a class of solutions of the linear acoustic equations where the field quantities depend on the spherical coordinates r and θ but not on the azimuthal angle ϕ. The Helmholtz equation for such circumstances has the form

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial\hat{p}}{\partial r} \right) + \frac{1}{r^2 \sin\theta} \frac{\partial}{\partial\theta} \left(\sin\theta \frac{\partial\hat{p}}{\partial\theta} \right) + k^2 \hat{p} = 0 \, . \tag{3.359}$$

A common technique is to build up solutions of this equation using the principle of superposition, with the individual terms being factored solutions of the form

$$\hat{p}_\ell = P_\ell(\cos\theta) \mathfrak{R}_\ell(kr) \, , \tag{3.360}$$

where ℓ is an integer that distinguishes the various particular separated solutions. Insertion of this product into the Helmholtz equation leads to the conclusion that each factor must satisfy an appropriate ordinary differential

equation, the two differential equations being (with η replacing kr)

$$\frac{1}{\sin\theta}\frac{\mathrm{d}}{\mathrm{d}\theta}\left(\sin\theta\,\frac{\mathrm{d}P_\ell}{\mathrm{d}\theta}\right)+\lambda_\ell P_\ell=0\,, \qquad (3.361)$$

$$\frac{\mathrm{d}}{\mathrm{d}\eta}\left(\eta^2\frac{\mathrm{d}\mathfrak{R}_\ell}{\mathrm{d}\eta}\right)-\lambda_\ell\mathfrak{R}_\ell+\eta^2\mathfrak{R}_\ell=0\,. \qquad (3.362)$$

Here λ_ℓ is a constant, termed the separation constant. Equivalently, with P_ℓ regarded as a function of $\xi=\cos\theta$, the first of these two differential equations can be written

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\left[\left(1-\xi^2\right)\frac{\mathrm{d}P_\ell}{\mathrm{d}\xi}\right]+\lambda_\ell P_\ell=0\,. \qquad (3.363)$$

Legendre Polynomials

Usually, one desires solutions that are finite at both $\theta=0$ and $\theta=\pi$, or at $\xi=1$ and $\xi=-1$, but the solutions for the θ-dependent factor are usually singular at one of the other of these two end points. However, for special values (eigenvalues) of the separation constant λ_ℓ, there exist particular solutions (eigenfunctions) that are finite at both points. To determine these functions, one postulates a series solution of the form

$$P_\ell(\xi)=\sum_{n=0}^{\infty}a_{\ell,n}\xi^n\,, \qquad (3.364)$$

and derives the recursion relation

$$n(n-1)a_{\ell,n}=[(n-1)(n-2)-\lambda_\ell]\,a_{\ell,n-2}\,. \qquad (3.365)$$

The series diverges as $\xi\to\pm1$ unless it only has a finite number of terms, and such may be so if for some n the quantity in brackets on the right side is zero. The general choice of the separation constant that allows this is

$$\lambda_\ell=\ell(\ell+1)\,, \qquad (3.366)$$

where ℓ is an integer, so that the recursion relation becomes

$$n(n-1)a_{\ell,n}=[(n-\ell-2)(n+\ell-1)]\,a_{\ell,n-2}\,. \qquad (3.367)$$

However, $a_{\ell,0}$ and $a_{\ell,1}$ can be chosen independently and the recursion relation can only terminate one of the two possible infinite series. Consequently, one must choose

$$a_{\ell,1}=0 \qquad \text{if } \ell \text{ even}\,;$$
$$a_{\ell,0}=0 \qquad \text{if } \ell \text{ odd}\,. \qquad (3.368)$$

If ℓ is even the terms correspond to $n=0$, $n=2$, $n=4$, up to $n=\ell$, while if ℓ is odd the terms correspond to $n=$

1, $n=3$, up to $n=\ell$. The customary normalization is that $P_\ell(1)=1$, and the polynomials that are derived are termed the Legendre polynomials. A general expression that results from examination of the recursion relation for the coefficients is

$$P_\ell(\xi)=a_{\ell,\ell}\left(\xi^\ell-\frac{\ell(\ell-1)}{2(2\ell-1)}\xi^{\ell-2}\right.$$
$$\left.+\frac{\ell(\ell-2)(\ell-1)(\ell-3)}{(2)(4)(2\ell-1)(2\ell-3)}\xi^{\ell-4}+\dots\right), \qquad (3.369)$$

where the last term has ξ raised to either the power of 1 or 0, depending on whether ℓ is odd or even. Equivalently, if one sets,

$$a_{\ell,\ell}=K_\ell\frac{(2\ell)!}{2^\ell(\ell!)^2}\,, \qquad (3.370)$$

where K_ℓ is to be selected, the series has the relatively simple form

$$P_\ell(\xi)=K_\ell\sum_{m=0}^{M(\ell)}(-1)^m\frac{(2\ell-2m)!}{2^\ell m!(\ell-m)!(\ell-2m)!}\xi^{\ell-2m}$$
$$=K_\ell\sum_{m=0}^{M(\ell)}b_{\ell,m}\xi^{\ell-2m}\,. \qquad (3.371)$$

Here $M(\ell)=\ell/2$ if ℓ is even, and $M(\ell)=(\ell-1)/2$ if ℓ is odd, so $M(0)=0$, $M(1)=0$, $M(2)=1$, $M(3)=1$, $M(4)=2$, etc.

The coefficients $b_{\ell,m}$ as defined here satisfy the relation

$$(\ell+1)b_{\ell+1,m}=(2\ell+1)b_{\ell,m}-\ell b_{\ell-1,m-1}\,, \qquad (3.372)$$

as can be verified by algebraic manipulation. A consequence of this relation is

$$(\ell+1)\frac{P_{\ell+1}(\xi)}{K_{\ell+1}}=(2\ell+1)\xi\frac{P_\ell(\xi)}{K_\ell}-\ell\frac{P_{\ell-1}(\xi)}{K_{\ell-1}}\,, \qquad (3.373)$$

when $\ell\geq1$.

The customary normalization is to take $P_\ell(1)=1$. The series for $\ell=0$ and $\ell=1$ are each of only one term, and the normalization requirement leads to $K_0=1$ and $K_1=1$. The relation (3.373) indicates that the normalization requirement will result, via induction, for all successive ℓ if one takes $K_\ell=1$ for all ℓ. With this definition, the relation (3.373) yields the recursion relation among polynomials of different orders

$$(\ell+1)P_{\ell+1}(\xi)=(2\ell+1)\xi P_\ell(\xi)-\ell P_{\ell-1}(\xi)\,. \qquad (3.374)$$
Fig. 3.25 Legendre polynomials for various orders

The latter holds for $\ell \geq 1$. With this, for example, given that $P_0(\xi) = 1$ and that $P_1(\xi) = \xi$, one derives

$$(2)P_2(\xi) = (3)\xi\xi - (1)(1) \, . \tag{3.375}$$

The first few of these polynomials are

$$P_0(\xi) = 1 \, , \tag{3.376}$$

$$P_1(\xi) = \xi \, , \tag{3.377}$$

$$P_2(\xi) = \frac{1}{2}(3\xi^2 - 1) \, , \tag{3.378}$$

$$P_3(\xi) = \frac{1}{2}(5\xi^3 - 3\xi) \, , \tag{3.379}$$

$$P_4(\xi) = \frac{1}{8}(35\xi^4 - 30\xi^2 + 3) \, , \tag{3.380}$$

$$P_5(\xi) = \frac{1}{8}(63\xi^5 - 70\xi^3 + 15\xi) \, , \tag{3.381}$$

with the customary identification of $\xi = \cos\theta$.

An alternate statement for the series expression (3.371), given $K_\ell = 1$, is the Rodrigues relation,

$$P_\ell(\xi) = \frac{1}{2^\ell \ell!} \frac{d^\ell}{d\xi^\ell}(\xi^2 - 1)^\ell \, . \tag{3.382}$$

This can be verified by using the binomial expansion

$$(\xi^2 - 1)^\ell = (-1)^\ell \sum_{n=1}^{\ell} (-1)^n \frac{\ell!}{n!(\ell-n)!} \xi^{2n} \, , \tag{3.383}$$

so that

$$\frac{d^\ell}{d\xi^\ell}(\xi^2 - 1)^\ell = (-1)^\ell \sum_{n=\ell-M}^{\ell} (-1)^n \frac{\ell!}{n!(\ell-n)!}$$
$$\times \frac{(2n)!}{(2n-\ell)!} \xi^{2n-\ell} \, , \tag{3.384}$$

or, with the change of summation index to $m = \ell - n$,

$$\frac{d^\ell}{d\xi^\ell}(\xi^2 - 1)^\ell = \sum_{m=0}^{M(\ell)} (-1)^m \frac{\ell!}{m!(\ell-m)!}$$
$$\times \frac{(2\ell-2m)!}{(\ell-2m)!} \xi^{\ell-2m} = \ell! 2^\ell P_\ell(\xi) \, . \tag{3.385}$$

Another derivable property of these functions is that they are orthogonal in the sense that

$$\int_0^\pi P_\ell(\cos\theta) P_{\ell'}(\cos\theta) \sin\theta \, d\theta = 0 \qquad \text{if } \ell \neq \ell' \, . \tag{3.386}$$

This is demonstrated by taking the differential equations (3.361) satisfied by P_ℓ and $P_{\ell'}$, multiplying the first by $P_{\ell'} \sin\theta$, multiplying the second by $P_\ell(\theta) \sin\theta$, then subtracting the second from the first, with a subsequent integration over θ from 0 to π. Given that $\lambda_\ell \neq \lambda_{\ell'}$ and that the two polynomials are finite at the integration limits, the conclusion is as stated above.

If the two indices are equal, the chosen normalization, whereby $P_\ell(1) = 1$, leads to

$$\int_0^\pi [P_\ell(\cos\theta)]^2 \sin\theta \, d\theta = \frac{2}{2\ell+1} \, . \tag{3.387}$$

The general derivation of this makes use of the Rodrigues relation (3.382) and of multiple integrations by parts. To carry through the derivation, one must first verify, for arbitrary nonnegative integers s and t, and with $s < t$, that

$$\frac{d}{d\xi^s}(\xi^2 - 1)^t = 0 \qquad \text{at } \xi = \pm 1 \, , \tag{3.388}$$

which is accomplished by use of the chain rule of differential calculus. With the use of this relation and of the

Rodrigues relation, one has

$$\int_{-1}^{1} [P_\ell(\xi)]^2 \, d\xi$$

$$= \left(\frac{1}{2^\ell \ell!}\right)^2 (-1)^\ell \int_{-1}^{1} (\xi^2 - 1)^\ell$$

$$\times \frac{d^{2\ell}}{d\xi^{2\ell}} (\xi^2 - 1)^\ell \, d\xi \qquad (3.389)$$

$$= \left(\frac{1}{2^\ell \ell!}\right)^2 (2\ell)! \int_{-1}^{1} (1 - \xi^2)^\ell \, d\xi$$

$$= \left(\frac{1}{2^\ell \ell!}\right)^2 (2\ell)! 2 \int_{0}^{\pi/2} \sin\theta^{2\ell+1} \, d\theta . \qquad (3.390)$$

The trigonometric integral I_ℓ in the latter expression is evaluated using the trigonometric identity

$$\frac{d}{d\theta}(\sin^{2\ell}\theta \cos\theta) = -\sin^{2\ell+1}\theta$$
$$+ 2\ell(\sin^{2\ell-2}\theta)(1 - \sin^2\theta) , \qquad (3.391)$$

the integral of which yields the recursion relation

$$I_\ell = \frac{2\ell}{(2\ell + 1)} I_{\ell-1} , \qquad (3.392)$$

and from this one infers

$$I_\ell = \frac{(2^\ell \ell!)^2}{(2\ell + 1)!} I_0 . \qquad (3.393)$$

The integral for $\ell = 0$ is unity, so one has

$$\int_{-1}^{1} [P_\ell(\xi)]^2 \, d\xi = \left(\frac{1}{2^\ell \ell!}\right)^2 (2\ell)! 2 \left(\frac{(2^\ell \ell!)^2}{(2\ell + 1)!}\right)$$

$$= \frac{2}{2\ell + 1} . \qquad (3.394)$$

Spherical Bessel Functions
The ordinary differential equation (3.362) for the factor $\mathfrak{R}_\ell(\eta)$ takes the form

$$\frac{d}{d\eta}\left(\eta^2 \frac{d\mathfrak{R}_\ell}{d\eta}\right) - \ell(\ell + 1)\mathfrak{R}_\ell + \eta^2 \mathfrak{R}_\ell = 0 , \qquad (3.395)$$

with the identification for the separation constant that results from the requirement that the θ-dependent fac-

tor be finite at $\theta = 0$ and $\theta = \pi$. For $\ell = 0$, a possible solution is

$$\mathfrak{R}_0 = A_0 \frac{e^{i\eta}}{\eta} , \qquad (3.396)$$

as can be verified by direct substitution, with A_0 being any constant. Since there is no corresponding θ dependence this is the same as the solution (3.327) for an outgoing spherical wave.

For arbitrary positive integer ℓ, a possible solution is

$$h_\ell^{(1)}(\eta) = -i\eta^\ell \left(-\frac{1}{\eta}\frac{d}{d\eta}\right)^\ell \frac{e^{i\eta}}{\eta} , \qquad (3.397)$$

so that, in particular,

$$h_0^{(1)}(\eta) = -i\frac{e^{i\eta}}{\eta} ;$$

$$h_1^{(1)}(\eta) = i\frac{d}{d\eta}\frac{e^{i\eta}}{\eta} = -\left(1 + \frac{i}{\eta}\right)\frac{e^{i\eta}}{\eta} . \qquad (3.398)$$

Alternately, both the real and imaginary parts should be solutions, so if one writes

$$h_\ell^{(1)}(\eta) = j_\ell(\eta) + iy_\ell(\eta) , \qquad (3.399)$$

then

$$j_\ell(\eta) = \eta^\ell \left(-\frac{1}{\eta}\frac{d}{d\eta}\right)^\ell \frac{\sin\eta}{\eta} , \qquad (3.400)$$

$$y_\ell(\eta) = -\eta^\ell \left(-\frac{1}{\eta}\frac{d}{d\eta}\right)^\ell \frac{\cos\eta}{\eta} , \qquad (3.401)$$

**Fig. 3.26** Spherical Bessel functions for various orders

Fig. 3.27 Spherical Neumann functions for various orders

are each solutions. The function $h_\ell^{(1)}(\eta)$ is referred to as the spherical Hankel function of the ℓ-th order and first kind (the second kind has i replaced by $-i$), while $j_\ell(\eta)$ is the spherical Bessel function of the ℓ-th order, and $y_\ell(\eta)$ is the spherical Neumann function of the ℓ-th order.

A proof that $h_\ell^{(1)}(\eta)$, as defined above, satisfies the ordinary differential equation for the corresponding value of ℓ proceeds by induction. The assertion is true for $\ell = 0$ and it is easily demonstrated also to be true for $\ell = 1$, and the definition (3.397) yields the recursion relation

$$h_{\ell+1}^{(1)}(\eta) = \frac{\ell}{\eta} h_\ell^{(1)} - \frac{d}{d\eta} h_\ell^{(1)} . \qquad (3.402)$$

The differential equation for $h_\ell^{(1)}$ and what results from taking the derivative of that equation gives one the relations,

$$\frac{d^2}{d\eta^2} h_\ell^{(1)} + \frac{2}{\eta} \frac{d}{d\eta} h_\ell^{(1)} + \left(1 - \frac{\ell(\ell+1)}{\eta^2}\right) h_\ell^{(1)} = 0 , \qquad (3.403)$$

$$\frac{d^2}{d\eta^2} \frac{h_\ell^{(1)}}{\eta} + \frac{2}{\eta} \frac{d}{d\eta} \frac{h_\ell^{(1)}}{\eta} + \frac{2}{\eta^2} \frac{d}{d\eta} h_\ell^{(1)}$$
$$+ \left(1 - \frac{\ell(\ell+1)}{\eta^2}\right) \frac{h_\ell^{(1)}}{\eta} = 0 , \qquad (3.404)$$

$$\frac{d^2}{d\eta^2} \frac{dh_\ell^{(1)}}{d\eta} + \frac{2}{\eta} \frac{d}{d\eta} \frac{dh_\ell^{(1)}}{d\eta} - \frac{2}{\eta^2} \frac{d}{d\eta} h_\ell^{(1)}$$
$$+ \frac{2}{\eta^3} \ell(\ell+1) h_\ell^{(1)} + \left(1 - \frac{\ell(\ell+1)}{\eta^2}\right) \frac{dh_\ell^{(1)}}{d\eta} = 0 . \qquad (3.405)$$

Multiplication of the second of these by ℓ, then subtracting the third, subsequently making use of the recursion relation, yields

$$\frac{d^2}{d\eta^2} h_{\ell+1}^{(1)} + \frac{2}{\eta} \frac{d}{d\eta} h_{\ell+1}^{(1)} + \frac{2(\ell+1)}{\eta^2} \frac{d}{d\eta} h_\ell^{(1)}$$
$$- \frac{2}{\eta^3} \ell(\ell+1) h_\ell^{(1)} + \left(1 - \frac{\ell(\ell+1)}{\eta^2}\right) h_{\ell+1}^{(1)} = 0 . \qquad (3.406)$$

A further substitution that makes use of the recursion relation yields

$$\frac{d^2}{d\eta^2} h_{\ell+1}^{(1)} + \frac{2}{\eta} \frac{d}{d\eta} h_{\ell+1}^{(1)} - \frac{2(\ell+1)}{\eta^2} h_{\ell+1}^{(1)}$$
$$+ \left(1 - \frac{\ell(\ell+1)}{\eta^2}\right) h_{\ell+1}^{(1)} = 0 , \qquad (3.407)$$

or, equivalently,

$$\frac{d^2}{d\eta^2} h_{\ell+1}^{(1)} + \frac{2}{\eta} \frac{d}{d\eta} h_{\ell+1}^{(1)}$$
$$+ \left(1 - \frac{(\ell+1)(\ell+2)}{\eta^2}\right) h_{\ell+1}^{(1)} = 0 , \qquad (3.408)$$

which is the differential equation that one desires $h_{\ell+1}^{(1)}$ to satisfy; it is the $\ell + 1$ counterpart of (3.403).

Another recursion relation derivable from (3.397) is

$$(\ell+1) h_{\ell+1}^{(1)} = -(2\ell+1) \frac{d}{d\eta} h_\ell^{(1)} + \ell h_{\ell-1}^{(1)} . \qquad (3.409)$$

Limiting approximate expressions for the spherical Hankel function and the spherical Bessel function are derivable from the definition (3.397). For $\eta \ll 1$, one has

$$h_0^{(1)}(\eta) \approx -\frac{i}{\eta} ; \quad h_\ell^{(1)}(\eta) \approx -i \frac{1 \cdot 3 \cdot 5 \cdots (2\ell-1)}{\eta^{\ell+1}} , \qquad (3.410)$$

$$j_0(\eta) \approx 1 - \frac{1}{6} \eta^2 ; \quad j_\ell(\eta) \approx \frac{\eta^\ell}{1 \cdot 3 \cdot 5 \cdots (2\ell+1)} . \qquad (3.411)$$

(The second term in the expansion for j_0 is needed in the event that one desires a nonzero first approximation

for the derivative.) In the asymptotic limit, when $\eta \gg 1$, one has

$$h_\ell^{(1)}(\eta) \to (-\mathrm{i})^{\ell+1} \frac{\mathrm{e}^{\mathrm{i}\eta}}{\eta} \,. \tag{3.412}$$

As is evident from the $\mathrm{e}^{\mathrm{i}\eta} = \mathrm{e}^{\mathrm{i}kr}$ factor that appears here, the spherical Hankel function of the first kind corresponds to a radially outgoing wave, given that one is using the $\mathrm{e}^{-\mathrm{i}\omega t}$ time dependence. Its complex conjugate, the spherical Hankel function of the second kind, corresponds to a radially incoming wave.

Plane Wave Expansion

A mathematical identity concerning the expansion of a plane wave in terms of Legendre polynomials and spherical Bessel functions results from consideration of

$$\mathrm{e}^{\mathrm{i}kr\cos\theta} = \sum_{\ell=0}^{\infty} \mathfrak{I}_\ell(kr) P_\ell(\cos\theta) \,. \tag{3.413}$$

Because the Legendre polynomials are a complete set, such an expansion is possible and expected to converge. The coefficients $\mathfrak{I}_\ell(kr)$ are determined with the use of the orthogonality conditions, (3.386) and (3.387), to be given by

$$\mathfrak{I}_\ell(\eta) = \frac{2\ell+1}{2} \int_0^\pi \mathrm{e}^{\mathrm{i}\eta\cos\theta} P_\ell(\cos\theta) \sin\theta \, \mathrm{d}\theta$$

$$= \frac{2\ell+1}{2} \int_{-1}^1 \mathrm{e}^{\mathrm{i}\eta\xi} P_\ell(\xi) \, \mathrm{d}\xi \,. \tag{3.414}$$

The integral above evaluates, for $\ell = 0$, to

$$\mathfrak{I}_0(\eta) = \frac{1}{2} \frac{1}{\mathrm{i}\eta}(\mathrm{e}^{\mathrm{i}\eta} - \mathrm{e}^{-\mathrm{i}\eta}) = j_\ell(\eta) \,, \tag{3.415}$$

and, for $\ell = 1$, to

$$\mathfrak{I}_1(\eta) = \frac{3}{2} \frac{\mathrm{d}}{\mathrm{d}(\mathrm{i}\eta)} \left(\frac{1}{\mathrm{i}\eta}(\mathrm{e}^{\mathrm{i}\eta} - \mathrm{e}^{-\mathrm{i}\eta}) \right)$$

$$= 3\mathrm{i} \left(\frac{\sin\eta}{\eta^2} - \frac{\cos\eta}{\eta} \right) = 3\mathrm{i} j_1(\eta) \,. \tag{3.416}$$

To proceed to larger values of ℓ, one makes use of the recursion relations, (3.374) and (3.409), and infers the general relation

$$\mathfrak{I}_\ell(\eta) = (2\ell+1)\mathrm{i}^\ell j_\ell(\eta) \,. \tag{3.417}$$

This relation certainly holds for $\ell = 0$ and $\ell = 1$, and a general proof for arbitrary integer ℓ follows by induc-

tion. One assumes the relation is true for $\ell - 1$ and ℓ, and considers

$$\mathfrak{I}_{\ell+1}(\eta)$$

$$= \frac{2\ell+3}{2} \int_{-1}^1 \mathrm{e}^{\mathrm{i}\eta\xi} P_{\ell+1}(\xi) \, \mathrm{d}\xi \tag{3.418}$$

$$= \frac{(2\ell+3)(2\ell+1)}{2(\ell+1)} \int_{-1}^1 \mathrm{e}^{\mathrm{i}\eta\xi} \xi P_\ell(\xi) \, \mathrm{d}\xi$$

$$- \frac{(2\ell+3)\ell}{2(\ell+1)} \int_{-1}^1 \mathrm{e}^{\mathrm{i}\eta\xi} P_{\ell-1}(\xi) \, \mathrm{d}\xi \tag{3.419}$$

$$= \frac{(2\ell+3)}{(\ell+1)}(-\mathrm{i}) \frac{\mathrm{d}}{\mathrm{d}\eta} \mathfrak{I}_\ell$$

$$- \frac{(2\ell+3)\ell}{(\ell+1)(2\ell-1)} \mathfrak{I}_{\ell-1} \tag{3.420}$$

where the second version results from the recursion relation (3.374). Then, with the appropriate insertions from (3.417), one has

$$\mathfrak{I}_{\ell+1}(\eta) = (2\ell+3)\mathrm{i}^{\ell+1}$$

$$\times \left[-\frac{(2\ell+1)}{(\ell+1)} \frac{\mathrm{d}}{\mathrm{d}\eta} j_\ell(\eta) \right.$$

$$\left. + \frac{\ell}{(\ell+1)} j_{\ell-1}(\eta) \right] \,. \tag{3.421}$$

The recursion relation (3.409) replaces the quantity in brackets by $j_{\ell+1}$, so one obtains

$$\mathfrak{I}_{\ell+1}(\eta) = (2\ell+3)\mathrm{i}^{\ell+1} j_{\ell+1}(\xi) \,, \tag{3.422}$$

which is the $\ell+1$ counterpart of (3.417). Thus the appropriate plane wave expansion is identified as

$$\mathrm{e}^{\mathrm{i}kr\cos\theta} = \sum_{\ell=0}^{\infty} (2\ell+1)\mathrm{i}^\ell j_\ell(kr) P_\ell(\cos\theta) \,. \tag{3.423}$$

3.11.5 Scattering by a Rigid Sphere

An application of the functions introduced above is the scattering of an incident plane wave by a rigid sphere (radius a). One sets the complex amplitude of the acoustic part of the pressure to

$$\hat{p} = \hat{P}_{\mathrm{inc}} \mathrm{e}^{\mathrm{i}kz} + \hat{p}_{\mathrm{sc}} \,. \tag{3.424}$$

The first term represents the incident wave, which has an amplitude $\hat{P}_{\mathrm{inc}}$, constant frequency ω and which is proceeding in the $+z$-direction. The second term rep-

resents the scattered wave. This term is required to be made up of waves that propagate out from the sphere, which is centered at the origin. With some generality, one can use the principle of superposition and set

$$\hat{p}_{sc} = \hat{P}_{inc} \sum_{\ell=0} A_\ell P_\ell(\cos\theta) h_\ell^{(1)}(kr) , \qquad (3.425)$$

with the factors in the terms in the sum representing the Legendre polynomials and spherical Hankel functions. The individual terms in the sum are sometimes referred to as partial waves. The analytical task is to determine the coefficients A_ℓ. (The expression above applies to scattering from any axisymmetric body, including spheroids and penetrable objects, where the properties might vary with r and θ. The discussion here, however, is limited to that of the rigid sphere.)

With the plane wave expansion (3.423) inserted for the direct wave, the sum of incident and scattered waves takes the form

$$\hat{p} = \hat{P}_{inc} \sum_{\ell=0}^{\infty} \left[(2\ell+1)i^\ell j_\ell(kr) + A_\ell h_\ell^{(1)}(kr) \right]$$
$$\times P_\ell(\cos\theta) . \qquad (3.426)$$

the boundary condition imposed by the rigidity of the sphere is that $\hat{v}_r = 0$ at $r = a$, or equivalently that $\partial\hat{p}/\partial r = 0$ at $r = a$. With the aid of the radial component of the Euler equation (3.175) and of the linear independence of the various Legendre polynomials, this yields

$$\frac{d}{dr}\left[(2\ell+1)i^\ell j_\ell(kr) + A_\ell h_\ell^{(1)}(kr) \right] = 0$$
$$\text{at} \quad r = a . \qquad (3.427)$$

The desired coefficients are consequently

$$A_\ell = -(2\ell+1)i^\ell \frac{\left[\frac{d}{dr} j_\ell(kr) \right]_{r=a}}{\left[\frac{d}{dr} h_\ell^{(1)}(kr) \right]_{r=a}} . \qquad (3.428)$$

Far–Field Scattering

In the limit of large kr, the asymptotic expression (3.412) for the spherical Hankel function can be used, and the scattered wave takes the asymptotic form

$$\hat{p}_{sc} \rightarrow \hat{P}_{inc} f(\theta) \frac{e^{ikr}}{kr} , \qquad (3.429)$$

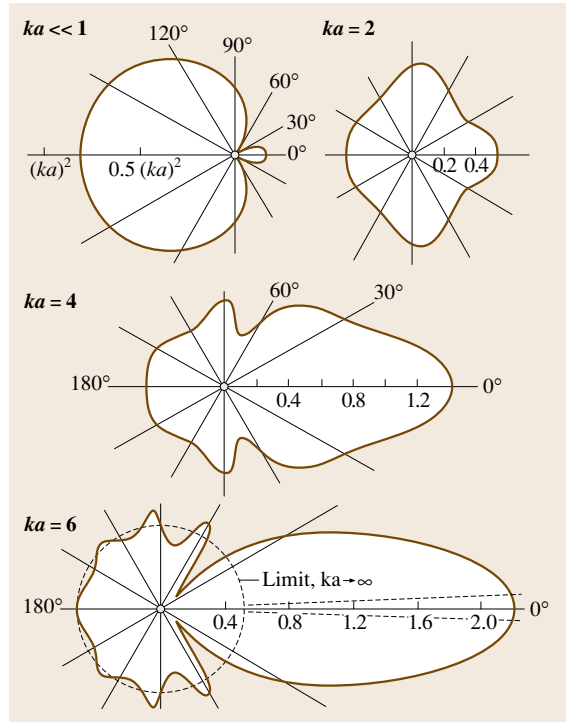
where

$$f(\theta) = \sum_{\ell=0}^{\infty} (-i)^{\ell+1} A_\ell P_\ell(\cos\theta) \qquad (3.430)$$

is a complex dimensionless function of only the angle θ.

This asymptotic form holds for scattering from any axisymmetric object of bounded extent. In the more general case when the object is not axisymmetric, one should regard the function f as being also a function of the azimuthal angle ϕ, so that

$$f(\theta) \rightarrow f(\theta, \phi) . \qquad (3.431)$$

The prediction in all cases is that the far-field scattered wave resembles an outgoing spherical wave, but with an amplitude that depends on the direction of propagation.


The far-field intensity associated with the scattered wave is asymptotically entirely in the radial direction, and in accord with (3.281), its time average is given by

$$I_{sc} = \frac{1}{2}\frac{1}{\rho c}|\hat{p}_{sc}|^2 , \qquad (3.432)$$

or,

$$I_{sc} = \frac{1}{2}\frac{|\hat{P}_{inc}|^2}{\rho c}|f(\theta,\phi)|^2 \frac{1}{k^2 r^2} . \qquad (3.433)$$

The differential scattering cross section is the power scattered per unit solid angle and per unit incident in-

Fig. 3.28 Angular distribution of plane wave scattering by a rigid sphere of radius a. The quantity $(d\sigma/d\Omega)^{1/2}/a$ is plotted versus the polar angle θ

tensity, and is consequently given by

$$\frac{d\sigma}{d\Omega} = \frac{r^2 I_{sc}}{I_{inc}} = \frac{1}{k^2} |f(\theta, \phi)|^2 . \tag{3.434}$$

(Here the notation is such that σ corresponds to the cross-sectional area, and Ω corresponds to the solid angle in steradians, with the total solid angle in a sphere being 4π steradians.)

The total scattering cross section is the total scattered power divided by the incident intensity, so that

$$\sigma = \frac{\mathcal{P}_{sc}}{I_{inc}} = \int \frac{d\sigma}{d\Omega} d\Omega = \frac{\mathcal{P}_{sc}}{I_{inc}}$$

$$= \int_0^{2\pi} \int_0^{\pi} \frac{1}{k^2} |f(\theta, \phi)|^2 \sin\theta \, d\theta \, d\phi . \tag{3.435}$$

For the case of an axially symmetric scatterer, this reduces to

$$\sigma = \frac{2\pi}{k^2} \int_0^{\pi} |f(\theta, \phi)|^2 \sin\theta \, d\theta$$

$$= \frac{2\pi}{k^2} \sum_{\ell} \sum_{\ell'} (-i)^{\ell - \ell'} A_\ell A_{\ell'} \int_0^{\pi} P_\ell P_{\ell'} \sin\theta \, d\theta . \tag{3.436}$$

The orthogonality of the Legendre polynomials reduces this to

$$\sigma = \frac{4\pi}{k^2} \sum_{\ell} \frac{1}{(2\ell + 1)} |A_\ell|^2 , \tag{3.437}$$

so the powers scattered by the individual partial waves are additive, even though there may be an intricate interference pattern in the angular directionality.

Rayleigh Scattering

When the object causing the scattering is much smaller than a wavelength, considerable simplification results, and the characteristic features that result are associated with the term *Rayleigh scattering*. In the case of scattering by a rigid sphere, only the $\ell = 0$ and $\ell = 1$ terms are significant, and both have comparable influence. The small-ka approximations for the spherical Bessel function and the spherical Hankel function yield

$$A_0 \approx i\frac{1}{3}(ka)^3 ; \qquad A_1 \approx i(ka)^3 . \tag{3.438}$$

Then with the appropriate identifications of the spherical Hankel function and the Legendre polynomial for $\ell = 0$ and $\ell = 1$, one obtains

$$\hat{p}_{sc} = -\hat{P}_{inc} \frac{k^2 a^3}{3} \left[1 - \frac{3}{2} \cos\theta \left(1 + \frac{i}{kr} \right) \right] \frac{e^{ikr}}{r} . \tag{3.439}$$

The corresponding expressions for the differential scattering cross section and the total cross section are

$$\frac{d\sigma}{d\Omega} = \frac{k^4 a^6}{9} \left(1 - \frac{3}{2} \cos\theta \right)^2 , \tag{3.440}$$

$$\sigma = \frac{7}{9} (ka)^4 \pi a^2 . \tag{3.441}$$

A feature of this expression is the characteristically strong dependence on frequency. The amplitude of the scattered wave varies as the square of the frequency, and the far-field intensity and scattering cross sections vary as the fourth power of the frequency. This type of frequency dependence is invariably true for all types of small scatterers (a notable exception being when the scatterer has an internal resonance at the incident frequency) and is the distinguishing feature of Rayleigh scattering.

3.12 Cylindrical Waves

The present section is concerned with a number of important situations where the appropriate coordinates are the cylindrical coordinates (w, ϕ, z).

3.12.1 Cylindrically Symmetric Outgoing Waves

For cylindrically symmetric waves, there is no dependence on the azimuthal angle ϕ or on the axial coordinate z, so the Laplacian in cylindrical coordinates

reduces to

$$\nabla^2 \psi = \frac{1}{w} \frac{\partial}{\partial w} \left(w \frac{\partial\psi}{\partial w} \right)$$

$$= \frac{\partial^2 \psi}{\partial w^2} + \frac{1}{w} \frac{\partial\psi}{\partial w}$$

$$= \frac{1}{\sqrt{w}} \frac{\partial^2 (\sqrt{w}\psi)}{\partial w^2} + \frac{\sqrt{w}\psi}{4w^{5/2}} , \tag{3.442}$$

Fig. 3.29 Cylindrical coordinates. A hypothetical listener point has cylindrical coordinates w_L, ϕ_L, and z_L

where w is here the radial distance from the z-axis. Consequently, the wave equation of (3.74) takes the form

$$\frac{\partial^2(\sqrt{w}\,p)}{\partial w^2} - \frac{1}{c^2}\frac{\partial^2(\sqrt{w}\,p)}{\partial t^2} + \frac{\sqrt{w}\,p}{4w^2} = 0\,, \quad (3.443)$$

and the Helmholtz equation of (3.176) takes the form

$$\frac{d^2\hat{p}}{dw^2} + \frac{1}{w}\frac{d\hat{p}}{dw} + k^2\hat{p} = 0\,. \quad (3.444)$$

General Transient Solution

A heuristic construction of an outgoing wave solution of (3.443) begins with an infinite line array of identical and synchronous point sources, equally spaced along the z-axis, and each giving rise to an identical spherical wave. Such waves differ, however, at any given distant point in that the radial distance R from the source depends on the z-coordinate z_0 of the source, so that

$$R = \left[w^2 + (z-z_0)^2\right]^{1/2}\,. \quad (3.445)$$

With the taking of an appropriate limit as the source separation interval goes to zero, one finds the general solution for an outgoing cylindrical wave to be

$$p(r, t) = \int_{-\infty}^{\infty} \frac{f[t-(R/c)]}{R}\, dz_0\,. \quad (3.446)$$

Here the function $f(t)$ is arbitrary. The argument $t - (R/c)$ of this function in the integrand is the retarded time, the time at which the incremental contribution was generated. With some effort, one can show that the integral in (3.446) is independent of z, and that it satisfies the cylindrical wave equation (3.443). A consequence of the above result is that outgoing cylindrical waves must have a tail. Even if the function $f(t)$ were to be zero except within a narrow time interval, the integral will give a nonzero value for times arbitrarily later than the time when the signal is first received. This is in contrast to the case for outgoing spherical waves, where there may be no tail.

If the distance w is sufficiently great, the resulting waveform will be such that it will be frozen in shape, and will decrease in amplitude as the inverse of the square root of w. The last term in (3.443) becomes insignificant and the appropriate limiting approximation is of the form

$$p(w, t) = \frac{1}{\sqrt{w}} F\left[t - (w/c)\right]\,. \quad (3.447)$$

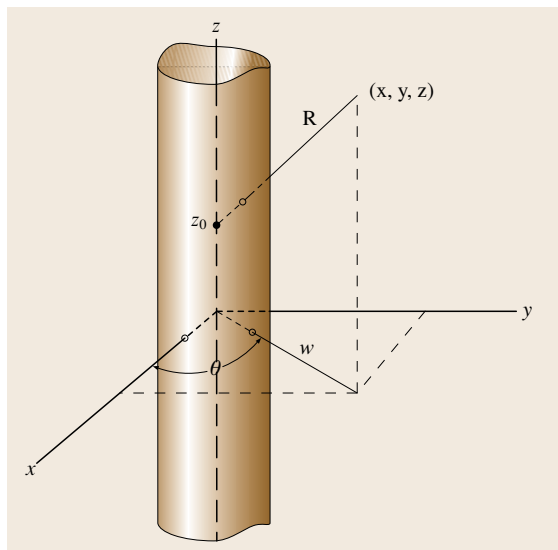
The function $F(t)$ that appears here is related to the $f(t)$ that appears in (3.446). The relationship (derived further


Fig. 3.30 Parameters involved in the construction of a cylindrical wave as a linear superposition of spherical waves from a continuous smear of simultaneous spherical sources spaced along a line. The quantity z_0 represents a source point along the z-axis, and R is the distance from that source point to a given listener point

below) is

$$F(t) = (2c)^{1/2} \int_{-\infty}^{t} \frac{f(\tau)}{(t-\tau)^{1/2}} \, d\tau \ . \tag{3.448}$$

Since $f(t)$ is arbitrary, one can equally well regard $F(t)$ as arbitrary. The expression (3.447) is readily seen to be an appropriate approximate solution of (3.442), since that wave equation implies that $\sqrt{w}p$ should satisfy the equation for plane waves when w is large.

Constant–Frequency Solution

The corresponding cylindrical wave solution for the Helmholtz equation is obtained by setting

$$f(t) \to A \, e^{-i\omega t} \ , \tag{3.449}$$

so that

$$\hat{p}(r) = A \int_{-\infty}^{\infty} \frac{e^{ikR}}{R} \, dz_0 \ , \tag{3.450}$$

or, equivalently,

$$\hat{p}(r) = i\pi A H_0^{(1)}(kw) \ . \tag{3.451}$$

Here A is an arbitrary constant and the quantity $H_0^{(1)}(\eta)$ is the Hankel function of the first kind and zeroth order,

$$H_0^{(1)}(\eta) = \frac{1}{i\pi} \int_{-\infty}^{\infty} \frac{e^{i[\eta^2+\zeta^2]^{1/2}}}{[\eta^2+\zeta^2]^{1/2}} \, d\zeta \ . \tag{3.452}$$

3.12.2 Bessel and Hankel Functions

The Hankel function that appears above is discussed extensively in the literature, and corresponds to an outgoing wave. The differential equation that it satisfies is obtained from the Helmholtz equation for cylindrical waves by setting $kw = \eta$, so that

$$\left(\frac{d^2}{d\eta^2} + \frac{1}{\eta}\frac{d}{d\eta} + 1 \right) H_0^{(1)}(\eta) = 0 \ . \tag{3.453}$$

This is a special case (with $\nu = 0$) of the second-order differential equation

$$\left[\frac{d^2}{d\eta^2} + \frac{1}{\eta}\frac{d}{d\eta} + \left(1 - \frac{\nu^2}{\eta^2}\right) \right] \mathscr{J}_\nu(\eta) = 0 \ , \tag{3.454}$$

whose general solution is

$$\mathscr{J}_\nu(\eta) = a \, J_\nu(\eta) + b Y_\nu(\eta) \ . \tag{3.455}$$

Here $J_\nu(\eta)$ and $Y_\nu(\eta)$ are the Bessel function and the Neumann function. The second, frequently denoted by $N_\nu(\eta)$, is sometimes referred to as Weber's function. The Hankel functions of the first and second kinds are given by

$$H_\nu^{(1)}(\eta) = J_\nu(\eta) + iY_\nu(\eta) \ ;$$
$$H_\nu^{(2)}(\eta) = J_\nu(\eta) - iY_\nu(\eta) \ . \tag{3.456}$$

Both $J_\nu(\eta)$ and $Y_\nu(\eta)$ are real when ν and η are real and positive, so the two Hankel functions are a complex conjugate pair under such circumstances.

An alternate mathematical representation for the Hankel function $H_0^{(1)}$ that is more amenable to numerical computation is

$$H_0^{(1)}(\eta) = \frac{2}{\pi} \int_0^{\pi/2} e^{i\eta\cos\phi} \, d\phi + \frac{2}{i\pi} \int_0^{\infty} e^{-\eta\sinh s} \, ds \ , \tag{3.457}$$

and from this one identifies expressions for the Bessel and Neumann functions as

$$J_0(\eta) = \frac{2}{\pi} \int_0^{\pi/2} \cos(\eta\cos\phi) \, d\phi \ , \tag{3.458}$$

$$Y_0(\eta) = \frac{2}{\pi} \int_0^{\pi/2} \sin(\eta\cos\phi) \, d\phi - \frac{2}{\pi} \int_0^{\infty} e^{-\eta\sinh s} \, ds \ . \tag{3.459}$$

In the limit of small η, the function $H_0^{(1)}$ has a logarithmic singularity, and is approximately given by

$$H_0^{(1)}(\eta) \approx 1 - \frac{1}{4}\eta^2 - \frac{2i}{\pi}\left[\ln(2/\eta) - \gamma\right] \ , \tag{3.460}$$
where

$$\gamma = \int_0^1 \frac{1-e^{-s}}{s} \, ds - \int_1^\infty \frac{e^{-s}}{s} \, ds = 0.5772157\ldots \tag{3.461}$$

is the Euler–Mascheroni constant. In the limit of large η, the corresponding limiting expression is

$$\lim_{\eta\to\infty} H_0^{(1)}(\eta) = \left(\frac{2}{\pi\eta}\right)^{1/2} e^{-i\pi/4} e^{i\eta} \ . \tag{3.462}$$

An expression valid for all positive ν and positive η is

$$H_\nu^{(1)}(\eta) = \frac{1}{\pi i} \int_{-\infty}^{\infty+i\pi} e^{\eta\sinh\alpha - \nu\alpha} \, d\alpha \ . \tag{3.463}$$

Fig. 3.31 Contour integral used for the definition of the Hankel function of the first kind

The latter is a contour integral, where a possible contour is from $-\infty$ along the negative real axis to the origin, then up the imaginary axis to $i\pi$, then parallel to the positive real axis with the imaginary part held fixed to $i\pi$ out to $\infty + i\pi$. The convergence along the latter leg is guaranteed because

$$\sinh(s + i\pi) = -\sinh(s) .\tag{3.464}$$

Thus, when written out explicitly for the contour just described, it becomes

$$H_\nu^{(1)}(\eta) = \frac{1}{\pi i} \int_0^\infty e^{-\eta \sinh s + \nu s} \, ds$$
$$+ \frac{1}{\pi} \int_0^\pi e^{i\eta \sin \theta - i\nu\theta} \, d\theta$$
$$+ \frac{e^{-i\nu\pi}}{\pi i} \int_0^\infty e^{-\eta \sinh s - \nu s} \, ds .\tag{3.465}$$

For $\nu = 0$, this reduces to the expression (3.457). That the above is indeed a solution of the ordinary differential equation (3.454) follows from substitution of the contour integral expression into the differential equation multiplied by η^2, followed by differentiation under the integral sign, so that one has

$$\frac{1}{\pi i} \int_{-\infty}^{\infty + i\pi} (\eta^2 \sinh^2 \alpha + \eta \sinh \alpha + \eta^2 - \nu^2)$$
$$\times e^{\eta \sinh \alpha - \nu\alpha} \, d\alpha$$
$$= \frac{1}{\pi i} \int_{-\infty}^{\infty + i\pi} \frac{d}{d\alpha} [(\eta \cosh \alpha + \nu) e^{\eta \sinh \alpha - \nu\alpha}] \, d\alpha = 0 .\tag{3.466}$$

The latter equality follows because the quantity being differentiated in the integrand vanishes at both ends of the integration contour.
Fig. 3.32 Contour integral along the path of steepest descents, used in the derivation of the asymptotic expression for the Hankel function

For arbitrary positive ν, the corresponding limiting expression at large η for the Hankel function can be derived using the method of steepest descents. The saddle point $\alpha_{\rm sp}$ for the integrand in (3.463) occurs on the imaginary axis where $\cosh \alpha = \nu/\eta$, which is close to $\alpha = i\pi/2$, so that the exponent near the saddle point is approximately

$$\eta \sinh \alpha - \nu\alpha \approx i(\eta - \nu\pi/2) + i\frac{1}{2}\eta(\alpha - \alpha_{\rm sp})^2 .\tag{3.467}$$

The path of steepest descent crosses the imaginary axis proceeding obliquely upwards at an angle of $\pi/4$, so the resulting asymptotic expression is

$$\lim_{\eta \to \infty} H_\nu^{(1)}(\eta) = \left(\frac{2}{\pi\eta}\right)^{1/2} e^{-i[(\nu/2)+(1/4)]\pi} e^{i\eta} .\tag{3.468}$$

The corresponding limiting expressions for $J_\nu(\eta)$ and $Y_\nu(\eta)$ result from taking the real and imaginary parts of this. The above reduces to (3.462) when $\nu = 0$. This asymptotic behavior, plus the requirement that the function satisfy the ordinary differential equation (3.454), is
Fig. 3.33 Graph of the Bessel function of the zeroth order, shown along with common approximations used for small and large values of the argument
Fig. 3.34 Graph of the Neumann function of the zeroth order, shown along with common approximations used for small and large values of the argument

sufficient to define the Hankel function uniquely. The definition (3.463) is also such that it is consistent with the requirement that the real part (the Bessel function) be finite for real positive ν.

For small values of the argument η and for nonzero integer n these functions have the limiting expressions

$$J_n(\eta) \to \frac{1}{n!}\left(\frac{\eta}{2}\right)^n , \tag{3.469}$$

$$Y_n(\eta) \to -\frac{(n-1)!}{\pi}\left(\frac{2}{\eta}\right)^n . \tag{3.470}$$

These expressions also apply for noninteger positive index ν providing that one replaces $n! \to \Gamma(\nu+1)$ and $(n-1)! \to \Gamma(\nu)$, with the use of the Gamma function. The expression for the Neumann function obtained in this way is not appropriate in the limit $\nu \to 0$, as the Gamma function has a singularity when its argument is zero. Instead, one must use the logarithmic expression given by the imaginary part of (3.460).

The definition given above of the Hankel functions for arbitrary index ν yields the recursion relations

$$\frac{d}{d\eta}H_0^{(1)}(\eta) = -H_1^{(1)}(\eta) , \tag{3.471}$$

$$\frac{d}{d\eta}H_\nu^{(1)}(\eta) = H_{\nu-1}^{(1)}(\eta) - \frac{\nu}{\eta}H_\nu^{(1)}(\eta) . \tag{3.472}$$

Analogous recursion relations hold for the Bessel and Neumann functions.

Factored Solutions
One principal use of the Hankel functions and the Bessel functions of arbitrary order is in the synthesis of solutions of the Helmholtz equation in cylindrical

coordinates,

$$\frac{\partial^2 \hat{p}}{\partial w^2} + \frac{1}{w}\frac{\partial \hat{p}}{\partial w} + \frac{1}{w^2}\frac{\partial^2 \hat{p}}{\partial \phi^2} + \frac{\partial^2 \hat{p}}{\partial z^2} + k^2 \hat{p} = 0 . \tag{3.473}$$

One uses factored solutions of the form

$$\hat{p} = \mathfrak{W}(w)\Phi(\phi)\mathcal{Z}(z) . \tag{3.474}$$

If one takes the latter two factors to satisfy the ordinary differential equations

$$\frac{d^2}{d\phi^2}\Phi + \nu^2\Phi = 0 , \tag{3.475}$$

$$\frac{d^2}{dz^2}\mathcal{Z} + \alpha^2\mathcal{Z} = 0 , \tag{3.476}$$

then the ordinary differential equation that results for the radial-coordinate-dependent factor is

$$\frac{d^2\mathfrak{W}}{dw^2} + \frac{1}{w}\frac{d\mathfrak{W}}{dw} - \frac{\nu^2}{w^2}\mathfrak{W} + (k^2 - \alpha^2)\mathfrak{W} = 0 . \tag{3.477}$$

The latter is recognized as the ordinary differential equation satisfied by Bessel functions and Hankel functions of the ν-th order, so possible solutions are

$$\mathfrak{W} = H_\nu^{(1)}[(k^2 - \alpha^2)^{1/2}w] ;$$
$$J_\nu[(k^2 - \alpha^2)^{1/2}w] ;$$
$$Y_\nu[(k^2 - \alpha^2)^{1/2}w] . \tag{3.478}$$

One can use combinations of such factored solutions for the synthesis of solutions of basic problems such as the scattering of a plane wave by a rigid cylinder. The solution is analogous to that discussed in a preceding section for scattering by a rigid sphere. For such problems in cylindrical coordinates, the applicable plane wave expansion theorem is

$$e^{ikw\cos\phi} = \sum_{n=0}^{\infty} 2\epsilon_n \cos(n\phi)J_n(kw) , \tag{3.479}$$

where

$$\epsilon_n = \left[\frac{1}{\pi}\int_0^{2\pi}\cos^2(n\phi)\,d\phi\right]^{-1} \tag{3.480}$$

is $1/2$ if $n = 0$ and 1 if $n \geq 0$. This expansion formula results because of the orthogonality of the trigonometric functions and because

$$J_n(kw) = \frac{1}{2\pi}\int_0^{2\pi} e^{ikw\cos\phi}\cos(n\phi)\,d\phi . \tag{3.481}$$

Cylindrical Waves at Large Distances

The asymptotic expression (3.462) indicates that, at sufficiently large w, the solution of the Helmholtz equation for outgoing cylindrical waves can be represented by

$$\hat{p} = \frac{B}{\sqrt{w}} e^{ikw} , \tag{3.482}$$

where B is a constant which is related to the A introduced previously through

$$B = i\pi \left(\frac{2}{\pi k} \right)^{1/2} e^{-i\pi/4} A . \tag{3.483}$$

Consequently, the relation between the functions $F(t)$ and $f(t)$ that appear in (3.446) and (3.447) must be such that

$$F(t) = 2(2\pi c)^{1/2} \text{Re} \int_0^\infty \frac{1}{\omega^{1/2}} e^{i\pi/4} \hat{f}(\omega) e^{-i\omega t} d\omega , \tag{3.484}$$

where $\hat{f}(\omega)$ is the Fourier transform of $f(t)$. To do the requisite integration, one inserts the counterpart of (3.167) for $\hat{f}(\omega)$ and then interchanges the order of integration. The result,

$$F(t) = (2c)^{1/2} \int_{-\infty}^t \frac{f(\tau)}{(t-\tau)^{1/2}} d\tau , \tag{3.485}$$

is what was previously given in (3.448).

Fluid Velocity for Cylindrical Waves

The fluid velocity induced by outgoing cylindrical waves is not as simply related to the corresponding acoustic pressure as that induced by a plane wave, although symmetry directs that the velocity must be in the appropriate radial direction when the propagation is cylindrically symmetric. For the constant-frequency case, when $\hat{p}$ is given by

$$\hat{p} = C H_0^{(1)}(kw) , \tag{3.486}$$

the radial component in cylindrical coordinates of the linearized Euler equation (3.175) requires

$$\hat{v}_w = \frac{C}{i\omega\rho} \frac{d}{dw} H_0^{(1)}(kw) . \tag{3.487}$$

At small distances, when (3.460) applies, one has

$$\hat{v}_w \approx \frac{C}{i\omega\rho} \frac{2i}{\pi} \frac{1}{w} = \frac{2C}{\pi\omega\rho} \frac{1}{w} . \tag{3.488}$$

This dependence on $1/w$ is characteristic of cylindrically spreading flow from a line source. The complex amplitude, $-i\omega d\hat{m}/d\ell$, of the mass efflux rate, the mass of fluid flowing out per unit axial length per unit time of the source, is $2\pi w\rho$ times the above, so that

$$-i\omega \frac{d\hat{m}}{d\ell} = \frac{4C}{\omega} . \tag{3.489}$$

This gives one a physical interpretation of the constant C, so that $-4iC$ is the complex amplitude of the second derivative with respect to time of the mass that has been expelled from a small cylinder surrounding the source per unit length of cylinder.

In the limit of large w, the asymptotic relation for the Hankel function is applicable, so that

$$\frac{d}{dw} H_0^{(1)} \approx ik H_0^{(1)}(kw) , \tag{3.490}$$

One consequently recovers the plane wave relation

$$\hat{v}_w = \frac{1}{\rho c} \hat{p} . \tag{3.491}$$

Since this holds for Fourier transforms and since ρc is independent of frequency, it should hold for transient cylindrical waves. (Here large w implies large compared to a characteristic wavelength, or compared to c divided by a characteristic angular frequency.)

The previous discussion concerning acoustic intensity implies that the intensity of an outgoing cylindrical wave should decrease with w as $1/w$ so that the power flow through any cylindrical surface around the z-axis should stay constant. This has to remain so, even when one expresses the field in terms of Hankel functions, so one would expect those functions to have some mathematical property that guarantees this. To show that this is indeed the case, one expresses the intensity for the constant-frequency case as

$$I_{w,\text{av}} = \left[\text{Re}(\hat{p} e^{-i\omega t}) \text{Re}(\hat{v}_w e^{-i\omega t}) \right]_{\text{av}}$$
$$= \frac{1}{2} \text{Re}(\hat{p}^* \hat{v}_w) , \tag{3.492}$$

in accordance with (3.182).

Then, with the explicit substitution of the expressions involving Bessel functions one obtains

$$I_{r,\text{av}} = \frac{|C|^2}{2\rho c} \text{Re}[(J_0 - iY_0)(Y_0' - iJ_0')]$$
$$= \frac{|C|^2}{2\rho c} W(J_0, Y_0) , \tag{3.493}$$

where

$$W(J_0, Y_0) = J_0 Y_0' - Y_0 J_0' \tag{3.494}$$

is the Wronskian for the Bessel and Neumann functions. Here the primes denote differentiation with respect to the argument $\eta = kw$ of the indicated function. One can derive from the differential equation (3.453) that these two functions independently satisfy the Wronskian relation

$$\eta W(J_0, Y_0) = \text{constant} , \qquad (3.495)$$

and this is so regardless of the specialized definitions of the two functions. The constant can be evaluated from values and derivatives at any given point. In particular, one can use the asymptotic expressions, and the derived constant is $2/\pi$. Thus one has

$$I_{w,\text{av}} = \frac{1}{\pi} \frac{|C|^2}{\rho cw} = \frac{1}{\rho cw} \frac{1}{16\pi} \left| \omega^2 \frac{d\hat{m}}{d\ell} \right|^2 . \qquad (3.496)$$

3.12.3 Radially Oscillating Cylinder

A classic example for the radiation of cylindrical waves is that where a cylinder has nominal radius a, and an instantaneous radius

$$w_{\text{cyl}}(t) = a + \frac{v_\text{o}}{\omega} \sin(\omega t) . \qquad (3.497)$$

Here v_o/ω is the amplitude of the deviations of the actual radius from the nominal value a. For the linear acoustics idealization to be valid, it is required that this deviation be substantially less than a, so that

$$v_\text{o} \ll \omega a . \qquad (3.498)$$

The boundary condition on the fluid dynamic equations should ideally be

$$v_w = v_\text{o} \cos(\omega t) \qquad \text{at} \quad w = w_{\text{cyl}}(t) , \qquad (3.499)$$

but (also in keeping with the linear acoustics idealization) it is replaced by

$$v_w = v_\text{o} \cos(\omega t) \qquad \text{at} \quad w = a . \qquad (3.500)$$

The corresponding boundary condition on the complex amplitude is

$$\hat{v}_w = v_\text{o} \qquad \text{at} \quad w = a . \qquad (3.501)$$

If one takes the complex amplitude of the acoustic pressure to be of the form

$$\hat{p} = A \, H_0^{(1)}(kw) , \qquad (3.502)$$

where A is a complex number to be determined, then the radial component of the fluid velocity is

$$\hat{v}_w = \frac{A}{i\omega\rho} \frac{d}{dw} H_0^{(1)}(kw) . \qquad (3.503)$$

The imposing of the boundary condition determines the value of A and one obtains

$$\hat{p} = i\omega\rho v_\text{o} \frac{H_0^{(1)}(kw)}{\left[\frac{d}{dw} H_0^{(1)}(kw) \right]_{w=a}} . \qquad (3.504)$$

3.12.4 Transversely Oscillating Cylinder

If the cylinder is rigid and oscillating back and forth in the x-direction, the analysis is similar to that for the transversely oscillating sphere. The complex amplitude of the acoustic part of the pressure should have the general form

$$\hat{p} = B \frac{d}{dx} H_0^{(1)}(kw) = B \cos\phi \frac{d}{dw} H_0^{(1)}(kw) , \qquad (3.505)$$

where B is to be determined from the boundary condition. The latter can also be written

$$\hat{p} = -kB \cos\phi H_1^{(1)}(kw) , \qquad (3.506)$$

in accord with the recursion relation (3.471). The latter version is of the standard form for a factored solution of the Helmholtz equation in cylindrical coordinates.

Euler's equation gives the radial component of the fluid velocity as

$$\hat{v}_w = \frac{1}{i\omega\rho} B \cos\phi \frac{d^2}{dw^2} H_0^{(1)}(kw) . \qquad (3.507)$$

The appropriate approximate boundary condition is that

$$\hat{v}_w = v_\text{c} \cos\phi \qquad \text{at} \quad w = a . \qquad (3.508)$$

This allows one to identify

$$B = \frac{i\omega\rho v_\text{c}}{\left[\frac{d^2}{dw^2} H_0^{(1)}(kw) \right]_{w=a}} . \qquad (3.509)$$

3.13 Simple Sources of Sound

Whatever generates an acoustic wave is termed a source. In acoustical analysis, sources are incorporated into the governing equations through either boundary conditions or source terms.

3.13.1 Volume Sources

Sources that are some distance from bounding surfaces and that are small compared to a wavelength can frequently be described by source terms. The simplest such source would be one that causes a net amount of mass of fluid to flow out of or into a fixed surface that encases it. The example of a radially oscillating sphere, discussed in a preceding section, is a classic example of such a source, and the surface through which the mass is flowing can be taken as a fixed spherical surface just outside the actual moving surface of the sphere. This mass passing out per unit time divided by the ambient density ρ is a quantity $Q_S(t)$ termed the source strength function or the source volume velocity. If such a source is concentrated at a point $\boldsymbol{x}_0$, then the appropriate inhomogeneous wave equation which would replace (3.74) would be

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -\rho\dot{Q}_S(t)\delta(\boldsymbol{x} - \boldsymbol{x}_0) , \qquad (3.510)$$

where $\delta(\boldsymbol{x})$ is the Dirac delta function, which has a volume integral of unity and that is concentrated at the point where its argument vanishes.

The solution of the above inhomogeneous wave equation for an isolated source at the origin ($\boldsymbol{r}_o = 0$) in an unbounded region is

$$p = \frac{\rho}{4\pi r}\dot{Q}_S[t - (r/c)] = \frac{S[t - (r/c)]}{r} , \qquad (3.511)$$

where

$$S(t) = \frac{\rho}{4\pi}\frac{\mathrm{d}}{\mathrm{d}t}Q_S(t) \qquad (3.512)$$

is called the monopole strength. The replacement of the argument by the retarded time $t - (r/c)$ accounts for the transit time lag r/c for the sound to propagate from the source to the listener.

For a radially oscillating small sphere, $Q_S(t)$ can be taken as the time derivative of the instantaneous volume within the sphere. Thus the radiated acoustic pressure is proportional to the volume acceleration, the second derivative with respect to time of the sphere's volume, so that

$$p = \frac{\rho}{4\pi r}\left(\frac{\mathrm{d}^2 V}{\mathrm{d}t^2}\right)_{t \to t-(r/c)} . \qquad (3.513)$$

This rule holds for bodies that are not necessarily spherically shaped, provided the largest dimensions are small compared to a characteristic wavelength and provided the acoustic pressure is measured at a sufficiently large distance from the source.

3.13.2 Small Piston in a Rigid Baffle

Another example of a volume source is that of a very small (relative to a wavelength) piston mounted in an infinite rigid baffle. If the piston has area A and outward normal velocity $v_n(t)$, then symmetry (or, equivalently, the inclusion of an image source) requires that the radiated sound be the same as from an isolated source with twice the volume velocity of the piston, so one has

$$p = \frac{\rho}{2\pi r}A\dot{v}_n\left[t - (r/c)\right] . \qquad (3.514)$$

3.13.3 Multiple and Distributed Sources

For assemblies of sources, each concentrated at a point, the generalization of (3.510) is to replace the right side by a sum of individual source terms; the solution to this inhomogeneous wave equation is given by

$$p = \sum_n \frac{S\left[t - (R_n/c)\right]}{R_n} , \qquad (3.515)$$

where R_n is the distance of the listener from the n-th source.

When the source is continuously distributed in space, the point-source term is replaced by a smoothly varying function, so the inhomogeneous wave equation is now of the form

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -\rho\dot{q}_S(\boldsymbol{x}, t) = -4\pi s(\boldsymbol{x}, t) . \qquad (3.516)$$

Fig. 3.35 Small piston source in a rigid baffle

The function q_S is termed the source strength density (source strength per unit volume). For an unbounded medium, the solution of this latter equation is given by the definite integral

$$p(\mathbf{x}, t) = \iiint \frac{1}{R} s(\mathbf{x}_0, t - (R/c)) \, dV_0 , \qquad (3.517)$$

where the volume integration ranges over source position $\mathbf{x}_0$, and where $R = |\mathbf{x} - \mathbf{x}_0|$ is the distance between the listener and source positions.

3.13.4 Piston of Finite Size in a Rigid Baffle

The concept of multiple sources and the mathematical description above allows an extension of (3.514) to the case when a finite piston is oscillating in a rigid baffle. An area element ΔA located on the $z = 0$ plane at (x_0, y_0) acts as a volume source where the time rate of change of the volume is $2v_n(x_0, y_0, t)\Delta A$. Here, as in (3.514), the factor of two results from the requirement that the contribution from this source element should give no increment of normal velocity on the surface outside of the area element. The normal velocity v_n is here the outward velocity of the piston, which is the velocity in the $+z$-direction, and is that appropriate to the surface point (x_0, y_0).

Superposition of the contribution from all the area elements subsequently yields, for the acoustic pressure
Fig. 3.36 Quantities involved in the integration to determine sound radiation from a planar surface in a state of nonuniform vibration

in the radiated wave,

$$p = \frac{\rho}{2\pi} \iint \frac{\dot{v}_n \left[x_0, y_0, t - (R/c) \right]}{R} \, dx_0 \, dy_0 , \qquad (3.518)$$

where

$$R = \left[(x - x_0)^2 + (y - y_0)^2 + z^2 \right]^{1/2} \qquad (3.519)$$

is the distance from the surface point $(x_0, y_0, 0)$ to the listener point (x, y, z). The integration extends over the portion of the surface that is moving.

If the surface is moving at a constant angular frequency ω, so that

$$v_n(x_0, y_0, t) = \mathrm{Re}\left[\hat{v}_n(x_0, y_0) e^{-i\omega t} \right] , \qquad (3.520)$$

then (3.518) yields the complex amplitude of the radiated pressure field as

$$\hat{p} = \frac{-i\omega\rho}{2\pi} \iint \hat{v}_n(x_0, y_0) \frac{e^{ikR}}{R} \, dx_0 \, dy_0 , \qquad (3.521)$$

with $k = \omega/c$.

Appropriate formulas for the far field when the piston is of limited extent and centered at the origin result when the quantity R in the denominator is replaced by r and when it is replaced by (with the use of the binomial expansion)

$$R \approx r - \frac{x}{r} x_0 - \frac{y}{r} y_0 \qquad (3.522)$$

in the exponent. Here r is the radial distance in spherical coordinates, and one can take

$$\frac{x}{r} = \sin\theta \cos\phi ; \qquad \frac{y}{r} = \sin\theta \sin\phi , \qquad (3.523)$$

with θ as the polar angle and ϕ as the azimuthal solution. In this far-field limit, the acoustic pressure takes the form

$$\hat{p} \rightarrow F(\theta, \phi) \frac{e^{ikr}}{r} , \qquad (3.524)$$

where the directivity function is given by

$$F(\theta, \phi) = \frac{-i\omega\rho}{2\pi} \iint \hat{v}_n(x_0, y_0) e^{-ikx_0 \sin\theta \cos\phi}$$
$$\times e^{-iky_0 \sin\theta \sin\phi} \, dx_0 \, dy_0 . \qquad (3.525)$$

The integrals (3.521) and (3.525) can be evaluated in terms of standard special functions when the piston is rigid and of a simple shape.

Rectangular Piston

If the piston is rectangular, with dimensions a and b, and centered at the origin, the far-field pattern is given by

$$F(\theta, \phi) = \frac{-\mathrm{i}\omega\rho v_0}{2\pi} ab \frac{\sin\left[(1/2)a\sin\theta\cos\phi\right]}{(1/2)a\sin\theta\cos\phi}$$
$$\times \frac{\sin\left[(1/2)b\sin\theta\sin\phi\right]}{(1/2)b\sin\theta\sin\phi} . \qquad (3.526)$$

Circular Piston

If the piston is circular of radius a, the corresponding expression is independent of the azimuthal angle and given by

$$F(\theta) = \frac{-\mathrm{i}\omega\rho v_0}{2\pi} \int_0^a \int_0^{2\pi} \mathrm{e}^{-\mathrm{i}kw_0\sin\theta\cos\phi_0} \,\mathrm{d}\phi_0 \, w_0 \,\mathrm{d}w_0 . \qquad (3.527)$$

Fig. 3.37 Far-field radiation patterns of a vibrating circular piston in an otherwise rigid baffle for various values of ka. The quantity plotted is the intensity at a large radial distance r relative to that when the polar angle θ is zero, which is $[2J_1(\xi)/\xi]^2$, with $\xi = ka\sin\theta$

The integral over the azimuthal angle on the piston yields a Bessel function, so one has

$$F(\theta) = -\mathrm{i}\omega\rho v_0 \int_0^a J_0(kw_0\sin\theta) w_0 \,\mathrm{d}w_0 . \qquad (3.528)$$

The recursion relation (3.472) implies that

$$\frac{\mathrm{d}}{\mathrm{d}\eta} J_1(\eta) = J_0(\eta) - \frac{1}{\eta} J_1(\eta) , \qquad (3.529)$$

so

$$\eta J_0(\eta) = \eta\frac{\mathrm{d}}{\mathrm{d}\eta} J_1(\eta) + J_1(\eta) = \frac{\mathrm{d}}{\mathrm{d}\eta}(\eta J_1(\eta)) . \qquad (3.530)$$

Consequently the integration in (3.528) can be performed in terms of the Bessel function of the first order, with the result

$$F(\theta) = -\mathrm{i}\omega\rho v_0 a^2 \left(\frac{J_1(ka\sin\theta)}{ka\sin\theta}\right) . \qquad (3.531)$$

3.13.5 Thermoacoustic Sources

The differential equation (3.516) arises when one suddenly adds heat to a fluid [3.71,72], as with a laser or by combustion, so that the entropy s per unit mass changes according to the thermodynamic relation

$$\rho T \mathrm{D}s/\mathrm{D}t = h , \qquad (3.532)$$

so that, to first order, the equation of state (3.87) yields

$$\frac{\partial p'}{\partial t} = c^2\frac{\partial\rho'}{\partial t} + \frac{c^2\beta}{c_p} h . \qquad (3.533)$$

Here h is the heat added per unit time and unit volume, β is the volume expansion coefficient defined by (3.30), and c_p is the specific heat at constant pressure.

Equation (3.533) changes the basic linear acoustic equations (3.71) and (3.72) to

$$\frac{\partial p}{\partial t} + \rho c^2\nabla\cdot\mathbf{v} = \frac{c^2\beta}{c_p} h , \qquad (3.534)$$

$$\rho_0\frac{\partial\mathbf{v}}{\partial t} + \nabla p = 0 , \qquad (3.535)$$

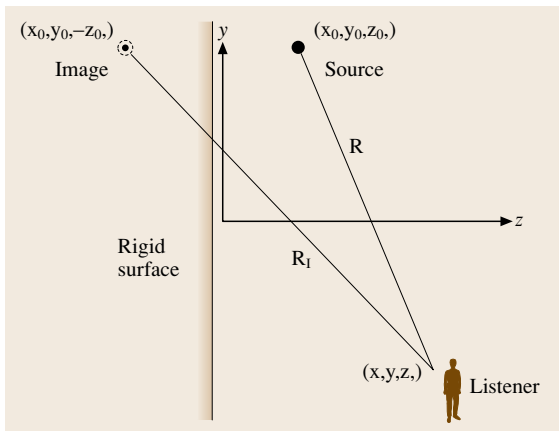
so the energy conservation corollary of (3.273) becomes

$$\frac{\partial w}{\partial t} + \nabla\cdot\mathbf{I} = \frac{\beta}{\rho c_p} ph , \qquad (3.536)$$

and the wave equation becomes

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -\frac{\beta}{c_p}\frac{\partial h}{\partial t} . \qquad (3.537)$$

The appropriate identification for the monopole strength density function $s(\boldsymbol{x}, t)$ in the integral expression of (3.517) is consequently given by

$$s(\boldsymbol{x}, t) = \frac{1}{4\pi} \frac{\beta}{c_p} \frac{\partial h}{\partial t} . \tag{3.538}$$


3.13.6 Green's Functions

The idealization of a point source of constant frequency is of basic importance in formulating solutions to complicated acoustic radiation problems. The resulting complex pressure amplitude of the field resulting from such a single source can be expressed as a constant times a Green's function, where the Green's function is a solution of the inhomogeneous Helmholtz equation

$$(\nabla^2 + k^2) G(\boldsymbol{x}|\boldsymbol{x}_0) = -4\pi \delta(\boldsymbol{x} - \boldsymbol{x}_0) . \tag{3.539}$$

(The inclusion of the factor 4π on the right is done in much of the literature, but not universally; its objective here is that the mathematical form of the Green's function be simpler.) If the medium surrounding the source is unbounded, then the Green's function is the free-space (no external boundaries) Green's function, which can be identified from (3.511) to have the form

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{R} e^{ikR} , \tag{3.540}$$

Fig. 3.38 Parameters involved in the construction of the Green's function corresponding to a point source outside a perfectly reflecting (rigid) wall. The quantity R is the direct distance from the source, and R_I is the distance from the image source

where R is the distance between the source and observation (listener) point. When external boundary conditions are imposed on the Green's function that satisfies (3.539), then the Green's function will have a form different from that of the free-space Green's function. However, in all such cases, the Green's function will approach $1/R$ plus a bounded function when the listener position approaches the source point.

An example of a Green's function that is not the free-space Green's function is that which corresponds to a point source on one side of an infinitely-extended rigid plane. If the source point is at (x_0, y_0, z_0) where $z_0 > 0$, and if the rigid plane is the $z = 0$ plane, then

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{R} e^{ikR} + \frac{1}{R_i} e^{ikR_i} , \tag{3.541}$$

where

$$R_i = [(x - x_0)^2 + (y - y_0)^2 + (z + z_0)^2]^{1/2} . \tag{3.542}$$

Because this Green's function is even in y, it automatically satisfies the boundary conditions that its normal derivative vanish at the rigid boundary.

3.13.7 Multipole Series

Radiation fields from sources of limited spatial extent in unbounded environments can be described either in terms of multipoles or spherical harmonics. That such descriptions are feasible can be demonstrated with the aid of the constant-frequency version of (3.517)

$$\hat{p}(\boldsymbol{x}) = \int \hat{s}(\boldsymbol{x}_0) \frac{e^{ikR}}{R} dV_0 , \tag{3.543}$$

which is the solution of the inhomogeneous Helmholtz equation with a continuous distribution of monopole sources taken into account.

The multipole series results from this when one expands $R^{-1} e^{ikR}$ in a power series in the coordinates of the source position $\boldsymbol{x}_0$ and then integrates term by term. Up to second order one obtains

$$\hat{p} = \hat{S} \frac{e^{ikr}}{r} - \sum_{\nu=1}^{3} \hat{D}_\nu \frac{\partial}{\partial x_\nu} \frac{e^{ikr}}{r}$$
$$+ \sum_{\mu,\nu=1}^{3} \hat{Q}_{\mu\nu} \frac{\partial^2}{\partial x_\mu \partial x_\nu} \frac{e^{ikr}}{r} , \tag{3.544}$$

where the coefficients are expressed by

$$\hat{S} = \int \hat{s}(\boldsymbol{x})\,\mathrm{d}V \,, \tag{3.545}$$

$$\hat{D}_v = -\int x_v \hat{s}(\boldsymbol{x})\,\mathrm{d}V \,, \tag{3.546}$$

$$\hat{Q}_{\mu v} = \frac{1}{2!}\int x_\mu x_v \hat{s}(\boldsymbol{x})\,\mathrm{d}V \,. \tag{3.547}$$

The three terms in (3.544) are said to be the monopole, dipole, and quadrupole terms, respectively. The coefficients $\hat{S}$, $\hat{D}_v$, and $\hat{Q}_{\mu v}$ are similarly labeled. The D_v are the components of a dipole moment vector, while the $Q_{\mu v}$ are the components of a quadrupole moment tensor. The general validity [3.73, 74] of such a description extends beyond the manner of derivation and is not restricted to sound generated by a continuous source distribution embedded in the fluid. It applies in particular to the sound radiated by a vibrating body of arbitrary shape.

3.13.8 Acoustically Compact Sources

If the source is acoustically compact, so that its largest dimension is much shorter than a wavelength, the multipole series converges rapidly, so one typically only need retain the first nonzero term. Sources exist whose net monopole strength is zero, and sources also exist whose dipole moment vector components are all zero as well. Consequently, compact sources are frequently classed as monopole, dipole, and quadrupole sources. The prototype of a monopole source is a body of oscillating volume. One for a dipole source is a rigid solid undergoing translational oscillations; another would be a vibrating plate or shell whose thickness changes negligibly. In the former case, the detailed theory shows that in the limit of sufficiently low frequency, the dipole moment vector is given by

$$\hat{D}_v = \hat{F}_v + m_\mathrm{d}\hat{a}_{\mathrm{C},v} \,, \tag{3.548}$$

where $\hat{F}_v$ is associated with the force which the moving body exerts on the surrounding fluid and where $\hat{a}_{\mathrm{C},v}$ is associated with the acceleration of the geometric center of the body. The quantity m_d is the mass of fluid displaced by the body.

The simplest example of a dipole source is that of a rigid sphere transversely oscillating along the z-axis about the origin. (This is discussed in general terms in a preceding section of this chapter.) If the radius of the sphere is a and if $ka \ll 1$, then the force and acceleration have only a z-component, and the force amplitude

is given by

$$\hat{F}_z = \frac{1}{2}m_\mathrm{d}\hat{a}_{\mathrm{C},z} \,. \tag{3.549}$$

The dipole moment when the center velocity has amplitude $\hat{v}_\mathrm{C}$ is consequently of the form

$$\hat{D}_z = -\frac{3}{2}\mathrm{i}\omega[(4/3)\rho\pi a^3]\hat{v}_\mathrm{C} \,. \tag{3.550}$$

Taking into account that the derivative of r with respect to z is $\cos\theta$, one finds the acoustic field from (3.544) to be given by

$$\hat{p} = -\hat{D}_z \cos\theta \frac{\mathrm{d}}{\mathrm{d}r}\frac{\mathrm{e}^{\mathrm{i}kr}}{r} \,. \tag{3.551}$$

When $kr \gg 1$, this approaches the limiting form

$$\hat{p} \to -\mathrm{i}k D_z \cos\theta \frac{\mathrm{e}^{\mathrm{i}kr}}{r} \,. \tag{3.552}$$

The far-field intensity, in accord with (3.276), has a time average of $|\hat{p}|^2/(2\rho c)$ and is directed in the radial direction in this asymptotic limit. The drop of intensity as $1/r^2$ with increasing radial distance is the same as for spherical spreading, but the intensity varies with direction as $\cos^2\theta$.

Vibrating bodies that radiate as quadrupole sources (and which therefore have no dipole radiation) usually do so because of symmetry. Vibrating bells [3.75] and tuning forks are typically quadrupole radiators.

A dipole source can be represented by two similar monopole sources, 180° out of phase with each other, and very close together. Since they are radiating out of phase, there is no total mass flow input into the medium. Such a dipole source will have a net acoustic power output substantially lower than that of either of the component monopoles when radiating individually. Similarly, a quadrupole can be formed by two identical but oppositely directed dipoles brought very close together. If the two dipoles have a common axis, then a longitudinal quadrupole results; when they are side by side, a lateral quadrupole results. In either case, the quadrupole radiation is much weaker than would be that from either dipole when radiating separately.

3.13.9 Spherical Harmonics

The closely related description of source radiation in terms of spherical harmonics results from (3.543) when one inserts the expansion [3.76–78]

$$\frac{\mathrm{e}^{\mathrm{i}kR}}{R} = \sum_{\ell=0}^{\infty}(2\ell+1)j_\ell(kr_0)h_\ell^{(1)}(kr)P_\ell(\cos\Theta) \,, \tag{3.553}$$

where j_ℓ is the spherical Bessel function and $h_\ell^{(1)}$ is the spherical Hankel function of order ℓ and of the first kind. (The expansion here assumes $r > r_0$; otherwise, one interchanges r and r_0 in the above.) The quantity $P_\ell(\cos \Theta)$ is the Legendre function of order ℓ, while Θ is the angle between the directions of x and x_0. Alternately, one uses the expansion

$$P_\ell(\cos \Theta) = \sum_{m=-\ell}^{\ell} \frac{(\ell - |m|)!}{(\ell + |m|)!} Y_\ell^m(\theta, \phi) Y_\ell^{-m}(\theta_0, \phi_0) \,, \tag{3.554}$$

where the spherical harmonics are defined by

$$Y_\ell^m(\theta, \phi) = e^{im\phi} P_\ell^{|m|}(\cos \theta) \,. \tag{3.555}$$

Here the functions $P_\ell^{|m|}(\cos \theta)$ are the associated Legendre functions. (The value of $P_0(\cos \Theta)$ is identically 1.)

If such an expansion is inserted into (3.543) and if r is understood to be sufficiently large that there are no sources beyond that radius, one has the relation

$$\hat{p}(r, \theta, \phi) = a_{00} h_0^{(1)}(kr)$$
$$+ \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} a_{\ell m} h_\ell^{(1)}(kr) Y_\ell^m(\theta, \phi) \,, \tag{3.556}$$

with coefficients given by

$$a_{\ell m} = ik(2\ell + 1) \frac{(\ell - |m|)!}{(\ell + |m|)!}$$
$$\times \int \hat{s}(r_0, \theta_0, \phi_0) j_\ell(kr_0) Y_\ell^{-m}(\theta_0, \phi_0) \, dV_0 \,. \tag{3.557}$$

These volume integrations are to be carried out in spherical coordinates. The general result of (3.557) holds for any source of limited extent; any such wave field in an unbounded medium must have such an expansion in terms of spherical Hankel functions and spherical harmonics.

The spherical Hankel functions have the asymptotic (large-r) form

$$h_\ell^{(1)}(kr) \to (-i)^{(\ell+1)} \frac{e^{ikr}}{kr} \,, \tag{3.558}$$

so the acoustic radiation field must asymptotically approach

$$\hat{p} \to \hat{F}(\theta, \phi) \frac{e^{ikr}}{r} \,, \tag{3.559}$$

where the function $\hat{F}(\theta, \phi)$ is a function of θ and ϕ that has an expansion in terms of spherical harmonics. In this asymptotic limit, the acoustic intensity is in the radial direction and given by

$$I_{r,\text{av}} = \frac{1}{2} \frac{|\hat{F}|^2}{\rho c r^2} \,. \tag{3.560}$$

For fixed θ and ϕ, the time-averaged intensity must asymptotically decrease as $1/r^2$. The coefficient of $1/r^2$ in the above describes the far-field radiation pattern of the source, having the units of watts per steradian.

Although the two types of expansions, multipoles and spherical harmonics, are related, the relationship is not trivial. The quadrupole term in (3.544), for example, cannot be equated to the sum of the $\ell = 2$ terms in (3.556). It is possible to have spherically symmetric quadrupole radiation, so an $\ell = 0$ term would have to be included.

3.14 Integral Equations in Acoustics

There are many common circumstances where the determination of acoustic fields and their properties is approached via the solution of integral equations rather than of partial differential equations.

3.14.1 The Helmholtz–Kirchhoff Integral

For the analysis of radiation of sound from a vibrating body of limited extent in an unbounded region, there is an applicable integral corollary of the Helmholtz equation of (3.176) which dates back to 19th century works of *Helmholtz* [3.47] and *Kirchhoff* [3.79].

One considers a closed surface S where the outward normal component of the particle velocity has complex amplitude $\hat{v}_n(x_S)$ and complex pressure amplitude $\hat{p}_S(x_S)$ at a point x_S on the surface. For notational convenience, one introduces a quantity defined by

$$\hat{f}_S = -i\omega\rho\hat{v}_n \,, \tag{3.561}$$

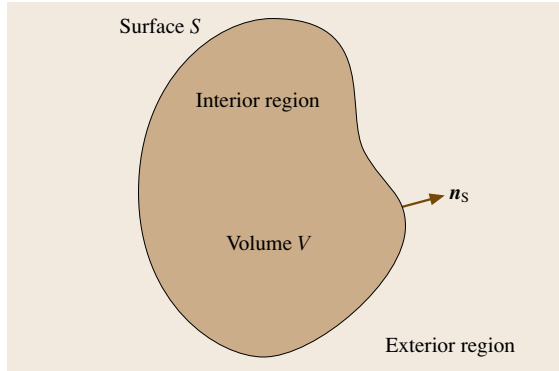
where $\hat{v}_n(x_S)$ is the normal component $n(x_S) \cdot \hat{v}(x_S)$ of the complex fluid velocity vector amplitude $\hat{v}(x)$ at the surface. One can regard $\hat{f}_S$ as a convenient grouping of symbols, either as a constant multiplied by the normal velocity, or as a constant multiplied by the normal ac-


Fig. 3.39 Arbitrary surface in an arbitrary state of vibration at constant frequency, with unit normal n_S

celeration, or as the normal component of the apparent body force, per unit volume, exerted on the fluid at the surface point x_S. Because of the latter identification, the use of the symbol f is appropriate. The subscript S is used to denote values appropriate to the surface.

Then, given that there are no sources outside the surface, a mathematical derivation, involving the differential equation of (3.539) for the free-space Green's function of (3.540), involving the Helmholtz equation, and involving the divergence theorem, yields

$$\hat{p}(x) = \mathfrak{M}(x, \hat{p}_S, \hat{f}_S) \qquad (3.562)$$

for the complex pressure amplitude $\hat{p}$ at a point x outside the surface. Here the right side is given by the expression

$$\mathfrak{M} = \frac{1}{4\pi} \int \left\{ \hat{f}_S(x'_S) G(x|x'_S) \right. $$
$$\left. + \hat{p}_S(x'_S) n(x'_S) \cdot \left[\nabla' G(x|x') \right]_{x'=x'_S} \right\} \, \mathrm{d}S' . $$
$$(3.563)$$

In the integrand of this expression, the point x'_S (after the evaluation of any requisite normal derivatives) is understood to range over the surface S, with the point x held fixed during the integration. The unit outward normal vector $n(x'_S)$ points out of the enclosed volume V at the surface point x'_S.

In (3.563), the integral $\mathfrak{M}$ is a function of the point x, but a functional (function of a function) of the function arguments $\hat{p}_S$ and $\hat{f}_S$.

3.14.2 Integral Equations for Surface Fields

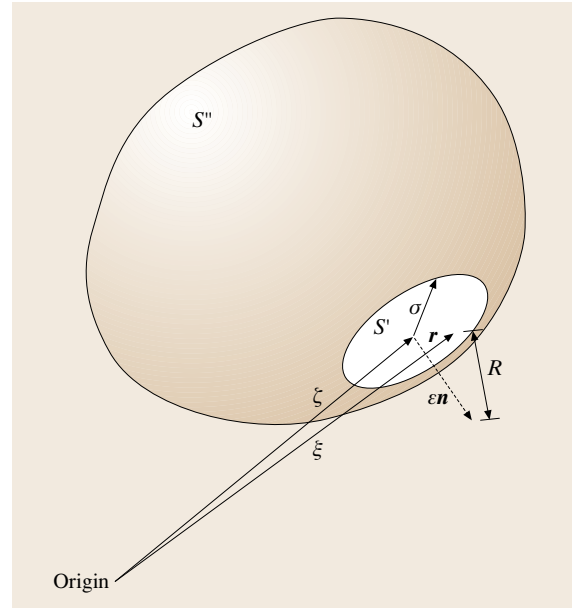
The functions $\hat{p}_S$ and $\hat{f}_S$ cannot be independently prescribed on the surface S. Specifying either one is


Fig. 3.40 Sketch illustrating the methodology for the derivation of an integral equation from the Helmholtz–Kelvin relation. The exterior point at $\xi = \zeta + n\epsilon$ is gradually allowed to approach an arbitrary point ζ on the surface, and the integration is represented as a sum of integrals over S' and S''. One considers the parameters ϵ and σ as small, but with $\sigma \gg \epsilon$, first takes the limit as $\epsilon \to 0$, then takes the limit as $\sigma \to 0$

a sufficient inner boundary condition on the Helmholtz equation. The corollary of (3.562) applies only if both functions correspond to a physically realizable radiation field outside the surface S. If this is so and if the point x is formally set to a point inside the enclosed volume, then analogous mathematics involving the properties of the Green's function leads to the deduction [3.80, 81]

$$\mathfrak{M}(x_{\text{inside}}, \hat{p}_S, \hat{f}_S) = 0 , \qquad (3.564)$$

which is a general relation between the surface value functions $\hat{p}_S$ and $\hat{f}_S$, holding for any choice of the point x inside the enclosed volume.

Equation (3.562) allows one to derive two additional relations (distinguished by the subscripts I and II) between the surface values of $\hat{p}_S$ and $\hat{f}_S$. One results when the off-surface point x is allowed to approach an arbitrary but fixed surface point x_S. For one of the terms in the integral defining the quantity $\mathfrak{M}$, the limit as x approaches x_S of the integral is not the same as the integral over the limit of the integrand as x approaches x_S. With

this subtlety taken into account, one obtains

$$\hat{p}_S(x_S) - \mathcal{L}_I(x_S, \hat{p}_S) = \mathfrak{H}_I(x_S, \hat{f}_S) \,, \tag{3.565}$$

where the two linear operators $\mathcal{L}_I$ and $\mathfrak{H}_I$ are

$$\mathcal{L}_I(x_S, \hat{p}_S)$$
$$= \frac{1}{2\pi} \int \hat{p}(x'_S) n(x'_S) [\nabla' G(x_S|x')]_{x'=x'_S} \, dS' \,, \tag{3.566}$$

$$\mathfrak{H}_I(x_S, \hat{f}_S)$$
$$= \frac{1}{2\pi} \int \hat{f}(x'_S) G(x'_S|x_S) \, dS' \,. \tag{3.567}$$

These linear operators operate on the surface values of $\hat{p}_S$ and $\hat{f}_S$, respectively, with the result in each case being a function of the position of the surface point x_S.

The second type of surface relationship [3.82] is obtained by taking the gradient of both sides of (3.562), subsequently setting x to $x_S + \epsilon n(x_S)$, where x_S is an arbitrary point on the surface, taking the dot product with $n(x_S)$, then taking the limit as ϵ goes to zero. The order of the processes, doing the integration and taking the limit, cannot be blindly interchanged, and some mathematical manipulations making use of the properties of the Green's function are necessary before one can obtain a relation in which all integrations are performed after all necessary limits are taken. The result

is

$$-\mathcal{L}_{II}(x_S, \hat{p}_S) = \hat{f}_S(x_S) + \mathfrak{H}_{II}(x_S, \hat{f}_S) \,, \tag{3.568}$$

where the relevant operators are as given by

$$\mathcal{L}_{II}(x, \hat{p}_S) = [n(x_S) \times \nabla] \cdot \frac{1}{2\pi} \int [n(x'_S) \times \nabla' \hat{p}_S(x'_S)]$$
$$\times G(x_S|x'_S) \, dS' + \frac{k^2}{2\pi}$$
$$\times \int n(x_S) \cdot n(x'_S) \hat{p}_S(x'_S) G(x_S|x'_S) \, dS' \,, \tag{3.569}$$

$$\mathfrak{H}_{II}(x_S, \hat{f}_S) = \frac{1}{2\pi} \int \hat{f}_S(x'_S) n(x_S)$$
$$\times [\nabla G(x|x'_S)]_{x=x_S} \, dS' \,. \tag{3.570}$$

With regard to (3.569), one should note that the operator $n(x_S) \times \nabla$ involves only derivatives tangential to the surface, so that the integral on which it acts needs only be evaluated at surface points x_S.

A variety of numerical techniques have been used and discussed in recent literature to solve either (3.564), (3.565), or (3.568), or some combination [3.83] of these for the surface pressure $\hat{p}_S$, given the surface force function $\hat{f}_S$. Once this is done, the radiation field at any external point x is found by numerical integration of the corollary integral relation of (3.562).

3.15 Waveguides, Ducts, and Resonators

External boundaries can channel sound propagation, and in some cases can create a buildup of acoustic energy within a confined space.

3.15.1 Guided Modes in a Duct

Pipes or ducts act as guides of acoustic waves, and the net flow of energy, other than that associated with wall dissipation, is along the direction of the duct. The general theory of guided waves applies and leads to a representation in terms of guided modes.

If the duct axis is the x-axis and the duct cross section is independent of x, the guided mode series [3.4,84] has the form

$$\hat{p} = \sum_n X_n(x) \Psi_n(y, z) \,, \tag{3.571}$$

where the $\Psi_n(y, z)$ are eigenfunctions of the equation

$$\left(\frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \Psi_n + \alpha_n^2 \Psi_n = 0 \,, \tag{3.572}$$

with the α_n^2 being the corresponding eigenvalues. The appropriate boundary condition, if the duct walls are idealized as being perfectly rigid, is that the normal component of the gradient of Ψ_n vanishes at the walls. Typically, the Ψ_n are required to conform to some normalization condition, such as

$$\int \Psi_n^2 \, dA = A \,, \tag{3.573}$$

where A is the duct cross-sectional area.

The general theory leads to the conclusion that one can always find a complete set of Ψ_n, which with the
Fig. 3.41 Generic sketch of a duct that carries guided sound waves

rigid wall boundary condition imposed, are such that the cross-sectional eigenfunctions are orthogonal, so that

$$\int \Psi_n \Psi_m \, dA = 0 \tag{3.574}$$

if n and m correspond to different guided modes. The eigenvalues α_n^2, moreover, are all real and nonnegative. However, for cross sections that have some type of symmetry, it may be that more than one linearly independent eigenfunction Ψ_n (modes characterized by different values of the index n) correspond to the same numerical value of α_n^2. In such cases the eigenvalue is said to be degenerate.

The variation of guided mode amplitudes with source excitation is ordinarily incorporated into the axial wave functions $X_n(x)$, which satisfy the one-dimensional Helmholtz equation

$$\frac{d^2 X_n}{dx^2} + (k^2 - \alpha^2) X_n = 0 . \tag{3.575}$$

Here $k = \omega/s$ is the free-space wavenumber. The form of the solution depends on whether α_n^2 is greater or less than k^2. If $\alpha_n^2 < k^2$, the mode is said to be a propagating mode and the solution for X_n is given by

$$X_n = A_n e^{ik_n x} + B_n e^{-ik_n x} , \tag{3.576}$$

where the k_n, defined by

$$k_n = (k^2 - \alpha_n^2)^{1/2} , \tag{3.577}$$

are the modal wavenumbers. However, if the value of α_n^2 is greater than k^2, the mode is evanescent (not prop-
Fig. 3.42 Cylindrical duct

agating), and one has

$$X_n = A_n e^{-\beta_n x} + B_n e^{\beta_n x} , \tag{3.578}$$

where β_n is given by

$$\beta_n = \left(\alpha_n^2 - k^2 \right)^{1/2} . \tag{3.579}$$

Unless the termination of the duct is relatively close to the source, waves that grow exponentially with distance from the source are not meaningful, so only the term that corresponds to exponentially dying waves is ordinarily kept in the description of sound fields in ducts.

3.15.2 Cylindrical Ducts

For a duct with circular cross section and radius a, the index n is replaced by an index set (q, m, s), and the eigenfunctions Ψ_n are described by

$$\Psi_n = K_{qm} J_m \left(\frac{\eta_{qm} w}{a} \right) \begin{Bmatrix} \cos m\phi \\ \sin m\phi \end{Bmatrix} . \tag{3.580}$$
Here either the cosine ($s = 1$) or the sine ($s = -1$) corresponds to an eigenfunction. The quantities K_{qm} are normalization constants, and the J_m are Bessel functions of order m. The corresponding eigenvalues are given by

$$\alpha_n = \eta_{qm}/a , \tag{3.581}$$

where the η_{qm} are the zeros of $\eta J_m'(\eta)$, arranged in ascending order with the index q ranging upwards from 1. The smaller roots [3.85] for the axisymmetric modes are $\eta_{1,0} = 0.00$, $\eta_{2,0} = 3.83171$, and $\eta_{3,0} = 7.01559$, while those corresponding to $m = 1$ are $\eta_{1,1} = 1.84118$, $\eta_{2,1} = 5.33144$, and $\eta_{3,1} = 8.53632$.

3.15.3 Low–Frequency Model for Ducts

In many situations of interest, the frequency of the acoustic disturbance is so low that only one guided mode can propagate, and all other modes are evanescent. Given that the walls can be idealized as rigid, there is always one mode that can propagate, this being the

Fig. 3.43 Volume velocity in a duct

Fig. 3.44 Two dissimilar ducts with a junction modeled as a continuous volume velocity two-port. The difference in pressures is related to the volume velocity by the junction impedance

plane wave mode for which the eigenvalue α_0 is identically zero. The other modes will all be evanescent if the value of k is less than the corresponding α_n for each such mode. This would be so if the frequency is less than the lowest cutoff frequency for any of the nonplanar modes. For the circular duct case discussed above, for example, this would require that the inequality,

$$f < \frac{1.84118}{2\pi} \frac{c}{a} , \qquad (3.582)$$

be satisfied.

When the single-guided-mode assumption is valid, and even if the duct cross-sectional area should vary with distance along the duct, the acoustic field equations can be replaced to a good approximation by the acoustic transmission-line equations,

$$\frac{\partial p}{\partial t} + \frac{\rho c^2}{A} \frac{\partial U}{\partial x} = 0 , \qquad (3.583)$$

$$\rho \frac{\partial U}{\partial t} = -A \frac{\partial p}{\partial x} . \qquad (3.584)$$

Here U, equal to Av_x, is the volume velocity, the volume of fluid passing through the duct per unit time.

One of the implications of the low-frequency model described by (3.583) and (3.584) is that the volume velocity and the pressure are both continuous, even when the duct has a sudden change in cross-sectional area. The pressure continuity assumption is not necessarily a good approximation, but becomes better with decreasing frequency. An improved model (continuous volume-velocity two-port) takes the volume velocities on both sides of the junction as being equal, and sets the difference of the complex amplitudes of the upstream and downstream pressures just ahead and after the junction to

$$\hat{p}_{\text{ahead}} - \hat{p}_{\text{after}} = Z_J \hat{U}_{\text{junction}} , \qquad (3.585)$$

where the junction's acoustic impedance Z_J is taken in the simplest approximation as $-\mathrm{i}\omega M_{A,J}$, and where

$M_{A,J}$ is a real number independent of frequency that is called the acoustic inertance of the junction. Approximate expressions for this acoustic inertance can be found in the literature [3.78,86–88]; a simple rule is that it is ordinarily less than $8\rho/3A_{\min}$, where $A_{\min}$ is the smaller of the two cross-sectional areas. One may note, moreover, that Z_J goes to zero when the frequency goes to zero.

When an incident wave is incident at a junction, reflected and transmitted waves are created in the two ducts. The pressure amplitude reflection and transmission coefficients are given by
$$\mathfrak{R} = \frac{Z_J + \rho c/A_2 - \rho c/A_1}{Z_J + \rho c/A_2 + \rho c/A_1} , \qquad (3.586)$$

$$\mathfrak{T} = \frac{2\rho c/A_2}{Z_J + \rho c/A_2 + \rho c/A_1} . \qquad (3.587)$$

At sufficiently low frequencies, these are further approximated by replacing Z_J by zero.

3.15.4 Sound Attenuation in Ducts

The presence of the duct walls affects the attenuation of sound and usually causes the attenuation coefficient to be much higher than for plane waves in open space.

Fig. 3.45 Geometrical parameters pertaining to acoustic attenuation in a duct. The total length L_P around the perimeter gives the transverse extent of the dissipative boundary layer at the duct wall

A simple theory for predicting this attenuation uses the concepts of acoustic, entropy, and vorticity modes, as is indicated by the decomposition of (3.89) in a previous section of this chapter. The entropy and vorticity mode fields exist in an acoustic boundary layer near the duct walls and are such that they combine with the acoustic mode field to satisfy the appropriate boundary conditions at the walls.

With viscosity and thermal conduction thus taken into account in the acoustic boundary layer, and with the assumption that the duct walls are much better heat conductors than the fluid itself, the approximate attenuation coefficient for the plane wave guided mode is given by [3.89]

$$\alpha = \alpha_{\text{walls}}$$
$$= \left(\frac{\omega}{8\rho c^2}\right)^{1/2}\left[\mu^{1/2} + (\gamma - 1)(\kappa/c_{\text{p}})^{1/2}\right]\frac{L_{\text{P}}}{A},$$
$$(3.588)$$

where L_{P} is the length of the perimeter of the duct cross section.

A related effect [3.90] is that sound travels slightly slower in ducts than in an open environment. The complex wavenumber corresponding to propagation down the axis of the tube is approximately

$$k \approx \frac{\omega}{c} + (1+\mathrm{i})\alpha_{\text{walls}},$$
$$(3.589)$$

and the phase velocity is consequently approximately

$$v_{\text{ph}} = \frac{\omega}{k_{\text{R}}} \approx c - \frac{c^2\alpha_{\text{walls}}}{\omega}.$$
$$(3.590)$$

For a weakly attenuated and weakly dispersive wave, the group velocity [3.74], the speed at which energy travels, is approximately

$$v_{\text{gr}} \approx \left(\frac{\mathrm{d}k_{\text{R}}}{\mathrm{d}\omega}\right)^{-1},$$
$$(3.591)$$

so, for the present situation,

$$v_{\text{gr}} \approx c - \frac{c^2\alpha_{\text{walls}}}{2\omega}.$$
$$(3.592)$$

Thus both the phase velocity and the group velocity are less than the nominal speed of sound.

3.15.5 Mufflers and Acoustic Filters

The analysis of mufflers [3.91, 92] is often based on the idealization that their acoustic transmission characteristics are independent of sound amplitudes, so they act as linear devices. The muffler is regarded as an insertion into a duct, which reflects waves back toward the source and which alters the transmission of sound beyond the muffler. The properties of the muffler vary with frequency, so the theory analyzes the muffler's effects on individual frequency components. The frequency is assumed to be sufficiently low that only the plane wave mode propagates in the inlet and outlet ducts. Because of the assumed linear behavior of the muffler, and the single-mode assumption, the muffler conforms to the model of a linear two-port, the ports being the inlet and outlet. The model leads to the prediction that one may characterize the muffler at any given frequency by a matrix, such that

$$\begin{pmatrix} \hat{p}_{\text{in}} \\ \hat{p}_{\text{out}} \end{pmatrix} = \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix} \begin{pmatrix} \hat{U}_{\text{in}} \\ \hat{U}_{\text{out}} \end{pmatrix},$$
$$(3.593)$$

where the coefficients K_{ij} represent the acoustical properties of the muffler. Reciprocity [3.30] requires that the determinant of the matrix be unity. Also, for a symmetric muffler, K_{12} and K_{21} must be identical.

It is ordinarily a good approximation that the waves reflected at the entrance of the muffler back to the source are significantly attenuated, so that they have negligible amplitude when they return to the muffler. Similarly, the assumption that the waves transmitted beyond the muffler do not return to the muffler (anechoic termination)
Fig. 3.46 Sketch of a prototype muffler configuration. Point G is a point on the input side of the muffler, and point H is on the output side. The noise source is upstream on the input side, and the tailpipe is downstream on the output side

is ordinarily valid. With these assumptions, the insertion of the muffler causes the mean squared pressure downstream of the muffler to drop by a factor

$$\tau = \left(\frac{1}{4} |K_{11} + K_{22} + \frac{\rho c}{A} K_{21} + \frac{A}{\rho c} K_{12}|^2 \right)^{-1}, \tag{3.594}$$

where A is the cross section of the duct ahead of and behind the muffler.

Acoustic mufflers can be divided into two broad categories: reactive mufflers and dissipative mufflers. In a reactive muffler, the basic property of the muffler is that it reflects a substantial fraction of the incident acoustic energy back toward the source. The dissipation of energy within the muffler itself plays a minor role; the reflection is caused primarily by the geometrical characteristics of the muffler. In a dissipative muffler, however, a low transmission of sound is achieved by internal dissipation of acoustic energy within the muffler. Absorbing material along the walls is ordinarily used to achieve this dissipation.

3.15.6 Non–Reflecting Dissipative Mufflers

When a segment of pipe of cross section A and length L is covered with a duct lining material that attenuates the amplitude of traveling plane waves by a factor of $e^{-\alpha L}$,

**Fig. 3.47** Sketch of a nonreflective dissipative muffler

Fig. 3.48 Sketch of an expansion chamber muffler

the muffler's K-matrix is given by

$$K = \begin{pmatrix} \cos(kL + i\alpha L) & -i\frac{\rho c}{A} \sin(kL + i\alpha L) \\ -i\frac{A}{\rho c} \sin(kL + i\alpha L) & \cos(kL + i\alpha L) \end{pmatrix}, \tag{3.595}$$

so the fractional drop in mean squared pressure reduces to

$$\tau = e^{-2\alpha L}. \tag{3.596}$$

3.15.7 Expansion Chamber Muffler

The simplest reactive muffler is the expansion chamber, which consists of a duct of length L and cross section A_M connected at both ends to a pipe of smaller cross section A_P.

The K-matrix for such a muffler is found directly from (3.595) by setting α to zero (no dissipation in the chamber), but replacing A by A_M. The corresponding result for the fractional drop in mean squared pressure is

$$\tau = \left[\cos^2 kL + \frac{1}{4}(m + m^{-1})^2 \sin^2 kl \right]^{-1}, \tag{3.597}$$

where m is the expansion ratio A_M/A_P. The relative reduction in mean square pressure is thus periodic with frequency. A maximum reduction occurs when the length L is an odd multiple of quarter-wavelengths. The greatest reduction in mean squared pressure is when τ has its minimum value, which is that given by

$$\tau = \frac{4}{(m + m^{-1})^2}. \tag{3.598}$$

3.15.8 Helmholtz Resonators

An idealized acoustical system [3.47, 93] that is the prototype of commonly encountered resonance phenomena

Fig. 3.49 Sketch of a Helmholtz resonator, showing the characteristic parameters involved in the analysis

consists of a cavity of volume V with a neck of length ℓ and cross-sectional area A.

In the limit where the acoustic frequency is sufficiently low that the wavelength is much larger than any dimension of the resonator, the compressible fluid in the resonator acts as a spring with spring constant

$$k_{sp} = \frac{\rho c^2 A^2}{V} ,\tag{3.599}$$

and the fluid in the neck behaves as a lumped mass of magnitude

$$m = \rho A \ell' .\tag{3.600}$$

Here ℓ' is ℓ plus the end corrections for the two ends of the neck. If ℓ is somewhat larger than the neck radius a, and if both ends are terminated by a flange, then the two end corrections are each $0.82a$. (The determination of end corrections has an extensive history; a discussion can be found in the text by the author [3.30].) The resonance frequency ω_r, in radians per second, of the resonator is given by

$$\omega_r = 2\pi f_r = (k_{sp}/m)^{1/2} = (M_A C_A)^{-1/2} ,\tag{3.601}$$

where

$$M_A = \rho \ell'/S\tag{3.602}$$

gives the acoustic inertance of the neck and

$$C_A = V/\rho c^2\tag{3.603}$$

gives the acoustic compliance of the cavity. The ratio of the complex pressure amplitude just outside the mouth of the neck to the complex volume velocity amplitude of flow into the neck is the acoustic impedance Z_{HR} of the Helmholtz resonator and given, with the neglect of damping, by

$$Z_{HR} = -i\omega M_A + \frac{1}{-i\omega C_A} ,\tag{3.604}$$

which vanishes at the resonance frequency.

If a Helmholtz resonator is inserted as a side branch into the wall of a duct, it acts as a reactive muffler that has a high insertion loss near the resonance frequency of the resonator. The analysis assumes that the acoustic pressures in the duct just before and just after the

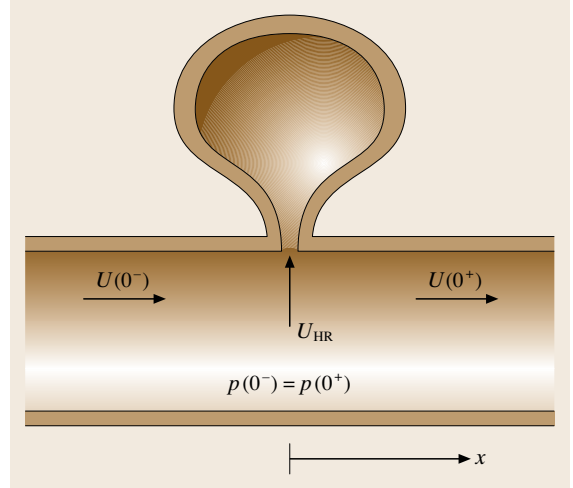

Fig. 3.50 Helmholtz resonator as a side-branch in a duct

resonator are the same as the pressure at the mouth of the resonator. Also, the acoustical analog of Kirchhoff's circuit law for currents applies, so that the volume velocity flowing in the duct ahead of the resonator equals the sum of the volume velocities flowing into the resonator and through the duct just after the resonator. These relations, with (3.604), allow one to work out expressions for the amplitude reflection and transmission coefficients at the resonator, the latter being given by

$$\mathfrak{T} = \frac{2Z_{HR}}{2Z_{HR} + \rho c/A_D} .\tag{3.605}$$

The fraction of incident power that is transmitted is consequently given by

$$\tau = \left(1 + \frac{1}{4\beta^2 (f/f_r - f_r/f)^2}\right)^{-1} ,\tag{3.606}$$

where β is determined by

$$\beta^2 = (M_A/C_A)(A_D/\rho c)^3 .\tag{3.607}$$

The fraction transmitted is formally zero at the resonance frequency, but if β is large compared with unity, the bandwidth over which the drop in transmitted power is small is narrow compared with f_r.

3.16 Ray Acoustics

When the medium is slowly varying over distances comparable to a wavelength and if the propagation dis-

tances are substantially greater than a wavelength, it is often convenient to regard acoustic fields as being car-

ried along rays. These can be regarded as lines or paths in space.

3.16.1 Wavefront Propagation

A wavefront is a hypothetical surface in space over which distinct waveform features are simultaneously received. The theory of plane wave propagation predicts that wavefronts move locally with speed c when viewed in a coordinate system in which the ambient medium appears at rest. If the ambient medium is moving with velocity $\boldsymbol{v}$, the wave velocity $c\boldsymbol{n}$ seen by someone moving with the fluid becomes $\boldsymbol{v} + c\boldsymbol{n}$ in a coordinate system at rest. Here $\boldsymbol{n}$ is the unit vector normal to the wavefront; it coincides with the direction of propagation if the coordinate system is moving with the local ambient fluid velocity $\boldsymbol{v}$. A ray can be defined [3.94] as the time trajectory of a point that is always on the same wavefront, and for which the velocity is

$$\boldsymbol{v}_{\text{ray}} = \boldsymbol{v} + \boldsymbol{n}c \, . \tag{3.608}$$

To determine ray paths without explicit knowledge of wavefronts, it is appropriate to consider a function $\tau(\boldsymbol{x})$, which gives the time at which the wavefront of interest passes the point $\boldsymbol{x}$. Its gradient $\boldsymbol{s}$ is termed the wave slowness vector and is related to the local wavefront
Fig. 3.51 Sketch illustrating the concept of a wavefront as a surface along which characteristic waveform features are simultaneously received. The time a given waveform passes a point $\boldsymbol{x}$ is $\tau(\boldsymbol{x})$ and the unit normal in the direction of propagation is $\boldsymbol{n}(\boldsymbol{x})$
Fig. 3.52 Multipaths and shadow zones. The situation depicted is when the sound speed decreases with distance above the ground so that rays are refracted upward

normal by the equations

$$\boldsymbol{s} = \frac{\boldsymbol{n}}{c + \boldsymbol{v} \cdot \boldsymbol{n}} \, , \tag{3.609}$$

$$\boldsymbol{n} = \frac{c\boldsymbol{s}}{\Omega} \, , \tag{3.610}$$

where the quantity Ω is defined by

$$\Omega = 1 - \boldsymbol{v} \cdot \boldsymbol{s} \, . \tag{3.611}$$

Given the concepts of ray position and the slowness vector, a purely kinematical derivation leads to the ray-tracing equations

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = \frac{c^2 \boldsymbol{s}}{\Omega} + \boldsymbol{v} \, , \tag{3.612}$$

$$\frac{\mathrm{d}\boldsymbol{s}}{\mathrm{d}t} = -\frac{\Omega}{c} \nabla c - (\boldsymbol{s} \cdot \nabla)\boldsymbol{v} - \boldsymbol{s} \times (\nabla \times \boldsymbol{v}) \, . \tag{3.613}$$

Simpler versions result when there is no ambient flow, or when the ambient variables vary with only one coordinate. If the ambient variables are independent of position, then the ray paths are straight lines.

The above equations are often used for analysis of propagation through inhomogeneous media (moving or nonmoving) when the ambient variables do not vary significantly over distances of the order of a wavelength, even though they may do so over the total propagation distance. The rays that connect the source and listener locations are termed the eigenrays for that situation. If there is more than one eigenray, one has multipath reception. If there is no eigenray, then the listener is in a shadow zone.

3.16.2 Reflected and Diffracted Rays

This theory is readily extended to take into account solid boundaries and interfaces. When an incident ray strikes a solid boundary, a reflected ray is generated whose

direction is determined by the trace velocity matching principle, such that angle of incidence equals angle of reflection. At an interface a transmitted ray is also generated, whose direction is predicted by Snell's law.

An extension of the theory known as the geometrical theory of diffraction and due primarily to *Keller* [3.95] allows for the possibility that diffracting edges can be a source of diffracted rays which have a multiplicity of directions. The allowable diffracted rays must have the same trace velocity along the diffracting edge as does the incident ray.

The ray paths connecting the source and listener satisfy *Fermat*'s principle [3.96], that the travel time along an actual eigenray is stationary relative to other geometrically admissible paths. *Keller*'s geometrical theory of diffraction [3.95] extends this principle to include paths which have discontinuous directions and which may have portions that lie on solid surfaces.

3.16.3 Inhomogeneous Moving Media

Determination of the amplitude variation along ray paths requires a more explicit use of the equations of linear acoustics. If there is no ambient fluid velocity then an appropriate wave equation is (3.73). When there is also an ambient flow present then an appropriate generalization [3.97, 98] for the acoustic mode is

$$\frac{1}{\rho}\nabla\cdot(\rho\nabla\Phi) - D_t\left(\frac{1}{c^2}D_t\Phi\right) = 0 \ . \tag{3.614}$$

Here D_t, defined by

$$D_t = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla \tag{3.615}$$

is the time derivative following the ambient flow. The dependent variable Φ is related to the acoustic pressure perturbation by

$$p = -\rho D_t\Phi \ . \tag{3.616}$$

This wave equation is derived from the linear acoustics equations for circumstances when the ambient variables vary slowly with position and time and neglects terms of second order in $1/\omega T$ and $c/\omega L$, where ω is a characteristic frequency of the disturbance, T is a characteristic time scale for temporal variations of the ambient quantities, and L is a characteristic length scale for spatial variations of these approximations. The nature of the entailed approximations is consistent with the notion that geometrical acoustics is a high-frequency approximation and yields results that are the same in the high-frequency limit as would be derived from the complete set of linear acoustic equations.

3.16.4 The Eikonal Approximation

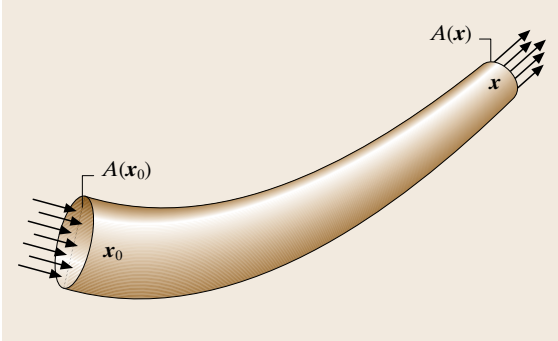
The equations of geometrical acoustics follow [3.99] from (3.614), if one sets the potential function Φ equal to the expression

$$\Phi(\boldsymbol{x}, t) = \Psi(\boldsymbol{x})F(t - \tau) \ . \tag{3.617}$$

Here the function F is assumed to be a rapidly varying function of its argument. The quantities Ψ and τ vary only with position. (It is assumed here that the ambient variables do not vary with time.)

When such a substitution is made, one obtains terms that involve the second, first, and zeroth derivatives of the function F. The geometrical acoustics or eikonal approximation results when one requires that the coefficients of F'' and F' both vanish identically, and thus assumes that the terms involving undifferentiated F are of lesser importance in the high-frequency limit. The setting to zero of the coefficient of the second derivative yields

$$(1 - \boldsymbol{v}\cdot\nabla\tau)^2 = c^2 (\nabla\tau)^2 \ , \tag{3.618}$$

which is termed the eikonal equation [3.100, 101]. The setting to zero of the coefficient of the first derivative yields


$$\nabla\cdot\left\{\frac{\rho\Psi^2}{c^2}\left[c^2\nabla\tau + (1 - \boldsymbol{v}\cdot\nabla\tau)\boldsymbol{v}\right]\right\} = 0 \ , \tag{3.619}$$

which is termed the transport equation. The convenient property of these equations is that they are independent of the nature of the waveform function F.

The eikonal equation, which is a nonlinear first-order partial differential equation for the eikonal $\tau(\boldsymbol{x})$ can be solved by Cauchy's method of characteristics, with $\boldsymbol{s} = \nabla\tau$. What results are the ray-tracing equations (3.612) and (3.613). However, the time variable t is replaced by the eikonal τ. The manner in which these equations solve the eikonal equation is such that if τ and its gradient $\boldsymbol{s}$ are known at any given point then the ray-tracing equations determine these same quantities at all other points on the ray that passes through this initial point. The initial value of $\boldsymbol{s}$ must conform to the eikonal equation itself, as is stated in (3.618). If this is so, then the ray-tracing equations insure that it conforms to the same equation, with the appropriate ambient variables, all along the ray.

Solution of the transport equation, given by (3.619), is facilitated by the concept of a ray tube. One conceives

Fig. 3.53 Sketch of a ray tube. Here x_0 and x are two points on the central ray

Fig. 3.54 Rectilinear propagation of sound. The wavefront at any point has two principal radii of curvature, which change with the propagation distance. In the case shown, the wavefront at the left is such that it is convex, with two different focal lengths, r_1 and r_2, these being the two radii of curvature. Over a short propagation distance ℓ, these reduce to $r_1 - \ell$ and $r_2 - \ell$

of a family of adjacent rays which comprise a narrow tube of cross-sectional area A, this area varying with distance ℓ along the path of the central ray of the tube. Then the transport equation reduces to

$$\frac{\mathrm{d}}{\mathrm{d}\ell}\left(A\frac{\rho\Psi^2}{c^2}\Omega v_{\mathrm{ray}}\right) = 0 \,, \tag{3.620}$$

so the quantity in brackets is constant along the ray tube.

Alternately, the relation of (3.616) implies that the acoustic pressure is locally given to an equivalent approximation by

$$p = P(\boldsymbol{x})f(t - \tau) \,, \tag{3.621}$$

where f is the derivative of F, and P is related to Ψ by

$$P = -\rho\Omega\Psi \,. \tag{3.622}$$

Then the transport equation (3.619) requires that

$$B = \frac{A\,P^2 v_{\mathrm{ray}}}{\rho c^2 \Omega} \tag{3.623}$$

be constant along a ray tube, so that

$$\frac{\mathrm{d}B}{\mathrm{d}\ell} = 0 \,. \tag{3.624}$$

This quantity B is often referred to as the Blokhintzev invariant.

If there is no ambient flow then the constancy of B along a ray tube can be regarded as a statement that the average acoustic power flowing along the ray tube is constant, for a constant-frequency disturbance, or in general that the power appears constant along a trajec-

tory moving with the ray velocity. The interpretation when there is an ambient flow is that the wave action is conserved [3.102].

Geometrical acoustics (insofar as amplitude prediction is concerned) breaks down at caustics, which are surfaces along which the ray tube areas vanish. Modified versions [3.103, 104] involving Airy functions and higher transcendental functions, of the geometrical acoustics theory have been derived which overcome this limitation.

3.16.5 Rectilinear Propagation of Amplitudes

A simple but important limiting case of geometrical acoustics is for propagation in homogeneous nonmoving media. The rays are then straight lines and perpendicular to wavefronts. A given wavefront has two principal radii of curvature, R_{I} and R_{II}. With the convention that these are positive when the wavefront is concave in the corresponding direction of principal curvature, and negative when it is convex, the curvature radii increase by a distance ℓ when the wave propagates through that distance. The ray tube area is proportional to the product of the two curvature radii, so the acoustic pressure varies with distance ℓ along the ray as

$$p = \left(\frac{R_{\mathrm{I}}R_{\mathrm{II}}}{(R_{\mathrm{I}}+\ell)(R_{\mathrm{II}}+\ell)}\right)^{1/2} f[t - (\ell/c)] \,. \tag{3.625}$$

Here R_{I} and R_{II} are the two principal radii of curvature when ℓ is zero. The relations (3.326) and (3.447) for spherical and cylindrical spreading are both limiting cases of this expression.

3.17 Diffraction

The bending of sound around corners or around objects into shadow zones is typically referred to as diffraction. The prototype for problems of diffraction around an edge is that of a plane wave impinging on a rigid half-plane (knife edge). The problem was solved exactly by *Sommerfeld* [3.105], and the solution has subsequently been rederived by a variety of other methods. The present chapter considers a generalization of this problem where a point source is near a rigid wedge. The Sommerfeld problem emerges as a limiting case.

3.17.1 Posing of the Diffraction Problem

The geometry adopted here is such that the right surface of the wedge occupies the region where $y = 0$ and $x > 0$; the diffracting edge is the z-axis. A cylindrical coordinate system is used where w is the radial distance from the z axis and where ϕ is the polar angle measured counterclockwise from the x-axis. The other surface of the wedge is at $\phi = \beta$, where $\beta > \pi$. The region occupied by the wedge has an interior angle of $2\pi - \beta$.

One seeks solutions of the inhomogeneous wave equation

$$\nabla^2 p - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = -4\pi S(t)\delta(\boldsymbol{x} - \boldsymbol{x_0}) \tag{3.626}$$

for the region

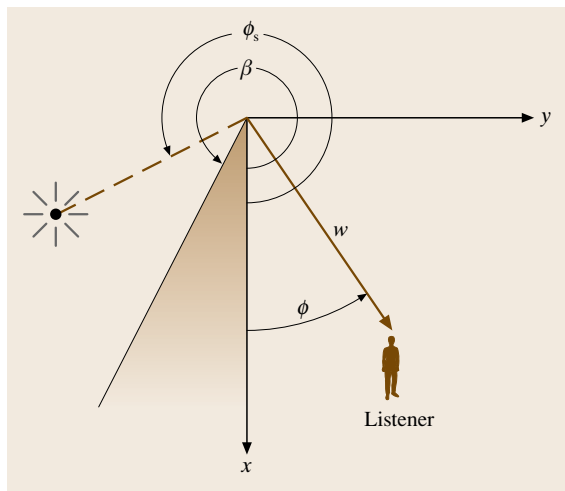
$$0 < \phi < \beta\,; \quad w \geq 0\,; \quad -\infty < z < \infty\,. \tag{3.627}$$


Fig. 3.55 Coordinate system and angles associated with the diffraction of sound by a wedge

The point source is located at $w = w_S$, $\phi = \phi_S$, and $z = 0$. It is assumed that the source is on the back side, so that $\phi_S > \pi$. (A person on the front face of the wedge should not be able to see the source.)

The quantity $S(t)$ is the time-dependent source strength, so that the transient acoustic pressure field near the source has a singular part given by

$$p \approx \frac{S\left[t - (R_D/c)\right]}{R_D}\,, \tag{3.628}$$

where R_D is the direct distance from the source,

$$R_D = \Big[(w\cos\phi - w_S\cos\phi_S)^2 \\ + (w\sin\phi - w_S\sin\phi_S)^2 + z^2\Big]^{1/2}\,, \tag{3.629}$$

or

$$R_D = \left[w^2 + w_S^2 - 2ww_S\cos(\phi - \phi_S) + z^2\right]^{1/2}\,. \tag{3.630}$$

Boundary conditions imposed by the rigid surfaces of the wedge are

$$\frac{\partial p}{\partial \phi} = 0 \quad \text{at} \quad \phi = 0 \quad \text{and at} \quad \phi = \beta\,. \tag{3.631}$$

There is also the requirement that the field at large radial distance w should represent an outgoing wave.

3.17.2 Rays and Spatial Regions

For the problem just posed, one can distinguish three regions, one where both a direct wave and a reflected

Fig. 3.56 Spatial regions associated with sound diffraction by a wedge

wave are possible, one where only the direct wave is possible, and one where neither the direct wave nor the reflected wave is possible. The borders of these two regions are the angles ϕ_A and ϕ_B, where

$$\phi_A = \phi_S - \pi ; \qquad \phi_B = 2\beta - \phi_S - \pi . \quad (3.632)$$

Reflected Wave Possible

In this region, characterized by the largest values of the azimuthal angle ϕ, the restriction is

$$\beta > \phi > \phi_B . \quad (3.633)$$

For such azimuthal angles, one can have an incident ray that hits the back side ($\phi = \beta$) of the wedge, reflects according to the law of mirrors, and then passes through the listener point. This reflected wave come from the image source location at $\phi = 2\beta - \phi_S$, $w = w_S$, $z = 0$. The path distance for this reflected wave arrival is

$$R_R = \left[w^2 + w_S^2 \right.$$
$$\left. -2ww_S \cos(\phi + \phi_S - 2\beta) + z^2 \right]^{1/2} . \quad (3.634)$$

The requirement that defines the border of this region is that any hypothetical straight line from the image source to the listener must pass through the back side of the wedge. Equivalently stated, there must be a reflection point on the back face of the wedge itself.

In this region, the geometrical acoustics (GA) portion of the acoustic pressure field is given by

$$p_{GA} = \frac{S\left[t - (R_D/c)\right]}{R_D} + \frac{S\left[t - (R_R/c)\right]}{R_R} . \quad (3.635)$$

Along the plane where $\phi = \phi_B$, the reflected path distance becomes

$$R_R \to L \quad \text{as} \quad \phi \to \phi_B , \quad (3.636)$$

where

$$L = \left[(w + w_0)^2 + z^2 \right]^{1/2} . \quad (3.637)$$

The discontinuity in the geometrical acoustics portion caused by the dropping of the reflected wave is consequently

$$p_{GA}(\phi_B + \epsilon) - p_{GA}(\phi_B - \epsilon) = \frac{S\left[t - (L/c)\right]}{L} . \quad (3.638)$$

Here the dependence of interest is that on the angular coordinate ϕ; the quantity ϵ is an arbitrarily small positive number.

Direct Wave, No Reflected Wave

This is the region of intermediate values of the azimuthal angle ϕ, where

$$\phi_B > \phi > \phi_A , \quad (3.639)$$

and the listener can still see the source directly, but the listener cannot see the reflection of the source on the backside of the wedge. There is a direct wave, but no reflected wave.

Here the geometrical acoustics (GA) portion of the acoustic pressure field is given by

$$p_{GA} = \frac{S\left[t - (R_D/c)\right]}{R_D} . \quad (3.640)$$

At the lower angular boundary ϕ_A of this region the direct wave propagation distance becomes

$$R_D \to L \quad \text{as} \quad \phi \to \phi_A , \quad (3.641)$$

where L is the same length as defined above in (3.637).

The discontinuity in the geometrical acoustics portion caused by the dropping of the incident wave is consequently

$$p_{GA}(\phi_A + \epsilon) - p_{GA}(\phi_A - \epsilon) = \frac{S\left[t - (L/c)\right]}{L} , \quad (3.642)$$

which is the same expression as for the discontinuity at ϕ_B.

No Direct Wave, No Reflected Wave

In this region, where

$$\phi_A > \phi > 0 , \quad (3.643)$$

the listener is in the true shadow zone and there is no geometrical acoustics contribution, so

$$p_{GA} = 0 . \quad (3.644)$$

3.17.3 Residual Diffracted Wave

The complete solution to the problem as posed above, for a point source outside a rigid wedge, is expressed with some generality as

$$p = p_{GA} + p_{diffr} . \quad (3.645)$$

The geometrical acoustics portion is as defined above; in one region it is a direct wave plus a reflected wave; in a second region it is only a direct wave; in a third region (shadow region) it is identically zero. The diffracted

wave is what is needed so that the sum will be a solution of the wave equation that satisfies the appropriate boundary conditions.

Whatever the diffracted wave is, it must have a discontinuous nature at the radial planes $\phi = \phi_A$ and $\phi = \phi_B$. This is because p_{GA} is discontinuous at these two values of ϕ and because the total solution should be continuous. Thus, one must require

$$p_{\text{diffr}}(\phi_B + \epsilon) - p_{\text{diffr}}(\phi_B - \epsilon) = -\frac{S\left[t - (L/c)\right]}{L} ,$$

(3.646)

$$p_{\text{diffr}}(\phi_A + \epsilon) - p_{\text{diffr}}(\phi_A - \epsilon) = -\frac{S\left[t - (L/c)\right]}{L} .$$

(3.647)

Also, except in close vicinity to these radial planes, the diffracted wave should spread out at large w as an outgoing wave. One may anticipate that, at large values
Fig. 3.57 Sketch supporting the geometrical interpretation of the parameter L as the diffracted ray length. The segment from source to edge makes the same angle γ with the edge as does the segment from edge to listener, and the sum of the two segment lengths is L

of w, the amplitude decreases with w as $1/\sqrt{w}$, as in cylindrical spreading.

Diffracted Path Length

In the actual solution given further below for the diffracted wave, a predominant role is played by the parameter L given by (3.637). This can be interpreted as the net distance from the source to the listener along the shortest path that touches the diffracting edge. This path can alternately be called the diffracted ray.

Such a path must touch the edge at a point where each of the two segments make the same angle with the edge. This is equivalent to a statement of Keller's law of geometrical diffraction [3.95]. Here, when the listener is at $z = z_L$, the source is at $z = 0$, and the edge is the z-axis, the z-coordinate where the diffracted path leaves the edge is $[w_S/(w_S + w_L)]z_L$. Thus one has

$$L = \frac{\left[w_S^2(w_S + w_L)^2 + w_0^2 z_L^2\right]^{1/2}}{w_S + w_L}$$
$$+ \frac{\left[w_L^2(w_S + w_L)^2 + w_L^2 z_L^2\right]^{1/2}}{w_S + w_L} .$$

(3.648)

The first term corresponds to the segment that goes from the source to the edge, while the second corresponds to the segment that goes from the edge to the listener. All this simplifies to

$$L = \left[(w_S + w)^2 + z^2\right]^{1/2} .$$

(3.649)

Here the listener z-coordinate is taken simply to be z, and its radial coordinate is taken simply to be w. The time interval L/c is the shortest time that it takes for a signal to go from the source to the listener via the edge.

As is evident from the discussion above of the discontinuities in the geometrical acoustics portion of the field, this diffracted wave path is the same as the reflected wave path on the radial plane $\phi = \phi_B$ and is the same as the direct wave path on the radial plane $\phi = \phi_A$.

There is another characteristic length that enters into the solution, this being

$$Q = \left[(w_S - w)^2 + z^2\right]^{1/2} .$$

(3.650)

It is a shorter length than L and is the distance from the source to a hypothetical point that has the same coordinates as that of the listener, except that the ϕ coordinate is the same as that of the source. These two quantities are related, so that

$$L^2 - Q^2 = 4w_S w ,$$

(3.651)

which is independent of the z-coordinate separation of the source and listener.

Satisfaction of Boundary Conditions

A function that satisfies the appropriate boundary conditions (3.631) can be built up from the functions

$$\sin(\nu x_q) \quad \text{and} \quad \cos(\nu x_q); \qquad q = 1, 2, 3, 4, \tag{3.652}$$

where

$$\nu = \frac{\pi}{\beta}, \tag{3.653}$$

$$\begin{aligned}
x_1 &= \pi + \phi + \phi_S = \phi - \phi_B + 2\beta, \\
x_2 &= \pi - \phi - \phi_S = -\phi - \phi_A, \\
x_3 &= \pi + \phi - \phi_S = \phi - \phi_A, \\
x_4 &= \pi - \phi + \phi_S = 2\beta - \phi_B - \phi.
\end{aligned} \tag{3.654}$$

The trigonometric functions that appear above are not periodic with period 2π in the angles ϕ and ϕ_S, so the definition must be restricted to ranges of these quantities between 0 and β.

The satisfaction of the boundary conditions at $\phi = 0$ and $\phi = \beta$ is achieved by any function of the general form

$$\sum_{q=1}^{4} \Psi(\cos x_q, \sin x_q), \tag{3.655}$$

where the function Ψ is an arbitrary function of two arguments. To demonstrate that the boundary condition at $\phi = 0$ is satisfied, it is sufficient to regard the function $\Psi(\cos x_q, \sin x_q)$ as only a function of x_q. One derives

$$\begin{aligned}
&\left(\frac{d}{d\phi} \sum_{q=1}^{4} \Psi(x_q) \right)_{\phi=0} \\
&= \{ \nu \Psi'[\nu(\pi + \phi_S)] - \Psi'[\nu(\pi - \phi_S)] \\
&\quad + \Psi'[\nu(\pi - \phi_S)] - \Psi'[\nu(\pi + \phi_S)] \} = 0.
\end{aligned} \tag{3.656}$$

The first and fourth terms cancel, and the second and third terms cancel.

The boundary condition at $\phi = \beta$, however, requires explicit recognition that the postulated function Ψ depends on x_q only through the two trigonometric functions. Both are periodic in ϕ with period 2β, because $\nu\beta = \pi$. Moreover, the sum of the first and fourth terms is periodic with period β, and the same is so for the sum of the second and third terms. The entire sum has this periodicity, so if the derivative with respect to ϕ vanishes at $\phi = 0$, it also has to vanish at $\phi = \beta$.

Discontinuities in the Diffraction Term

Two of the individual x_q defined above are such that $\cos(\nu x_q)$ is unity at one or the other of the two radial planes $\phi = \phi_A$ and $\phi = \phi_B$. One notes that

$$\cos(\nu x_3) = 1 \qquad \text{at} \quad \phi = \phi_A, \tag{3.657}$$

$$\cos(\nu x_1) = 1 \qquad \text{at} \quad \phi = \phi_B. \tag{3.658}$$

Near the radial plane $\phi = \phi_A = \phi_S - \pi$, one has

$$x_3 = \phi - \phi_A; \quad \cos(\nu x_3) \approx 1 - \frac{1}{2}(\nu^2)(\phi - \phi_A)^2;$$

$$\sin(\nu x_3) \approx (\nu)(\phi - \phi_A). \tag{3.659}$$

Similarly, near the radial plane $\phi = \phi_B = 2\beta - \phi_S - \pi$,

$$x_1 = 2\beta + \phi - \phi_B; \quad \cos(\nu x_1) \approx 1 - \frac{1}{2}(\nu^2)(\phi - \phi_B)^2;$$

$$\sin(\nu x_1) \approx (\nu)(\phi - \phi_B). \tag{3.660}$$

This behavior allows one to construct a discontinuous function of the generic form

$$U(\phi) = \sum_{q=1}^{4} \int_{L}^{\infty} \frac{M(\xi) \sin(\nu x_q)}{F(\xi) - \cos(\nu x_q)} \, d\xi, \tag{3.661}$$

where $M(\xi)$ and $F(\xi)$ are some specified functions of the dummy integration variable, such that $F \geq 1$, and $F = 1$ at only one value of ξ. This allows one to compute the discontinuity at ϕ_A, for example, as

$$U(\phi_A + \epsilon) - U(\phi_A - \epsilon)$$

$$= 2\nu\epsilon \int_{L}^{\infty} \frac{M(\xi)}{F(\xi) - 1 + \frac{1}{2}\nu^2\epsilon^2} \, d\xi, \tag{3.662}$$

where it is understood that one is to take the limit of $\epsilon \to 0$. The dominant contribution to the integration should come from the value of ξ at which $F = 1$. There are various possibilities where this limit is finite and nonzero. The one of immediate interest is where $F(L) = 1$, where the derivative is positive at $\xi = L$, and where M is singular as $1/(\xi - L)^{1/2}$ near $\xi = L$. For these circumstances the limit is

$$\lim_{\epsilon \to 0} [U(\phi_A + \epsilon) - U(\phi_A - \epsilon)]$$

$$= 4\pi \left(\frac{1}{2F'} \right)_L^{1/2} [(\xi - L)^{1/2} M]_L \tag{3.663}$$

where the subscript L implies that the indicated quantity is to be evaluated at $\xi = L$.

3.17.4 Solution for Diffracted Waves

The details [3.30, 106–111] that lead to the solution vary somewhat in the literature and are invariably intricate. The procedure typically involves extensive application of the theory of the functions of a complex variable. The following takes some intermediate results from the derivation in the present author's text [3.30] and uses the results derived above to establish the plausibility of the solution.

The diffracted field at any point depends linearly on the time history of the source strength, and the shortest time for source to travel as a diffracted wave from source to listener is L/c, so the principles of causality and linearity allow one to write, with all generality, the diffracted wave as

$$p_{\text{diffr}} = -\frac{1}{\beta} \int_{L}^{\infty} S\left(t - \frac{\xi}{c}\right) K_\nu(\xi) \, d\xi \,, \qquad (3.664)$$

where the function $K_\nu(\xi)$ depends on the positions of the source and listener, as well as on the angular width of the wedge. The factor $-1/\beta$ in front of the integral is for mathematical convenience.

The boundary conditions at the rigid wedge are satisfied if one takes the dependence on ϕ and ϕ_S to be of the form of (3.655). The proper jumps will be possible if one takes the general dependence on the trigonometric functions to be as suggested in (3.661). The appropriate identification (substantiated further below) is

$$K_\nu = \frac{1}{(\xi^2 - Q^2)^{1/2}} \frac{1}{(\xi^2 - L^2)^{1/2}}$$
$$\times \sum_{q=1}^{4} \frac{\sin(\nu x_q)}{\cosh \nu s - \cos(\nu x_q)} \,. \qquad (3.665)$$

The quantity s is a function of ξ, defined as

$$s = 2 \tanh^{-1} \left(\frac{\xi^2 - L^2}{\xi^2 - Q^2}\right)^{1/2} \,, \qquad (3.666)$$

so that

$$\xi^2 = L^2 + (L^2 - Q^2) \sinh^2(s/2) \,, \qquad (3.667)$$

$$\cosh \nu s$$
$$= \frac{1}{2} \left[\left(\frac{(\xi^2 - Q^2)^{1/2} - (\xi^2 - L^2)^{1/2}}{(\xi^2 - Q^2)^{1/2} + (\xi^2 - L^2)^{1/2}}\right)^\nu \right.$$
$$\left. + \left(\frac{(\xi^2 - Q^2)^{1/2} + (\xi^2 - L^2)^{1/2}}{(\xi^2 - Q^2)^{1/2} - (\xi^2 - L^2)^{1/2}}\right)^\nu \right] \,. \qquad (3.668)$$

That this solution has the proper jump behavior at ϕ_A and ϕ_B follows because, for ξ near L,

$$-\frac{1}{\beta} \frac{1}{(\xi^2 - Q^2)^{1/2}} \frac{1}{(\xi^2 - L^2)^{1/2}}$$
$$\rightarrow -\left(\frac{1}{\beta(L^2 - Q^2)^{1/2}(2L)^{1/2}}\right) \frac{1}{(\xi - L)^{1/2}} \,, \qquad (3.669)$$

$$\cosh \nu s \rightarrow 1 + \frac{4\nu^2 L}{L^2 - Q^2}(\xi - L) \,. \qquad (3.670)$$

The result in (3.663) consequently yields

$$p_{\text{diffr}}(\phi_A + \epsilon) - p_{\text{diffr}}(\phi_A - \epsilon)$$
$$= -\left(\frac{4\pi}{\beta(L^2 - Q^2)^{1/2}(2L)^{1/2}}\right) \left(\frac{(L^2 - Q^2)^{1/2}}{2\nu(2L)^{1/2}}\right)$$
$$\times S\left[t - (L/c)\right] = -\frac{S\left[t - (L/c)\right]}{L} \,, \qquad (3.671)$$

which is the same as required in (3.647).

(The solution has here been shown to satisfy the boundary conditions and the jump conditions. An explicit proof that the total solution satisfies the wave equation can be found in the text by the author [3.30].)

3.17.5 Impulse Solution

An elegant feature of the above transient solution is that no integration is required for the case when the source function is a delta function (impulse source). If

$$S(t) \rightarrow A\delta(t) \,, \qquad (3.672)$$

then the integration properties of the delta function yield

$$p_{\text{diffr}} \rightarrow -\frac{Ac}{\beta} H(ct - L) \frac{1}{(c^2 t^2 - Q^2)^{1/2}}$$
$$\times \frac{1}{(c^2 t^2 - L^2)^{1/2}} \sum_{q=1}^{4} \frac{\sin(\nu x_q)}{\cosh \nu s - \cos(\nu x_q)} \,, \qquad (3.673)$$

where $\cosh \nu s$ is as given by (3.668), but with ξ replaced by ct. The function $H(ct - L)$ is the unit step function, equal to zero when its argument is negative and equal to unity when its argument is positive.

(In recent literature, an equivalent version of this solution is occasionally referred to as the *Biot–Tolstoy* solution [3.111], although its first derivation was by *Friedlander* [3.110]. In retrospect, it is a simple deduction from the constant-frequency solution given by *MacDonald* [3.106], *Whipple* [3.107], *Bromwich* [3.108],

and *Carslaw* [3.109]. In the modern era with digital computers, where the numerical calculation of Fourier transforms is virtually instantaneous and routine, an explicit analytical solution for the impulse response is often a good starting point for determining diffraction of waves of constant frequency.)

3.17.6 Constant–Frequency Diffraction

The transient solution (3.664) above yields the solution for when the source is of constant frequency. One makes the substitution

$$S(t) \to \hat{S} e^{-i\omega t} \,, \tag{3.674}$$

and obtains

$$\hat{p}_{\text{diffr}} = -\frac{\hat{S}}{\beta} \int_L^\infty e^{ik\xi} K_\nu(\xi) \, d\xi \,. \tag{3.675}$$

The integral that appears here can be reduced to standard functions in various limits. A convenient first step is to change the integration variable to the parameter s, so that

$$\xi^2 = L^2 + (L^2 - Q^2) \sinh^2(s/2) \,, \tag{3.676}$$

$$\frac{d\xi}{[\xi^2 - Q^2]^{1/2} [\xi^2 - L^2]^{1/2}} = \frac{ds}{2\xi} \,, \tag{3.677}$$

and so that the range of integration on s is from 0 to ∞. One notes that the integrand is even in s, so that it is convenient to extend the integration from $-\infty$ to ∞, and then divide by two. Also, one can use trigonometric identities to combine the x_1 term with the x_2 term and to combine the x_3 term with the x_4 term. All this yields the result

$$\hat{p}_{\text{diffr}} = \frac{\hat{S} \sin \nu\pi}{2\beta} \sum_{+,-} \int_{-\infty}^\infty \frac{e^{ik\xi}}{\xi} F_\nu(s, \phi \pm \phi_S) \, ds \,, \tag{3.678}$$

where

$$F_\nu(s, \phi) = \frac{U_\nu(\phi) - J(\nu s) \cos \nu\phi}{J^2(\nu s) + 2J(\nu s) V_\nu^2(\phi) + U_\nu^2(\phi)} \,, \tag{3.679}$$

with the abbreviations

$$J(\nu s) = \cosh \nu s - 1 \,, \tag{3.680}$$

$$U_\nu(\phi) = \cos \nu\pi - \cos \nu\phi \,, \tag{3.681}$$

$$V_\nu(\phi) = (1 - \cos \nu\phi \cos \nu\pi)^{1/2} \,. \tag{3.682}$$

The requisite integrals exist, except when either $U_\nu(\phi + \phi_S)$ or $U_\nu(\phi - \phi_S)$ should be zero. The angles at which one or the other occurs correspond to boundaries between different regions of the diffracted field.

3.17.7 Uniform Asymptotic Solution

Although the integration in (3.678) can readily be completed numerically, considerable insight and useful formulas arise when one considers the limit when both the source and the listener are many wavelengths from the edge. One argues that the dominant contribution to the integration comes from values of s that are close to 0 (where the phase of the exponential is stationary), so one approximates

$$\xi \to L + \frac{(L^2 - Q^2)}{8L} s^2 = L + \frac{\pi}{2k} \Gamma^2 s^2 \,, \tag{3.683}$$

$$\frac{e^{ik\xi}}{\xi} \to \frac{e^{ikL}}{L} e^{i(\pi/2)\Gamma^2 s^2} \,, \tag{3.684}$$

$$J(\nu s) = \cosh \nu s - 1 \to \frac{\nu^2}{2} s^2 \,, \tag{3.685}$$

$$F_\nu(s, \phi) \to \frac{U_\nu(\phi)}{U_\nu^2(\phi) + \nu^2 V_\nu^2(\phi) s^2} \,,$$
$$= \frac{1}{2\nu V_\nu(\phi)} \left(\frac{1}{M_\nu(\phi) + is} + \frac{1}{M_\nu(\phi) - is} \right) \,. \tag{3.686}$$

The expression (3.686) uses the abbreviation

$$M_\nu(\phi) = \frac{U_\nu(\phi)}{\nu V_\nu(\phi)} = \frac{\cos \nu\pi - \cos \nu\phi}{\nu (1 - \cos \nu\phi \cos \nu\pi)^{1/2}} \,, \tag{3.687}$$

while (3.684) uses the abbreviation

$$\Gamma^2 = k \frac{(L^2 - Q^2)}{4\pi L} = \frac{k w w_S}{\pi L} \,, \tag{3.688}$$

where the latter version follows from the definitions (3.649) and (3.650).

One also notes that the symmetry in the exponential factor allows one to identify

$$\int_{-\infty}^\infty \frac{e^{i(\pi/2)\Gamma^2 s^2}}{M_\nu + is} \, ds = \int_{-\infty}^\infty \frac{e^{i(\pi/2)\Gamma^2 s^2}}{M_\nu - is} \, ds \,, \tag{3.689}$$

so the number of required integral terms is halved. A further step is to change the the integration variable to

$$u = (\pi/2)^{1/2} \Gamma e^{-i\pi/4} s \,. \tag{3.690}$$

All this results in the uniform asymptotic expression

$$\hat{p}_{\text{diffr}} = \hat{S} \frac{e^{ikL}}{L} \frac{e^{i\pi/4}}{\sqrt{2}} \sum_{+,-} \frac{\sin \nu\pi}{V_\nu(\phi \pm \phi_S)}$$
$$\times A_D \left[\Gamma M_\nu(\phi \pm \phi_S) \right] \tag{3.691}$$

for the diffracted wave. Here one makes use of the definition

$$A_D(X) = \frac{1}{\pi 2^{1/2}} \int_{-\infty}^{\infty} \frac{e^{-u^2} \, du}{(\pi/2)^{1/2} X - e^{-i\pi/4} u} , \tag{3.692}$$

of a complex-valued function of a single real variable. The properties of this function are discussed in detail below.

3.17.8 Special Functions for Diffraction

The diffraction integral (3.692) is a ubiquitous feature in diffraction theories. It changes sign,

$$A_D(-X) = -A_D(X) , \tag{3.693}$$

when its argument X changes sign (as can be demonstrated by changing the integration variable to $-u$ after changing the sign of X). The function is complex, so one can write in general

$$A_D(X) = \text{sign}(X) \left[f(|X|) - i g(|X|) \right] , \tag{3.694}$$

where the functions f and g (referred to as the auxiliary Fresnel functions) represent the real and negative imaginary parts of $A_D(|X|)$.

To relate $A_D(X)$ to the often encountered Fresnel integrals, one makes use of the identity (with $\zeta = (\pi/2)^{1/2}|X|$ being positive)

$$\frac{1}{\zeta - e^{-i\pi/4} u} = e^{-i\pi/4} \int_0^{\infty} \exp[i(\zeta e^{i\pi/4} - u)q] \, dq . \tag{3.695}$$

Then, one has

$$\int_{-\infty}^{\infty} \frac{e^{-u^2} \, du}{\zeta - e^{-i\pi/4} u}$$
$$= e^{-i\pi/4} e^{-i\zeta^2} \int_0^{\infty} e^{-y^2} \left(\int_{-\infty}^{\infty} e^{-(u+iq/2)^2} \, du \right) dq , \tag{3.696}$$

with the abbreviation $y = q/2 + e^{-i\pi/4}\zeta$. The inner integral over u yields $\sqrt{\pi}$, and one sets

$$\int_0^{\infty} e^{-y^2} \, dq = 2 \int_{\zeta e^{-i\pi/4}}^{\infty} e^{-y^2} \, dy$$
$$= 2 \int_{\zeta e^{-i\pi/4}}^{0} e^{-y^2} \, dy + 2 \int_0^{\infty} e^{-y^2} \, dy . \tag{3.697}$$

The second term in the latter expression is $\sqrt{\pi}$, and in the first term one changes the variable of integration to $t = (2/\pi)^{1/2} y e^{i\pi/4}$, so that

$$\int_{\zeta e^{-i\pi/4}}^{0} e^{-y^2} \, dy = -(\pi/2)^{1/2} e^{-i\pi/4}$$
$$\times \int_0^{(2/\pi)^{1/2}\zeta} e^{i(\pi/2)t^2} \, dt . \tag{3.698}$$

The analytical steps outlined above lead to the result

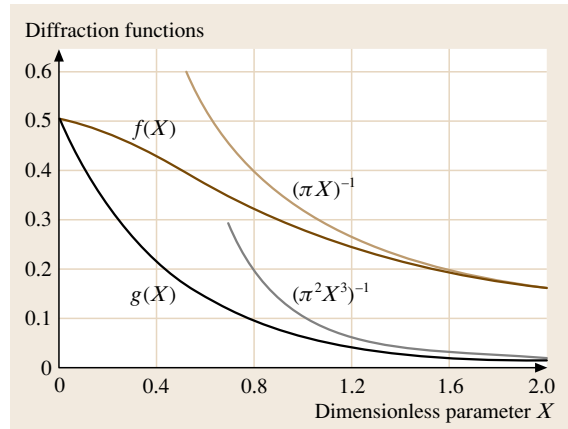
$$A_D(X) = \frac{(1-i)}{2} e^{-i[\pi/2]X^2}$$
$$\times \{\text{sign}(X) - (1-i) [C(X) + iS(X)]\} , \tag{3.699}$$


Fig. 3.58 Real and imaginary parts of the diffraction integral. Also shown are the appropriate asymptotic forms that are applicable at large arguments

where $C(X)$ and $S(X)$ are the Fresnel integrals

$$C(X) = \int_0^X \cos\left(\frac{\pi}{2}t^2\right) dt \; ; \tag{3.700}$$

$$S(X) = \int_0^X \sin\left(\frac{\pi}{2}t^2\right) dt \; . \tag{3.701}$$

In accordance with (3.693), the above representation of $A_D(X)$ is an odd function of X, the two Fresnel integrals themselves being odd in X. The discontinuity in $A_D(X)$ is readily identified from this representation as

$$A_D(0+\epsilon) - A_D(0-\epsilon) = 1 - i \; ; \tag{3.702}$$

The behavior of the two auxiliary Fresnel functions at small to moderate values of $|X|$ can be determined by expanding the terms in (3.699) in a power series in X, so that one identifies

$$f(|X|) \approx \frac{1}{2} - \frac{\pi}{4}X^2 + \frac{\pi}{3}|X|^3 - \dots \, , \tag{3.703}$$

$$g(|X|) \approx \frac{1}{2} - |X| + \frac{\pi}{2}X^2 - \dots \, . \tag{3.704}$$

To determine the behavior at large values of $|X|$, it is expedient to return to the expression (3.692) and expand the integrand in powers of $1/X$ and then integrate term by term. Doing this yields

$$f(|X|) \to \frac{1}{\pi|X|} - \frac{3}{\pi^3|X|^5} + \dots \, , \tag{3.705}$$

$$g(|X|) \to \frac{1}{\pi^2|X|^3} - \frac{15}{\pi^4|X|^7} + \dots \, . \tag{3.706}$$

These are asymptotic series, so one should retain at most only those terms which are of decreasing value. The leading terms are a good approximation for $|X| > 2$.

3.17.9 Plane Wave Diffraction

The preceding analysis, for when the source is a point source at a finite distance from the edge, can be adapted to the case when one idealizes the incident wave as a plane wave, propagating in the direction of the unit vector

$$\boldsymbol{n}_{inc} = n_x \boldsymbol{e}_x + n_y \boldsymbol{e}_y + n_z \boldsymbol{e}_z \, , \tag{3.707}$$

which points from a distant source (cylindrical coordinates w_S, ϕ_S, z_S) toward the coordinate origin, so

that

$$n_x = \frac{-w_S \cos\phi_S}{\left(w_S^2 + z_S^2\right)^{1/2}} \; ; \quad n_y = \frac{-w_S \sin\phi_S}{\left(w_S^2 + z_S^2\right)^{1/2}} \; ;$$

$$n_z = \frac{-z_S}{\left(w_S^2 + z_S^2\right)^{1/2}} \; . \tag{3.708}$$

Without any loss of generality, one can consider z_S to be negative, so that n_z is positive. Then at the point on the edge where $z = 0$, the direct wave makes an angle

$$\gamma = \cos^{-1}\left(\frac{-z_S}{\left(w_S^2 + z_S^2\right)^{1/2}}\right) \tag{3.709}$$

with the edge of the wedge, and this definition yields

$$\sin\gamma = \frac{w_S}{\left(w_S^2 + z_S^2\right)^{1/2}}; \quad \cos\gamma = n_z \; . \tag{3.710}$$

One lets $\hat{p}_{inc}$ be the complex amplitude of the incident wave at the origin (the point on the edge where $z = 0$), so that

$$\hat{S}\frac{1}{\left(w_S^2 + z_S^2\right)^{1/2}} e^{i\left(w_S^2 + z_S^2\right)^{1/2}} \to \hat{p}_{inc} \, , \tag{3.711}$$

and one holds this quantity constant while letting $(w_S^2 + z_S^2)^{1/2}$ become arbitrarily large. Then, with appropriate use of Taylor series (or binomial series) expansions, one has

$$R_D \to \left(w_S^2 + z_S^2\right)^{1/2} - w\sin\gamma \cos(\phi - \phi_S) + z\cos\gamma \, , \tag{3.712}$$

$$R_R \to \left(w_S^2 + z_S^2\right)^{1/2} - w\sin\gamma \cos(\phi + \phi_S - 2\beta) + z\cos\gamma \, , \tag{3.713}$$

$$L \to \left(w_S^2 + z_S^2\right)^{1/2} + w\sin\gamma + z\cos\gamma \, , \tag{3.714}$$

$$\Gamma \to \left(\frac{kw\sin\gamma}{\pi}\right)^{1/2} \, . \tag{3.715}$$

In this limit, the geometrical acoustics portion of the solution, for waves of constant frequency, is given by one of the following three expressions. In the region $\beta > \phi > \phi_B$, one has

$$\hat{p}_{GA} = \hat{p}_{inc}\, e^{ikn_z z}(e^{ikn_x x}\, e^{ikn_y y} + e^{-ikw\sin\gamma \cos(\phi + \phi_S - 2\beta)}) \, , \tag{3.716}$$

where the two terms correspond to the incident wave and the reflected wave. In the region $\phi_B > \phi > \phi_A$, one has

$$\hat{p}_{GA} = \hat{p}_{inc}\, e^{ikn_z z}\, e^{ikn_x x}\, e^{ikn_y y} \, , \tag{3.717}$$

which is the incident wave only. Then, in the shadow region, where $\phi_A > \phi > 0$, one has

$$\hat{p}_{GA} = 0 , \tag{3.718}$$

and there is neither an incident wave nor a reflected wave.

The diffracted wave, in this plane wave limit, becomes

$$\hat{p}_{\text{diffr}} = \hat{p}_{\text{inc}} \, e^{ikz\cos\gamma} \, e^{ikw\sin\gamma} \frac{e^{i\pi/4}}{\sqrt{2}}$$
$$\times \sum_{+,-} \frac{\sin\nu\pi}{V_\nu(\phi\pm\phi_S)} A_D\left[\Gamma M_\nu(\phi\pm\phi_S)\right] , \tag{3.719}$$

where Γ is now understood to be given by (3.715). This result is, as before, for the case when the listener is many wavelengths from the edge, so that the parameter Γ is large compared with unity.

3.17.10 Small-Angle Diffraction

Simple approximate formulas emerge from the above general results when one limits one's attention to the diffracted field near the edge of the shadow zone boundary.

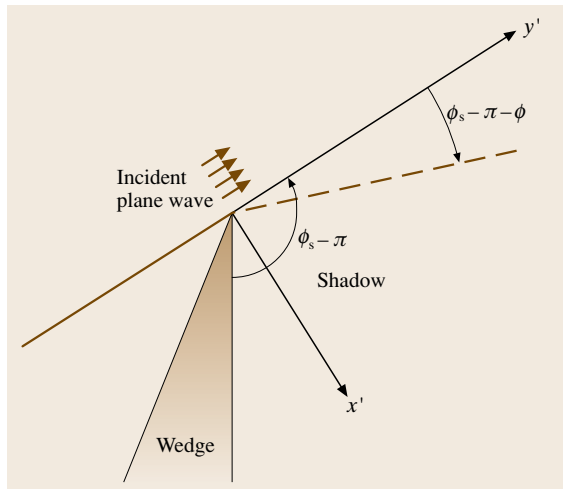
The incident wave is taken as having its direction lying in the (x, y) plane and one introduces rotated coordinates (x', y'), so that the y'-axis is in the direction of the incident sound, with the coordinate origin remaining at the edge of the wedge. One regards y' as


Fig. 3.59 Geometry and parameters used in discussion of small-angle diffraction of a plane wave by a rigid wedge

being large compared to a wavelength. The magnitude $|x'|$ is regarded as substantially smaller than y', but not necessarily small compared to a wavelength.

In the plane wave diffraction expression (3.719) the angle γ is $\pi/2$, and the only term of possible significance is that corresponding to the minus sign, so one has

$$\hat{p}_{\text{diffr}} = \hat{p}_{\text{inc}} \, e^{ikw} \frac{e^{i\pi/4}}{\sqrt{2}} \frac{\sin\nu\pi}{V_\nu(\phi - \phi_S)}$$
$$\times A_D\left[\Gamma M_\nu(\phi - \phi_S)\right] . \tag{3.720}$$

Also, because $|x'|$ is small compared with y', one can assume that $|\phi_S - \pi - \phi|$ is small compared with unity, so that

$$\cos\nu(\phi - \phi_S) \approx \cos\nu\pi + (\nu\sin\nu\pi)(\phi - \phi_S + \pi) , \tag{3.721}$$

$$V_\nu(\phi - \phi_S) \approx \sin\nu\pi , \tag{3.722}$$

$$M_\nu(\phi - \phi_S) \approx \phi_S - \pi - \phi \approx \frac{x'}{y'} . \tag{3.723}$$

Further approximations that are consistent with this small-angle diffraction model are to set $w \to y'$ in the expression for Γ, but to set

$$w \to y' + \frac{1}{2}\frac{(x')^2}{y'} \tag{3.724}$$

in the exponent. The second term is needed if one needs to take into account any phase shift relative to that of the incident wave.

The approximations just described lead to the expression

$$\hat{p}_{\text{diffr}} = \hat{p}_{\text{inc}} \, e^{iky'} \frac{1+i}{2} e^{(\pi/2)X^2} A_D(X) , \tag{3.725}$$

with

$$X = \left(\frac{k}{\pi y'}\right) x' . \tag{3.726}$$

A remarkable feature of this result is that it is independent of the wedge angle β. It applies in the same approximate sense equally for diffraction by a thin screen and by a right-angled corner.

The total acoustic field in this region just above and just where the shadow zone begins can be found by adding the incident wave for $x' < 0$. In the shadow zone there is no incident wave, and one accounts for this by using a step function $H(-X)$. Thus the total field is approximated by

$$\hat{p}_{GA} + \hat{p}_{\text{diffr}} \to p_{\text{inc}} \, e^{iky'}$$
$$\times \left[H(-X) + \frac{(1+i)}{2} e^{i(\pi/2)X^2} A_D(X) \right] . \tag{3.727}$$

Fig. 3.60 Characteristic diffraction pattern as a function of the diffraction parameter X. The function is the absolute magnitude of the complex amplitude of the received acoustic pressure, incident plus diffracted, relative to that of the incident wave

One can now substitute into this the expression (3.699), with the result

$$\hat{p}_{GA} + \hat{p}_{diffr} = \hat{p}_{inc}\, e^{iky} \left(\frac{1-i}{2} \right)$$
$$\times \left\{ \left[\frac{1}{2} - C(X) \right] + i \left[\frac{1}{2} - S(X) \right] \right\}, \tag{3.728}$$

or, equivalently,

$$\hat{p}_{GA} + \hat{p}_{diffr} = \hat{p}_{inc}\, e^{iky} \left(\frac{1-i}{2} \right) \int_{X}^{\infty} e^{i(\pi/2)u^2}\, du\,. \tag{3.729}$$

Characteristic diffraction pattern

The definitions of the diffraction integral and of the Fresnel integrals are such that, in the latter expressions, one does not need a step function.

The expressions just given, or their equivalents, are what are most commonly used in assessments of diffraction. The plot of the magnitude squared, relative to that of the incident wave,

$$\left| \frac{\hat{p}_{GA} + \hat{p}_{diffr}}{\hat{p}_{inc}} \right|^2 = \frac{1}{2} \left| \int_{X}^{\infty} e^{i(\pi/2)u^2}\, du \right|^2, \tag{3.730}$$

shows a monotonic decay in the shadow region ($X > 0$) and a series of diminishing ripples about unity in the illuminated region ($X < 0$). The peaks are interpreted as resulting from constructive interference of the incident and diffracted waves. The valleys result from destructive interference.

3.17.11 Thin-Screen Diffraction

For the general case of plane wave diffraction, not necessarily at small angles, a relatively simple limiting case

is when the wedge is a thin screen, so that $\beta = 2\pi$ and the wedge index ν is $1/2$. Additional simplicity results for the case where the incident wave's direction $\mathbf{n}_{inc}$ is perpendicular to the edge, so that $\gamma = \pi/2$. In this limiting case, $\sin \nu\pi = 1$ and $\cos \nu\pi = 0$, so, with reference to (3.682), one finds $V_\nu(\phi \pm \phi_S) = 1$, and with reference to (3.687), one finds

$$M_\nu(\phi \pm \phi_S) = -2 \cos \frac{1}{2}(\phi \pm \phi_S)\,. \tag{3.731}$$

Then, with use of the fact that $A_D(X)$ is odd in X, one obtains

$$\hat{p}_{diffr} = \frac{-\hat{p}_{inc}\, e^{i(kw + \pi/4)}}{\sqrt{2}}$$
$$\times \sum_{+,-} A_D \left[\left(\frac{4kw}{\pi} \right)^{1/2} \cos \frac{1}{2}(\phi \pm \phi_S) \right]\,. \tag{3.732}$$

Although derived here for the asymptotic limit when kw is large, this result is actually exact and holds for all values of w. It was derived originally by *Sommerfeld* in 1896 [3.105].

3.18 Parabolic Equation Methods

It is often useful in propagation analyses to replace the Helmholtz equation or its counterpart for inhomogeneous media by a partial differential equation that is first

order, rather than second order, in the coordinate that corresponds to the primary direction of propagation. Approximations that achieve this are known gener-

ally as parabolic equation approximations and stem from early work by *Fock* [3.112] and *Tappert* [3.113]. Their chief advantage is that the resulting equation is no longer elliptic, but parabolic, so it is no longer necessary to check whether a radiation condition is satisfied at large propagation distances. This is especially convenient for numerical computation, for the resulting algorithms march out systematically in propagation distance, without having to look far ahead for the determination of the field at a subsequent point.

A simple example of a parabolic equation approximation is that of two-dimensional propagation in a medium where the sound speed and density vary primarily with the coordinate y, but weakly with x. A wave of constant angular frequency ω is propagating primarily in the x-direction but is affected by the y variations of the ambient medium, and by the presence of interfaces that are nearly parallel to the x-direction. The propagation is consequently governed by the two-dimensional reduced wave equation,

$$\frac{\partial}{\partial x}\left(\frac{1}{\rho}\frac{\partial \hat{p}}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial \hat{p}}{\partial y}\right) + \frac{\omega^2}{\rho c^2}\hat{p} = 0 \qquad (3.733)$$

which can be obtained from (3.73) by use of the complex amplitude convention.

In the parabolic approximation, the exact solution $\hat{p}$ of (3.733), with a radiation condition imposed, is represented by

$$\hat{p}(x, y) = \mathrm{e}^{\mathrm{i}\chi(x)}F(x, y), \qquad (3.734)$$

where

$$\chi(x) = \int_0^x k_0 \,\mathrm{d}x. \qquad (3.735)$$

Here $k_0(x)$ is a judiciously chosen reference wavenumber (possibly dependent on the primary coordinate x). The crux of the method is that the function $F(x, y)$ is taken to satisfy an approximate partial differential equation (parabolic equation (PE)) that differs from what would result were (3.734) inserted into (3.733) with no discarded terms.

The underlying assumption is that the x-dependence of the complex pressure amplitude is mostly accounted for by the exponential factor, so the characteristic scale for variation of the amplitude factor F with the coordinate x is much greater than the reciprocal of k_0. Consequently second derivatives of F with respect to x can be neglected in the derived differential equation. The y derivatives of the ambient variables are also neglected. The resulting approximate equation is given by

$$\frac{\partial}{\partial x}\left(\frac{k_0}{\rho}F\right) + \frac{k_0}{\rho}\frac{\partial F}{\partial x} = \mathrm{i}\frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial F}{\partial y}\right)$$
$$+ \mathrm{i}\frac{k_0^2}{\rho}(n^2 - 1)F, \qquad (3.736)$$

where n, the apparent index of refraction, is an abbreviation for $k_0^{-1}\omega/c$. If the reference wavenumber k_0 is selected to be independent of x, then (3.736) reduces to

$$2k_0\frac{\partial F}{\partial x} = \mathrm{i}\rho\frac{\partial}{\partial y}\left(\frac{1}{\rho}\frac{\partial F}{\partial y}\right) + \mathrm{i}k_0^2(n^2 - 1)F. \qquad (3.737)$$

Although the computational results must depend on the selection of the reference wavenumber k_0, results for various specific cases tend to indicate that the sensitivity to such a selection is not great.

4. Sound Propagation in the Atmosphere

Keith Attenborough

Propagation of sound close to the ground outdoors involves geometric spreading, air absorption, interaction with the ground, barriers, vegetation and refraction associated with wind and temperature gradients. After a brief survey of historical aspects of the study of outdoor sound and its applications, this chapter details the physical principles associated with various propagation effects, reviews data that demonstrate them and methods for predicting them. The discussion is concerned primarily with the relatively short ranges and spectra of interest when predicting and assessing community noise rather than the frequencies and long ranges of concern, for example, in infrasonic global monitoring or used for remote sensing of the atmosphere. Specific phenomena that are discussed include spreading losses, atmospheric absorption, diffraction by barriers and buildings, interaction of sound with the ground (ground waves, surface waves, ground impedance associated with porosity and roughness, and elasticity effects), propagation through crops, shrubs and trees, wind and temperature gradient effects, shadow zones and incoherence due to atmospheric turbulence. The chapter concludes by suggesting a few areas that require further research.

4.1 A Short History of Outdoor Acoustics

Early experiments on outdoor sound were concerned with the speed of sound [4.1]. Sound from explosions and the firing of large guns contains substantial low-frequency content ($< 100\,\text{Hz}$) and is able to travel for

considerable distances outdoors. The Franciscan friar, Marin Mersenne (1588–1648), suggested timing the interval between seeing the flash and hearing the report of guns fired at a known distance. William Derham (1657–1735), the rector of a small church near London, observed and recorded the influence of wind and temperature on sound speed. Also Derham noted the difference in the sound of church bells at the same distance over newly fallen snow and over a hard frozen surface.

Before enough was known for the military exploitation of outdoor acoustics, there were many unwitting influences of propagation conditions on the course of battle [4.2]. In June 1666, Samuel Pepys noted that the sounds of a naval engagement between the British and

Dutch fleets were heard clearly at some spots but not at others a similar distance away or closer [4.3]. During the First World War, acoustic shadow zones, similar to those observed by Pepys, were observed during the battle of Antwerp. Observers also noted that battle sounds from France only reached England during the summer months whereas they were best heard in Germany during the winter. After the war there was great interest in these observations among the scientific community. Large amounts of ammunition were detonated throughout England and the public was asked to listen for sounds of explosions. Despite the continuing interest in atmospheric acoustics after World War 1, the advent of the submarine encouraged greater efforts in underwater acoustics research during and after World War 2.

4.2 Applications of Outdoor Acoustics

Although much current interest in sound propagation in the atmosphere relates to the prediction and control of noise from land and air transport and from industrial sources, outdoor acoustics has continued to have extensive military applications in source acquisition, ranging and identification [4.4]. Acoustic disturbances in the atmosphere give rise to solid particle motion in porous ground, induced by local pressure variations as well as air-particle motion in the pores. There is a distinction between the seismic disturbances associated with direct seismic excitation of the ground and solid-particle motion in the ground induced by airborne sounds. This has enabled the design of systems that distinguish between airborne and ground-borne sources and the application of acoustical techniques to the detection of buried land mines [4.5]. The many other applications of studies of outdoor sound propagation include aspects of animal bioacoustics [4.6] and acoustic remote sounding of the atmosphere [4.7].

Atmospheric sound propagation close to the ground is sensitive to the acoustical properties of the ground surface as well as to meteorological conditions. Most natural ground surfaces are porous. The surface porosity allows sound to penetrate and hence to be absorbed and delayed through friction and thermal exchanges. There is interference between sound traveling directly between source and receiver and sound reflected from the ground. This interference, known as the ground effect [4.8, 9], is similar to the Lloyd's mirror effect in optics but is not directly analogous. Usually, the propagation of light may be described by rays. At the lower end of the audible frequency range (20–500 Hz)

and near grazing incidence to the ground, the consequences of the curvature of the expanding sound waves from a finite source are significant. Consequently, ray-based modeling is not appropriate and it is necessary to use full-wave techniques. Moreover, there are few outdoor surfaces that are mirror-like to incident sound waves. Most ground surfaces cause changes in phase as well as amplitude during reflection. Apart from the relevance to outdoor noise prediction, the sensitivity of outdoor sound propagation to ground surface properties has suggested acoustical techniques for determining soil physical properties such as porosity and air permeability [4.10–12]. These are relatively noninvasive compared with other methods.

The last two decades have seen considerable advances in numerical and analytical methods for outdoor sound prediction [4.13]. Details of these are beyond the scope of this work but many are described in the excellent text by *Salomons* [4.14] and a 2003 review [4.15]. Among the numerical methods borrowed and adapted from underwater acoustics are the fast field program (FFP) and that based on the parabolic equation (PE). The parabolic equation method enables predictions that allow for changes in atmospheric and ground conditions with range whereas the FFP intrinsically does not. On the other hand the PE method is essentially a *one-way* transmission method which does not allow for back scattering. Methods for predicting outdoor noise are undergoing considerable assessment and change in Europe as a result of European Commission (EC) directive [4.16] and the associ-

ated requirements for noise mapping. A sophisticated scheme for this purpose is NORD2000 [4.17]. European projects HARMONOISE [4.18] and IMAGINE [4.19] have developed a comprehensive source-independent scheme for outdoor sound prediction. As in NORD2000 various relatively simple formulae, predicting the effect of topography for example, have been derived and tested against numerical predictions.

4.3 Spreading Losses

Distance alone will result in wavefront spreading. In the simplest case of a sound source radiating equally in all directions, the intensity I [W^{-2}] at a distance r m from the source of power P [W], is given by

$$I = \frac{P}{4\pi r^2} \,, \tag{4.1}$$

This represents the power per unit area on a spherical wavefront of radius r. In logarithmic form the relationship between sound pressure level L_p and sound power L_W, may be written

$$L_p = L_W - 20 \log r - 11 \text{ dB} \,. \tag{4.2}$$

From a point sound source, this means a reduction of $20 \log 2$ dB, i.e., 6 dB, per distance doubling in all directions (a point source is omnidirectional). Most sources appear to be point sources when the receiver is at a sufficient distance from them. If the source is directional then (4.2) is modified by inclusion of the directivity index DI.

$$L_p = L_W + DI - 20 \log r - 11 \text{dB} \,. \tag{4.3}$$

The directivity index is $10 \log DF$ dB where DF is the directivity factor, given by the ratio of the actual intensity in a given direction to the intensity of an omnidirectional source of the same power output.
Fig. 4.1 Comparison of attenuation due to geometrical spreading from point, infinite line and finite line sources

Such directivity is either inherent or location-induced. A simple case of location-induced directivity arises if the point source, which would usually create spherical wavefronts of sound, is placed on a perfectly reflecting flat plane. Radiation from the source is thereby restricted to a hemisphere. The directivity factor for a point source on a perfectly reflecting plane is 2 and the directivity index is 3 dB. For a point source at the junction of a vertical perfectly reflecting wall with a horizontal perfectly reflecting plane, the directivity factor is 4 and the directivity index is 6 dB. It should be noted that these adjustments ignore phase effects and assume incoherent reflection [4.20].

From an infinite line source, the wavefronts are cylindrical, so wavefront spreading means a reduction of 3 dB per distance doubling. Highway traffic may be approximated by a line of incoherent point sources on an acoustically hard surface. If a line source of length l consists of contiguous omnidirectional incoherent elements of length dx and source strength $P dx$, the intensity at a location halfway along the line and at a perpendicular distance d from it, so that $dx = r d\theta / \cos \theta$, where r is the distance from any element at angle θ from the perpendicular, is given by

$$I = \int_{-l/2}^{l/2} \frac{P}{2\pi r^2} \, dx = \frac{P}{2\pi d} \left[2 \tan^{-1} \left(\frac{l}{2d} \right) \right] \,,$$

This results in

$$L_p = L_W - 10 \log d - 8$$
$$+ 10 \log \left[2 \tan^{-1} \left(\frac{l}{2d} \right) \right] \text{dB} \,. \tag{4.4}$$

Figure 4.1 shows that the attenuation due to wavefront spreading from the finite line source behaves as that from an infinite line (cylindrical spreading) at distances much less than the length of the source and as that from a point source (spherical spreading) at distances greater than the length of the source.

4.4 Atmospheric Absorption

A proportion of sound energy is converted to heat as it travels through the air. There are heat conduction, shear viscosity and molecular relaxation losses [4.21]. The resulting air absorption becomes significant at high frequencies and at long range so air acts as a low-pass filter at long range. For a plane wave, the pressure p at distance x from a position where the pressure is p_0 is given by

$$p = p_0 e^{-\alpha x/2} . \tag{4.5}$$

The attenuation coefficient α for air absorption depends on frequency, humidity, temperature and pressure and may be calculated using (4.6) through (4.8) [4.22].

$$\alpha = f^2 \left[\left(\frac{1.84 \times 10^{-11}}{\left(\frac{T_0}{T}\right)^{\frac{1}{2}} \frac{p_s}{p_0}} \right) \right.$$
$$+ \left(\frac{T_0}{T}\right)^{2.5} \left(\frac{0.10680 \, e^{-3352/T} \, f_{r,N}}{f^2 + f_{r,N}^2} \right.$$
$$\left. + \frac{0.01278 \, e^{-2239.1/T} \, f_{r,O}}{f^2 + f_{r,O}^2} \right) \left. \frac{Np}{m \, atm} \right] , \tag{4.6}$$

where $f_{r,N}$ and $f_{r,O}$ are relaxation frequencies associated with the vibration of nitrogen and oxygen molecules respectively and are given by

$$f_{r,N} = \frac{p_s}{p_{s0}} \left(\frac{T_0}{T}\right)^{\frac{1}{2}}$$

$$\times \left(9 + 280 H e^{-4.17\left[(T_0/T)^{1/3} - 1\right]} \right) , \tag{4.7}$$

$$f_{r,O} = \frac{p_s}{p_{s0}} \left(24.0 + 4.04 \times 10^4 H \frac{0.02 + H}{0.391 + H} \right) , \tag{4.8}$$

where f is the frequency. T is the absolute temperature of the atmosphere in Kelvin, $T_0 = 293.15$ K is the reference value of T (20 °C), H is the percentage molar concentration of water vapor in the atmosphere $= \rho_{sat} r_h p_0 / p_s$, r_h is the relative humidity (%); p_s is the local atmospheric pressure and p_0 is the reference atmospheric pressure (1 atm $= 1.01325 \times 10^5$ Pa); $\rho_{sat} = 10^{C_{sat}}$, where $C_{sat} = -6.8346(T_0/T)^{1.261} + 4.6151$. These formulae give estimates of the absorption of pure tones to an accuracy of $\pm 10\%$ for $0.05 < H < 5$, $253 < T < 323$, $p_0 < 200$ kPa.

Outdoor air absorption varies through the day and the year [4.23, 24].

Absolute humidity H is an important factor in the diurnal variation and usually peaks in the afternoon. Usually the diurnal variations are greatest in the summer. It should be noted that the use of (arithmetic) mean values of atmospheric absorption may lead to overestimates of attenuation when attempting to establish worst-case exposures for the purposes of environmental noise impact assessment. Investigations of local climate statistics, say hourly means over one year, should lead to more accurate estimates of the lowest absorption values.

4.5 Diffraction and Barriers

Purpose-built noise barriers have become a very common feature of the urban landscape of Europe, the Far East and America. In the USA, over 1200 miles of noise barriers were constructed in 2001 alone. The majority of barriers are installed in the vicinity of transportation and industrial noise sources to shield nearby residential properties. Noise barriers are cost effective only for the protection of large areas including several buildings and are rarely used for the protection of individual properties. Noise barriers of usual height are generally ineffective in protecting the upper levels of multi-storey dwellings. Over many years environmental noise barriers have been the subject of extensive studies, the results of which have been consolidated in the form of national and international standards and prediction models [4.25–27]. Extensive guides to the acoustic and visual design of noise barriers are available [4.28, 29]. Some issues remain to be resolved relating to the degradation of the noise-barrier performance in the presence of wind and temperature gradients, the influence of localized atmospheric turbulence, temporal effects from moving traffic, the influence of local vegetation, the aesthetic quality of barriers and their environmental impact.

4.5.1 Single-Edge Diffraction

A noise barrier works by blocking the direct path from the noise source to the receiver. The noise then reaches the receiver only via diffraction around the barrier edges. The calculation of barrier attenuation is therefore mainly dependent on the solution of the diffraction problem. Exact integral solutions of the diffraction problem were available as early as the late 19th [4.30] and early 20th century [4.31]. For practical calculations however it is necessary to use approximations to the exact solutions. Usually this involves assuming that the source and receiver are more than a wavelength from the barrier and the receiver is in the shadow zone,which is valid in almost all applications of noise barriers. The Kirchhoff–Fresnel approximation [4.32], in terms of the Fresnel numbers for thin rigid screens (4.10), and the geometrical theory of diffraction [4.33] for wedges and thick barriers have been used for deriving practical formulae for barrier calculations. For a rigid wedge barrier, the solution provided by *Hadden* and *Pierce* [4.34] is relatively easy to calculate and highly accurate. A line integral solution, based on the Kirchhoff–Fresnel approximation [4.35] describes the diffracted pressure from a distribution of sources along the barrier edge and has been extended to deal with barriers with jagged edges [4.36]. There is also a time-domain model [4.37].

As long as the transmission loss through the barrier material is sufficiently high, the performance of a barrier is dictated by the geometry (Fig. 4.2).

The total sound field in the vicinity of a semi-infinite half plane depends on the relative position of source, receiver, and the thin plane. The total sound field p_T in each of three regions shown in Fig. 4.2 is given as follows:

In front of the barrier: $p_T = p_i + p_r + p_d$,   (4.9a)

Above the barrier: $p_T = p_i + p_d$,   (4.9b)

In the shadow zone: $p_T = p_d$.   (4.9c)

The Fresnel numbers of the source and image source are denoted, respectively, by N_1 and N_2, and are defined as follows:

$$N_1 = \frac{R' - R_1}{\lambda/2} = \frac{k}{\pi}\left(R' - R_1\right) , \qquad (4.10a)$$

$$\text{and } N_2 = \frac{R' - R_2}{\lambda/2} = \frac{k}{\pi}\left(R' - R_2\right) . \qquad (4.10b)$$

where $R' = r_s + r_r$ is the shortest source–edge–receiver path.

The attenuation (Att) of the screen, sometimes known as the insertion loss IL, is often used to assess the acoustics performance of the barrier. It is defined as follows,

$$\text{Att} = \text{IL} = 20\lg\left(\left|\frac{p_w}{p_{w/o}}\right|\right) \text{ dB} , \qquad (4.11)$$

where p_w and $p_{w/o}$ is the total sound field with or without the presence of the barrier. Note that the barrier attenuation is equal to the insertion loss only in the absence of ground effect.

Maekawa [4.38] has provided a chart that expresses the attenuation of a thin rigid barrier based on the Fresnel number N_1 associated with the source. The chart was derived empirically from extensive laboratory experimental data but use of the Fresnel number was suggested by the Kirchhoff–Fresnel diffraction theory. Maekawa's chart extends into the illuminated zone where N_1 is taken to be negative. Maekawa's chart has been proved to be very successful and has become the de facto standard empirical method for barrier calculations. Many of the barrier calculation methods embodied in national and international standards [4.25, 39] stem from this chart. There have been many attempts to fit the chart with simple formulae. One of the simplest formulae [4.40] is

$$\text{Att} = 10\lg(3 + 20N) \text{ dB} . \qquad (4.12)$$

The *Maekawa* curve can be represented mathematically by [4.41]

$$\text{Att} = 5 + 20\lg\frac{\sqrt{2\pi N_1}}{\tanh\sqrt{2\pi N_1}} . \qquad (4.13)$$

Fig. 4.2 Diffraction of sound by a thin barrier

An improved version of this result, using both Fresnel Numbers (4.10), is [4.42]

$$\text{Att} = \text{Att}_s + \text{Att}_b + \text{Att}_{sb} + \text{Att}_{sp} , \quad (4.14a)$$

$$\text{where } \text{Att}_s = 20 \lg \frac{\sqrt{2\pi N_1}}{\tanh \sqrt{2\pi N_1}} - 1 , \quad (4.14b)$$

$$\text{Att}_b = 20 \lg \left[1 + \tanh \left(0.6 \lg \frac{N_2}{N_1} \right) \right] , \quad (4.14c)$$

$$\text{Att}_{sb} = \left(6 \tanh \sqrt{N_2} - 2 - \text{Att}_b \right) \\ \times \left(1 - \tanh \sqrt{10 N_1} \right) , \quad (4.14d)$$

$$\text{Att}_{sp} = -10 \lg \frac{1}{(R'/R_1)^2 + (R'/R_1)} . \quad (4.14e)$$

The term Att_s is a function of N_1, which is a measure of the relative position of the receiver from the source. The second term depends on the ratio of N_2/N_1, which depends on the proximity of either the source or the receiver to the half plane. The third term is only significant when N_1 is small and depends on the proximity of the receiver to the shadow boundary. The last term, a function of the ratio R'/R_1, accounts for the diffraction effect due to spherical incident waves.

4.5.2 Effects of the Ground on Barrier Performance

Equations (4.12–4.14) only predict the amplitude of sound and do not include wave interference effects. Such interference effects result from the contributions from different diffracted wave paths in the presence of ground (see also Sect. 4.6).

Consider a source S_g located at the left side of the barrier, a receiver R_g at the right side of the barrier and E is the diffraction point on the barrier edge (Fig. 4.3).
Fig. 4.3 Diffraction by a barrier on impedance ground

The sound reflected from the ground surface can be described by an image of the source S_i. On the receiver side, sound waves will also be reflected from the ground. This effect can be considered in terms of an image of the receiver R_i. The pressure at the receiver is the sum of four terms that correspond to the sound paths $S_g E R_g$, $S_i E R_g$, $S_g E R_i$ and $S_i E R_i$. If the surface is a perfectly reflecting ground, the total sound field is the sum of the diffracted fields of these four paths,

$$P_T = P_1 + P_2 + P_3 + P_4 , \quad (4.15)$$

where

$$\begin{aligned} P_1 &= P \left(S_g, R_g, E \right) , \\ P_2 &= P \left(S_i, R_g, E \right) , \\ P_3 &= P \left(S_g, R_i, E \right) , \\ P_4 &= P \left(S_i, R_i, E \right) . \end{aligned}$$

$P(S, R, E)$ is the diffracted sound field due to a thin barrier for given positions of source S, receiver R and the point of diffraction at the barrier edge E. If the ground has finite impedance (such as grass or a porous road surface) then the pressure corresponding to rays reflected from these surfaces should be multiplied by the appropriate spherical wave reflection coefficient(s) to allow for the change in phase and amplitude of the wave on reflection as follows,

$$P_T = P_1 + Q_s P_2 + Q_R P_3 + Q_s Q_R P_4 , \quad (4.16)$$

where Q_s and Q_R are the spherical wave reflection coefficients for the source and receiver side respectively. The spherical wave reflection coefficients can be calculated for different types of ground surfaces and source/receiver geometries (Sect. 4.6).

Usually, for a given source and receiver position, the acoustic performance of the barrier on the ground is assessed by use of either the excess attenuation (EA) or the insertion loss (IL). They are defined as follows,

$$\text{EA} = SPL_f - SPL_b , \quad (4.17)$$
$$\text{IL} = SPL_g - SPL_b , \quad (4.18)$$

where SPL_f is the free field noise level, SPL_g is the noise level with the ground present and SPL_b is the noise level with the barrier and ground present. Note that, in the absence of a reflecting ground, the numerical value of EA (which was called Att previously) is the same as IL. If the calculation is carried out in terms of amplitude only, then the attenuation Att_n for each sound path can be directly determined from the appropriate

Fresnel number F_n for that path. The excess attenuation of the barrier on a rigid ground is then given by

$$A_{\rm T} = 10 \lg \left(10^{-\left| \frac{\rm Att_1}{10} \right|} + 10^{-\left| \frac{\rm Att_2}{10} \right|} \right.$$
$$\left. + 10^{-\left| \frac{\rm Att_3}{10} \right|} + 10^{-\left| \frac{\rm Att_4}{10} \right|} \right) . \qquad (4.19)$$

The attenuation for each path can either be calculated by empirical or analytical formulae depending on the complexity of the model and the required accuracy.

A modified form of the empirical formula for the calculation of barrier attenuation is [4.25]

$$\mathrm{IL} = 10 \log_{10} \left[3 + \left(C_2 \frac{\delta_1}{\lambda} \right) C_3 K_{\rm met} \right] , \qquad (4.20)$$

where $C_2 = 20$ and includes the effect of ground reflections; $C_2 = 40$ if ground reflections are taken into account elsewhere; C_3 is a factor to take into account a double diffraction or finite barrier effect, $C_3 = 1$ for a single diffraction and $\delta_1 = (r_{\rm s} + r_{\rm r}) - R_1$ (Fig. 4.2). The C_3 expression for double diffraction is given later.

The term $K_{\rm met}$ in (4.15) is a correction factor for average downwind meteorological effects, and is given by

$$K_{\rm met} = \mathrm{e}^{-\frac{1}{2000} \sqrt{\frac{r_{\rm s} r_{\rm r} r_o}{2 \delta_1}}}$$

for $\delta_1 > 0$ and $K_{\rm met} = 1$ for $\delta_1 \leq 0$.

The formula reduces to the simple formula (4.12) when the barrier is thin, there is no ground and if meteorological effects are ignored.

There is a simple approach capable of modeling wave effects in which the phase of the wave at the receiver is calculated from the path length via the top of the screen, assuming a phase change in the diffracted wave of $\pi/4$ [4.43]. This phase change is assumed to be constant for all source–barrier–receiver geometries. The diffracted wave, for example, for the path $S_{\rm g} E R_{\rm g}$ would thus be given by

$$P_1 = \mathrm{Att}_1 \, \mathrm{e}^{-\mathrm{i}[k(r_0 + r_{\rm r}) + \pi/4]} . \qquad (4.21)$$

This approach provides a reasonable approximation for the many situations of interest where source and receiver are many wavelengths from the barrier and the receiver is in the shadow zone.

For a thick barrier of width w, the International Standards Organization (ISO) standard ISO 9613-2

[4.25] provides the following form of correction factor C_3 for use in (4.20)

$$C_3 = \frac{\left[1 + \left(\frac{5\lambda}{w} \right)^2 \right]}{\left[\frac{1}{3} + \left(\frac{5\lambda}{w} \right)^2 \right]} ,$$

where for double diffraction, $\delta_1 = (r_{\rm s} + r_{\rm r} + w) - R_1$.

Note that this empirical method is for rigid barriers of finite thickness and does not take absorptive surfaces into account.

4.5.3 Diffraction by Finite–Length Barriers and Buildings

All noise barriers have finite length and for certain conditions sound diffracting around the vertical ends of the barrier may be significant. This will also be the case for sound diffracting around buildings. Figure 4.4 shows eight diffracted ray paths contributing to the total field behind a finite-length barrier situated on finite-impedance ground. In addition to the four normal ray paths diffracted at the top edge of the barrier (Fig. 4.3), four more diffracted ray paths result from the vertical edges – two ray paths from each one. The two rays at either side are, respectively, the direct diffracted ray and the diffracted–reflected ray. Strictly, there are two further ray paths at each side which involve two reflections at the ground as well as diffraction at the vertical edge but usually these are neglected.

The reflection angles of the two diffracted–reflected rays are independent of the barrier position. They will either reflect at the source side or on the receiver side of the barrier, which are dependent on the relative positions of the source, receiver and barrier. The total field is given by

$$P_T = P_1 + Q_{\rm s} P_2 + Q_{\rm R} P_3 + Q_{\rm s} Q_{\rm R} P_4 + P_5$$
$$+ Q_{\rm R} P_6 + P_7 + Q_{\rm R} P_8 , \qquad (4.22)$$

where P_1–P_4 are those given earlier for the diffraction at the top edge of the barrier.

Although accurate diffraction formulas may be used to compute P_i ($i = 1, \ldots, 8$), a simpler approach is to assume that each diffracted ray has a constant phase shift of $\pi/4$ regardless of the position of source, receiver and diffraction point.

To predict the attenuation due to a single building, the double diffraction calculations mentioned earlier could be used. For a source or receiver situated in a built-up area, ISO 9613-2 [4.25] proposes an em-

pirical method for calculating the combined effects of screening and multiple reflections. The net attenuation A_{build} dB (< 10 dB) is given by

$$A_{build} = A_{build,1} + A_{build,2} \tag{4.23}$$
$$A_{build,1} = 0.1Bd_0 \, ,$$
$$A_{build,2} = -10 \log \left[1 - \frac{p}{100} \right] ,$$

where B is the area density ratio of buildings (total plan area/total ground area) and d_0 is the length of the refracted path from source to receiver that passes through buildings. $A_{build,2}$ is intended to be used only where there are well defined but discontinuous rows of buildings near to a road or railway and, p is the percentage of the length of facades relative to the total length of the road or railway. As with barrier attenuation, the attenuation due to buildings is to be included only when it is predicted to be greater than that due to ground effect. The ISO scheme offers also a frequency dependent attenuation coefficient (dB/m) for propagation of industrial noise through an array of buildings
Fig. 4.4 Ray paths around a finite-length barrier or building on the ground

on an industrial site. It should be noted that there are considerable current efforts devoted to studying sound propagation through buildings and along streets but this work is not surveyed here.

4.6 Ground Effects

Ground effects (for elevated source and receiver) are the result of interference between sound traveling directly from source to receiver and sound reflected from the ground when both source and receiver are close to the ground. Sometimes the phenomenon is called ground absorption but, since the interaction of outdoor sound with the ground involves interference, there can be enhancement associated with constructive interference as well as attenuation resulting from destructive interference. If source and receiver are close to nonporous concrete or asphalt, the sound pressure is doubled more or less over a wide range of audible frequencies. Such ground surfaces are described as *acoustically hard*. Over acoustically-hard surfaces the frequencies of the destructive interferences may be calculated from

$$f_n = (2n+1)\frac{c}{2}(R_2 - R_1) \, , \quad n = 0, 1, 2, \dots \tag{4.24}$$

where R_2 and R_1 are the lengths of the ground-reflected and direct ray paths from source to receiver respectively.

A moving vehicle such as a passenger car can be represented by two point sources of sound; one at 0.01 m height corresponds to the tire/road contact source and the other at 0.3 m height corresponds to the engine source [4.18]. The A-weighted sound power

spectrum for a car moving at 70 km/h peaks near 1 kHz. For a listener located at 1.5 m height and at a horizontal distance of 10 m from the car, the $f_0 = 1.9$ kHz and there would be doubling of sound pressure, i.e. an increase in the sound level due to the car of 6 dB up to this frequency. However at a 4 m high receiver and for the engine source $f_0 = 760$ Hz and the destructive interference would have a significant effect on the car noise spectrum. Indeed hard ground is predicted to increase the engine level by only 3 dB rather than 6 dB at the higher receiver. The corresponding values of f_0 for the tire/road source are 5.7 kHz for the 1.5 m high receiver and 2.4 kHz for the 4 m high receiver. Over porous surfaces, such as soil, sand and snow, the destructive interferences occur at lower frequencies than over hard ground since incident sound is able to penetrate the pores and the surface reflection is changed in amplitude and phase. The presence of vegetation tends to make the surface layer of ground including the root zone more porous but has to be relatively tall and dense to influence sound levels (Sect. 4.7). On the other hand frequent mowing or rolling causes the surface of grass covered ground to be compacted and therefore more acoustically-hard. Snow is significantly more porous than soil and sand. The layer of partly decayed matter

on the floor of a forest is also highly porous. Porous ground surfaces are sometimes called *acoustically soft*.

4.6.1 Boundary Conditions at the Ground

For most environmental noise predictions the solid particulate framework in porous ground may be considered to be rigid, so only one wave type, i.e., the wave penetrating the pores, need be considered. With this assumption, the speed of sound in the ground (c_1) is typically much smaller than that (c) in the air, i.e., $c \gg c_1$. The propagation of sound in the air gaps between the solid particles of which the ground is composed, is impeded by viscous friction. This in turn means that the index of refraction in the ground $n_1 = c/c_1 \gg 1$ and any incoming sound ray is refracted towards the normal as it propagates from air into the ground. This type of ground surface is called *locally reacting* because the air–ground interaction is independent of the angle of incidence of the incoming waves. The acoustical properties of locally reacting ground may be represented simply by its relative normal-incidence surface impedance (Z), or its inverse (the relative admittance β) and the ground is said to form a finite-impedance boundary. A perfectly hard ground has infinite impedance (zero admittance). A perfectly soft ground has zero impedance (infinite admittance). If the ground is not locally reacting, i.e., it is externally reacting, the impedance condition is replaced by two separate conditions governing the continuity of pressure and the continuity of the normal component of air particle velocity.

4.6.2 Attenuation of Spherical Acoustic Waves over the Ground

The idealized case of a point (omnidirectional) source of sound at height z_s and a receiver at height z, separated by a horizontal distance r above a finite-impedance plane (admittance β) is shown in Fig. 4.5.

Between source and receiver, a direct sound path of length R_1 and a ground-reflected path of length R_2 are identified. With the restrictions of long range ($r \approx R_2$), high frequency ($kr \gg 1$, $k(z + z_s) \gg 1$, where $k = \omega/c$ and $\omega = 2\pi f$, f being frequency) and with both the source and receiver located close ($r \gg z + z_s$) to a relatively hard ground surface ($|\beta|^{\text{big}} \ll 1$), the total sound field at (x, y, z) can be determined from

$$p(x, y, z) = \frac{e^{-ikR_1}}{4\pi R_1} + \frac{e^{-ikR_2}}{4\pi R_2} + \Phi_p + \phi_s , \qquad (4.25)$$
Fig. 4.5 Sound propagation from a point source to a receiver above a ground surface

where

$$\Phi_p \approx 2i\sqrt{\pi} \left(\frac{1}{2} k R_2 \right)^{1/2} \beta e^{-w^2} \text{erfc}(iw) \frac{e^{-ikR_2}}{4\pi R_2} \qquad (4.26)$$

and w, sometimes called the numerical distance, is given by

$$w \approx \frac{1}{2}(1 - i)\sqrt{k R_2}(\cos\theta + \beta) . \qquad (4.27)$$

ϕ_s represents a surface wave and is small compared with Φ_p under most circumstances. It is included in careful computations of the complementary error function erfc(x) [4.44]. In all of the above a time dependence of $e^{i\omega t}$ is understood.

After rearrangement, the sound field due to a point monopole source above a locally reacting ground becomes

$$p(x, y, z) = \frac{e^{-ikR_1}}{4\pi R_1} + \left[R_p + \left(1 - R_p \right) F(w) \right]$$
$$\times \frac{e^{-ikR_2}}{4\pi R_2} , \qquad (4.28)$$

where $F(w)$, sometimes called the boundary loss factor, is given by

$$F(w) = 1 - i\sqrt{\pi} w \exp(-w^2) \text{erfc}(iw) \qquad (4.29)$$

and describes the interaction of a spherical wavefront with a ground of finite impedance [4.45]. The term in the square bracket of (4.28) may be interpreted as the spherical wave reflection coefficient

$$Q = R_p + \left(1 - R_p \right) F(w) , \qquad (4.30)$$

which can be seen to involve the plane wave reflection coefficient R_p and a correction (the second term of Q), which allows for the fact that the wavefronts are spherical rather than plane. The contribution of the wavefront

curvature correction to the total sound field has been called the *ground wave*, in analogy with the corresponding term in the theory of amplitude-modulated (AM) radio reception [4.46]. It represents a contribution from the vicinity of the image of the source in the ground plane. If the wavefront is plane ($R_2 \to \infty$) then $|w| \to \infty$ and $F \to 0$. If the surface is acoustically hard, then $|\beta| \to 0$, which implies $|w| \to 0$ and $F \to 1$. If $\beta = 0$, corresponding to a perfect reflector, the sound field consists of two terms: a direct-wave contribution and a wave from the image source corresponding to specular reflection and the total sound field may be written

$$p(x, y, z) = \frac{e^{-ikR_1}}{4\pi R_1} + \frac{e^{-ikR_2}}{4\pi R_2} \ .$$

This has a first minimum corresponding to destructive interference between the direct and ground-reflected components as given by (4.24), i. e. when $k(R_2 - R_1) = \pi$, or $f = c/2(R_2 - R_1)$. Normally, for source and receiver close to the ground, this destructive interference is at too high a frequency to be of importance in outdoor sound prediction. The higher the frequency of the first minimum in the ground effect, the more likely that it will be destroyed by turbulence (Sect. 4.8).

For $|\beta| \ll 1$ but at grazing incidence ($\theta = \pi/2$, so that $R_\mathrm{p} = -1$ and

$$p(x, y, z) = \frac{2F(w)e^{-ikr}}{r} \ , \tag{4.31}$$

the numerical distance w is given by

$$w = \frac{1}{2}(1 - i)\beta\sqrt{kr} \ . \tag{4.32}$$

If the plane wave reflection coefficient had been used instead of the spherical wave reflection coefficient for grazing incidence, it would have led to the prediction of zero sound field when both source and receiver are on the ground. Equations (4.28)–(4.30) comprise the most widely used analytical solution for predicting sound field above a locally reacting ground in a homogeneous atmosphere. There are many other accurate asymptotic and numerical solutions available but no significant numerical differences between various predictions have been revealed for practical geometries and typical outdoor ground surfaces.

4.6.3 Surface Waves

Although, numerically, it is part of the calculation of the complementary error function (4.29), physically the surface wave is a separate contribution propagating close to and parallel to the porous ground surface.

It produces elliptical motion of air particles as a result of combining motion parallel to the surface with that normal to the surface in and out of the pores. The surface wave decays with the inverse square root of range rather than inversely with range as is true for other components. At grazing incidence on an impedance plane, with normalized admittance $\beta = \beta_r + i\beta_x$, the condition for the existence of the surface wave is

$$\frac{1}{\beta_x^2} > \frac{1}{\beta_r^2} + 1 \ . \tag{4.33}$$

For a surface with large impedance, i. e., where $|\beta| \to 0$, the condition is simply that the imaginary part of the ground impedance (the reactance) is greater than the real part (the resistance). This type of surface impedance is possessed by cellular or lattice layers placed on smooth, hard surfaces. Surface waves due to a point source have been generated and studied extensively over such surfaces in laboratory experiments [4.47–49]. The outdoor ground type most likely to produce a measurable surface wave is a thin layer of snow over a frozen ground. By using blank pistol shots in experiments over snow, *Albert* [4.50] has confirmed the existence of the predicted type of surface wave outdoors.

There are some cases where it is not possible to model the ground surface as an impedance plane, i. e., n_1 is not sufficiently high to warrant the assumption that $n_1 \gg 1$. In this case, the refraction of the sound wave depends on the angle of incidence as sound enters the porous medium. This means that the apparent impedance depends not only on the physical properties of the ground surface but also, critically, on the angle of incidence. It is possible to define an *effective* admittance, β_e defined by

$$\beta_\mathrm{e} = \varsigma_1\sqrt{n_1^2 - \sin^2\theta} \ , \tag{4.34}$$

where $\varsigma_1 = \rho/\rho_1$ is the ratio of air density to the (complex) density of the rigid, porous ground.

This allows use of the same results as before but with the admittance replaced by the effective admittance for a semi-infinite non-locally reacting ground [4.51]. There are some situations where there is a highly porous surface layer above a relatively nonporous substrate. This is the case with forest floors consisting of partly decomposed litter layers above soil with a relatively high flow resistivity, with freshly fallen snow on a hard ground or with porous asphalt laid on a nonporous substrate. The minimum depth d_m for such a multiple layer ground to be treated as a semi-infinite externally reacting ground to satisfy the above condition depends on

the acoustical properties of the ground and the angle of incidence. We can consider two limiting cases. If the propagation constant within the surface layer is denoted by $k_1 = k_r - \mathrm{i}k_x$, and for normal incidence, where $\theta = 0$, the required condition is simply

$$d_\mathrm{m} > \frac{6}{k_x} \, . \tag{4.35}$$

For grazing incidence where $\theta = \pi/2$, the required condition is

$$d_\mathrm{m} > 6 \left(\sqrt{\frac{(k_r^2 - k_x^2 - 1)^2}{4} + k_r^2 k_x^2} \right.$$

$$\left. - \frac{k_r^2 - k_x^2 - 1}{2} \right)^{\frac{1}{2}} \, . \tag{4.36}$$

It is possible to derive an expression for the effective admittance of ground with an arbitrary number of layers. However, sound waves can seldom penetrate more than a few centimeters in most outdoor ground surfaces. Lower layers contribute little to the total sound field above the ground and, normally, consideration of ground structures consisting of more than two layers is not required for predicting outdoor sound. Nevertheless, the assumption of a double-layer structure [4.51] has been found to enable improved agreement with data obtained over snow [4.52]. It has been shown rigorously that, in cases where the surface impedance depends on angle, replacing the normal surface impedance by the grazing incidence value is sufficiently accurate for predicting outdoor sound [4.53].

4.6.4 Acoustic Impedance of Ground Surfaces

For most applications of outdoor acoustics, porous ground may be considered to have a rigid, rather than elastic, frame. The most important characteristic of a porous ground surface that affects its acoustical character is its flow resistivity. Soil scientists tend to refer to air permeability, which is proportional to the inverse of flow resistivity. Flow resistivity is a measure of the ease with which air can move into and out of the ground. It represents the ratio of the applied pressure gradient to the induced volume flow rate per unit thickness of material and has units of $\mathrm{Pa\,s\,m^{-2}}$. If the ground surface has a high flow resistivity, it means that it is difficult for air to flow through the surface. Flow resistivity increases as porosity decreases. For example, conventional hot-rolled asphalt has a very high flow resistivity

($10\,000\,000\,\mathrm{Pa\,s\,m^{-2}}$) and negligible porosity, whereas drainage asphalt has a volume porosity of up to 0.25 and a relatively low flow resistivity ($< 30\,000\,\mathrm{Pa\,s\,m^{-2}}$). Soils have volume porosities of between 10% and 40%. A wet compacted silt may have a porosity as low as 0.1 and a rather high flow resistivity ($4\,000\,000\,\mathrm{Pa\,s\,m^{-2}}$). Newly fallen snow has a porosity of around 60% and a fairly low flow resistivity ($< 10\,000\,\mathrm{Pa\,s\,m^{-2}}$). The thickness of the surface porous layer and whether or not it has acoustically hard substrate are also important factors.

A widely used model [4.54] for the acoustical properties of outdoor surfaces involves a single parameter, the *effective* flow resistivity σ_e, to characterize the ground. According to this single-parameter model, the propagation constant k and normalized characteristic impedance Z are given by

$$\frac{k}{k_1} = \left[1 + 0.0978 \, (f/\sigma_\mathrm{e})^{-0.700} \right.$$

$$\left. - \mathrm{i}0.189 \, (f/\sigma_\mathrm{e})^{-0.595} \right] \, , \tag{4.37a}$$

$$Z = \frac{\rho_1 c_1}{\rho c} = 1 + 0.0571 \, (f/\sigma_\mathrm{e})^{-0.754}$$

$$- \mathrm{i}0.087 \, (f/\sigma_\mathrm{e})^{-0.732} \, . \tag{4.37b}$$

This model may be used for a locally reacting ground as well as for an extended reaction surface. On the other hand, there is considerable evidence that (4.37a) tends to overestimate the attenuation within a porous material with high flow resistivity. On occasion better agreement with grassland data has been obtained by assuming that the ground surface is that of a hard-backed porous layer of thickness d [4.55] such that the surface impedance Z_S is given by

$$Z_\mathrm{S} = Z \coth(\mathrm{i}kd) \, . \tag{4.37c}$$

The result of using (4.37) is a two-parameter impedance model, the second parameter being the layer thickness. A model based on an exponential change in porosity with depth has been suggested [4.56–58]. Although this model is suitable only for high flow resistivity, i. e., a locally reacting ground, it has enabled better agreement with measured data for the acoustical properties of many outdoor ground surfaces than (4.37) [4.59]. The two adjustable parameters are the effective flow resistivity (σ_e) and the effective rate of change of porosity with depth (α_e). The impedance of the ground surface is predicted by

$$Z = 0.436(1 - \mathrm{i})\sqrt{\frac{\sigma_\mathrm{e}}{f}} - 19.74\mathrm{i}\frac{\alpha_\mathrm{e}}{f} \, . \tag{4.38}$$

More-sophisticated theoretical models for the acoustical properties of rigid, porous materials introduce porosity, the tortuosity (or *twistiness*) of the pores, factors related to pore shape [4.60] and multiple layering. Models that introduce viscous and thermal characteristic dimensions of pores [4.61] are based on a formulation by *Johnson* et al. [4.62]. Recently, it has been shown possible to obtain explicit relationships between the characteristic dimensions and grain size by assuming a specific microstructure of identical stacked spheres [4.63]. Other developments allowing for a log-normal pore-size distribution, while assuming pores of identical shape [4.60, 64], are based on the work of *Yamamoto* and *Turgut* [4.65]. As mentioned previously, sometimes it is important to include multiple layering as well. Standard methods for obtaining ground impedance are based on short-range measurements of excess attenuation [4.66, 67]. Values of parameters deduced from data according to (4.37) and (4.38) and other models show that there can be a wide range of parameter values for grassland and that better fits to short range data than obtained with (4.37) are possible for many grass-covered and other ground surfaces using two- or three-parameter models [4.59].

4.6.5 Impedance Discontinuity

Many outdoor sound propagation situations involve at least one significant change in the ground impedance. A typical example is sound propagation from a road where the road traffic source is over an acoustically-hard surface such as hot-rolled asphalt but the receiver
Fig. 4.6 Sound propagation from a point source to a receiver above a ground surface containing an impedance discontinuity

Fig. 4.7 Schematic of geometry used to calculate soft ground effects or crop effects (Sect. 4.7)

might be above grassland adjacent to the road. The form of solution proposed by *De Jong* et al. [4.68] is particularly useful for a single impedance discontinuity. It is an empirical combination of the formulas for diffraction of spherical waves at a rigid half plane (Sect. 4.5.1) and the field due to a point source over an impedance plane described by the spherical wave reflection coefficient calculation (Eqns. (4.28)–(4.29)) and, hence, it offers a relatively straightforward computation. According to the De Jong model, the excess attenuation over the single discontinuity between portions of ground with impedance Z_a and Z_b, respectively, the source being over Z_a, is given by

$$\text{EA} = 20 \log \left| \frac{P}{P_1} \right| , \tag{4.39}$$

where

$$\frac{P}{P_a} = 1 + \frac{R_a}{R_2} Q_{a,b} \exp[ik(R_b - R_a)](Q_b - Q_a)$$
$$\times \frac{\exp\left(\frac{-i\pi}{4}\right)}{\sqrt{\pi}} \frac{R_a}{R_d} \{F_{da} \pm F_{db} \exp[ik(R_b - R_a)]\} . \tag{4.40}$$

$Q_{a,b}$ is replaced by Q_a, the spherical wave reflection coefficient for the portion of the ground with impedance Z_a (4.30) and the positive sign in the curly brackets is used when the point of specular reflection falls on that portion of ground. Conversely $Q_{a,b}$ is replaced by Q_b, the spherical wave reflection coefficient for the portion of the ground with impedance Z_b, and the negative sign in the curly brackets is used when the point of specular reflection falls on that portion of ground. $F_{da} \equiv F\left[\sqrt{k(R_d - R_a)}\right]$ and $F_{db} \equiv F\left[\sqrt{k(R_d - R_b)}\right]$ are Fresnel integrals of the form $F(x) \equiv \int_x^\infty \exp(iw)^2 \, dw$ and the path lengths are defined in Fig. 4.6. R_d is the source-discontinuity-receiver path.

Using appropriate parameter values, impedance models and (4.40) it is possible to calculate the potential effects on the attenuation of road traffic noise of replacing acoustically-hard ground by acoustically-soft ground.

In the situation shown in Fig. 4.7 with 1.5 and 4 m high receivers 50 m from the nearest traffic noise source on a two lane urban road (95% light vehicles and 5% heavy vehicles traveling at 50 km/h with sound power spectra calculated according to [4.18]), replacing a 45 m wide area of hard ground by any soft ground is predicted to decrease levels by at least 5 dB at the lower receiver and by between 1 and 3.5 dB at the higher
Table 4.1 Predicted urban road noise reductions (dB) at a horizontal distance of 50 m from the nearside traffic lane due to 45 m wide strips of soft ground (two types) compared with hard ground (Fig. 4.7)

| Surface | Distance to treatment | Receiver height | | | | | |
| | | 1.5 m | | | 4 m | | |
	x (m)	Lane 1	Lane 2	Combined	Lane 1	Lane 2	Combined
Sports-field	0	6.2	6.2	6.2	3.6	2.8	3.2
	2.5	6.1	5.9	6.0	2.8	2.1	2.4
	5	5.8	5.6	5.7	2.1	1.4	1.7

	2.5	8.9	8.3	8.6	4.0	2.5	3.2
	5	8.2	7.4	7.8	2.6	1.5	2.0

Table 4.2 Fitted impedance model parameters for two ground types (Table 4.1) (after [4.59])

Surface	Porosity	Flow resistivity (kPa s m^{-2})
Sports-field	0.22	664.0
Long grass	0.36	104.0

receiver (Table 4.1). Significant variation in the noise reduction is predicted associated with different fitted ground parameters (Table 4.2). Use of low rather than high flow resistivity grassland is predicted to give 3 dB greater sound level reductions at the 1.5 m high receiver as long as the soft ground extends from 2.5 m from the road edge to the receiver. The relatively high flow resistivity of a sportsfield for example may be the result of compaction through frequent rolling and mowing. However the noise reductions predicted for all soft ground types are similar if the width of hard ground before the start of the soft ground is increased to 5 m and if the receiver height is 4 m.

4.6.6 Effects of Small–Scale Roughness

Some surface impedance spectra derived directly from measurements of complex excess attenuation over uncultivated grassland [4.69] indicate that the surface impedance tends to zero above 3 kHz. The effects of incoherent scatter from a randomly rough porous surface may explain these measurements [4.70]. Using a boss approach, an approximate effective admittance for grazing incidence on a hard surface containing randomly distributed two-dimensional (2-D) roughness normal to the roughness axes, may be written [4.71]

$$\beta \approx \left(\frac{3V^2 k^3 b}{2} \right) \left(1 + \frac{\delta^2}{2} \right) + \mathrm{i} V k (\delta - 1) , \qquad (4.41)$$

where V is the roughness volume per unit area of surface (equivalent to mean roughness height), b is the

mean center-to-center spacing, δ is an interaction factor depending on the roughness shape and packing density and k is the wave number. An interesting consequence of (4.41) is that a surface that would be acoustically hard if smooth has, effectively, a finite impedance at grazing incidence when rough. The real part of the admittance allows for incoherent scatter from the surface and varies with the cube of the frequency and the square of the roughness volume per unit area. The same approach can be extended to give the effective normalized surface admittance of a porous surface containing 2-D roughness [4.70, 72]. For a randomly rough porous surface near grazing incidence [4.73] it is possible to obtain the following approximation

$$Z_r \approx Z_s - \left(\frac{\langle H \rangle R_s}{\gamma \rho_0 c_0} \right) \left(\frac{2}{\nu} - 1 \right) , \quad [\mathrm{Re}(Z_r) \geq 0] , \tag{4.42}$$

where $\nu = 1 + \frac{2}{3}\pi \langle H \rangle$, $\langle H \rangle$ is the root mean square roughness height and Z_s is the impedance of the porous surface if it were smooth. This can be used with an impedance model or measured smooth surface impedance to predict the effect of surface roughness for long wavelengths.

Figure 4.8 shows the results of laboratory measurements of excess attenuation (4.40) spectra obtained with (point) source height of 0.07 m, receiver height 0.07 m separated by 0.7 m over an acoustically-hard glass sheet over rough surfaces formed (Fig. 4.8a) by adding between 1 and 15 semi-elliptical wooden strips (0.008 m height, 0.02 m width) with center-to-center spacing of 5 cm starting with the first placed at the specular reflection point and subsequent strips placed symmetrically about this point (Fig. 4.8b) by five random arrangements of 15 wooden 15 triangular strips (0.015 m high and 0.03 m wide) with mean center-to-center spacing of 5 cm [4.74].

a) Sound level (dB re free field)

b) Sound level (dB re free field)
Fig. 4.8a,b Excess attenuation spectra measured with (point) source height of 0.07 m, receiver height 0.07 m separated by 0.7 m over an acoustically-hard glass sheet over rough surfaces formed **(a)** by adding between 1 and 15 semi-elliptical wooden strips (0.008 m height, 0.02 m width) with center-to-center spacing of 5 cm and **(b)** by five random arrangements of 15 wooden 15 triangular strips (0.015 m high and 0.03 m wide) with mean center-to-center spacing of 5 cm (after [4.75])

The presence of only one semi-elliptical strip at the specular reflection point is sufficient to shift the destructive interference obtained over the smooth glass sheet from 12.4 to 11 kHz. The addition of further identical strips symmetrically about this point causes the destructive interference to be reduced further and up to three excess attenuation maxima (shown as minima) to appear. In contrast for the same geometry, randomly placed strips give rise to relatively broad interference patterns (Fig. 4.8b).

Cultivation practices can have important influences on ground effect since they change the surface properties. *Aylor* [4.76] noted a significant change in the excess attenuation at a range of 50 m over a soil after disking without any noticeable change in the meteorological conditions. Another cultivation practice is sub-soiling, which is intended to break up soil compaction 300 mm or more beneath the ground surface caused, for example, by the repeated passage of heavy vehicles. It is achieved by creating cracks in the compacted layer by means of a single- or double-bladed tine with sharpened leading edges. Sub-soiling only has a small effect on the surface profile of the ground. Plowing turns the soil surface over to a depth of about 0.15 m. Measurements taken over cultivated surfaces before and after sub-soiling and plowing have been shown to be consistent with the predicted effects of the resulting changes in surface roughness and flow resistivity [4.70, 74].

4.6.7 Examples of Ground Attenuation Under Weakly Refracting Conditions

Pioneering studies of the combined influences of ground surface and meteorological conditions [4.77, 78] were carried out using a fixed Rolls Royce Avon jet engine as a source at two airfields. The wind speeds and temperatures were monitored at two heights and therefore it was possible to deduce something about the wind and temperature gradients during the measurements. However, perhaps because the role of turbulence was not appreciated (Sect. 4.8.3), the magnitude of turbulence was not monitored. This was the first research to note and quantify the change in ground effect with type of surface. Examples of the resulting data, quoted as the difference between sound pressure levels at 19 m (the reference location) and more distant locations corrected for the decrease expected from spherical spreading and air absorption, are shown in Fig. 4.9. During slightly downwind conditions with low wind speed ($< 2\,\mathrm{m\,s^{-1}}$) and small temperature gradients ($< 0.01\,°\mathrm{C/m}$), the ground attenuation over grass-covered ground at Hatfield, although still a major propagation factor of more than 15 dB near 400 Hz, was less than that over the other grass-covered ground at Radlett and its maximum value occurred at a higher frequency. Snowfall during the period of the measurements also enabled observation of the large change resulting from the presence of snow at low frequencies, i. e., over

Corrected level difference (dB re 19 m)
Fig. 4.9 Parkin and Scholes data for the level difference between microphones at a height of 1.5 m and at distances of 19 m and 347 m from a fixed jet engine source (nozzle-center height 1.82 m) corrected for wavefront spreading and air absorption. □ and ◇ represent data over airfields (grass covered) at Radlett and Hatfield respectively with a positive vector wind between source and receiver of 1.27 m/s (5 ft/s); × represent data obtained over approximately 0.15 m thick (6−9 inch) snow at Hatfield and a positive vector wind of 1.52 m/s (6 ft/s) (after [4.77, 78])

20 dB attenuation in the 63 and 125 Hz third-octave bands.

Noise measurements have been made to distances of 3 km during aircraft engine run-ups with the aim of defining noise contours in the vicinity of airports [4.79].

Measurements were made for a range of power settings during several summer days under weakly refracting weather conditions (wind speed < 5 m/s, temperature 20−25 °C). 7−10 measurements were made at every measurement station (in accordance with International Civil Aviation Organization (ICAO) annex 16 requirements) and the results have been averaged. Example results are shown in Fig. 4.10. It can be shown that these data are consistent with nearly acoustically neutral, i.e., zero gradient of the sound of speed, conditions. Note that at 3 km, the measured levels are more than 30 dB less than would be expected from wavefront spreading and air absorption only.

Up to distances of 500−700 m from the engine, the data suggest attenuation rates near to the concrete or spherical spreading plus air absorption predictions. Beyond 700 m the measured attenuation rate is nearer to the soil prediction or between the soil and grass predictions. These results are consistent with the fact that

Sound level difference (dB(A) re 100 m)
Fig. 4.10 Measured differences between the A-weighted sound level at 100 m and those measured at ranges up to 3 km during an Il-86 aircraft's engine test in the direction of maximum jet noise generation (≈ 40° from exhaust axis) and predictions for levels due to a point source at the engine center height assuming spherical spreading plus air absorption and various types of ground (after [4.79])

the run-ups took place over the concrete surface of an apron and further away (i.e., between 500−700 m in various directions) the ground surface was soil and/or grass.

4.6.8 Effects of Ground Elasticity

Noise from sonic booms, blasting operations and heavy weapons shooting create low-frequency impulsive sound waves that propagate over long distances. The latter can create a major environmental problem for military training fields. Such impulsive sound sources tend to disturb neighbors more through the vibration and rattling induced in buildings, than by the direct audible sound itself [4.80, 81]. Human perception of whole-body vibration includes frequencies down to 1 Hz [4.82]. Moreover, the fundamental natural frequencies of buildings are in the range 1−10 Hz. Planning tools to predict and control such activities must therefore be able to handle sound propagation down to these low frequencies.

Despite their valuable role in many sound-propagation predictions, locally reacting ground impedance models have the intrinsic theoretical shortcoming that they fail to account for air-to-ground coupling through interaction between the atmospheric sound wave and elastic waves in the ground. This occurs particularly

at low frequencies. Indeed air–ground coupled surface waves at low frequencies have been of considerable interest in geophysics, both because of the measured ground-roll caused by intense acoustic sources and the possible use of air sources in ground layering studies. Theoretical analyses have been carried out for spherical wave incidence on a ground consisting either of a fluid or solid layer above a fluid or solid half-space [4.83]. However, to describe the phenomenon of acoustic-to-seismic coupling accurately it has been found that the ground must be modeled as an elastic porous material [4.84, 85]. The resulting theory is relevant not only to predicting the ground vibration induced by low-frequency acoustic sources but also, as we shall see, in predicting the propagation of low-frequency sound above the ground.

The classical theory for a porous and elastic medium predicts the existence of three wave types in the porous medium: two dilatational waves and one rotational wave. In a material consisting of a dense solid frame with a low-density fluid saturating the pores, the first kind of dilatational wave has a velocity very similar to the dilatational wave (or geophysical P wave) traveling in the drained frame. The attenuation of the first dilatational wave type is however, higher than that of the P wave in the drained frame. The extra attenuation comes from the viscous forces in the pore fluid acting on the pore walls. This wave has negligible dispersion and the attenuation is proportional to the square of the frequency, as is the case for the rotational wave. The viscous coupling leads to some of the energy in this propagating wave being carried into the pore fluid as the second type of dilatational wave.

In air-saturated soils, the second dilatational wave has a much lower velocity than the first and is often called the slow wave, while the dilatational wave of the first kind being called the fast wave. The attenuation of the slow wave stems from viscous forces acting on the pore walls and from thermal exchange with the pore walls. Its rigid-frame limit is very similar to the wave that travels through the fluid in the pores of a rigid, porous solid [4.86]. It should be remarked that the slow wave is the only wave type considered in the previous discussions of ground effect. When the slow wave is excited, most of the energy in this wave type is carried in the pore fluid. However, the viscous coupling at the pore walls leads to some propagation within the solid frame. At low frequencies, it has the nature of a diffusion process rather than a wave, being analogous to heat conduction. The attenuation for the slow wave is higher than that of the first in most materials and, at low frequencies, the real and imaginary parts of the propagation constant are nearly equal.

The rotational wave has a very similar velocity to the rotational wave carried in the drained frame (or the S wave of geophysics). Again there is some extra attenuation due to the viscous forces associated with differential movement between solid and pore fluid. The fluid is unable to support rotational waves, but is driven by the solid.

The propagation of each wave type is determined by many parameters relating to the elastic properties of the solid and fluid components. Considerable efforts have been made to identify these parameters and determine appropriate forms for specific materials.

In the formulation described here, only equations describing the two dilatational waves are introduced. The coupled equations governing the propagation of dilatational waves can be written as [4.87]

$$\nabla^2 (He - C\xi) = \frac{\partial^2}{\partial t^2} (\rho e - \rho_f \xi) \ , \tag{4.43}$$

$$\nabla^2 (Ce - M\xi) = \frac{\partial^2}{\partial t^2} (\rho_f e - m\xi) - \frac{\eta}{k} \frac{\delta \xi}{\delta t} F(\lambda) \ , \tag{4.44}$$

where $e = \nabla \cdot u$ is the dilatation or volumetric strain vector of the skeletal frame; $\xi = \Omega \nabla \cdot (u - U)$ is the relative dilatation vector between the frame and the fluid; u is the displacement of the frame, U is the displacement of the fluid, $F(\lambda)$ is the viscosity correction function, ρ is the total density of the medium, ρ_f is the fluid density, μ is the dynamic fluid viscosity and k is the permeability.

The second term on the right-hand side of (4.44), $\frac{\mu}{k} \frac{\partial \xi}{\partial t} F(\lambda)$, allows for damping through viscous drag as the fluid and matrix move relative to one another; m is a dimensionless parameter that accounts for the fact that not all the fluid moves in the direction of macroscopic pressure gradient as not all the pores run normal to the surface and is given by $m = \frac{\tau \rho_f}{\Omega}$, where τ is the tortuosity and Ω is the porosity.

H, C and M are elastic constants that can be expressed in terms of the bulk moduli K_s, K_f and K_b of the grains, fluid and frame, respectively and the shear modulus μ of the frame [4.61].

Assuming that e and ξ vary as $\mathrm{e}^{\mathrm{i}\omega t}$, $\partial/\partial t$ can be replaced by $\mathrm{i}\omega$ and (4.43) can be written [4.86] as

$$\nabla^2 (Ce - M\xi) = -\omega \left[\rho_f e - \rho(\omega)\xi \right] \ , \tag{4.45}$$

where $\rho(\omega) = \frac{\tau \rho_f}{\Omega} - \frac{\mathrm{i}\mu}{\omega k} F(\lambda)$ is the dynamic fluid density. The original formulation of $F(\lambda)$ (and hence of

$\rho(\omega)$) was a generalization from the specific forms corresponding to slit-like and cylindrical forms but assuming pores with identical shape. Expressions are also available for triangular and rectangular pore shapes and for more arbitrary microstructures [4.60, 61, 64]. If plane waves of the form $e = A \exp[-\mathrm{i}(lx - \omega t)]$ and $\xi = B \exp[-\mathrm{i}(lx - \omega t)]$ are assumed, then the dispersion equations for the propagation constants may be derived. These are

$$A\left(l^2 H - \omega^2 \rho\right) + B\left(\omega^2 \rho_\mathrm{f} - l^2 C\right) = 0, \qquad (4.46)$$

and

$$A\left(l^2 C - \omega^2 \rho_\mathrm{f}\right) + B\left[m\omega^2 - l^2 M - \mathrm{i}\omega F(\lambda)\frac{\eta}{k}\right] = 0. \qquad (4.47)$$

A nontrivial solution of (4.46) and (4.47) exists only if the determinant of the coefficient vanishes, giving

$$\begin{vmatrix} l^2 H - \omega^2 \rho & \omega^2 \rho_\mathrm{f} - l^2 C \\ l^2 C - \omega^2 \rho_\mathrm{f} & m\omega^2 - l^2 M - \mathrm{i}\omega F(\lambda)\frac{\eta}{k} \end{vmatrix} = 0. \qquad (4.48)$$

There are two complex roots of this equation from which both the attenuation and phase velocities of the two dilatational waves are calculated.

At the interface between different porous elastic media there are six boundary conditions that may be applied. These are:

1. Continuity of total normal stress
2. Continuity of normal displacement
3. Continuity of fluid pressure
4. Continuity of tangential stress
5. Continuity of normal fluid displacement
6. Continuity of tangential frame displacement.

At an interface between a fluid and the poro-elastic layer (such as the surface of the ground) the first four boundary conditions apply.

The resulting equations and those for a greater number of porous and elastic layers are solved numerically [4.61].

The spectrum of the ratio between the normal component of the soil particle velocity at the surface of the ground and the incident sound pressure, the acoustic-to-seismic coupling ratio or transfer function, is strongly influenced by discontinuities in the elastic wave properties within the ground. At frequencies corresponding to peaks in the transfer function, there are local maxima in the transfer of sound energy into the soil [4.84]. These

are associated with constructive interference between down- and up-going waves within each soil layer. Consequently there is a relationship between near-surface layering in soil and the peaks or *layer resonances* that appear in the measured acoustic-to-seismic transfer function spectrum: the lower the frequency of the peak in the spectrum, the deeper the associated layer. Figure 4.11 shows example measurements and predictions of the acoustic-to-seismic transfer function spectrum at the soil surface [4.12]. The measurements were made using a loudspeaker sound source and a microphone positioned close to the surface, vertically above a geophone buried just below the surface of a soil that had a loose surface layer. Seismic refraction survey measurements at the same site were used to determine the wave speeds. The predictions have been made by using a computer code known as the fast field program for layered air–ground systems (FFLAGS) that models sound propagation in a system of fluid layers and porous elastic layers [4.85].

This numerical theory (FFLAGS) may be used also to predict the ground impedance at low frequencies. In Fig. 4.12, the predictions for the surface impedance at a grazing angle of $0.018°$ are shown as a function of frequency for the layered porous and elastic system described by Table 4.3 and compared with those for a rigid porous ground with the same surface flow resistivity and porosity.

The influence of ground elasticity is to reduce the magnitude of the impedance considerably below 50 Hz.

Fig. 4.12 Predicted surface impedance at a grazing angle of 0.018° for poro-elastic and rigid porous ground (four-layer system, Table 4.3)

Fig. 4.13 Normalized surface impedance predicted for the four-layer structure, speed of sound in air $= 329$ m/s (corresponding to an air temperature of $-4\,°C$) for grazing angles between 0.018° and 5.7°

Potentially this is significant for predictions of low-frequency noise, e.g., blast noise, at long range.

Figure 4.12 shows that the surface impedance of this four-layer poro-elastic system varies between grazing angles of 5.7° and 0.57° but remains more or less constant for smaller grazing angles. The predictions show two resonances. The lowest-frequency resonance is the most angle dependent. The peak in the real part changes from 2 Hz at 5.7° to 8 Hz at 0.057°. On the other hand the higher-frequency resonance peak near 25 Hz remains relatively unchanged with range.

The peak at the lower frequency may be associated with the predicted coincidence between the Rayleigh wave speed in the ground and the speed of sound in air (Fig. 4.14). Compared with the near pressure doubling predicted by classical ground impedance models, the predicted reduction of ground impedance at low frequencies above layered elastic ground can be interpreted as the result of coupling of a significant fraction of the incident sound energy into ground-borne Rayleigh waves.

Numerical theory has also been used to explore the consequences of this coupling for the excess attenuation of low-frequency sound above ground [4.88].

Figure 4.15 shows the excess attenuation spectra predicted for source height 2 m, receiver height 0.1 m and horizontal range of 6.3 km over a layered ground profile corresponding to Table 4.3 (assumed a speed of sound in air of 329 m/s) and by classical theory for a point source above an impedance (locally reacting) plane (4.22) using the impedance calculated for a 0.018° grazing angle (Z_{eff}, broken lines in Fig. 4.15).

The predictions show a significant extra attenuation for 2–10 Hz. The predictions also indicate that, for an
Fig. 4.14 Rayleigh-wave dispersion curve predicted for the system described by Table 4.3

Fig. 4.15 Excess attenuation spectra predicted for source height 2 m, receiver height 0.1 m and horizontal range of 6.3 km by FFLAGS (assumed speed of sound in air of 329 m/s) and by classical theory using impedance calculated for 0.018° grazing angle

assumed speed of sound in air of 329 m/s, and, apart from an enhancement near 2 Hz, the excess attenuation spectrum might be predicted tolerably well by using modified classical theory instead of a full poro-elastic layer calculation.

It is difficult to measure the surface impedance of the ground at low frequencies [4.89, 90]. Consequently the predictions of significant ground elasticity effects have been validated only by using data for acoustic-to-seismic coupling, i.e., by measurements of the ratio of ground surface particle velocity relative to the incident sound pressure [4.88].

4.7 Attenuation Through Vegetation

Aylor [4.76, 91] has measured sound transmission loss (horizontal level difference spectra) through various crops, bushes and trees including (corn) maize, hemlock, red pine, hardwood brush and dense reeds in water. Many of his measurements used a loudspeaker source and receiving microphone heights lower than the height of the vegetation. In addition to ground effect, Aylor found extra attenuation of sound at higher frequencies (> 1 kHz) associated with the presence of foliage. The extra attenuation is the result of a combination of (reverberant) multiple scattering, viscous and thermal dissipation at leaf surfaces and sound-induced vibrations of leaves. The viscous and thermal losses are proportional to $FL\sqrt{f}$ where F/m is the foliage area per unit volume (sometimes called Leaf Area Density), L [m] is the length of the propagation path and f [Hz] is

frequency. The losses due to (reverberant) multiple scattering depend on the scattering parameter ka where k is the wavenumber and a is the mean leaf width. The attenuation (Att) in dB/m due to vegetation may be predicted from

$$\frac{\text{Att}}{\sqrt{(FL)}} = A[1 - \exp(c - b(ka))] , \quad ka \geq \frac{c}{b} .$$

(4.49)

A, b and c are constants. Values of 3, 0.5 and 0.3 respectively fit Aylor's data. The lower limit on ka avoids negative values of attenuation.

Measurements of horizontal level difference spectra have been made in a field of winter wheat at Butt's Close experimental farm in Woburn Sands, Bedfordshire, UK. The plants were about 1 m tall. A continuous,

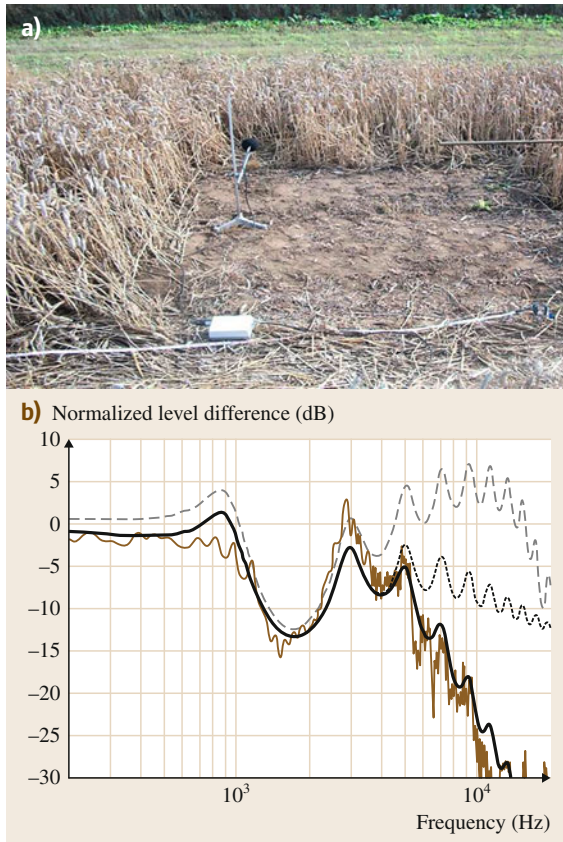
b) Normalized level difference (dB)


Fig. 4.16 (a) Cleared area in a winter wheat crop at Woburn; **(b)** measured spectrum of the difference in levels received by receivers at 1 and 10 m from the loudspeaker source (*solid blue line*); predicted ground effect alone – *broken red line*; ground effect plus incoherence plus multiple scattering by stems – *broken black line*; ground effect plus incoherence plus multiple scattering by stems plus viscous and thermal attenuation ((4.49) with $F = 20/m$ and $a = 0.008$ m) – *black solid line*

broadband sound was generated by a Tannoy driver attached to a 0.6 m long brass tube such that the end of the tube acts as a point source. The height of the source was 0.3 m. Microphones were placed at horizontal distances of 1.0, 3.0, 5.0, 7.5 and 10.0 m from the source and also 0.3 m above the ground. The first of the microphones has been used as a reference and a set of horizontal level difference spectra (the transfer function between microphone at a given distance and that positioned 1 m from the source) were obtained and corrected for the geometrical spreading (i. e., by adding $20\log(R_2/R_1)$).

Short-range level difference measurements were made also over an area of $1.5\,m^2$ which was carefully cleared of crops to determine the acoustic impedance of the ground surface (Fig. 4.16a). The parallel slit pore model of ground impedance [4.59] with a porosity of 0.37 and flow resistivity of between 200 and $250\,kPa\,s\,m^{-2}$ was found to enable a good fit of the short-range spectra measured in the cleared area up to 3 kHz. The winter wheat stems from the cleared area were counted and their diameters were measured. The number of stems in a square meter was 414. The mean stem diameter was 2.6 mm and the standard deviation was 0.8 mm. The attenuation due to multiple scattering by stems in dB/m has been added to the predicted normalized level difference due to ground effect. The comparisons between predictions and data (Fig. 4.16.) indicate that, although (reverberant) multiple scattering by the stems can account for part of the extra attenuation above 3 kHz at 10 m range in the wheat crop, it does not account for all of it. Additional attenuation may be due to viscous and thermal effects in the leaves of the winter wheat plants. Since information about the leaf sizes on the winter wheat crop is not available, values of F (20/m) and a (0.008 m) in (4.49) have been adjusted to fit the data (with $A = 3$, $b = 0.5$ and $c = 0.3$). The total predicted attenuation is a good fit to data. Use of higher values of F (30/m) and a (0.012 m) in (4.49) instead of calculating the multiple scattering by stems enables a simpler and more or less as good a fit. This leads a relatively straightforward way of calculating the attenuation of traffic noise due to an area of crops.

Calculations of reductions in noise from a two lane urban road (95% light vehicles, 5% heavy vehicles, mean speed 50 km/h, with sound power spectra according to [4.18]) have been made for the geometry shown in Fig. 4.7 with $x = 5$ m by adding attenuation (calculated from (4.49)) along the path lengths between sources and receiver that pass through 1 m high dense corn ($F = 6.3/m$, $a = 0.0784$ m) to ground effect for a soft ground (4.28) while allowing for the discontin-

Table 4.4 Predicted two-lane urban road noise reduction (dB) due to ground effect and dense corn on an arable ground (Nordtest #7: porosity 0.5, flow resistivity $106\,kPa\,s\,m^{-2}$) (after [4.59]) for the geometry shown in Fig. 4.7 with $x = 5$ m

Also shown is the foliage attenuation predicted according to ISO 9613-2 (after [4.25])

uous impedance between the road and the soft ground containing crops according to (4.38). Example predictions shown in Table 4.4 suggest a potential contribution of crops to the total attenuation of 7.5 dB at a 1.5 m high receiver and about 5 dB at a 4 m high receiver.

Conventional wisdom is that trees have no practical part to play in reducing noise along the propagation path between source and receiver. This belief stems from the fact that there are too many holes in a belt of trees to offer a significant barrier. Yet, there is increasing evidence that dense tree plantings, particularly with foliage to ground level, can offer significant reductions as a consequence of similar mechanisms to that contribute to attenuation by crop-covered ground. Moreover dense periodic plantings could exploit *sonic crystal* effects [4.92], i. e., stop bands produced by three dimensional (3-D) arrays or regularly-spaced cylinders. After deliberate introduction of defects such arrays can be used to direct sound away from receivers. A mature forest or woodland has three types of influence on sound. First is the ground effect. This is particularly significant if there is a thick litter layer of partially decomposing vegetation on the forest floor, so that the ground surface consists of a thick highly porous layer with rather low flow resistivity. This results in a primary excess attenuation maximum at lower frequencies than observed over typical grassland, similar to that over snow. Secondly the trunks and branches scatter the sound out of the path between source and receiver. Thirdly the foliage attenuates the sound by viscous fric-

tion. To predict the total attenuation through woodland, *Price* et al. [4.93] simply added the predicted contributions to attenuation for large cylinders (representing trunks), small cylinders (representing foliage), and the ground. The predictions are in qualitative agreement with their measurements, but it is necessary to adjust several parameters to obtain quantitative agreement. Price et al. found that foliage has the greatest effect above 1 kHz and the foliage attenuation increased in approximately a linear fashion with frequency. Figure 4.17 shows a typical variation of attenuation with frequency and linear fits to the foliage attenuation.

Often the insertion loss of tree belts alongside highways is considered relative to that over open grassland. A Danish study found relative attenuation of 3 dB in the A-weighted L_{eq} due to traffic noise for tree belts 15–41 m wide [4.94]. Data obtained in the UK [4.95] indicates a maximum reduction of the A-weighted L_{10} level due to traffic noise of 6 dB through 30 m of dense spruce compared with the same depth of grassland. This study also found that the effectiveness of the vegetation was greatest closest to the road. A relative reduction of 5 dB in the A-weighted L_{10} level was found after 10 m of vegetation.

Through 100 m of red pine forest, *Heisler* et al. [4.96] have found 8 dB reduction in the A-weighted L_{eq} due to road traffic compared with open grassland. The edge of the forest was 10 m from the edge of the highway and the trees occupied a gradual downward slope from the roadway extending about 325 m in each direction along the

Part A | 4.7

highway from the study site. Compared with open grassland *Huisman* [4.97] has predicted an extra 10 dB(A) attenuation of road traffic noise through 100 m of pine forest. He has remarked also that, whereas downward-refracting conditions lead to higher sound levels over grassland, the levels in woodland are comparatively unaffected. This suggests that extra attenuation obtained through the use of trees should be relatively robust to changing meteorology.

Defrance et al. [4.98] have compared results from both numerical calculations and outdoor measurements for different meteorological situations. A numerical parabolic equation code has been developed [4.99] and adapted to road traffic noise situations [4.100] where road line sources are modeled as series of equivalent point sources of height 0.5 m. The data showed a reduction in A-weighted L_{eq} due to the trees of 3 dB during downward-refracting conditions, 2 dB during homogeneous conditions and 1 dB during upward-refracting conditions. The numerical predictions suggest that in downward-refracting conditions the extra attenuation due to the forest is 2–6 dB(A) with the receiver at least 100 m away from the road. In upward-refracting conditions, the numerical model predicts that the forest may increase the received sound levels somewhat at large distances but this is of less importance since levels at larger distances tend to be relatively low anyway. In homogeneous conditions, it is predicted that sound propagation through the forest is affected only by scattering by trunks and foliage. *Defrance* et al. [4.98] have concluded that a forest strip of at least 100 m wide appears to be a useful natural acoustical barrier. Nevertheless both the data and numerical simulations were compared to sound levels without the trees present, i. e., over ground from which the trees had simply been removed. This means that the ground effect both with and without trees would have been similar. This is rarely likely to be the case. A similar numerical model has been developed [4.101] including allowance for ground effect, wind speed gradient through foliage and assuming effective wave numbers deduced from multiple scattering theory for the scattering effects of trunks, branches and foliage. The model predicts that the large wind speed gradient in the foliage tends to refract sound towards the ground and has an important effect particularly during upwind conditions. However, neither of the PE models [4.99, 101] include back-scatter or turbulence effects. The neglect of the back-scatter is inherent to the PE, which is a *one-way* prediction method. While this is not a serious problem for propagation over flat ground because the back-scatter is small, nor over an impermeable barrier because the back-scattered field, though strong, does not propagate through the barrier, back scatter is likely to be significant for a forest. Indeed acoustic reflections from the edges of forests are readily detectable [4.102].

The potential of regularly spaced trees for noise reduction has been investigated using nursery trees [4.103]. Typically trees would have to be planted unrealistically close together to offer a substantial attenuation. On the other hand regular arrangements of trees at realistic planting densities can give rise to *sonic crystal* effects which can contribute extra attenuation. The finite difference time domain (FDTD) numerical method has been used to simulate the acoustical performance of tree belts including ground, tree trunks, understorey and foliage [4.104]. Unlike a conventional noise barrier, which reduces the contribution of ground effect as a result of the increased mean sound path height above the ground, the stop bands due to a ground-mounted sonic crystal add to the destructive interference due to ground effect. It has been predicted that a practically-realisable 15 m wide tree belt consisting of trees of at least 22 cm diameter with a lattice constant of 2 m could give an overall attenuation for passenger car noise of at least 6 dB of which 3 dB is contributed by the *soft* ground effect. On this basis a 15 m wide vegetation belt could compete with the traffic noise insertion loss of a thin, classical noise barrier (on grassland) with a height of between 1 and 1.5 m in a non-refracting atmosphere. Some perturbation of a regular arrangement has been found to be beneficial with regard to sound transmission loss through an array of cylinders on a soft ground surface since it can reduce pass bands without affecting (or even enhancing) stop bands [4.105].

4.8 Wind and Temperature Gradient Effects on Outdoor Sound

The atmosphere is constantly in motion as a consequence of wind shear and uneven heating of the Earth's surface (Fig. 4.18).

Any turbulent flow of a fluid across a rough solid surface generates a boundary layer. Most interest, from the point of view of community noise prediction, fo-

cuses on the lower part of the meteorological boundary layer called the surface layer. In the surface layer, turbulent fluxes vary by less than 10% of their magnitude but the wind speed and temperature gradients are largest. In typical daytime conditions the surface layer extends over 50–100 m. Usually, it is thinner at night. Turbulence may be modeled in terms of a series of moving eddies or *turbules* with a distribution of sizes.

In most meteorological conditions, the speed of sound changes with height above the ground. Usually, temperature decreases with height (the adiabatic lapse condition). In the absence of wind, this causes sound waves to bend, or refract, upwards. Wind speed adds or subtracts from sound speed. When the source is downwind of the receiver the sound has to propagate upwind. As height increases, the wind speed increases and the amount being subtracted from the speed of sound increases, leading to a negative gradient in the speed of sound. Downwind, sound refracts downwards. Wind effects tend to dominate over temperature effects when both are present. Temperature inversions, in which air temperature increases up to the inversion height, cause sound waves to be refracted downwards below that height. Under inversion conditions, or downwind, sound levels decrease less rapidly than would be expected from wavefront spreading alone.

In general, the relationship between the speed of sound profile $c(z)$, temperature profile $T(z)$ and wind speed profile $u(z)$ in the direction of sound propagation is given by

$$c(z) = c(0)\sqrt{\frac{T(z) + 273.15}{273.15}} + u(z) , \qquad (4.50)$$

where T is in °C and u is in m/s.

4.8.1 Inversions and Shadow Zones

If the air temperature first increases up to some height before conforming to the usual decrease with height, then there is an inversion. Sound from sources beneath the inversion height will tend to be refracted towards the ground. This is a favorable condition for sound propagation and may lead to higher levels than would be the case under acoustically neutral conditions. This will also be true for receivers downwind of a source. In terms of rays between source and receiver it is necessary to take into account any ground reflections. However, rather than use plane wave reflection coefficients to describe these ground reflections, a better approximation is to use spherical wave reflection coefficients (Sect. 4.6.2).
Fig. 4.18 Schematic representation of the daytime atmospheric boundary layer and turbulent eddy structures. The curve on the *left* shows the mean wind speed (U) and the potential temperature profiles ($\theta = T + \gamma_d z$, where $\gamma_d = 0.098$ °C/km is the dry adiabatic lapse rate, T is the temperature and z is the height)

There are distinct advantages in assuming a linear effective speed of sound profile in ray tracing and ignoring the vector wind since this assumption leads to circular ray paths and relatively tractable analytical solutions. With this assumption, the effective speed of sound c can be written,

$$c(z) = c_0(1 + \zeta z) , \qquad (4.51)$$

where ζ is the normalized sound velocity gradient $(dc/dz)/c_0$ and z is the height above ground. If it also assumed that the source–receiver distance and the effective speed of sound gradient are sufficiently small that there is only a single *ray bounce*, i.e., a single ground reflection between the source and receiver, it is possible to use a simple adaptation of the formula (4.28), replacing the geometrical ray paths defining the direct and reflected path lengths by curved ones. Consequently, the sound field is approximated by

$$p = \frac{\left[\exp(-ik_0\xi_1) + Q\exp(-ik_0\xi_2)\right]}{4\pi d} , \qquad (4.52a)$$

where Q is the appropriate spherical wave reflection coefficient, d is the horizontal separation between the source and receiver, and ξ_1 and ξ_2 are, respectively, the acoustical path lengths of the direct and reflected waves. These acoustical path lengths can be determined by [4.106]

$$\xi_1 = \int_{\phi_<}^{\phi_>} \frac{d\phi}{\varsigma \sin\phi} = \varsigma^{-1} \log_e\left[\frac{\tan\frac{\phi_>}{2}}{\tan\frac{\phi_<}{2}}\right] \qquad (4.52b)$$

and

$$\xi_2 = \int_{\theta_<}^{\theta_>} \frac{d\theta}{\varsigma \sin\theta}$$

$$= \varsigma^{-1} \log_e \left[\frac{\tan\frac{\theta_>}{2} \tan^2\frac{\theta_0}{2}}{\tan\frac{\theta_<}{2}} \right], \tag{4.52c}$$

where $\phi(z)$ and $\theta(z)$ are the polar angles (measured from the positive z-axis) of the direct and reflected waves.

The subscripts $>$ and $<$ denote the corresponding parameters evaluated at $z_>$ and $z_<$ respectively, $z_> \equiv \max(z_s, z_r)$ and $z_< \equiv \min(z_s, z_r)$.

The computation of $\phi(z)$ and $\theta(z)$ requires the corresponding polar angles (ϕ_0 and θ_0) at $z=0$ [4.107]. Once the polar angles are determined at $z=0$, $\phi(z)$ and $\theta(z)$ at other heights can be found by using Snell's law

$$\sin\vartheta = (1 + \varsigma z) \sin\vartheta_0,$$

where $\vartheta = \phi$ or θ. Substitution of these angles into (4.52b) and (4.52c) and, in turn, into (4.52a) makes it possible to calculate the sound field in the presence of a linear sound-velocity gradient.

For downward refraction, additional rays will cause a discontinuity in the predicted sound level because of the inherent approximation used in ray tracing. It is possible to determine the critical range r_c at which there are two additional ray arrivals. For $\varsigma > 0$, this critical range

Fig. 4.19 Maximum ranges for which the single-bounce assumption is valid for a linear speed of sound gradient based on (4.53) and assuming equal source and receiver heights: 1 m (*solid line*); 3.5 m (*broken line*) and 10 m (*dot–dash line*)

is given by

$$r_c = \frac{\left\{ \left[\sqrt{(\varsigma z_>)^2 + 2\varsigma z_>} + \sqrt{(\varsigma z_<)^2 + 2\varsigma z_<} \right]^{2/3} \right\}^{3/2}}{\varsigma}$$

$$+ \frac{\left\{ \left[\sqrt{(\varsigma z_>)^2 + 2\varsigma z_>} - \sqrt{(\varsigma z_<)^2 + 2\varsigma z_<} \right]^{2/3} \right\}^{3/2}}{\varsigma}. \tag{4.53}$$

Figure 4.19 shows that, for source and receiver at 1 m height, if predictions are confined to a horizontal separation of less than 1 km and a normalized speed of sound gradient of less than $0.0001\,\mathrm{m}^{-1}$ (corresponding, for example, to a wind speed gradient of less than $0.1\,\mathrm{s}^{-1}$) then, it is reasonable to assume a single ground bounce in ray tracing. The critical range for the single-bounce assumption increases as the source and receiver heights increase.

A negative sound gradient means upward refraction and the creation of a sound shadow at a distance from the source that depends on the gradient. The presence of a shadow zone means that the sound level decreases faster than would be expected from distance alone. A combination of a slightly negative temperature gradient, strong upwind propagation and air absorption has been observed, in carefully monitored experiments, to reduce sound levels, 640 m from a 6 m-high source over relatively hard ground, by up to 20 dB more than expected from spherical spreading [4.108]. Since shadow zones can be areas in which there is significant excess attenuation, it is important to be able to locate their boundaries even if only approximately.

For upward-refracting conditions, ray tracing is incorrect when the receiver is in the shadow and penumbra zones. The shadow boundary can be determined from geometrical considerations. For a given source and receiver heights, the critical range r'_c is determined as

$$r'_c = \frac{\sqrt{(\varsigma' z_>)^2 + 2\varsigma' z_>} + \sqrt{\varsigma'^2 z_<(2z_> - z_<) + 2\varsigma' z_<}}{\varsigma'}, \tag{4.54}$$

where

$$\varsigma' = \frac{|\varsigma|}{1 - |\varsigma| z_>}.$$

Figure 4.20 shows that, for source and receiver heights of 1 m and a normalized speed of sound gradient of $0.0001\,\mathrm{m}^{-1}$, the distance to the shadow zone boundary is about 300 m. As expected the distance to the shadow-zone boundary is predicted to increase as the source and receiver heights are increased.
Fig. 4.20 Distances to shadow-zone boundaries for linear speed of sound gradient based on (4.54) assuming equal source and receiver heights: 1 m (*solid line*); 3.5 m (*broken line*) and 10 m (*dot–dash line*)

A good approximation of (4.54), for the distance to the shadow zone, when the source is close to the ground and ζ is small, is

$$r_c = \left[\frac{2c_0}{-\frac{dc}{dz}} \right]^{1/2} \left(\sqrt{h_s} + \sqrt{h_r} \right) , \qquad (4.55)$$

where h_s and h_r are the heights of source and receiver respectively and dc/dz must be negative for a temperature-induced shadow zone.

Conditions of weak refraction may be said to exist where, under downward-refracting conditions, the ground-reflected ray undergoes only a single bounce and, under upward-refracting conditions, the receiver is within the illuminated zone.

When wind is present, the combined effects of temperature lapse and wind will tend to enhance the shadow zone upwind of the source, since wind speed tends to increase with height. Downwind of the source, however, the wind will counteract the effect of temperature lapse, and the shadow zone will be destroyed. In any case, an acoustic shadow zone is never as complete as an optical one would be, as a result of diffraction and turbulence. In the presence of wind with a wind speed gradient of du/dz, the formula for the distance to the shadow-zone boundary is given by

$$r_c = \left[\frac{2c_0}{\frac{du}{dz}\cos\beta - \frac{dc}{dz}} \right]^{1/2} \left(\sqrt{h_s} + \sqrt{h_r} \right) , \qquad (4.56)$$

where β is the angle between the direction of the wind and the line between source and receiver.

Note that there will be a value of the angle β, (say β_c), given by

$$\frac{du}{dz} \cos\beta_c = \frac{dc}{dz}$$

or

$$\beta_c = \cos^{-1} \left(\frac{\frac{dc}{dz}}{\frac{du}{dz}} \right) \qquad (4.57)$$

at and beyond which there will not be a shadow zone. This represents the critical angle at which the effect of wind counteracts that of the temperature gradient.

4.8.2 Meteorological Classes for Outdoor Sound Propagation

There is a considerable body of knowledge about meteorological influences on air quality in general and the dispersion of plumes from stacks in particular. Plume behavior depends on vertical temperature gradients and hence on the degree of mixing in the atmosphere. Vertical temperature gradients decrease with increasing wind. The stability of the atmosphere in respect to plume dispersion is described in terms of Pasquill classes. This classification is based on incoming solar radiation, time of day and wind speed. There are six Pasquill classes (A–F) defined in Table 4.5.

Data are recorded in this form by meteorological stations and so, at first sight, it is a convenient classification system for noise prediction.

Class A represents a very unstable atmosphere with strong vertical air transport, i. e., mixing. Class F represents a very stable atmosphere with weak vertical transport. Class D represents a meteorologically neutral atmosphere. Such an atmosphere has a logarithmic wind speed profile and a temperature gradient corresponding to the normal decrease with height (adiabatic lapse rate). A meteorologically neutral atmosphere occurs for high wind speeds and large values of cloud cover. This means that a meteorologically neutral atmosphere may be far from *acoustically* neutral. Typically, the atmosphere is unstable by day and stable by night. This means that classes A–D might be appropriate classes by day and D–F by night. With practice, it is possible to estimate Pasquill stability categories in the field, for a particular time and season, from a visual estimate of the degree of cloud cover.

The Pasquill classification of meteorological conditions has been adopted as a classification system for

Table 4.5 Pasquill (meteorological) stability categories

Wind speed[a] (m/s)	Daytime Incoming solar radiation (mW/cm^2)				1 h before sunset or after sunrise	Nighttime cloud cover (octas)		
	> 60	30–60	< 30	Overcast		0–3	4–7	8
≤ 1.5	A	A–B	B	C	D	F or G[b]	F	D
2.0–2.5	A–B	B	C	C	D	F	E	D
3.0–4.5	B	B–C	C	C	D	E	D	D
5.0–6.0	C	C–D	D	D	D	D	D	D
> 6.0	D	D	D	D	D	D	D	D

[a] Measured to the nearest 0.5 m/s at 11 m height
[b] Category G is an additional category restricted to nighttime with less than 1 octa of cloud and a wind speed of less than 0.5 m/s

Table 4.6 CONCAWE meteorological classes for noise prediction

Meteorological category	Pasquill stability category and wind speed (m/s) Positive is towards receiver		
	A, B	C, D, E	F, G
1	$v < -3.0$	–	–
2	$-3.0 < v < -0.5$	$v < -3.0$	–
3	$-0.5 < v < +0.5$	$-3.0 < v < -0.5$	$v < -3.0$
4[a]	$+0.5 < v < +3.0$	$-0.5 < v < +0.5$	$-3.0 < v < -0.5$
5	$v > +3.0$	$+0.5 < v < +3.0$	$-0.5 < v < +0.5$
6	–	$v > +3.0$	$+0.5 < v < +3.0$

[a] Category with assumed zero meteorological influence

Table 4.7 Values of the meteorological corrections for CONCAWE categories 1 and 6

Octave band center frequency (Hz)	63	125	250	500	1000	2000	4000
Category 1	8.9	6.7	4.9	10.0	12.2	7.3	8.8
Category 6	− 2.3	− 4.2	− 6.5	− 7.2	− 4.9	− 4.3	− 7.4

noise-prediction schemes [4.39, 109]. However, it is clear from Table 4.5, that the meteorologically neutral category (C), while being fairly common in a temperate climate, includes a wide range of wind speeds and is therefore not very suitable as a category for noise prediction. In the CONservation of Clean Air and Water in Europe (CONCAWE) scheme [4.109], this problem is addressed by defining six noise-prediction categories based on Pasquill categories (representing the temperature gradient) and wind speed. There are 18 subcategories depending on wind speed. These are defined in Table 4.6.

CONCAWE category 4 is specified as that in which there is zero meteorological influence. So CONCAWE category 4 is equivalent to acoustically neutral conditions.

The CONCAWE scheme requires octave band analysis. Meteorological corrections in this scheme are based primarily on analysis of data from *Parkin* and

Scholes [4.77, 78] together with measurements made at several industrial sites. The excess attenuation in each octave band for each category tends to approach asymptotic limits with increasing distance. Values at 2 km for CONCAWE categories 1 (strong wind from receiver to source, hence upward refraction) and 6 (strong downward refraction) are listed in Table 4.7.

Wind speed and temperature gradients are not independent. For example, very large temperature and wind speed gradients cannot coexist. Strong turbulence associated with high wind speeds does not allow the development of marked thermal stratification.

Table 4.8 shows a rough estimate of the probability of occurrence of various combinations of wind and temperature gradients (TG) [4.108].

With regard to sound propagation, the component of the wind vector in the direction between source and receiver is most important. So the wind categories (W) must take this into account. Moreover, it is possible to

Table 4.8 Estimated probability of occurrence of various combinations of wind and temperature gradient

Temperature gradient	Zero wind	Strong wind	Very strong wind
Very large negative temperature gradient	Frequent	Occasional	Rare or never
Large negative temperature gradient	Frequent	Occasional	Occasional
Zero temperature gradient	Occasional	Frequent	Frequent
Large positive temperature gradient	Frequent	Occasional	Occasional
Very large positive temperature gradient	Frequent	Occasional	Rare or never

Table 4.9 Meteorological classes for noise prediction based on qualitative descriptions

W1	Strong wind ($> 3-5$ m/s) from receiver to source
W2	Moderate wind ($\approx 1-3$ m/s) from receiver to source, or strong wind at $45°$
W3	No wind, or any cross wind
W4	Moderate wind ($\approx 1-3$ m/s) from source to receiver, or strong wind at $45°$
W5	Strong wind ($> 3-5$ m/s) from source to receiver
TG1	Strong negative: daytime with strong radiation (high sun, little cloud cover), dry surface and little wind
TG2	Moderate negative: as T1 but one condition missing
TG3	Near isothermal: early morning or late afternoon (e.g., one hour after sunrise or before sunset)
TG5	Moderate positive: nighttime with overcast sky or substantial wind
TG6	Strong positive: nighttime with clear sky and little or no wind

Table 4.10 Qualitative estimates of the impact of meteorological condition on noise levels

	W1	W2	W3	W4	W5
TG1	–	Large attenuation	Small attenuation	Small attenuation	–
TG2	Large attenuation	Small attenuation	Small attenuation	Zero meteorological influence	Small enhancement
TG3	Small attenuation	Small attenuation	Zero meteorological influence	Small enhancement	Small enhancement
TG4	Small attenuation	Zero meteorological influence	Small enhancement	Small enhancement	Large enhancement
TG5	–	Small enhancement	Small enhancement	Large enhancement	–

give more detailed but qualitative descriptions of each of the meteorological categories (W and TG, see Table 4.9). As mentioned earlier, TG4 corresponds to the unlikely condition of an acoustically-neutral atmosphere so does not have a table entry.

In Table 4.10, the revised categories are identified with qualitative predictions of their effects on noise levels. The classes are not symmetrical around zero meteorological influence. Typically there are more meteorological condition combinations that lead to attenuation than lead to enhancement. Moreover, the increases in noise level (say $1-5$ dB) are smaller than the decreases (say $5-20$ dB).

Using the values at 500 Hz as a rough guide for the likely corrections on overall A-weighted broadband levels it is noticeable that the CONCAWE meteorological corrections are not symmetrical around zero. The CONCAWE scheme suggests meteorological variations of between 10 dB less than the acoustically neutral level for strong upward refraction between source and receiver and 7 dB more than the acoustically neutral level for strong downward refraction between the source and receiver.

4.8.3 Typical Speed of Sound Profiles

Outdoor sound prediction requires information on wind speed, direction and temperature as a function of height near to the propagation path. These determine the speed of sound profile. Ideally, the heights at which the meteorological data are collected should reflect the application. If this information is not available, then there are alternative procedures. It is possible, for example, to generate an approximate speed of sound profile from
Fig. 4.21 Two downward-refracting speed of speed of sound profiles relative to the sound speed at the ground obtained from similarity theory. The *continuous curve* is approximately logarithmic corresponding to a large Obukhov length and to a cloudy, windy night. The *broken curve* corresponds to a small Obukhov length as on a calm clear night and is predominantly linear away from the ground

temperature and wind speed at a given height using the Monin–Obukhov similarity theory [4.110] and to input this directly into a prediction scheme.

According to this theory, the wind speed component (m/s) in the source–receiver direction and temperature (°C) at height z are calculated from the values at ground level and other parameters as follows

$$u(z) = \frac{u_*}{k} \left[\ln\left(\frac{z+z_M}{z_M}\right) + \psi_M\left(\frac{z}{L}\right) \right] , \qquad (4.58)$$

$$T(z) = T_0 + \frac{T_*}{k} \left[\ln\left(\frac{z+z_H}{z_H}\right) + \psi_H\left(\frac{z}{L}\right) \right] + \Gamma z , \qquad (4.59)$$

where the parameters are defined in Table 4.11.

For a neutral atmosphere, $1/L = 0$ and $\psi_M = \psi_H = 0$.

The associated speed of sound profile, $c(z)$, is calculated from (4.34).

Note that the resulting profiles are valid in the surface or boundary layer only but not at zero height. In fact, the profiles given by the above equations, sometimes called Businger–Dyer profiles [4.111], have been found to give good agreement with measured profiles up to 100 m. This height range is relevant to sound propagation over distances up to 10 km [4.112]. However

improved profiles are available that are valid to greater heights. For example [4.113],

$$\psi_M = \psi_H = -7\ln\frac{z}{L} - \frac{4.25}{\frac{z}{L}}$$
$$+ \frac{0.5}{\left(\frac{z}{L}\right)^2} - 0.852 \quad \text{for } z > 0.5L . \qquad (4.60)$$

Often z_M and z_H are taken to be equal. The roughness length varies, for example, between 0.0002 (still water) and 0.1 (grass). More generally, the roughness length can be estimated from the Davenport classification [4.114].

Figure 4.21 gives examples of speed of sound (difference) profiles $(c(z) - c(0))$ generated from (4.58) through (4.60) using

1. $z_M = z_H = 0.02$, $u_* = 0.34$, $T_* = 0.0212$, $T_{av} = 10$, $T_0 = 6$, (giving $L = 390.64$),
2. $z_M = z_H = 0.02$, $u_* = 0.15$, $T_* = 0.1371$, $T_{av} = 10$, $T_0 = 6$, (giving $L = 11.76$),

and $\Gamma = -0.01$. These parameters are intended to correspond to a cloudy windy night and a calm, clear night respectively [4.97].

Salomons et al. [4.115] have suggested a method to obtain the remaining unknown parameters, u_*, T_*, and L from the relationship

$$L = \frac{u_*^2}{kgT_*} \qquad (4.61)$$

and the Pasquill category (P).

From empirical meteorological tables, approximate relationships between the Pasquill class P the wind speed u_{10} at a reference height of 10 m and the fractional cloud cover N_c have been obtained. The latter determines the incoming solar radiation and therefore the heating of the ground. The former is a guide to the degree of mixing. The approximate relationship is

$$P(u_{10}, N_c) = 1 + 3\left[1 + \exp\left(3.5 - 0.5u_{10} - 0.5N_c\right)\right]^{-1}$$
$$\text{during the day}$$
$$= 6 - 2\left[1 + \exp\left(12 - 2u_{10} - 2N_c\right)\right]^{-1}$$
$$\text{during the night} . \qquad (4.62)$$

A proposed relationship between the Obukhov length L [m] as a function of P and roughness length $z_0 < 0.5$ m is:

$$\frac{1}{L(P, z_0)} = B_1(P)\log(z_0) + B_2(P) , \qquad (4.63a)$$

Table 4.11 Definitions of parameters used in equations

u_*	Friction velocity (m/s)	(depends on surface roughness)
z_M	Momentum roughness length	(depends on surface roughness)
z_H	Heat roughness length	(depends on surface roughness)
T_*	Scaling temperature K	The precise value of this is not important for sound propagation. A convenient value is 283 K
k	Von Karman constant	$(= 0.41)$
T_0	Temperature (°C) at zero height	Again it is convenient to use 283 K
Γ	Adiabatic correction factor	$= -0.01\,°\text{C/m}$ for dry air. Moisture affects this value but the difference is small
L	Obukhov length (m) $> 0 \rightarrow$ stable, $< 0 \rightarrow$ unstable	$= \pm \frac{u_*^2}{kgT_*}(T_{av}+273.15)$, the thickness of the surface or boundary layer is given by $2L$ m
T_{av}	Average temperature (°C)	It is convenient to use $T_{av} = 10$ so that $(T_{av}+273.15) = \theta_0$
ψ_M	Diabatic momentum profile correction (mixing) function	$= -2\ln\left(\frac{(1+\chi_M)}{2}\right) - \ln\left(\frac{(1+\chi_M^2)}{2}\right) + 2\arctan(\chi_M) - \pi/2$ if $L < 0$ $= 5\frac{z}{L}$ if $L > 0$
ψ_H	Diabatic heat profile correction (mixing) function	$= -2\ln\left(\frac{(1+\chi_H)}{2}\right)$ if $L < 0$ $= 5\frac{z}{L}$ if $L > 0$ or for $z \leq 0.5L$
χ_M	Inverse diabatic influence or function for momentum	$= \left(1 - \frac{16z}{L}\right)^{0.25}$
χ_H	Inverse diabatic influence function for momentum	$= \left(1 - \frac{16z}{L}\right)^{0.5}$

where

$$B_1(P) = 0.0436 - 0.0017P - 0.0023P^2 \qquad (4.63b)$$

and

$$B_2(P) = \min(0, 0.045P - 0.125) \text{ for } 1 \leq P \leq 4$$
$$\max(0, 0.025P - 0.125) \text{ for } 4 \leq P \leq 6 . \qquad (4.63c)$$

Alternatively, values of B_1 and B_2 may be obtained from Table 4.12.

Equations (4.63) give

$$L = L(u_{10}, N_c, z_0) . \qquad (4.64)$$

Also u_{10} is given by (4.42) with $z = 10$ m, i.e.,

$$u(z) = \frac{u_*}{k}\left[\ln\left(\frac{10+z_M}{z_M}\right) + \psi_M\left(\frac{10}{L}\right)\right] . \qquad (4.65)$$

Table 4.12 Values of the constants B1 and B2 for the six Pasquill classes

Pasquill class	A	B	C	D	E	F
B_1	0.04	0.03	0.02	0	−0.02	−0.05
B_2	−0.08	−0.035	0	0	0	0.025

Equations (4.43), (4.44) and (4.65) may be solved for u_*, T_*, and L. Hence it is possible to calculate ψ_M, ψ_H, $u(z)$ and $T(z)$.

Figure 4.22 shows the results of this procedure for a ground with a roughness length of 0.1 m and two upwind and downwind daytime classes defined by the parameters listed in the caption.

As a consequence of atmospheric turbulence, instantaneous profiles of temperature and wind speed show considerable variations with both time and position. These variations are eliminated considerably by averaging over a period of the order of 10 minutes. The Monin–Obukhov or Businger–Dyer models give good descriptions of the averaged profiles over longer periods.

The Pasquill category C profiles shown in Fig. 4.18 are approximated closely by logarithmic curves of the form

$$c(z) = c(0) + b\ln\left[\frac{z}{z_0} + 1\right] , \qquad (4.66)$$

where the parameter b (> 0 for downward refraction and < 0 for upward refraction) is a measure of the strength of the atmospheric refraction. Such logarith-
Fig. 4.22 Two daytime speed of sound profiles (upwind – *dashed* and *dotted*; downwind – *solid* and *dash-dot*) determined from the parameters listed in Table 4.12

mic speed of sound profiles are realistic for open ground areas without obstacles particularly in the daytime.

A better fit to nighttime profiles is obtained with power laws of the form

$$c(z) = c(0) + b \left(\frac{z}{z_0} \right)^{\alpha} , \qquad (4.67)$$

where $\alpha = 0.4(P - 4)^{1/4}$.

The temperature term in the effective speed of sound profile given by (4.66) can be approximated by truncating a Taylor expansion after the first term to give

$$c(z) = c[T_0] + \frac{1}{2} \sqrt{\frac{\kappa R}{T_0}} [T(z) - T_0] + u(z) . \qquad (4.68)$$

When combined with (4.46) this leads to a linear dependence on temperature and a logarithmic dependence on wind speed with height. By comparing with 12 months of meteorological data obtained at a 50 m-high meteorological tower in Germany, *Heimann* and *Salomons* [4.116] found that (4.48) is a reasonably accurate approximation to vertical profiles of effective speed of sound even in unstable conditions and in situations where Monin–Obukhov theory is not valid. By making a series of sound level predictions (using the parabolic equation method) for different meteorological conditions it was found that a minimum of 25 meteorological classes is necessary to ensure 2 dB or less deviation in the estimated annual average sound level from the reference case with 121 categories.

There are simpler, linear-segment profiles deduced from a wide range of meteorological data that may be used to represent worst-case noise conditions, i.e., best conditions for propagation. The first of these profiles may be calculated from a temperature gradient of +15 °C/km from the surface to 300 m and 8 °C/km above that, assuming a surface temperature of 20 °C. This type of profile can occur during the daytime or at night downwind due to wind shear in the atmosphere or a very high temperature inversion. If this is considered too extreme, or too rare a condition, then a second possibility is a shallow inversion, which occurs regularly at night. A typical depth is 200 m. The profile may be calculated from a temperature gradient of +20 °C/km from the surface to 200 m and −8 °C/km above that assuming a surface temperature of 20 °C.

The prediction of outdoor sound propagation also requires information about turbulence.

4.8.4 Atmospheric Turbulence Effects

Shadow zones due to atmospheric refraction are penetrated by sound scattered by turbulence and this sets a limit of the order of 20–25 dB to the reduction of sound levels within the sound shadow [4.117, 118].

Sound propagating through a turbulent atmosphere will fluctuate both in amplitude and phase as a result of fluctuations in the refractive index caused by fluctuations in temperature and wind velocity. When predicting outdoor sound, it is usual to refer to these fluctuations in wind velocity and temperature rather than the cause of the turbulence. The amplitude of fluctuations in sound level caused by turbulence initially increase with increasing distance of propagation, sound frequency and strength of turbulence but reach a limiting value fairly quickly. This means that the fluctuation in overall sound levels from distant sources (e.g., line of sight from an aircraft at a few km) may have a standard deviation of no more than about 6 dB [4.118].

There are two types of atmospheric instability responsible for the generation of turbulent kinetic energy: shear and buoyancy. Shear instabilities are associated with mechanical turbulence. High-wind conditions and a small temperature difference between the air and ground are the primary causes of mechanical turbulence. Buoyancy or convective turbulence is associated with thermal instabilities. Such turbulence prevails when the ground is much warmer than the overlying air, such as, for example, on a sunny day. The irregularities in the temperature and wind fields are directly related to the scattering of sound waves in the atmosphere.

Fluid particles in turbulent flow often move in *loops* (Fig. 4.18) corresponding to swirls or eddies. Turbulence can be visualized as a continuous distribution of eddies in time and space. The largest eddies can extend to the height of the boundary layer, i.e., up to $1-2$ km on a sunny afternoon. However, the outer scale of usual interest in community noise prediction is of the order of meters. In the size range of interest, sometimes called the inertial subrange, the kinetic energy in the larger eddies is transferred continuously to smaller ones. As the eddy size becomes smaller, virtually all of the energy is dissipated into heat. The length scale at which at which viscous dissipation processes begin to dominate for atmospheric turbulence is about 1.4 mm.

The size of eddies of most importance to sound propagation, for example in the shadow zone, may be estimated by considering Bragg diffraction [4.119]. For a sound with wavelength λ being scattered through angle θ (Fig. 4.23), the important scattering structures have a spatial periodicity D satisfying

$$\lambda = 2D \sin \frac{\theta}{2} . \tag{4.69}$$

At a frequency of 500 Hz and a scattering angle of $10°$, this predicts a size of 4 m.

When acoustic waves propagate nearly horizontally, the (overall) variance in the effective index of refraction $\langle \mu^2 \rangle$ is related approximately to those in velocity and temperature by [4.120]

$$\langle \mu^2 \rangle = \frac{\langle u'^2 \rangle}{c_0^2} \cos^2 \phi + \frac{\langle v'^2 \rangle}{c_0^2} \sin^2 \phi$$
$$+ \frac{\langle u'T \rangle}{c_0} \cos \phi + \frac{\langle T^2 \rangle}{4T_0^2} , \tag{4.70}$$
Fig. 4.23 Bragg diffraction condition for acoustic scattering from turbulence

where T, u' and v' are the fluctuations in temperature, horizontal wind speed parallel to the mean wind and horizontal wind speed perpendicular to the mean wind, respectively. ϕ is the angle between the wind and the wavefront normal. Use of similarity theory gives [4.121]

$$\langle \mu^2 \rangle = \frac{5u_*^2}{c_0^2} + \frac{2.5u_* T_*}{c_0 T_0} \cos \phi + \frac{T_*^2}{T_0^2} , \tag{4.71}$$

where u_* and T_* are the friction velocity and scaling temperature ($= -Q/u_*$, Q being the surface temperature flux), respectively.

Typically, during the daytime, the velocity term in the effective index of refraction variance always dominates over the temperature term. This is true, even on sunny days, when turbulence is generated by buoyancy rather than shear. Strong buoyant instabilities produce vigorous motion of the air. Situations where temperature fluctuations have a more significant effect on acoustic scattering than velocity fluctuations occur most often during clear, still nights.

Although the second term (the covariance term) in (4.47) may be at least as important as the temperature term [4.121], it is often ignored for the purpose of predicting acoustic propagation. Estimations of the fluctuations in terms of u_* and T_* and the Monin–Obukhov length L are given by [4.122], for $L > 0$ (stable conditions, e.g., at night)

$$\sqrt{\langle u'^2 \rangle} = \sigma_u = 2.4u_* , \quad \sqrt{\langle v'^2 \rangle} = \sigma_v = 1.9u_* ,$$
$$\sqrt{\langle T^2 \rangle} = \sigma_T = 1.5T_*$$

for $L < 0$ (unstable conditions, e.g., daytime)

$$\sigma_u = \left(12 - 0.5 \frac{z}{L} \right)^{1/3} u_* ,$$
$$\sigma_v = 0.8 \left(12 - 0.5 \frac{z}{L} \right)^{1/3} u_* ,$$
$$\sigma_T = 2 \left(1 - 18 \frac{z}{L} \right)^{-1/2} T_* .$$

For line-of-sight propagation, the mean squared fluctuation in the phase of plane sound waves (sometimes called the strength parameter) is given by [4.123]

$$\Phi^2 = 2 \langle \mu^2 \rangle k_0^2 X L ,$$

where X is the range and L is the inertial length scale of the turbulence. Alternatively, the variance in the log-amplitude fluctuations in a plane sound wave prop-

Part A | 4.8
Fig. 4.24 A von Karman spectrum of turbulence and two Gaussian spectra chosen to match it at low wave numbers and over a narrow range of high wave numbers, respectively

agating through turbulence is given by [4.124]

$$\left\langle \chi^2 \right\rangle = \frac{k_0^2 X}{4} \left(L_T \frac{\sigma_T^2}{T_0^2} + L_v \frac{\sigma_v^2}{c_0^2} \right) ,$$

where L_T, σ_T^2 and L_v, σ_v^2 are integral length scales and variances of temperature and velocity fluctuations respectively.

There are several models for the size distribution of turbulent eddies. In the Gaussian model of turbulence statistics, the energy spectrum $\phi_n(K)$ of the index of refraction is given by

$$\phi_n (K) = \left\langle \mu^2 \right\rangle \frac{L^2}{4\pi} \exp \left(-\frac{K^2 L^2}{4} \right) , \qquad (4.72)$$

where L is a single length scale (integral or outer length scale) proportional to the correlation length (inner length scale) ℓ_G, i.e.,

$$L = \ell_G \frac{\sqrt{\pi}}{2} .$$

The Gaussian model has some utility in theoretical models of sound propagation through turbulence since it allows many results to be obtained in simple analytical form. However, as shown below, it provides a poor overall description of the spectrum of atmospheric turbulence [4.123].

In the von Karman spectrum, known to work reasonably well for turbulence with high Reynolds number, the spectrum of the variance in index of refraction is given

by

$$\phi_n(K) = \left\langle \mu^2 \right\rangle \frac{L}{\pi \left(1 + K^2 \ell_K^2 \right)} , \qquad (4.73)$$

where $L = \ell_K \sqrt{\pi} \Gamma(5/6)/\Gamma(1/3)$.

Figure 4.24 compares the spectral function $(K\phi(K)/\left\langle \mu^2 \right\rangle)$ given by the von Karman spectrum for $\left\langle \mu^2 \right\rangle = 10^{-2}$ and $\ell_K = 1\,\mathrm{m}$ with two spectral functions calculated assuming a Gaussian turbulence spectrum, respectively for $\left\langle \mu^2 \right\rangle = 0.818 \times 10^{-2}$ and $\ell_G = 0.93\,\mathrm{m}$ and $\left\langle \mu^2 \right\rangle = 0.2 \times 10^{-2}$ and $\ell_G = 0.1\,\mathrm{m}$. The variance and inner length scale for the first Gaussian spectrum have been chosen to match the von Karman spectrum exactly for the low wave numbers (larger eddy sizes). It also offers a reasonable representation near to the spectral peak. Past the spectral peak and at high wave numbers, the first Gaussian spectrum decays far too rapidly. The second Gaussian spectrum clearly matches the von Karman spectrum over a narrow range of smaller eddy sizes. If this happens to be the wave number range of interest in scattering from turbulence, then the Gaussian spectrum may be satisfactory.

Many calculations of turbulence effects on outdoor sound have relied on estimated or best-fit values rather than measured values of turbulence parameters. Under these circumstances, there is no reason to assume spectral models other than the Gaussian one.

Typically, the high-wave-number part of the spectrum is the main contributor to turbulence effects on sound propagation. This explains why the assumption of a Gaussian spectrum results in best-fit parameter values that are rather less than those that are measured.

Turbulence destroys the coherence between direct and ground-reflected sound and consequently reduces the destructive interference in the ground effect. Equation (4.22) may be modified [4.125] to obtain the mean-squared pressure at a receiver in a turbulent but *acoustically neutral* (no refraction) atmosphere

$$\left\langle p^2 \right\rangle = \frac{1}{R_1^2} + \frac{|Q|^2}{R_2^2} + \frac{2|Q|}{R_1 R_2} \cos \left[k \left(R_2 - R_1 \right) + \theta \right] T , \qquad (4.74)$$

where θ is the phase of the reflection coefficient, $(Q = |Q|\mathrm{e}^{-\mathrm{i}\theta})$, and T is the coherence factor determined by the turbulence effect.

Hence the sound pressure level P is given by

$$P = 10 \log_{10} \left(p^2 \right) . \qquad (4.75)$$
Fig. 4.25 Excess attenuation versus frequency for a source and receiver above an impedance ground in an acoustically neutral atmosphere predicted by (4.50)–(4.56) for three values of $\langle \mu^2 \rangle$ between 0 and 10^{-6}. The assumed source and receiver heights are 1.8 and 1.5 m, respectively, and the assumed separation is 600 m. A two-parameter impedance model (4.32) has been used with values of $300\,000\,\mathrm{N\,s\,m^{-4}}$ and $0.0\,\mathrm{m^{-1}}$

For a Gaussian turbulence spectrum, the coherence factor T is given by [4.126]

$$T = \mathrm{e}^{-\sigma^2(1-\rho)} , \tag{4.76}$$

where σ^2 is the variance of the phase fluctuation along a path and ρ is the phase covariance between adjacent paths (e.g. direct and reflected)

$$\sigma^2 = A\sqrt{\pi}\left\langle \mu^2 \right\rangle k^2 R L_0 , \tag{4.77}$$

of the index of refraction, and L_0 is the outer (inertial) scale of turbulence.

The coefficient A is given by

$$A = 0.5 , \quad R > kL_0^2 , \tag{4.78a}$$
$$A = 1.0 , \quad R < kL_0^2 . \tag{4.78b}$$

The parameters $\langle \mu^2 \rangle$ and L_0 may be determined from field measurements or estimated.

The phase covariance is given by

$$\rho = \frac{\sqrt{\pi}}{2}\frac{L_0}{h}\,\mathrm{erf}\left(\frac{h}{L_0}\right) , \tag{4.79}$$

a) Excess Attenuation (dB re free field)

b) Horizontal level difference (dB)
Fig. 4.26 (**a**) Data for the propagation of a 424 Hz tone as a function of range out to 1.5 km (after [4.127]) compared to FFP predictions with and without turbulence (after [4.126]) and (**b**) broadband data to 2500 Hz for four 26 s averages (*lines*) of the spectra of the horizontal level differences between sound level measurements at 6.4 m high receivers, 152.4 and 762 m from a fixed jet engine source (nozzle exit centered at 2.16 m height) compared to FFP predictions with (*diamonds*) and without (*crosses*) turbulence (after [4.126])

where h is the maximum transverse path separation and $\mathrm{erf}(x)$ is the error function defined by

$$\mathrm{erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x \mathrm{e}^{-t^2}\,\mathrm{d}t , \tag{4.80}$$

For a sound field consisting *only* of direct and reflected paths (which will be true at short ranges) in the absence of refraction, the parameter h is given by

$$\frac{1}{h} = \frac{1}{2}\left(\frac{1}{h_s} + \frac{1}{h_r}\right) , \tag{4.81}$$

where h_s and h_r are the source and receiver heights respectively. *Daigle* [4.128] uses half this value to obtain better agreement with data.

When $h \to 0$, then $\rho \to 1$ and $T \to 1$. This is the case near grazing incidence.

For $h \to$ large, then $T \to$ maximum. This will be the case for a greatly elevated source and/or receiver. The mean-squared refractive index may be calculated from the measured instantaneous variation of wind speed and temperature with time at the receiver. Specifically

$$\left\langle \mu^2 \right\rangle = \frac{\sigma_w^2 \cos^2 \alpha}{C_0^2} + \frac{\sigma_T^2}{4T_0^2} ,$$

where σ_w^2 is the variance of the wind velocity, σ_T^2 is the variance of the temperature fluctuations, α is the wind vector direction, and C_0 and T_0 are the ambient sound speed and temperature, respectively. Typical values of best-fit mean-squared refractive index are between 10^{-6} for calm conditions and 10^{-4} for strong turbulence. A typical value of L_0 is 1 m but in general a value equal to the source height should be used.

Figure 4.25 shows example results of computations of excess attenuation spectra using (4.74) through (4.80). Note that increasing turbulence reduces the depth of the main ground-effect dip.

Figures 4.26a, b show comparisons between measured data [4.129] and theoretical predictions using a full-wave numerical solution (FFP) with and without turbulence [4.126]. The data in Fig. 4.26a were obtained with a loudspeaker source [4.130] in strong upwind conditions modeled by the logarithmic speed of sound gradient [4.127]

$$c(z) = 340.0 - 2.0\ln\left(\frac{z}{6 \times 10^{-3}}\right) , \tag{4.82}$$

where z is the height in m.

Those in Fig. 4.26b were obtained with a fixed jet engine source during conditions with a negative temperature gradient (modeled by two linear segments) and a wind speed that was more or less constant with height at $4\,\mathrm{m\,s^{-1}}$ in the direction between receivers and source.

The agreement obtained between the predictions from the FFP including turbulence and the data, while not perfect, represents a large improvement over the results of calculations without turbulence and, in the case of Fig. 4.26a, is similar to that obtained with predictions given by the parabolic equation method [4.127].

4.9 Concluding Remarks

There are several areas of outdoor acoustics in which further research is needed. This concluding section discusses current trends and lists some objectives that are yet to be fulfilled.

4.9.1 Modeling the Interaction of Meteorological and Topographical Effects

Trends in research concerned with atmospheric and topographical effects and with the interaction between meteorology and topography [4.129, 131, 132] include the combination of mesoscale meteorological models with acoustic propagation models. The steady improvement in readily available computational power has encouraged the development of computationally intensive finite-difference time-domain (FDTD) models, which are based on numerical solutions of Euler's equations [4.133, 134] and models combining computational

fluid dynamics (CFD) and FDTD [4.135]. Work remains to be done on the acoustical effects of barriers and hills in the presence of wind- and temperature-gradients. Noise barrier performance is degraded when wind blows from source to receiver, i.e. in conditions of downward refraction. Just behind the barrier, the air flow is blocked and the resulting relatively windless region causes compression of the streamlines above the barrier leading to additional downward refraction. The acoustic shadow region behind the barrier becomes smaller and the barrier efficiency is decreased. Barriers also give rise to extra turbulence leading to additional sound scattering into the shadow zone. Typically this is important only deep inside the shadow zone. One method of reducing barrier-induced downward refraction effects is to add a row of tress on the receiver side of the barrier [4.136]. In principle, vegetation on berms may also have a useful effect. However many berms are relatively streamlined compared to a conventional noise

fence. The effects of vegetation need to be confirmed by outdoor measurements.

4.9.2 Low-Frequency Interaction with the Ground

Predictions of significant ground elasticity effects have been validated only by data for acoustic-to-seismic coupling, i. e., by measurements of the ratio of ground surface particle velocity relative to the incident sound pressure. Nevertheless given the significant predicted effects of layered ground elasticity on low-frequency propagation above ground it remains of interest to make further efforts to measure them.

4.9.3 Rough-Surface Effects

The potential for increasing the attenuation of sound over an acoustically-hard ground by deliberate introduction of various forms of roughness has been explored so far only to a limited extent [4.67]. It will be of interest to investigate the extent to which the frequency dependence of the resulting ground effect can be tailored for example by making the roughness elements acoustically resonant.

Coastal communities are regularly exposed to aircraft noise. To reduce the noise impact of sonic booms from civil supersonic flights, it is likely that, wherever possible, the aircraft will pass through the sound barrier over the sea. This means that prediction of aircraft noise in general, and sonic boom characteristics in particular, in coastal areas will be important and will involve propagation over the sea as well as the land. Given that the specific impedance of seawater is greater than that of air by four orders of magnitude, the sea surface may be considered to be acoustically hard. However, it is likely

that sound propagation is modified during near-grazing propagation above a rough sea surface. Such propagation is likely to be of interest also when predicting sound propagation from near-ground explosions and from offshore wind turbines. Although the sea surface is continuously in motion associated with winds and currents, so that the scattered field is not constant, a sonic boom or blast waveform is sufficiently short compared with the period of the sea surface motion that the roughness may be considered to be static. As long as the incident acoustic wavelengths are large compared with the water wave heights and periods, the effect of the diffraction of sound waves by roughness may be modeled by an effective impedance. This is a convenient way to incorporate the acoustical properties of a rough sea surface into sonic boom and blast sound propagation models. Some modeling work has been carried out on this basis [4.137]. However it remains to be validated by data.

4.9.4 Predicting Outdoor Noise

Most current prediction schemes for outdoor sources such as transportation and industrial plant are empirical. To some extent, this is a reflection of the complexity arising from the variety of source properties, path configurations and receiver locations. On the other hand, apart from distinctions between source types and properties, the propagation factors are common. As discussed in this chapter, there has been considerable progress in modeling outdoor sound. The increasing computational power that is available for routine use makes several of the semi-analytical results and recent numerical codes of more practical value. Consequently, it can be expected that a trend towards schemes that implement a common propagation package but employ differing source descriptors [4.18] will continue.

5. Underwater Acoustics

William A. Kuperman, Philippe Roux

It is well established that sound waves, compared to electromagnetic waves, propagate long distances in the ocean. Hence, in the ocean as opposed to air or a vacuum, one uses sound navigation and ranging (SONAR) instead of radar, acoustic communication instead of radio, and acoustic imaging and tomography instead of microwave or optical imaging or X-ray tomography. Underwater acoustics is the science of sound in water (most commonly in the ocean) and encompasses not only the study of sound propagation, but also the masking of sound signals by interfering phenomenon and signal processing for extracting these signals from interference. This chapter we will present the basics physics of ocean acoustics and then discuss applications.

During the two World Wars, both shallow and deep-water acoustics studies were pursued, but during the Cold War, emphasis shifted sharply to deep water. The post-World War II (WWII) history of antisubmarine warfare (ASW) actually started in 1943 with Ewing and Worzel discovering the deep sound channel (DSC) caused by a minimum in the temperature-dependent sound speed. (Brekhovskikh of the Soviet Union also discovered it independently, but later.) This minimum has been mapped (dotted line in Fig. 5.1), and typically varies from the cold surface at the poles to a depth of about 1300 m at the equator. Since sound refracts toward lower sound speeds, the DSC produces a refraction-generated waveguide (gray lines) contained
Fig. 5.1 Schematic of a long-range passive detection of a submarine in polar waters by a surveillance system in a temperate region (after [5.1])

within the ocean, such that sound paths oscillate about the sound speed minimum and can propagate thousands of kilometers.

Exploiting the DSC, the US Navy created the multi-billion dollar sound ocean surveillance system (SOSUS) network to monitor Soviet ballistic-missile nuclear submarines. Acoustic antennas were placed on ocean mountains or continental rises whose height extended into the DSC. These antennas were hard-wired to land stations using reliable undersea telephone cable technology. Submarines typically go down to depths of a few hundred meters. With many submarines loitering in polar waters, they were coupling into the DSC at shallower depths. Detections were made on very narrow-band radiation caused by imperfect, rotating machinery such as propellers. The advantage of detecting a set of narrow-band lines is that most of the broadband ocean noise can be filtered out. Though it was a Cold War, the multi-decade success of SOSUS was, in effect, a major Naval victory. The system was compromised by a spy episode, when the nature of the system was revealed. The result was a Soviet submarine quietening program and over the years, the Soviet fleet became quieter, reducing the long-range capabil-

ity of the SOSUS system. The end of the Cold War led to an emphasis on the issue of detecting very quiet diesel–electric submarines in the noisy, shallow water that encompasses about 5% of the World's oceans on the continental shelves, roughly the region from the beach to the shelfbreak at about ≈ 200 m depth. However, there are also signs of a rekindling of interest in deep-water problems.

Parallel to these military developments, the field of ocean acoustics also grew for commercial, environmental and other purposes. Since the ocean environment has a large effect on acoustic propagation and therefore SONAR performance, acoustic methods to map and otherwise study the ocean were developed. As active SONARs were being put forward as a solution for the detection of quiet submarines, there was a growing need to study the effects of sound on marine mammals. Commercially, acoustic methods for fish finding and counting were developed as well as bottom-mapping techniques, the latter being having both commercial and military applications. All in all, ocean acoustics research and development has blossomed in the last half-century and many standard monographs and textbooks are now available ([5.2–10]).

5.1 Ocean Acoustic Environment

The acoustic properties of the ocean, such as the paths along which sound from a localized source travel, are mainly dependent on the ocean sound speed structure, which in turn is dependent on the oceanographic environment. The combination of water column and bottom properties leads to a set of generic sound-propagation paths descriptive of most propagation phenomena in the ocean.

5.1.1 Ocean Environment

Sound speed in the ocean water column is a function of temperature, salinity and ambient pressure. Since the ambient pressure is a function of depth, it is customary to express the sound speed (c) in m/s as an empirical function of temperature (T) in degrees centigrade, salinity (S) in parts per thousand and depth (z) in meters, for example [5.7, 11, 12]

$$c = 1449.2 + 4.6T - 0.055T^2 + 0.00029T^3 + (1.34 - 0.01T)(S - 35) + 0.016z . \quad (5.1)$$
Fig. 5.2 Generic sound-speed profiles. The profiles reflect the tendencies that sound speed varies directly with temperature and hydrostatic pressure. Near-surface mixing can lead to almost isovelocity in that region. In polar waters, the coldest region is at the surface

Figure 5.2 shows a typical set of sound speed profiles indicating the greatest variability near the surface. In a warmer season (or warmer part of the day, sometimes referred to as the *afternoon effect*), the temperature increases near the surface and hence the sound speed increases toward the sea surface. In nonpolar regions where mixing near the surface due to wind and wave activity is important, a *mixed layer* of almost constant temperature is often created. In this isothermal layer the sound speed increases with depth because of the increasing ambient pressure, the last term in (5.1). This is the *surface duct* region. Below the mixed layer is the thermocline where the temperature and hence the sound speed decreases with depth. Below the thermocline, the temperature is constant and the sound speed increases because of increasing ambient pressure. Therefore, between the deep isothermal region and the mixed layer, there is a depth at minimum sound speed referred to as the axis of the *deep sound channel*. However, in polar regions, the water is coldest near the surface so that the minimum sound speed is at the surface. Figure 5.3 is a contour display of the sound speed structure of the North and South Atlantic with the deep sound channel axis indicated by the heavy dashed line. Note that the deep sound channel becomes shallower toward the poles. Aside from sound speed effects, the ocean volume is absorptive and causes attenuation that increases with acoustic frequency.

Shallower water such as that in continental shelf and slope regions is not deep enough for the depth-pressure term in (5.1) to be significant. Thus the winter profile tends to isovelocity, simply because of mixing, whereas the summer profile has a higher sound speed near the surface due to heating; both are schematically represented in Fig. 5.4.

The sound speed structure regulates the interaction of sound with the boundaries. The ocean is bounded above by air, which is a nearly perfect reflector; however, the sea surface is often rough, causing sound to scatter in directions away from the specular reflecting angle. The ocean bottom is typically a complicated, rough, layered structure supporting elastic waves. Its geoacoustic properties are summarized by density, compressional and shear speed, and attenuation profiles. The two basic interfaces, air/sea and sea/bottom, can be thought of as the boundaries of an acoustic waveguide whose internal index of refraction is determined by the
Fig. 5.3 Sound-speed contours at 5 m/s intervals taken from the North and South Atlantic along 30.50° W. The *dashed line* indicates the axis of the deep sound channel (after [5.13]). The sound channel is deepest near the equator and comes to the surface at the poles

fundamental oceanographic parameters represented in the sound speed equation (5.2).

Due to the density stratification of the water column, the interior of the ocean supports a variety of waves, just as the ocean surface does. One particularly important type of wave in both shallow water and deep water is the internal gravity wave (IW) [5.14]. This wave type is bounded in frequency between the inertial frequency, $f = 2\Omega \sin\theta$, where Ω is the rotation frequency of the earth and θ is the latitude, and the highest buoyancy frequency (or Brunt–Vaisala frequency) $N_{\max}(z)$, where $N^2(z) = -(g/\rho)\,\mathrm{d}\rho/\,\mathrm{d}z$, and $\rho(z)$ is the density of the fluid as a function of depth z. The inertial frequency varies from two cycles per day at the poles to zero cycles per day at the equator, and the maximum buoyancy frequency is usually on the order of $5-10$ cycles per hour.
Fig. 5.4 Typical summer and winter shallow-water sound-speed profiles. Warming causes the high-speed region near the surface in the summer. Without strong heating, mixing tends to make the shallow-water region isovelocity in the winter

Two categories of IWs are found in stratified coastal waters: linear and nonlinear waves. The linear waves, found virtually everywhere, obey a standard linear wave equation for the displacement of the surfaces of constant density (*isopycnal* surfaces). The nonlinear IWs, which are generated under somewhat more specialized circumstances than the linear waves (and thus are not always present), can obey a family of nonlinear wave equations. The most useful and illustrative of them is the familiar Korteweg–deVries equation (KdV), which governs the horizontal components of the nonlinear internal waves. The vertical component of the nonlinear internal waves obeys a normal-mode equation.

5.1.2 Basic Acoustic Propagation Paths

Sound propagation in the ocean can be qualitatively broken down into three classes: very-short-range, deep-water and shallow-water propagation.

Very–Short–Range Propagation

The pressure amplitude from a point source in free space falls off with range r as r^{-1}; this geometric loss is called *spherical spreading*. Most sources of interest in the deep ocean are closer to the surface than to the bottom. Hence, the two main short-range paths are the direct path and the surface reflected path. When these two paths *interfere*, they produce a spatial distribution of sound often referred to as a Lloyd mirror pattern, as shown in insert of Fig. 5.5. Also, with reference to Fig. 5.5, note that the *transmission loss* is a decibel measure of the decay with distance of acoustic intensity from a source relative to its value at unit distance (see Appendix), the latter being proportional to the square of the acoustic amplitude.

Long–Range Propagation Paths

Figure 5.6 is a schematic of propagation paths in the ocean resulting from the sound-speed profiles (indicated by the dashed line) described above in Fig. 5.2. These paths can be understood from *Snell's law*,

$$\frac{\cos \theta(z)}{c(z)} = \text{constant} , \qquad (5.2)$$

which relates the ray angle $\theta(z)$ with respect to the horizontal, to the local sound speed $c(z)$ at depth z. The equation requires that, the higher the sound speed, the smaller the angle with the horizontal, meaning that sound bends away from regions of high sound speed; or said another way, sound bends toward regions of low sound speed. Therefore, paths 1, 2, and 3 are the simplest to explain since they are paths that oscillate about the local sound speed minima. For example, path 3 depicted by a ray leaving a source near the deep sound channel axis at a small horizontal angle propagates in the deep sound channel. This path, in temperate latitudes where the sound speed minimum is far from the surface, permits propagation over distances of thousands of kilometers.

The upper turning point of this path typically interacts with the thermocline, which is a region of strong internal wave activity. Path 4, which is at slightly steeper angles and is usually excited by a near-surface source, is *convergence zone* propagation, a spatially periodic (35–65 km) refocusing phenomenon producing zones of high intensity near the surface due to the upward refracting nature of the deep sound-speed profile. Regions between these zones are referred to as shadow regions. Referring back to Fig. 5.2, there may be a depth in the deep isothermal layer at which the sound speed is the same as it is at the surface. This depth is called the *critical depth* and is the lower limit of the deep sound channel. If the critical depth is in the water column, the environment supports long-distance propagation without bottom interaction whereas if there is no critical depth in the water column, the ocean bottom is the lower boundary of the deep sound channel. The *bottom bounce* path 5 is also a periodic phenomenon but with a shorter cycle distance and shorter propagation distance because of losses when sound is reflected from the ocean bottom. Finally, note that when bottom baths are described in the general context of the spectral properties of waveguide propagation, they are described in terms of the continuous horizontal wavenumber region as explained in the discussion associated with Fig. 5.32a.
Fig. 5.5 The insert shows the geometry of the Lloyd's mirror effect. The plots show a comparison of Lloyd's mirror (*full line*) to spherical spreading (*dashed line*). Transmission losses are plotted in decibels corresponding to losses of $10 \log r^2$ and $10 \log r^4$, respectively, as explained in Sect. 5.1.3

Shallow Water and Waveguide Propagation

In general the ocean can be thought of as an acoustic waveguide [5.1]; this waveguide physics is particularly evident in shallow water (inshore out to the continental slope, typically to depths of a few hundred meters). Snell's law applied to the summer profile in Fig. 5.4 produces rays which bend more toward the bottom than winter profiles in which the rays tend to be straight. This implies two effects with respect to the ocean bottom: (1) for a given range, there are more bounces off
Fig. 5.6 Schematic representation of various types of sound propagation in the ocean. An intuitive guide is that Snell's law has sound turning toward lower-speed regions. That alone explains all the refractive paths: 1, 2, 3 and 4. It will also explain any curvature associated with paths 5 and 6. Thus, the summer profile would have path 6 curving downward (this curvature is not shown in the figure) while the deep sound-speed profile below the minimum curves upward (4)

a)

b) Ray-mode analogy

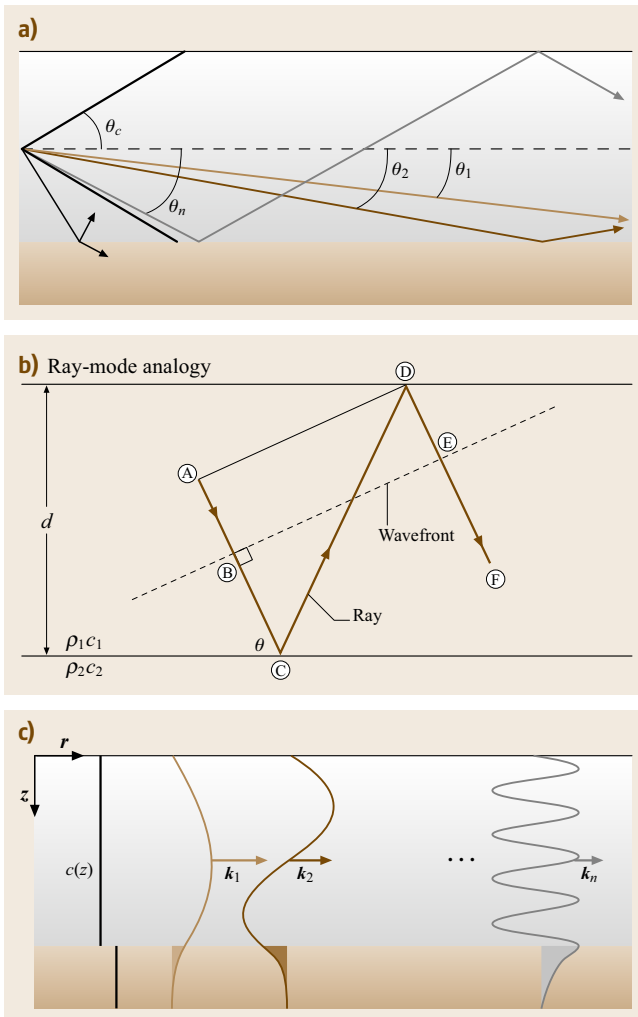
c)


Fig. 5.7a–c Ocean waveguide propagation. (**a**) Long-distance propagation occurs within the critical angle cone of $2\theta_c$. (**b**) For the example shown, the condition for constructive interference is that the phase change along BCDE be a multiple of 2π. (**c**) The constructive interference can be interpreted as discrete modes traveling in the waveguide, each with their own horizontal wavenumber

than winter paths, summer shallow-water propagation is lossier than winter. This result is tempered by rough winter surface conditions that generate large scattering losses at the higher frequencies.

For simplicity we consider an isovelocity waveguide bounded above by the air–water interface and below by a two-fluid interface that is classically defined as a Pekeris waveguide. From Sect. 5.2.3, we have perfect reflection with a 180° phase change at the surface and for grazing angles lower than the bottom critical angle, there will also be perfect bottom reflection. Therefore, as schematically indicated in Fig. 5.7a, ray paths within a cone of $2\theta_c$ will propagate unattenuated down the waveguide. Because the up- and down-going rays have equal amplitudes, preferred angles will exist for which constructive interference occurs. These particular angles are associated with the normal modes of the waveguide, as formally derived from the wave equation in the Sect. 5.4. However, it is instructive to understand the geometric origin of the waveguide modal structure. Figure 5.7b is a schematic of a ray reflected from the bottom and then the surface of a Pekeris waveguide. Consider a ray along the path ACDF and its wavefront, which is perpendicular to the ray. The two down-going rays of equal amplitude, AC and DF, will constructively interfere if points B and E have a phase difference of a multiple of 2π (and similarly for up-going rays). The phase change at the two boundaries must be included. There is a discrete set of angles up to the critical angle for which this constructive interference takes place and, hence, for which sound propagates. This discrete set, in terms of wave physics, are called the normal modes of the waveguide, illustrated in Fig. 5.7c. They correspond to the ray schematic of Fig. 5.7a. Mode propagation is further discussed in the Sect. 5.4.4.

5.1.3 Geometric Spreading Loss

The energy per unit time emitted by a sound source is flowing through a larger area with increasing range. Intensity is the power flux through a unit area, which translates to the energy flow per unit time through a unit area. The simplest example of geometric loss is spherical spreading for a point source in free space where the area increases as r^2, where r is the range from the point source. So spherical spreading results in an intensity decay proportional to r^{-2}. Since intensity is proportional to the square of the pressure amplitude, the fluctuations in pressure induced by the sound p, decay as r^{-1}. For range-independent ducted propagation, that is, where rays are refracted or reflected back towards the horizon-

the ocean bottom in summer than in the winter, and (2) the ray angles intercepting the bottom are steeper in the summer than in the winter. A qualitative understanding of the reflection properties of the ocean bottom should therefore be very revealing of sound propagation in summer versus winter. Basically, near-grazing incidence is much less lossy than larger, more-vertical angles of incidence. Since summer propagation paths have more bounces, each of which are at steeper angles

tal direction, there is no loss associated with the vertical dimension. In this case, the spreading surface is the area of the cylinder whose axis is in the vertical direction passing through the source $2\pi rH$, where H is the depth of the duct (waveguide), and is constant. Geometric loss in the near-field Lloyd-mirror regime requires consideration of interfering beams from direct and surface reflected paths. To summarize, the geometric spreading laws for the pressure field (recall that intensity is proportional to the square of the pressure.) are:

- Spherical spreading loss: $p \propto r^{-1}$;
- Cylindrical spreading loss: $p \propto r^{-1/2}$;
- Lloyd-mirror loss: $p \propto r^{-2}$.

5.2 Physical Mechanisms

The physical mechanisms associated with the generation, reception, attenuation and scattering of sound in the ocean are discussed in this section.

5.2.1 Transducers

A transducer converts some sort of energy to sound (source) or converts sound energy (receiver) to an electrical signal [5.15]. In underwater acoustics piezoelectric and magnetostrictive transducers are commonly used; the former connects electric polarization to mechanical strain and the latter connects the magnetization of a ferromagnetic material to mechanical strain. Piezoelectric transducers represent more than 90% of the sound sources used in the ocean. Magnetostrictive transducers are more expensive, have poor efficiency and a narrow frequency bandwidth. However, they allow large vibration amplitudes and are relevant to low-frequency high-power applications. In addition there are: electrodynamic transducers in which sound pressure oscillations move a current-carrying coil through a magnetic field causing a back emf, and electrostatic transducers in which charged electrodes moving in a sound field change the capacitance of the system. Explosives, air guns, electric discharges, and lasers are also used as wide-band sources.

Hydrophones, underwater acoustic receivers, are commonly piezoelectric devices with good sensitivity and low internal noise levels. Hydrophones usually work on large frequency bandwidths since they do not need to be adjusted to a resonant frequency. They are associated with low-level electronics such as preamplifiers and filters.

Because the field of transducers is large by itself, we concentrate in this section on some very practical issues that are immediately necessary to either convert received voltage levels to pressure levels or transmitter excitation to pressure levels. Practical issues about transducers and hydrophones deal with the understanding of specification sheets given by the manufacturer.

Among those, we will describe, based on a practical example, the definition and the use of the following quantities:

- Transmitting voltage response
- Open-circuit receiving response
- Transmitting and receiving beam patterns at specific frequencies
- Impedance and/or admittance versus frequency
- Resonant frequency, maximum voltage and maximum source level (for a transducer).

Figure 5.8 is a specification sheet provided by the ITC (Internationsal Transducer Corp.) for a deep-water omnidirectional transducer. Figure 5.8a corresponds to the transmitting sensitivity versus frequency. The units are in dB re µPa/V@1m, which means that, at the resonant frequency 11.5 kHz for example, the transducer excited with a 1 V amplitude transmits at one meter a pressure p_t such that $20\log_{10}\left(\frac{p_t}{1\times10^{-6}}\right) = 149$ dB, i.e. $p_t \approx 28.2$ Pa. Similarly, Fig. 5.8b shows the receiving sensitivity versus frequency. The units are now in dB re1V/µPa which means that, at 11.5 kHz for example, the transducer converts a 1 µPa amplitude field into a voltage V_r such that $20\log_{10}\left(\frac{V_r}{1}\right) = -186$ dB, i.e. $V_r \approx 5\times10^{-10}$ V. Figure 5.8c shows the admittance versus frequency. The complex admittance Y is the inverse of the complex impedance Z. The real part of the admittance is called the conductance G; the imaginary part is the susceptance B. Those curves directly yield the calculation of the electrical impedance of the transducer. For example, the impedance of ITC-1007 at the resonant frequency is $|Z| = 1/(\sqrt{G^2+B^2}) \approx 115\,\Omega$. When used as a source, the transducer electrical impedance has to match the output impedance of the power amplifier to allow for a good power transfer through the transducer. In the case where the impedances do not match, a customized matching box will be necessary. Knowing the electrical impedance $|Z|$ and the input power $I = 10\,000$ W, the maximum voltage can be determined as $U_{max} = \sqrt{|Z|\,I} \approx 1072$ V. According to

Specifications (nominal)

Type	Projector/Hydrophone
Resonance frequency f_r	11,5 kHz

the transmitting voltage response, this corresponds to a source level of nearly 210 dB re µPa at the resonant frequency. Finally, Fig. 5.8d represents the directionality pattern at a given frequency. It shows that the ITC-1007 is omnidirectional at 10 kHz.

When transducers have to be coupled to a power amplifier or another electronic device, it may be useful to model the transducer as an electronic circuit (Fig. 5.9a). The frequency dependence of the conductance G and susceptance B (Fig. 5.8c) yield the components of the

equivalent circuit, as shown in Fig. 5.9b. Similarly, an important parameter is the quality factor Q, which measures the ratio between the mechanical energy transmitted by the transducer and the energy dissipated (Fig. 5.10). Finally, the equivalent circuit leads to the measure of the electroacoustic power efficiency k^2 that corresponds to the ratio of the output acoustic power and the input electric power.

Hydrophones are usually described with the same characteristics as transducers but they are only designed to work in reception. To this goal, hydrophones are usually connected to a preamplifier with high input impedance to avoid any loss in the signal reception. A typical hydrophone exhibits a flat receiving response on a large bandwidth far away from its resonance frequency (Fig. 5.11a). As expected, the sensitivity of a hydrophone is much higher than the sensitivity of a transducer. Low electronic noise below the ocean ambient-noise level is also an important characteristic for hydrophones (Fig. 5.11b). Finally, hydrophones are typically designed to be omnidirectional (Fig. 5.11c).

5.2.2 Volume Attenuation

Attenuation is characterized by an exponential decay of the sound field. If A_0 is the root-mean-square (rms) amplitude of the sound field at unit distance from the source, then the attenuation of the sound field causes the amplitude to decay with distance along the path r

$$A = A_0 \exp(-\alpha r) , \qquad (5.3)$$

where the unit of α is Nepers/distance. The attenuation coefficient can be expressed in decibels per unit distance by the conversion $\alpha' = 8.686\alpha$. Volume attenuation increases with frequency and the frequency dependence of attenuation can be roughly divided into four regimes as displayed in Fig. 5.12. In region I, leakage out of the sound channel is believed to be the main cause of attenuation. The main mechanisms associated with regions II and III are boric acid and magnesium sulfate chemical relaxation. Region IV is dominated by the shear and bulk viscosity associated with fresh water. A summary of the approximate frequency dependence (f in kHz) of attenuation (in units of dB/km) is given by

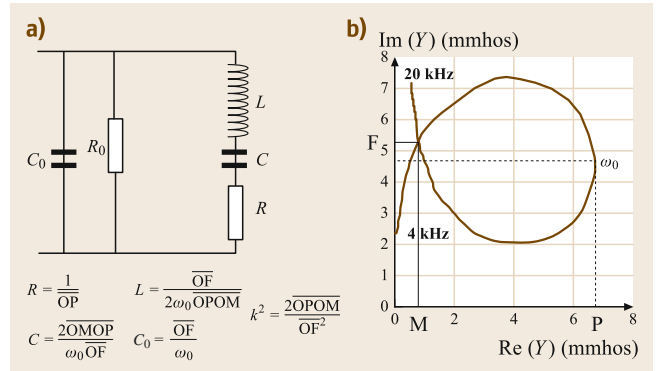
$$\alpha'(\text{dB/km}) = 3.3 \times 10^{-3} + \frac{0.11f^2}{1+f^2}$$
$$+ \frac{43f^2}{4100+f^2} + 2.98 \times 10^{-4} f^2 ,$$
$$(5.4)$$


Fig. 5.9 (a) Representation of the transducer as an electronic circuit around the resonant frequency. The resistor R_0 corresponds to the dielectric loss in the transducer and is commonly supposed infinite. C_0 is the transducer capacity, L and C are the mass and rigidity of the material, respectively. R includes both the mechanic loss and the energy mechanically transmitted by the transducer. **(b)** The values of C_0, L, C and R are obtained from the positions of the points F, M and P in the real–imaginary admittance curve given in the specification sheet

with the terms sequentially associated with regions I–IV in Fig. 5.12.

In Fig. 5.6, the losses associated with path 3 only include volume attenuation and scattering because this path does not involve boundary interactions. The volume scattering can be biological in origin or arise from interaction with internal wave activity in the vicinity

of the upper part of the deep sound channel where paths are refracted before they interact with the surface. Both of these effects are small at low frequencies. This same internal wave region is also on the lower boundary of the surface duct, allowing scattering out of the surface duct, thereby also constituting a loss mechanism for the surface duct. This mechanism also leaks sound into the deep sound channel, a region that without scattering would be a shadow zone for a surface duct source. This type of scattering from internal

waves is also a source of fluctuation of the sound field.

5.2.3 Bottom Loss

The structure of the ocean bottom affects those acoustic paths which interact with it. This bottom interaction is summarized by *bottom reflectivity*, the amplitude ratio of reflected and incident plane waves at the ocean–bottom interface as a function of grazing angle, θ
Fig. 5.12 Regions of the different dominant attenuation processes for sound propagating in seawater (after [5.16]). The attenuation is given in dB per kilometer

(Fig. 5.13a). For a simple bottom, which can be represented by a semi-infinite half-space with constant sound speed c_2 and density ρ_2, the reflectivity is given by

$$R(\theta) = \frac{\rho_2 k_{1z} - \rho_1 k_{2z}}{\rho_2 k_{1z} + \rho_1 k_{2z}} , \qquad (5.5)$$

with the subscripts 1 and 2 denoting the water and ocean bottom, respectively; the wavenumbers are given by

$$k_{iz} = (\omega/c_i)\sin\theta_i = k\sin\theta_i \; ; \; i = 1, 2 . \qquad (5.6)$$

The incident and transmitted grazing angles are related by Snell's law,

$$c_2 \cos\theta_1 = c_1 \cos\theta_2 , \qquad (5.7)$$

and the incident grazing angle θ_1 is also equal to the angle of the reflected plane wave.

For this simple water–bottom interface for which we take $c_2 > c_1$, there exists a critical grazing angle θ_c below which there is perfect reflection,

$$\cos\theta_c = \frac{c_1}{c_2} . \qquad (5.8)$$

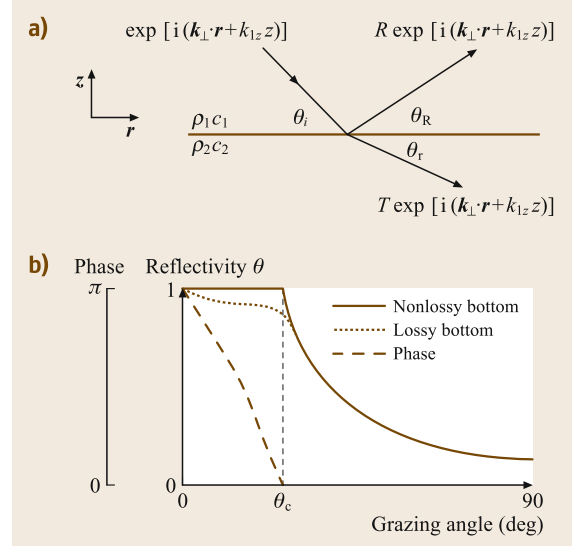
For a lossy bottom, there is no perfect reflection, as also indicated in a typical reflection curve in Fig. 5.13b. These results are approximately frequency indepen-


Fig. 5.13a,b The reflection and transmission process. Grazing angles are defined relative to the horizontal. (**a**) A plane wave is incident on an interface separating two media with densities and sound speeds ρ, c. $R(\theta)$ and $T(\theta)$ are reflection and transmission coefficients. Snell's law is a statement that $k_\perp$, the horizontal component of the wave vector, is the same for all three waves. (**b**) Rayleigh reflection curve $R(\theta)$ as a function of the grazing angle indicating critical angle θ_c. The dashed curve shows that, if the second medium is lossy, there is no perfect reflection below the critical angle. Note that for the non-lossy bottom, there is complete reflection below the critical angle, but with a phase change

dent. However, for a layered bottom, the reflectivity has a complicated frequency dependence. It should be pointed out that, if the density of the second medium vanishes, the reflectivity reduces to the pressure release case of $R(\theta) = -1$.

5.2.4 Scattering and Reverberation

Scattering caused by rough boundaries or volume heterogeneities is a mechanism for loss (attenuation), reverberant interference and fluctuation. Attenuation from volume scattering is addressed in Sect. 5.2.2. In most cases, it is the mean or coherent (or specular) part of the acoustic field which is of interest for a SONAR or communications application and scattering causes part of the acoustic field to be randomized. Rough surface scattering out of the *specular direction* can be thought of as an attenuation of the mean acoustic field and typ-

ically increases with increasing frequency. A formula often used to describe reflectivity from a rough boundary is

$$R'(\theta) = R(\theta) \exp\left(-\frac{\Gamma^2}{2}\right), \tag{5.9}$$

where $R(\theta)$ is the reflection coefficient of the smooth interface and Γ is the Rayleigh roughness parameter defined as $\Gamma \equiv 2k\sigma \sin \theta$ where $k = 2\pi/\lambda$, λ is the acoustic wavelength, and σ is the rms roughness height [5.18–20].

The scattered field is often referred to as reverberation. Surface, bottom or volume scattering strength, $S_{S,B,V}$ is a simple parameterization of the production of reverberation and is defined as the ratio in decibels of the sound scattered by a unit surface area or volume referenced to a unit distance I_{scat} to the incident plane wave intensity I_{inc}

$$S_{S,B,V} = 10 \log \frac{I_{\text{scat}}}{I_{\text{inc}}}. \tag{5.10}$$

The Chapman–Harris [5.21] curves predicts the ocean surface scattering strength in the 400–6400 Hz region,

$$S_S = 3.3\beta \log \frac{\theta}{30} - 42.4 \log \beta + 2.6 ;$$
$$\beta = 107(w f^{1/3})^{-0.58}, \tag{5.11}$$

a) $10 \log \int_0^d M_z \, dZ$

b)

Frequency (kHz)

Fig. 5.14 (a) Day and **(b)** night scattering strength measurements using an explosive source as a function of frequency (after [5.17]). The spectra measured at various times after the explosion are labeled with the depth of the nearest scatterer that could have contributed to the reverberation. The ordinate corresponds to S_V in (5.13)

where θ is the grazing angle in degrees, w the wind speed in m/s and f the frequency in Hz. Ocean surface scattering is further discussed in [5.22].

The simple characterization of bottom backscattering strength utilizes Lambert's rule for diffuse scattering,

$$S_B = A + 10 \log \sin^2 \theta , \tag{5.12}$$

where the first term is determined empirically. Under the assumption that all incident energy is scattered into the water column with no transmission into the bottom, A is -5 dB. Typical realistic values for A [5.23] which have been measured are -17 dB for the large basalt mid-Atlantic ridge cliffs and -27 dB for sediment ponds.

The volume scattering strength is typically reduced to a surface scattering strength by taking S_V as an average volume scattering strength within some layer at a particular depth; then the corresponding surface scattering strength is

$$S_S = S_V + 10 \log H , \tag{5.13}$$

where H is the layer thickness. The column or integrated scattering strength is defined as the case for which H is the total water depth.

Volume scattering usually decreases with depth (about 5 dB per 300 m) with the exception of the deep scattering layer. For frequencies less than 10 kHz, fish with air-filled swim bladders are the main scatterers. Above 20 kHz, zooplankton or smaller animals that feed upon phytoplankton and the associated biological chain are the scatterers. The deep scattering layer (DSL) is deeper in the day than in the night, changing most rapidly during sunset and sunrise. This layer produces a strong scattering increase of 5–15 dB within 100 m of the surface at night and virtually no scattering in the daytime at the surface since it migrates down to hundreds of meters. Since higher pressure compresses the fish swim bladder, the backscattering acoustic resonance (Sect. 5.2.6) tends to be at a higher frequency during the day when the DSL migrates to greater depths. Examples of day and night scattering strengths are shown in Fig. 5.14.

Finally, as explained in Sect. 5.2.6, near-surface bubbles and bubble clouds can be thought of as either volume or surface scattering mechanisms acting in concert with the rough surface. Bubbles have resonances (typically greater than 10 kHz) and at these resonances, scattering is strongly enhanced. Bubble clouds have collective properties; among these properties is that a bubbly mixture, as specified by its void fraction (total bubble gas volume divided by water volume) has a considerable lower sound speed than water.
5.2.5 Ambient Noise

There are essentially two types of ocean acoustic noise: manmade and natural. Generally, shipping is the most important source of manmade noise, though noise from offshore oil rigs is becoming increasingly prevalent. See also Table 5.2 in the Marine Mammal section for specific examples of manmade noise. Typically, natural noise dominates at low frequencies (below 10 Hz) and high frequencies (above a few hundred Hz). Shipping fills in the region between ten and a few hundred Hz and this component is increasing over time [5.25, 26]. A summary of the spectrum of noise is shown in Fig. 5.15. The higher-frequency noise is usually parameterized according to the sea state (also Beaufort number) and/or wind. Table 5.1 summarizes the description of the sea state.

The sound-speed profile affects the vertical and angular distribution of noise in the deep ocean. When there is a critical depth (Sect. 5.1.2), sound from surface sources travels long distances without interacting with the ocean bottom, but a receiver below this critical depth should sense less surface noise because propagation involves interaction with lossy boundaries, the surface and/or bottom. This is illustrated in Fig. 5.16a,b which shows a deep-water environment with measured ambient noise. Figure 5.16c is an example of vertical directionality of noise which also follows the propagation physics discussed above. The shallower depth is at the axis of the deep sound channel while the other is at the critical depth. The pattern is narrower at the critical depth where the sound paths tend to be horizontal since the rays are turning around at the lower boundary of the deep sound channel.

In a range-independent ocean, Snell's law predicts a horizontal noise notch at depths where the speed of sound is less than the near-surface sound speed. Returning to (5.2) and reading off the sound speeds

Table 5.1 Descriptor of the ocean sea surface (after [5.24])

Sea criteria	Beau-fort scale	Wind speed range knots (m/s)	mean knots (m/s)	12 h wind Wave height[a,b] ft (m)	Fully arisen sea Wave height[a,b] ft (m)	Duration[b,c] h	Fetch[b,c] naut. miles (km)	Sea-state scale
Mirror-like	0	< 1 (< 0.5)						0
Ripples	1	1–3 (0.5–1.7)	2 (1.1)					0.5
Small wavelets	2	4–6 (1.8–3.3)	5 (2.5)	< 1 (< 0.30)	< 1 (< 0.30)			1
Large wavelets, scattered whitecaps	3	7–10 (3.4–5.4)	8.5 (4.4)	1–2 (0.30–0.61)	1–2 (0.30–0.61)	< 2.5	< 10 (< 19)	2
Small waves, frequent whitecaps	4	11–16 (5.5–8.4)	13.5 (6.9)	2–5 (0.61–1.5)	2–6 (0.61–1.8)	2.5–6.5	10–40 (19–74)	3
Moderate waves, many whitecaps	5	17–21 (8.5–11.1)	19 (9.8)	5–8 (1.5–2.4)	6–10 (1.8–3.0)	6.5–11	40–100 (74–185)	4
Large waves, whitecapes everywhere, spray	6	22–27 (11.2–14.1)	24.5 (12.6)	8–12 (2.4–3.7)	10–17 (3.0–5.2)	11–18	100–200 (185–370)	5
Heaped-up sea, blown spray, streaks	7	28–33 (14.2–17.2)	30.5 (15.7)	12–17 (3.7–5.2)	17–26 (5.2–7.9)	18–29	200–400 (370–740)	6

at the surface ($c = 1530$ m/s) and say, 300 m (1500 m/s) , a horizontal ray ($\theta = 0$) launched from the ocean surface would have an angle with respect to the horizontal of about $11°$ at 300 m depth. All other rays would arrive with greater vertical angles. Hence we expect this horizontal notch. However, the horizontal notch is often not seen at shipping noise frequencies. That is because shipping tends to be concentrated in continental-shelf regions and propagation down a continental slope converts high-angle rays to lower angles at each bounce. There are also deep-sound-channel shoaling effects that result in the same trend in angle conversion.

The vertical directionality of noise in shallow water has a simple environmental dependence [5.27]. For example, in the summer with a downward refracting profile, the same discussion as above leads to a horizon-

tal noise notch. However the vertical directionality of noise from the surface in the winter tends to be driven by bottom properties. Thus, if the bottom is not very lossy, surface sources exciting low-order modes can come from large distances (and hence large areas). These paths are close to the horizontal and noise will then tend to have a strong horizontal component. On the other hand, a very lossy bottom will prevent long-range propagating paths from contributing to the noise field and the noise will tend to be local and subsequently vertical.

5.2.6 Bubbles and Bubbly Media

Bubbles not only occur naturally in the ocean, but the swim bladders of fish can also be thought of as bubbles. The physics of bubbles is a large area of activity in acoustics [5.7, 28]. Here we will confine ourselves to some aspects relevant to ocean acoustics. First we discuss some properties of bubbles in terms of resonators, scatterers and then go on to some aspects of bubbly media and scattering from bubbles.

Bubble scattering follows two regimes depending on the magnitude of the bubble radius oscillations in response to the incident fluctuating pressure field [5.29]:

1. For small pressure amplitudes, the response is linear. The first step in any linear analysis is the identification of the resonance frequency of an oscillating bubble and the measurement of the bubble scattering cross section.
2. Due to nonlinear terms in the governing equations, the response of a bubble will be affected by nonlinearities as the amplitude of the pressure field is increased. In this case, the bubble may continue to oscillate stably (stable acoustic cavitation) generating (sub)harmonics in the scattered field. Under other circumstances, the change in bubble size during a single cycle of oscillation becomes so large that the bubble undergoes a cycle of explosive cavitation growth and violent collapse. Such a response is termed *transient acoustic cavitation* and is distinguished from stable acoustic cavitation by the fact that the bubble radius changes by several orders of magnitude during each cycle.

The Bubble as a Scatterer

The calculation of the natural acoustic resonance of an oscillating bubble in the linear regime requires considerable algebra combining: (1) the equation of motion, (2) mass conservation, and (3) continuity relations at the bubble surface. These developments go beyond the

scope of this chapter. In the following, we simply summarize the final results, which are the expression of the bubble natural acoustic resonance ω_0^2, and the expression for the scattered field from an acoustic bubble under an incident pressure field at frequency ω.

The acoustic resonance in the linear regime of a single bubble of radius a is

$$\omega_0^2 = \left[\frac{3\gamma p_0}{\rho_w a^2} + (3\gamma - 1)\frac{2T}{\rho_w a^3} \right] , \qquad (5.14)$$

where p_0 is the ambient pressure outside the bubble, T is surface tension (tensile force/length in units N/m), ρ_w is the density of water and γ is the ratio of specific heats. Neglecting surface tension in (5.14) for bubble sizes larger than $1\,\mu$m and considering the acoustic expansion/compression process to be adiabatic ($c_{air}^2 = \gamma p_0/\rho_{air}$), we obtain the approximate expression

$$\omega_0 = \frac{1}{a}\sqrt{\frac{3c_{air}^2 \rho_{air}}{\rho_w}} , \qquad (5.15)$$

and for $c_{air} \simeq 340\,$m/s, we get $f_0 \simeq \frac{3}{a}$ with a in m and f_0 in Hz.

We now consider an incident plane wave at frequency ω in the regime $ka = \omega a/c = 2\pi a/\lambda \ll 1$. The far-field expression for the spatial part of the radiated acoustic field p_r is

$$p_r(r) = -\frac{a}{r} p_i \exp\left[-\frac{i\omega}{c}(r - a) \right]$$
$$\times \left[1 - \frac{\omega_0^2}{\omega^2}\left(1 - \frac{i\omega a}{c} \right) \right]^{-1} . \qquad (5.16)$$

First, we note that in the high-frequency limit, we recover $p_r(r, t) = -\frac{a}{r} p_i \left(t - \frac{r-a}{c} \right)$ that was given by the boundary conditions at the bubble surface.

To understand the effect of the resonance frequency, consider two cases. The first case is $\omega \gg \omega_0$ for which we obtain

$$p_r(r) = -\frac{a}{r} p_i \, e^{-\frac{i\omega}{c}(r-a)} , \qquad (5.17)$$

whereas for the case $\omega = \omega_0$ we get

$$p_r(r) = -\frac{ic}{\omega r} p_i \, e^{-\frac{i\omega}{c}(r-a)} = -\frac{i\lambda}{2\pi r} p_i \, e^{-\frac{i\omega}{c}(r-a)} . \qquad (5.18)$$

Comparing the two equations, (5.18) appears to be the field radiating from a sphere of radius $\lambda/2\pi$ which is much larger than a. For example, neglecting surface tension, at 1 atm, $\omega_0 a \approx 20$ so that $\lambda \approx 500a$. This resonance effect is also quite apparent when considering the scattering cross section of the bubble.
Fig. 5.16a–c Noise in the deep ocean. (**a**) Sound-speed profile and (**b**) noise level as a function of depth in the Pacific (after [5.30]). (**c**) The vertical directionality of noise at the axis of the deep sound channel and at the critical depth in the Pacific (after [5.31])

The scattering cross section σ_s is the ratio of the total scattered power (intensity × area = pressure × velocity × enclosing area) to the incident plane-wave intensity (given by $p_i^2/2\rho_w c$, with the factor of $1/2$ coming from averaging over a cycle) and therefore has the units of area. We perform this calculation in the far field using (5.16) to obtain

$$\sigma_s = \frac{4\pi a^2}{\left[1 - \frac{\omega_0^2}{\omega^2}\left(1 - \frac{i\omega a}{c} \right) \right]^2} \xrightarrow{\omega = \omega_0} \frac{\lambda^2}{\pi} , \qquad (5.19)$$

which is consistent with a surface area associated with the discussion below (5.18). The resonance makes the bubble appear larger in surface area than its dimension. On the other hand, for the case $\omega \ll \omega_0$, we have

$$\sigma_s = 4\pi a^2 \left(\frac{\omega}{\omega_0} \right)^4 , \qquad (5.20)$$
Fig. 5.17 (a) Wave breaking on the shore; **(b)** magnified view of individual bubbles within the plumes taken a second or so after wave breaking. The void fraction of air in these plumes is a few percent and bubbles range in size from less than 50 μm to a few mm radius. Bubble plumes found beneath breaking waves in 15–20 m/s winds in the open ocean have a similar size distribution (Courtesy of Grant Deane, Scripps Institution of Oceanography)

which is Rayleigh scattering. The analogous mechanism in electromagnetics explains why the sky is blue: blue has a higher frequency than red so it is scattered more. The above derivations only included radiation damping and we have not included lossy effects caused by thermal conductivity and shear viscosity. Looking at, for example (5.16), we can think of the radiation damping constant to be $\delta_r = ka$ or, in other words, at resonance $\sigma_s = 4\pi a^2/\delta_r^2$. Finally, we mention that the extinction cross section is the sum of the scattering cross section and the absorption cross section. The damping coefficients for thermal conductivity and shear viscosity are typically experimentally determined.

Bubbly Media

The region immediately below the surface of the ocean is a bubbly medium (Fig. 5.17). The existence of bubbles changes the effective compressibility of the water. We define a volume fraction of bubble (also called the void fraction) μ so that the density of the mixture is simply $\rho_m = \mu\rho_b + (1-\mu)\rho_w$ where the subscripts b and w refer to a bubble and water, respectively. We consider low frequencies with respect to resonance and we use the compressibility, the inverse of the bulk modulus $B = \rho(\delta p/\delta\rho)$, since it is additive and permits us to write down the compressibility of the mixture,

$$K_m = \mu K_b + (1-\mu)K_w \rightarrow \frac{1}{B_m}$$
$$= \mu\frac{1}{B_b} + (1-\mu)\frac{1}{B_w}. \qquad (5.21)$$

Using the above discussion relating sound speed and the adiabatic bulk modulus for the air bubble with $\gamma = 1.4$ (the bulk modulus of water is 2.3×10^9 Pa) we then obtain:

$$\frac{1}{\rho_m c_m^2} = \frac{\mu}{1.4 p_b} + \frac{(1-\mu)}{\rho_w c_w^2} \rightarrow c_m^2$$
$$= \left(\frac{1.4 p_b}{\mu\rho_w c_w^2 + 1.4 p_b(1-\mu)}\right) c_w^2, \qquad (5.22)$$

where we have taken $\rho_m \approx \rho_w$. Substituting some typical numbers, we use atmospheric pressure, $p_b \approx 10^5$ Pa, $\rho_w \approx 10^3$ kg/m³, $c_w = 1500$ m/s and we consider two void fractions: μ of 0.0001 and 0.001 (large). The corresponding sound speeds in the bubbly mixture are about 930 m/s and 370 m/s, respectively. A small amount a bubbles significantly changes the compressibility of the medium and therefore drastically changes the sound speeds. In reality, the speed of sound through the bubbly medium varies with frequency since compressibility is the ratio of the fractional change in volume to the incident pressure. The volume change is related to the bubble surface displacement and hence to velocity or radiated pressure as per (5.16). Therefore, the bubble compressibility is actually frequency dependent and a more rigorous treatment of propagation in bubbly media would show the dispersion of the speed through the bubbly medium.

When sound propagates through a bubbly medium, the scattering will also cause attenuation due to scattering and absorption. As stated above, the extinction cross section, σ_e, is a measure of this phenomenon. For

a bubbly medium (and for the simple case of single-sized bubbles), an acoustic beam will be altered by the absorption and scattering out of the beam. For an incident plane wave of intensity I_0, the power removed by each bubble is $I_0\sigma_e$ so that the rate of change of intensity as the beam travels through a bubble medium of N bubbles per unit volume is

$$\frac{\mathrm{d}I}{\mathrm{d}x} = -I_0\sigma_e N \rightarrow I = I_0 \exp\left(-\sigma_e N x\right) . \qquad (5.23)$$

Therefore, a bubbly medium changes the sound speed, absorbs sound, and is dispersive.

5.3 SONAR and the SONAR Equation

A major application of underwater acoustics is SONAR system technology. The performance of SONAR is often approximately described by the SONAR equation. The methodology of the SONAR equation is analogous to an accounting procedure involving acoustic signal, interference and system characteristics. Figure 5.18 provides a schematic of passive and active SONARs.

5.3.1 Detection Threshold and Receiver Operating Characteristics Curves

The detection threshold (DT) [5.16] is a decibel number that essentially incorporates the SONAR system's (which includes the operator) ability to decide that a detection is made or not made. The detection process includes the following probabilities:

- the probability of detection (PD): the probability that a signal is detected if it is present;
- 1-PD: the probability the signal will not be detected if it is present;
- the probability of false alarm (PFA): the probability that a signal is detected when it is not present;
- 1-PFA: the probability that the signal will not be detected when it is not present.

In practical terms, since the signal and noise are fluctuating, the detection is made (over a time interval) when the fluctuating sum of the signal and noise exceeds a threshold that is determined from empirically derived probability density functions (PDFs) of noise and signal plus noise. For example, the case that the noise alone rises above the threshold contributes to the PFA. Therefore, the process for determining a detection threshold level will depend on the PD and PFA. Typically numbers might be a PD of 0.5 and PFA of 0.0001. The probabilities will themselves be a function of the relation between the signal and noise statistics, as represented by their mean and variance. The detection index d succinctly characterizes this relation in that it indicates how easy it is to observe a signal in noise,

$$d = \frac{(M_{sn} - M_n)^2}{\sigma_n^2} , \qquad (5.24)$$

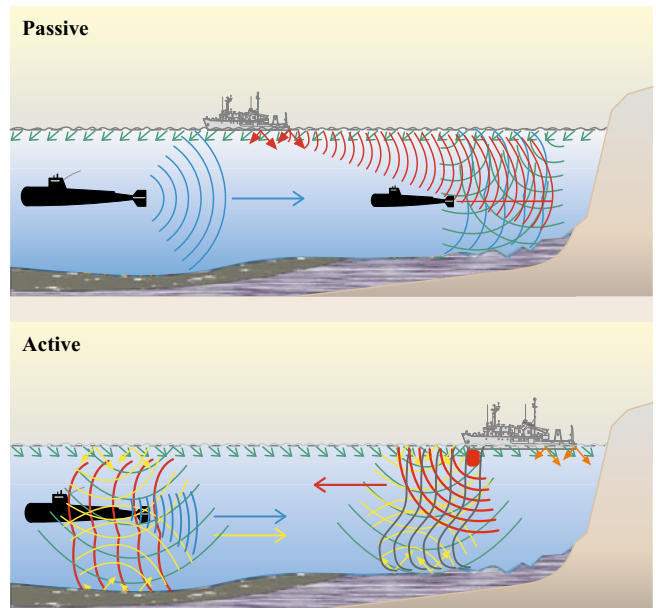
where M_{sn} is the mean of the signal plus noise, M_n is the noise mean and σ_n^2 is the noise variance. Figure 5.19 shows schematically the implications of the detection index where the relative proximity of the two probability density functions (PDFs) determine the detection


Fig. 5.18 Passive and active SONAR for submarine detection. *Passive*: the submarine on the right tries to detect sounds (*blue*) from the other submarine using a towed array (antenna). These sounds are distorted by the shallow-water environment and are embedded in ocean surface noise (*green*) and surface shipping noise (*red*). *Active*: the ship on the right sends out a pulse (*red*) and an echo (*blue*), distorted by the shallow-water environment, is returned to the ship SONAR which tries to distinguish it from backscattered reverberation (*yellow*) and ocean noise (*green*) (after [5.1])
Fig. 5.19 Probability density functions (PDF) of noise and signal+noise. Various probabilities as explained in the text are related to specific regions under the curves. Thus, the probability of detection (PD) is the *light-shaded area* under the signal+noise PDF curve that is to the right of DT, the detection threshold (*thick vertical line*). Similarly, the probability of false alarm is the *dark shaded area* under the noise PDF curve that is to the right of DT

statistics. We first note that the PD is the area under the signal-plus-noise curve to the right of the DT and the PFA is the area under the noise curve to the right of the DT. Then, for example, if the mean of the signal-plus-noise PDF was further to the right (higher signal-to-noise ratio (SNR)), the detection index and PD would be larger.

We could then move the DT to the right, changing the PD, but the PFA would be smaller. Receiver operating characteristics (ROC) curves are plots of PD versus PFA parameterized by d (Fig. 5.19). Figure 5.20 gives a typical example of using this methodology and refer the reader to the SONAR literature [5.16] for a more complete treatment. A square-law detector is commonly used for a passive system dealing with unknown signal. In that case, it has been shown that the detection index for a small-SNR, narrow-band signal in Gaussian noise is given by

$$d = \omega t \left(\frac{S}{N} \right)^2 , \tag{5.25}$$

where ω, t, S and N are the bandwidth (taken to be larger than the width of the spectral line of the signal), integration time, signal power and noise power in the bandwidth, respectively. If 1 Hz is the noise bandwidth reference, the detection index is $d = \omega t (S/N_0)$, where N_0 is the noise in a 1 Hz band. This gives a relation between the signal-to-noise ratio at the output of an en-

ergy detector of a narrow-band signal in Gaussian noise to the detection index

$$\text{SNR} = 5 \log \left(\frac{d}{\omega t} \right) \equiv \text{DT} , \tag{5.26}$$

where the equivalence symbol is for a detection criteria of a specified PD, PFA.

In reality, there are correction factors for the detection threshold related to the length of observations used to make a decision, human factors, and others that we omit from this discussion. Since the criteria are specified through the ROC curves, we can now estimate the DT for specific cases. We simply go to the the ROC curves for a selected PD versus PFA and read off the detection index, from which we can compute the detection threshold. For example, from Fig. 5.20, for a PD of 50% and a PFA of 0.01%, the detection index is $d = 16$. Using unit bandwidth and integration time, the detection threshold is DT$= 5 \log 16 = 6$ dB. This methodology is an example of the meaning of the DT term in the SONAR equation below, though the relationship between DT and d is different depending on the type of receiver and SONAR.

5.3.2 Passive SONAR Equation

A passive SONAR system uses the radiated sound from a target to detect and locate the target. A radiating object of source level (SL) (all units are in decibels) is received at a hydrophone of a SONAR system at a lower signal level S because of the transmission loss (TL) it suffers (e.g., cylindrical spreading plus attenuation or a TL computed from one of the propagation models of Sect. 5.4),

$$S = SL - TL . \tag{5.27}$$

The noise, N at a single hydrophone is subtracted from (5.27) to obtain the signal-to-noise ratio at a single hydrophone,

$$\text{SNR} = SL - TL - N . \tag{5.28}$$

Typically a SONAR system consists of an array or antenna of hydrophones which provides signal-to-noise enhancement through a beam-forming process (Sect. 5.6). This process is quantified in decibels by the array gain (AG) (see Sect. 5.6.2) that is added to the single-hydrophone SNR to give the SNR at the output of the beam-former (BF),

$$\text{SNR}_{\text{BF}} = SL - TL - N + AG . \tag{5.29}$$

As discussed, because detection involves additional factors including SONAR operator ability, it is necessary to specify a detection threshold, DT level above the SNR_{BF} at which there is a 50% (by convention) probability of detection. The difference between these two quantities is called the signal excess (SE),

$$SE = SL - TL - N + AG - DT . \tag{5.30}$$

This decibel bookkeeping leads to an important SONAR engineering descriptor called the figure of merit (FOM) which is the transmission loss that gives a zero signal excess,

$$FOM = SL - N + AG - DT . \tag{5.31}$$

The FOM encompasses the various parameters a SONAR engineer must deal with: expected source level, the noise environment, array gain and the detection threshold. Conversely since the FOM is a transmission loss, one can use the output of a propagation model (or if appropriate, a simple geometric loss plus attenuation) to estimate the minimum range at which a 50% probability of detection can be expected. This range changes with oceanographic conditions and is often referred to as the range of the day in navy SONAR applications. Finally, we mention that formal detection theory involves a criterion involving the probability of detection PD versus probability of false alarm PFA. Plots of PD versus PFA as parameterized by, say, SNR, are called receiver operating characteristic (ROC) curves [5.16]. Clearly, for a PFA of 1, the probability of detection goes to unity.

5.3.3 Active SONAR Equation

A monostatic active SONAR transmits a pulse to a target and its echo is detected at a receiver co-located with the transmitter. A bistatic active SONAR has the receiver in a different location than the transmitter. The main differences between the passive and active cases are the addition of a target strength (TS) term; reverberation (reverberation level, RL) is usually the dominant source of interference, as opposed to noise; and the transmission loss is over two paths: transmitter to target and target
Fig. 5.20 Example of ROC curves. For a given signal plus noise, different threshold settings correspond to different PD and PFA. The ROC curves summarizes the relation between PD and PFA for different thresholds as parameterized through the detection index (after [5.16])

to receiver. In the monostatic case, the transmission loss is 2TL, where TL is the one-way transmission loss, and in the bistatic case, the transmission loss is the sum (in dB) over paths from the transmitter to the target and the target to the receiver, $TL_1 + TL_2$. The concept of the detection threshold is useful for both passive and active SONARs. Hence, for signal excess, we have

$$SE = SL - TL_1 + TS - TL_2 \\ - (RL + N) + AG - DT . \tag{5.32}$$

The corresponding FOM for an active system is defined for the maximum allowable two-way transmission loss with $TS = 0\,dB$.

5.4 Sound Propagation Models

The wave equation describing sound propagation is derived from the equations of hydrodynamics and its coefficients and boundary conditions are descriptive of the ocean environment. There are essentially four types of models (computer solutions to the wave equation [5.4]) to describe sound propagation in the sea: ray theory,

Part A | 5.4

the spectral method or fast field program (FFP), normal mode (NM) and parabolic equation (PE). All of these models allow for the fact that the ocean environment varies with depth. A model that also takes into account horizontal variations in the environment (i. e., sloping bottom or spatially variable oceanography) is termed range-dependent. For high frequencies (a few kilohertz or above), ray theory is the most practical. The other three model types are more applicable and useable at lower frequencies (below 1 kHz). Between these frequencies, one can choose either, noting that the wave solution is the most accurate and should probably be used in all cases where the the calculation is still feasible and/or practical. The models discussed here are essentially two-dimensional models since the index of refraction has much stronger dependence on depth than on horizontal distance. Nevertheless, bottom topography and strong ocean features can cause horizontal refraction (out of the range–depth plane). Ray models are most easily extendable to include this added complexity. Full three-dimensional wave models are extremely computationally intensive. A compromise that often works for weakly three-dimensional problems is the $N \times 2D$ approximation that combines two-dimensional solutions along radials to produce a three-dimensional solution.

5.4.1 The Wave Equation and Boundary Conditions

The wave equation for the pressure p in cylindrical coordinates with the range coordinates denoted by $r = (x, y)$ and the depth coordinate denoted by z (taken positive downward) for a source-free region is

$$\nabla^2 p(\mathbf{r}, z, t) - \frac{1}{c^2(\mathbf{r}, z)} \frac{\partial^2 p(\mathbf{r}, z, t)}{\partial t^2} = 0 , \quad (5.33)$$

where $c(\mathbf{r}, z)$ is the sound speed in the wave-propagating medium.

It is convenient to solve (5.33) in the frequency domain by assuming a solution with a frequency dependence of $\exp(-\mathrm{i}\omega t)$ to obtain the Helmholtz equation ($K \equiv \omega/c$),

$$\nabla^2 p(\mathbf{r}, z) + K^2 p(\mathbf{r}, z) = 0 \quad (5.34)$$

with

$$K^2(\mathbf{r}, z) = \frac{\omega^2}{c^2(\mathbf{r}, z)} . \quad (5.35)$$

The range-dependent environment manifests itself as the coefficient $K^2(\mathbf{r}, z)$ of the partial differential equation for the appropriate sound speed profile. The

range-dependent bottom type and topography appears as boundary conditions. In underwater acoustics both fluid and elastic (shear-supporting sediments and bottom strata) media are of interest. For simplicity we only consider fluid media below. This is most often a good approximation to describing the bottom near the bottom interface since the material typically has a low shear speed which can be inserted into the fluid equation solution by a perturbation procedure [5.32].

The most common plane-interface boundary conditions encountered in underwater acoustics are the pressure release condition at the ocean surface,

$$p = 0 , \quad (5.36)$$

and at the ocean–bottom interface, continuity of pressure

$$p_1 = p_2 , \quad (5.37)$$

and vertical particle velocity

$$\frac{1}{\rho_1} \frac{\partial p_1}{\partial z} = \frac{1}{\rho_2} \frac{\partial p_2}{\partial z} , \quad (5.38)$$

where the ρ_i are the densities of the two media. These latter boundary conditions applied to the plane-wave fields in Fig. 5.13a yield the Rayleigh reflection coefficient given by (5.5).

The Helmholtz equation for an acoustic field from a point source is

$$\nabla^2 G(\mathbf{r}, z) + K^2(\mathbf{r}, z) G(\mathbf{r}, z) = -\delta^2(\mathbf{r} - \mathbf{r}_s)\delta(z - z_s) , \quad (5.39)$$

where the subscript 's' denotes the source coordinates. The acoustic field from a point source, $G(\mathbf{r})$ is either obtained by solving the boundary-value problem of (5.39) (spectral method or normal modes) or by approximating (5.39) using an initial-value problem (ray theory, parabolic equation).

5.4.2 Ray Theory

Ray theory is a geometrical, high-frequency approximate solution to (5.39) of the form

$$G(\mathbf{R}) = A(\mathbf{R}) \exp[\mathrm{i}S(\mathbf{R})] , \quad (5.40)$$

where the exponential term allows for rapid variations as a function of range and $A(\mathbf{R})$ is a more slowly varying *envelope* that incorporates both geometrical spreading and loss mechanisms. The geometrical approximation is that the amplitude varies slowly with range (i. e., $(1/A)\nabla^2 A \ll K^2$) so that (5.34) yields the

eikonal equation

$$(\nabla S)^2 = K^2 \,. \tag{5.41}$$

The ray trajectories are perpendicular to surfaces of constant phase (wavefronts), S, and may be expressed mathematically as follows

$$\frac{\mathrm{d}}{\mathrm{d}l}\left(K\frac{\mathrm{d}\boldsymbol{R}}{\mathrm{d}l}\right) = \nabla K \,, \tag{5.42}$$

where l is the arc length along the direction of the ray and $\boldsymbol{R}$ is the displacement vector to a point on the ray. The direction of average flux (energy) follows that of the trajectories and the amplitude of the field at any point can be obtained from the density of rays.

The ray theory method is computationally rapid and extends to range-dependent problems. Furthermore, the ray traces give a physical picture of the acoustic paths. It is helpful in describing how sound redistributes itself when propagating long distances over paths that include shallow and deep environments and/or mid-latitude to polar regions. The disadvantage of conventional ray theory is that it does not include diffraction, including effects that describe the low-frequency dependence (degree of trapping) of ducted propagation.

5.4.3 Wavenumber Representation or Spectral Solution

The wave equation can be solved efficiently with spectral methods when the ocean environment does not vary with range. The term fast field program (FFP) had been used because the spectral methods became practical with the advent of the fast Fourier transform (FFT). Assume a solution of (5.39) of the form

$$G(\boldsymbol{r}, z) = \frac{1}{2\pi}\int \mathrm{d}^2\boldsymbol{k}\,g(\boldsymbol{k}, z, z_s)\exp[\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}-\boldsymbol{r}_s)]\,, \tag{5.43}$$

which then leads to the equation for the depth-dependent Green's function $g(\boldsymbol{k}, z, z_s)$,

$$\frac{\mathrm{d}^2 g}{\mathrm{d}z^2} + \left[K^2(z) - k^2\right]g = -\frac{1}{2\pi}\delta(z - z_s)\,. \tag{5.44}$$

Furthermore, we assume azimuthal symmetry, $kr > 2\pi$ and $\boldsymbol{r}_s = 0$ so that (5.43) reduces to

$$G(r, z) = \frac{\exp(-\mathrm{i}\pi/4)}{(2\pi r)^{1/2}}$$
$$\times \int_{-\infty}^{+\infty} \mathrm{d}k\,k^{1/2}g(k, z, z_s)\exp(\mathrm{i}kr)\,. \tag{5.45}$$

This integral is then evaluated using the fast Fourier transform algorithm. Although the method was initially labeled *fast field* it is fairly slow because of the time required to calculate the Green's functions (solve (5.44)). However, it has advantages when one wishes to calculate the near-field region or to include shear-wave effects in elastic media; it is also often used as a benchmark for other less exact techniques. With a great deal of additional computational effort, this method is extendable to range-dependent environments.

5.4.4 Normal–Mode Model

Rather than solve (5.44) for each g for the complete set of ks (typically thousands of times), one can utilize a normal-mode expansion of the form

$$g(\boldsymbol{k}, z) = \sum a_n(\boldsymbol{k})u_n(z)\,, \tag{5.46}$$

where the quantities u_n are eigenfunctions of the following eigenvalue problem

$$\frac{\mathrm{d}^2 u_n}{\mathrm{d}z^2} + \left[K^2(z) - k_n^2\right]u_n(z) = 0\,. \tag{5.47}$$

The eigenfunctions u_n are zero at $z = 0$, satisfy the local boundary conditions descriptive of the ocean bottom properties and satisfy a radiation condition for $z \to \infty$. For pressure, they form an orthonormal set in a Hilbert space with weighting function $\rho^{-1}(z)$, the local density. The range of discrete eigenvalues corresponding to the poles in the integrand of (5.45) is given by the condition

$$\min[K(z)] < k_n < \max[K(z)]\,. \tag{5.48}$$

These discrete eigenvalues correspond to discrete angles within the critical angle cone in Fig. 5.7a as discussed in Sect. 5.1.2. The eigenvalues k_n typically have a small imaginary part α_n, which serves as the modal attenuation representative of all the losses in the ocean environment. Solving (5.39) using the normal-mode expansion given by (5.46) yields (for the source at the origin).

$$G(r, z) = \frac{\mathrm{i}}{4\rho(z_s)}\sum_n u_n(z_s)u_n(z)H_0^1(k_n r)\,. \tag{5.49}$$

The asymptotic form of the Hankel function can be used in the above equation to obtain the well-known normal-mode representation of a waveguide in cylindrical coordinates

$$G(r, z) = \frac{\mathrm{i}}{(8\pi r)^{1/2}\rho(z_s)}\exp(-\mathrm{i}\pi/4)$$
$$\times \sum_n \frac{u_n(z_s)u_n(z)}{k_n^{1/2}}\exp(\mathrm{i}k_n r)\,. \tag{5.50}$$

Equation (5.50) is a far-field solution of the wave equation and neglects the continuous spectrum of modes ($k_n < \min[K(z)]$ of (5.48)). For the purposes of illustrating the various portions of the acoustic field, we note that k_n is a horizontal wavenumber so that a ray angle associated with a mode with respect to the horizontal can be taken to be $\theta = \cos^{-1}[k_n/K(z)]$. For a simple waveguide the maximum sound speed is the bottom sound speed corresponding to $\min[K(z)]$. At this value of $K(z)$, we have from Snell's law $\theta = \theta_c$, the bottom critical angle. In effect, if we look at a ray picture of the modes, the continuous portion of the mode spectrum corresponds to rays with grazing angles greater than the bottom critical angle of Fig. 5.13b and therefore outside the cone of Fig. 5.7a. This portion undergoes severe loss. Hence, we note that the continuous spectrum is the near (vertical) field and the discrete spectrum is the far (more-horizontal, profile-dependent) field falling within the cone in Fig. 5.7a.

The advantages of the normal-mode procedure are that: the solution is available for all source and receiver configurations once the eigenvalue problem is solved; it is easily extended in moderately range-dependent conditions using the adiabatic approximation; it can be applied (with more effort) to extremely range-dependent environments using coupled-mode theory. However, it does not include a full representation of the near field.

Adiabatic Mode Theory

All of the range-independent normal-mode calculation method developed for environmental ocean acoustic modeling applications can be adapted to mildly range-dependent conditions using adiabatic mode theory. The underlying assumption is that individual propagating normal modes adapt to the local environment, but do not scatter or couple into each other. The coefficients of the mode expansion, a_n in (5.46), now become mild functions of range, i. e., $a_n(\mathbf{k}) \to a_n(\mathbf{k}, \mathbf{r})$. This modifies (5.45) as follows

$$G(\mathbf{r}, z) = \frac{i\rho(z_s)}{(8\pi r)^{1/2}} \exp(-i\pi/4)$$
$$\times \sum_n \frac{u_n(z_s)v_n(z)}{\overline{k_n}^{1/2}} \exp(i\overline{k_n}r), \quad (5.51)$$

where the range-averaged wavenumber (eigenvalue) is

$$\overline{k_n} = \frac{1}{r} \int_0^r k_n(r')\,dr', \quad (5.52)$$

and the $k_n(r')$ are obtained at each range segment from the eigenvalue problem (5.47) evaluated for the environment at that particular range along the path. The quantities u_n and v_n are the sets of modes at the source and the field positions, respectively.

Simply stated, the adiabatic mode theory leads to a description of sound propagation such that the acoustic field is a function of the modal structure at both the source and the receiver and some average propagation conditions between the two. Thus, for example, when sound emanates from a shallow region where only two discrete modes exist and propagates into a deeper region with the same bottom (same critical angle), the two modes from the shallow region adapt to the form of the first two modes in the deep region. However, the deep region can support many more modes; intuitively, we therefore expect the resulting two modes in the deep region will take up a smaller, more-horizontal part of the cone of Fig. 5.7a than they take up in the shallow region. This means that sound rays going from shallow to deep regions tend to become more horizontal, which is consistent with a ray picture of down-slope propagation. Finally, fully coupled mode theory for range-dependent environments has been developed but requires intensive computation.

Mode Dispersion in a Waveguide

Acoustical propagation in simple free space is nondispersive. That is, all plane waves travel with speeds independent of frequency. Further, their group and phase speeds are the same as the medium sound speed. However, geometric dispersion is a property of waveguide propagation.

We consider a shallow-water waveguide of the Pekeris type, i. e., a homogeneous water column overlying a homogeneous and denser fluid bottom. A waveguide of this type supports modal propagation, where each modes is characterized by a depth-dependent modal amplitude $u_n(z)$ and a horizontally projected propagating wavenumber k_n. Each mode is characterized by a group velocity v_{gn} and a phase velocity $v_{\varphi n}$, which are related through the formula

$$\frac{1}{v_{gn}} = v_{\varphi n} \int_0^\infty \frac{u_n^2(z)}{\rho(z)\,c^2(z)}\,dz. \quad (5.53)$$

In the case of a perfect waveguide with a constant sound speed c and no penetration in the bottom, (5.53) takes the simplest form $v_{gn}v_{pn} = c^2$. The difference in group velocities between modes results in modal dispersion in a waveguide (Fig. 5.21).

In shallow water, lower-order modes usually travel faster than higher-order modes (Figs. 5.22 and 5.23).

In deep water, where the deep sound channel behaves as a waveguide, the fastest modes are the higher-order modes (Fig. 5.24), a property of refraction-dominated modal propagation. Since modal wavenumbers k_n are frequency dependent, the modes can be plotted in a frequency–wavenumber space that is the Fourier transform of the time-range representation of the dispersed field in Fig. 5.25. As already seen in Fig. 5.21, Fig. 5.26 shows that modes have a cut-off frequency and that there exist a finite number of propagating modes at a given frequency.

Dispersion and The Waveguide Invariant [5.3]

There is actually a fairly robust parameter, the waveguide invariant, that describes dispersion over a (sometimes large) interval of a group of modes. The waveguide invariant β has two important interpretations; first, it is related the local change in the modal group velocity with respect to the change in phase velocity,

$$\frac{1}{\beta} = -\frac{\partial S_g}{\partial S_p}, \tag{5.54}$$

where S_g and S_p and group and phase slowness, where slowness is the inverse of speed.

It turns out that β often has a rather robust value for certain circumstances. For example, it is unity for many shallow-water situations that are dominated by bottom reflection; on the other hand it is negative for refraction-dominated propagation.

Figure 5.27 shows a calculation for a Pacific deep-water case. Note from the definition that β is negative up to a phase speed of about 1540; this region is one of refraction such as deep sound channel and convergence zone propagation. Beyond 1540, β is positive; this is the bottom bounce region dominated by reflections rather than refraction.

The invariant also relates the change in range in the locations of the interference peaks of a transmission loss curve to a change in frequency

$$\frac{\Delta r}{r} = \frac{1}{\beta} \frac{\Delta \omega}{\omega}. \tag{5.55}$$

In Fig. 5.28, we show a set of TL curves for different frequencies; the interference peaks are shifted according to the invariant formula. Another way of representing this shift is through the striations, where TL is the third dimension of a frequency–range plot as shown in Fig. 5.29, which was derived from shallow-water transmission loss data. If one represents range as the product of the velocity of the radiator and time, then, the range axis can be replaced by time and one has
Fig. 5.21 Frequency dependence of the group speed (lower curves 1–6) and phase speed (upper curves 1–6) of modes 1–6 in a Pekeris waveguide with a 100 m water depth, a bottom sound speed c_b and density of 1600 m/s and 1800 kg/m³. Sound speed in water c_ω is constant and equal to 1500 m/s. The bold vertical lines show the cut-off frequencies of modes 4–6, respectively

a frequency–time plot, often called a spectrogram. The TL curve is a slice through the spectrogram for a given frequency and time converted to the appropriate range.
Fig. 5.22a,b Acoustic dispersion in a shallow water waveguide. The *right panel* (**b**) corresponds to the waveguide response at $R = 20$ km to the emitted signal (central frequency = 100 Hz, 50 Hz bandwidth) displayed in the *left panel*. (**a**) Source depth is at 40 m and the receiver depth at 60 m. Waveguide parameters are the same as in Fig. 5.21
Fig. 5.23 Depth-versus-time representation of the field intensity after a $R = 20$ km propagation in a shallow-water waveguide. The waveguide characteristics are the same as in Fig. 5.21. Source depth is 40 m. The color scale is in dB with a 0 dB source level amplitude at the source

Doppler Shift in a Waveguide

The theory of Doppler shifts involving either a moving source and/or receiver is well known in acoustics, particularly in free space. However, in a waveguide, even if we limit ourselves to horizontal motion, the results are slightly more complex. The individual paths associated with modal propagation, as per Fig. 5.7a, all have finite and different angles with respect to the horizontal. Thus, each mode has a different Doppler shift. The waveguide
Fig. 5.24 Depth-versus-time representation of the field intensity after a $R = 2000$ km propagation in a deep-water waveguide. We used the Munk profile as a depth-dependent sound-speed profile. Source depth is 900 m, source frequency is 22.5 Hz with a 15 Hz bandwidth. The color scale is in dB with a 0 dB source level amplitude at the source

theory for both source and/or receiver has been worked out (see [5.33], in which there is also a review of the pertinent literature). We return to (5.50) for a harmonic source of angular frequency ω, which therefore results in an additional, identical (when there is no motion) factor for each term of $e^{-i\omega t}$ in the time domain. We now consider a source with a frequency spectrum $S(\omega)$. For constant, horizontal velocities, the normal-mode field results in the *receiver reference frame* are still valid

$$\psi(\mathbf{r}_0 + \mathbf{v}_r t, z, \omega) = \frac{i}{4\rho(z_s)} \\ \times \sum_n S(\Omega_n) u_n(z_s) u_n(z) H_0^1(k_n r),$$

(5.56)

but with Doppler shifted modal wavenumbers

$$k_n \rightarrow k_n \left(1 + \frac{v_r}{v_{g} n} \cos \theta_r\right),$$

(5.57)

and Doppler-shifted frequencies (now for each modal term in the summation) of

$$\Omega_n = \omega - k_n (v_s \cos \theta_s - v_r \cos \theta_r),$$

(5.58)

where v_{gn} is the group velocity of the n-th mode, $v_s \cos \theta_s$ is the radial speed of the source, and $v_r \cos \theta_r$ is the radial speed of the receiver. Here, radial refers to the projection of the velocities onto the horizontal line between the source and receiver. Note that this latter expression, when multiplied through by the wavenumber, shows that the frequency shift is proportional to the ratio of speeds to the modal phase speed, as opposed to the wavenumber shift which involves the group speed.

5.4.5 Parabolic Equation (PE) Model

The PE method was introduced into ocean acoustics and made viable with the development of the *Tappert split-step algorithm*, which utilized fast Fourier transforms at each range step [5.6]. Subsequent numerical developments greatly expanded the applicability and accuracy of the parabolic equation method.

Standard PE Split–Step Algorithm

The PE method is presently the most practical and all-encompassing wave-theoretic range-dependent propagation model. In its simplest form, it is a far-field narrow-angle ($\approx \pm 20°$) with respect to the horizontal – adequate for many underwater propagation problems – approximations to the wave equation. Assuming azimuthal symmetry about a source, we express the

solution of (5.34) in cylindrical coordinates in a source-free region in the form

$$p(r, z) = \psi(r, z)H(r) , \tag{5.59}$$

and we define $K^2(r, z) \equiv K_0^2 n^2$, n therefore being an *index of refraction* c_0/c, where c_0 is a reference sound speed. Substituting (5.59) into (5.34) and taking K_0^2 as the separation constant we end up with a Bessel equation for H that has a Hankel function as the outgoing solution. If we use the asymptotic form of the Hankel function, $H_0^1(K_0 r)$, and invoke the *paraxial* (narrow-angle) approximation,

$$\frac{\partial^2 \psi}{\partial r^2} \ll 2K_0 \frac{\partial \psi}{\partial r} , \tag{5.60}$$

we obtain the parabolic equation (in r),

$$\frac{\partial^2 \psi}{\partial z^2} + 2iK_0 \frac{\partial \psi}{\partial r} + K_0^2(n^2 - 1)\psi = 0 , \tag{5.61}$$

where we note that n is a function of range and depth. We use a marching solution to solve the parabolic equation. There has been an assortment of numerical solutions but the one that still remains a standard is the so-called *split-step* range-marching algorithm,

$$\psi(r + \Delta r, z) = \exp\left[\frac{iK_0}{2}(n^2 - 1)\Delta r\right] F^{-1}$$
$$\times \left\{\left[\exp\left(-\frac{i\Delta r}{2K_0}s^2\right)\right] F[\psi(r, z)]\right\} . \tag{5.62}$$
Fig. 5.25 Range-versus-time representation of the field intensity for the same waveguide and source–receiver depth as in Fig. 5.21. The figure clearly shows that modes travel at different speed. The retarded time t is $t - R/c_\omega$. The color scale is in dB with a 0 dB reference at range 5 km

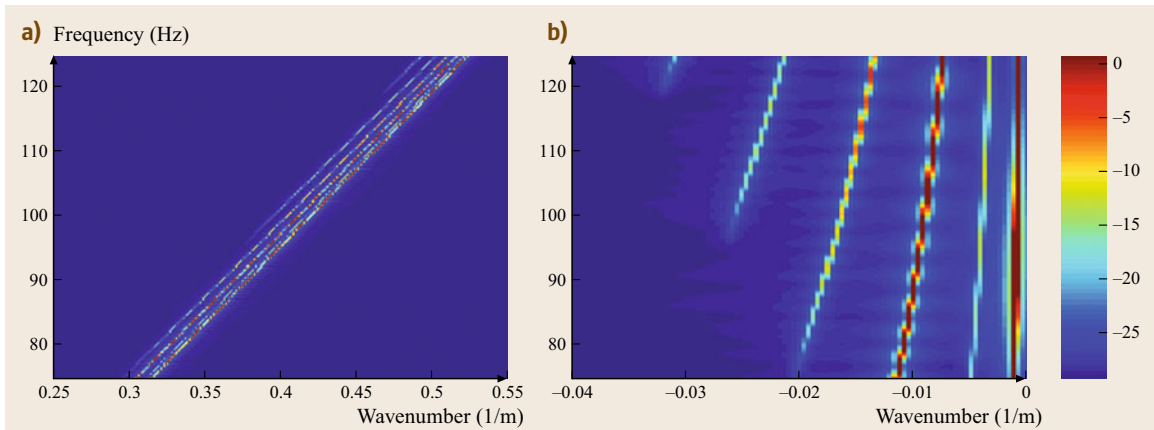
The Fourier transforms F, are performed using FFTs. Equation (5.62) is the solution for n constant, but the error introduced when n (profile or bathymetry) varies with range and depth can be made arbitrarily small by increasing the transform size and decreasing the range-step size. It is possible to modify the split-step algorithm to increase its accuracy with respect to higher-angle propagation.


Fig. 5.26a,b Frequency–wavenumber representation of the dispersed field in the waveguide. (**a**) Obtained from a two-dimensional FFT of the range–time plot in Fig. 5.25. The wavenumbers of propagating modes are bounded by the upper and lower sound speeds in waveguide, ω/c_ω and ω/c_b. (**b**) A rotated version of (**a**), so that the sound speed in water appears infinite. This representation is easier to see the mode separation and the mode cut-off frequency. The color scale is in dB

Effective group velocity (m/s)
Fig. 5.27 Group speed versus phase speed in the Pacific Deep water case. The *curves* are for different frequencies starting with the lowest frequency 60 Hz being on *top*. Low phase velocity corresponds to low mode number ◄

that become more vertical such as when the bottom has a very high speed and hence, large critical angle with respect to the horizontal. In addition, for elastic propagation, the compressional and shear waves span a wide angle interval. Finally, Fourier synthesis for pulse modeling requires high accurate in phase and the high-angle PEs are more accurate in phase, even at low angles.

Equation (5.61) with the second-order range derivative which was neglected because of (5.60) can be written in operator notation as

$$\left[P^2 + 2iK_0 P + K_0^2(Q^2 - 1) \right] \psi = 0 , \tag{5.63}$$

where

$$P \equiv \frac{\partial}{\partial r} , \qquad Q \equiv \sqrt{n^2 + \frac{1}{K_0^2} \frac{\partial^2}{\partial z^2}} . \tag{5.64}$$

Factoring (5.64) assuming weak range dependence and retaining only the factor associated with outgoing propagation yields a one-way equation

$$P\psi = iK_0(Q - 1)\psi , \tag{5.65}$$

which is a generalization of the parabolic equation beyond the narrow-angle approximation associated with (5.60). If we define $Q = \sqrt{1 + q}$ and expand Q in a Taylor series as a function of q, the standard PE method is recovered by $Q \approx 1 + 0.5q$. The wide-angle PE to arbitrary accuracy in angle, phase, etc. can be obtained from a Padé series representation of the Q operator,

$$Q \equiv \sqrt{1 + q} = 1 + \sum_{j=1}^{n} \frac{a_{j,n} q}{1 + b_{j,n} q} + O(q^{2n+1}) , \tag{5.66}$$

where n is the number of terms in the Padé expansion and

$$a_{j,n} = \frac{2}{2n+1} \sin^2\left(\frac{j\pi}{2n+1}\right) b_{j,n}$$
$$= \cos^2\left(\frac{j\pi}{2n+1}\right) . \tag{5.67}$$

Fig. 5.28 Transmission loss versus range from 130 to 170 Hz calculated by OASES (Ocean Acoustic Seismic Exploration Synthesis) for an environment composed of a 200 m homogeneous fluid layer overlying a homogeneous, absorbing fluid half-space. The fluid layer has a 1450 m/s sound speed, whereas the bottom half-space has a sound speed of 1500 m/s and an attenuation of 10 dB/λ. The curves for increasing frequencies are progressively offset in 1 dB steps. The source and receiver depths are 20 and 100 m, respectively

The solution of (5.65) using Eqs. (5.66) and (5.67) has been implemented using finite-difference techniques for fluid and elastic media.

Generalized or Higher-Order PE Methods

Methods of solving the parabolic equation, including extensions to higher-angle propagation, elastic media, and direct time-domain solutions including nonlinear effects have recently appeared (for example, see [5.34]). In particular, accurate high-angle solutions are important when the environment supports acoustic paths

5.4.6 Propagation and Transmission Loss

Propagation loss (PL) and transmission loss (TL) are decibel (see Appendix) quantities that are either measured or derived from propagation models. They represent the loss in intensity of the acoustic field as a function of range as referenced to some location. For modeling, we typically use the intensity at one meter range from the source using the assumption of spherical spreading over that one meter. Hence, if P is the output of a propagation code, the propagation loss is

$$\text{PL} = 20 \log \left| \frac{P}{p_0(r=1)} \right| \equiv -\text{TL} \,, \tag{5.68}$$

where p_0 is the pressure of the source in free space. Transmission loss is a positive quantity.

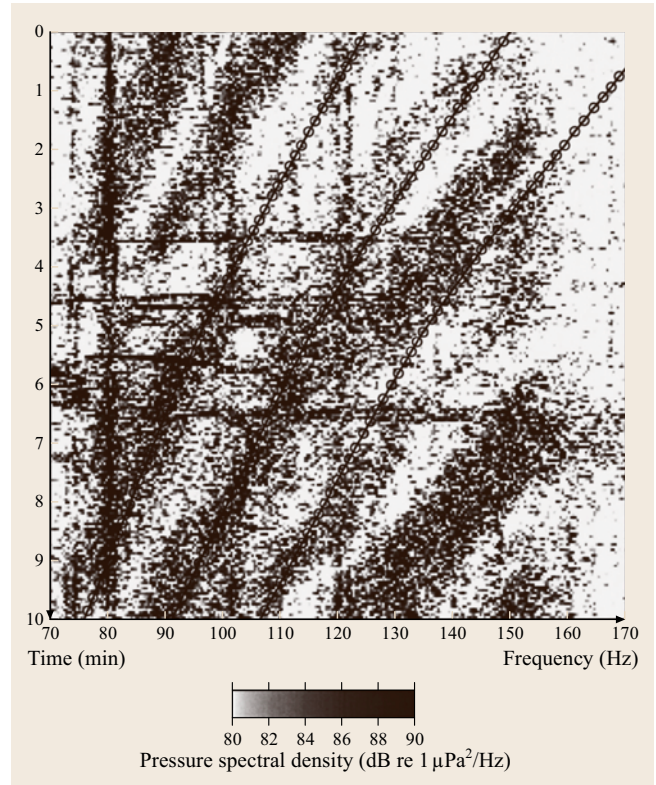
Often, one sees references to coherent and incoherent propagation loss, which can be confusing. Deterministic physics has all acoustic propagation as coherent. If the medium has some randomness, than phase information is lost by some sort of averaging process. This leads to the idea of incoherent propagation. In normal-mode theory, the results is that the cross terms involving differences of modal wavenumbers do not contribute and the propagation curve is therefore smooth, without the interference pattern (Fig. 5.30c). Clearly such a calculation is easy with modes, but there is no equivalent simple way for the other wave models other than actually to introduce randomness. Figure 5.30 shows an application of this incoherent sum of modes. In shallow water an incoherent sum of modes is more or less equivalent to frequency smoothing, over, for example a third of an octave. The environment shown in Fig. 5.30a corresponds to experimental data contours of third-octave transmission loss as a function of frequency and range shown in Fig. 5.30b. Normal-mode model runs are shown in Fig. 5.30c, in which the modes are summed incoherently. Figure 5.30d is a model result of the same type of mode computations, but over the whole frequency spectrum; note the excellent agreement. This kind of analysis can be iteratively used to estimate the environment. Figures 5.30b and 5.30d are referred to an optimum frequency curves in the sense that $300–400\,\text{Hz}$ appears to be the optimum frequency of propagation. For example, a vertical slice at $60\,\text{km}$ indicates that the minimum loss is in that frequency interval. The curves in Fig. 5.30c are horizontal slices of the contour plot in Fig. 5.30d. The optimum frequency comes from the combination of high loss into the bottom at low frequency because


Fig. 5.29 A data example of spectrogram of a broadband moving source. The striations are the peaks in the interference pattern of the transmission loss. The time axis is converted to range if one knows the path and speed of the source (after [5.35])

of increased penetration into the lossy bottom and high losses at high frequency caused by scattering and other water volume attenuation effects that tend to have a frequency-squared dependence. Hence, the existence of an intermediate frequency at which bottom loss is small and frequency-squared dependence is not yet dominant.

Finally we note that there is also an incoherent sum of rays in which ray intensities and not amplitudes with phases are summed. This is not the equivalent of an incoherent sum of mode. For example, an incoherent sum of modes does not produce convergence zones while incoherent rays show convergence-zone properties.

5.4.7 Fourier Synthesis of Frequency–Domain Solutions

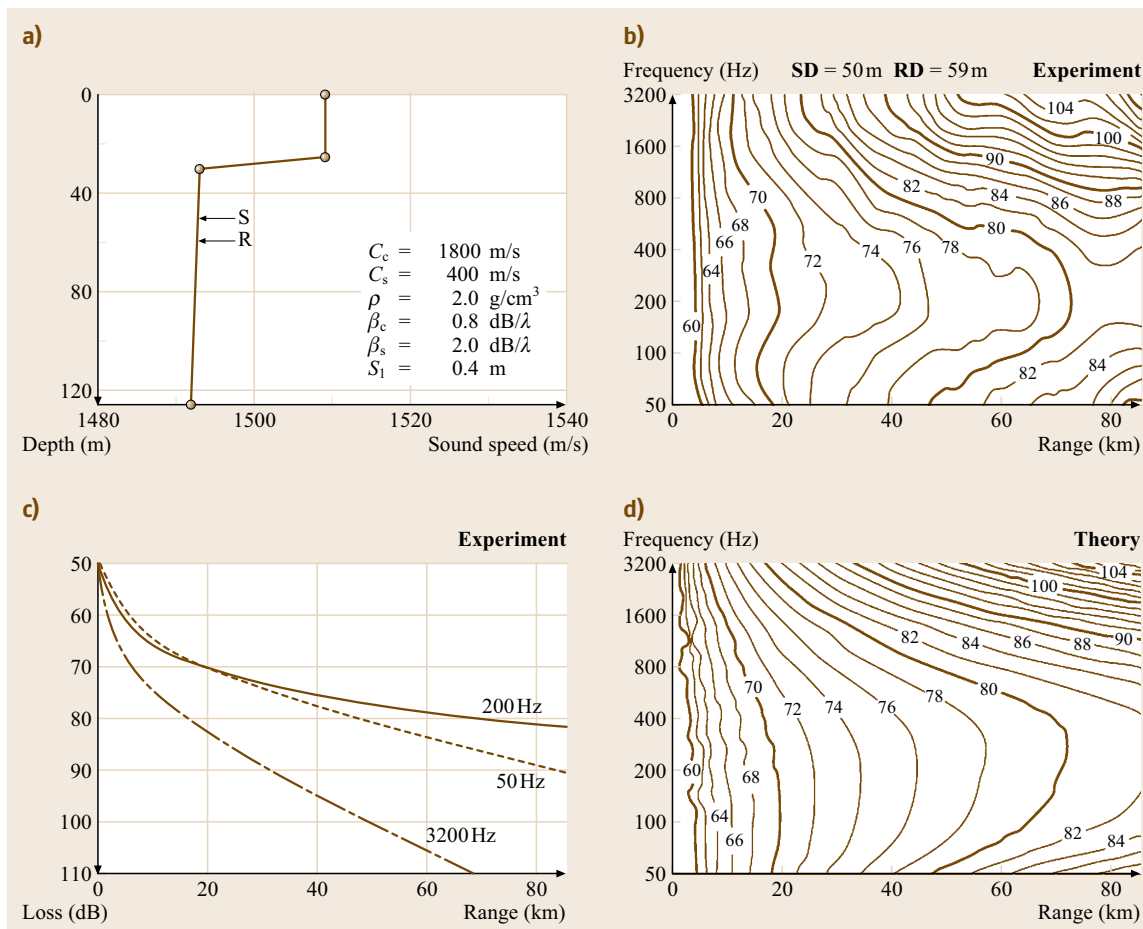
Using a Fourier transform, the frequency-domain solution $p(r, z, \omega)$ of the wave equation can be transformed


Fig. 5.30a–d Optimum frequency curves for a shallow-water environment. (**a**) The shallow-water environment. Source and receiver depths are marked by the arrows. (**b**) Contour of third-octave transmission loss data over frequency and range. (**c**) Incoherent normal-mode transmission loss. (**d**) Contour of incoherent transmission loss looking very much like the data in (**b**)

into the time-dependent solution $p(r, z, t)$. We have

$$p(r, z, t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} S(\omega) p(r, z, \omega) \, e^{-i\omega t} \, d\omega \, .$$

(5.69)

$S(\omega)$ is the source spectrum defined as

$$S(\omega) = \int_{-\infty}^{+\infty} s(t) e^{i\omega t} \, dt \, ,$$

(5.70)

where $s(t)$ is the pulse source for which the time-domain solution $p(r, z, t)$ is investigated. Before (5.69)

can be used, the transfer function $p(r, z, \omega)$ has to be determined from one of the frequency-domain (or continuous-wave (CW)) propagation models described above at a number of discrete frequencies within the frequency band of interest. This means the ocean response to a pulse $s(t)$ is obtained by combining the convenient and computationally efficient CW codes (spectral integrals, normal-mode or parabolic equations) with a Fourier synthesis approach. Even if this last step is conceptually simple, there are several numerical issues that have to be addressed like frequency and time windowing, and aliasing.

The first step in evaluating the frequency integral by means of a (fast) Fourier transform is to reduce the in-

tegration interval. The source pulse $s(t)$ being known, a frequency interval $(\omega_{min}, \omega_{max})$ is determined, outside which the source does not emit any significant energy. Moreover, the final time-domain solution $p(r, z, t)$ being real, we know that $p(r, z, -\omega) = \overline{p(r, z, \omega)}$. This reduces the integration performed in (5.69) to the interval $[\omega_{min}, \omega_{max}]$

$$
p(r, z, t) = \text{Re} \left[\frac{1}{\pi} \int_{\omega_{min}}^{\omega_{max}} S(\omega) p(r, z, \omega) \, e^{-i\omega t} \, d\omega \right].
$$

(5.71)

Now, the set of discrete frequencies on which the integration has to be performed on the interval $[\omega_{min}, \omega_{max}]$ depends on both the choice of the sampling frequency F_s of the signal and some a priori knowledge of the time spread T of the final solution $p(r, z, t)$. First, the sampling frequency F_s has to satisfy the Nyquist criterium $F_s > 2 f_{max} = (\omega_{max}/\pi)$. Typically, to allow for a reasonably looking graphical signal display, an appropriate value is $F_s = 8 f_{max}$. Second, the time window T of the signal after propagation through the ocean should be taken as short as possible. However, this time window must be chosen in accordance with the waveguide physics. A conservative way to estimate the time spread is to consider that T is bounded by the slowest and fastest available speeds for the particular environment:

$$
T = t_{max} - t_{min} \geq R \left(\frac{1}{c_{min}} - \frac{1}{c_{max}} \right),
$$

(5.72)

where R is the propagation range. With the proper choice of T and F_s, we construct an N-point time vector $t = [0 : \frac{1}{F_s} : T]$, with $N = F_s T + 1$ and a frequency vector $\frac{\omega}{2\pi} = [0 : \frac{F_s}{N} : F_s(1 - \frac{1}{N})]$. The time vector t corresponds to the time axis on which the time-dependent solution $p(r, z, t)$ will be computed from the frequency bins of the frequency vector ω inside the interval $[\omega_{min}, \omega_{max}]$. Before computing the Fourier transform, it is necessary to add a retarded time to the integral $\exp(-it_{min}\omega)$ so that the time vector t starts at the earliest possible arrival $t = t_{min} + [0 : \frac{1}{F_s} : T]$. From (5.80), a reasonable choice for t_{min} is $t_{min} = (R/c_{max})$. It follows:

$$
p(r, z, t) = Re \left\{ \text{IFFT} \left[S(\omega) p(r, z, \omega) e^{-i\omega t_{min}} \right]_{\omega_{min}}^{\omega_{max}} \right\},
$$

(5.73)

where the inverse fast Fourier transform (IFFT) is performed on the frequency vector ω in the interval $[\omega_{min}, \omega_{max}]$. We do not discuss here the numerous (fast) Fourier transform algorithms, which can be found in signal processing or numerical methods books. Typical results of this broadband modeling are presented in Figs. 5.22–5.25.

5.5 Quantitative Description of Propagation

All of the models described above attempt to describe reality and to solve in one way or another the Helmholtz equation. They therefore should be consistent and there is much insight to be gained from understanding this consistency. The models ultimately compute propagation loss which is taken as the decibel ratio (see Appendix) of the pressure at the field point to a reference pressure, typically one meter from the source.

Figure 5.31 shows convergence-zone-type propagation for a simplified profile. The ray trace in Fig. 5.31b shows the cyclic focusing discussed in Sect. 5.1.2. The same profile is used to calculate normal modes, shown in Fig. 5.31c which, when summed according to (5.50) referenced to 1 m, exhibits the same cyclic pattern as the ray picture. Figure 5.31d shows both the normal-mode (wave theory) and ray theory result. Ray theory exhibits sharply bounded shadow regions as expected whereas the normal-mode theory, which includes

diffraction, shows that the acoustic field does exist in the shadow regions and the convergence zones have structure.

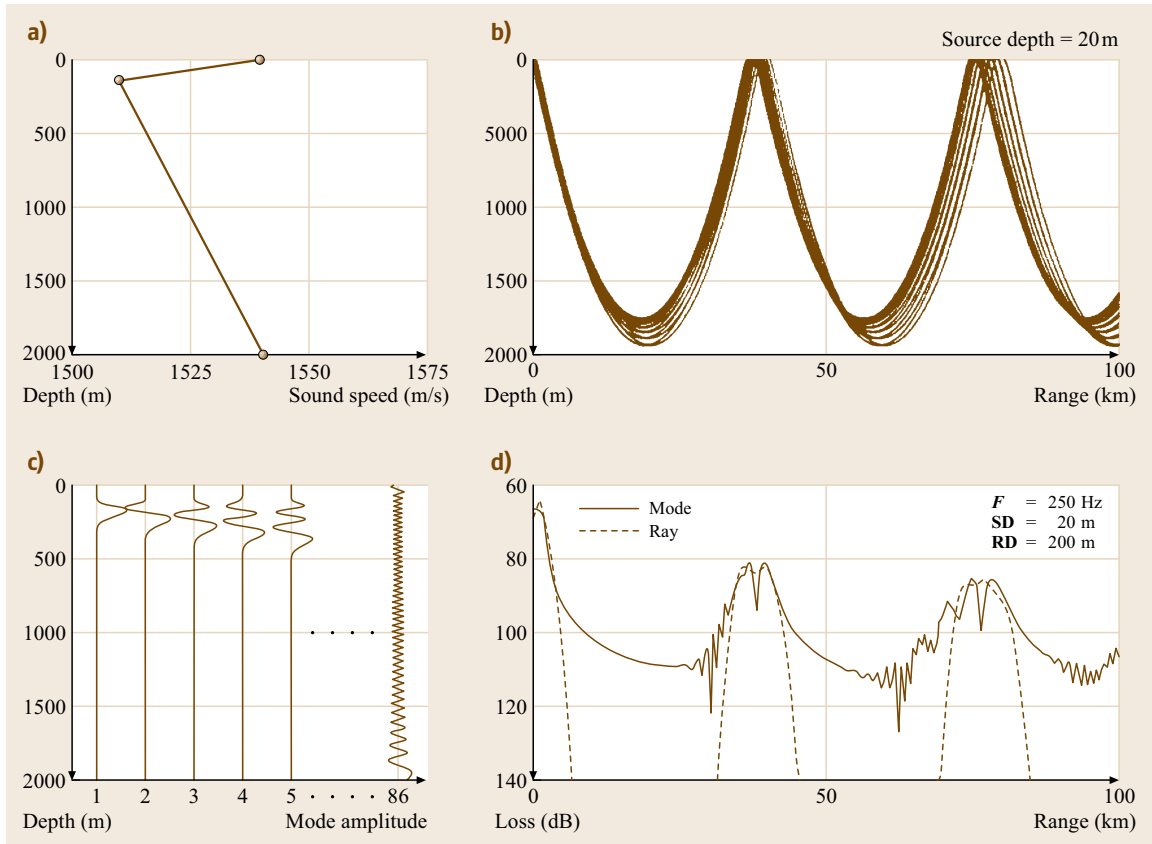
Normal-mode models sum the discrete modes that roughly correspond to angles of propagation within the cone of Fig. 5.7a. The spectral method can include the full field, discrete plus continuous, the latter corresponding to larger angles. The discussion below (5.50) defines these angles in terms of horizontal wavenumbers, and the eigenvalues of the normal-mode problem are a discrete set of horizontal wavenumbers. Hence the integrand (Green's function) of the spectral method has peaks at the eigenvalues associated with the normal modes. These peeks are shown on the right of Fig. 5.32a. The smoother portion of the spectrum is the continuous part, corresponding to the larger angles. Therefore, the consistency we expect between the normal-mode and the spectral method and the physics


Fig. 5.31a–d Consistency between ray theory and normal mode theory. (**a**) Sound-speed profile, (**b**) ray trace, (**c**) normal modes, (**d**) propagation calculations. The shadow zones in (**d**) are much sharper for ray theory which does not include diffraction effects

of Fig. 5.7 is that the continuous portion of the spectral solution decays rapidly with range so that there should be complete agreement at long range between the normal-mode and spectral solutions. The Lloyd's mirror effect, a near-field effect, should also be exhibited in the spectral solution but not the normal-mode solution. These aspects are apparent in Fig. 5.32b. The PE solution is in good agreement with the other solutions but with some phase error associated with the average wavenumber that must be chosen in the split-step method. The PE solution, which contains part of the continuous spectrum including the Lloyd's mirror beams, is more accurate than the normal-mode solution at short range; however, the generalized PE can be made arbitrarily accurate at short range by including more expansion terms in (5.66).

Range-dependent results are shown in Fig. 5.33. A ray trace, a ray trace field result, a PE result and data are plotted together for a range-dependent sound-speed profile environment. The models agree with the data in general, with the exception that the ray results predict too sharp a leading edge for the convergence zone.

Up-slope propagation is modeled with the PE in Fig. 5.34. As the field propagates up-slope, sound is dumped into the bottom in what appears to be discrete beams. The flat region has three modes and each is cut off successively as sound propagates into the shallower water. The ray picture also has a consistent explanation for this phenomenon. The rays for each mode become steeper as they propagate up-slope. When the ray angle exceeds the critical angle the sound is significantly transmitted into the bottom.

5.6 SONAR Array Processing

Signal processing is common to many fields [5.36–38]. In this section we emphasize applications to underwater acoustics, mainly concentrating on spatial processing of pressure fields. We note, though, that there is also growing interest in processing vector fields such as acoustic displacement, velocity or acceleration [5.39]. Further, the array processing discussed below for passive SONARs is also applicable to active SONAR signal processing. Spatial sampling of a sound field is usually done by an array of transducers, although the synthetic aperture array, in which a sensor is moved through space to obtain measurements in both the time and space domains, is an important exception. Spatial sampling is analogous to temporal sampling with the sampling interval replaced by the sensor spacing. The Nyquist criterion requires that the sensor spacing be at least twice the spatial wavenumber of the measured sound field. Finally, we note that recently work of processing ambient noise fields have proven to yield information about the ocean environment [5.40, 41].

5.6.1 Linear Plane-Wave Beam-Forming and Spatio-Temporal Sampling

The simplest example of array processing is phase shading in the frequency domain (or time delay in the time domain) to search for the bearing of a plane-wave signal. This procedure is referred to as plane wave beam-forming, or delay and sum beam-forming in the time domain. For simplicity we consider a liner array and we take θ as the bearing angle associated with the plane-wave signal as shown in Fig. 5.35a.

Frequency-Domain Processing
A plane wave can be represented as

$$s(\theta) = \exp(i\boldsymbol{k} \cdot \boldsymbol{r}) \,, \tag{5.74}$$

where we have suppressed the time dependence $\exp(-i\omega t)$ and $k = |\boldsymbol{k}| = (\omega/c)$. The field is summed in phase if the receiving element (hydrophone or microphone) inputs at position $\boldsymbol{d}$ is multiplied by the complex conjugate of the plane-wave phase factor,

$$\omega_i^* = \exp(-i\boldsymbol{k}_s \cdot \boldsymbol{d}_i) = \exp\left[-id(k\sin\theta_s)\right] \,, \tag{5.75}$$

where θ_s is a scanning angle. This process will have a maximum when the scanning angle equals the incident angle of the signal.

The output of this beam-forming process is denoted $B(\theta_s)$, but often it is the power output of the beamformer that is of interest:

$$
\begin{aligned}
B(\theta_s) &= \left| \sum_{i=1}^{m} \omega_i^*(\theta_s)\left[s_i(\theta) + n_i\right] \right|^2 \\
&= \sum_{i,j=1}^{m} \omega_i^*(\theta_s)\left(s_{ij} + n_{ij}\right)\omega_j(\theta_s) \,, \tag{5.76}
\end{aligned}
$$

where s_i and n_i are the signal and noise at the i-th receiving element and where $s_{ij} + n_{ij}$ are elements of a cross-spectral density matrix which, when obtained from data, would involve Fourier transforms and ensemble averages as mentioned in the discussion below (5.78) augmented by Fig. 5.35b. In writing down the right-hand side of (5.76), the signal and noise fields were assumed to be mutually incoherent.

We can write the above expression in matrix notation where the boldface lower-case letters denote vectors and boldface upper-case letters denote matrices. Define a steering column vector $\boldsymbol{w}$ whose i-th element is w_i and a cross-spectral density matrix (CSDM) $\boldsymbol{K}$ of

the signal and noise with elements $K_{ij} = s_{ij} + n_{ij}$ since the signal and noise are assumed to be independent. Equation (5.76) can be rewritten as

$$B(\theta_s) = \boldsymbol{w}^{\dagger}(\theta_s)\boldsymbol{K}(\theta_{true})\boldsymbol{w}(\theta_s) \equiv \boldsymbol{w}^{\dagger}\boldsymbol{K}\boldsymbol{w} , \qquad (5.77)$$

where $\dagger$ denotes the complex transpose. The CSDM or the covariance of the field is composed of uncorrelated signal and noise covariances,

$$\boldsymbol{K} = \boldsymbol{K}_s + \boldsymbol{K}_n . \qquad (5.78)$$

The data across the array as represented in the matrix $\boldsymbol{K}$ contains the information that the source is in the direction θ_{true}. Sometimes $\boldsymbol{w}(\theta_s)$ is referred to as a replica and this beam-forming process is viewed as matching the received data across the array with a replica. The type of beam-former represented by (5.77) is called a linear or Bartlett beam-former.

For the sample covariance estimation we assume we have an array with N sensors located at $\boldsymbol{d}_i$, $i = 1, 2, \cdots , N$ and a narrow-band model as illustrated in Fig. 5.35b. These covariances are estimated by segmenting the received data, $r_i(t)$ into *snapshots* using a sampling window, $W(t)$, that is unity in the interval $[0, T_w]$,

$$R_i^l(f) = \int_{T_l}^{T_l+T_w} r_i(t)W(t - T_l)e^{-i2\pi ft}\,dt , \qquad (5.79)$$

where here the notation uses frequency f, rather than angular frequency ω. In most beam-forming algorithms the data vectors are averaged to form the sample covariance matrix

$$\hat{K}(f) = \frac{1}{L}\sum_{l=1}^{L} R^l(f)R^l(f)^H , \qquad (5.80)$$

where L is the number of snapshots.

Time–Domain Processing

Time delaying a signal is the time-domain analog to phase shading of the signal in the frequency domain. In general, the time domain is a viable alternative to frequency analysis when processing coherent broadband signals such as temporal impulse. Time-delay beam-forming is then the frequency equivalent of the phase beam-forming described in Sect. 5.6.1. Indeed, it can be derived formally by taking the Fourier transform of the beam-forming process with the result that the beam-

former output is

$$b(\theta, t) = \int_{-\infty}^{\infty} B(\theta, \omega) \exp(i\omega t) \, d\omega$$

$$= \int_{-\infty}^{\infty} \sum_i R_i(\omega) \exp\left(-i\frac{\omega}{c_i} d_i \sin\theta\right)$$

$$\times \exp(i\omega t) \, d\omega$$

$$= \sum_i R_i(t - \frac{d_i}{c_i} \sin\theta) , \qquad (5.81)$$

where $R_i(t)$ is the time domain data, d_i the location and c_i the sound speed at the i-th phone. Physically speaking, the delay $\tau_i = (d_i/c_i) \sin\theta$ is, to a first approximation, the time delay associated with the phase shift in the frequency-domain array processing. A more rigorous approach in the case of a strong depth dependence of the sound-speed profile leads to

$$\tau_i = \int_{d_0}^{d_i} \sqrt{\frac{1}{c^2(z)} - \frac{\cos^2(\theta)}{c^2(d_0)}} \, dz , \qquad (5.82)$$

where d_0 is the depth of a reference hydrophone on the array. Note that, in the case of a uniform sound speed profile over the array, the above processes are plane-wave beam-forming.

Examples of the practical use of time-domain versus frequency-domain beam-forming are discussed below. Consider an incident field on a 20-element vertical array made of seven pulses arriving at different angles in a noisy waveguide environment (Fig. 5.36). The SNR ratio does not allow an accurate detection and identification of the echoes. Time-delay beam-forming results applied on these broadband signals is presented in Fig. 5.37. The SNR of the time-domain processing is a combination of array gain and frequency-coherent processing. In comparison, phase beam-forming performed on the same data and averaged incoherently over frequencies show a degraded detection of the incident echoes (Fig. 5.38).

5.6.2 Some Beam-Former Properties

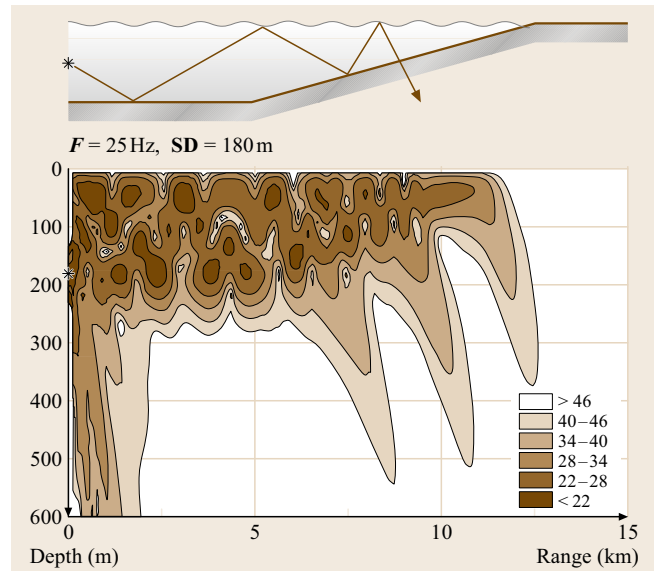
Figure 5.39 shows the output results of some frequency-domain plane-wave beam-formers for the cases of one and two incident signals. To be noted are the side-lobes of the Bartlett processor and the high-resolution performance of the adaptive processors (discussed in the next section). Some of the general attributes of an array beam-former are:


Fig. 5.34 Relation between up-slope propagation (from PE calculation) showing individual mode cut-off and energy dumping in the bottom, and a corresponding ray schematic. In this case, three modes were excited in the flat region. The ray picture shows that a ray becomes steeper as it bounces up slope and when its grazing angle exceeds the critical angle, it is partially transmitted into the bottom (and subsequently with more and more transmission with each successive, higher angle bounce)

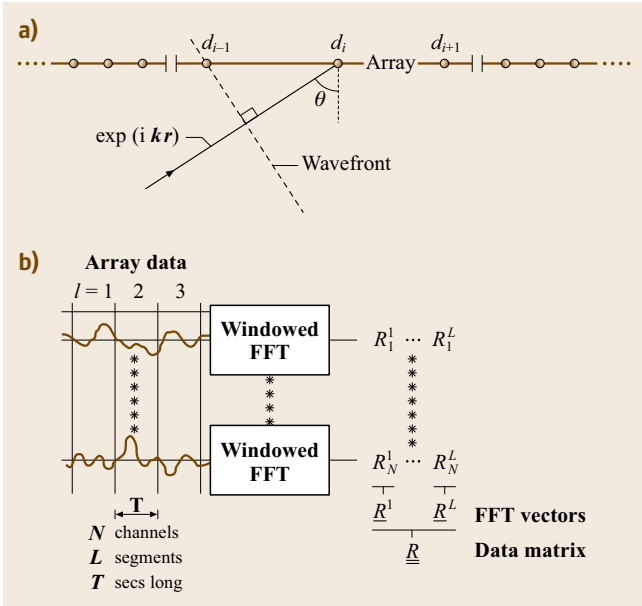
- The main response axis (MRA): generally, one normalizes the beam pattern to have 0 dB, or unity gain in the steered direction.
- Beam width: an array with finite extent, or aperture, must have a finite beam width centered about the MRA, which is termed the *main lobe*.
- Side-lobes: angular or wavenumber regions where the array has a relatively strong response. Sometimes they can be comparable to the MRA, but in a well-designed array, they are usually -20 dB or lower, i. e., the response of the array is less than 0.1 of a signal in the direction of a side-lobe.
- Wavenumber processing: rather than scan through incident angles, one can scan through wavenumbers, $k \sin\theta_s \equiv \kappa_s$; scanning through all possible values of κ_s results in nonphysical angles that correspond to waves not propagating at the acoustic medium speed. Such waves can exist, such as those associated with array vibrations. The beams associated with these wavenumbers are sometimes referred to as virtual beams. An important aspect of these beams is that their


Fig. 5.35a,b Array processing. (**a**) Geometry for plane-wave beam-forming. (**b**) The data is transformed to the frequency domain in which the plane-wave processing takes place. The cross-spectral-density matrix (CSDM) is an outer product of the data vector for a given frequency

side-lobes can be in the physical angle region, thereby interfering with acoustic propagating signals.

- Array gain: defined as the decibel ratio of the signal-to-noise ratios of the array output to a single phone
Fig. 5.36 Depth-versus-time representation of simulated broadband coherent data received on a vertical array in the presence of ambient noise. The wavefronts corresponding to different sources are nearly undistinguishable

output. If the noise field is isotropic, the array gain is also termed the directionality index.

5.6.3 Adaptive Processing

There are high-resolution methods to suppress side-lobes, usually referred to as adaptive methods since the signal processing procedure constructs weight vectors that depend on the received data itself. We briefly describe one of these procedures: the minimum-variance distortionless processor (MV), sometimes also called the maximum-likelihood method (MLM) directional spectrum-estimation procedure.

We seek a weight vector $\boldsymbol{w}_{\mathrm{MV}}$ applied to the matrix $\boldsymbol{K}$ such that its effect will be to minimize the output of the beam-former (5.77) except in the look direction, where we want the signal to pass undistorted. The weight vector is therefore chosen to minimize the functional [5.38]. From (5.72)

$$F = \boldsymbol{w}_{\mathrm{MV}} \boldsymbol{K} \boldsymbol{w}_{\mathrm{MV}} + \alpha(\boldsymbol{w}_{\mathrm{MV}} \boldsymbol{w} - 1) . \tag{5.83}$$

The first term is the mean-square output of the array and the second term incorporates the constraint of unity gain by means of the Lagrangian multiplier α. Following the method of Lagrange multipliers, we obtain the MV weight vector,

$$\boldsymbol{w}_{\mathrm{MV}} = \frac{\boldsymbol{K}^{-1}\boldsymbol{w}}{\boldsymbol{w}\boldsymbol{K}^{-1}\boldsymbol{w}} . \tag{5.84}$$

This new weight vector depends on the received data as represented by the cross-spectral density matrix; hence, the method is adaptive. Substituting back into (5.77) gives the output of our MV processor,

$$B_{\mathrm{MV}}(\theta_{\mathrm{s}}) = [\boldsymbol{w}(\theta_{\mathrm{s}})\boldsymbol{K}^{-1}(\theta_{\mathrm{true}})\boldsymbol{w}(\theta_{\mathrm{s}})]^{-1} . \tag{5.85}$$

The MV beam-former should have the same peak value at θ_{true} as the Bartlett beam-former, (5.77) but with side-lobes suppressed and a narrower main beam, indicating that it is a high-resolution beam-former. Examples are shown in Fig. 5.39. Of particular practical interest for this type of processor is the estimation procedure associated with Fig. 5.35b and (5.80). One must take sufficient snapshots to allow the stable inversion of the CSDM. This requirement may conflict with source motion when the source moves through multiple beams along the time interval needed to construct the CSDM.

5.6.4 Matched Field Processing, Phase Conjugation and Time Reversal

Matched field processing (MFP) [5.42] is a generalization of plane-wave beam-forming in which data

Fig. 5.37 Angle-versus-time representation of the simulated data in Fig. 5.36 after time-delay beam-forming. All sources appear clearly above the noise with their corresponding arrival angle ▶

on an array is correlated with replicas from a (waveguide) propagation model for candidate locations $\hat{r}$, $\hat{z}$ (Fig. 5.40). Localization of a source is accomplished with a resolution consistent with the modal structure and SNR. The central difficulty with MFP is specifying the coefficients and boundary conditions of the acoustic wave equation for shallow water propagation, *i.e.*, knowing the ocean environment in order to generate the replicas. An alternative to performing this model-based processing is phase conjugation (PC), in the frequency domain or, time reversal (TR) in the time domain, in which the conjugate or time-reversed data is used as source excitations on a transmit array co-located with the receive array (Fig. 5.41a) [5.43]. The PC/TR process is equivalent to correlating the data with the *actual* transfer function from the array to the original source location. In other words, both MFP and PC are signal processing analogs to the mechanical lens adjustment feedback technique used in adaptive optics: MFP uses data together with a model (note the feedback arrow in Fig. 5.40) whereas PC/TR is an active form of adaptive optics simply retransmitting phase-conjugate/time-reversed signal through the same medium (e.g., see result of Fig. 5.41). Though time reversal is thought of as as active process, it is presented in this section because of its relation to passive MFP.

Ocean Time–Reversal Acoustics
Phase conjugation, first demonstrated in nonlinear optics and its Fourier conjugate version, time reversal is a process that has recently implemented in ultrasonic laboratory acoustic experiments [5.44]. Implementation of time reversal in the ocean for single elements [5.45] and using a finite spatial aperture of sources, referred to as a *time-reversal mirror* (TRM) [5.46], is now well established.

The geometry of a time-reversal experiment is shown in Fig. 5.41. Using the well-established theory of PC and TRM in a waveguide, we just write down the result of the phase-conjugation and time-reversal process, respectively, propagating toward the focal position

$$P_{\mathrm{pc}}(r, z, \omega) = \sum_{j=1}^{J} G_{\omega}(r, z, z_j) G_{\omega}^*(R, z, z_{\mathrm{ps}}) S^*(\omega)$$

(5.86)

and
$$P_{\mathrm{trm}}(r, z, t) = \frac{1}{(2\pi)^2} \sum_{j=1}^{J} \iint G(r, z, t''; 0, z_j, t')$$
$$\times G(R, z_j, t'; 0, z_{\mathrm{ps}}, 0)$$
$$\times S(t'' - t + T) \, \mathrm{d}t \, \mathrm{d}t'' ,$$

(5.87)

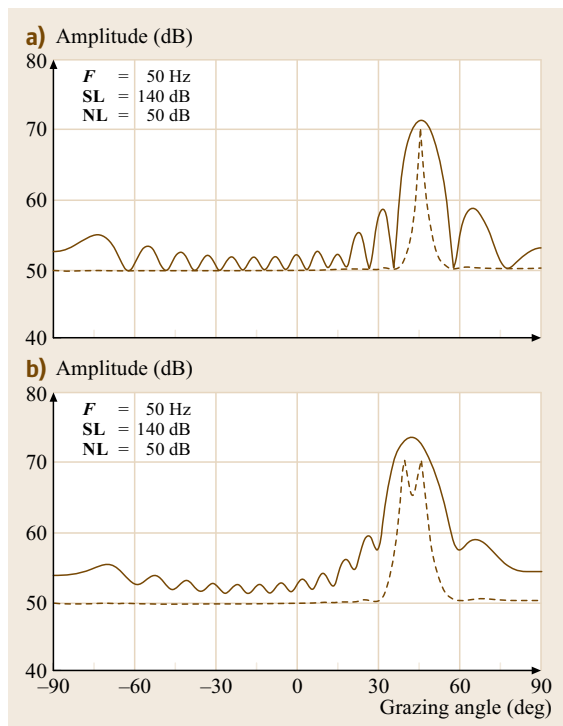
where S is the source function, $G_{\omega}^*(R, z, z_{\mathrm{ps}})$ is the frequency-domain Green's function and $G(R, z_j, t'; 0, z_{\mathrm{ps}}, 0)$ is the time-domain Green's function (TDGF) from the probe source at depth z_{ps} to each element of the SRA at range R and depth z_j. Emphasizing the time-domain process, $G(r, z, t''; 0, z_j, t')$ is the TDGF
Fig. 5.38 Comparison between coherent time-delay beam-forming (*in red*) and incoherent frequency-domain beam-forming (*in blue*) for the simulated data shown in Fig. 5.35. When data come from coherent broadband sources, time-domain bema-forming show better performance than frequency analysis


Fig. 5.39a,b Simulated beam-former outputs. (**a**) Single sources at a bearing of 45°. (**b**) Two sources with 6.3° angular separation. *Solid line*: linear processor (Bartlett). *Dashed line*: minimum variance distortion-less processor (MV) showing that the side-lobes are suppressed

from each element of the SRA back to range r and depth z. The focused field at the probe source position is $P_{trm}(R, z_{ps}, t)$. The summation is performed on the J elements of the TRM. The signal $S(t'' - t + T)$ of duration τ is the time-reversed version of the original probe source signal and the derivation of (5.87) uses the causality requirement, $T > 2\tau$, i.e., the time reversal interval T must contain the total time of reception and transmission at the SRA, 2τ.

Figure 5.41a–c shows the result of a TRM experiment. The size of the focus is consistent with the spatial structure of the highest-order mode surviving the two-way propagation and can also be mathematically described by a virtual array of sources using image theory in a waveguide.

Matched Field Processing

Linear matched field processing (MFP) can be thought of as the passive signal-processing implementation of phase conjugation. Referring to the phase-conjugation process described by (5.86), rename S^*G^* as the data at each array element and call the data vector on the array $R(a_{true})$, where a_{true} represents the (unknown) location of the source (Fig. 5.35b). Now in phase conjugation, G represents an actual propagation from the source array. In MPF, we do the propagation numerically using one of the acoustic models, but rather than use the actual Green's function, we use a normalized version of it called a replica: $\omega(a) = G(a)/|G(a)|$, where $G(a)$ is a vector of Green's functions of dimension of the number of array elements that represents the propagation from a candidate source position to the array elements and is the magnitude of the vector over the array elements. Taking the square of the PC process with replica's replacing the Green's functions yields the beam-former of the matched field processor

$$B_{mf}(a) = \omega^H(a)K(a_{true})\omega(a) , \qquad (5.88)$$

where a realization of the CSDM on the array is then $K(a_{true} = R(a_{true})R^H(a_{true})$ and a sample CSDM is built up as per (5.80).

MFP works because the unique spatial structure of the field permits localization in range, depth and azimuth depending on the array geometry and complexity of the ocean environment. The process is shown schematically in Fig. 5.40. MFP is usually implemented by systematically placing a test point source at each point of a search grid, computing the acoustic field (replicas) at all the elements of the array and then correlating this modeled field with the data from the real point source, $K(a_{true}) = RR^H$, whose location is unknown. When the test point source is co-located with the true point source, the correlation will be a maximum. The scalar function $B_{mf}(a)$ is also referred to as the ambiguity function (or surface) of the matched field processor because it also contains ambiguous peaks which are analogous to the side-lobes of a conventional plane-wave beam-former. Side-lobe suppression can often be accomplished by using the adaptive beam-forming methods discussed in the plane-wave section.

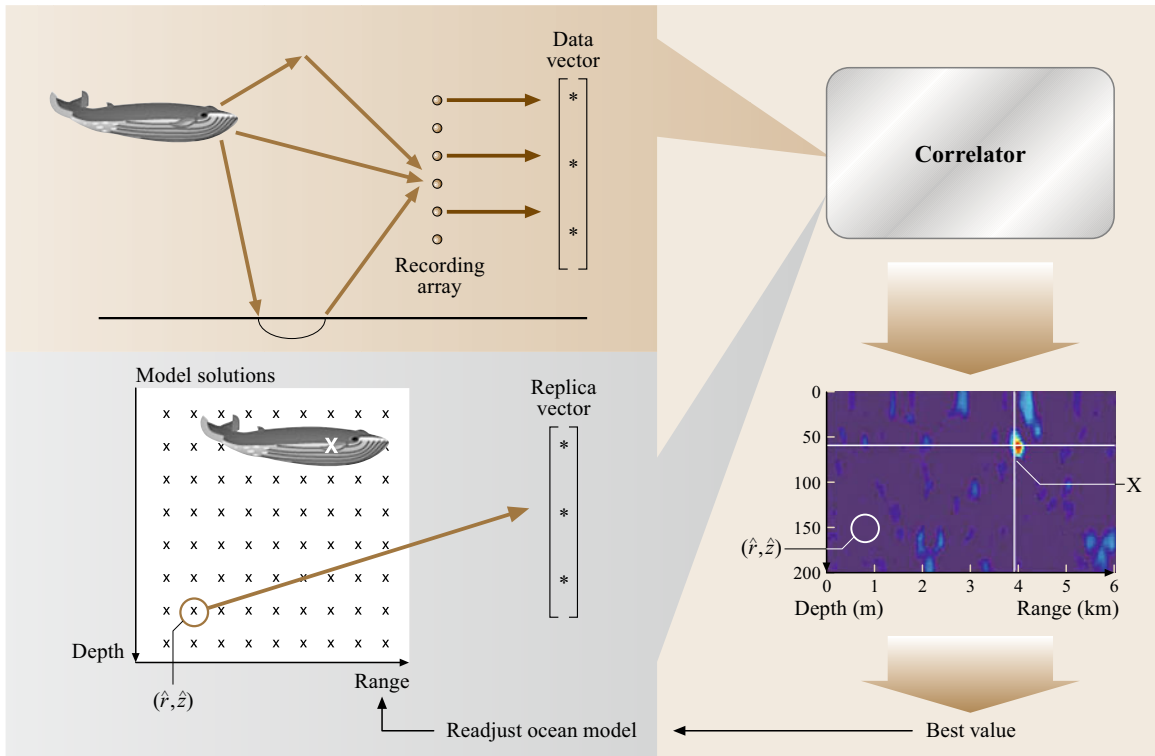
Adaptive processors are very sensitive to the accuracy of the replica functions which, in turn, require almost impossible knowledge of the environment. Hence, much work has been done on developing robust forms of adaptive processing such as the white-noise constraint method and others [5.47, 48]. An example of matched field processing performed incoherently on eight tones between 50 Hz and 200 Hz is shown in Fig. 5.42.


Fig. 5.40 Matched field processing (MFP). Here, the example consists in localizing a singing whale in the ocean. If your model of waveguide propagation is sufficiently accurate for this environment, then comparing the recorded sounds – the whale's data vector – one frequency at a time, for example, with replica data based on best guesses of the location $(\hat{r}, \hat{z})$ that the model provides, will eventually yield its location. The red peak in the data indicates the location of highest correlation. The small, circled × represents a bad guess, which thus does not compare well with the measured data. The feedback loop suggests a way to optimize the model: by fine-tuning the focus – the peak resolution in the plot – one can readjust the model's bases (for example, the sound-speed profile). That feedback describes a signal-processing version of adaptive optics. Matched field processing can then be used to perform acoustic tomography in the ocean (after [5.49])

5.7 Active SONAR Processing

An active SONAR system transmits a pulse and extracts information from the echo it receives as opposed to a passive SONAR system, which extracts information from signals received from radiating sources. An active SONAR system and its associated waveform is designed to detect targets and estimate their range, Doppler (speed) and bearing or to determine some properties of the medium such as ocean bottom bathymetry, ocean currents, winds, particulate concentration, etc. The spatial processing methods already discussed are applicable to the active problem so that in this section we emphasize the temporal aspects of active signal processing.

5.7.1 Active SONAR Signal Processing

The basic elements of an active SONAR are: the (waveform) transmitter, the channel through which the signal, echo and interference propagates, and the receiver [5.50]. The receiver consists of some sort of matched filter, a square-law device, and possibly a threshold device for the detector and range, Doppler and bearing scanners for the estimator.

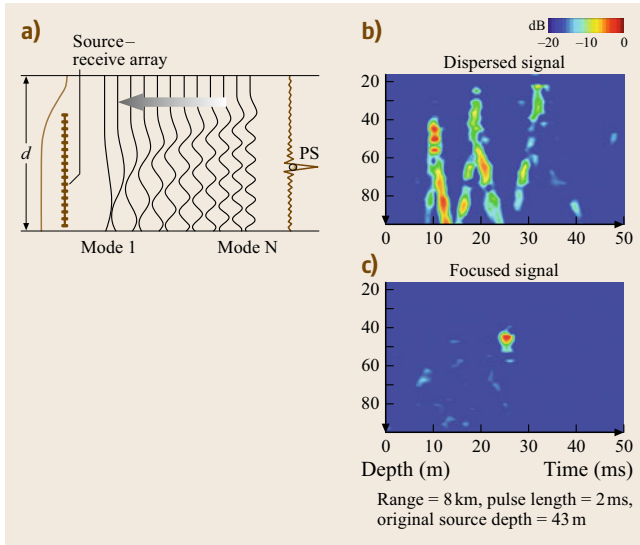
The matched filter maximizes the ratio of the peak output signal power to the variance of the noise and is implemented by correlating the received signal with


Fig. 5.41a–c Ocean acoustic time-reversal mirror (**a**) The acoustic field from a probe source (PS) is received on a source–receive array (SRA). (**b**) The signal received on the SRA with the first mode arriving first. At the SRA the signal is digitized, time-reversed and retransmitted. (**c**) The time-reversed signal received on an array at the same range as PS. The signal has been refocused at the probe source position with a resolution determined by the highest-order mode surviving the two-way process ◄

uncertainty compared to a wavelength, T is the range delay time, f_c is the center frequency of the transmitted signal and f_d is the Doppler shift caused by the target. The correlation process will have an output related to the following process,

$$C(a) = \left| \int \tilde{r}(t)\tilde{s}(t; a)\,dt \right|^2 , \qquad (5.90)$$

where $\tilde{s}(t; a)$ is a replica of the transmitted signal modified by a parameter set a which include the propagation–reflection process, e.g., range delay and Doppler rate. For the detection problem, the correlation receiver is used to generate a sufficient statistic which is the basis for a threshold comparison in making a decision if a target is present. The performance of the detector is described by receiving operating characteristic (ROC) curves which plot the detection of probability versus false-alarm probability, as parameterized by a statistics of the signal and noise levels. The parameters a set the range and Doppler value in the particular resolution cell of concern. To estimate these parameters, the correlation is done as a function of a.

For a matched filter operating in a background of white noise detecting a point target in a given range–Doppler resolution cell, the detection signal-to-noise ratio depends on the average energy-to-noise ratio and not on the shape of the signal. The waveform becomes

the transmitted signal. A simple description of the received signal, $r(t)$, is that it is an attenuated, delayed, and Doppler-shifted version of the transmitted signal $s_t(t)$,

$$r(t) \rightarrow \mathrm{Re}\left[\alpha\,e^{i\theta}\tilde{}\, s_t(t - T)\,e^{2\pi i f_c t}\,e^{2\pi i f_d t} + n(t)\right],$$
$$(5.89)$$

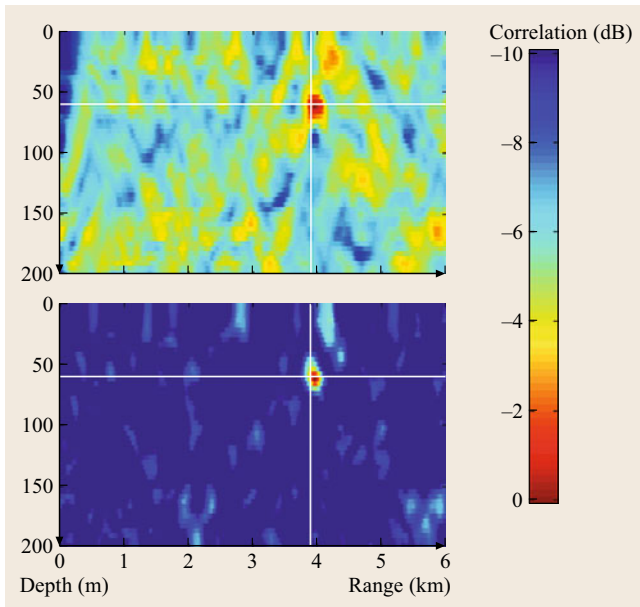
where α is the attenuation transmission loss and target cross section, θ is a random phase from the range


Fig. 5.42a,b Matched field processing example for a vertical array in a shallow-water environment. Specific information regarding the experiment can be found on the web at http://www.mpl.ucsd.edu/swellex96/. (**a**) Bartlett result with significant side-lobes only 3 dB down. (**b**) Adaptive processor results shows considerable side-lobe suppression. The processor is actually a *white-noise constrained* MVDP for which the diagonal of the CSDM is deliberately loaded by a specific algorithm to stabilize the processor to some uncertainty in the environment and/or array configuration. The ambiguity surfaces in (**a**) and (**b**) are an incoherent average over eight tones at 53, 85, 101, 117, 133, 149, 165, 181, and 197 Hz ◄

a factor when there is a reverberant environment and when one is concerned with estimating target range and Doppler. A waveform's potential for range and Doppler resolution can be ascertained from the ambiguity function of the transmitted signal. This ambiguity function is related to the correlation process of (5.90) for a transmitted signal scanned as a function of range and Doppler,

$$\Theta(\hat{T}, T_t, \hat{f}_d, f_{d_t})$$
$$\propto \left| \int \tilde{s}(t - T)\tilde{s}_t(t - \hat{T}) e^{2\pi i (f_{d_t} - \hat{f}_d)t} \, dt \right|^2 , \quad (5.91)$$

where T_t and f_{d_t} are the true target range (time) and Doppler, and $\hat{T}$ and $\hat{f}_d$ are the scanning estimates of the range and Doppler. Figure 5.43 are sketches of ambiguities functions of some typical waveforms. The range resolution is determined by the reciprocal of the bandwidth and the Doppler resolution by the reciprocal of the duration. A coded or pseudo-random (PR) sequence can attain good resolution of both by appearing as long-duration noise with a wide bandwidth. Ambiguity functions can be used to design desirable waveforms for particular situations. However, one must also consider the randomizing effect of the real ocean. The *scattering function* describes how a transmitted signal statistically redistributes its energy in the reverberant ocean environment which causes multipath and Doppler spread. In particular, in a reverberation-limited environment, only increasing the transmitted power does not change the signal-to-reverberation level. Signal design should minimize the overlap of the ambiguity function of the target displaced to its range and Doppler and the scattering function.

5.7.2 Underwater Acoustic Imaging

Imaging can be divided into categories concerned with water column and bottom properties. Here we describe several applications of active SONAR to imaging the ocean.

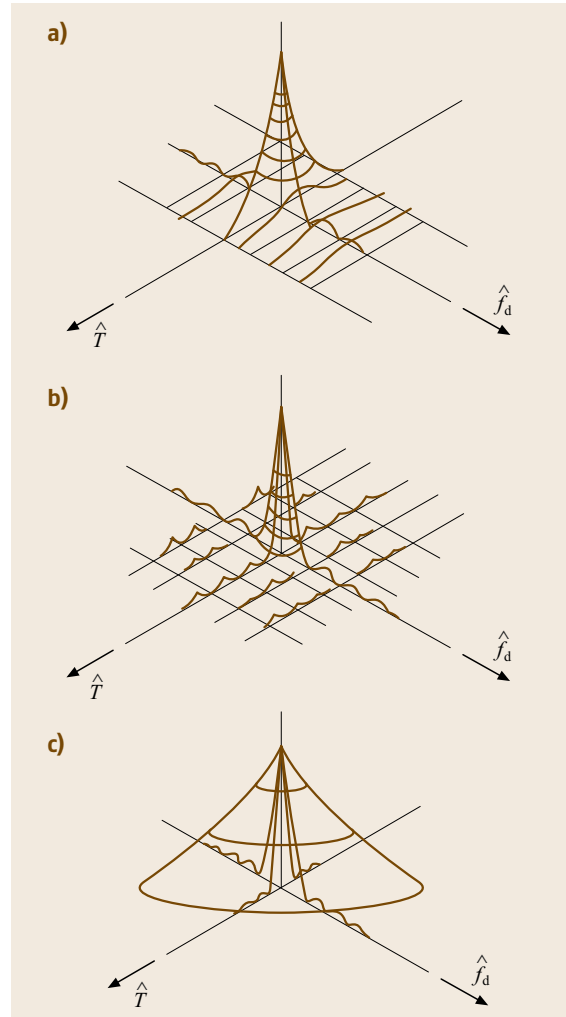
Water Column Imaging. Backscatter from particulate objects that move along with the water motion (such as biological matter, bubbles sediments) contains velocity information because of the Doppler shift. An acoustic Doppler current profiler (ADCP) might typically consist of three or four source–receivers pointed in slightly different directions but generally up (from the bottom) or down (from a ship). The multiple directions are for resolving motion in different directions. The Doppler


Fig. 5.43a–c Ambiguity function for several SONAR signals: (**a**) rectangular pulse; (**b**) coded pulses; (**c**) chirped FM pulse

shift of the returning scattered field is simply $-2f(v/c)$ (as opposed to the more-complicated long-range waveguide Doppler shift discussed in Sect. 5.4.4), where f is the acoustic frequency, v is the radial velocity of the scatterer (water motion), and c is the sound speed. With three or four narrow-beam transducers, the current vector can be ascertained as a function of distance from an ADCP by gating the received signal and associating a distance with the time gated segment of the signal. Water-column motion associated with internal waves can be determined by this process also where essentially one uses a kind of ADCP points in the horizontal
Fig. 5.44 Depth–time representation of the East–West component of water velocity over the Kaena ridge west of Oahu. The dominant signal is the 12.4 h tide, which has downward propagating crests of long vertical wavelength. The SONAR is at ≈390 m, where there is a fine scar in the record. The scar at ≈ 550 m is the echo of the sea floor at 1100 m, aliased back into the record (Courtesy Rob. Pinkel, Scripps Institution of Oceanography)

direction. For elaborate images of currents and the internal wave motion (Fig. 5.44), the Doppler measurements of backscattering off zooplankton are combined with array-processing techniques used in bottom mapping as discussed below.

Bottom Mapping. Because of many industrial applications, there exists a huge literature on multibeam systems for bottom mapping. Among the material avail-

able on the web, we would like to refer to two complete courses on submarine acoustic imaging methods available: (1) from the Ocean Mapping Group (University of New Brunswick, Canada) at http://www.omg.unb.ca/GGE/; (2) under a PDF format (*Multibeam Sonar: Theory of Operation*) from L3 Communication SeaBeam Instruments at http://www.mbari.org/data/mbsystem/formatdoc/. The scope of the paragraph below is to describe the basics and keywords associated with bottom mapping in underwater acoustics.

Active SONARs are devices that emit sound with specific waveforms and listen for the echoes from remote objects in the water. Among many applications, SONAR systems are used as echo-sounders for measuring water depths by transmitting acoustic pulses from the ocean surface and listening for their reflection (or echo) from the sea floor. The time between transmission of a pulse and the return of its echo is the time it takes the sound to travel to the bottom and back. Knowing this time and the speed of sound in water allows one to calculate the range to the bottom. This technique has been widely used to map much of the world's water-covered areas and has permitted ships to navigate safely through the world's oceans. The purpose of a large-scale bathymetric survey is to produce accurate depth measurements for many neighboring points on the sea floor such that an accurate picture of the geography of the bottom can be established. To do this efficiently, two things are required of the SONAR used: it must produce accurate
Fig. 5.45a,b Surveying an irregular sea floor **(a)** with a wide-beam SONAR and **(b)** with a narrow-beam SONAR (Courtesy L-3 Communications SeaBeam Instruments)

depth measurements that correspond to well-defined locations on the sea floor (that is, specific latitudes and longitudes); and it must be able to make large numbers of these measurements in a reasonable amount of time. In addition, information derived from echo sounding has aided in laying transoceanic telephone cables, exploring and drilling for offshore oil, locating important underwater mineral deposits, and improving our understanding of the Earth's geological processes.

The earliest, most basic and still most widely used echo-sounding devices are *single-beam echo sounders*. The purpose of these instruments is to make serial measurements of the ocean depth at many locations. Recorded depths can be combined with their physical locations to build a three-dimensional map of the ocean floor. In general, single-beam depth sounders are set up to make measurements from a vessel in motion. Until the early 1960s most depth sounding used single-beam echo sounders. These devices make a single depth measurement with each acoustic pulse (or ping) and include both wide- and narrow-beam systems (Fig. 5.45a,b). Relatively inexpensive wide-beam sounders detect echoes within a large solid angle under a vessel and are useful for finding potential hazards for safe navigation. However, these devices are unable to provide much detailed information about the sea bottom. On the other hand, more-expensive narrow-beam sounders are capable of providing high spatial resolution with the small solid angle encompassed by their beam, but can cover only a limited survey area with each ping. Neither system provides a method for creating detailed maps of the sea floor that minimizes ship time and is thus cost-effective.

A *multibeam SONAR* is an instrument that can map more than one location on the ocean floor with a single ping and with higher resolution than those of conventional echo sounders. Effectively, the function of a narrow single-beam echo sounder is performed at several different locations on the bottom at once. These bottom locations are arranged such that they map a contiguous area of the bottom – usually a strip of points in a direction perpendicular to the path of the survey vessel (Fig. 5.46). Clearly, this is highly advantageous. Multibeam SONARs can map complete scans of the bottom in roughly the time it takes for the echo to return from the farthest angle. Because they are far more complex, the cost of a multibeam SONAR can be many times that of a single-beam SONAR. However, this cost is more than compensated by the savings associated with reduced ship operating time. As a consequence, multibeam SONARs are the survey instrument of choice in most mapping applications, particularly in deep
Fig. 5.46 Bottom mapping with a multibeam SONAR system (Courtesy L-3 Communications SeaBeam Instruments)

ocean environments where ship operating time is expensive [5.51]. Multibeam SONARs often utilize the *Mills Cross* technique which takes advantage of the high resolution obtained from two intersecting focusing regions from a perpendicular linear source and receive array.

Instead of measuring the depth to the ocean bottom, a *side-scan SONAR* reveals information about the sea-floor composition by taking advantage of the different sound absorbing and reflecting characteristics of different materials. Some types of material, such as metals or recently extruded volcanic rock, are good reflectors. Clay and silt, on the other hand, do not reflect sound well. Strong reflectors create strong echoes, while weak reflectors create weaker echoes. Knowing these characteristics, you can use the strength of acoustic returns to examine the composition of the sea floor. Reporting the strength of echoes is essentially what a side-scan SONAR is designed to do. Combining bottom-composition information provided by a side-scan SONAR with the depth information from a range-finding SONRA can be a powerful tool for examining the characteristics of an ocean bottom.

The name *side scan* is used for historical reasons – because these SONARs were originally built to be sensitive to echo returns from bottom locations on either side of a survey ship, instead of directly below, as was the case for a traditional single-beam depth sounder [5.52].

Side-scan SONAR employs much of the same hardware and processes as conventional depth-sounding SONAR. Pulses are transmitted by a projector (or array of projectors), and hydrophones receive echoes of those pulses from the ocean floor and pass them to a receiver system. Where side-scan SONAR differs from a depth-sounding system is in the way it processes these returns. While a single-beam echo sounder is only concerned with the time between transmission and the earliest return echo, this first returned echo only marks when
and the echo of the reflective feature, the observer can compute the range to the feature from the SONAR.

As a practical instrument, the simplistic side-scan SONAR described above is not very useful. While it provides the times of echoes, it does not provide their direction. Most side-scan SONARs deal with this problem by introducing some directionality into their projected pulses, and, to some degree, their receivers. This is done by using a line array of projectors to send pulses. The long axis of the line array is oriented parallel to the direction of travel of the SONAR survey vessel (often the arrays are towed behind the ship). In practice, side-scan SONARs tend to mount both the line array and hydrophones on a towfish, a device that is towed in the water below the surface behind a survey vessel (Fig. 5.48). As the survey vessel travels, the towfish transmits and listens to the echoes of a series of pulses. The echoes of each pulse are used to build up amplitude-versus-time plots for each side of the vessel. To adjust for the decline in the strength of echoes due to attenuation, a time-varying gain is applied to the amplitude values so that sea-floor features with similar reflectivities have similar amplitudes. Eventually the noise inherent in the system (which remains constant) becomes comparable to the amplitude of the echo, and the amplified trace becomes dominated by noise. Recording of each trace is usually cut off before this occurs so that the next ping can be transmitted.

Figure 5.49 shows an example of ship-wreck discovery using side-scan SONAR data performed from an automated underwater vehicle (AUV) in a 1500 m-deep ocean.

Often one is interested in sub-bottom profiling that requires high spatial and therefore temporal resolution to image closely spaced interfaces. Frequency-modulated (FM) sweeps provide such high-resolution high-intensity signals after matched filtering. Thus, for example, a matched filter output of a 1 s FM sweep from 2–12 kHz would compresses the energy of the 1 s pulse into one that has the temporal resolution of a 0.1 ms. With such high resolution, reflection coefficients from chirp SONARs can be related to sedimentary characteristics [5.53, 54]. Figure 5.50 is an example of a chirp SONAR output indicating very finely layered interfaces. Figure 5.50a shows the range dependency of the seabed

things start to get interesting to a side-scan SONAR (Fig. 5.47a). As it continues its spherical propagation, the transmitted pulse still interacts with the bottom, thus creating at the receiver a continuous series of weakening echoes in time (Fig. 5.47b).

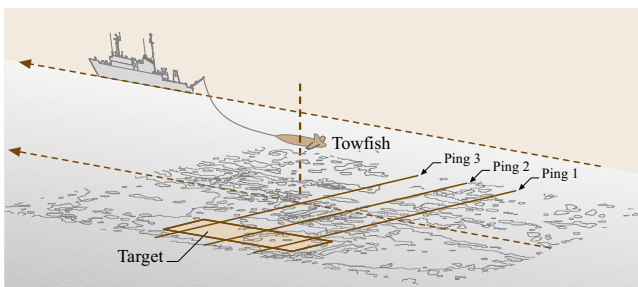
In the example presented in Fig. 5.47, the side-scan SONAR detects a bottom feature (the box). From the amplitude-versus-time plot, an observer can tell there is a highly reflective feature on the bottom. From the time difference between the first echo (which is presumed to be due to the bottom directly below the SONAR system)


Fig. 5.48 Schematic of a side-scan SONAR imaging the ocean floor with successive pings (Courtesy L-3 Communications SeaBeam Instruments)

along the cross-shelf track taken by a chirp SONAR. Sand ridges with less acoustic penetration occupy most of the mid-shelf area with a few km spacing. In the outer-shelf area, dipping layers over the distinct *R reflector* are detected. The spikes in the water column at the mid-shelf area are schools of fish near the bottom, which were mostly seen during the surveys conducted in daylight. Figure 5.50b shows the sub-bottom profile of the along-shelf track with acoustic penetration as deep as 40 m. Along-shelf track is relatively less range-dependent. However, several scour marks ($\approx$100 m wide, a few m deep) are detected on the sea floor. These scour marks are attributed to gouging by iceberg keels and the resultant deformations of deeper sublayers is also displayed [A. Turgut, personal communications].

5.7.3 Acoustic Telemetry

Because electromagnetic waves do not propagate in the ocean, underwater acoustic data transmission have many applications, including:

- Communication between two submarines or a submarine and a support vessel
- Communication between a ship and an automated underwater vehicle (AUV) either to get data available without recovering the instruments or to control the instruments onboard the AUV or the AUV itself
- Data transmission to an automated system

Underwater acoustic communications [5.55] are typically achieved using digital signals. We usually distinguish between coherent and incoherent transmissions. For example, incoherent transmissions might consist of transmitting the symbols "0" and "1" at different frequencies (frequency shift keying (FSK)), whereas coherent transmissions might encode using different phases of a given sinusoid (phase shift keying (PSK)) (Fig. 5.51).

Acoustic telemetry can be performed from one source to one receiver in a single-input single-output mode (SISO). To improve performance in terms of data rate and error rate, acoustic networks are now commonly used. In particular, recent works in underwater acoustic communications deal with multiple-input multiple-output (MIMO) configurations (Fig. 5.52) in shallow-water oceans [5.56].

The trend toward MIMO is justified by the fact that the amount of information – known as the information capacity, I – that can be sent between arrays of transmitters and receivers is larger than in a SISO case. Indeed, the SISO information capacity is given by Shannon's
Fig. 5.49 Side-scan SONAR data obtained in 2001 from the HUGIN 3000 AUVs of a ship sunk in the Gulf of Mexico during World War II. C&C Technology Inc. (Courtesy of the National D-Day Museum, New Orleans)

famous formula [5.57]

$$I = \log_2 \left(1 + \frac{S}{N} \right) \text{ bits s}^{-1}\text{Hz}^{-1} \,, \tag{5.92}$$

where S is the received signal power, N the noise power and the Shannon capacity I is measured in bits per second per Hertz of bandwidth available for transmission. Equation (5.92) states that the channel capacity increases with the signal-to-noise ratio. In a MIMO configuration with M_t transmitters and M_r receivers, (5.92) is changed into [5.58]

$$I \sim M_i \log_2 \left(1 + \frac{SM_r/M_t}{N} \right) \text{ bits s}^{-1}\text{Hz}^{-1} \,, \tag{5.93}$$

with $M_r \geq M_t$ to be able to decode the M_t separate transmitted signals. Sending M_t different bitstreams is advantageous since it gives a factor of M_t outside the log, linearly increasing the channel capacity I compared to a logarithmic increase when playing on the output power S.

Beside the optimized allocation of power between the M_r and M_t receivers and transmitters (the so-called water-filling approach [5.59]), other particular issues in underwater acoustic telemetry deal with Doppler tracking, channel estimation and signal-to-noise ratios. Those combined parameters often result in a tradeoff between data rate and error rate. For example, low frequencies propagate further with better signal-to-noise ratios and hence lower error rates but the data rate is poor. High frequencies provide high data rates but suffer from strong loss in the acoustic channel, potentially resulting in large error rates.

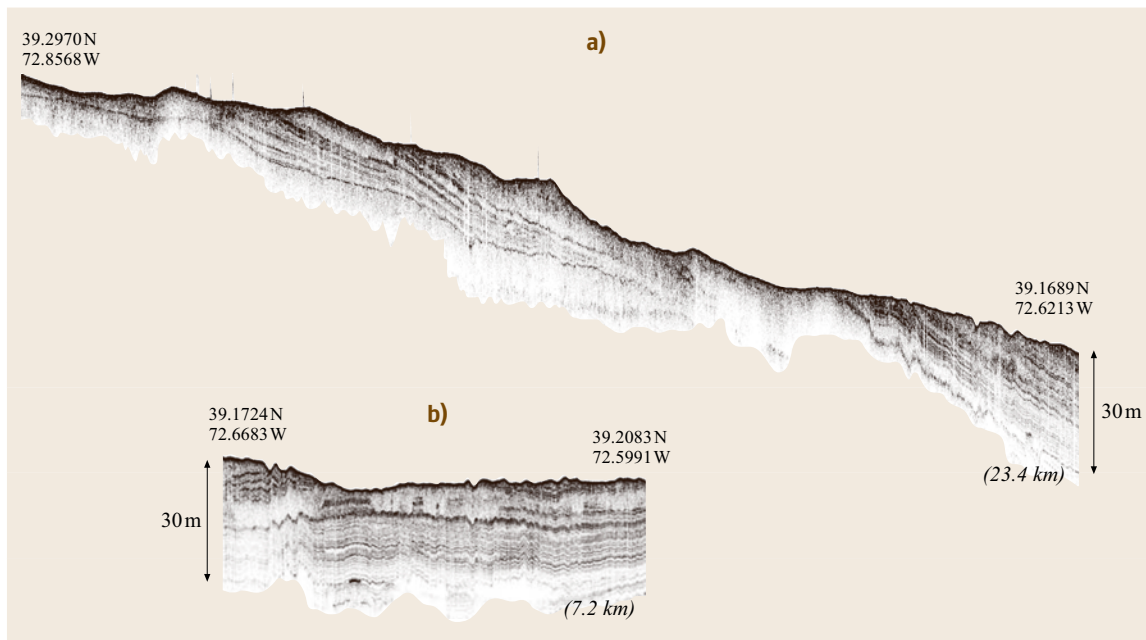
Another difficulty has to do with multipath propagation and/or reverberation in the ocean, causing intersymbol interference (ISI) and scattering, also called


Fig. 5.50a,b Sub-bottom profiles along (**a**) cross-shelf and (**b**) along-shelf tracks on the New Jersey shelf collected by a hull-mounted chirp SONAR (2–12 kHz) during the shallow-water acoustic technology experiment (SWAT2000) (Courtesy A. Turgut, Naval Research Laboratory)

the fading effect (Fig. 5.53). As a consequence, the performance of a given system depends strongly on the acoustic environment.

Figure 5.54 shows examples of experimental channel impulse responses recorded at different frequencies in shallow-water waveguides. The difference in temporal dispersion (relative to the acoustic period) between Fig. 5.54a and Fig. 5.54c shows that high-frequency transmissions suffer from stronger ISI and shorter coherence time.

Fig. 5.51 Example of signal space diagrams for coherent communications

In the presence of ISI, Eqs. (5.92, 93) can be generalized so that the channel capacity I still depends on the signal-to-noise ratio S/N where the noise N now includes ISI [5.60]. However, there exist many ways to reduce propagation effects on the quality of the acoustic transmission. One technological solution is to use directional arrays/antenna. Another one is to further code digital signals (code division multiple access (CDMA) or turbo codes [5.61]) in order to detect and potentially correct transmission errors. But, most importantly, there are many powerful signal-processing techniques derived from telecommunications to take into account at the receiver of the channel impulse response. An efficient one is adaptive equalization that uses a time-dependent channel estimate in order to decode the next symbols from the previously decoded one [5.62]. Other methods to deal with multipath complexities use time-reversal methods, either alone or with equalization methods [5.63–65].

5.7.4 Travel–Time Tomography

Tomography [5.9, 66] generally refers to applying some form of inverse theory to observations in order to infer properties of the propagation medium. The received

field from a source emitting a pulse will be spread in time as a result of multiple paths, in which different paths have different arrival times (Fig. 5.55). Hence the arrival times are related to the acoustic sampling of the medium. In contrast, standard medical X-ray tomography utilizes the different attenuation of the paths rather than arrival time for the inversion process. Since the ocean sound speed is a function of temperature and other oceanographic parameters, the arrival structure is ultimately related to a map of these oceanographic parameters. Thus, measuring the fluctuations of the arrival times through the experiments theoretically leads to the knowledge of the spatial-temporal scale of the ocean fluctuations.

Tomographic inversion in the ocean has typically relied on these three points. First, only the arrival time (and not the amplitude) of the multipath structure is used as an observable (Table 5.2) [5.67]. Enhanced time-of-arrival resolution is typically obtained using pulse-compression techniques [5.68] as mentioned in the bottom-mapping section above. Depending on the experimental configuration, a choice of compression is to be made between M-sequences [5.69], which are strongly Doppler sensitive but have low temporal side-lobes and frequency-modulated chirps that are Doppler insensitive with higher side-lobes (Fig. 5.43). Second, the inversion is performed by comparing the experimental arrival times to those given by a model (Fig. 5.56). Last, tomographic inversion algorithm classically deals with a linearized problem. This means that the model has to match the experimental data so that the inversion only deals with small perturbations.

Thus, ocean tomography starts from a sound-speed profile $c(\boldsymbol{r})$ on which small perturbations are added $\delta c(\boldsymbol{r}, t) \ll c$. The ocean model $c(\boldsymbol{r})$ has to be accurate enough to relate without ambiguity an experimentally measured travel time T_i to a model-deduced ray path Γ_i. Typically, some baseline oceanographic information is known so that one searches for departures from this baseline information. The perturbation infers a change of travel time δT_i along the ray such that, in a first linear approximation

$$\delta T_i \approx \int_{\Gamma_i} \frac{-\delta c}{c^2} \, \mathrm{d}s \,, \tag{5.94}$$

where Γ_i correspond to the Fermat path of the unperturbed ray. An efficient implementation of the inversion procedure utilizes a projection of the local sound-speed fluctuations $\delta c(\boldsymbol{r}, t)$ on a set of chosen functions $\Psi_k(\boldsymbol{r})$
Channel 1   Channel 2

Fig. 5.52 Experimental examples of eight quadrature amplitude modulation (QAM) transmissions in a multiple-input multiple-output configuration (MIMO) at 3.5 kHz in a 9 km-long, 120 m-deep shallow-water ocean. The SNR is 30 dB on channel 1 and 2, the symbol duration is 1 ms (data rate is 8 kB/s per channel) and bit error rate (BER) is 1×10^{-4} (Courtesy H.C. Song, Scripps Institution of Oceanography)

that constitutes a basis of the ocean structure. We have then

$$\delta c(\boldsymbol{r}, t) = \sum_{k=1}^{N} p_k(t) \psi_k(\boldsymbol{r}) \,, \tag{5.95}$$

where $p_k(t)$ is a set of unknown parameters. In its most primitive form, the ocean can be discretized into elementary cells, each cell being characterized by an unknown sound-speed perturbation p_k. Combining the

One bit

(**c**) Central frequency $= 15\,\text{kHz}$ with a $10\,\text{kHz}$ bandwidth, $160\,\text{m}$ range in a $12\,\text{m}$-deep waveguide ◄

Allowing for some noise in the measurement and assuming a set of arrival times δT_i, $i \in [1, M]$, (5.94) can be rewritten in an algebraic form [5.71]:

$$\delta T = G p + n \, . \tag{5.97}$$

There exists many algorithms to obtain an estimate of the parameters $\tilde{p}$ of the parameters p from the data δT knowing the matrix G. For example, when $N > M$, a least-mean-square estimator gives

$$\tilde{p} = G^T (GG^T)^{-1} \delta T \, . \tag{5.98}$$

Considerations about pertinent functions $\Psi_k(r)$ such as empirical orthogonal functions (EOFs) and the optimal inversion procedure can be found in the literature [5.72, 73].

Tomographic experiments have been performed to greater than megameter ranges. For example, two major experiments in the 1990s were performed by the Thetis 2 group in the western Mediterranean over a seasonal cycle [5.74] and by the North Pacific Acoustic Laboratory (NPAL) in the North Pacific basin [5.75]. The NPAL experiment was directed at using travel-time data obtained from a few acoustic sources and receivers located throughout the North Pacific Ocean to study temperature variations at large scale [5.76, 77]. The idea behind the project, known as acoustic thermometry of ocean climate (ATOC), is that sound travels slightly faster in warm water than in cold water. Thus, precisely measuring the time it takes for a sound signal to travel between two points reveals the average temperature along the path. Sound travels at about $1500\,\text{m/s}$ in water, while typical changes in the sound speed of the ocean as a result of temperature changes are only $5–10\,\text{m/s}$. The tomography

two above equations, it follows

$$\delta T_i = \int_{\Gamma_i} \frac{-1}{c^2} \sum_{k=1}^N p_k \psi_k(r) \, ds$$

$$= \sum_{k=1}^N p_k \int_{\Gamma_i} \frac{-\Psi_k(r)}{c^2} \, ds = \sum_{k=1}^N p_k G_{ik} \, . \tag{5.96}$$
Fig. 5.55 (**a**) Reference sound-speed profile $C_0(z)$. (**b**) corresponding ray traces. Table 5.2 identifies all plotted rays. Note the shallow and deep turning groups of rays as well as the axial ray (after [5.70]) (Courtesy Peter Worcester, Scripps Institution of Oceanography) ◄

a) Depth (km)   b)

C (km/s)   Range (km)

technique is very sensitive, and experiments so far have shown that temperatures in the ocean can be measured to a precision of $0.01\,°C$, which is needed to detect subtle variations and trends of the ocean basin.

New trends in ocean tomography deal with full-wave inversion involving the use of both travel times and amplitudes of echoes for a better accuracy in the inversion algorithm. In this case, a full-wave kernel for acoustic propagation has to be used [5.78], which includes the sensitivity of the whole Green's functions (both travel times and amplitudes) to sound speed variations. In the case of high frequencies, the application of the travel-time-sensitivity kernel to an ocean acoustic waveguide gives a picture close to the ray-theoretic one. However, in the low-frequency case of interest in ocean acoustic tomography, there are significant deviations. Low-frequency travel times are sensitive to sound-speed changes in Fresnel-zone-scale areas surrounding the eigen-rays, but not on the eigen-rays themselves, where the sensitivity is zero. This diffraction phenomenon known as the *banana–doughnut* [5.79] debate is still actively discussed in the field of ocean and seismic tomography [5.80].

Table 5.2 Identification of rays (after [5.70]). The identifier is $\pm n(\theta_s, \theta_R, \hat{z}^+, \hat{z}^-)$, where positive (negative) rays depart upward (downward) from the source, n is the total number of upper and lower turning points, θ_s is the departure angle at the source, θ_R is the arrival angle at the receiver, and $\hat{z}^+$ and $\hat{z}^-$ are the upper and lower turning depths, respectively (Courtesy Peter Worcester, Scripps Institution of Oceanography)

5.8 Acoustics and Marine Animals

In the context of contemporary acoustics, marine animal life is typically divided into the categories of marine mammals and non-marine mammals which include fish and others sea animals. The acoustics dealing with fish relates to either finding, counting and catching them. The acoustics concerned with marine mammals is for either studying their behavior or determining to what extent manmade sounds are harmful to them.

5.8.1 Fisheries Acoustics

An extensive introduction to fisheries acoustics is [5.81] and can be found online at http://www.fao.org/docrep/X5818E/x5818e00.htm#Contents. For more-detailed information, we recommend two special issues in [5.82, 83].

Following the development of SONAR systems, acoustic technology has had a major impact on fishing and on fisheries research. SONARs and echo sounders are now used as standard tools to search for concentrations of fish or to assess for biomass stock. With SONAR, it is possible to sample the water column much faster than trawl fishing. Moreover, SONARs have helped in our understanding of how fish are distributed in the ocean and how they behave over time. Depending on the fish density in the water column, echo-counting or echo-integration [5.84] are used to evaluate the fish biomass in the water column. Research on the signature of the echo return for a specific fish [5.85] or for a fish school [5.86, 87] is still an active area of research.

Fisheries acoustics experiments are performed with SONAR in the same way as bottom profiling [5.88–90]. The ship covers the area of interest by transect lines [5.91] while the SONAR sends and receives acoustic pulses (pings) as often as allowed by the SONAR system and the water depth (the signal from the previous ping has to die out before the next ping is transmitted). Typical SONAR frequencies are $38\,kHz$, $70\,kHz$, and $120\,kHz$. An echogram is a display of the instantaneous received intensity along the ship track. The echograms in Fig. 5.57a,b reveal individual fish echoes as well as fish school backscattered signals.
Fig. 5.56 Comparison of the predicted and measured arrival patterns (after [5.70]). The predicted arrival pattern was calculated from $C_0(z)$ as shown in Fig. 5.55. Geometric arrivals are labeled $\pm n$ as in Table 5.2. The peaks connected by *dashed lines* are the ray arrivals actually used (Courtesy Peter Worcester, Scripps Institution of Oceanography)

From a practical point of view, the relationship between an acoustic target and its received echo can be understood from the SONAR equation. With the procedure of Sect. 5.3.2 and 5.3.3, the echo level (in decibels) of a given target is

$$\text{EL} = \text{SL} + \text{RG} + \text{TS} - 2\text{TL} , \tag{5.99}$$

where SL is the source level and TL is the geometrical spreading loss in the medium. The target strength TS is defined as $\text{TS} = 10 \log_1 0(\sigma/4\pi)$, where σ is the backscattering cross section of the target. The receiver gain RG is often set up as a time-varied gain (TVG), which compensates for the geometrical spreading loss.

In (5.99), the target is supposed to be on the acoustic axis of the transducer. In general, a single-beam SONAR cannot distinguish between a small target on the transducer axis and a big target off-axis. The two echoes may have the same amplitude because the lower TS for the small target will be compensated by the off-axis power loss for the big target. One way to remove this ambiguity is to use a dual-beam SONAR [5.92] (or split-beam SONAR) that provides the position of the target in the beam pattern.

Echo-integration consists of integrating in time (as changed into depth from $R = ct/2$) the received intensity coming from the fish along the ship transects [5.93]. This value is then converted to a biomass via the backscattering cross section σ. In the case of a single target (Fig. 5.57a), the intensity of the echo E_1 is

$$E_1 = \overline{\sigma}\phi^2(r)\left[\frac{\exp(-2\beta r)}{r^4}\right] , \tag{5.100}$$

where $\phi^2(R)$ is the depth-dependent (or time-varying) gain; the term in bracket describes the geometrical spreading ($1/r^4$) and loss ($\exp(-2\beta r)$) of the echo during its round trip between the source and the receiver and $\overline{\sigma}$ is the scattering cross section of the target averaged over the bandwidth of the transmitted signal. In (5.100) we did not include the effect of the beam pattern and the sensitivity of the system in emission-reception. These parameters depend on the type of SONAR used and are often measured in situ from a calibration experiment [5.94,95]. In the case of a distributed targets in the water column [5.96,97] (Fig. 5.57b), the received intensity E_h is integrated over a layer h at a depth r, which

Fig. 5.57a,b Typical echogram obtained during an echo-integration campaign using a single-beam SONAR on the Gambie river. **(a)** Biomass made of individual fish. **(b)** Biomass made of fish school (Courtesy Jean Guillard, INRA) ▶

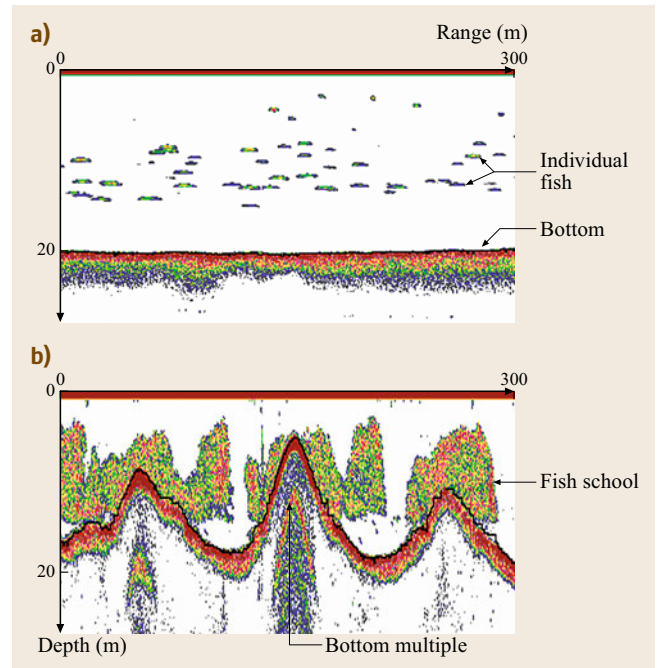
gives

$$E_h = h\overline{\sigma}n\phi^2(r) \left[\frac{\exp(-2\beta r)}{r^2} \right] , \qquad (5.101)$$

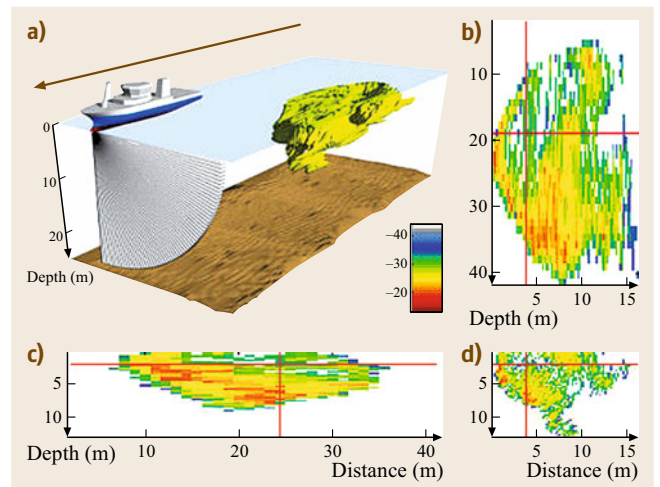
where n corresponds to the density of fish per unit volume in the layer h. Equation (5.101) is based on the linearity principle assumption, which states that, on the average over many pings, the intensity E_h is equal to the sum of the intensity produced by each fish individually [5.98].

In the case of either a single or multiple targets, the idea is to relate directly the echo-integrated result E_1 or E_h to the fish scattering amplitudes $\overline{\sigma}$ or $n\overline{\sigma}$. To that goal, the time-varying gain $\phi^2(r)$ has to compensate appropriately for the geometric and attenuation loss. For a volume integration, $\phi^2(r) = R^2 \exp(2\beta r)$, the so-called $20 \log r$ gain is used while a $40 \log r$ gain is applied in the case of individual echoes.

As a matter of fact, acoustic instruments, such as echo sounders and SONAR, are unique as underwater sampling tools since they detect objects at ranges of many hundreds of meters, independent of water clarity and depth. However, until recently, these instruments could only operate in two dimensions, providing observational slices through the water column. New trends in fisheries acoustics incorporate the use of multibeam SONAR – typically used in bottom mapping, see Sect. 5.7.2 – which provides detailed data describing the internal and external three-dimensional (3-D) structure of underwater objects such as fish schools [5.99] (Fig. 5.58). Multibeam SONARs are now used in a wide variety of fisheries research applications including: (1) three-dimensional descriptions of school structure and position in the water column [5.100]; knowledge of schooling is vital for understanding many aspects of

Fig. 5.58a–d Images of a fish school of *Sardinella aurita* from a multibeam SONAR. *Arrows* indicate vessel route. **(a)** 3-D reconstruction of the school. Multibeam SONAR receiving beams are shown at the front of the vessel. Remaining panels show cross sections of density in fish from: **(b)** the horizontal plane, **(c)** the vertical plane along-ships, **(d)** the vertical plane athwart ships. Red cross-hairs indicate location of the other two cross sections (Courtesy Francois Gerlotto, IRD) ▶


fish (and fisheries) ecology [5.101]; (2) detailed internal images of fish schools, providing insights into the organization of fish within a school, for example, indicating the presence of large gaps or vacuoles and areas of higher densities or nuclei (Fig. 5.58b,d) [5.102].

In general, one tries to convert the echo-integration result into a biomass or fish density. This requires the knowledge of the target strength TS or the equivalent backscattering cross section σ of the target under


investigation [5.103]. Several models attempt to develop equations expressing σ/λ^2 as a function of L/λ, where L is the fish length. However, physiological and behavioral differences between species make a more-empirical approach necessary, which often is of the form

$$\text{TS} = 20\log L + b \,, \tag{5.102}$$

where b depends on the acoustic frequency and the fish species. For example, we have $b = -71.3\,\text{dB}$ for herring and $b = -67.4\,\text{dB}$ for cod at 38 kHz, which makes the cod scattering cross section twice that of herring for the same fish length. In situ measurements of TS with fish at sea [5.104,105] or in cages [5.106] have also been attempted to classify fish species acoustically.

Similar works on size distribution assessment have been performed at higher frequency (larger than 500 kHz) on small fish or zooplankton using multi-element arrays [5.107] and wide-band or multi-frequency methods [5.108, 109]. The advantage of combining the acoustic signature of fish at various frequencies is to provide an accurate target sizing. When multi-elements are used, then the position of each individual inside the acoustic beam is known. Using simultaneously multi-element arrays and broadband approaches may also be the key for the unsolved problem of species identification in fisheries acoustics.

In conclusion, SONAR systems and echo integration are now well-established techniques for the measurement of fish abundance. They provide quick results and accurate information about the pelagic fish distribution in the area covered by the ship during the survey. The recent development of multibeam SONAR has improved the reliability of the acoustic results and now provides 3-D information about fish-school size and shape. However, some important sources of error remain when performing echo-integration, among which are:

1. The discrimination between fish echoes and unwanted target echoes
2. The difficulty of adequately sampling a large area in a limited time
3. The problems related to the fish behavior (escaping from the transect line, for example)
4. The physiological parameters that determine the fish target strength.

5.8.2 Marine Mammal Acoustics

In order to put into perspective both the sound levels that mammals emit and hear, we mention an assortment of sounds and noise found in the ocean. Note that the underwater acoustic decibel scale used is, as per the Appendix, relative to 1 µPa. For source levels, one is also referencing the sound level at 1 m. Lightening can be as high has 260 dB and a seafloor volcanic eruption can be as high as 255 dB. Heavy rain increases the background noise by as much as 35 dB in a band from a few hundred Hz to 20 kHz Snapping shrimp individually can have broadband source levels greater than 185 dB while fish choruses can raise ambient noise levels 20 dB in the range of 50–5000 Hz. Of course, the Wenz curves in Fig. 5.15 show a distribution of natural and manmade noise levels whereas specific examples of manmade noise are given in Table 5.3.

Table 5.3 Examples of manmade noise

Ships underway	Broadband source level (dB re 1 µPa at 1 m)
Tug and barge (18 km/hour)	171
Supply ship (example: Kigoriak)	181
Large tanker	186
Icebreaking	193
Seismic survey	**Broadband source level (dB re 1 µPa at 1 m)**
Air-gun array (32 guns)	259 (peak)
Military SONARS	**Broadband source level (dB re 1 µPa at 1 m)**
AN/SQS-53C (US Navy tactical mid-frequency SONAR, center frequencies 2.6 and 3.3 kHz)	235
AN/SQS-56 (US Navy tactical mid-frequency sonar, center frequencies 6.8 to 8.2 kHz)	223
Surveillance Towed Array Sensor System Low Frequency Active (SURTASS-LFA) (100–500 Hz)	215 dB per projector, with up to 18 projectors in a vertical array operating simultaneously
Ocean acoustic studies	**Broadband source level (dB re 1 µPa at 1 m)**
Heard island feasibility test (HIFT) (center frequency 57 Hz)	206 dB for a single projector, with up to 5 projectors in a vertical array operating simultaneously
Acoustic thermometry of ocean climate (ATOC)/North Pacific acoustic laboratory (NPAL) (center frequency 75 Hz)	195
Fig. 5.59a–c Whale spectrogram power spectral density are in units of dB re $1\,\mu Pa^2/Hz$. The blue-whale broadband signals denoted by (a), (b) and (c) are designated *type A calls*. The FM sweeps are *type B calls*. The multiple vertical energy bands between 20 and 30 Hz have the appearance of fin-whale vocalizations (after [5.110])

Marine mammal sounds span the spectrum from $10-200\,000$ kHz. Examples are: blue (see spectrogram in Fig. 5.59) and fin whales in the 20 Hz region with source levels as high as 190 dB, Wedell seals in the $1-10$ kHz region producing 193 dB levels; bottlenose dolphin, 228 dB in a noisy background, sperm whale clicks are the loudest recorded levels at 232 dB. A list of typical levels is shown in Table 5.4. Most of the levels listed are substantial and strongly suggest acoustics as a modality for monitoring marine mammals. Thus, for example, Fig. 5.60 shows the acoustically derived track of a blue whale over 43 days and thousands of kilometers as determined from SOSUS arrays (see Introduction to this chapter) in the Atlantic Ocean.

The issues mostly dealt with in marine mammal acoustics are: understanding the physiology and behavior associated with the production and reception of sounds, and the effects that manmade sounds have on marine mammals from actual physical harm to causing changes in behavior. Physical harm includes actual

Table 5.4 Marine-mammal sound levels

Source	Broadband source level (dB re 1 μPa at 1 m)
Sperm whale clicks	163–223
Beluga whale echo-location click	206–225 (peak to peak)
White-beaked dolphin echo-location clicks	194–219 (peak to peak)
Spinner dolphin pulse bursts	108–115
Bottlenose dolphin whistles	125–173
Fin whale moans	155–186
Blue white moans	155–188
Gray whale moans	142–185
Bowhead whale tonals, moans and song	128–189
Humpback whale song	144–174
Humpback whale fluke and flipper slap	183–192
Southern right whale pulsive call	172–187
Snapping shrimp	183–189 (peak to peak)

Part A | 5.8

is to determine the safe levels of manmade sounds. Acoustics has now become an important research tool in the marine mammal arena [5.111–116].

Tables 5.3 and 5.4 have been taken form University of Rhode web site: http://www.dosits.org/science/ssea/2.htm with references to [5.24, 25, 117].

Advances in the bandwidth and data-storage capabilities of sea-floor autonomous acoustic recording packages (ARPs) have enabled the study of odontocete (toothed-whale) long-term acoustic behavior. Figure 5.61 illustrates one day of broadband (10 Hz–100 kHz) acoustic data collected in the Santa Barbara Channel. The passage of vocalizing dolphins is recorded by the aggregate spectra from their echolocation clicks (> 20 kHz) and whistles (5–15 kHz). Varying proportions of clicks and whistles are seen for

damage (acoustic trauma) and permanent and temporary threshold shifts in hearing. A major ongoing effort
Fig. 5.61 Broadband (10 Hz–100 kHz) acoustic data collected in the Santa Barbara Channel, illustrating spectra from dolphin echolocation clicks (> 20 kHz) and whistles (5–15 kHz) as seen in a daily sonogram (Sept 22, 2005). Passages of individual commercial ships are seen at mid and low frequencies (< 15 kHz) (Courtesy John Hildebrand, Scripps Institution of Oceanography)

each calling bout. These data allow for study of the acoustic behavior under varying conditions (day–night) and for the determination of the seasonal presence of calling animals.

5.A Appendix: Units

The decibel (dB) is the dominant unit in underwater acoustics and denotes a ratio of intensities (not pressures) expressed in terms of a logarithmic (base 10) scale. Two intensities, I_1 and I_2 have a ratio I_1/I_2 in decibels of $10 \log I_1/I_2$ dB. Absolute intensities can therefore be expressed by using a reference intensity. The presently accepted reference intensity in underwater acoustics is based on a reference pressure of one micropascal. Therefore, taking I_2 as the intensity of a plane wave of pressure 1 μPa, a sound wave having an intensity, of, say, one million times that of a plane wave of rms pressure 1 μPa has a level of $10 \log(10^6/1) \equiv 60$ dB re 1 μPa. Pressure (p) ratios are expressed in dB re 1 μPa by taking $20 \log p_1/p_2$, where it is understood that the reference originates from the intensity of a plane wave of pressure equal to 1 μPa.

The average intensity, I, of a plane wave with rms pressure p in a medium of density ρ and sound speed c is $I = p^2/\rho c$. In seawater, $(\rho c)_{\text{water}}$ is 1.5×10^6 Pa sm^{-1} so that a plane wave of rms pressure 1 μPa has an intensity of 6.76×10^{-19} W/m^2.

For reference, we also mention the relevant units in air, where the reference pressure is related, more or less, to the minimum level of sound we can hear is. This is a pressure level 26 dB higher than the water reference. Further, since the intensity level associated with this reference is 10^{-12} W/m^2. Therefore, one should be careful when relating units between water and air, as the latter's reference intensity is higher.

Part B

Physical and Nonlinear Acoustics

Part B Physical and Nonlinear Acoustics

6. Physical Acoustics

Mack A. Breazeale, Michael McPherson

An overview of the fundamental concepts needed for an understanding of physical acoustics is provided. Basic derivations of the acoustic wave equation are presented for both fluids and solids. Fundamental wave concepts are discussed with an emphasis on the acoustic case. Discussions of different experiments and apparatus provide examples of how physical acoustics can be applied and of its diversity. Nonlinear acoustics is also described.

Physical acoustics involves the use of acoustic techniques in the study of physical phenomena as well as the use of other experimental techniques (optical, electronic, etc.) to study acoustic phenomena (including the study of mechanical vibration and wave propagation in solids, liquids, and gasses). The subject is so broad that a single chapter cannot cover the entire subject. For example, recently the 25th volume of a series of books entitled *Physical Acoustics* was published [6.1]. *Mason* [6.2] began the series in 1964. The intermediate volumes are not repetitious, but deal with different aspects of physical acoustics. Even though all of physical acoustics cannot be covered in this chapter, some examples will illustrate the role played by physical acoustics in the development of physics.

Since much of physics involves the use and study of waves, it is useful to begin by mentioning some different types of waves and their properties. The most

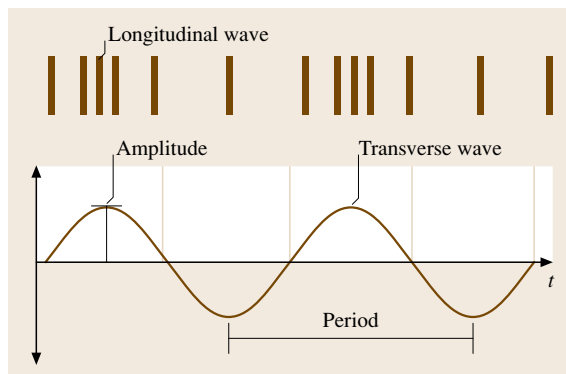
basic definition of a wave is a disturbance that propagates through a medium. A simple analogy can be made with a stack of dominoes that are lined up and knocked over. As the first domino falls into the second, it is knocked over into the third, which is knocked over into the next one, and so on. In this way, the disturbance travels down the entire chain of dominoes (which we may think of as particles in a medium) even though no particular domino has moved very far. Thus, we may consider the motion of an individual domino, or the motion of the disturbance which is traveling down the entire chain of dominoes. This suggests that we define two concepts, the average particle velocity of the individual dominoes and the wave velocity (of the disturbance) down the chain of dominoes. Acoustic waves behave in a similar manner. In physical acoustics it is necessary to distinguish between particle velocity and wave (or phase) velocity.

There are two basic types of waves: longitudinal waves, and transverse waves. These waves are defined according to the direction of the particle motion in the medium relative to the direction in which the wave travels. Longitudinal waves are waves in which the particle motion in the medium is in the same direction as the wave is traveling. Transverse waves are those in which the particle motion in the medium is at a right angle to the direction of wave propagation. Figure 6.1 is a depiction of longitudinal and transverse waves. Another less common type of wave, known as a torsional wave, can also propagate in a medium. Torsional waves are waves in which particles move in a circle in a plane perpendicular to the direction of the wave propagation. Figure 6.2 shows a commonly used apparatus for the demonstration of torsional waves.

There also are more-complicated types of waves that exist in acoustics. For example, surface waves (Rayleigh waves, Scholte–Stonley waves, etc.) can propagate along the boundary between two media. Another example of a more complicated type of wave propagation is that of Lamb waves, which can propagate along thin plates. A familiar example of Lamb waves are the waves that propagate along a flag blowing in a wind.

In acoustics, waves are generally described by the pressure variations that occur in the medium (solid or fluid) due to the wave. As an acoustic wave passes through the medium, it causes the pressure to vary as the acoustic energy causes the distance between the molecules or atoms of the fluid or solid to change periodically. The total pressure is given by

$$p_T(x, t) = p_0(x, t) + p_1(x, t) . \tag{6.1}$$

Here p_0 represents the ambient pressure of the fluid and p_1 represents the pressure fluctuation caused by the acoustic field. Since pressure is defined as the force per unit area, it has units of newtons per square meter (N/m^2). The official SI designation for pressure is the pascal $(1\,Pa = 1\,N/m^2)$. Atmospheric pressure at sea level is 1 atmosphere $(atm) = 1.013 \times 10^5\,Pa$. The types of sounds we encounter cause pressure fluctuations in the range from $10^{-3} - 10\,Pa$.


One can also describe the strength of the sound wave in terms of the energy that it carries. Experimentally, one can measure the power in the acoustic wave, or the amount of energy carried by the wave per unit time. Rather than trying to measure the power at every point in space, it is usual to measure the power only at the location of the detector. So, a more convenient measurement is the power density, also referred to as the acoustic intensity I. In order to make a definition which does not depend on the geometry of the detector, one considers the power density only over an infinitesimal area of size dA

$$I = \frac{dP}{dA} , \tag{6.2}$$

where dP is the portion of the acoustic power that interacts with the area dA *of the detector* oriented perpendicular to the direction of the oncoming acoustic wave. The units of acoustic intensity are watts per square meter (W/m^2).

The human ear can generally perceive sound pressures over the range from about $20\,\mu Pa$ up to about $200\,Pa$ (a very large dynamic range). Because the range of typical acoustic pressures is so large, it is convenient to work with a relative measurement scale rather than an absolute measurement scale. These scales are expressed using logarithms to compress the dynamic range. In acoustics, the scale is defined so that every factor of ten increase in the amount of energy carried by the wave is represented as a change of 1 bel (named after Alexander Graham Bell). However, the bel is often too large to be useful. For this reason, one uses the decibel scale (1/10 of a bel). Therefore, one can write the sound intensity

Fig. 6.1 Longitudinal and transverse waves
Fig. 6.2 Apparatus for the demonstration of torsional waves

level (SIL) as the logarithm of two intensities:

$$\text{SIL}(\text{dB}) = 10 \log \left(\frac{I}{I_{\text{ref}}} \right), \tag{6.3}$$

where I is the intensity of the sound wave and I_{ref} is a reference intensity. (One should note that the bel, or decibel, is not a unit in the typical sense; rather, it is simply an indication of the relative sound level).

In order for scientists and engineers to communicate meaningfully, certain standard reference values have been defined. For the intensity of a sound wave in air, the reference intensity is defined to be $I_{\text{ref}} = 10^{-12} \, \text{W/m}^2$.

In addition to measuring sound intensity levels, it is also common to measure sound pressure levels (SPL). The sound pressure level is defined as

$$\text{SPL}(\text{dB}) = 20 \log \left(\frac{p}{p_{\text{ref}}} \right), \tag{6.4}$$

where p is the acoustic pressure and p_{ref} is a reference pressure. (The factor of 20 comes from the fact that I is proportional to p^2.) For sound in air, the reference pressure is defined as $20 \, \mu\text{Pa}$ ($2 \times 10^{-5} \, \text{Pa}$).

For sound in water, the reference is $1 \, \mu\text{Pa}$ (historically other reference pressures, for example, $20 \, \mu\text{Pa}$ and 0.1 Pa, have been defined). It is important to note that sound pressure levels are meaningful only if the reference value is defined. It should also be noted that this logarithmic method of defining the sound pressure level makes it easy to compare two sound levels. It can be shown that $\text{SPL}_2 - \text{SPL}_1 = 20 \log \left(\frac{p_2}{p_1} \right)$; hence, an SPL difference depends only on the two pressures and not on the choice of reference pressure used.

Since both optical and acoustic phenomena involve wave propagation, it is illustrative to contrast them. Optical waves propagate as transverse waves. Acoustic waves in a fluid are longitudinal; those in a solid can be transverse or longitudinal. Under some conditions, waves may propagate along interfaces between media; such waves are generally referred to as surface waves. Sometimes acoustic surface waves correspond with an optical analogue. However, since the acoustic wavelength is much larger than the optical wavelength, the phenomenon may be much more noticeable in physical acoustics experiments. Many physical processes produce acoustic disturbances directly. For this reason, the study of the acoustic disturbance often gives information about a physical process. The type of acoustic wave should be examined to determine whether an optical model is appropriate.

6.1 Theoretical Overview

6.1.1 Basic Wave Concepts

Although the domino analogy is useful for conveying the idea of how a disturbance can travel through a medium, real waves in physical systems are generally more complicated. Consider a spring or slinky that is stretched along its length. By rapidly compressing the end of the spring, one can send a pulse of energy down the length of the spring. This pulse would essentially be a longitudinal wave pulse traveling down the length of the spring. As the pulse traveled down the length, the material of the spring would compress or *bunch up* in the region of the pulse and *stretch out* on either side of it. The compressed regions are known as condensations and the stretched regions are known as rarefactions.

It is this compression that one could actually witness traveling down the length of the spring. No part of the spring itself would move very far (just as no domino moved very far), but the disturbance would travel down the entire length of the spring. One could also repeatedly drive the end of the spring back and forth (along its length). This would cause several pulses (each creating compressions with stretched regions around them) to propagate along the length of the spring, with the motion of the spring material being along the direction of the propagating disturbance. This would be a multipulse longitudinal wave.

Now, let us consider an example of a transverse wave, with particle motion perpendicular to the direction of propagation. Probably the simplest example is a string with one end fastened to a wall and the opposite end driven at right angles to the direction along which the string lies. This drive sends pulses down the length of the string. The motion of the particles in the string is at right angles to the motion of the disturbance, but the disturbance itself (whether one pulse or several) travels down the length of the string. Thus, one sees a transverse wave traveling down the length of the string.

Any such periodic pulsing of disturbances (whether longitudinal or transverse) can be represented mathematically as a combination of sine and/or cosine waves through a process known as Fourier decomposition. Thus, without loss of generality, one can illustrate ad-
Fig. 6.3 One cycle of a sinusoidal wave traveling to the right

ditional wave concepts by considering a wave whose shape is described mathematically by a sine wave.

Figure 6.3 shows one full cycle of a sinusoidal wave which is moving to the right (as a sine-shaped wave would propagate down a string, for example). The initial wave at $t = 0$ and beginning at $x = 0$ can be described mathematically. Let the wave be traveling along the x-axis direction and let the particle displacement be occurring along the y-axis direction. In general, the profile or shape of the wave is described mathematically as

$$y(x) = A \sin(kx + \varphi) , \tag{6.5}$$

where A represents the maximum displacement of the string (i. e., the particle displacement) in the y-direction and k represents a scaling factor, the wave number. The argument of the sine function in (6.5) is known as the phase. For each value of x, the function $y(x)$ has a unique value, which leads to a specific y value (sometimes called a point of constant phase). The term φ is known as the phase shift because it causes a shifting of the wave profile along the x-axis (forward for a positive phase shift and backward for a negative phase shift). Such a sine function varies between $+A$ and $-A$, and one full cycle of the wave has a length of $\lambda = \frac{2\pi}{k}$. The length λ is known as the wavelength, and the maximum displacement A is known as the wave amplitude.

As this disturbance shape moves toward the right, its position moves some distance $\Delta x = x_f - x_o$ during some time interval Δt, which means the disturbance is traveling with some velocity $c = \frac{\Delta x}{\Delta t}$. Thus, the distance the wave has traveled shows this profile both before and after it has traveled the distance Δx (Fig. 6.3). The traveling wave can be expressed as a function of both position (which determines its profile) and time (which determines the distance it has traveled). The equation

for a traveling wave, then, is given by

$$y(x, t) = A \sin[k(x - ct) + \varphi] , \tag{6.6}$$

where $t = 0$ gives the shape of the wave at $t = 0$ (which here is assumed constant), and $y(x, t)$ gives the shape and position of the wave disturbance as it travels. Again, A represents the amplitude, k represents the wave number, and φ represents the phase shift. Equation (6.6) is applicable for all types of waves (longitudinal, transverse, etc.) traveling in any type of medium (a spring, a string, a fluid, a solid, etc.).

Thus far, we have introduced several important basic wave concepts including wave profile, phase, phase shift, amplitude, wavelength, wave number, and wave velocity. There is one additional basic concept of great importance, the wave frequency. The frequency is defined as the rate at which (the number of times per second) a point of constant phase passes a point in space. The most obvious points of constant phase to consider are the maximum value (crest) or the minimum value (trough) of the wave. One can think of the concept of frequency less rigorously as the number of pulses generated per second by the source causing the wave. The velocity of the wave is the product of the wavelength and the frequency.

One can note that, rather than consisting of just one or a few pulses, (6.6) represents a continually varying wave propagating down some medium. Such waves are known as continuous waves. There is also a type of wave that is a bit between a single pulse and an infinitely continuous wave. A wave that consists of a finite number of cycles is known as a wave packet or a tone burst. When dealing with a tone burst, the concepts of phase velocity and group velocity are much more evident. Generally speaking, the center of the tone burst travels at the phase velocity – the ends travel close to the group velocity.

6.1.2 Properties of Waves

All waves can exhibit the following phenomena: reflection, refraction, interference and diffraction. (Transverse waves can also exhibit a phenomenon known as polarization, which allows oscillation in only one plane.)

Reflection
The easiest way to understand reflection is to consider the simple model of a transverse wave pulse traveling down a taut string that is affixed at the opposite end (as seen in Fig. 6.4. (A pulse is described here for purposes
Fig. 6.4 Reflection of a wave from a fixed boundary

of clarity, but the results described apply to continuous waves as well.) As the pulse reaches the end of the string, the particles start to move upward, but they cannot because the string is fastened to the pole. (This is known as a fixed or rigid boundary.) The pole exerts a force on the particles in the string, which causes the pulse to rebound and travel in the opposite direction. Since the force of the pole on the string in the *y*-direction must be downward (to counteract the upward motion of the particles), there is a 180° phase shift in the wave. This is seen in the figure where the reflected pulse has flipped upside down relative to the incident pulse.

Figure 6.5 shows a different type of boundary from which a wave (or pulse) can reflect; in this case the end of the string is on a massless ring that can slide freely up and down the pole. (This situation is known as a free boundary.) As the wave reaches the ring, it drives
Fig. 6.5 Reflection of a wave from a free boundary

the ring upwards. As the ring moves back down, a reflected wave, which travels in a direction opposite to that of the incoming wave, is also generated. However, there is no 180° phase shift upon reflection from a free boundary.

Acoustic Impedance

Another important wave concept is that of wave impedance, which is usually denoted by the variable Z. When the reflection of the wave is not total, part of the energy in the wave can be reflected and part transmitted. For this reason, it is necessary to consider acoustic waves at an interface between two media and to be able to calculate how much of the energy is reflected and how much is transmitted. The definition of media impedance facilitates this. For acoustic waves, the impedance Z is defined as the ratio of sound pressure to particle velocity. The units for impedance are the Rayl, so named in honor of Lord Rayleigh. 1 Rayl = 1 Pa s/m.

Often one speaks of the *characteristic impedance* of a medium (a fluid or solid); in this case one is referring to the medium in the *open space* condition where there are no obstructions to the wave which would cause the wave to reflect or scatter. The characteristic impedance of a material is usually denoted by Z_0, and it can be determined by the product of the mean density of the medium ρ with the speed of sound in the medium. In air, the characteristic impedance near room temperature is about, 410 Rayl.

The acoustic impedance concept is particularly useful. Consider a sound wave that passes from an initial medium with one impedance into a second medium with a different impedance. The efficiency of the energy transfer from one medium into the next is given by the ratio of the two impedances. If the impedances (ρc) are identical, their ratio will be 1; and all of the acoustic energy will pass from the first medium into the second across the interface between them. If the impedances of the two media are different, some of the energy will be reflected back into the initial medium when the sound field interacts with the interface between the two media. Thus the impedance enables one to characterize the acoustic transmission and reflection at the boundary of the two materials. The difference in Z, which leads to some of the energy being reflected back into the initial medium, is often referred to as the impedance mismatch. When the (usual) acoustic boundary conditions apply and require that the particle velocity and pressure be continuous across the interface between the two media, one can calculate the percentage of the energy that is reflected back into the medium. This is given

in fractional form by the reflection coefficient given by

$$R = \left(\frac{Z_2 - Z_1}{Z_2 + Z_1}\right)^2 , \qquad (6.7)$$

where Z_1 and Z_2 are the impedances of the two media. Since both values of Z must be positive, R must be less than one. The fraction of the energy transmitted into the second medium is given by $T = 1 - R$ because 100% of the energy must be divided between T and R.

Refraction

Refraction is a change of the direction of wave propagation as the wave passes from one medium into another across an interface. Bending occurs when the wave speed is different in the two media. If there is an angle between the normal to the plane of the boundary and the incident wave, there is a brief time interval when part of the wave is in the original medium (traveling at one velocity) and part of the wave is in the second medium (traveling at a different velocity). This causes the bending of the waves as they pass from the first medium to the second. (There is no bending at normal incidence.)

Reflection and refraction can occur simultaneously when a wave impinges on a boundary between two media with different wave propagation speeds. Some of the energy of the wave is reflected back into the original medium, and some of the energy is transmitted and refracted into the second medium. This means that a wave incident on a boundary can generate two waves: a reflected wave and a transmitted wave whose direction of propagation is determined by Snell's law.

All waves obey Snell's law. For optical waves the proper form of Snell's law is:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 , \qquad (6.8)$$

where n_1 and n_2 are the refractive indices and θ_1 and θ_2 are propagation directions. For acoustic waves the proper form of Snell's law is

$$\frac{\sin \theta_1}{v_1} = \frac{\sin \theta_2}{v_2} , \qquad (6.9)$$

where v_1 is the wave velocity in medium 1 and v_2 is the wave velocity in medium 2. These two forms are very similar since the refractive index is $n = c/C_m$, where c is the velocity of light in a vacuum and C_m is the velocity of light in the medium under consideration.

Interference

Spatial Interference. Interference is a phenomenon that occurs when two (or more) waves add together. Consider two identical transverse waves traveling to the right (one after the other) down a string towards a boundary at the end. When the first wave encounters the boundary, it reflects and travels in the leftward direction. When it encounters the second, rightward moving wave the two waves add together linearly (in accordance with the principle of superposition). The displacement amplitude at the point in space where two waves combine is either greater than or less than the displacement amplitude of each wave. If the resultant wave has an amplitude that is smaller than that of either of the original two waves, the two waves are said
Fig. 6.6a,b Two waves passing through each other exhibiting (a) destructive and (b) constructive interference

to have destructively interfered with one another. If the combined wave has an amplitude that is greater than either of its two constituent waves, then the two waves are said to have constructively interfered with each other. The maximum possible displacement of the combination is the sum of the maximum possible displacements of the two waves (complete constructive interference); the minimum possible displacement is zero (complete destructive interference for waves of equal amplitude). It is important to note that the waves interfere only as they pass through one another. Figure 6.6 shows the two special cases of complete destructive and complete constructive interference (for clarity only a portion of the wave is drawn).

If a periodic wave is sent down the string and meets a returning periodic wave traveling in the opposite direction, the two waves interfere. This results in wave superposition, i. e., the resulting amplitude at any point and time is the sum of the amplitudes of the two waves. If the returning wave is inverted (due to a fixed boundary reflection) and if the length of the string is an integral multiple of the half-wavelength corresponding to the drive frequency, conditions for resonance are sat-

isfied. This resonance produces a standing wave. An example of a standing wave is shown in Fig. 6.7. The points of maximum displacement are known as the standing-wave antinodes. The points of zero displacement are known as the standing-wave nodes.

Resonance Behavior. Every vibrating system has some characteristic frequency that allows the vibration amplitude to reach a maximum. This characteristic frequency is determined by the physical parameters (such as the geometry) of the system. The frequency that causes maximum amplitude of vibration is known as the resonant frequency, and a system driven at its resonant frequency is said to be in resonance. Standing waves are simply one type of resonance behavior.

Longitudinal acoustic waves can also exhibit resonance behavior. When the distance between a sound emitter and a reflector is an integer number of half wavelengths, the waves interfere and produce standing waves. This interference can be observed optically, acousticly or electronically. By observing a large number of standing waves one can obtain an accurate value of the wavelength, and hence an accurate value of the wave velocity.

One of the simplest techniques for observing acoustic resonances in water, or any other transparent liquid, is to illuminate the resonance chamber, then to focus a microscope on it. The microscope field of view images the nodal lines that are spaced half an acoustic wavelength apart. A screw that moves the microscope perpendicular to the lines allows one to make very accurate wavelength measurements, and hence accurate sound velocity measurements.

Temporal Interference. So far we have considered the interference of two waves that are combining in space (this is referred to as spatial interference). It is also possible for two waves to interfere because of a difference in frequency (which is referred to as temporal interference). One interesting example of this is the phenomenon of wave beating.

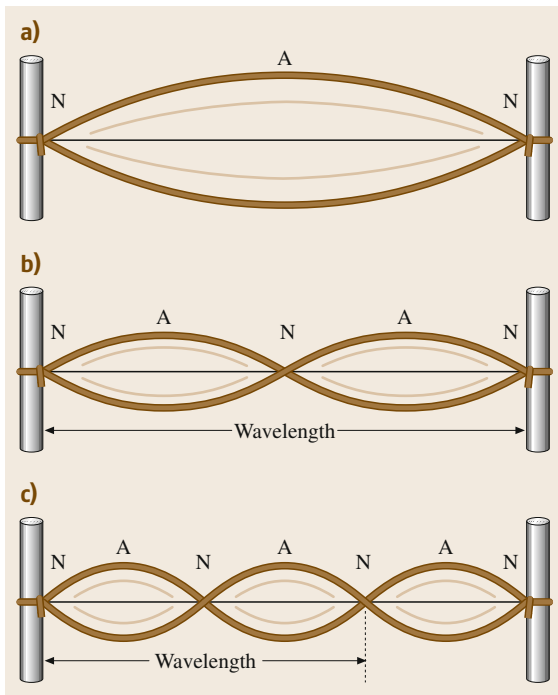
Consider two sinusoidal acoustic waves with slightly different frequencies that arrive at the same point in space. Without loss of generality, we can assume that these two waves have the same amplitude. The superposition principle informs us that the resultant pressure caused by the two waves is the sum of the pressure caused by each wave individually. Thus, we have for the total pressure


Fig. 6.7a–c Standing waves in a string with nodes and antinodes indicated. (**a**) The fundamental; (**b**) the second harmonic; (**c**) the third harmonic

$$p_{\mathrm{T}}(t) = A\left[\cos\left(\omega_1 t\right) + \cos\left(\omega_2 t\right)\right]. \tag{6.10}$$

By making use of a standard trigonometric identity, this can be rewritten as

$$p_T(t) = 2A \cos\left(\frac{(\omega_1 - \omega_2)}{2}t\right)\cos\left(\frac{(\omega_1 + \omega_2)}{2}t\right).$$

(6.11)

Since the difference in frequencies is small, the two waves can be in phase, causing constructive interference and reinforcing one another. Over some period of time, the frequency difference causes the two waves to go out of phase, causing destructive interference (when $\omega_1 t$ eventually leads $\omega_2 t$ by 180°). Eventually, the waves are again in phase and, they constructively interfere again. The amplitude of the combination will rise and fall in a periodic fashion. This phenomenon is known as the beating of the two waves. This beating phenomenon can be described as a separate wave with an amplitude that is slowly varying according to

$$p(t) = A_0(t)\cos(\omega_{avg}t)$$

(6.12)

where

$$A_0(t) = 2A \cos\left(\frac{\omega_1 - \omega_2}{2}t\right)$$

(6.13)

and

$$\omega_{avg} = \frac{(\omega_1 + \omega_2)}{2}.$$

(6.14)

The cosine in the expression for $A_0(t)$ varies between positive and negative 1, giving the largest amplitude in each case. The period of oscillation of this amplitude variation is given by

$$T_b = \frac{2\pi}{\omega_1 - \omega_2} = \frac{2\pi}{\omega_b} = \frac{1}{f_b}.$$

(6.15)

The frequency f_b of the amplitude variation is known as the beat frequency. Figure 6.8 shows the superposition of two waves that have two frequencies that are different but close together. The beat frequency corresponds to the difference between the two frequencies that are beating.

The phenomenon of beating is often exploited by musicians in tuning their instruments. By using a reference (such as a 440 Hz tuning fork that corresponds to the A above middle C) one can check the tuning of the instrument. If the A above middle C on the instrument is out of tune by 2 Hz, the sounds from the tuning fork and the note generate a 2 Hz beating sound when they are played together. The instrument is then tuned until the beating sound vanishes. Then the frequency of the instrument is the same as that of the tuning fork. Once the A is in tune, the other notes can be tuned relative to
Fig. 6.8 The beating of two waves with slightly different frequencies

the A by counting the beats per unit time when different notes are played in various combinations.

Multi-frequency Sound

When sound consists of many frequencies (not necessarily all close together), one needs a means of characterizing the sound level. One may use a weighted average of the sound over all the frequencies present, or one may use information about how much energy is distributed over a particular range of frequencies. A selected range of frequencies is known as a frequency band. By means of filters (either acoustic or electrical, depending on the application) one can isolate the various frequency bands across the entire frequency spectrum. One can then talk of the acoustic pressure due to a particular frequency band. The *band pressure level* (PL) is given by

$$PL_{band} = 20 \log_{10}\left(\frac{p_{band}}{p_{ref}}\right)$$

(6.16)

where p_{band} is the room-mean-square (rms) average pressure of the sound in the frequency band range and p_{ref} is the standard reference for sound in air, 20 μPa. The average of the pressures of the frequency bands over the complete spectrum is the average acoustic signal. However, the presence of multiple frequencies complicates the situation: one does not simply add the frequency band pressures or the band pressure levels. Instead, it is the p^2 values which must be summed

$$p_{rms}^2 = \sum p_{band}^2$$

(6.17)

or

$$\text{SPL} = 10 \log_{10} \left(\frac{p_{\text{rms}}^2}{p_{\text{ref}}^2} \right) = 10 \log_{10} \sum \left(\frac{p_{\text{band}}}{p_{\text{ref}}} \right)^2 \tag{6.18}$$

or, simplifying further

$$\text{SPL} = 10 \log_{10} \sum (10)^{(\text{PL}_{\text{band}}/10)} \; . \tag{6.19}$$

The octave is a common choice for the width of a frequency band. With a one-octave filter, only frequencies up to twice the lowest frequency of the filter are allowed to pass. One should also note that, when an octave band filter is labeled with its center frequency, this is determined by the geometric mean (not the arithmetic mean), i. e.,

$$f_{\text{center}} = \sqrt{f_{\text{low}} f_{\text{high}}} = \sqrt{2 f_{\text{low}}^2} = \sqrt{2} f_{\text{low}} \; . \tag{6.20}$$

Coherent Signals

Two signals are coherent if there is a fixed relative phase relation between them. Two loudspeakers driven by the same source would be coherent. However, two loudspeakers being driven by two compact-disc (CD) players (even if each player was playing a copy of the same CD) would not be coherent because there is no connection causing a constant phase relationship. For two incoherent sources, the total pressure is

$$p_{\text{tot}}^2 = \left(p_{1(\text{rms})} + p_{2(\text{rms})} \right)^2 = p_{1(\text{rms})}^2 + p_{2(\text{rms})}^2 \tag{6.21}$$

(where the $2 p_{1(\text{rms})} p_{2(\text{rms})}$ term has averaged out to zero). For coherent sources, however, the fixed phase relationship allows for the possibility of destructive or constructive interference. Therefore, the signal can vary in amplitude between $(p_{1(\text{rms})} + p_{2(\text{rms})})^2$ and $(p_{1(\text{rms})} - p_{2(\text{rms})})^2$.

Diffraction

In optics it is usual to begin a discussion of diffraction by pointing out grating effects. In acoustics one seldom encounters grating effects. Instead, one encounters changes in wave direction of propagation resulting from diffraction. Thus, in acoustics it is necessary to begin on a more fundamental level.

The phenomenon of diffraction is the bending of a wave around an edge. The amount of bending that occurs depends on the relative size of the wavelength compared to the size of the edge (or aperture) with which it interacts. When considering refraction or reflection it is often convenient to model the waves by drawing a single ray in the direction of the wave's propagation. However, the ray approach does not provide a means to model the bending caused by diffraction. The bending of a wave by diffraction is the result of wave interference. The more accurate approach, then, is to determine the magnitude of each wave that is contributing to the diffraction and to determine how it is interfering with other waves to cause the diffraction effect observed.

It is useful to note that diffraction effects can depend on the shape of the wavefronts that encounter the edge around which the diffraction is occurring. Near the source the waves can have a very strong curvature relative to the wavelength. Far enough from the source the curvature diminishes significantly (creating essentially plane waves). Fresnel diffraction occurs when curved wavefronts interact. Fraunhofer diffraction occurs when planar wavefronts interact. In acoustics these two regions are known as the near field (the Fresnel zone) and the far field (the Fraunhofer zone), respectively. In optics these two zones are distinguished by regions in which two different integral approximations are valid.

6.1.3 Wave Propagation in Fluids

The propagation of an acoustic wave is described mathematically by the acoustic wave equation. One can use the approach of continuum mechanics to derive equations appropriate to physical acoustics [6.3]. In the continuum approach one postulates fields of density, stress, velocity, etc., all of which must satisfy basic conservation laws. In addition, there are constitutive relations which characterize the medium. For illustration, acoustic propagation through a compressible fluid medium is considered first. As the acoustic disturbance passes through a small area of the medium, the density of the medium at that location fluctuates. As the crest of the acoustic pressure wave passes through the region, the density in that region increases; this compression is known as the acoustic condensation. Conversely, when the trough of the acoustic wave passes through the region, the density of the medium at that location decreases; this expansion is known as the acoustic rarefaction.

In a gas, the constitutive relationship needed to characterize the pressure fluctuations is the ideal gas equation of state, $PV = nRT$, where P is the pressure of the gas, V is the volume of the gas, n is the number of moles of the gas, R is the universal gas constant ($R = 8.3145 \, \text{J/mol K}$), and T is the temperature of the gas. In

a given, small volume of the gas, there is a variation of the density ρ from its equilibrium value ρ_0 caused by the change in pressure $\Delta P = P - P_0$ as the disturbance passes through that volume. (Here P is the pressure at any instant in time and P_0 is the equilibrium pressure.)

In many situations, there are further constraints on the system which simplify the constitutive relationship. A gas may act as a heat reservoir. If the processes occur on a time scale that allows heat to be exchanged, the gas is maintained at a constant temperature. In this case, the constitutive relationship can be simplified and expressed as $P_0 V_0 = PV = $ a constant. Since the number of gas molecules (and hence the mass) is constant, we can express this as the isothermal condition

$$\frac{P}{P_0} = \frac{\rho}{\rho_0} , \tag{6.22}$$

which relates the instantaneous pressure to the equilibrium pressure.

Most acoustic processes occur with no exchange of heat energy between adjacent volumes of the gas. Such processes are known as adiabatic or isentropic processes. Under such conditions, the constitutive relation is modified according to the adiabatic condition. For the adiabatic compression of an ideal gas, it has been found that the relationship

$$PV^\gamma = P_0 V_0^\gamma \tag{6.23}$$

holds, where γ is the ratio of the specific heat of the gas at constant pressure to the specific heat at constant volume. This leads to an adiabatic constraint for the acoustic process given by

$$\frac{P}{P_0} = \left(\frac{\rho}{\rho_0} \right)^\gamma . \tag{6.24}$$

When dealing with a real gas, one can make use of a Taylor expansion of the pressure variations caused by the fluctuations in density

$$P = P_0 + \left[\frac{\partial P}{\partial \rho} \right]_{\rho_0} (\Delta \rho)$$
$$+ \frac{1}{2} \left[\frac{\partial^2 P}{\partial \rho^2} \right]_{\rho_0} (\Delta \rho)^2 + \dots , \tag{6.25}$$

where

$$\Delta \rho = (\rho - \rho_0) . \tag{6.26}$$

When the fluctuations in density are small, only the first-order terms in $\Delta \rho$ are nonnegligible. In this case, one can rearrange the above equation as

$$\Delta P = P - P_0 = \left[\frac{\partial p}{\partial \rho} \right]_{\rho_0} \Delta \rho = B \frac{\Delta \rho}{\rho_0} , \tag{6.27}$$

where $B = \rho_0 \left[\frac{\partial p}{\partial \rho} \right]_{\rho_0}$ is the adiabatic bulk modulus of the gas. This equation describes the relationship between the pressure of the gas and its density during an expansion or contraction. (When the fluctuations are not small one has finite-amplitude (or nonlinear) effects which are considered later.)

Let us now consider the physical motion of a fluid as the acoustic wave passes through it. We begin with an infinitesimal volume element dV that is fixed in space, and we consider the motion of the particles as they pass through this region. Since mass is conserved, the net flux of mass entering or leaving this fixed volume must correspond to a change in the density of the fluid contained within that volume. This is expressed through the continuity equation,

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \boldsymbol{u}) . \tag{6.28}$$

The rate of mass change in the region is

$$\frac{\partial \rho}{\partial t} \, dV , \tag{6.29}$$

and the net influx of mass into this region is given by

$$-\nabla \cdot (\rho \boldsymbol{u}) \, dV . \tag{6.30}$$

Consider a volume element of fluid as it moves with the fluid. This dV of fluid contains some infinitesimal amount of mass, dm. The net force acting on this small mass of fluid is given by Newton's second law, $d\boldsymbol{F} = \boldsymbol{a} \, dm$. It can be shown that Newton's second law leads to a relationship between the particle velocity and the acoustic pressure. This relationship, given by

$$\rho_0 \frac{\partial \boldsymbol{u}}{\partial t} = -\nabla p , \tag{6.31}$$

is known as the linear Euler equation.

By combining our adiabatic pressure condition with the continuity equation and the linear Euler equation, one can derive the acoustic wave equation. This equation takes the form

$$\nabla^2 p = \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} , \tag{6.32}$$

where c is the speed of the sound wave which is given by

$$c = \sqrt{B/\rho_0} . \tag{6.33}$$

6.1.4 Wave Propagation in Solids

Similarly, one can consider the transmission of an acoustic wave through a solid medium. As an example, consider the one-dimensional case for propagation of an acoustic wave through a long bar of length L and cross-sectional area S. In place of the pressure, we consider the stress applied to the medium, which is given by the relationship

$$\sigma = F/S \tag{6.34}$$

where σ is the stress, F is the force applied along the length (L) of the bar, and S is the cross sectional area of the bar.

A stress applied to a material causes a resultant compression or expansion of the material. This response is the strain ζ. Strain is defined by the relationship,

$$\zeta = \Delta L/L_{\text{o}} , \tag{6.35}$$

where ΔL is the change in length of the bar, and L_{o} is the original length of the bar.

Let us consider the actual motion of particles as an acoustic wave passes through some small length of the bar $\mathrm{d}x$. This acoustic wave causes both a stress and a strain. The Hooke's law approximation, which can be used for most materials and vibration amplitudes, provides the constitutive relationship that relates the stress applied to the material with the resulting strain. Hooke's law states that stress is proportional to strain, or

$$\sigma = -Y\zeta . \tag{6.36}$$

If we consider the strain over our small length $\mathrm{d}x$, we can write this as

$$\frac{F}{S} = -Y\left(\frac{\mathrm{d}L}{\mathrm{d}x}\right) \tag{6.37}$$

or

$$F = -YS\left(\frac{\mathrm{d}L}{\mathrm{d}x}\right) . \tag{6.38}$$

The net force acting on our segment $\mathrm{d}x$ is given by

$$\mathrm{d}F = -\left(\frac{\partial F}{\partial x}\right)\mathrm{d}x = YS\left(\frac{\partial^2 L}{\partial x^2}\right)\mathrm{d}x . \tag{6.39}$$

Again, we can make use of Newton's second law, $\boldsymbol{F} = m\boldsymbol{a}$, and express this force in terms of the mass and acceleration of our segment. The mass of the segment of length $\mathrm{d}x$ is simply the density times the volume, or $\mathrm{d}m = \rho\,\mathrm{d}V = \rho S\,\mathrm{d}x$. Thus,

$$\mathrm{d}F = \left(\frac{\partial^2 L}{\mathrm{d}t^2}\right)\mathrm{d}m = \rho S\left(\frac{\partial^2 L}{\mathrm{d}t^2}\right)\mathrm{d}x , \tag{6.40}$$

where $\frac{\partial^2 L}{\mathrm{d}t^2}$ is the acceleration of the particles along the length $\mathrm{d}x$ as the acoustic wave stresses it. Equating our two expressions for the net force acting on our segment, $\mathrm{d}F$,

$$\frac{\partial^2 L}{\partial x^2} = \frac{1}{c^2}\left(\frac{\partial^2 L}{\partial t^2}\right) , \tag{6.41}$$

where

$$c = \sqrt{Y/\rho} \tag{6.42}$$

is the speed at which the acoustic wave is traveling through the bar. The form of the equation for the propagation of an acoustic wave through a solid medium is very similar to that for the propagation of an acoustic wave through a fluid.

Both of the wave equations developed so far have implicitly considered longitudinal compressions; for example, the derivation of the wave equation for an acoustic wave traveling down a thin bar assumed no transverse components to the motion. However, if we consider transverse motion, the resulting wave equation is of the same form as that for longitudinal waves. For longitudinal waves, the solution to the wave equation is given by

$$L(x, t) = A\cos(\omega t \pm kx + \phi)\ (\text{longitudinal}) , \tag{6.43}$$

where $L(x, t)$ represents the amount of compression or rarefaction at some position x and time t. For transverse waves, the solution to the wave equation is given by

$$y(x, t) = A\cos(\omega t \pm kx + \phi)\ (\text{transverse}) , \tag{6.44}$$

where $y(x, t)$ represents the vibration orthogonal to the direction of wave motion as a function of x and t. In both cases, A is the vibration amplitude, $k = 2\pi/\lambda$ is the wave number, and ϕ is the phase shift (which depends on the initial conditions of the system).

One can also consider an acoustic disturbance traveling in two dimensions; let us first consider a thin,
Fig. 6.9 Definitions necessary for the representation of a two-dimensional wave

stretched membrane as seen in Fig. 6.9. Let σ_s be the areal surface density (with units of kg/m^2), and let Γ be the tension per unit length. The transverse displacement of an infinitesimally small area of the membrane dS will now be a function of the spatial coordinates x and y along the two dimensions and the time t. Let us define the infinitesimal area $dS = dx\,dy$ and the displacement of dS as the acoustic disturbance passes through it to be $u(x, y, t)$. Newton's second law can now be applied to our areal element dS

$$
\begin{aligned}
&\left[(\Gamma\partial u/\partial x)_{x+dx,y} - (\Gamma\partial u/\partial y)_{x,y}\right]dy \\
&+ \left[(\Gamma\partial u/\partial y)_{x,y+dy} - (\Gamma\partial u/\partial x)_{x,y}\right]dx \\
&= \Gamma\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right)dx\,dy
\end{aligned}
\tag{6.45}
$$

and

$$
\Gamma\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right)dx\,dy = \sigma_s\frac{\partial^2 u}{\partial t^2}dx\,dy
\tag{6.46}
$$

or

$$
\nabla^2 u = \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) = \frac{1}{c^2}\frac{\partial^2 u}{\partial t^2},
\tag{6.47}
$$

where $c = \sqrt{\Gamma/\sigma_s}$ is the speed of the acoustic wave in the membrane. Equation (6.47) now describes a two-dimensional wave propagating along a membrane.

The extension of this idea to three dimensions is fairly straightforward. As an acoustic wave passes through a three-dimensional medium, it can cause pressure fluctuations (leading to a volume change) in all three dimensions. The displacement u is now a function four variables $u = u(x, y, z, t)$. The volume change of a cube is given by

$$
\Delta V = \Delta x\Delta y\Delta z\left(1 + \frac{\partial u}{\partial x}\right)\left(1 + \frac{\partial u}{\partial y}\right)\left(1 + \frac{\partial u}{\partial z}\right),
\tag{6.48}
$$

$$
\Delta V \approx \Delta x\Delta y\Delta z\left(1 + \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} + \frac{\partial u}{\partial z}\right),
\tag{6.49}
$$

where the higher-order cross terms are negligibly small and have been dropped. This can be rewritten as

$$
\Delta V = \Delta x\Delta y\Delta z\left(1 + \nabla\cdot\boldsymbol{u}\right).
\tag{6.50}
$$

If the mass is held constant, and only the volume changes, the density change is given by

$$
\rho_0 + \rho_1 = \frac{\rho_0}{1 + \nabla\cdot\boldsymbol{u}}.
\tag{6.51}
$$

But since the denominator is very close to unity, we may rewrite this using the binomial expansion. Solving for ρ_1 we have

$$
\rho_1 \approx -\rho_0\nabla\cdot\boldsymbol{u}.
\tag{6.52}
$$

Again we can consider Newton's second law; without loss of generality, consider the force exerted along the x-direction from the pressure due to the acoustic wave, which is given by

$$
F_x = \left[p(x, t) - p(x + \Delta x, t)\right]\Delta y\Delta z,
\tag{6.53}
$$

where $\Delta y\Delta z$ is the infinitesimal area upon which the pressure exerts a force. We can rewrite this as

$$
F_x = -\Delta y\Delta z\left[\left(\frac{\partial p}{\partial x}\right)\Delta x\right],
\tag{6.54}
$$

where the results for F_y and F_z are similar. Combining these, we can express the total force vector as

$$
\boldsymbol{F} = -\nabla p\Delta x\Delta y\Delta z.
\tag{6.55}
$$

Using the fact that the mass can be expressed in terms of the density, we can rewrite this as

$$
-\nabla p = \rho_0\frac{\partial^2\boldsymbol{u}}{\partial t^2}.
\tag{6.56}
$$

As in the case with fluids, we need a constitutive relationship to finalize the expression. For most situations in solids, the adiabatic conditions apply and the pressure fluctuation is a function of the density only. Making use of a Taylor expansion, we have

$$
p \approx p(\rho_0) + (\rho - \rho_0)\frac{dp}{d\rho}
\tag{6.57}
$$

but since $p = p_0 + p_1$, we can note that

$$
p_1 = \rho_1\frac{\partial p}{\partial\rho}.
\tag{6.58}
$$

Using (6.52), we can eliminate ρ_1 from (6.58) to yield

$$
p_1 = -\rho_0\left(\frac{dp}{d\rho}\right)\nabla\cdot\boldsymbol{u}.
\tag{6.59}
$$

We can eliminate the divergence of the displacement vector from this equation by taking the divergence of (6.56) and the second time derivative of (6.59). This gives two expressions that both equal $-\rho_0\partial^2\left(\nabla\cdot\boldsymbol{u}\right)/dt^2$ and thus are equal to each other. From this we can determine the full form of our wave equation

$$
\frac{\partial^2 p_1}{\partial t^2} = c^2\nabla^2 p_1,
\tag{6.60}
$$

where c is again the wave speed and is given by

$$c^2 = \frac{dp}{d\rho} . \tag{6.61}$$

It should be noted that the above considerations were for an isotropic solid. In a crystalline medium, other complications can arise. These will be noted in a subsequent section.

6.1.5 Attenuation

In a real physical system, there are mechanisms by which energy is dissipated. In a gas, the dissipation comes from thermal and viscous effects. In a solid, dissipation comes from interactions with dislocations in the solid (holes, displaced atoms, interstitial atoms of other materials, etc.) and grain boundaries between adjacent parts of the solid, In practice, loss of energy over one acoustic cycle is negligible. However, as sound travels over a longer path, one expects these energy losses to cause a significant decrease in amplitude. In some situations, these dissipation effects must be accounted for in the solution of the wave equation.

The solution of the wave equation can be written in exponential form,

$$A = A_0 \, e^{i(k'x - \omega t)} . \tag{6.62}$$

If one wishes to account for dissipation effects, one can assume that the wave number k' has an imaginary component, i. e.

$$k' = k + i\alpha , \tag{6.63}$$

where k and α are both real and $i = \sqrt{-1}$. Using this value of k' for the new wave number we have

$$A = A_0 \, e^{i(k'x - \omega t)} = A_0 \, e^{i[(k + i\alpha)x - \omega t]} . \tag{6.64}$$

Simplifying, one has

$$A = A_0 \, e^{i(kx - \omega t) + i^2 \alpha x} = A_0 \, e^{i(kx - \omega t) - \alpha x}$$
$$= A_0 \, e^{-\alpha x} \, e^{i(kx - \omega t)} , \tag{6.65}$$

where α is known as the absorption coefficient. The resulting equation is modulated by a decreasing exponential function; i. e., an undriven acoustic wave passing through a lossy medium is damped to zero amplitude as $x \to \infty$.

6.2 Applications of Physical Acoustics

There are several interesting phenomena associated with the application of physical acoustics. The first is the wave velocity itself. Table 6.1 shows the wave velocity of sound in various fluids (both gases and liquids). Table 6.2 shows the wave velocity of sound in various solids (both metals and nonmetals). The velocity increases as one goes from gases to liquids to solids. The velocity variation from gases to liquids comes from the fact that gas molecules must travel farther before striking another gas molecule. In a liquid, molecules are closer together, which means that sound travels faster.

The change from liquids to solids is associated with increase of binding strength as one goes from liquid to solid. The rigidity of a solid leads to higher sound velocity than is found in liquids.

6.2.1 Crystalline Elastic Constants

Another application of physical acoustics involves the measurement of the crystalline elastic constants in a lattice. In Sect. 6.1.2, we considered the propagation of an acoustic field along a one-dimensional solid (in which

Table 6.1 Typical values of the sound velocity in fluids ($25\,^\circ$C)

Gas	Velocity (m/s)	Liquid	Velocity (m/s)
Air	331	Carbon tetrachloride (CCl_4)	929
Carbon dioxide (CO_2)	259	Ethanol (C_2H_6O)	1207
Hydrogen (H_2)	1284	Ethylene glycol ($C_2H_6O_2$)	1658

Nylon	2620	1070

the internal structure of the solid played no role in the propagation of the wave). Real solids exist in three dimensions, and the acoustic field propagation depends on the internal structure of the material. The nature of the forces between the atoms (or molecules) that make up the lattice cause the speed of sound to be different along different directions of propagation (since the elastic force constants are different along the different directions). The measurement of crystal elastic constants depends on the ability to make an accurate determination of the wave velocity in different directions in a crystalline lattice. This can be done by cutting (or lapping) crystals in such a manner that parallel faces are in the directions to be measured.

For an isotropic solid one can determine the compressional modulus and the shear modulus from a single sample since both compressional and shear waves can be excited. For cubic crystals at least two orientations are required since there are three elastic constants (and still only two waves to be excited). For other crystalline symmetries a greater number of measurements is required.

6.2.2 Resonant Ultrasound Spectroscopy (RUS)

Recently a new technique for measuring crystalline elastic constants, known as resonant ultrasound spectroscopy (RUS), has been developed [6.4]. Typically, one uses a very small sample with a shape that has known acoustic resonant modes (usually a small parallelepiped, though sometimes other geometries such as

cylinders are used). The sample is placed so that the driving transducer makes a minimal contact with the surface of the sample (the boundaries of the sample must be pressure-free and (shearing) traction-free for the technique to work). Figure 6.10 shows a photograph of a small parallelepiped sample mounted in an RUS apparatus.

After the sample is mounted, the transducer is swept through a range of frequencies (usually from a few hertz to a few kilohertz) and the response of the material is
Fig. 6.10 Sample mounted for an RUS measurement. Sample dimensions are 2.0 mm × 2.5 mm × 3.0 mm

measured. Some resonances are caused by the geometry of the sample (just as a string of fixed length has certain resonant frequencies determined by the length of the string). In the RUS technique, some fairly sophisticated software eliminates the geometrical resonances; the remaining resonances are resonances of the internal lattice structure of the material. These resonances are determined by the elastic constants. The RUS technique, then, is used to evaluate all elastic constants from a single sample from the spectrum of resonant frequencies produced by the various internal resonances.

Measurement of Attenuation with the RUS Technique

The RUS technique is also useful for measuring the attenuation coefficients of solid materials. The resonance curves generated by the RUS experiment are plots of the response amplitude of the solid as a function of input frequency (for a constant input amplitude). Every resonance curve has a parameter known as the Q of the system. The Q value can be related to the maximum amplitude $1/e$ value, which in turn can be related to the attenuation coefficient. Thus, the resonance curves generated by the RUS experiment can be used to determine the attenuation in the material at various frequencies.

6.2.3 Measurement Of Attenuation (Classical Approach)

Measurement of attenuation at audible frequencies and below is very difficult. Attenuation is usually measured at ultrasonic frequencies since the plane-wave approximation can be satisfied. The traditional means of measuring the acoustic attenuation requires the measurement of the echo train of an acoustic tone burst as it travels through the medium. Sound travels down the length of the sample, reflects from the opposite boundary and returns to its origin. During each round trip, it travels a distance twice the length of the sample. The transducer used to emit the sound now acts as a receiver and measures the amplitude as it strikes the initial surface. The sound then continues to reflect back and forth through the sample. On each subsequent round trip, the sound amplitude is diminished.

Measured amplitude values are then fit to an exponential curve, and the value of the absorption coefficient is determined from this fit. Actually, this experimental arrangement measures the insertion loss of the system, the losses associated with the transducer and the adhesive used to bond the transducer to the sample as well as the attenuation of sound in the sample. However,

the values of the insertion loss of the system and the attenuation inside the sample are usually very close to each other. If one needs the true attenuation in the sam-
Fig. 6.11 (a) Fine rice on a plate; **(b)** as the plate is excited acoustically the rice begins to migrate to the nodes; **(c)** the Chladni pattern has formed

ple, one can use various combinations of transducers to account for the other losses in the system [6.5].

Losses in a sample can come from a number of sources: viscosity, thermal conductivity, and molecular relaxation. Viscosity and thermal conductivity are usually referred to as classical losses. They can be calculated readily. Both are linearly dependent on frequency. Relaxation is a frequency-dependent phenomenon. The maximum value occurs when the sound frequency is the same as the relaxation frequency, which is determined by the characteristics of the medium. Because of this complication, determination of the attenuation to be expected can be difficult.

6.2.4 Acoustic Levitation

Acoustic levitation involves the use of acoustic vibrations to move objects from one place to the other, or to keep them fixed in space. Chladni produced an early form of acoustic levitation to locate the nodal planes in a vibrating plate. Chladni discovered that small particles on a plate were moved to the nodal planes by plate vibrations. An example of Chladni figures is shown in Fig. 6.11. Plate vibrations have caused powder to migrate toward nodal planes, making them much more obvious.

The use of radiation pressure to counterbalance gravity (or buoyancy) has recently led to a number of situations in which levitation is in evidence.

1. The force exerted on a small object by radiation pressure can be used to counterbalance the pull of gravity [6.6].
2. The radiation force exerted on a bubble in water by a stationary ultrasonic wave has been used to counteract the hydrostatic or buoyancy force on the bubble. This balance of forces makes it possible for the bubble to remain at the same point indefinitely. Single-bubble sonoluminescence studies are now possible [6.7].
3. Latex particles having a diameter of 270 μm or clusters of frog eggs can be trapped in a potential well generated by oppositely directed focused ultrasonic beams. This makes it possible to move the trapped objects at will. Such a system has been called *acoustic tweezers* by *Wu* [6.8].

6.2.5 Sonoluminescence

Sonoluminescence is the conversion of high-intensity acoustic energy into light. Sonoluminescence was first discovered in water in the early 1930s [6.9, 10]. However, interest in the phenomenon languished for several decades.

In the late seventies, a new type of sonoluminescence was found to occur in solids [6.11, 12]. This can occur when high-intensity Lamb waves are generated along a thin plate of ferroelectric material which is driven at the frequency of mechanical resonance in a partial vacuum (the phenomenon occurs at about 0.1 atm). The acoustic fields interact with dislocations and defects in the solid which leads to the generation of visible light in ferroelectric materials. Figure 6.12 shows a diagram of the experimental setup and a photograph of the light emitted during the excitation of solid-state sonoluminescence.

In the early 1990s, sonoluminescence emissions from the oscillations of a single bubble in water were discovered [6.7]. With single-bubble sonoluminescence, a single bubble is placed in a container of degassed water (often injected by a syringe). Sound is used to push the bubble to the center of the container and to set the bubble into high-amplitude oscillation. The dynamic range
Fig. 6.12 (a) Block diagram of apparatus for solid-state sonoluminescence and **(b)** photograph of light emitted from a small, thin plate of LiNbO$_3$

for the bubble radius through an oscillation can be as great as $50\,\mu m$ to $5\,\mu m$ through one oscillation [6.13–15]. The light is emitted as the bubble goes through its minimum radius. Typically, one requires high-amplitude sound corresponding to a sound pressure level in excess of $110\,dB$. The frequency of sound needed to drive the bubble into sonoluminescence is in excess of $30\,kHz$, which is just beyond the range of human hearing.

Another peculiar feature of the sonoluminescence phenomenon is the regularity of the light emissions. Rather than shining continuously, the light is emitted as a series of extremely regular periodic flashes. This was not realized in the initial sonoluminescence experiments, because the rate at which the flashes appear requires a frequency resolution available only in the best detectors. The duration of the pulses is less than $50\,ps$. The interval between pulses is roughly $35\,\mu s$. The time between flashes varies by less than $40\,ps$.

The discovery of single-bubble sonoluminescence has caused a resurgence of interest in the phenomenon. The light emitted appears to be centered in the near-ultraviolet and is apparently black body in nature (unfortunately water absorbs much of the higher-frequency light, so a complete characterization of the spectrum is difficult to achieve). Adiabatic compression of the bubble through its oscillation would suggest temperatures of about $10\,000\,K$ (with pressures of about $10\,000\,atm$). The temperatures corresponding to the observed spectra are in excess of $70\,000\,K$ [6.13]. In fact, they may even be much higher.

Since the measured spectrum suggests that the actual temperatures and pressures within the bubble may be quite high, simple compression does not seem to be an adequate model for the phenomenon. It is possible that the collapsing bubble induces a spherically symmetric shockwave that is driven inward towards the center of the bubble. These shocks could possibly drive the temperatures and pressures in the interior of the bubble high enough to generate the light. (Indeed, some physicists have suggested that sonoluminescence might enable the ignition of fusion reactions, though as of this writing that remains speculation).

6.2.6 Thermoacoustic Engines (Refrigerators and Prime Movers)

Another interesting application of physical acoustics is that of thermoacoustics. Thermoacoustics involves the conversion of acoustic energy into thermal energy or the reverse process of converting thermal energy into sound [6.16]. Figure 6.13 shows a photograph of
Fig. 6.13 A thermoacoustic engine

a thermoacoustic engine. To understand the processes involved in thermoacoustics, let us consider a small packet of gas in a tube which has a sound wave traveling through it (thermoacoustic effects can occur with either standing or progressive waves). As the compression of the wave passes through the region containing the packet of gas, three effects occur:

1. The gas compresses adiabatically, its temperature increases in accordance with Boyle's law (due to the compression), and the packet is displaced some distance down the tube.
2. As the rarefaction phase of the wave passes through the gas, this process reverses.
3. The wall of the tube acts as a heat reservoir. As the packet of gas goes through the acoustic process, it deposits heat at the wall during the compression phase (the wall literally conducts the heat away from the compressed packet of gas).

This process is happening down the entire length of the tube; thus a temperature gradient is established down the tube.

To create a useful thermoacoustic device, one must increase the surface area of wall that the gas is in contact with so that more heat is deposited down the tube. This is accomplished by inserting a *stack* into the tube. In the inside of the tube there are several equally spaced plates which are also in contact with the exterior walls of the tube. Each plate provides additional surface area for the deposition of thermal energy and increases the overall thermoacoustic effect. (The stack must not impede the wave traveling down the tube, or the thermoacoustic effect is minimized.) Modern stacks use much more complicated geometries to improve the efficiency of the thermoacoustic device (indeed the term stack now is a misnomer, but the principle remains the same). Figure 6.14 shows a photograph of a stack used in a modern thermoacoustic engine. The stack shown in Fig. 6.14 is made of a ceramic material.
Fig. 6.14 A stack used in a thermoacoustic engine. Pores allow the gas in the tube to move under the influence of the acoustic wave while increasing the surface area for the gas to deposit heat

A thermoacoustic device used in this way is a thermoacoustic refrigerator. The sound generated down the tube (by a speaker or some other device) is literally pumping heat energy from one end of the tube to the other. Thus, one end of the tube gets hot and the other cools down (the cool end is used for refrigeration).

The reverse of this thermoacoustic refrigeration process can also occur. In this case, the tube ends are fitted with heat exchangers (one exchanger is hot, one is cold). The heat delivered to the tube by the heat exchangers does work on the system and generates sound in the tube. The frequency and amplitudes of the generated waves depend on the geometry of the tube and the stacks. When a thermoacoustic engine is driven in this way (converting heat into sound), it is known as a prime mover.

Though much research to improve the efficiency of thermoacoustic engines is ongoing, the currently obtainable efficiencies are quite low compared to standard refrigeration systems. Thermoacoustic engines, however, offer several advantages: they have no moving parts to wear out, they are inexpensive to manufacture, and they are highly reliable, which is useful if refrigeration is needed in inaccessible places.

One practical application for thermoacoustic engines is often cited: the liquefaction of natural gas for transport. This is accomplished by having two thermoacoustic engines, one working as a prime mover and the other working as a refrigerator. A small portion of the gas is ignited and burned to produce heat. The heat is applied to the prime mover to generate sound. The sound is directed into a second thermoacoustic engine that acts as a refrigerator. The sound from the prime mover pumps enough heat down the refrigerator to cool the gas enough to liquefy it for storage. The topic of thermoacoustics is discussed in greater detail in Chap. 7.

6.2.7 Acoustic Detection of Land Mines

Often, during wars and other armed conflicts, mine fields are set up and later abandoned. Even today it is not uncommon for mines originally planted during World War II to be discovered still buried and active. According to the humanitarian organization CARE, 70 people are killed each day by land mines, with the vast majority being civilians. Since most antipersonnel mines manufactured today contain no metal parts, electromagnetic-field-based metal detectors cannot locate them for removal. Acoustic detection of land mines offers a potential solution for this problem.

The approach used in acoustic land-mine detection is conceptually simple but technically challenging. Among the first efforts made at acoustic land-mine detection were those of *House* and *Pape* [6.17]. They sent sounds into the ground and examined the reflections from buried objects. *Don* and *Rogers* [6.18] and *Caulfield* [6.19] improved the technique by including a reference beam that provided information for comparison with the reflected signals. Unfortunately, this technique yielded too many false positives to be practical because one could not distinguish between a mine and some other buried object such as a rock or the root of a tree.

Newer techniques involving the coupling of an acoustic signal with a seismic vibration have been developed with much more success [6.20–24]. They make use of remote sensing and analysis by computer. Remote measurement of the acoustic field is done with a laser Doppler vibrometer (LDV), which is a an optical device used to measure velocities and displacements of vibrating bodies without physical contact. With this technique, the ground is excited acousticly with lower frequencies (usually on the order of a few hundred Hz). The LDV is used to measure the vibration of the soil as it responds to this driving force. If an object is buried under the soil in the region of excitation, it alters the resonance characteristics of the soil and introduces nonlinear effects. With appropriate digital signal processing and analysis, one can develop a system capable of rec-

ognizing different types of structures buried beneath the soil. This reduces the number of false positives and makes the system more efficient.

6.2.8 Medical Ultrasonography

For the general public, one of the most familiar applications of physical acoustics is that of medical ultrasonography. Medical ultrasonography is a medical diagnostic technique which can use sound information to construct images for the visualization of the size, structure and lesions of internal organs and other bodily tissues. These images can be used for both diagnostic and treatment purposes (for example enabling a surgeon to visualize an area with a tumor during a biopsy). The most familiar application of this technique is obstetric ultrasonography, which uses the technique to image and monitor the fetus during a pregnancy. An ultrasonograph of a fetus is shown in Fig. 6.15.

This technique relies on the fact that in different materials the speed of sound and acoustic impedance are different. A collimated beam of high-frequency sound is projected into the body of the person being examined. The frequencies chosen will depend on the application. For example, if the tissue is deeper within the body, the sound must travel over a longer path and attenuation affects can present difficulties. Using a lower ultrasonic frequency reduces attenuation. Alternatively, if a higher resolution is needed, a higher frequency is used. In each position where the density of the tissue changes, there is an acoustic impedance mismatch. Therefore, at each interface between various types of tissues some of the sound is reflected. By measuring the time between echoes, one can determine the spatial position of the various tissues.

If a single, stationary transducer is used; one gets spatial information that lies along a straight line. Typically, the probe contains a phased array of transducers that are used to generate image information from different directions around the area of interest. The different transducers in the probe send out acoustic pulses that are reflected from the various tissues. As the acoustic signals return, the transducers receive them and convert the information into a digital, pictorial representation. One must also match the impedances between the surface of the probe and the body. The head of the probe is usually soft rubber, and the contact between the probe and the body is impedance-matched by a water-based gel.

Fig. 6.15 Ultrasonograph of a fetus

To construct the image, each transducer (which themselves are separated spatially somewhat) measures the strength of the echo. This measurement indicates how much sound has been lost due to attenuation (different tissues have different attenuation values). Additionally, each transducer measures the delay time between echoes, which indicates the distance the sound has traveled before encountering the interface causing the echo (actually since the sound has made a round trip during the echo the actual displacement between the tissues is $\frac{1}{2}$ of the total distance traveled). With this information a two-dimensional image can be created. In some versions of the technique, computers can be used to generate a three-dimensional image from the information as well.

A more esoteric form of ultrasonography, Doppler ultrasonography, is also used. This technique requires separate arrays of transducers, one for broadcasting a continuous-wave acoustic signal and another for receiving it. By measuring a frequency shift caused by the Doppler effect, the probe can detect structures moving towards or away from the probe. For example, as a given volume of blood passes through the heart or some other organ, its velocity and direction can be determined and visualized. More-recent versions of this technique make use of pulses rather than continuous waves and can therefore use a single probe for both broadcast and reception of the signal. This version of the technique requires more-advanced analysis to determine the frequency shift. This technique presents advantages because the timing of the pulses and their echoes can be measured to provide distance information as well.

6.3 Apparatus

Given the diverse nature of physical acoustics, any two laboratories conducting physical acoustics experiments might have considerably different types of equipment and apparatus (for example, experiments dealing with acoustic phenomena in water usually require tanks to hold the water). As is the case in any physics laboratory, it is highly useful to have access to a functioning machine shop and electronics shop for the design, construction, and repair of equipment needed for the physical acoustics experiment that is being conducted. Additionally, a wide range of commercial equipment is available for purchase and use in the lab setting.

6.3.1 Examples of Apparatus

Some typical equipment in an acoustic physics lab might include some of the following:

- Loudspeakers;
- Transducers (microphones/hydrophones);
- Acoustic absorbers;
- Function generators, for generating a variety of acoustic signals including single-frequency sinusoids, swept-frequency sinusoids, pulses, tone bursts, white or pink noise, etc.;
- Electronics equipment such as multimeters, impedance-matching networks, signal-gating equipment, etc.;
- Amplifiers (acoustic, broadband, Intermediate Frequency (IF), lock-in);
- Oscilloscopes. Today's digital oscilloscopes (including virtual oscilloscopes implemented on personal computers) can perform many functions that previously required several different pieces of equipment; for example, fast Fourier transform (FFT) analysis previously required a separate spectrum analyzer; waveform averaging previously required a separate boxcar integrator, etc.);
- Computers (both for control of apparatus and analysis of data).

For audible acoustic waves in air the frequency range is typically $20-20\,000$ Hz. This corresponds to a wavelength range of 16.5 m–16.5 mm. Since these wavelengths often present difficulties in the laboratory, and since the physical principles apply at all frequencies, the laboratory apparatus is often adapted to a higher frequency range. The propagating medium is often water since a convenient ultrasonic range of $1-100$ MHz gives

a convenient wavelength range of $0.014-1.4$ mm. The experimental arrangements to be described below are for some specialized applications and cover this wavelength range, or somewhat lower. The results, however, are useful in the audio range as well.

6.3.2 Piezoelectricity and Transduction

In physical acoustics transducers play an important role. A transducer is a device that can convert a mechanical vibration into a current or vice versa. Transducers can be used to generate sound or to detect sound. Audible frequencies can be produced by loudspeakers and received by microphones, which often are driven electromagnetically. (For example, a magnet interacting with a current-carrying coil experiences a magnetic force that can accelerate it, or if the magnet is moved it can induce a corresponding current in the coil.) The magnet could be used to drive the cone of a loudspeaker to convert a current into an audible tone (or speech, or music, etc.). Similarly, one can use the fact that the capacitance between two parallel-plate capacitors varies as a function of the separation distance between two plates. A capacitor with one plate fixed and the other allowed to vibrate in response to some form of mechanical forcing (say the force caused by the pressure of an acoustic wave) is a transducer. With a voltage across the two plates, an electrical current is generated as the plates move with respect to one another under the force of the vibration of an acoustic wave impinging upon it. These types of transducers are described in Chap. 24.

The most common type of transducers used in the laboratory for higher-frequency work are piezoelectric-element-based transducers. In order to understand how these transducers work (and are used) we must first examine the phenomenon of piezoelectricity.

Piezoelectricity is characterized by the both direct piezoelectric effect, in which a mechanical stress applied to the material causes a potential difference across the surface of the faces to which the stress is applied, and the secondary piezoelectric effect, in which a potential difference applied across the faces of the material causes a deformation (expansion or contraction). The deformation caused by the direct piezoelectric effect is on the order of nanometers, but leads to many uses in acoustics such as the production and detection of sound, microbalance applications (where very small masses are measured by determining the change in the resonance frequency of a piezoelectric crystal when it is loaded

with the small mass), and frequency generation/control for oscillators.

Piezoelectricity arises in a crystal when the crystal's unit cell lacks a center of symmetry. In a piezoelectric crystal, the positive and negative charges are separated by distance. This causes the formation of electric dipoles, even though the crystal is electrically neutral overall. The dipoles near one another tend to orient themselves along the same direction. These small regions of aligned dipoles are known as domains because of the similarity to the magnetic analog. Usually, these domains are oriented randomly, but can be aligned by the application of a strong electric field in a process known as poling (typically the sample is poled at a high temperature and cooled while the electric field is maintained). Of the 32 different crystal classifications, 20 exhibit piezoelectric properties and 10 of those are polar (i. e. spontaneously polarized). If the dipole can be reversed by an applied external electric field, the material is additionally known as a ferroelectric (in analogy to ferromagnetism).

When a piezoelectric material undergoes a deformation induced by an external mechanical stress, the symmetry of the charge distribution in the domains is disturbed. This gives rise to a potential difference across the surfaces of the crystal. A 2 kN force ($\approx$ 500 lbs) applied across a 1 cm cube of quartz can generate up to 12 500 V of potential difference.

Several crystals are known to exhibit piezoelectric properties, including tourmaline, topaz, rochelle salt, and quartz (which is most commonly used in acoustic applications). In addition, some ceramic materials with perovskite or tungsten bronze structures, including barium titanate ($BaTiO_3$), lithium niobate ($LiNbO_3$), PZT [$Pb(ZrTi)O_3$], $Ba_2NaNb_5O_5$, and $Pb_2KNb_5O_{15}$, also exhibit piezoelectric properties. Historically, quartz was the first piezoelectric material widely used for acoustics applications. Quartz has a very sharp frequency response, and some unfavorable electrical properties such as a very high electrical impedance which requires impedance matching for the acoustic experiment. Many of the ceramic materials such as PZT or lithium niobate have a much broader frequency response and a relatively low impedance which usually does not require impedance matching. For these reasons, the use of quartz has largely been supplanted in the acoustics lab by transducers fashioned from these other materials. Although in some situations (if a very sharp frequency response is desired), quartz is still the best choice.

In addition to these materials, some polymer materials behave as electrets (materials possessing a quasi-permanent electric dipole polarization). In most piezoelectric crystals, the orientation of the polarization is limited by the symmetry of the crystal. However, in an electret this is not the case. The electret material polyvinylidene fluoride (PVDF) exhibits piezoelectricity several times that of quartz. It can also be fashioned more easily into larger shapes.

Since these materials can be used to convert a sinusoidal electrical current into a corresponding sinusoidal mechanical vibration as well as convert a mechanical vibration into a corresponding electrical current, they provide a connection between the electrical system and the acoustic system. In physical acoustics their ability to produce a single frequency is especially important. The transducers to be described here are those which are usually used to study sound propaga-
Fig. 6.16 Transducer housing

tion in liquids or in solids. The frequencies used are ultrasonic.

The first transducers were made from single crystals. Single crystals of *x*-cut quartz were preferred for longitudinal waves, and *y*-cut for transverse waves, their thickness determined by the frequency desired. Single crystals are still used for certain applications; however, the high-impedance problems were solved by introduction of polarized ceramics containing barium titanate or strontium titanate. These transducers have an electrical impedance which matches the $50\,\Omega$ impedance found on most electrical apparatus. Low-impedance transducers are currently commercially available.

Such transducers can be used to generate or receive sound. When used as a receiver in liquids such transducers are called hydrophones. For the generation of ultrasonic waves in liquids, one surface of the transducer material should be in contact with the liquid and the other surface in contact with air (or other gas). With this arrangement, most of the acoustic energy enters the liquid. In the laboratory it is preferable to have one surface at the ground potential and electrically drive the other surface, which is insulated. Commercial transducers which accomplish these objectives are available. They are designed for operation at a specific frequency. A transducer housing is shown in Fig. 6.16. The transducer crystal and the (insulated) support ring can be changed to accommodate the frequency desired. In the figure a strip back electrode is shown. For generating acoustic vibration over the entire surface, the back of the transducer can be coated with an electrode. The width which produces a Gaussian output in one dimension is
Fig. 6.17 Coaxial transducer

described in [6.25]. The use of a circular electrode that can produce a Gaussian amplitude distribution in two dimensions is described in [6.26].

For experiments with solids the transducer is often bonded directly to the solid without the need for an external housing. For single-transducer pulse-echo operation the opposite end of the sample must be flat because it must reflect the sound. For two-transducer operation one transducer is the acoustic transmitter, the other the receiver.

With solids it is convenient to use coaxial transducers because both transducer surfaces must be electrically accessible. The grounded surface in a coaxial transducer can be made to wrap around the edges so it can be accessed from the top as well. An example is shown in Fig. 6.17. The center conductor is the high-voltage terminal. The outer conductor is grounded; it is in electrical contact with the conductor that covers the other side of the transducer.

6.3.3 Schlieren Imaging

Often it is useful to be able to see the existence of an acoustic field. The Schlieren arrangement shown in Fig. 6.18 facilitates the visualization of sound fields in water. Light from a laser is brought to focus on a circular aperture by lens 1. The circular aperture is located at a focus of lens 2, so that the light emerges parallel. The water tank is located in this parallel light. Lens 3 forms a real image of the contents of the water tank on the screen, which is a photographic negative for photographs. By using a wire or an ink spot on an optical flat at the focus of lens 3, one produces conditions for dark-field illumination. The image on the screen, then, is an image of the ultrasonic wave propagating through the water. The fact that the ultrasonic wave is propagating through the water means that the individual wavefronts are not seen. To see the individual wavefronts, one must add a stroboscopic light source synchronized with the ultrasonic wave. In this way the light can be on at the frequency of the sound and produce a photograph which shows the individual wavefronts.

On some occasions it may be useful to obtain color images of the sound field; for example, one can show an incident beam in one color and its reflection from an interface in a second color for clarity. The resultant photographs can be beautiful; however, to a certain extent their beauty is controlled by the operator. The merit of color Schlieren photography may be more from its aesthetic or pedagogical value, rather than its practical application. This is the reason that color Schlieren pho-
Fig. 6.18 Diagram of a Schlieren system

tographs are seldom encountered in a physical acoustic laboratory. For completeness, however, it may be worthwhile to describe the process.

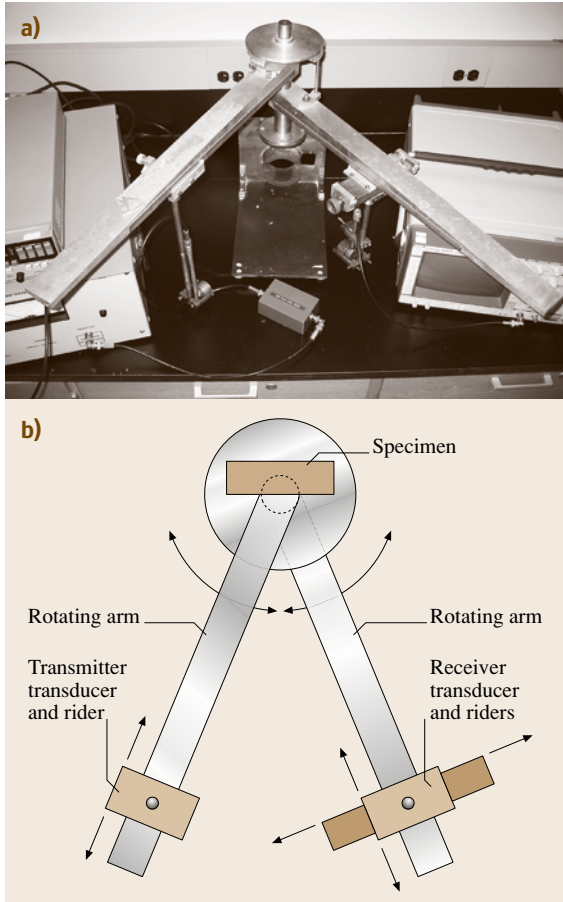
The apparatus used is analogous to that given in Fig. 6.18. The difference is that a white-light source
Fig. 6.19 Spectra formed by the diffraction of light through a sound field
Fig. 6.20a–c Schlieren photographs showing reflection and diffraction of ultrasonic waves by a solid immersed in water


Fig. 6.21 **(a)** Photograph of a goniometer system; **(b)** diagram of a goniometer system ◄

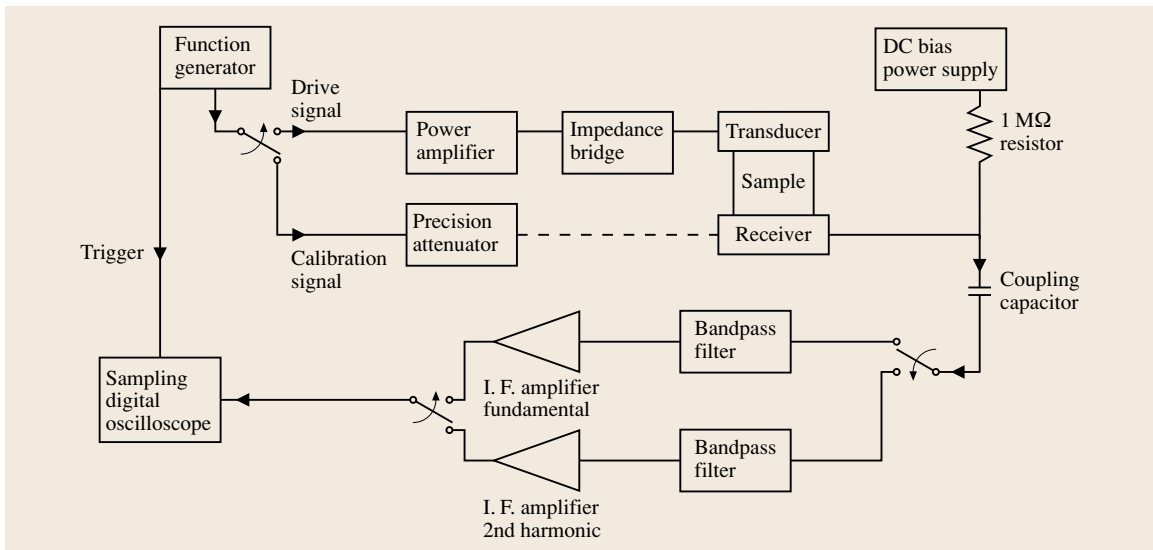
is used in the place of the monochromatic light from the laser. As the light diffracts, the diffraction pattern formed at the focus of lens 3 is made up of complete spectra (with each color of the spectra containing a complete image of the acoustic field). A photograph showing the spectra produced is shown in Fig. 6.19. If the spectra are allowed to diverge beyond this point of focus, they will combine into a white-light image of the acoustic field. However, one can use a slit (rather than using a wire or an ink spot at this focus to produce dark-field illumination) to pass only the desired colors. The position of the slit selects the color of the light producing the image of the sound field. If one selects the blue-colored incident beam from one of the spectra, and the red-colored reflected beam from another spectrum (blocking out all the other colors), a dual-colored image results. Since each diffraction order contains enough information to produce a complete sound field image, the operator has control over its color. Spatial filtering, then, becomes a means of controlling the color of the various parts of the image. Three image examples are given in Fig. 6.20. Figure 6.20a is reflection of a sound beam from a surface. Figure 6.20b shows diffraction of sound around a cylinder. Figure 6.20c shows backward displacement at a periodic interface. The incident beam is shown in a different color from that of the reflected beam and the diffraction order.


Fig. 6.22 Block Diagram of apparatus for absolute amplitude measurements
Fig. 6.23 Mounting system for room-temperature measurement of absolute amplitudes of ultrasonic waves in solids

6.3.4 Goniometer System

For studies of the propagation of an ultrasonic pulse in water one can mount the ultrasonic transducers on a goniometer such as that shown in Fig. 6.21. This is a modification of the pulse-echo system. The advantage of this system is that the arms of the goniometer allow for the adjustments indicated in Fig. 6.21b. By use of this goniometer it is possible to make detailed studies of the reflection of ultrasonic waves from a variety of

water–solid interfaces. By immersing the goniometer in other liquids, the type of liquid can also be changed.

6.3.5 Capacitive Receiver

In many experiments, one measures acoustic amplitude relative to some reference amplitude, which is usually determined by the parameters of the experiment. However, in some studies it is necessary to make a measurement of the absolute amplitude of acoustic vibration. This is especially true of the measurement of the nonlinearity of solids. For the measurement of the absolute acoustic amplitude in a solid, a capacitive system can be used. If the end of the sample is coated with a conductive material, it can act as one face of a parallel-plate capacitor. A bias voltage is put across that capacitance, which enables it to work as a capacitive microphone. As the acoustic wave causes the end of the sample to vibrate, the capacitor produces an electrical signal. One can relate the measured electrical amplitude to the acoustic amplitude because all quantities relating to them can be determined.

The parallel-plate approximation, which is very well satisfied for plate diameters much larger than the plate separation, is the only approximation necessary. The electrical apparatus necessary for absolute amplitude measurements in solids is shown in the block diagram of Fig. 6.22. A calibration signal is used in such a manner that the same oscilloscope can be used for the calibration and the measurements. The mounting system for room-temperature measurements of a sample is shown in Fig. 6.23. Since stray capacitance affects the impedance of the resistor, this impedance must be measured at the frequencies used. The voltage drop in the resistor can be measured with either the calibration signal or the signal from the capacitive receiver. A comparison of the two completes the calibration. With this system acoustic amplitudes as small as 10^{-14} m (which is approximately the limit set by thermal noise) have been measured in copper single crystals [6.27].

6.4 Surface Acoustic Waves

It has been discovered that surface acoustic waves are useful in industrial situations because they are relatively slow compared with bulk waves or electromagnetic waves. Many surface acoustic wave devices are made

by coating a solid with an interdigitated conducting layer. In this case, the surface acoustic wave produces the desired delay time and depends for its generation on a fringing field (or the substrate may be piezoelec-
Fig. 6.24a,b Sound waves at a liquid–solid interface

tric). The inverse process can be used to receive surface acoustic waves and convert them into an electrical signal, which can then be amplified.

Another type of surface wave is possibly more illustrative of the connection between surface acoustic waves and physical acoustics. This is the surface acoustic wave generated when the trace velocity of an incident wave is equal to the velocity of the surface acoustic wave. This occurs when a longitudinal wave is incident on a solid from a liquid. This is analogous to the optical case of total internal reflection [6.28], but new information comes from the acoustic investigation.

The interface between a liquid and a solid is shown in Fig. 6.24, in which the various waves and their angles are indicated. The directions in which the various waves propagate at a liquid–solid interface can be calculated from Snell's law, which for this situation can be written

$$\frac{\sin\theta_i}{v} = \frac{\sin\theta_r}{v} = \frac{\sin\theta_L}{v_L} = \frac{\sin\theta_S}{v_S}, \quad (6.66)$$

where the velocity of the longitudinal wave in the liquid, that in the solid, and the velocity of the shear wave in the solid are, respectively, v, v_L, and v_S. The propagation directions of the various waves are indicated in Fig. 6.24.

Since much of the theory has been developed in connection with geology, the theoretical development

of *Ergin* [6.29] can be used directly. Ergin has shown that the energy reflected at an interface is proportional to the square of the amplitude reflection coefficient, which can be calculated directly [6.29]. The energy reflection coefficient is given by

$$R_E = \left(\frac{\cos\beta - A\cos\alpha(1-B)}{\cos\beta + A\cos\alpha(1-B)}\right)^2, \quad (6.67)$$

where

$$A = \frac{\rho_1 V_L}{\rho V} \quad \text{and}$$

$$B = 2\sin\gamma\sin 2\gamma\left(\cos\gamma - \frac{v_S}{v_L}\cos\beta\right). \quad (6.68)$$

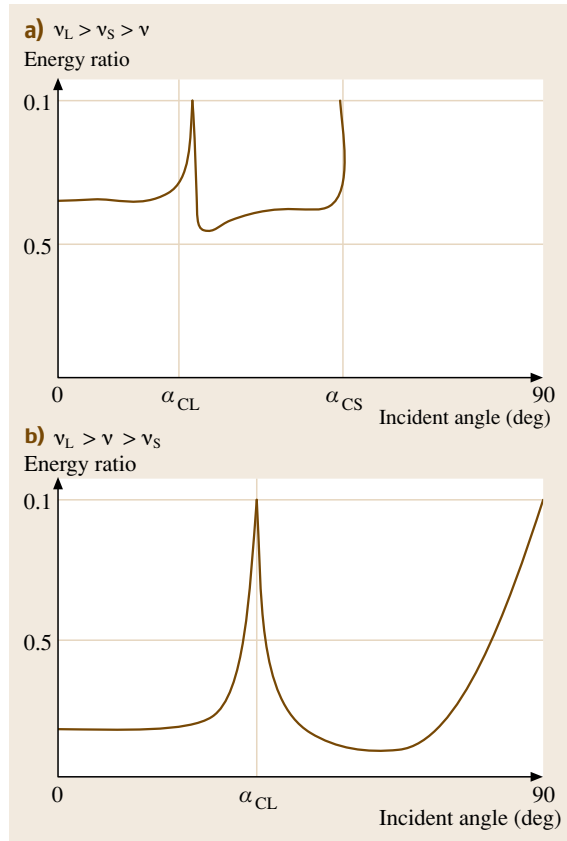
The relationship among the angles α, β and γ can be determined from Snell's law as given in (6.66). The book by *Brekhovskikh* [6.30] is also a good source of information on this subject.


Fig. 6.25a,b Behavior of energy reflected at a liquid–solid interface
Fig. 6.26 A 2 MHz ultrasonic wave reflected at a liquid–solid interface

Typical plots of the energy reflection coefficient as a function of incident angle are given in Fig. 6.25 in which the critical angles are indicated. Usually, $v_L > v_S > v$, so the curve in Fig. 6.25a is observed. It will be noticed immediately that there is a critical angle for both the longitudinal and transverse waves in the solid. In optics there is no longitudinal wave; therefore the curve has only one critical angle.

If one uses a pulse-echo system to verify the behavior of an ultrasonic pulse at an interface between a liquid and a solid, one gets results that can be graphed as shown in Fig. 6.26. At an angle somewhat greater than the critical angle for a transverse wave in the solid, one finds a dip in the data. This dip is associated with the generation of a surface wave. The surface wave is excited when the projection of the wavelength of the incident wave onto the interface matches the wavelength of the surface wave. The effect of the surface wave can be seen in the Schlieren photographs in Fig. 6.27.

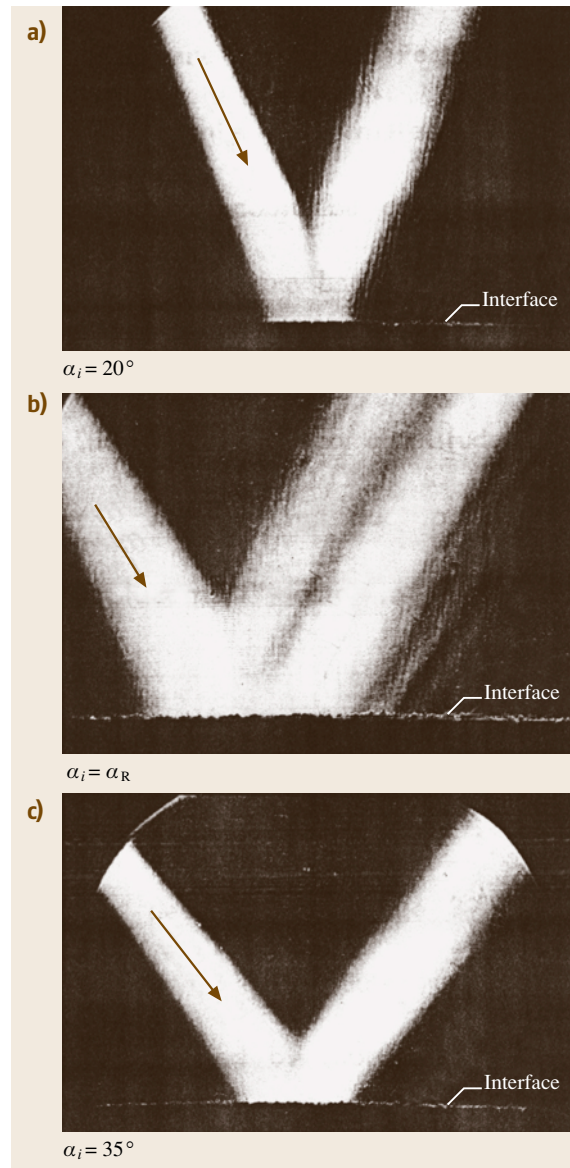
Figure 6.27 shows the reflection at a water–aluminum interface at an angle less than that for excitation of a surface wave (a Rayleigh surface wave), at the angle at which a surface wave is excited, and an angle greater. When a surface wave is excited the reflected beam contains two (or more) components: the specular beam (reflected in a normal manner) and a beam displaced down the interface. Since most of the energy is contained in the displaced beam, the minimum in the data shown in Fig. 6.24 is caused by the excitation of the displaced beam by the surface wave. This has been shown to be the case by displacing the receiver to follow the displaced beam with a goniometer system, as shown in Fig. 6.21. This minimizes the dip in data shown in Fig. 6.24. *Neubauer* has


Fig. 6.27a−c Schlieren photographs showing the behavior of a 4 MHz ultrasonic beam reflected at a water–aluminium interface

shown that the ultrasonic beam excited by the surface wave is 180° out of phase with the specularly reflected beam [6.31]. Destructive interference resulting from phase cancelation causes these beams to be separated by a null strip. Although a water–aluminum interface has been used in these examples, the phenomenon occurs at all liquid–solid interfaces. It is less noticeable
Fig. 6.28 Schlieren photograph showing backward displacement of a 6 MHz ultrasonic beam at a corrugated water–brass interface

Fig. 6.29 Diagram of incident beam coupling to a backward-directed leaky wave to produce backward displacement of the reflected beam

at higher ultrasonic frequencies since the wavelength is smaller.

At a corrugated interface it is possible that the incident beam couples to a negatively directed surface wave so that the reflected beam is displaced in the negative direction. This phenomenon was predicted for optical waves by *Tamir* and *Bertoni* [6.32]. They deter-

mined that the optimum angle for this to occur is given by

$$\sin \theta_i = V_{\text{liq}} \left(\frac{1}{fd} - \frac{1}{V_R} \right) \tag{6.69}$$

where d is the period, f is the frequency, V_{liq} is the wave propagation velocity in the liquid, and V_R is the propagation velocity of the leaky surface wave. Figure 6.28 is a Schlieren photograph which shows what happens in this case [6.33]. Figure 6.29 is a diagram of the phenomenon [6.33]. The incident beam couples to a backward-directed surface wave to produce backward displacement of the reflected beam.

6.5 Nonlinear Acoustics

There are several sources of nonlinearity whether the propagating medium be a gas, liquid, or solid. They are described in more detail in Chap. 8. Even in an ideal medium in which one considers only interatomic forces, there is still a source of nonlinear behavior since compression requires a slightly different force from dilatation. With Hooke's law (strain is proportional to stress) one assumes that they are equal. This is seldom true. The subject of nonlinear acoustics has been developed to the point that it is now possible to go beyond the linear approximation with many substances.

6.5.1 Nonlinearity of Fluids

If one assumes an ideal gas and keeps the first set of nonlinear terms, *Beyer* has shown that the equation of motion in one dimension becomes [6.34]

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{c_0^2}{\left(1 + \frac{\partial \xi}{\partial a} \right)^{\gamma + 1}} \frac{\partial^2 \xi}{\partial a^2} . \tag{6.70}$$

This form of the nondissipative wave equation in one dimension in Lagrangian coordinates includes nonlin-

ear terms. In this equation γ is the ratio of specific heats and

$$c_0^2 = \frac{\gamma p_0}{\rho_0} \frac{1}{\left(1 + \frac{\partial \xi}{\partial a}\right)^{\gamma-1}} . \tag{6.71}$$

One can also generalize this equation in a form which applies to all fluids. By expanding the equation of state $p = p_0 \left(\frac{\rho}{\rho_0}\right)^{\gamma}$ in powers of the condensation $s = \frac{\rho - \rho_0}{\rho_0}$, one obtains

$$p = p_0 + As + \frac{B}{2!}s^2 + \dots \quad \text{and}$$
$$c^2 = c_0^2 \left[1 + \left(\frac{B}{A}\right)s + \dots\right] . \tag{6.72}$$

This makes it possible to obtain the nonlinear wave equation in the form [6.24]

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{c_0^2}{\left(1 + \frac{\partial \xi}{\partial a}\right)^{2 + \frac{B}{A}}} \frac{\partial^2 \xi}{\partial a^2} . \tag{6.73}$$

In this form one can recognize that the quantity $2 + B/A$ for fluids plays the same role as $\gamma + 1$ for ideal gases. Values of B/A for fluids given in Table 6.3 indicate that nonlinearity of fluids, even in the absence of bubbles of air, cannot always be ignored. The nonlinearity of fluids is discussed in greater detail in Chap. 8.

6.5.2 Nonlinearity of Solids

The propagation of a wave in a nonlinear solid is described by first introducing third-order elastic constants. When extending the stress–strain relationship (which essentially is a force-based approach) it becomes difficult to keep a consistent approximation among the various nonlinear terms. However, If one instead uses an energy approach, a consistent approximation is automatically maintained for all the terms of higher order.

Beginning with the elastic potential energy, one can define both the second-order constants (those determining the wave velocity in the linear approximation) and the third-order elastic constants simultaneously. The

Table 6.3 Values of B/A

Substance	T (°C)	B/A
Distilled water	0	4.2
	20	5.0
	40	5.4

Nonlinearity parameter β	$\gamma + 1$	$\frac{B}{A} + 2$	$-\left(\frac{K_3}{K_2} + 3\right)$

where the η are the strains, C_{ijkl} are the second-order elastic constants, and C_{ijklmn} are the third-order elastic constants. For cubic crystals there are only three second-order elastic constants: C_{11}, C_{12} and C_{44}, and only six third-order elastic constants: C_{111}, C_{112}, C_{144}, C_{166}, C_{123} and C_{456}. This makes the investigation of cubic crystals relatively straightforward [6.35]. By using the appropriate form of Lagrange's equations, specializing to a specific orientation of the coordinates with respect to the ultrasonic wave propagation direction, and neglecting attenuation and higher-order terms, one can write the nonlinear wave equation for propagation in the directions that allow the propagation of purely longitudinal waves (with no excitation of transverse waves). In a cubic crystalline lattice there are three of these *pure mode* directions for longitudinal waves and the nonlinear wave equation has the form [6.35]

$$\rho_0 \frac{\partial^2 u}{\partial t^2} = K_2 \frac{\partial^2 u}{\partial a^2} + (3K_2 + K_3) \frac{\partial u}{\partial a} \frac{\partial^2 u}{\partial a^2} + \dots ,$$
(6.75)

where both K_2 and K_3 depend on the orientation considered. The quantity K_2 determines the wave velocity: $K_2 = c_0^2 \rho_o$. The quantity K_3 contains only third-order elastic constants. The quantities K_2 and K_3 are given for the three pure-mode directions in a cubic lattice in Table 6.4. The ratio of the coefficient of the nonlinear term to that of the linear term has a special significance. It is often called the *nonlinearity parameter* β and its magnitude is $\beta = 3 + \frac{K_3}{K_2}$. Since K_3 is an inherently negative quantity and is usually greater in magnitude than $3K_2$, a minus sign is often included in the definition

$$\beta = -\left(3 + \frac{K_3}{K_2}\right).$$
(6.76)

The nonlinearity parameters of many cubic solids have been measured. As might be expected, there is a difference between the quantities measured in the three pure-mode directions (usually labeled as the [100], [110] and [111] directions). These differences, however, are not great. If one averages them, one gets the results shown in Table 6.5. The nonlinearity parameters cover the range 2–15. This means that for cubic crystals the coefficient of the nonlinear term in the nonlinear wave equation is 2–15 times as large as the coefficient of the linear term. This gives an impression of the approximation involved when one ignores nonlinear acoustics.

There is also a source of nonlinearity of solids that appears to come from the presence of domains in lithium niobate; this has been called *acoustic memory* [6.36].

It is possible to measure all six third-order elastic constants of cubic crystals. To do so, however, it is necessary to make additional measurements. The procedure that minimizes errors in the evaluation of third-order elastic constants from combination of nonlinearity parameters with the results of hydrostatic-pressure measurements has been considered by *Breazeale* et al. [6.37] and applied to the evaluation of the third-order elastic constants of two perovskite crystals.

6.5.3 Comparison of Fluids and Solids

To facilitate comparison between fluids and solids, it is necessary to use a binomial expansion of the denominator of (6.73)

$$\left(1 + \frac{\partial \xi}{\partial a}\right)^{-\left(\frac{B}{A} + 2\right)} = 1 + \left(\frac{B}{A} + 2\right) \frac{\partial \xi}{\partial a} + \dots \quad (6.77)$$

Using this expression, (6.73) becomes

$$\frac{\partial^2 \xi}{\partial t^2} = c_0^2 \frac{\partial^2 \xi}{\partial a^2} + c_0^2 \left(\frac{B}{A} + 2\right) \frac{\partial \xi}{\partial a} \frac{\partial^2 \xi}{\partial a^2} + \dots \quad (6.78)$$

This form of the equation can be compared directly with (6.74) for solids. The ratio of the coefficient of the nonlinear term to that of the linear term can be evaluated

directly. The nonlinearity parameters of the various substances are listed in Table 6.6. Use of Table 6.6 allows one to make a comparison between the nonlinearity of fluids as listed in Table 6.3 and the nonlinearity parameters of solids listed in Table 6.5. Nominally, they are of the same order of magnitude. This means that solids exhibit intrinsic nonlinearity that is comparable to that exhibited by fluids. Thus, the approximation made by assuming that Hooke's law (strain is proportional to stress) is valid for solids is comparable to the approximation made in the derivation of the linear wave equation for fluids.

Thermoacoustics

7. Thermoacoustics

Gregory W. Swift

Thermodynamic and fluid-dynamic processes in sound waves in gases can convert energy from one form to another. In these *thermoacoustic* processes [7.1, 2], high-temperature heat or chemical energy can be partially converted to acoustic power, acoustic power can produce heat, acoustic power can pump heat from a low temperature or to a high temperature, and acoustic power can be partially converted to chemical potential in the separation of gas mixtures. In some cases, the thermoacoustic perspective brings new insights to decades-old technologies. Well-engineered thermoacoustic devices using extremely intense sound approach the power conversion per unit volume and the efficiency of mature energy-conversion equipment such as internal combustion engines, and the simplicity of few or no moving parts drives the development of practical applications.

This chapter surveys thermoacoustic energy conversion, so the reader can understand how thermoacoustic devices work and can estimate some relevant numbers. After a brief history, an

initial section defines vocabulary and establishes preliminary concepts, and subsequent sections explain engines, dissipation, refrigeration, and mixture separation. Combustion thermoacoustics is mentioned only briefly. Transduction and measurement systems that use heat-generated surface and bulk acoustic waves in solids are not discussed.

7.1 History

The history of thermoacoustic energy conversion has many interwoven roots, branches, and trunks. It is a complicated history because invention and technology development outside of the discipline of acoustics have sometimes preceded fundamental understanding; at other times, fundamental science has come first.

Rott [7.3, 4] developed the mathematics describing acoustic oscillations in a gas in a channel with an axial temperature gradient, with lateral channel dimensions of the order of the gas thermal penetration depth (typically ≈ 1 mm), this being much shorter than the wavelength (typically ≈ 1 m). The problem had been investigated by Rayleigh and by Kirchhoff, but without quantitative success. In Rott's time, the

motivation to understand the problem arose largely from the cryogenic phenomenon known as Taconis oscillations – when a gas-filled tube is cooled from ambient temperature to a cryogenic temperature, the gas sometimes oscillates spontaneously, with large heat transport from ambient to the cryogenic environment. *Yazaki* [7.5] demonstrated convincingly that Rott's analysis of Taconis oscillations was quantitatively accurate.

A century earlier, *Rayleigh* [7.6] understood the qualitative features of such heat-driven oscillations:

If heat be given to the air at the moment of greatest condensation (i. e., greatest density) or be taken

from it at the moment of greatest rarefaction, the vibration is encouraged.

He had studied Sondhauss oscillations [7.7], the glassblowers' precursor to Taconis oscillations.

Applying Rott's mathematics to a situation where the temperature gradient along the channel was too weak to satisfy Rayleigh's criterion for spontaneous oscillations, *Hofler* [7.8] invented a standing-wave thermoacoustic refrigerator, and demonstrated [7.9] again that Rott's approach to acoustics in small channels was quantitatively accurate. In this type of refrigerator, the coupled oscillations of gas motion, temperature, and heat transfer in the sound wave are phased in time so that heat is absorbed from a load at a low temperature and waste heat is rejected to a sink at a higher temperature.

Meanwhile, completely independently, pulse-tube refrigeration was becoming the most actively investigated area of cryogenic refrigeration. This development began with *Gifford*'s [7.10] accidental discovery and subsequent investigation of the cooling associated with square-wave pulses of pressure applied to one end of a pipe that was closed at the other end. Although the relationship was not recognized at the time, this phenomenon shared much physics with Hofler's refrigerator. *Mikulin*'s [7.11] attempt at improvement in heat transfer in one part of this basic pulse-tube refrigerator

led unexpectedly to a dramatic improvement of performance, and *Radebaugh* [7.12] realized that the resulting *orifice* pulse-tube refrigerator was in fact a variant of the Stirling cryocooler.

Development of Stirling engines and refrigerators started in the 19th century, the engines at first as an alternative to steam engines [7.13]. Crankshafts, multiple pistons, and other moving parts seemed at first to be essential. An important modern chapter in their development began in the 1970s with the invention of *free-piston* Stirling engines and refrigerators, in which each piston's motion is determined by interactions between the piston's dynamics and the gas's dynamics rather than by a crankshaft and connecting rod. Analysis of such complex, coupled phenomena is complicated, because the oscillating motion causes oscillating pressure differences while simultaneously the oscillating pressure differences cause oscillating motion. *Ceperley* [7.14, 15] added an explicitly acoustic perspective to Stirling engines and refrigerators when he realized that the time phasing between pressure and motion oscillations in the heart of their regenerators is that of a traveling acoustic wave. Many years later, acoustic versions of such engines were demonstrated by *Yazaki* [7.16], *de Blok* [7.17, 18], and *Backhaus* [7.19], the last achieving a heat-to-acoustic energy efficiency comparable to that of other mature energy-conversion technologies.

7.2 Shared Concepts

7.2.1 Pressure and Velocity

For a monofrequency wave, oscillating variables can be represented with complex notation, such as

$$p(x, t) = p_m + \text{Re}\left[p_1(x)e^{i\omega t}\right] \tag{7.1}$$

for the pressure p, where p_m is the mean pressure, $\text{Re}(z)$ indicates the real part of z, $\omega = 2\pi f$ is the angular frequency, f is the frequency, and the complex number p_1 specifies both the amplitude and the time phase of the oscillating part of the pressure. For propagation in the x direction through a cross-sectional area A in a duct, p_1 is a function of x. In the simple lossless, uniform-area situation the sinusoidal x dependence can be found from the wave equation, which can be written with $i\omega$ substituted for time derivatives as

$$\omega^2 p_1 + c^2 \frac{d^2 p_1}{dx^2} = 0, \tag{7.2}$$

where $c^2 = (\partial p/\partial \rho)_s$ is the square of the adiabatic sound speed, with ρ the density and s the entropy. In thermoacoustics, intuition is well served by thinking of (7.2) as two first-order differential equations coupling two variables, pressure p_1 and the x component of volume velocity U_1,

$$\frac{dp_1}{dx} = -\frac{i\omega \rho_m}{A} U_1, \tag{7.3}$$

$$\frac{dU_1}{dx} = -\frac{i\omega A}{\rho_m c^2} p_1. \tag{7.4}$$

For a reasonably short length of duct Δx, these can be written approximately as

$$\Delta p_1 = -i\omega L\, U_1, \tag{7.5}$$

$$p_1 = -\frac{1}{i\omega C} \Delta U_1, \tag{7.6}$$

Table 7.1 The acoustic–electric analog. The basic building blocks of thermoacoustic energy-conversion devices are inertances L, compliances C, viscous and thermal resistances R_{visc} and R_{therm}, gains (or losses) G, and power transducers

Acoustic variables	Electric variables
Pressure p_1	Voltage
Volume velocity U_1	Current
Inertance L	Series inductance
Viscous resistance R_{visc}	Series resistance
Compliance C	Capacitance to ground
Thermal-hysteresis resistance R_{therm}	Resistance to ground
Gain/loss along temperature gradient, G	Proportionally controlled current injector
Stroke-controlled transducer	Current source
Force-controlled transducer	Voltage source

where

$$L = \frac{\rho_{\mathrm{m}} \Delta x}{A} \, , \tag{7.7}$$

$$C = \frac{A \Delta x}{\rho_{\mathrm{m}} c^2} \, . \tag{7.8}$$

As introduced in Chap. 6 (Physical Acoustics) (7.3) is the acoustic Euler equation, the inviscid form of the momentum equation. It describes the force that the pressure gradient must exert to overcome the gas's inertia. In the lumped-element form (7.5), the geometrical and gas-property aspects of the inertia of the gas in the duct are represented by the duct's inertance L. Similarly introduced in Chap. 6, (7.4) and (7.6) are, respectively, the differential and lumped-element versions of the continuity equation combined with the gas's adiabatic equation of state. These describe the compressibility of the gas in response to being squeezed along the x-direction. In the lumped-element form (7.6), the geometrical and gas-property aspects of the compressibility of the gas in the duct are represented by the duct's compliance C.

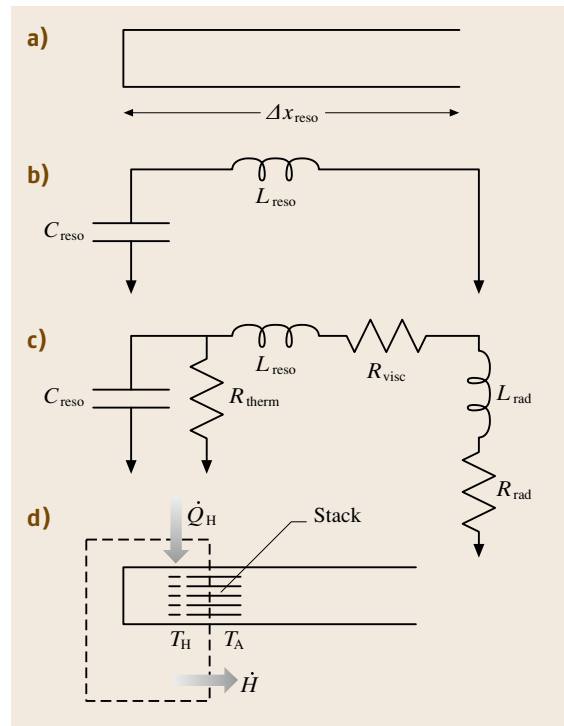
Accurate calculation of the wave in a long duct or a long series of ducts requires analytical or numerical integration of differential equations [7.1], but for the purposes of this chapter we will consider lumped-element approximations, because they are satisfactorily accurate for many estimates, they allow a *circuit model* representation of devices, and they facilitate intuition based on experience with alternating-current (AC) electrical circuits. Table 7.1 shows the analogy between acoustic devices and electrical circuits.


Fig. 7.1a–d Quarter-wavelength resonator. (**a**) A quarter-wavelength resonator: a tube closed at one end and open at the other. (**b**) A simple lossless lumped-element model of the resonator as a compliance C_{reso} in series with an inertance L_{reso}. (**c**) A more complicated lumped-element model, including thermal-hysteresis resistance R_{therm} in the compliance, viscous resistance R_{visc} in the inertance, and radiation impedance $R_{\mathrm{rad}} + i\omega L_{\mathrm{rad}}$. (**d**) An illustration of the first law of thermodynamics for a control volume, shown enclosed by the dashed line, which intersects the stack of a well-insulated standing-wave engine. In steady state, the thermal power $\dot{Q}_{\mathrm{H}}$ that flows into the system at the hot heat exchanger must equal the total power $\dot{H}$ that flows along the stack

For example, the closed–open resonator shown in Fig. 7.1a has a resonance frequency that can be calculated by setting its length Δx_{reso} equal to a quarter wavelength of sound; the result is $f_{\mathrm{reso}} = c/4\Delta x_{\mathrm{reso}}$. The simplest lumped-element approximation of the quarter-wavelength resonator is shown in Fig. 7.1b. We assign compliance C_{reso} to the left half of the resonator, because the compressibility of the gas is more important than its inertia in the left half, where $|p_1|$ is high and $|U_1|$ is low. Similarly, we assign inertance L_{reso} to the right half of the resonator, because the inertia is

more important in the right half where $|U_1|$ is high. Setting $\Delta x = \Delta x_{reso}/2$ in (7.7) and (7.8), and recalling that the resonance frequency of an electrical LC circuit is given by $\omega^2 = 1/LC$, we find $f_{reso} = c/\pi \Delta x_{reso}$, differing from the exact result only by a factor of $4/\pi$. Such accuracy will be acceptable for estimation and understanding in this chapter.

Circuit models can include as much detail as is necessary to convey the essential physics [7.1]. When the viscosity is included in the momentum equation, the lumped-element form becomes

$$\Delta p_1 = -\left(i\omega L + R_{visc}\right) U_1 , \qquad (7.9)$$

and when the thermal conductivity and a temperature gradient in the x direction are included in the continuity equation, the lumped-element form becomes

$$\Delta U_1 = -\left(i\omega C + \frac{1}{R_{therm}}\right) p_1 + G U_{in,1} . \qquad (7.10)$$

Figure 7.1c is a better model than Fig. 7.1b for the closed–open resonator of Fig. 7.1a, because it includes thermal-hysteresis resistance in the compliance, viscous resistance in the inertance, and the inertial and resistive radiation impedance at the open end. This model would yield reasonably accurate estimates for the free-decay time and quality factor of the resonator as well as its resonance frequency.

Ducts filled with porous media and having temperature gradients in the x-direction play a central role in thermoacoustic energy conversion [7.1]. The pore size is characterized by the hydraulic radius r_h, defined as the ratio of gas volume to gas–solid contact area. In a circular pore, r_h is half the circle's radius; in the gap between parallel plates, r_h is half the gap. The term *stack* is used for a porous medium whose r_h is comparable to the gas thermal penetration depth

$$\delta_{therm} = \sqrt{2k/\omega\rho_m c_p} , \qquad (7.11)$$

where k is the gas thermal conductivity and c_p is its isobaric heat capacity per unit mass, while a porous medium with $r_h \ll \delta_{therm}$ is known as a *regenerator*. The viscous penetration depth

$$\delta_{visc} = \sqrt{2\mu/\omega\rho_m} , \qquad (7.12)$$

where μ is the viscosity, is typically comparable to, but smaller than, the thermal penetration depth. If the distance between a particular mass of gas and the nearest solid wall is much greater than the penetration depths, thermal and viscous interactions with the wall do not affect that gas.

In such porous media with axial temperature gradients, the gain/loss term $G U_{in,1}$ in (7.10) is responsible for the creation of acoustic power by engines and for the thermodynamically required consumption of acoustic power by refrigerators. This term represents cyclic thermal expansion and contraction of the gas as it moves along and experiences the temperature gradient in the solid. In regenerators, the gain G is nearly real, and ΔU_1 caused by the motion along the temperature gradient is in phase with U_1 itself, because of the excellent

Table 7.2 Expressions for the lumped-element building blocks L, R_{visc}, C, R_{therm}, and $G U_1$, and for the total power $\dot{H}$, in the boundary-layer limit $r_h \gg \delta$ and in the small-pore limit $r_h \ll \delta$. The symbol "$\sim$" in the small-pore limit indicates that the numerical prefactor depends on the shape of the pore

	Boundary-layer limit	Small-pore limit
L	$\dfrac{\rho_m \Delta x}{A}$	$\sim \dfrac{\rho_m \Delta x}{A}$
R_{visc}	$\dfrac{\mu \Delta x}{A r_h \delta_{visc}}$	$\sim \dfrac{2\mu \Delta x}{A r_h^2}$
C	$\dfrac{A \Delta x}{\rho_m c^2} = \dfrac{A \Delta x}{\gamma p_m}$	$\dfrac{\gamma A \Delta x}{\rho_m c^2} = \dfrac{A \Delta x}{p_m}$
R_{therm}	$\dfrac{\rho_m^2 c_p^2 T_m r_h \delta_{therm}}{k A \Delta x}$	$\sim \dfrac{3 k T_m}{4\omega^2 r_h^2 A \Delta x}$
$G U_1$	$\dfrac{1-i}{2}\dfrac{1}{1+\sqrt{\sigma}}\dfrac{\delta_{therm}}{r_h}\dfrac{\Delta T_m}{T_m} U_1$	$\dfrac{\Delta T_m}{T_{in,m}} U_{in,1}$
$\dot{H}$	$\dfrac{\delta_{therm}}{4 r_h (1+\sigma)} \operatorname{Re}\left\{ \tilde{p}_1 U_1 \left[i\left(1+\sqrt{\sigma}\right) + \left(1-\sqrt{\sigma}\right)\right]\right\} - \dfrac{\delta_{therm}\rho_m c_p \left(1 - \sigma\sqrt{\sigma}\right) |U_1|^2}{4 r_h A \omega \left(1-\sigma^2\right)} \dfrac{\Delta T}{\Delta x}$ $+ \dot{E} - \left(Ak + A_{solid} k_{solid}\right) \dfrac{\Delta T}{\Delta x}$	$-A_{solid} k_{solid} \dfrac{\Delta T}{\Delta x}$

thermal contact between the gas in small pores and the walls of the pores. (Positive G indicates gain; negative G indicates loss.) In stacks, a nonzero imaginary part of G reflects imperfect thermal contact in the pores and the resultant time delay between the gas's cyclic motion along the solid's temperature gradient and the gas's thermal expansion and contraction.

Table 7.2 gives expressions for the impedances in the boundary-layer limit, $r_h \gg \delta_{therm}$ and $r_h \gg \delta_{visc}$, which is appropriate for large ducts, and in the small-pore limit appropriate for regenerators. Boundary-layer-limit entries are usefully accurate in stacks, in which $r_h \sim \delta$. General expressions for arbitrary r_h and many common pore shapes are given in [7.1].

The lumped-element approach summarized in Table 7.1 and the limiting expressions given in Table 7.2 are sufficient for most of this overview, but quantitatively accurate thermoacoustic analysis requires slightly more sophisticated techniques and includes more phenomena [7.1]. Every differential length dx of duct has dL, dC, dR_{visc}, and $d(1/R_{therm})$, and if $dT_m/dx \neq 0$ it also has dG, so a finite-length element is more analogous to an electrical transmission line than to a few lumped impedances. In addition to smoothly varying x dependencies for all variables, important phenomena include turbulence, which increases R_{visc} above the values given in Table 7.2; pore sizes which are in neither of the limits given in Table 7.2; nonlinear terms in the momentum and continuity equations, which cause frequency doubling, tripling, etc., so that the steady-state wave is a superposition of waves of many frequencies; and streaming flows caused by the wave itself. Many of these subjects are introduced in Chap. 8 (Nonlinear Acoustics). Thermoacoustics software that includes most or all of these phenomena and has the properties of several commonly used gases is available [7.20, 21].

For estimating the behavior of thermoacoustic devices, it is useful to remember some properties of common ideal gases [7.22]. The equation of state is

$$p = \frac{\rho R_{univ} T}{M} ,$$

(7.13)

where $R_{univ} = 8.3 \, \text{J/(mole K)}$ is the universal gas constant and M is the molar mass. The ratio of isobaric to isochoric specific heats, γ, is 5/3 for monatomic gases such as helium and 7/5 for diatomic gases such as nitrogen and air near ambient temperature, and appears in both the adiabatic sound speed

$$c = \sqrt{\frac{\gamma R_{univ} T}{M}}$$

(7.14)

and the isobaric heat capacity per unit mass

$$c_p = \frac{\gamma R_{univ}}{(\gamma - 1) M} .$$

(7.15)

The viscosity of many common gases (e.g., air, helium, and argon) is about

$$\mu \simeq (2 \times 10^{-5} \, \text{kg/m s}) \left(\frac{T}{300 \, \text{K}} \right)^{0.7} ,$$

(7.16)

and the thermal conductivity k can be estimated by remembering that the Prandtl number

$$\sigma = \frac{\mu c_p}{k}$$

(7.17)

is about 2/3 for pure gases, but somewhat lower for gas mixtures [7.23].

7.2.2 Power

In addition to ordinary acoustic power $\dot{E}$, the time-averaged thermal power $\dot{Q}$, total power $\dot{H}$, and exergy flux $\dot{X}$ are important in thermoacoustic energy conversion. These thermoacoustic powers are related to the simpler concepts of work, heat, enthalpy, and exergy that are encountered in introductory [7.22] and advanced [7.24] thermodynamics.

Just as acoustic intensity is the time-averaged product of pressure and velocity, acoustic power $\dot{E}$ is the time-averaged product of pressure and volume velocity. In complex notation,

$$\dot{E} = \frac{1}{2} \text{Re} \, (\tilde{p}_1 U_1) ,$$

(7.18)

where the tilde denotes complex conjugation. At transducers, it is apparent that acoustic power is closely related to thermodynamic work, because a moving piston working against gas in an open space with volume V transforms mechanical power to acoustic power (or vice versa) at a rate $f \oint p \, dV$, which is equal to (7.18) for sinusoidal pressure and motion. Resistances R dissipate acoustic power; the gain/loss term GU_1 in components with temperature gradients can either consume or produce acoustic power, and inertances L and compliances C neither dissipate nor produce acoustic power, but simply pass it along while changing p_1 or U_1.

Time-averaged thermal power $\dot{Q}$ (i.e., time-averaged heat per unit time) is added to or removed from the gas at heat exchangers, which are typically arrays of tubes, high-conductivity fins, or both, spanning a duct. Thermal power can be supplied to an engine by high-temperature combustion products flowing through

such tubes or by circulation of a high-temperature heat-transfer fluid through such tubes and a source of heat elsewhere. Thermal power is often removed from engines and refrigerators by ambient-temperature water flowing through such tubes.

Of greatest importance is the total time-averaged power

$$\dot{H} = \int \left[\frac{1}{2} \rho_{\mathrm{m}} \mathrm{Re} \left(\tilde{h}_1 u_1 \right) - k \frac{\mathrm{d}T_{\mathrm{m}}}{\mathrm{d}x} \right] \mathrm{d}A , \qquad (7.19)$$

based on the x component u of velocity and the enthalpy h per unit mass, which is the energy of most utility in fluid mechanics. Figure 7.1d uses a simple standing-wave engine (discussed more fully below) to illustrate the centrality of $\dot{H}$ to the first law of thermodynamics in thermoacoustics. The figure shows a heat exchanger and stack in a quarter-wavelength resonator. When heat is applied to the hot heat exchanger, the resonance is driven by processes (described below) in the stack. The dashed line in Fig. 7.1d encloses a volume whose energy must be constant when the engine is running in steady state. If the side walls of the engine are well insulated and rigid within that volume, then the only

energy flows per unit time into and out of the volume are $\dot{Q}_{\mathrm{H}}$ and whatever power flows to the right through the stack. We define the total power flow through the stack to be $\dot{H}$, and the first law of thermodynamics ensures that $\dot{H} = \dot{Q}_{\mathrm{H}}$ in this simple engine.

As shown in (7.19), the total power $\dot{H}$ is the sum of ordinary steady-state heat conduction (most importantly in the solid parts of the stack or regenerator and the surrounding duct walls) and the total power carried convectively by the gas itself. Analysis of the gas contribution requires spatial and temporal averaging of the enthalpy transport in the gas [7.4], and shows that the most important contributions are acoustic power flowing through the pores of the stack and a shuttling of energy by the gas that occurs because entropy oscillations in the gas are nonzero and have a component in phase with velocity. Remarkably, these two phenomena nearly cancel in the small pores of a regenerator.

Finally, the exergy flux $\dot{X}$ represents the rate at which thermodynamic work can be done, in principle, with unrestricted access to a thermal bath at ambient temperature [7.1, 24]. Exergy flux is sometimes used in complex systems to analyze sources of inefficiency according to location or process.

7.3 Engines

Implicit in Rayleigh's criterion [7.6] for spontaneous oscillations,

> *If heat be given to the air at the moment of greatest (density) or be taken from it at the moment of greatest rarefaction, the vibration is encouraged,*

is the existence of a vibration in need of encouragement, typically a resonance with a high quality factor. Today, we would express Rayleigh's criterion in either of two ways, depending on whether we adopt a Lagrangian perspective, focusing on discrete masses of gas as they move, or an Eulerian perspective, focusing on fixed locations in space as the gas moves past them. In the Lagrangian perspective, some of the gas in a thermoacoustic engine must experience $\oint p \, \mathrm{d}V > 0$, where V is the volume of an identified mass of gas. In the Eulerian perspective, part of the device must have $\mathrm{d}\dot{E}/\mathrm{d}x > 0$, arising from $\mathrm{Re}\left(\tilde{p}_1 \, \mathrm{d}U_1/\mathrm{d}x \right) > 0$ and the G term in (7.10).

By *engine* we mean a prime mover, i.e., something that converts heat to work or acoustic power.

We describe three varieties: standing-wave engines, traveling-wave engines, and pulse combustors.

7.3.1 Standing–Wave Engines

Continuing the quarter-wavelength example introduced in Fig. 7.1, Fig. 7.2 shows a simple standing-wave engine, of a type that is available as a classroom demonstration [7.25]. A stack and hot heat exchanger are near the left end of the resonator, and its right end is open to the air. When heat $\dot{Q}_{\mathrm{H}}$ is first applied to the hot heat exchanger, the heat exchanger and the adjacent end of the stack warm up, establishing an axial temperature gradient from hot to ambient in the stack. When the gradient is steep enough (as explained below), the acoustic oscillations start spontaneously, and grow in intensity as more heat is added and a steady state is approached. In the steady state, total power $\dot{H}$ equal to $\dot{Q}_{\mathrm{H}}$ (minus any heat leak to the room) flows through the stack, creating acoustic power, some of which is dissipated elsewhere in the resonator and some of which is radiated into the room. To the right of the stack, where an ambient-

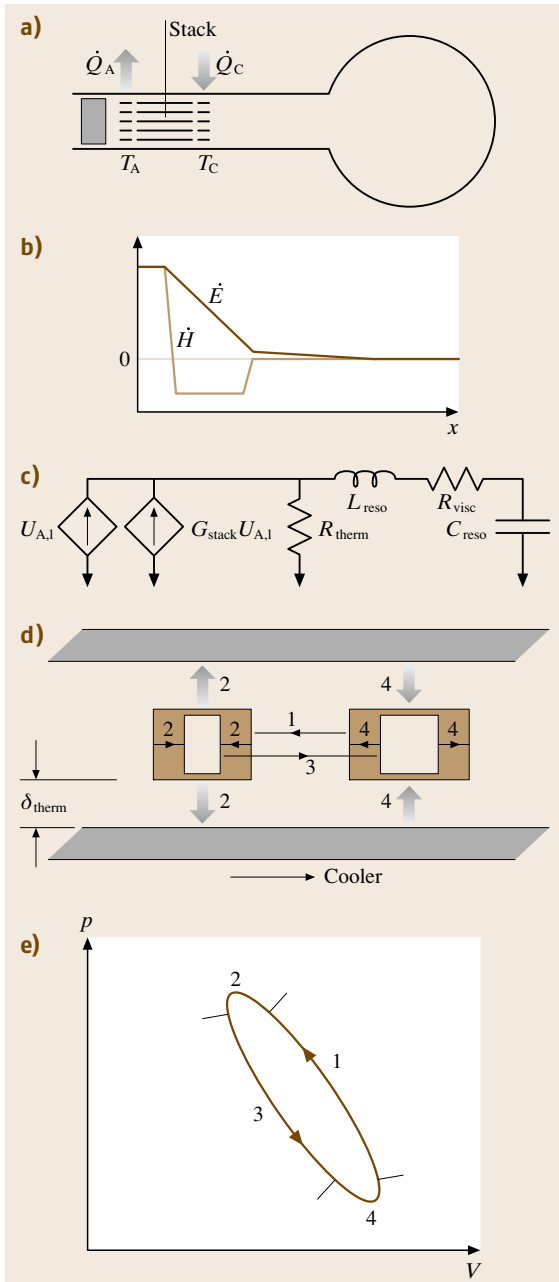
Heat $\dot{Q}_H$ is injected at the hot heat exchanger, and the device radiates acoustic power $\dot{E}_{rad}$ into the surroundings. **(b)** Total power flow $\dot{H}$ and acoustic power $\dot{E}$ as functions of position x in the device. Positive power flows in the positive-x direction. **(c)** Lumped-element model of the device. **(d)** Close-up view of part of one pore in the stack of **(a)**, showing a small mass of gas going through one full cycle, imagined as four discrete steps. *Thin arrows* represent motion, and *wide, open arrows* represent heat flow. **(e)** Plot showing how the pressure p and volume V of that small mass of gas evolve with time in a clockwise elliptical trajectory. *Tick marks* show approximate boundaries between the four numbered steps of the cycle shown in **(d)** ◄

Fig. 7.2e; the mass's temperature, entropy, density, and other properties also vary sinusoidally in time. However, for qualitative understanding of the processes, we describe the cycle as if it were a time series of four discrete steps, numbered 1–4 in Fig. 7.2d and Fig. 7.2e. In step 1, the gas is simultaneously compressed to a smaller volume and moved leftward by the wave a distance $2 |\xi_1|$, which is much smaller than the length Δx of the stack. While the gas is moving leftwards, the pressure changes by $2 |p_1|$ and the temperature would change by $2 |T_1| = 2T_m(\gamma - 1) |p_1| / \gamma p_m$ if the process were adiabatic. This suggests the definition of a critical temperature gradient

$$\nabla T_{crit} = |T_1| / |\xi_1| \ . \tag{7.20}$$

Thermal contact in the stack's large pores is imperfect, so step 1 is actually not too far from adiabatic. However, the temperature gradient imposed on the stack is greater than ∇T_{crit}, so the gas arrives at its new location less warm than the adjacent pore walls. Thus, in step 2, heat flows from the solid into the gas, warming the gas and causing thermal expansion of the gas to a larger volume. In step 3, the gas is simultaneously expanded to a larger volume and moved rightward by the wave. It arrives at its new location warmer than the adjacent solid, so in step 4 heat flows from the gas to the solid, cooling the gas and causing thermal contraction of the gas to a smaller volume. This brings it back to the start of the cycle, ready to repeat step 1.

Although the mass of gas under consideration returns to its starting conditions each cycle, its net effect on its surroundings is nonzero. First, its thermal expansion occurs at a higher pressure than its thermal contraction, so $\oint p \, dV > 0$: the gas does work on its sur-

temperature heat exchanger would often be located, the heat is carried rightward and out of this resonator by streaming-driven convection in the resonator, while fresh air at ambient temperature T_A streams inwards.


The most important process in the standing-wave engine is illustrated in Fig. 7.2d and Fig. 7.2e from a Lagrangian perspective. Figure 7.2d shows a greatly magnified view of a mass of gas inside one pore of the stack. The sinusoidal thermodynamic cycle of that mass of gas in pressure p and volume V is shown in

roundings, satisfying Rayleigh's criterion. This work is responsible for the positive slope of $\dot{E}$ versus x in the stack in Fig. 7.2b and is represented by the gain element $G_{\text{stack}}U_{\text{H},1}$ in Fig. 7.2c. All masses of gas within the stack contribute to this production of acoustic power; one can think of the steady-state operation as due to all masses of gas within the stack adding energy to the oscillation every cycle, to make up for energy lost from the oscillation elsewhere, e.g., in viscous drag in the resonator and acoustic radiation to the surroundings. Second, the gas absorbs heat from the solid at the left extreme of its motion, at a relatively warm temperature, and delivers heat to the solid farther to the right at a lower temperature. In this way, all masses of gas within the stack pass heat along the solid, down the temperature gradient from left to right; within a single pore, the gas masses are like members of a bucket brigade (a line of people fighting a fire by passing buckets of water from a source of water to the fire while passing empty buckets back to the source). This transport of heat is responsible for most of $\dot{H}$ inside the stack, shown in Fig. 7.2b.

This style of engine is called *standing wave* because the time phasing between pressure and motion is close to that of a standing wave. (If it were *exactly* that of a standing wave, $\dot{E}$ would have to be exactly zero at all x.) To achieve the time phasing between pressure and volume changes that is necessary for $\oint p\,dV > 0$, imperfect thermal contact between the gas and the solid in the stack is required, so that the gas can be somewhat thermally isolated from the solid during the motion in steps 1 and 3 but still exchange significant heat with the solid during steps 2 and 4. This imperfect thermal contact occurs because the distance between the gas and the nearest solid surface is of the order of δ_{therm}, and it causes R_{therm} to be significant, so standing-wave engines are inherently inefficient. Nevertheless, standing-wave engines are exceptionally simple. They include milliwatt classroom demonstrations like the illustration in Fig. 7.2, similar demonstrations with the addition of a water- or air-cooled heat exchanger at the ambient end of the stack, research engines [7.26, 27] up to several kW, and the Taconis and Sondhauss oscillations [7.5, 7]. Variants based on the same physics of intrinsically irreversible heat transfer include the *no-stack* standing-wave engine [7.28], which has two heat exchangers but no stack, and the Rijke tube [7.29], which has only a single, hot heat exchanger and uses a superposition of steady and oscillating flow of air through that heat exchanger to create $\oint p\,dV > 0$.

7.3.2 Traveling-Wave Engines

One variety of what acousticians call traveling-wave engines has been known for almost two centuries as a Stirling engine [7.13, 30, 31], and is illustrated in Fig. 7.3a,b,f,g. A regenerator bridges the gap between two heat exchangers, one at ambient temperature T_{A} and the other at hot temperature T_{H}; this assembly lies between two pistons, whose oscillations take the gas through a sinusoidal cycle that can be approximated as four discrete steps: compression, displacement rightward toward higher temperature, expansion, and displacement leftward toward lower temperature. For a small mass of gas in a single pore in the heart of the regenerator, the four steps of the cycle are illustrated in Fig. 7.3f. In step 1, the gas is compressed by rising pressure, rejecting heat to the nearby solid. In step 2, it is moved to the right, toward higher temperature, absorbing heat from the solid and experiencing thermal expansion as it moves. In step 3, the gas is expanded by falling pressure, and absorbs heat from the nearby solid. In step 4, the gas is moved leftward, toward lower temperature, rejecting heat to the solid and experiencing thermal contraction as it moves. The Stirling engine accomplishes $\oint p\,dV > 0$ in Fig. 7.3g for each mass of gas in the regenerator, and this work production allows the hot piston to extract more work from the gas in each cycle than the ambient piston delivers to the gas.

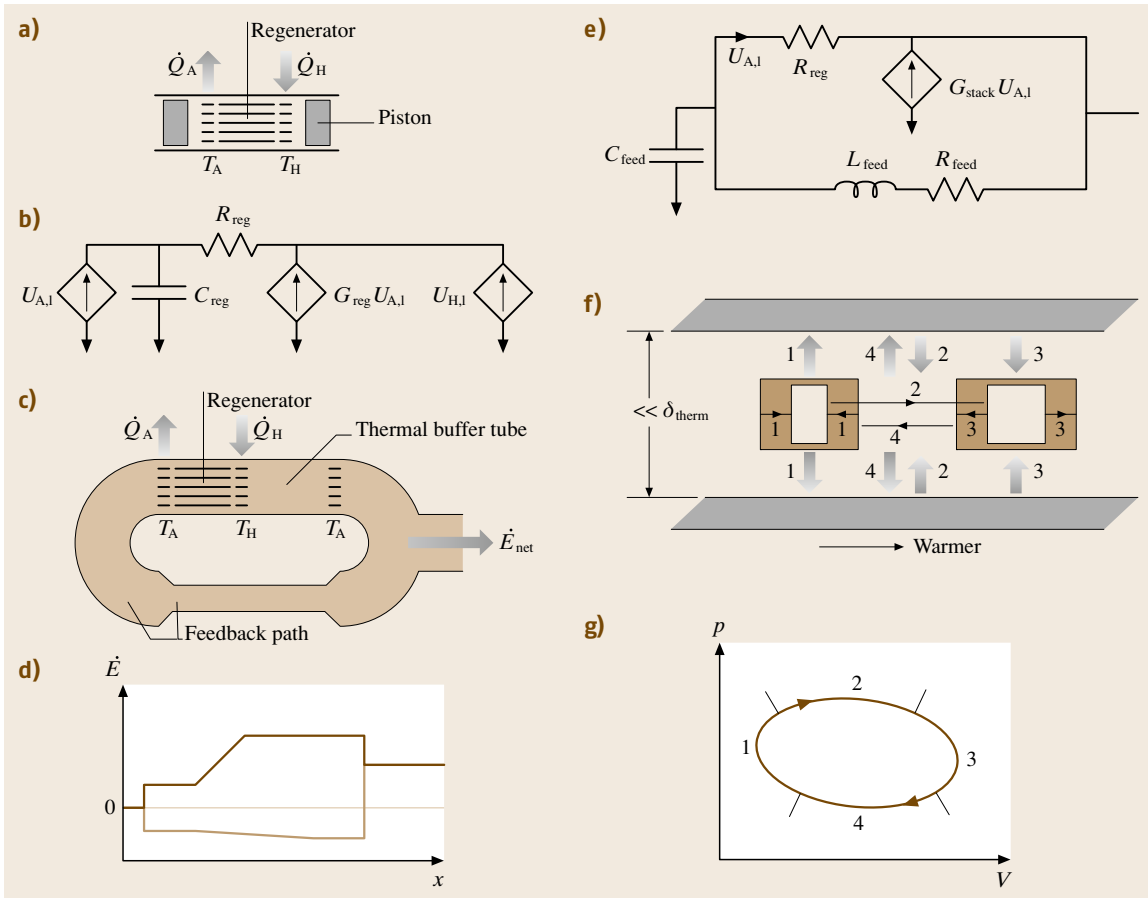
The similarities and differences between this process and the standing-wave process of Fig. 7.2 are instructive. Here, the pore size is $\ll \delta_{\text{therm}}$, so the thermal contact between the gas and the solid in the regenerator is excellent and the gas is always at the temperature of the part of the solid to which it is adjacent. Thus, the thermal expansion and contraction occur during the motion parts of the cycle, instead of during the stationary parts of the cycle in the standing-wave engine, and the pressure must be high during the rightward motion and low during the leftward motion to accomplish $\oint p\,dV > 0$. This is the time phasing between motion and pressure that occurs in a traveling wave [7.14, 15], here traveling from left to right. The small pore size maintains thermodynamically reversible heat transfer, so R_{therm} is negligible, and traveling-wave engines have inherently higher efficiency than standing-wave engines. One remaining source of inefficiency is the viscous resistance R_{visc} in the regenerator, which can be significant because the small pores necessary for thermal efficiency cause R_{visc} to be large. To minimize the impact of R_{visc}, traveling-wave engines have $|p_1| > \rho_{\text{m}}c\,|U_1|\,/A$, so the magnitude of the specific


Fig. 7.3a–g Traveling-wave engines. (**a**) A Stirling engine. From *left to right*, the ambient piston, the ambient heat exchanger, the regenerator, the hot heat exchanger, and the hot piston. Time-averaged thermal power $\dot{Q}_H$ is injected into the gas at hot temperature T_H, waste thermal power $\dot{Q}_A$ is removed at ambient temperature T_A, and net mechanical power is extracted by the two pistons. (**b**) Lumped-element model of the engine in (**a**). (**c**) Acoustic–Stirling hybrid engine, with the same processes as (**a**) in the regenerator and its two adjacent heat exchangers, but with additional acoustic components replacing the two pistons. (**d**) Acoustic power $\dot{E}$ as a function of position x in the device shown in (**c**). Positive power flows in the positive-x direction, so the bottom branch of the curve represents power flowing leftward through the feedback path. Total power $\dot{H}$ is not shown, because it is essentially zero in the regenerator and essentially identical to $\dot{E}$ in the open parts of the device. (**e**) Lumped-element model of the engine in (**c**). (**f**) Close-up view of part of one pore in the regenerator of (**a**) or (**c**), showing a small mass of gas going through one full cycle, imagined as four discrete steps. (**g**) Plot showing how the pressure p and volume V of that small mass of gas evolve with time in a clockwise elliptical trajectory. *Tick marks* show approximate boundaries between the four steps of the cycle shown in (**f**)

acoustic impedance $|z_{ac}| = |p_1| A / |U_1|$ is greater than that of a traveling wave.

The gain G listed in Table 7.2 takes on a particularly simple form in the tight-pore limit: $G_{reg} = \Delta T_m / T_{in,m}$. In the engine of Fig. 7.3a, the initial temperature is T_A, and $\Delta T_m = T_H - T_A$, so the extra volume velocity

that the lumped-element model injects at the right end of the regenerator is $U_{A,1} (T_H - T_A) / T_A$ and the total volume velocity at the right end of the regenerator is $U_{A,1} T_H / T_A$. Thus, the regenerator acts like an amplifier of volume velocity, with amplification T_H / T_A. If R_{reg} is small so that p_1 is nearly the same on both sides of the
Fig. 7.4a,b Pulsed combustor. **(a)** From *left to right*, check valve for admitting fresh air, fuel injection, combustion cavity, neck. **(b)** Lumped-element model of the combustor

regenerator, then the regenerator amplifies $\dot{E}$ by nearly T_H/T_A.

Figure 7.3c–e illustrates a thermoacoustic–Stirling hybrid engine [7.16–19], in which the processes in the regenerator and its adjacent heat exchangers are the same as in the Stirling engine and in Fig. 7.3f and Fig. 7.3g, but with acoustic elements replacing the Stirling engine's pistons. The toroidal topology of the thermoacoustic–Stirling hybrid allows some of the acoustic power that leaves the hot end of the regenerator to be fed back to the ambient end of the regenerator, eliminating the need for the Stirling engine's ambient piston. The feedback path has an inertance L_{feed} (with an unavoidable but small viscous resistance R_{feed}) and a compliance C_{feed}, with $1/L_{feed}C_{feed} \gg \omega^2$ and with ωL_{feed} significantly smaller than the regenerator viscous resistance R_{reg}. These choices let the $L_{feed}C_{feed}$ feedback path boost p_1 as acoustic power flows through it, providing the extra p_1 needed to drive U_1 into the regenerator at its ambient end.

The Stirling engine in Fig. 7.3a has a hot piston, which extracts acoustic power from the gas. From the hot piston's face, mechanical power flows from T_H to T_A along a temperature gradient in a moving part, either the piston itself or a connecting rod. In the thermoacoustic–Stirling hybrid engine of Fig. 7.3c, this thermal isolation function is accomplished by the thermal buffer tube, a thermally stratified column of moving gas. A well-designed thermal buffer tube passes acoustic power with little attenuation and has $\dot{H} \simeq \dot{E}$, so almost no thermal power flows from hot to ambient along the tube and little thermal power need be removed at the auxiliary heat exchanger at the thermal buffer tube's ambient end. Minimizing streaming and attendant heat convection in thermal buffer tubes, which

otherwise causes $\dot{H} \neq \dot{E}$, is a topic of current research in thermoacoustics.

Traditional Stirling engines are used for propulsion in some submarines [7.32] and for auxiliary power in boats [7.33], and are under development for residential cogeneration of electricity and space heating [7.34], concentrated solar electricity generation, and nuclear generation of electricity for spacecraft [7.35]. In most of these applications, piston motion is converted to electricity via relative motion of wires and permanent magnets, either with a rotary alternator for crankshaft-coupled pistons or a linear alternator (reminiscent of a loudspeaker) for resonant *free-piston* configurations. Thermoacoustic-Stirling hybrid engines are under consideration for small-scale natural-gas liquefaction [7.26, 36] and for spacecraft power [7.37]. In the former case, acoustic power is fed directly from the engine to cryogenic acoustic refrigerators, without transduction to electrical power.

7.3.3 Combustion

In the standing-wave and traveling-wave engines, Rayleigh's criterion $\oint p \, dV > 0$ is met with volume changes that arise from temperature changes; those temperature changes, in turn, arise from thermal contact between the gas and nearby solid surfaces. In pulsed combustion, the volume changes needed to meet Rayleigh's criterion arise from both temperature and mole-number changes, which in turn are due to time-dependent chemical reactions whose rate is controlled by the time-dependent pressure or time-dependent velocity [7.38, 39].

Figure 7.4 illustrates one configuration in which pulsed combustion can occur. At the closed end of a closed–open resonator, a check valve periodically lets fresh air into the resonator and a fuel injector adds fuel, either steadily or periodically. If the rate of the exothermic chemical reaction increases with pressure (e.g., via the temperature's adiabatic dependence on pressure), positive dV occurs when p is high, meeting Rayleigh's criterion. A four-step diagram of the process, resembling Fig. 7.2d and Fig. 7.3f, is not included in Fig. 7.4 because the process is fundamentally not cyclic: a given mass of gas does not return to its starting conditions, but rather each mass of fresh-air–fuel mixture burns and expands only once.

Combustion instabilities can occur in rockets, jet engines, and gas turbines, with potentially devastating consequences if the pressure oscillations are high enough to cause structural damage. Much of the

literature on thermoacoustic combustion is devoted to understanding such oscillations and using active or passive means to prevent them. However, some devices such as high-efficiency residential gas-fired furnaces deliberately use pulsed combustion as illustrated in Fig. 7.4 to pump fresh air in and exhaust gases out of the combustor. This eliminates the need to leave the exhaust gases hot enough for strong chimney convection, so a larger fraction of the heat of combustion can be delivered to the home.

7.4 Dissipation

The dissipative processes represented above by R_{visc} and R_{therm} occur whenever gas-borne sound interacts with solid surfaces. Figure 7.5 illustrates this in the case of a short length dx of a large-radius duct with no axial temperature gradient. The origin of the viscous dissipation of acoustic power is viscous shear within the viscous penetration depth δ_{visc}, as shown in Fig. 7.5c. Most people find viscous dissipation intuitively plausible, imagining the frictional dissipation of mechanical energy when one surface rubs on another. More subtle is the thermal relaxation of acoustic power, illustrated in Fig. 7.5d,e. Gas is pressurized nearly adiabatically in step 1, then shrinks during thermal equilibration with the surface in step 2. It is depressurized nearly adiabatically in step 3, and then thermally expands during thermal equilibration with the surface during step 4. As shown in Fig. 7.5e, the net effect is $\oint p \, dV < 0$: the gas absorbs acoustic power from the wave, because the contraction occurs at high pressure and the expansion at low pressure. To avoid a hopelessly cluttered illustration, Fig. 7.5d shows the thermal-hysteresis process superimposed on the left–right oscillating motion in steps 1 and 3, but the thermal-hysteresis process occurs even in the absence of such motion.

Fig. 7.5a–e Boundary dissipation in acoustic waves. (**a**) A duct with no temperature gradient, with one short length dx identified. (**b**) Each length dx has inertance, viscous resistance, compliance, and thermal hysteresis resistance. (**c**) The dissipation of acoustic power by viscous resistance is due to shear in the gas within roughly δ_{visc} of the boundary, here occurring during steps 1 and 3 of the cycle. (**d**) and (**e**) The dissipation of acoustic power by thermal relaxation hysteresis occurs within roughly δ_{therm} of the boundary. Gas is pressurized nearly adiabatically in step 1, then shrinks during thermal equilibration with the surface in step 2. It is depressurized nearly adiabatically in step 3, and then thermally expands during thermal equilibration with the surface during step 4. The net effect is that the gas absorbs acoustic power from the wave ▶
Differentiating (7.18) with respect to x shows that the dissipation of acoustic power in the duct in length dx is given by

$$dĖ = \frac{1}{2} \operatorname{Re} \left(\frac{d\tilde{p}_1}{dx} U_1 + \tilde{p}_1 \frac{dU_1}{dx} \right) dx , \qquad (7.21)$$

and examination of (7.10) and (7.9) associates R_{visc} with the first term and R_{therm} with the second term. Expressions for R_{visc} and R_{therm} in the boundary-layer approximation are given in Table 7.2, and allow the expression of (7.21) in terms of the dissipation of acoustic power per unit of surface area S:

$$dĖ = \frac{1}{4} \rho_m |u_1|^2 \omega \delta_{visc} \, dS$$
$$+ \frac{1}{4} (\gamma - 1) \frac{|p_1|^2}{\rho_m c^2} \omega \delta_{therm} \, dS , \qquad (7.22)$$

where $u_1 = U_1/A$ is the velocity outside the boundary layer, parallel to the surface. Each term in this result expresses a dissipation as the product of a stored energy per unit volume $\rho_m |u_1|^2 /4$ or $(\gamma - 1) |p_1|^2 /4\rho_m c^2$, a volume $\delta_{visc} \, dS$ or $\delta_{therm} \, dS$, and a rate ω.

7.5 Refrigeration

7.5.1 Standing-Wave Refrigeration

The thermal-hysteresis process described in Sect. 7.4 consumes acoustic power without doing anything thermodynamically useful. Standing-wave refrigeration consumes acoustic power via a similar process, but achieves a thermodynamic purpose: pumping heat up a temperature gradient, either to remove heat from a temperature below ambient or (less commonly) to deliver heat to a temperature above ambient. Figure 7.6a–c shows a standing-wave refrigerator of the style pioneered by *Hofler* [7.8, 9] and recently studied by *Tijani* [7.40]. At the left end, a driver such as a loudspeaker injects acoustic power $Ė$, which flows rightward through the stack, causing a leftward flow of total energy $Ḣ$.

The most important process in a standing-wave refrigerator is illustrated in Fig. 7.6d,e from a Lagrangian perspective. Figure 7.6d shows a greatly magnified view of a small mass of gas inside one pore of the stack. The sinusoidal thermodynamic cycle of that mass of gas in pressure p and volume V is shown in Fig. 7.6e; the mass's temperature, entropy, density, and other properties also vary sinusoidally in time. However, for qualitative understanding of the processes, we describe them as if they are a time series of four discrete steps, numbered 1–4 in Fig. 7.6d,e. In step 1, the gas is simultaneously compressed to a smaller volume and moved leftward by the wave. Thermal contact is imperfect in the pores of a stack, so during step 1 the gas experiences a nearly adiabatic temperature increase due to the pressure increase that causes the compression. It arrives at its new location warmer than the adjacent solid because the temperature gradient in the solid is less than the critical temperature gradient ∇T_{crit} defined in (7.20). Thus,

in step 2, heat flows from the gas into the solid, cooling the gas and causing thermal contraction of the gas to a smaller volume. In step 3, the gas is simultaneously expanded to a larger volume and moved rightward by the wave. It arrives at its new location cooler than the adjacent solid, so in step 4 heat flows from the solid to the gas, warming the gas and causing thermal expansion of the gas to a larger volume. This brings it back to the start of the cycle, ready to repeat step 1.

The mass of gas shown in Fig. 7.6d has two time-averaged effects on its surroundings. First, the gas absorbs heat from the solid at the right extreme of its motion, at a relatively cool temperature, and delivers heat to the solid farther to the left at a higher temperature. In this way, all masses of gas within the stack pass heat along the solid, up the temperature gradient from right to left – within a single pore, the gas masses are like members of a bucket brigade passing water. This provides the desired refrigeration or heat-pumping effect. If the left heat exchanger is held at ambient temperature, as shown in Fig. 7.6a, then the system is a refrigerator, absorbing thermal power $Q̇_C$ from an external load at the right heat exchanger at one end of the bucket brigade at T_C, as waste thermal power is rejected to an external ambient heat sink at the other end of the bucket brigade at T_A. (The system functions as a heat pump if the right heat exchanger is held at ambient temperature; then the left heat exchanger is above ambient temperature.) Second, the gas's thermal expansion occurs at a lower pressure than its thermal contraction, so $\oint p \, dV < 0$: the gas absorbs work from its surroundings. This work is responsible for the negative slope of $Ė$ versus x in the stack in Fig. 7.6b and is represented by the gain element $G_{stack} U_{A,1}$ in Fig. 7.6c. All masses of gas within the stack contribute to this con-

sumption of acoustic power, which must be supplied by the driver.

As in the standing-wave engine, the time phasing between pressure and motion in the standing-wave refrigerator is close to that of a standing wave. Imperfect thermal contact between the gas and the solid in the stack is required to keep the gas rather isolated from the solid during the motion in steps 1 and 3 but still able to exchange significant heat with the solid during steps 2 and 4. This imperfect thermal contact occurs because the distance between the gas and the nearest solid surface is of the order of δ_{therm}, and it causes R_{therm} to be significant, so standing-wave refrigerators are inherently inefficient.

7.5.2 Traveling–Wave Refrigeration

Several varieties of traveling-wave refrigerator are commercially available or under development. At their core is a regenerator, in which the process shown in Fig. 7.7a,b operates. In step 1 of the process, the gas is compressed by rising pressure, rejecting heat to the nearby solid. In step 2, it is moved to the right, toward lower temperature, rejecting heat to the solid and experiencing thermal contraction as it moves. In step 3, the gas is expanded by falling pressure, and absorbs heat from the nearby solid. In step 4, the gas is moved leftward, toward higher temperature, absorbing heat from the solid and experiencing thermal expansion as it moves. The heat transfers between gas and solid in steps 2 and 4 are equal and opposite, so the net thermal effect of each mass of gas on the solid is due to steps 1 and 3, and is to move heat from right to left, up the temperature gradient. As before, the motion of any particular mass of gas is less than the length of the regenerator, so the heat is passed bucket-brigade fashion from the cold end of the regenerator to the ambient end. Each mass of gas absorbs $\oint p \, \mathrm{d}V$ of acoustic power from the wave as shown in Fig. 7.7b, because the thermal contraction in step 2 oc-

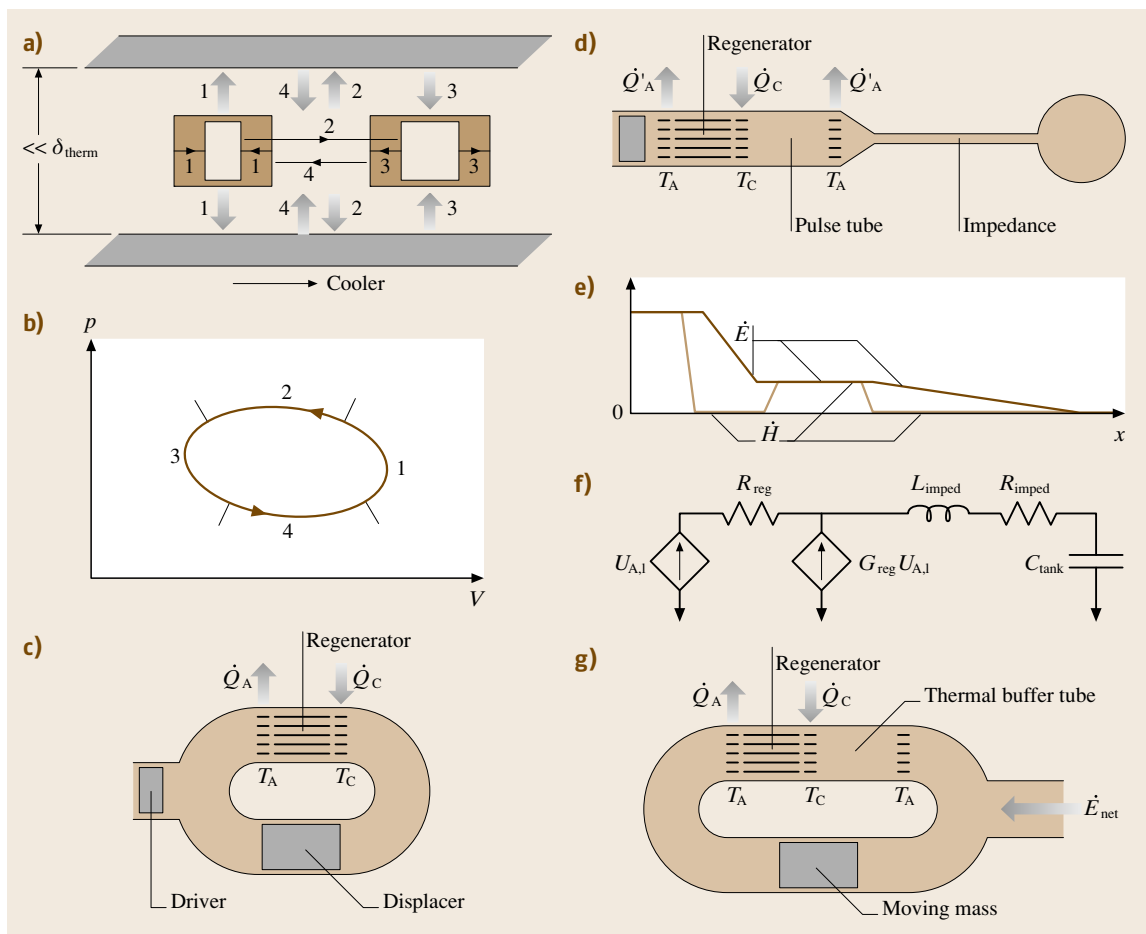
Fig. 7.6a–e A standing-wave refrigerator. (**a**) From *left to right*, a piston, ambient heat exchanger, stack, cold heat exchanger, tube, and tank. Acoustic power is supplied to the gas by the piston to maintain the standing wave, and results in thermal power $\dot{Q}_{\mathrm{C}}$ being absorbed by the gas from a load at cold temperature T_{C} while waste thermal power $\dot{Q}_{\mathrm{A}}$ is rejected by the gas to an external heat sink at ambient temperature T_{A}. (**b**) Total power flow $\dot{H}$ and acoustic power $\dot{E}$ as functions of position x in the device. Positive power flows in the positive-x direction. (**c**) Lumped-element model of the device. (**d**) Close-up view of part of one pore in the stack of (**a**), showing a small mass of gas going through one full cycle, imagined as four discrete steps. (**e**) Plot showing how the pressure p and volume V of that small mass of gas evolve with time in a counter-clockwise elliptical trajectory. *Tick marks* show approximate boundaries between the four steps of the cycle shown in (**d**) ◄


Fig. 7.7a–g Traveling-wave refrigerators. (**a**) Close-up view of part of one pore in the regenerator of a traveling-wave refrigerator, showing a small mass of gas going through one full cycle, imagined as four discrete steps. (**b**) Plot showing how the pressure p and volume V of that small mass of gas evolve with time in a counterclockwise elliptical trajectory. Tick marks show approximate boundaries between the four steps of the cycle shown in (**a**). (**c**) A traditional Stirling refrigerator. From *left to right*, the ambient driver piston; the ambient heat exchanger, the regenerator, and the cold heat exchanger are across the top; the displacer is below. Time-averaged thermal power $\dot{Q}_C$ is removed by the gas from an external heat load at cold temperature T_C, while waste thermal power $\dot{Q}_A$ is rejected by the gas to an external heat sink at ambient temperature T_A and net acoustic power is supplied to the gas by the driver. (**d**) Pulse-tube refrigerator, with the same processes as (**c**) in the regenerator and its two adjacent heat exchangers, but with the displacer replaced by acoustic components. (**e**) Acoustic power $\dot{E}$ and total power $\dot{H}$ as functions of position x in the device shown in (**d**). Positive power flows in the positive-x direction. (**f**) Lumped-element model of the pulse-tube refrigerator in (**d**). (**g**) A refrigerator in which the thermal-buffer function and moving-mass function of (**c**)'s displacer are in two separate components

curs at high pressure and the thermal expansion in step 4 occurs at low pressure. The small pore size, $r_h \ll \delta_{therm}$, maintains thermodynamically reversible heat transfer, so R_{therm} is negligible, and traveling-wave refrigerators have an inherently high efficiency. Acoustically, the process shown in Fig. 7.7a represents acoustic power

traveling from left to right through the regenerator, and being partly consumed as it goes. Different varieties of traveling-wave refrigerator use different methods to create the necessary amplitudes and relative time phasing of motion and pressure to achieve this acoustic power flow through the regenerator.

The traditional Stirling refrigerator [7.41] uses two moving pistons, which can be either crankshaft-coupled in a configuration like that of the engine in Fig. 7.3a or of the *free-displacer* variety shown in Fig. 7.7c. In the free-displacer Stirling refrigerator (often called *free piston*), the solid displacer moves in response to the gas-pressure forces on it, without linkage to any external motor. Its area and mass are selected to give its motion the desired amplitude and time phase [7.30]. Acoustic power is transmitted through it, from right to left, so that the acoustic power that flows out of the right end of the regenerator is fed through the displacer to the left, added to the acoustic power supplied by the driver, and injected into the left end of the regenerator. The displacer must be a thermal insulator, because its right end is at T_C and its left end at T_A. Crankshaft-coupled Stirling refrigerators were used in the 19th century to keep beef cold on the long sea voyage from South America to Britain. Free-piston Stirling cryocoolers are in common use today for cooling infrared sensors in military night-vision goggles and surveillance satellites, and a free-piston Stirling refrigerator built into a small, portable *ice chest* is commercially available at low cost for picnics [7.42].

The pulse-tube refrigerator [7.12], illustrated in Fig. 7.7d–f, uses only one piston. The acoustic power flowing out of the right end of the regenerator is absorbed in an acoustic impedance, instead of being fed back to the left end of the regenerator. This gives the pulse-tube refrigerator a lower efficiency than the Stirling refrigerator, but for cryogenic applications the reduced efficiency is a small price to pay for the elimination of the Stirling's cold moving part. The lumped-element model of the impedance and adjacent tank shown in Fig. 7.7f correctly suggests that proper design of L_{imped}, R_{imped}, and C_{tank} can create almost any desired ratio of $|U_1|$ to $|p_1|$ and time phasing between U_1 and p_1 at the right end of the regenerator. The desired impedance is often achieved by choosing $R_{visc} \sim \omega L_{imped} \gg 1/\omega C_{imped}$. The so-called pulse tube, and the ambient heat exchanger to its right, thermally isolate the cold heat exchanger from the dissipation of acoustic power in the impedance, just as the thermal buffer tube performs that function in Fig. 7.3c. Pulse-tube refrigerators are in common use today in satellites [7.43] and are under development for many other applications such as small-scale oxygen liquefaction and cooling superconducting equipment.

Another variation of the theme is shown in Fig. 7.7g, where the thermal buffer tube and the moving mass perform the thermal-insulation and inertial functions of the free displacer of Fig. 7.7c in two separate locations [7.44, 45]. This variety is under development for commercial food refrigeration [7.46]. Yet another variety [7.47] replaces the inertial moving mass of Fig. 7.7g with inertial moving gas, similar to the thermoacoustic–Stirling hybrid engine of Fig. 7.3c.

7.6 Mixture Separation

In thermoacoustic mixture separation, acoustic power causes the components of a gas mixture to separate [7.48, 49]. The process is loosely analogous to the pumping of heat through the stack in a standing-wave refrigerator. The expenditure of acoustic power results in an increase in the Gibbs free energy of the mixture's components, and the efficiency of the process is comparable to that of some other practical separation processes [7.50].

Figure 7.8 illustrates the process for a binary gas mixture of heavy and light molecules, whose motions are indicated by filled and open arrows, respectively. The motion of the molecules in steps 1 and 3 of the process is bulk motion of the gas, and the motion during steps 2 and 4 is thermal diffusion, in which light molecules diffuse toward higher temperature and heavy molecules diffuse toward lower temperature. In step 1, the gas in the center of the pore moves leftward and its pressure rises, so its temperature rises nearly adiabatically. Trapped by the viscous boundary layer near the wall of the tube is some other gas that does not move and whose thermal contact with the pore wall keeps its temperature from rising. During step 2, the temperature difference between the central gas and the peripheral gas causes light atoms to diffuse into the center and heavy atoms to diffuse out of the center, enriching the center in light atoms. Bulk motion rightward in step 3 carries this central light-enriched gas to the right. Simultaneously, the pressure drops in step 3, and hence the central temperature drops nearly adiabatically. Thus thermal diffusion in step 4 pulls heavy molecules into the center and drives light molecules out of the center, leaving the center enriched in heavy molecules so that the leftward motion dur-
Fig. 7.8 Close-up view of part of one pore in a thermo-acoustic mixture separator, showing a small body of gas in the center of the pore going through one full cycle, imagined as four discrete steps, and exchanging mass with neighboring, immobile gas. The *gray* and *brown arrows* in steps 2 and 4 signify thermally driven diffusion of light and heavy molecules between the central gas and the peripheral gas close to the wall of the pore. In steps 1 and 3, the *gray* and *brown arrows* signify bulk motion of the gas, without diffusion ◀

ing step 1 carries heavy-enriched gas leftward. The net effect of steps 1 and 3 is to move heavy molecules leftward and light molecules rightward. The process takes place when the mole-fraction gradient is less than a critical gradient, analogous to the critical tempera-ture gradient below which standing-wave refrigeration occurs.

As is evident from Fig. 7.8, the process works best for tubes with r_h somewhat larger than δ_{therm} and δ_{visc}.

However, unlike the description above, the process ac-tually works best near traveling-wave phasing, because two 45° phase shifts were ignored in that description. High separation purities require long tubes, and high mole fluxes will require many passages in parallel, per-haps in structures similar to the stacks of standing-wave engines and refrigerators.

In a 2 m-long tube, a 50–50 helium–argon mixture has been separated to yield 70% helium, 30% argon at one end and 30% helium, 70% argon at the other end; and a measurable enrichment of ^{22}Ne from natural neon has been achieved [7.51].

8. Nonlinear Acoustics in Fluids

Werner Lauterborn, Thomas Kurz, Iskander Akhatov

At high sound intensities or long propagation distances at sufficiently low damping acoustic phenomena become nonlinear. This chapter focuses on nonlinear acoustic wave properties in gases and liquids. The origin of nonlinearity, equations of state, simple nonlinear waves, nonlinear acoustic wave equations, shock-wave formation, and interaction of waves are presented and discussed. Tables are given for the nonlinearity parameter B/A for water and a range of organic liquids, liquid metals and gases. Acoustic cavitation with its nonlinear bubble oscillations, pattern formation and sonoluminescence (light from sound) are modern examples of nonlinear acoustics. The language of nonlinear dynamics needed for understanding chaotic dynamics and acoustic chaotic systems is introduced.

Part B | 8

Acoustics belongs to those areas of physics, where nonlinear phenomena were observed first [8.1–4]. All musical instruments including the human voice belong to nonlinear acoustics as they generate sound waves. Generation processes are necessarily nonlinear as new phenomena appear that are not proportional to already existing ones. Propagation, on the other hand, is normally linear for propagation distances that are not too long and only shows nonlinear effects at high intensities (finite amplitudes). As mankind started to speak early in its history and also is supposed to have made music early on, nonlinear acoustics belongs to the oldest parts of science. Sorge in 1745 and Tartini in 1754 report that, when two tones of frequency f_1 and $f_2 > f_1$ are presented to the ear at high intensities, the difference frequency $f_2 - f_1$ is additionally heard. For a long time there was a de-

bate of whether these tones are generated in the ear or are already present in the propagating medium. Today we know that in this case the ear generates the difference frequency. But we also know today that a difference frequency can be generated in a nonlinear medium during the propagation of a sound wave [8.5]. This fact is used in the parametric acoustic array to transmit and receive highly directed low-frequency sound beams. Under suitable circumstances generally a series of combination frequencies $f_{mn} = m f_1 + n f_2$ with $m, n = 0, \pm 1, \pm 2, \ldots$ can be generated.

A special case is a single harmonic wave of frequency f propagating in a nonlinear medium. It generates the higher harmonics $f_m = m f$. This leads to a steepening of the wave and often to the formation of shock waves. Further nonlinear effects are

subsumed under the heading of self-action, as changes in the medium are produced by the sound wave that act back on the wave. Examples are self-focusing and self-transparency.

Also forces may be transmitted to the medium setting it into translatory motion, as exemplified by the phenomenon of acoustic streaming. Acoustic radiation forces may be used to levitate objects and keep them in traps. In other areas of science this is accomplished by electrical or electromagnetical forces (ion traps, optical tweezers). Nonlinear acoustics is the subject of many books, congress proceedings and survey articles [8.1–4, 6–21].

In liquids a special phenomenon occurs, the rupture of the medium by sound waves, called *acoustic cavitation* [8.22–30]. It leads to the formation of cavities or cavitation bubbles with very peculiar dynamical behavior [8.31–35] and gives rise to a plethora of special effects bringing acoustics in contact with almost any

other of the natural sciences. Via the dynamics of the cavities or bubbles, particles and contaminations can be removed from surfaces (ultrasonic cleaning [8.36–39]), light emission may occur upon bubble collapse (sonoluminescence [8.40–47]) and chemical reactions may be initiated (sonochemistry [8.48–51]).

The general theory of nonlinear dynamics has led to the interesting finding that nonlinear dynamical systems may not just show the simple scenario of combination tones and self-actions, but complicated dynamics resembling stochastic behavior. This is known as deterministic chaos or, in the context of acoustics, *acoustic chaos* [8.52–55].

Nonlinear acoustics also appears in wave propagation in solids. In this case, further, entirely different, nonlinear phenomena appear, because not only longitudinal but also transverse waves are supported that may interact. A separate chapter of the Handbook is devoted to this topic.

8.1 Origin of Nonlinearity

All acoustic phenomena necessarily become nonlinear at high intensities. This can be demonstrated when looking at the propagation of a harmonic sound wave in air. In Fig. 8.1 a harmonic sound wave is represented graphically. In the upper diagram the sound pressure p is plotted versus location x. The static pressure p_{stat} serves as a reference line around which the sound pressure oscillates. This pressure p_{stat} is normally about 1 bar. In the lower diagram the density distribution is given schematically in a grey scale from black to white for the pressure range of the sound wave.

Assuming that the sound pressure amplitude is increased steadily, a point is reached where the sound pressure amplitude attains p_{stat} giving a pressure of zero in the sound pressure minimum. It is impossible to go below this point as there cannot be less than zero
Fig. 8.2 Symmetric nonlinear expansion and compression laws compared to a linear law (*straight dotted line*) with soft spring behavior (*solid line*) and hard spring behavior (*dashed line*)

Fig. 8.1 Graphical representation of a harmonic sound wave

air molecules in the minimum. However, air can be compressed above the pressure p_{stat} just by increasing the force. Therefore, beyond a sound pressure amplitude $p = p_{stat}$ no harmonic wave can exist in a gas; it must become nonlinear and contain harmonics. The obvious reason for the nonlinearity in this case (a gas) is the asymmetry in density between compression and expansion.

However, symmetric expansion and compression also lead to nonlinear effects when they are not proportional to an applied force or stress. Figure 8.2 shows two types of symmetric nonlinearities: hard and soft spring behavior upon expansion and compression with reference to a linear law represented by a straight (dotted) line. An example of hard spring behavior is a string on a violin, because the average string tension increases with increasing wave amplitude. It is intrinsically symmetric, as positive and negative elongation are equivalent. An example of soft spring behavior is the

pendulum, also having a symmetric force–displacement law in a homogeneous gravitational field. An example of an asymmetric mixed type, but with overall soft spring behavior, is a bubble in water oscillating in a sound field. Upon compression a bubble shows hard spring behavior, upon expansion soft spring behavior in such a way that soft spring behavior dominates.

Acoustic waves also show nonlinear behavior in propagation, even without any nonlinearity of the medium. This is due to the cumulative effect of distortion of the wave profile by convection, introduced by the particle velocity that itself constitutes the sound wave. Larger particle velocities propagate faster than slower ones, leading to distortion of an acoustic wave upon propagation. This property can be considered an intrinsic self-action of the wave, leading to an intrinsic nonlinearity in acoustics. This aspect of nonlinearity is discussed below in the context of the coefficient of nonlinearity β.

8.2 Equation of State

The compression and expansion of a medium is described by the equation of state, for which an interrelation between three quantities is needed, usually the pressure p, density ϱ and specific entropy s (entropy per unit mass). Often the variation of entropy can be neglected in acoustic phenomena and the calculations can be carried out at constant entropy; the equations are then called isentropic. A basic quantity in acoustics, the velocity of sound or sound speed c of a medium, is related to these quantities,

$$c^2 = \left(\frac{\partial p}{\partial \varrho}\right)_s . \tag{8.1}$$

The subscript index s indicates that the entropy is to be held constant to give the isentropic velocity of sound.

Even an ideal gas is nonlinear, because it obeys the isentropic equation of state

$$p = p_0 \left(\frac{\varrho}{\varrho_0}\right)^\gamma , \tag{8.2}$$

where p_0 and ϱ_0 are the reference (ambient) pressure and density, respectively, and

$$\gamma = \frac{c_p}{c_v} , \tag{8.3}$$

where γ is the quotient of the specific heat c_p at constant pressure and c_v that at constant volume.

An empirical formula, the Tait equation, is often used for liquids, obviously constructed similarly to the

equation of state of the ideal gas

$$p = P \left(\frac{\varrho}{\varrho_0}\right)^{\gamma_L} - Q \tag{8.4}$$

or

$$\frac{p+Q}{p_\infty + Q} = \left(\frac{\varrho}{\varrho_0}\right)^{\gamma_L} . \tag{8.5}$$

The two quantities Q and γ_L have to be fitted to the experimental pressure–density curve. For water $\gamma_L = 7$, $P = p_\infty + Q = 3001$ bar and $Q = 3000$ bar are used. (Note that γ_L in the Tait equation is not the quotient of the specific heats.)

There is another way of writing the equation of state where the pressure is developed as a Taylor series as a function of density and entropy [8.19]. In the isentropic case it reads [8.56–58]

$$p - p_0 = \left(\frac{\partial p}{\partial \varrho}\right)_{s,\varrho=\varrho_0} (\varrho - \varrho_0)$$
$$+ \frac{1}{2}\left(\frac{\partial^2 p}{\partial \varrho^2}\right)_{s,\varrho=\varrho_0} (\varrho - \varrho_0)^2 + \dots \tag{8.6}$$

or

$$p - p_0 = A\frac{\varrho - \varrho_0}{\varrho_0} + \frac{B}{2}\left(\frac{\varrho - \varrho_0}{\varrho_0}\right)^2$$
$$+ \frac{C}{6}\left(\frac{\varrho - \varrho_0}{\varrho_0}\right)^3 + \dots \tag{8.7}$$

with

$$A = \varrho_0 \left(\frac{\partial p}{\partial \varrho} \right)_{s,\varrho=\varrho_0} = \varrho_0 c_0^2 \ , \tag{8.8}$$

$$B = \varrho_0^2 \left(\frac{\partial^2 p}{\partial \varrho^2} \right)_{s,\varrho=\varrho_0} \ , \tag{8.9}$$

$$C = \varrho_0^3 \left(\frac{\partial^3 p}{\partial \varrho^3} \right)_{s,\varrho=\varrho_0} \ . \tag{8.10}$$

Here, c_0 is the velocity of sound under the reference conditions. The higher-order terms of the Taylor series can normally be neglected.

8.3 The Nonlinearity Parameter *B/A*

To characterize the strength of the nonlinearity of a medium properly the relation of B to the linear coefficient A is important [8.66, 67]. Therefore A and B are combined as B/A, the *nonlinearity parameter*, a pure number.

It is easy to show that for an ideal gas we get from (8.2) together with (8.8) and (8.9)

$$\frac{B}{A} = \gamma - 1 \ , \tag{8.11}$$

so that $B/A = 0.67$ for a monatomic gas (for example noble gases) and $B/A = 0.40$ for a diatomic gas (for example air). Moreover, it can be shown that

$$\frac{C}{A} = (\gamma - 1)(\gamma - 2) \tag{8.12}$$

for an ideal gas, leading to negative values.

When there is no analytic expression for the equation of state recourse must be made to the direct definitions of A and B and appropriate measurements. From the expressions for A (8.8) and B (8.9) a formula for the nonlinearity parameter B/A is readily found,

$$\frac{B}{A} = \frac{\varrho_0}{c_0^2} \left(\frac{\partial^2 p}{\partial \varrho^2} \right)_{s,\varrho=\varrho_0} \ . \tag{8.13}$$

To determine B/A from this formula, as well as the density and sound velocity the variation in pressure effected by an isentropic (adiabatic) variation in density

has to be measured. Due to the small density variations with pressure in liquids and the error-increasing second derivative this approach is not feasible.

Fortunately, equivalent expressions for B/A have been found in terms of more easily measurable quantities, namely the variation of sound velocity with pres-

sure and temperature. Introducing the definition of the sound velocity the following formulation chain holds: $(\partial^2 p/\partial \varrho^2)_{s,\varrho=\varrho_0} = (\partial c^2/\partial \varrho)_{s,\varrho=\varrho_0} = 2c_0(\partial c/\partial \varrho)_{s,\varrho=\varrho_0} = 2c_0(\partial c/\partial p)_{s,p=p_0}(\partial p/\partial \varrho)_{s,\varrho=\varrho_0} = 2c_0^3(\partial c/\partial p)_{s,p=p_0}$. Insertion of this result into (8.9) yields

$$B = \varrho_0^2 \left(\frac{\partial^2 p}{\partial \varrho^2} \right)_{s,\varrho=\varrho_0} = 2\varrho_0^2 c_0^3 \left(\frac{\partial c}{\partial p} \right)_{s,p=p_0} \tag{8.14}$$

and into (8.13) results in

$$\frac{B}{A} = 2\varrho_0 c_0 \left(\frac{\partial c}{\partial p} \right)_{s,p=p_0} . \tag{8.15}$$

Here B/A is essentially given by the variation of sound velocity c with pressure p at constant entropy s. This quantity can be measured with sound waves when the pressure is varied sufficiently rapidly but still smoothly (no shocks) to maintain isentropic conditions.

Equation (8.15) can be transformed further [8.67, 76] using standard thermodynamic manipulations and definitions. Starting from $c = c(p, t, s = \text{const.})$ it follows that $dc = (\partial c/\partial p)_{T,p=p_0} dp + (\partial c/\partial p)_{p,T=T_0} dT$ or

$$\left(\frac{\partial c}{\partial p} \right)_{s,p=p_0} = \left(\frac{\partial c}{\partial p} \right)_{T,p=p_0}$$
$$+ \left(\frac{\partial c}{\partial T} \right)_{p,T=T_0} \left(\frac{\partial T}{\partial p} \right)_{s,p=p_0} . \tag{8.16}$$

From the general thermodynamic relation $T ds = c_p dT - (\alpha_T/\varrho) T dp = 0$ for the isentropic case the relation

$$\left(\frac{\partial T}{\partial p} \right)_{s,p=p_0} = \frac{T_0 \alpha_T}{\varrho_0 c_p} . \tag{8.17}$$

follows, where

$$\alpha_T = \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_{p,T=T_0} = -\frac{1}{\varrho_0} \left(\frac{\partial \varrho}{\partial T} \right)_{p,T=T_0} \tag{8.18}$$

is the isobaric volume coefficient of the thermal expansion and c_p is the specific heat at constant pressure of the liquid. Insertion of (8.17) into (8.16) together with (8.15) yields

$$\frac{B}{A} = 2\varrho_0 c_0 \left(\frac{\partial c}{\partial p} \right)_{T,p=p_0}$$
$$+ 2 \frac{c_0 T_0 \alpha_T}{\varrho_0 c_p} \left(\frac{\partial c}{\partial T} \right)_{p,T=T_0} . \tag{8.19}$$

This form of B/A divides its value into an isothermal (first) and isobaric (second) part. It has been found that the isothermal part dominates.

For liquids, B/A mostly varies between 2 and 12. For water under normal conditions it is about 5. Gases (with B/A smaller than one, see before) are much less nonlinear than liquids. Water with gas bubbles, however, may have a very large value of B/A, strongly depending on the volume fraction, bubble sizes and frequency of the sound wave. Extremely high values on the order of 1000 to 10 000 have been reported [8.77, 78]. Tables with values of B/A for a large number of materials can be found in [8.66, 67].

As water is the most common fluid two tables (Tables 8.1 and 8.2) of B/A for water as a function of temperature and pressure are given (see also [8.79]). Two more tables (Tables 8.3 and 8.4) list B/A values for organic liquids and for liquid metals and gases, both at atmospheric pressure.

8.4 The Coefficient of Nonlinearity β

In a sound wave the propagation velocity dx/dt of a quantity (pressure, density) as observed by an outside stationary observer changes along the wave. As shown by *Riemann* [8.80] and *Earnshaw* [8.81], for a forward-traveling plane wave it is given by

$$\frac{dx}{dt} = c + u , \tag{8.20}$$

c being the sound velocity in the medium without the particle velocity u introduced by the sound wave. The sound velocity c is given by (8.1), $c^2 = (\partial p/\partial \varrho)_s$, and contains the nonlinear properties of the medium. It is customary to incorporate this nonlinearity in (8.20) in

a second-order approximation as [8.82, 83]

$$\frac{dx}{dt} = c_0 + \beta u , \tag{8.21}$$

introducing a *coefficient of nonlinearity* β. Here c_0 is the sound velocity in the limit of vanishing sound pressure amplitude. The coefficient of nonlinearity β is related to the parameter of nonlinearity B/A as derived from the Taylor expansion of the isentropic equation of state [8.7] via

$$\beta = 1 + \frac{B}{2A} . \tag{8.22}$$

The number 1 in this equation comes from the u in (8.20). For an ideal gas [8.2] $B/A = \gamma - 1$ (8.11) and thus

$$\beta = 1 + \frac{\gamma - 1}{2} = \frac{\gamma + 1}{2} \ . \tag{8.23}$$

The quantity β is made up of two terms. They can be interpreted as coming from the nonlinearity of the medium (second term) and from convection (first term).

This convective part is inevitably connected with the sound wave and is an inherent (kinematic) nonlinearity that is also present when there is no nonlinearity in the medium (thermodynamic nonlinearity) [8.83].

The introduction of β besides B/A is justified because it not only incorporates the nonlinearity of the medium, as does B/A, but also the inherent nonlinearity of acoustic propagation. The deformation of a wave as it propagates is described by β.

8.5 Simple Nonlinear Waves

In the linear case the wave equation is obtained for the quantities pressure $p - p_0$, density $\varrho - \varrho_0$ and each component of the particle velocity $\mathbf{u} - \mathbf{u}_0$ (p_0 ambient pressure, ρ_0 ambient density, $\mathbf{u}_0$ constant (mean) velocity, often $\mathbf{u}_0 = 0$) from the equations for a compressible fluid. In the spatially one-dimensional case, when φ denotes one of the perturbational quantities, one gets

$$\varphi_{tt} - c_0^2 \varphi_{xx} = 0 \ , \tag{8.24}$$

where c_0 is the propagation velocity of the perturbation, given by $c_0^2 = (\partial p / \partial \varrho)_{s, \varrho = \varrho_0}$, and the subscripts t and x denote partial differentiation with respect to time and space, respectively. A simple way to incorporate the influence of nonlinearities of the medium without much mathematical effort consists in considering the propagation velocity no longer as constant. One proceeds as follows. As nonlinear waves do not superpose interaction-free, and because waves running in opposite directions (*compound waves*) would cause problems, the wave equation above is written as

$$\left(\frac{\partial}{\partial t} - c_0 \frac{\partial}{\partial x} \right) \left(\frac{\partial}{\partial t} + c_0 \frac{\partial}{\partial x} \right) \varphi = 0 \tag{8.25}$$

and only one part, i.e. a wave running in one direction only, called a *progressive* or *traveling wave*, is taken, for instance:

$$\varphi_t + c_0 \varphi_x = 0 \ , \tag{8.26}$$

a forward, i.e. in the $+x$-direction, traveling wave. The general solution of this equation is

$$\varphi(x, t) = f(x - c_0 t) \ . \tag{8.27}$$

The function f can be a quite general function of the argument $x - c_0 t$. A nonlinear extension can then be written as

$$\varphi_t + v(\varphi) \varphi_x = 0 \ , \tag{8.28}$$

whereby now the propagation velocity $v(\varphi)$ is a function of the perturbation φ. In this way the simplest propagation equation for nonlinear waves is obtained; it already leads to the problem of breaking waves and the occurrence of shock waves.

A solution to the nonlinear propagation equation (8.28) can be given in an implicit way,

$$\varphi(x, t) = f[x - v(\varphi)t] \ , \tag{8.29}$$

as can be proven immediately by insertion. This seems of little use for real calculations of the propagation of the perturbation profile. However, the equation allows for a simple physical interpretation, that is, that the quantity φ propagates with the velocity $v(\varphi)$. This leads to a simple geometric construction for the propagation of a perturbation (Fig. 8.3).

To this end the *initial-value problem* (restricted to progressive waves in one direction only and cutting out one wavelength traveling undisturbed) is considered,

$$\varphi(x, t = 0) = f(\xi) \ . \tag{8.30}$$

To each ξ value belongs a value $f(\xi)$ that propagates with the velocity $v[f(\xi)]$

$$\left. \frac{\mathrm{d}x}{\mathrm{d}t} \right|_f = v[f(\xi)] \tag{8.31}$$

or

$$x = \xi + v[f(\xi)]t \ . \tag{8.32}$$

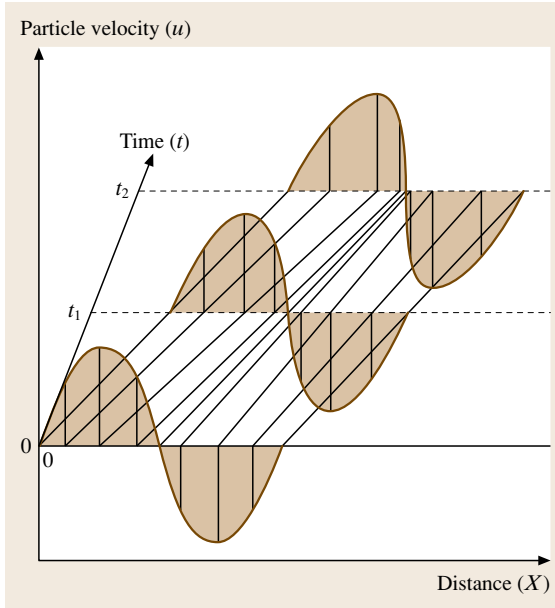
This is the equation of a straight line in the (x, t)-plane that crosses $x(t = 0) = \xi$ with the derivative $v(f(\xi))$. Along this straight line φ stays constant. These lines are called *characteristics* and were introduced by *Riemann* [8.80]. In this way the solution of (hyperbolic) partial differential equations can be transformed to the solution of ordinary differential equations, which is of great advantage numerically.


Fig. 8.3 Characteristics and the construction of the waveform for nonlinear progressive wave propagation (after *Beyer* [8.3])

Fig. 8.4 Form of the sound wave at the launch site (*lower*) and after three meters of propagation (*upper*) in a tube filled with air. Measurement done at the Drittes Physikalisches Institut, Göttingen

The initial-value problem (8.30) is difficult to realize experimentally. Normally a sound wave is launched by a loudspeaker or transducer vibrating at some location. For one-dimensional problems a piston in a tube is a good approximation to a *boundary condition* $\varphi(x = 0, t) = g(t)$, when the finite amplitude of the piston can be neglected. (The piston cannot vibrate and stay stationary at $x = 0$.) Also, simple waves are produced from the outset without the complications of compound waves and their mixed flow being produced by an initial condition in which the perturbation values are given in space at a fixed time ($t = 0$) [8.84].

The steepening of a wavefront has been measured this way by sending a strong sound wave through a nonlinear medium and monitoring the wave with a microphone. Figure 8.4 shows the steepening of a sound wave in air after three meters of propagation. The wave at a frequency of 2 kHz was guided inside a plastic tube. As the horizontal axis denotes time, the steepening is on the left flank, the flank of the propagation direction that passes the microphone first.

8.6 Lossless Finite-Amplitude Acoustic Waves

How elastic waves propagate through a medium is a main topic in acoustics and has been treated to various degrees of accuracy. The starting point is a set of equations from fluid mechanics. For plane acoustic waves in nondissipative fluids this set is given by three equations: the equation of continuity, the Euler equation and the equation of state,

$$\frac{\partial \varrho}{\partial t} + u \frac{\partial \varrho}{\partial x} + \varrho \frac{\partial u}{\partial x} = 0 \,, \tag{8.33}$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{1}{\varrho} \frac{\partial p}{\partial x} = 0 \,, \tag{8.34}$$

$$p = p(\varrho) \,. \tag{8.35}$$

The quantities ϱ, u and p are the density of the fluid, the particle velocity and the pressure, respectively. The three equations can be condensed into two in view of the unique relation between p and ϱ. From (8.35) it follows that $\partial p / \partial x = c^2 \partial \varrho / \partial x$ and with (8.34) we obtain

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{c^2}{\varrho} \frac{\partial \varrho}{\partial x} = 0 \,, \tag{8.36}$$

where c is the sound velocity of the medium. The following relation between u and ϱ holds for forward-

traveling waves [8.80, 81] (see also [8.1])

$$\frac{\partial u}{\partial x} = \frac{c}{\varrho}\frac{\partial \varrho}{\partial x} \tag{8.37}$$

giving the propagation equation

$$\frac{\partial u}{\partial t} + (u+c)\frac{\partial u}{\partial x} = 0 \tag{8.38}$$

for a plane progressive wave without dissipation. The propagation velocity c (here for the particle velocity we use u) due to the nonlinearity of the medium to a second-order approximation follows from $u + c = c_0 + \beta u$ (see (8.21) and (8.22)) as

$$c = c_0 + \frac{B}{2A}u . \tag{8.39}$$

The corresponding relation for an ideal gas,

$$c = c_0 + \frac{\gamma - 1}{2}u , \tag{8.40}$$

is exact.

Comparing the propagation equation (8.38) with (8.28) where a general function $v(\varphi)$ was introduced for the nonlinear propagation velocity with φ a disturbance of the medium, for instance u, the function can now be specified as

$$v(u) = u + c(u) . \tag{8.41}$$

This finding gives rise to the following degrees of approximation.

The linear approximation

$$v(u) = c_0 , \tag{8.42}$$

the kinematic approximation, where the medium is still treated as linear,

$$v(u) = u + c_0 , \tag{8.43}$$

the quadratic approximation

$$v(u) = u + c_0 + \frac{B}{2A}u = c_0 + \beta u , \tag{8.44}$$

and so forth, as further approximations are included. From these equations it follows that $v(u=0) = c_0$ regardless of the degree of approximation. This means that the wave as a whole propagates with the linear velocity c_0; its form, however, changes. This holds true as long as the form of the wave stays continuous. Also, there is no truly linear case. Even if the medium is considered linear the kinematic approximation reveals that there is a distortion of the wave. Only in the limit of infinitely small amplitude of the particle velocity u

(implying also an infinitely small amplitude of acoustic pressure $p - p_0$) does a disturbance propagate linearly. There is no finite amplitude that propagates linearly. This is different from the transverse waves that appear in solids, for instance, and in electromagnetic wave propagation. In these cases, linear waves of finite amplitude exist, because they do not experience distortion due to a kinematic term u.

A solution to the propagation equation (8.38) to a second-order approximation,

$$\frac{\partial u}{\partial t} + (c_0 + \beta u)\frac{\partial u}{\partial x} = 0 , \tag{8.45}$$

can be given in implicit form as for (8.28)

$$u(x, t) = f[x - (c_0 + \beta u)t] . \tag{8.46}$$

For the boundary condition (source or signaling problem)

$$u(x = 0, t) = u_a \sin \omega t \tag{8.47}$$

the implicit solution reads with the function $f = u_a \sin(\omega t - kx)$ and $k = \omega/v(u)$:

$$u(x, t) = u_a \sin\left(\omega t - \frac{\omega}{c_0 + \beta u}x\right) , \tag{8.48}$$

or, when expanding and truncating the denominator in the argument of the sine wave

$$u(x, t) = u_a \sin\left[\omega t - \frac{\omega}{c_0}\left(1 - \beta\frac{u}{c_0}\right)x\right] . \tag{8.49}$$

With the wave number

$$k_0 = \frac{\omega}{c_0} , \tag{8.50}$$

$\omega = 2\pi f$, where f is the frequency of the sound wave, and

$$M_a = \frac{u_a}{c_0} , \tag{8.51}$$

is the initial (peak) acoustic Mach number, the solution reads:

$$\frac{u(x, t)}{u_a} = \sin\left[\omega t - k_0 x\left(1 + \beta M_a\frac{u(x, t)}{u_a}\right)\right] . \tag{8.52}$$

This implicit solution can be turned into an explicit one, as shown by Fubini in 1935 [8.85] (see also [8.82, 86–88]), when the solution is expanded in a Fourier series ($\varphi = \omega t - k_0 x$) later

$$\frac{u}{u_a} = \sum_{n=1}^{\infty} B_n \sin(n\varphi) \tag{8.53}$$

with

$$B_n = \frac{1}{\pi} \int_0^{2\pi} \frac{u}{u_a} \sin(n\varphi) \mathrm{d}\varphi . \tag{8.54}$$

After insertion of (8.52) into (8.54) and some mathematical operations the Bessel functions J_n of the first kind of order n yield

$$B_n = \frac{2}{\beta M_a k_0 n x} J_n(\beta M_a k_0 n x) . \tag{8.55}$$

The explicit solution then reads

$$\frac{u(x, t)}{u_a}$$
$$= \frac{2}{\beta M_a k_0} \sum_{n=1}^{\infty} \frac{J_n(\beta M_a k_0 n x)}{n x} \sin n(\omega t - k_0 x) . \tag{8.56}$$

The region of application of this solution is determined by $\beta M_a k_0$. The inverse has the dimensions of a length

$$x_\perp = \frac{1}{\beta M_a k_0} , \tag{8.57}$$

and is called the *shock distance*, because at this distance the wave develops a vertical tangent, the beginning of becoming a shock wave. The solution is valid only up to this distance $x = x_\perp$.

To simplify the notation the dimensionless normalized distance σ may be introduced

$$\sigma = \frac{x}{x_\perp} . \tag{8.58}$$

The Fubini solution then reads

$$\frac{u}{u_a} = 2 \sum_{n=1}^{\infty} \frac{J_n(n\sigma)}{n\sigma} \sin n(\omega t - k_0 x) . \tag{8.59}$$

When a pure spatial sinusoidal wave is taken as the initial condition [8.87]

$$u(x, t = 0) = u_a \sin k_0 x , \tag{8.60}$$

the implicit solution reads

$$u(x, t) = u_a \sin k_0 [x - (c_0 + \beta u)t] , \tag{8.61}$$

or, with the acoustic Mach number $M_a = u_a/c_0$ as before,

$$\frac{u(x, t)}{u_a} = \sin k_0 \left[x - c_0 t \left(1 + \beta M_a \frac{u(x, t)}{u_a} \right) \right] . \tag{8.62}$$

When again doing a Fourier expansion the explicit solution emerges,

$$\frac{u(x, t)}{u_a} = \frac{2}{\beta M_a k_0 c_0} \sum_{n=1}^{\infty} (-1)^{n+1}$$
$$\times \frac{J_n(\beta M_a k_0 c_0 n t)}{n t} \sin n k_0 (x - c_0 t) . \tag{8.63}$$

The region of application is determined by $\beta M_a k_0 c_0$. The inverse has the dimension of time

$$t_\perp = \frac{1}{\beta M_a k_0 c_0} . \tag{8.64}$$

Fig. 8.5 Waveform of the Fubini solution (8.66) at the shock formation time $t_\perp$ ($\sigma_t = 1$) for the initial-value problem. λ is the wavelength of the sound wave
Fig. 8.6 Waveform of the Fubini solution (8.59) at the shock distance $x_\perp$ ($\sigma = 1$) for the source problem. T is the period of the sound wave. Compare the experiment in Fig. 8.4
Fig. 8.7 Growth of the harmonics upon propagation for the Fubini solution (8.59) (source problem) at different normalized distances σ up to the shock distance

Fig. 8.8 Growth of the first five spectral components B_n of a plane wave as a function of the normalized distance σ for the Fubini solution. The *inset* gives the waveform at $\sigma = 1$ for the source problem, T being the period of the sound wave (after [8.87])

The quantity $t_\perp$ is called the *shock formation time*, because at this time the wave develops a vertical tangent. The solution is valid only up to this time $t = t_\perp$. To simplify the notation the dimensionless normalized time σ_t may be introduced

$$\sigma_t = \frac{t}{t_\perp} . \qquad (8.65)$$

The Fubini solution then reads

$$\frac{u(x,t)}{u_a} = 2 \sum_{n=1}^{\infty} (-1)^{n+1} \frac{J_n(n\sigma_t)}{n\sigma_t} \sin nk_0(x - c_0 t) . \qquad (8.66)$$

When comparing $t_\perp$ with $x_\perp$, the relation

$$c_0 t_\perp = x_\perp \qquad (8.67)$$

is noted. This means that the shock distance is reached in the shock formation time when the wave travels at the linear sound speed c_0. This is in agreement with the earlier observation that the wave travels at the linear sound speed regardless of the nonlinearity as long as the wave stays continuous. In the case of the quadratic approximation the range in space and time for which this property holds can be quantified explicitly.

To give an impression of what the wave looks like when having propagated the shock distance $x_\perp$ in the shock formation time $t_\perp$, Fig. 8.5 shows two wavelengths at the shock formation time $t_\perp$ and Fig. 8.6 shows two periods at the shock distance $x_\perp$.

A set of spectra of the waveform for different normalized distances σ is plotted in Fig. 8.7 for the source problem, where all harmonics have positive value. The growth of the harmonics B_n (8.55) in the spectrum on the way to the shock distance is visualized. Similar plots have been given by *Fubini Ghiron* [8.85]. A plot of the first five Fourier coefficients B_n as a function of σ is given in Fig. 8.8. In the inset the waveform at the shock distance $x_\perp$ is plotted for two periods of the wave.

The solutions (8.59) and (8.66) are given for the particle velocity u. This quantity is difficult to measure. Instead, in experiments, pressure is the variable of

choice. When combining the equation of state for an ideal gas with the definition of sound velocity (see (8.2) and (8.1)) a relation between pressure and sound velocity is obtained

$$\frac{p}{p_0} = \left(\frac{c}{c_0}\right)^{2\gamma/(\gamma-1)} . \tag{8.68}$$

Insertion of the expression $c = c_0 + [(\gamma-1)/2]u$ (8.40) yields

$$p = p_0 \left(1 + \frac{\gamma-1}{2}\frac{u}{c_0}\right)^{2\gamma/(\gamma-1)} . \tag{8.69}$$

Inserting the solution for the particle velocity u into this equation will give the pressure p and the acoustic pressure $p - p_0$. This operation is easy to perform numerically but not analytically. However, the approximation scheme for moderate-strength finite-amplitude waves, $|u/c_0| \ll 1$, is only consistent when expanding (8.69) and taking only the linear part. This leads to the *linear* relation between acoustic pressure $p - p_0$ and acoustic particle velocity u (local linearity property for weak nonlinearity) [8.84, 89]

$$p - p_0 = \varrho_0 c_0 u , \tag{8.70}$$

where the expression $\varrho_0 c_0$ is known as the impedance. When the boundary condition (8.47) is rewritten as

$$(p - p_0)(x = 0, t) = \varrho_0 c_0 u_a \sin \omega t$$
$$= (p_a - p_0) \sin \omega t \tag{8.71}$$

with $p_a - p_0 = \varrho_0 c_0 u_a$, the relation

$$\frac{p - p_0}{p_a - p_0} = \frac{u}{u_a} \tag{8.72}$$

is obtained. The normalized Fubini solution then reads in terms of the acoustic pressure for the boundary-value or source problem

$$\frac{p - p_0}{p_a - p_0} = 2\sum_{n=1}^{\infty} \frac{J_n(n\sigma)}{n\sigma} \sin n(\omega t - k_0 x) , \tag{8.73}$$

and for the initial-value problem

$$\frac{p - p_0}{p_a - p_0} = 2\sum_{n=1}^{\infty} (-1)^{n+1} \frac{J_n(n\sigma_t)}{n\sigma_t} \sin n k_0(x - c_0 t) . \tag{8.74}$$

The steepening of acoustic waves upon propagation may occur in musical wind instruments, e.g., the trombone [8.90]. It has been shown that depending on the playing level the emitted sound waves steepen when going from piano to fortissimo, even up to shock waves. Indeed, the brightness (the *metallic* sound) of loudly played brass instruments (in particular the trumpet and the trombone as opposed to the saxhorns) is attributed to the increasing harmonic content connected with wave steepening, as exemplified in Fig. 8.7.

8.7 Thermoviscous Finite-Amplitude Acoustic Waves

Because of the inherently nonlinear nature of acoustic wave propagation steep gradients of physical quantities (pressure, density, temperature, ...) inevitably appear after some time of traveling, after which losses can no longer be neglected. In the steep gradients brought about by nonlinearity, linear phenomena that could be neglected before become important [8.91]. These are losses by *diffusive* mechanisms, in particular viscosity and heat conduction, and spreading phenomena by *dispersive* mechanisms as in frequency dispersion. When losses balance nonlinearity, the characteristic waveforms of *shock waves* appear, when frequency dispersion balances nonlinearity the characteristic form of *solitons* appear. Both are given about equal space in this treatment. The inclusion of thermoviscous losses is treated in this chapter, the inclusion of frequency dispersion, small in pure air and water, but large in water with bubbles, is treated in Sect. 8.10 on liquids containing bubbles.

The extension of (8.45) when thermoviscous losses are included as a small effect leads to the Burgers equation

$$\frac{\partial u}{\partial t} + (c_0 + \beta u)\frac{\partial u}{\partial x} = \frac{1}{2}\delta\frac{\partial^2 u}{\partial x^2} . \tag{8.75}$$

Here δ, comprising the losses, has been called the diffusivity of sound by *Lighthill* [8.92]

$$\delta = \frac{1}{\rho_0}\left(\frac{4}{3}\mu + \mu_B\right) + \frac{\kappa}{\rho_0}\left(\frac{1}{c_v} - \frac{1}{c_p}\right)$$
$$= \nu\left(\frac{4}{3} + \frac{\mu_B}{\mu} + \frac{\gamma-1}{Pr}\right) \tag{8.76}$$

where μ is the shear viscosity, μ_B the bulk viscosity, $\nu = \mu/\varrho_0$ the kinematic viscosity, κ the thermal conductivity, c_v and c_p the specific heats at constant volume and constant pressure, respectively, and Pr being the Prandtl number, $Pr = \mu c_p/\kappa$. The equation is an ap-

proximation to a more exact second-order equation that, however, does not lend itself to an exact solution as does the Burgers equation above. In the context of acoustics this relation was first derived by *Mendousse*, although for viscous losses only [8.93]. The derivations make use of a careful comparison of the order of magnitude of derivatives retaining the leading terms. The above form of the Burgers equation is best suited to initial-value problems. Source problems are best described when transforming (8.75) to new coordinates (x, τ) with the retarded time $\tau = t - x/c_0$

$$\frac{\partial u}{\partial x} - \frac{\beta}{c_0^2} u \frac{\partial u}{\partial \tau} = \frac{\delta}{2c_0^3} \frac{\partial^2 u}{\partial \tau^2} . \tag{8.77}$$

The equation can be normalized to a form with only one parameter,

$$\frac{\partial W}{\partial \sigma} - W \frac{\partial W}{\partial \varphi} = \frac{1}{\Gamma} \frac{\partial^2 W}{\partial \varphi^2} , \tag{8.78}$$

where $W = u/u_0$, $\sigma = x/x_\perp$, $\varphi = \omega\tau = \omega t - k_0 x$, $\Gamma = \beta M_0 k_0/\alpha = 2\pi \beta M_0/\alpha\lambda$, with α being the damping constant for linear waves,

$$\alpha = \frac{\delta k_0^2}{2c_0} . \tag{8.79}$$

Γ is called the Gol'dberg number after *Gol'dberg* [8.94] who introduced this normalization (*Blackstock* [8.95]). It can be written as

$$\Gamma = \frac{1/x_\perp}{\alpha} \tag{8.80}$$

where $1/x_\perp = \beta M_0 k_0$ is the strength of the nonlinearity and α is the strength of the damping. The Gol'dberg number is therefore a measure of the importance of nonlinearity in relation to damping. For $\Gamma > 1$ nonlinearity takes over and for $\Gamma < 1$ damping takes over. For $\Gamma \gg 1$ nonlinearity has time to accumulate its effects, for $\Gamma \ll 1$ damping does not allow nonlinear effects to develop.

The Burgers equation is exactly integrable by the Hopf–Cole transformation [8.96, 97],

$$W = \frac{2}{\Gamma} \frac{1}{\zeta} \frac{\partial \zeta}{\partial \varphi} = \frac{2}{\Gamma} \frac{\partial \ln \zeta}{\partial \varphi} \tag{8.81}$$

that is best done in two steps [8.10]

$$W = \frac{\partial \psi}{\partial \varphi} , \tag{8.82}$$

$$\psi = \frac{2}{\Gamma} \ln \zeta . \tag{8.83}$$

By this transformation the nonlinear Burgers equation is reduced to the linear heat conduction or diffusion equation

$$\frac{\partial \zeta}{\partial \sigma} = \frac{1}{\Gamma} \frac{\partial^2 \zeta}{\partial \varphi^2} . \tag{8.84}$$

For this equation a general explicit solution is available,

$$\zeta(\sigma, \varphi)$$
$$= \sqrt{\frac{\Gamma}{4\pi\sigma}} \int_{-\infty}^{+\infty} \zeta(0, \varphi') \exp\left(-\Gamma \frac{(\varphi' - \varphi)^2}{4\sigma}\right) d\varphi' . \tag{8.85}$$

For a specific solution the initial or boundary conditions must be specified. A common problem is the piston that starts to vibrate sinusoidally at time $t = 0$. This problem has been treated by *Blackstock* [8.95] whose derivation is closely followed here. The boundary condition is given by

$$\begin{aligned} u(0, t) &= 0 & \text{for} \quad t \le 0 , \\ u(0, t) &= u_a \sin \omega t & \text{for} \quad t > 0 , \end{aligned} \tag{8.86}$$

or in terms of the variable $W(\sigma, \varphi)$

$$\begin{aligned} W(0, \varphi) &= 0 & \text{for} \quad \varphi \le 0 , \\ W(0, \varphi) &= \sin \varphi & \text{for} \quad \varphi > 0 . \end{aligned} \tag{8.87}$$

To solve the heat conduction equation the boundary condition is needed for $\zeta(\sigma, \varphi)$. To this end the Hopf–Cole transformation (8.81) is reversed,

$$\zeta(\sigma, \varphi) = \exp\left(\frac{\Gamma}{2} \int_{-\infty}^{\varphi} W(\sigma, \varphi') d\varphi'\right) . \tag{8.88}$$

Insertion of $W(0, \varphi)$ yields as the boundary condition for ζ,

$$\begin{aligned} \zeta(0, \varphi) &= 1 & \text{for} \quad \varphi \le 0 \\ \zeta(0, \varphi) &= e^{\frac{1}{2}\Gamma(1-\cos\varphi)} & \text{for} \quad \varphi > 0 \end{aligned} \tag{8.89}$$

and insertion into (8.85) yields the solution in terms of ζ. Using $\bar{\sigma} = \sqrt{4\sigma/\Gamma}$ and $q = (\varphi' - \varphi)/\bar{\sigma}$ the solution for the vibrating piston in terms of ζ reads

$$\zeta(\sigma, \varphi) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{-\varphi/\bar{\sigma}} e^{-q^2} dq$$

$$+ \frac{1}{\sqrt{\pi}} e^{\frac{1}{2}\Gamma} \int_{-\varphi/\bar{\sigma}}^{\infty} e^{-\frac{1}{2}\Gamma\cos(\bar{\sigma}q+\varphi)} e^{-q^2} dq . \tag{8.90}$$

This solution is involved and also contains the transients after starting the oscillation. When $\varphi \to \infty$ these transients decay and the steady-state solution is obtained,

$$
\zeta(\sigma, \varphi \,|\, \varphi \to \infty)
$$
$$
= \frac{1}{\sqrt{\pi}} \, e^{\frac{1}{2}\Gamma} \int_{-\infty}^{\infty} e^{-\frac{1}{2}\Gamma \cos(\bar{\sigma}q + \varphi)} \, e^{-q^2} \, dq \,. \quad (8.91)
$$

With the help of the modified Bessel functions of order n, $I_n(z) = i^{-n} J_n(iz)$, and the relation [8.98]

$$
e^{z \cos \theta} = I_0(z) + 2 \sum_{n=1}^{\infty} I_n(z) \cos n\theta \quad (8.92)
$$

the expression

$$
e^{-\frac{1}{2}\Gamma \cos(\bar{\sigma}q + \varphi)}
$$
$$
= I_0\left(-\tfrac{1}{2}\Gamma\right) + 2 \sum_{n=1}^{\infty} I_n\left(-\tfrac{1}{2}\Gamma\right) \cos n(\bar{\sigma}q + \varphi)
$$
$$
= I_0\left(\tfrac{1}{2}\Gamma\right) + 2 \sum_{n=1}^{\infty} (-1)^n I_n\left(\tfrac{1}{2}\Gamma\right) \cos n(\bar{\sigma}q + \varphi)
$$
$$
\quad (8.93)
$$

is valid. Inserting this into (8.91) and integrating yields, observing that $\int_{-\infty}^{+\infty} \exp(-q^2 x^2) \cos[p(x + \lambda)] dx = (\sqrt{\pi}/q) \exp[-p^2/(4q^2)] \cos p\lambda$ [8.99],

$$
\zeta(\sigma, \varphi \,|\, \varphi \to \infty)
$$
$$
= e^{\frac{1}{2}\Gamma} \left[I_0\left(\tfrac{1}{2}\Gamma\right) + 2 \sum_{n=1}^{\infty} (-1)^n I_n\left(\tfrac{1}{2}\Gamma\right) e^{-n^2\sigma/\Gamma} \cos n\varphi \right].
$$
$$
\quad (8.94)
$$

This is the exact steady-state solution for the oscillating piston problem given for ζ as a Fourier series. Transforming to $W(\sigma, \varphi)$ via (8.81) gives

$$
W(\sigma, \varphi)
$$
$$
= \frac{4\Gamma^{-1} \sum_{n=1}^{\infty} (-1)^{n+1} n I_n\left(\tfrac{1}{2}\Gamma\right) e^{-n^2\sigma/\Gamma} \sin n\varphi}{I_0\left(\tfrac{1}{2}\Gamma\right) + 2 \sum_{n=1}^{\infty} (-1)^n I_n\left(\tfrac{1}{2}\Gamma\right) e^{-n^2\sigma/\Gamma} \cos n\varphi} \,.
$$
$$
\quad (8.95)
$$

Finally, for $u(x, t)$ the solution reads

$$
\frac{u(x, t)}{u_a}
$$
$$
= \frac{4\Gamma^{-1} \sum_{n=1}^{\infty} (-1)^{n+1} n I_n\left(\tfrac{1}{2}\Gamma\right) e^{-n^2\alpha x} \sin n(\omega t - k_0 x)}{I_0\left(\tfrac{1}{2}\Gamma\right) + 2 \sum_{n=1}^{\infty} (-1)^n I_n\left(\tfrac{1}{2}\Gamma\right) e^{-n^2\alpha x} \cos n(\omega t - k_0 x)} \,.
$$
$$
\quad (8.96)
$$

The equation for the acoustic pressure $p - p_0$ again can be obtained via the approximation (8.72) as before in the lossless case: $(p - p_0)/(p_a - p_0) = u/u_a$ gives the identical equation.

There are regions of the parameter Γ and the independent variables x and t where the solution is difficult to calculate numerically. However, in these cases approximations can often be formulated.

For $\Gamma \to \infty$ and $\sigma = x/x_\perp \ll 1$ the Fubini solution is recovered.

For $\sigma \gg \Gamma$, i.e. far away from the source, the first terms in the numerator and the denominator in (8.96) dominate, leading to

$$
\frac{u(x, t)}{u_a} = \frac{4}{\Gamma} \frac{I_1(\Gamma/2)}{I_0(\Gamma/2)} \, e^{-\alpha x} \sin(\omega t - k_0 x) \,. \quad (8.97)
$$

When additionally $\Gamma \gg 1$, i.e. nonlinearity dominates over attenuation, $I_0(\Gamma/2) \approx I_1(\Gamma/2)$ and therefore

$$
u(x, t) = u_a \frac{4}{\Gamma} \, e^{-\alpha x} \sin(\omega t - k_0 x)
$$
$$
= 4 u_a \alpha x_\perp \, e^{-\alpha x} \sin(\omega t - k_0 x)
$$
$$
= \frac{4\alpha c_0^2}{\beta \omega} \, e^{-\alpha x} \sin(\omega t - k_0 x) \quad (8.98)
$$
$$
= \frac{2\delta\omega}{\beta c_0} \, e^{-\alpha x} \sin(\omega t - k_0 x) \,. \quad (8.99)
$$

This series of equations for the amplitude of the sinusoidal wave radiated from a piston in the far field lends itself to several interpretations. As it is known that for $\Gamma \gg 1$ harmonics grow fast at first, these must later decay leaving the fundamental to a first approximation. The amplitude of the fundamental in the far field is independent of the amplitude u_a of the source, as can be seen from the third row (8.98). This means that there is a saturation effect. Nonlinearity together with attenuation does not allow the amplitude in the far field to increase in proportion to u_a because of the extra damping introduced by the generation of harmonics that are damped more strongly than the fundamental. This even works asymptotically because otherwise u_a would finally appear. The damping constant is frequency dependent (8.79), leading to the last row (8.99). It is seen that the asymptotic amplitude of the fundamental grows with the frequency $f = \omega/2\pi$. This continues until other effects come into play, for instance relaxation effects in the medium. Equations (8.98) and (8.99) for u are different from the equations for the acoustic pressure, as they cannot be normalized with u_a or $p_a - p_0$, respec-

tively. They are related via the impedance $\varrho_0 c_0$ (8.70),

$$(p - p_0)(x, t) = \frac{4\alpha \varrho_0 c_0^3}{\beta \omega} e^{-\alpha x} \sin(\omega t - k_0 x) \quad (8.100)$$

$$= \frac{2\delta \varrho_0 \omega}{\beta} e^{-\alpha x} \sin(\omega t - k_0 x) . \quad (8.101)$$

Good approximations for $\Gamma \gg 1$ have been given by *Fay* [8.101],

$$\frac{u(x, t)}{u_a} = \sum_{n=1}^{\infty} \frac{2/\Gamma}{\sinh[n(1 + x/x_\perp)/\Gamma]} \sin n(\omega t - k_0 x) , \quad (8.102)$$

and *Blackstock* [8.95]:

$$\frac{u(x, t)}{u_a}$$

$$= \frac{2}{\Gamma} \sum_{n=1}^{\infty} \frac{1 - (n/\Gamma^2) \coth[n(1 + x/x_\perp)/\Gamma]}{\sinh[n(1 + x/x_\perp)/\Gamma]}$$

$$\times \sin n(\omega t - k_0 x) . \quad (8.103)$$

With an error of less than 1% at $\Gamma = 50$ Fay's solution is valid for $\sigma > 3.3$ and Blackstock's solution for $\sigma > 2.8$, rapidly improving with σ. The gap in σ from about one to three between the Fubini and Fay solution has been closed by Blackstock. He connected both solutions using weak shock theory giving the Fubini–Blackstock–Fay solution ([8.100], see also [8.1]). Figure 8.9 shows the first three harmonic components of the Fubini–Blackstock–Fay solution from [8.100]. Similar curves have been given by *Cook* [8.88]. He developed a numerical scheme for calculating the harmonic content of a wave as it propagates by including the losses in small spatial steps linearly for each harmonic component. As there are occurring only harmonic waves that do not break the growth in each small step is given by the Fubini solution.

In the limit $\Gamma \to \infty$ the Fay solution reduces to

$$\frac{u(x, t)}{u_a} = \sum_{n=1}^{\infty} \frac{2}{1 + x/x_\perp} \sin n(\omega t - k_0 x) , \quad (8.104)$$

a solution that is also obtained by weak shock theory.

Fig. 8.9 Growth and decay of the first three harmonic components B_n of a plane wave as a function of the normalized distance σ according to the Fubini–Blackstock–Fay solution (after *Blackstock* [8.100])

When Fay's solution (8.102) is taken and $\sigma \gg \Gamma$ (farfield), the old-age region of the wave is reached. Then $\sinh[n(1 + x/x_\perp)/\Gamma] \simeq \frac{1}{2}(e^{nx/x_\perp \Gamma} - e^{-nx/x_\perp \Gamma}) \simeq \frac{1}{2} e^{nx/x_\perp \Gamma} = \frac{1}{2} e^{n\alpha x}$ and

$$u(x, t) = \frac{4\alpha c_0^2}{\beta \omega} , \sum_{n=1}^{\infty} e^{-n\alpha x} \sin n(\omega t - k_0 x) \quad (8.105)$$

is obtained similarly as for the fundamental (8.98). Additionally all harmonics that behave like the fundamental, i.e. that are not dependent on the initial peak particle velocity u_a, are obtained. Moreover, they do not decay (as linear waves do) proportionally to $e^{-n^2 \alpha x}$ but only proportionally to $e^{-n\alpha x}$.

In the range $\sigma > 1$ shock waves may develop. These are discussed in the next section.

8.8 Shock Waves

The characteristics of Fig. 8.3 must cross. According to the geometrical construction the profile of the wave then becomes multivalued. This is easily envisaged with water surface waves. With pressure or density waves, however, there is only one pressure or one density at one place. The theory is therefore oversimplified and must be expanded with the help of physical arguments and the corresponding mathematical formulation. Shortly before overturning, the gradients of pressure and density become very large, and it is known that damping

effects brought about by viscosity and heat conduction can no longer be neglected. When these effects are taken into account, the waves no longer turn over. Instead, a thin zone is formed, a *shock wave*, in which the values of pressure, density, temperature, etc. vary rapidly. A theoretical formulation has been given in the preceding section for thermoviscous sound waves based on the Burgers equation.

It has been found that damping effects do not necessarily have to be included in the theory, but that an extended damping free theory can be developed by introducing certain shock conditions that connect the variables across a discontinuity. A description of this theory can be found in the book by *Whitham* [8.10]. The result can be described in a simple construction. In Fig. 8.10 the profile of the wave has been determined according to the methods of characteristics for a time where the characteristics have already crossed. The shock wave then has to be inserted in such a way that the areas between the shock wave and the wave profile to the left and the right are equal (the equal area rule). Moreover, it can be shown that the velocity of the shock wave is approximately given by

$$v_s = \frac{1}{2}(v_1 + v_2),$$ (8.106)

where v_1 and v_2 are the propagation velocities of the wave before and behind the shock, respectively.

Shock waves are inherently difficult to describe by Fourier analysis as a large number of harmonics are needed to approximate a jump-like behavior. A time-domain description is often more favorable here. Such solutions have been developed for the propagation of sound waves in the shock regime. For $\Gamma > \sigma > 3$, *Khokhlov* and *Soluyan* [8.102] have given the following

Fig. 8.11a,b Waveforms of the Khokhlov–Soluyan solution for Gol'dberg numbers $\Gamma = 10$ (**a**) and $\Gamma = 100$ (**b**) for different σ (the *age* of the wave)

solution

$$\frac{u(x,t)}{u_a} = \frac{1}{1 + x/x_\perp} \left(-\varphi + \pi \tanh \frac{\pi \Gamma \varphi}{2(1 + x/x_\perp)} \right)$$ (8.107)

for $-\pi < \varphi = \omega t - k_0 x < \pi$, covering a full cycle of the wave.

Figure 8.11 shows the waveforms for $\Gamma = 10$ and $\Gamma = 100$ for different $\sigma = x/x_\perp$. When the wave is followed at fixed Γ for increasing σ (i.e. increasing x), the decay and change of the waveform upon propagation can be observed.

The solution and the waveforms are remarkable as they are exact solutions of the Burgers equation, but

Fig. 8.10 Condition for the location of the shock wave for an overturning wave, the equal area rule
Fig. 8.12 Shock waves (*dark circles*) and bubbles (*dark spheres*) from laser-induced breakdown in water. Reconstructed image from a hologram $1.75\,\mu s$ after breakdown. The size of the picture is $1.1 \times 1.6\,mm$ ◄

approximate solutions with respect to the boundary condition.

When the wave gets very steep, i. e., in the case $\Gamma \to \infty$, it attains the shape of a sawtooth ($\sigma > 3$),

$$\frac{u(x,t)}{u_a} = \begin{cases} \dfrac{1}{1+x/x_\perp}[-\varphi+\pi] & 0 < \varphi \le \pi\,, \\[2mm] \dfrac{1}{1+x/x_\perp}[-\varphi-\pi] & -\pi \le \varphi < 0\,, \end{cases}$$
$$(8.108)$$

where $\varphi = \omega t - k_0 x$. The amplitude of the jump is

$$\frac{u(x,t)}{u_a} = \frac{\pi}{1+x/x_\perp}\,,\qquad (8.109)$$

the actual jump height from peak to peak being two times this value and falling off rapidly with x. This so-

lution, too, is an exact solution of the Burgers equation, albeit for $1/\Gamma \equiv 0$, i. e., with the diffusion term missing in the Burgers equation.

The Fourier form solution of the sawtooth wave (8.108) is given by

$$\frac{u(x,t)}{u_a} = \frac{2}{1+x/x_\perp}\sum_{n=1}^{\infty}\frac{1}{n}\sin n(\omega t - k_0 x)\,.\quad (8.110)$$

This form can also be derived as approximation from the Fay solution (see (8.104)). This can be considered a consistency proof in the approximation approaches, one proceeding in the time domain, the other in the frequency domain.

An example of the occurrence of shock waves, albeit spherical ones, is given in Fig. 8.12. A laser pulse has been focused into water, leading to four spots of breakdown, the emission of four shock waves and the growth of four bubbles. Laser-produced bubbles are used in cavitation research to investigate bubble dynamics in liquids and their effects [8.32]. Focused shock waves are used in lithotripsy to fragment kidney stones to small enough pieces to fit through the urinary tract [8.103].

8.9 Interaction of Nonlinear Waves

Linear waves do not interact, in the sense that upon superposition they propagate independently, each according to their own parameters. This makes Fourier theory a powerful technique for linear systems. In nonlinear systems, however, the harmonic components of which an initial perturbation is composed interact and produce new components that again interact, etc. Even a single harmonic oscillation creates higher harmonics, as set out in the preceding sections.

For the description of strong nonlinear acoustic wave interaction it is very fortunate that the Burgers equation (8.78) allows for a linearizing transformation. The superposition can then be evaluated in the linear variables, giving the result of the nonlinear interaction when transforming back.

Of special interest is the interaction of two (primary) waves in the course of which the sum and, in particular, the difference frequency can be generated. A highly di-

rectional high-frequency source can be transformed into a highly directed low-frequency source (the parametric array). As the low-frequency beam generated has lower damping than the high-frequency beams it propagates to longer distances. Applications are sound navigation and ranging (SONAR) and surface and subsurface scanning of the ocean bottom.

Taking two waves with amplitudes $u_{1,2}$ and frequencies $\omega_{1,2}$, starting at $t = 0$, the boundary condition becomes

$$u(x=0,t) = \begin{cases} 0 & t < 0\,, \\ u_1\sin(\omega_1 t) + u_2\sin(\omega_2 t) & t \ge 0\,, \end{cases}$$
$$(8.111)$$

or with the normalized variables $W = u/u_0$, $\varphi = \omega\tau = \omega(t - x/c_0)$, $\sigma = x/x_\perp$,

$W(\sigma = 0, \varphi)$

$$= \begin{cases} 0 & \varphi < 0 , \\ W_1 \sin(\Omega_1\varphi) + W_2 \sin(\Omega_2\varphi) , & \varphi \geq 0 . \end{cases} \quad (8.112)$$

Here, $\Omega_{1,2} = \omega_{1,2}/\omega$ denote the input frequencies normalized to the reference frequency ω and $W_{1,2} = u_{1,2}/u_0$ the amplitudes normalized to the reference amplitude u_0. The inverse Hopf–Cole transformation (8.88) gives the initial condition for the linearized problem in the variable ζ. For $\varphi < 0$ we obtain $\zeta(\sigma = 0, \varphi) = 1$, while for $\varphi \geq 0$,

$\zeta(\sigma = 0, \varphi)$

$$= \exp\left[\frac{\Gamma}{2} \int_0^\varphi W(\sigma = 0, \varphi')\, d\varphi' \right]$$

$$= \exp\left\{ -\frac{\Gamma}{2} \left[\frac{W_1}{\Omega_1} \cos(\Omega_1\varphi') + \frac{W_2}{\Omega_2} \cos(\Omega_2\varphi') \right]_0^\varphi \right\} . \tag{8.113}$$

To simplify notation, introduce the Gol'dberg numbers $\Gamma_{1,2} = \Gamma W_{1,2}/\Omega_{1,2}$ which agree with the definition (8.80) applied to the two input waves, respectively. Then

$$\zeta(\sigma = 0, \varphi \geq 0) = \underbrace{\exp\left(\frac{\Gamma_1}{2} + \frac{\Gamma_2}{2} \right)}_{=:C}$$

$$\times \exp\left[-\frac{\Gamma_1}{2} \cos(\Omega_1\varphi) - \frac{\Gamma_2}{2} \cos(\Omega_2\varphi) \right] . \tag{8.114}$$

With this initial condition, the solution (8.85) of the diffusion equation (8.84) reads

$$\zeta(\sigma, \varphi) = \sqrt{\frac{\Gamma}{4\pi\sigma}} \int_{-\infty}^0 \exp\left(-\Gamma \frac{(\varphi' - \varphi)^2}{4\sigma} \right) d\varphi'$$

$$+ C\sqrt{\frac{\Gamma}{4\pi\sigma}} \int_0^{+\infty} \exp\left[-\frac{\Gamma_1}{2} \cos(\Omega_1\varphi') \right.$$

$$\left. -\frac{\Gamma_2}{2} \cos(\Omega_2\varphi') - \Gamma \frac{(\varphi' - \varphi)^2}{4\sigma} \right] d\varphi'$$

$$= \sqrt{\frac{\Gamma}{4\pi\sigma}} \int_{-\infty}^{-\varphi} \exp\left(-\Gamma \frac{\varphi'^2}{4\sigma} \right) d\varphi'$$

$$+ C\sqrt{\frac{\Gamma}{4\pi\sigma}} \int_{-\varphi}^{+\infty} \exp\left\{ -\frac{\Gamma_1}{2} \cos[\Omega_1(\varphi' + \varphi)] \right.$$

$$\left. -\frac{\Gamma_2}{2} \cos[\Omega_2(\varphi' + \varphi)] - \Gamma \frac{\varphi'^2}{4\sigma} \right\} d\varphi' .$$

This general solution is quite complicated as the integration limits depend on the phase φ. To dismiss the transients caused by the starting of the waves at $\varphi = 0$, again the limit $\varphi \to \infty$ is considered. This means that at a certain position $x = \sigma x_\perp$ in the medium the wave is examined a long time after the passage of the initial perturbation that started at $x = 0$, $t = 0$. Then, the first integral of (8.115) vanishes, and the second integral can be evaluated from $-\infty$ to $+\infty$ by using the expansion (8.92), written in the following form

$$\exp(z \cos\theta) = I_0(z) + 2 \sum_{n=1}^\infty I_n(z) \cos(n\theta)$$

$$=: \sum_{n=0}^\infty b_n I_n(z) \cos(n\theta) , \tag{8.115}$$

where the numerical factors $b_0 = 1$, $b_n = 2$ for $n > 0$ have been introduced for convenient notation. Substituting this series in (8.115) and noting that I_n is an even (odd) function for even (odd) n, we get

$\zeta(\sigma, \varphi)$

$$= C\sqrt{\frac{\Gamma}{4\pi\sigma}} \sum_{m=0}^\infty \sum_{n=0}^\infty (-1)^{m+n} b_m b_n I_m\left(\frac{\Gamma_1}{2} \right) I_n\left(\frac{\Gamma_2}{2} \right)$$

$$\times \int_{-\infty}^{+\infty} \cos[m\Omega_1(\varphi' + \varphi)] \cos[n\Omega_2(\varphi' + \varphi)]$$

$$\times \exp\left(-\Gamma \frac{\varphi'^2}{4\sigma} \right) d\varphi' . \tag{8.116}$$

Using $\cos(\alpha)\cos(\beta) = (1/2)[\cos(\alpha + \beta) + \cos(\alpha - \beta)]$, and proceeding as in the derivation of (8.94) we get

$\zeta(\sigma, \varphi)$

$$= \frac{C}{2} \sum_{m=0}^\infty \sum_{n=0}^\infty (-1)^{m+n} b_m b_n I_m\left(\frac{\Gamma_1}{2} \right) I_n\left(\frac{\Gamma_2}{2} \right)$$

$$\times \left[\exp\left(-\frac{(\Omega_{mn}^+)^2}{\Gamma} \sigma \right) \cos\left(\Omega_{mn}^+ \varphi \right) \right.$$

$$\left. + \exp\left(-\frac{(\Omega_{mn}^-)^2}{\Gamma} \sigma \right) \cos\left(\Omega_{mn}^- \varphi \right) \right] .$$

Here, a short-hand notation for the combination frequencies has been introduced: $\Omega_{mn}^\pm = m\Omega_1 \pm n\Omega_2$. Transforming back to the original variable yields

$$W(\sigma, \varphi) = \frac{2}{\Gamma} \frac{1}{\zeta(\sigma, \varphi)} \frac{\partial \zeta(\sigma, \varphi)}{\partial \varphi}$$

$$= \frac{\sum\limits_{m=0}^{\infty} \sum\limits_{n=0}^{\infty} (-w_{mn})[\Omega_{mn}^+ e_{mn}^+ \sin(\Omega_{mn}^+ \varphi) + \Omega_{mn}^- e_{mn}^- \sin(\Omega_{mn}^- \varphi)]}{(\Gamma/2) \sum\limits_{m=0}^{\infty} \sum\limits_{n=0}^{\infty} w_{mn}[e_{mn}^+ \cos(\Omega_{mn}^+ \varphi) + e_{mn}^- \cos(\Omega_{mn}^- \varphi)]},$$

$$(8.117)$$

where

$$w_{mn} = (-1)^{m+n} b_m b_n I_m \left(\frac{\Gamma_1}{2}\right) I_n \left(\frac{\Gamma_2}{2}\right),$$

$$e_{mn}^+ = \exp\left(-\frac{(\Omega_{mn}^+)^2}{\Gamma} \sigma\right),$$

$$e_{mn}^- = \exp\left(-\frac{(\Omega_{mn}^-)^2}{\Gamma} \sigma\right).$$

It is seen that for $\sigma > 0$ the solution in φ contains all combination frequencies $m\Omega_1 \pm n\Omega_2$ of the two input frequencies due to the nonlinear interaction. Note also that for $\Omega_1 = 1$, $\Gamma_1 = \Gamma$, $\Omega_2 = 0$, $\Gamma_2 = 0$ the solution (8.96) is recovered. In its full generality, the expression is rather cumbersome to analyze. However, as higher frequencies are more strongly damped for $\sigma \to \infty$ only a few frequencies remain with sufficient amplitude. In particular, if Ω_1 and $\Omega_2 < \Omega_1$ are close, the difference frequency $\Delta\Omega = \Omega_1 - \Omega_2$ ($m = n = 1$) will be small and give a strong component with

$$W_-(\sigma, \varphi) = -\frac{4\Delta\Omega}{\Gamma} \frac{I_1\left(\frac{\Gamma_1}{2}\right) I_1\left(\frac{\Gamma_2}{2}\right)}{I_0\left(\frac{\Gamma_1}{2}\right) I_0\left(\frac{\Gamma_2}{2}\right)}$$

$$\times \exp\left(-\frac{(\Delta\Omega)^2}{\Gamma} \sigma\right) \sin(\Delta\Omega \varphi), \quad (8.118)$$

or, returning to physical coordinates and constants,

$$u_-(x, t)$$

$$= -\frac{2\Delta\omega \delta}{c_0 \beta} \frac{I_1\left(\frac{\Gamma_1}{2}\right) I_1\left(\frac{\Gamma_2}{2}\right)}{I_0\left(\frac{\Gamma_1}{2}\right) I_0\left(\frac{\Gamma_2}{2}\right)}$$

$$\times \exp\left(-\frac{\delta(\Delta\omega)^2}{2c_0^3} x\right) \sin[\Delta\omega(t - x/c_0)]$$

$$= u_-^{(0)} \exp\left(-\frac{\delta(\Delta\omega)^2}{2c_0^3} x\right) \sin[\Delta\omega(t - x/c_0)].$$

$$(8.119)$$

The Gol'dberg numbers of the interacting waves determine the quantity $u_-^{(0)}$ of the resulting difference-frequency wave. For $\Gamma_{1,2} \ll 1$, i.e., for low-power waves, $I_0(\Gamma/2) \approx 1$ and $I_1(\Gamma/2) \approx \Gamma/4$, thus the value

$$u_-^{(0)} = -\frac{2\Delta\omega \delta}{c_0 \beta} \frac{\Gamma_1 \Gamma_2}{16} = -\frac{\Delta\omega \beta c_0}{2\delta} \frac{u_{01} u_{02}}{\omega_1 \omega_2} \quad (8.120)$$

is proportional to the product of the amplitudes of the interacting waves. For very intense waves, $\Gamma_{1,2} \gg 1$, as $\lim_{\xi \to \infty} I_1(\xi)/I_0(\xi) = 1$, the quantity $u_-^{(0)}$ of the difference-frequency wave becomes independent of u_{01} and u_{02},

$$u_-^{(0)} = -\frac{2\Delta\omega \delta}{c_0 \beta}. \quad (8.121)$$

The difference-frequency wave (8.121) has been given for the far field where the two incoming waves have essentially ceased to interact. There, the wave propagates linearly and is exponentially damped by thermoviscous dissipation.

8.10 Bubbly Liquids

Liquids with bubbles have strongly pronounced nonlinear acoustic properties mainly due to the nonlinear oscillations of the bubbles and the high compressibility of the gas inside. Within recent decades theoretical and experimental investigations have detected many kinds of nonlinear wave phenomena in bubbly fluids. To mention just a few of these: ultrasound self-focusing [8.104, 105], acoustic chaos [8.52], sound self-transparency [8.106], wavefront conjugation [8.106], the acoustic phase echo [8.107] intensification of sound waves in nonuniform bubbly fluids [8.108, 109], sub-harmonic wave generation [8.110], structure formation

in acoustic cavitation [8.111, 112], difference-frequency sound generation [8.113, 114]. These phenomena are discussed in several books and review papers [8.2, 9, 32, 115–118].

In this section we are going to discuss some phenomena related to nonlinear acoustic wave propagation in liquids with bubbles. First, the mathematical model for pressure-wave propagation in bubbly liquids will be presented. Second, this model will be used to investigate long nonlinear pressure waves, short pressure wave trains, and some nonlinear interactions between them.

Let α_l and α_g be the volume fractions and ρ_l and ρ_g the densities of the liquid and the gas (vapor), respectively. Then the density of the two-phase mixture ρ in the bubbly liquid mixture is given by

$$\rho = \alpha_l \rho_l + \alpha_g \rho_g ,\tag{8.122}$$

where $\alpha_l + \alpha_g = 1$. Note that the gas (vapor) volume fraction depends on the instantaneous bubble radius R,

$$\alpha_g = \frac{4}{3}\pi R^3 n ,\tag{8.123}$$

where n is the number density of bubbles in the mixture. Equation (8.123) is true in general and applicable to the case in which bubbles oscillate in an acoustic field, as considered in the following.

8.10.1 Incompressible Liquids

First, we consider the case when the liquid can be treated as incompressible. The bubbly fluid model in this case is based on the *bubble-in-cell* technique [8.115], which divides the bubbly liquid mixture into cells, with each cell consisting of a liquid sphere of radius R_c with a bubble of radius R at its center. A similar approach has been used recently to model wet foam drop dynamics in an acoustic field [8.119] and the acoustics of bubble clusters in a spherical resonator [8.120].

It should be mentioned here that the bubble-in-cell technique may be treated as a first-order correction to a bubbly fluid dynamics model due to a small bubble volume fraction. This technique is not capable of capturing the entire bubbly fluid dynamics for high concentration of bubbles when bubbles lose their spherical shape.

According to the bubble-in-cell technique, the radius R_c of the liquid sphere comprising each cell and the embedded bubble, are related to the local void fraction at any instant by

$$\frac{R}{R_c} = \alpha_g^{1/3} .\tag{8.124}$$

We note that R_c, R, and α_g are variable in time.

The liquid conservation of mass equation and the assumed liquid incompressibility imply that the radial velocity around a single bubble depends on the radial coordinate

$$v' = \frac{R^2 \dot{R}}{r'^2}, \quad R \le r' \le R_c ,\tag{8.125}$$

where $R(t)$ is the instantaneous radius of the bubble, primed quantities denote local (single-cell) variables,

namely, r' is the radial coordinate with origin at the bubble's center, v' is the radial velocity of the liquid at radial location r', and the dot denotes a time derivative (i. e., $\dot{R} = \mathrm{d}R/\mathrm{d}t$).

The dynamics of the surrounding liquid is analyzed by writing the momentum equation for an incompressible, inviscid liquid as

$$\frac{\partial v'}{\partial t} + v' \frac{\partial v'}{\partial r'} + \frac{1}{\rho_l} \frac{\partial p'}{\partial r'} = 0 .\tag{8.126}$$

Integrating this equation over $r' \le R_c$ from R to some arbitrary r' and using (8.125) yields

$$p' = p_R - \rho_l \left[R\ddot{R} + \frac{3}{2}\dot{R}^2 \right.$$
$$\left. - \left(R\ddot{R} + 2\dot{R}^2 \right) \frac{R}{r'} + \frac{1}{2}\dot{R}^2 \left(\frac{R}{r'}\right)^4 \right] ,\tag{8.127}$$

where p' is the liquid pressure at location r' around a bubble, and p_R is the liquid pressure at the bubble interface. Evaluating (8.127) at the outer radius of the cell, $r' = R_c$, and using (8.124), results in

$$\frac{p_R - p_c}{\rho_l} = \left(1 - \alpha_g^{1/3}\right) R\ddot{R}$$
$$+ \frac{3}{2}\left(1 - \frac{4}{3}\alpha_g^{1/3} + \frac{1}{3}\alpha_g^{4/3}\right) \dot{R}^2 .\tag{8.128}$$

This equation bears a resemblance to the well-known Rayleigh–Plesset equation that governs the motion of a single bubble in an infinite liquid. Indeed, in the limit of vanishing void fraction, $\alpha_g \to 0$, the pressure at the outer radius of the cell (p_c) becomes the liquid pressure far from the bubble ($p_c \to p_\infty$), and (8.128) reduces to the Rayleigh–Plesset equation

$$\frac{p_R - p_\infty}{\rho_l} = R\ddot{R} + \frac{3}{2}\dot{R}^2 .\tag{8.129}$$

Let us assume that the gas pressure inside the bubble p_g is spatially uniform. The momentum jump condition requires that the gas pressure differs from the liquid pressure at the bubble wall due to surface tension and viscous terms according to

$$p_R = p_g - \frac{2\sigma}{R} - \frac{4\mu_l \dot{R}}{R} ,\tag{8.130}$$

where σ is the surface tension and μ_l is the liquid viscosity. Furthermore, the gas pressure may be assumed to be governed by a polytropic gas law of the form

$$p_g = \left(p_0 + \frac{2\sigma}{R_0}\right) \left(\frac{R}{R_0}\right)^{-3\kappa} ,\tag{8.131}$$

where R_0 is the equilibrium radius of the bubble (i. e., the bubble radius at ambient pressure) and κ is a polytropic exponent. Combining (8.128)–(8.131) gives the following relationship between the liquid pressure at the edge of the cell (p_c) and the radius of the bubble (R),

$$
p_c = \left(p_0 + \frac{2\sigma}{R} \right) \left(\frac{R}{R_0} \right)^{-3\kappa} - \frac{2\sigma}{R} - \frac{4\mu_1 \dot{R}}{R}
$$
$$
- \rho_1 \left[\left(1 - \alpha_g^{1/3} \right) R \ddot{R} \right.
$$
$$
\left. + \frac{3}{2} \left(1 - \frac{4}{3}\alpha_g^{1/3} + \frac{1}{3}\alpha_g^{4/3} \right) \dot{R}^2 \right] . \tag{8.132}
$$

Equation (8.132) can be integrated to find the bubble radius, $R(t)$, given the time-dependent pressure at $r' = R_c$ and the initial conditions.

Next, we connect the various cells at points on their outer radii and replace the configuration with an equivalent fluid whose dynamics approximate those of the bubbly liquid. We assume that the velocity of the translational motion of the bubbles in such a fluid is equal to the velocity of the bubbly fluid v. The fluid is required to conserve mass, thus

$$
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0 , \tag{8.133}
$$

where ρ is given by (8.122). The fluid also satisfies Euler's equation,

$$
\rho \frac{dv}{dt} + \nabla p = 0 , \tag{8.134}
$$

where $d/dt = \partial/\partial t + v \cdot \nabla$ is the material derivative, and p is the mean fluid pressure, which is approximately the pressure at the outer radius of a cell, p_c.

The mass and bubble densities are related by requiring that the total mass of each cell does not change in time. The initial volume of one cell is $V_0 = 1/n_0$, so the initial mass of the cell is $M_0 = \rho_0/n_0$, where $\rho_0 = \alpha_{l0}\rho_{l0} + \alpha_{g0}\rho_{g0}$. Requiring that the mass of each cell remains constant gives

$$
\frac{\rho}{n} = \frac{\rho_0}{n_0} . \tag{8.135}
$$

This set of equations describes the nonlinear dynamics of a bubbly liquid mixture over a wide range of pressures and temperatures.

We can now linearize these equations by assuming that the time-dependent quantities only vary slightly from their equilibrium values. Specifically, we write $\rho = \rho_0 + \tilde{\rho}$, $n = n_0 + \tilde{n}$, $p = p_0 + \tilde{p}$, $v = \tilde{v}$, $\alpha_g = \alpha_{g0} + \tilde{\alpha}_g$, and $R = R_0 + \tilde{R}$. The perturbed quantities are

assumed to be small, so that any product of the perturbations may be neglected. When these assumptions are introduced into (8.132), we arrive at the following linearized equation,

$$
\tilde{p} = - \left[\left(p_0 + \frac{2\sigma}{R_0} \right) \frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2} \right] \tilde{R}
$$
$$
- \frac{4\mu_1}{R_0} \frac{\partial \tilde{R}}{\partial t} - \rho_1 \left(1 - \alpha_{g0}^{1/3} \right) R_0 \frac{\partial^2 \tilde{R}}{\partial t^2} . \tag{8.136}
$$

Linearizing (8.135) gives

$$
\tilde{n} = \frac{n_0}{\rho_0} \tilde{\rho} . \tag{8.137}
$$

Similarly, linearizing the density in (8.122) taking into account that $\rho_g/\rho_1 \ll 1$ and using (8.137) yields

$$
\tilde{\rho} = -4\pi R_0^2 \rho_0 n_0 \tilde{R}, \tag{8.138}
$$

where $\rho_0 \approx \rho_1 (1 - \alpha_{g0})$. By combining (8.136) and (8.138) we obtain a pressure–density relationship for the bubbly fluid

$$
\tilde{p} = \frac{C_b^2}{\omega_b^2} \left(\omega_b^2 \tilde{\rho} + 2\delta_b \frac{\partial \tilde{\rho}}{\partial t} + \frac{\partial^2 \tilde{\rho}}{\partial t^2} \right) , \tag{8.139}
$$

where C_b represents the low-frequency sound speed in the bubbly liquid

$$
C_b^2 = \frac{3\kappa p_0 + (3\kappa - 1)\dfrac{2\sigma}{R_0}}{3\alpha_{g0}(1 - \alpha_{g0})\rho_1} , \tag{8.140}
$$

and ω_b is the natural frequency of a bubble in the cell

$$
\omega_b^2 = \frac{\omega_M^2}{1 - \alpha_{g0}^{1/3}} . \tag{8.141}
$$

We note that ω_M is the natural frequency of a single bubble in an infinite liquid (i. e. the so-called Minnaert frequency),

$$
\omega_M^2 = \frac{3\kappa p_0 + (3\kappa - 1)\dfrac{2\sigma}{R_0}}{\rho_1 R_0^2} . \tag{8.142}
$$

In (8.139) the parameter δ_b represents the dissipation coefficient due to the liquid viscosity,

$$
\delta_b = \frac{2\mu_1}{\rho_1 R_0^2 \left(1 - \alpha_{g0}^{1/3} \right)} . \tag{8.143}
$$

Actually acoustic wave damping in bubbly liquids occurs due to several different physical mechanisms:

liquid viscosity, gas/vapor thermal diffusivity, acoustic radiation, etc. The contribution of each of these dissipation mechanisms to the total dissipation during bubble oscillations depends on frequency, bubble size, the type of gas in a bubble and liquid compressibility [8.115]. For convenience one can use an effective dissipation coefficient in the form of a viscous dissipation

$$\delta_{\text{eff}} = \frac{2\mu_{\text{eff}}}{\rho_l R_0^2 \left(1 - \alpha_{g0}^{1/3}\right)} , \tag{8.144}$$

where μ_{eff} denotes an effective viscosity (instead of just the liquid viscosity), which implicitly includes all the aforementioned dissipation mechanisms in a bubbly liquid. The value for μ_{eff} should be chosen to fit experimental observations and the theoretical data of amplitude versus frequency for a single bubble.

We can also linearize (8.133) and (8.134) to obtain

$$\frac{\partial \tilde{\rho}}{\partial t} + \rho_0 \nabla \cdot \boldsymbol{v} = 0 , \tag{8.145}$$

$$\rho_0 \frac{\partial \boldsymbol{v}}{\partial t} + \nabla \tilde{p} = 0 . \tag{8.146}$$

Combining the time derivative of (8.145) with the divergence of (8.146) results in

$$\frac{\partial^2 \tilde{\rho}}{\partial t^2} = \nabla^2 \tilde{p} . \tag{8.147}$$

Combining this result with (8.139) gives a wave equation for the bubbly liquid of the form

$$\frac{\partial^2 \tilde{p}}{\partial t^2} - C_b^2 \left(1 + \frac{2\delta_{\text{eff}}}{\omega_b^2} \frac{\partial}{\partial t} + \frac{1}{\omega_b^2} \frac{\partial^2}{\partial t^2}\right) \nabla^2 \tilde{p} = 0 . \tag{8.148}$$

Equation (8.148) describes the propagation of a linear acoustical pressure perturbations in a liquid with bubbles when the liquid can be treated as incompressible. It also accounts for the effect of a small but finite void fraction on wave propagation [8.9, 115, 116].

8.10.2 Compressible Liquids

When the pressure waves are very intense, and the void fraction is small ($\alpha_g \ll 1$), one should take into account liquid compressibility, which may lead to acoustic radiation by the oscillating bubbles. In this case, correction terms of $\alpha_g^{1/3}$, $\alpha_g^{4/3}$ in (8.128) may be neglected, and in order to account for acoustic radiation (8.128) should be rewritten as follows [8.121, 122],

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 = \frac{p_R - p}{\rho_{10}} + \frac{R}{\rho_{10} C_1} \frac{\text{d}}{\text{d}t} (p_R - p) , \tag{8.149}$$

where C_1 is the speed of sound in the liquid. In (8.149) the liquid density ρ_l is taken as a constant ρ_{10} although the equation of state of the liquid can be approximated as

$$p = p_0 + C_1^2 (\rho_l - \rho_{10}) . \tag{8.150}$$

After linearization (8.149) becomes (compare with (8.136))

$$\tilde{p} = -\left[\left(p_0 + \frac{2\sigma}{R_0}\right) \frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2}\right] \tilde{R}$$
$$- \frac{4\mu_1}{R_0} \frac{\partial \tilde{R}}{\partial t} - \rho_{10} R_0 \left(1 + \frac{R_0}{C_1} \frac{\partial}{\partial t}\right)^{-1} \frac{\partial^2 \tilde{R}}{\partial t^2} . \tag{8.151}$$

In order to evaluate the last term in (8.151) and to incorporate acoustic radiation losses into an *effective* viscosity scheme we use the following approximation for the differential operator,

$$\left(1 + \frac{R_0}{C_1} \frac{\partial}{\partial t}\right)^{-1} \approx 1 - \frac{R_0}{C_1} \frac{\partial}{\partial t} . \tag{8.152}$$

Then (8.151) becomes

$$\tilde{p} \approx -\left[\left(p_0 + \frac{2\sigma}{R_0}\right) \frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2}\right] \tilde{R} - \frac{4\mu_1}{R_0} \frac{\partial \tilde{R}}{\partial t}$$
$$- \rho_{10} R_0 \frac{\partial^2 \tilde{R}}{\partial t^2} + \frac{\rho_{10} R_0^2}{C_1} \frac{\partial^3 \tilde{R}}{\partial t^3} . \tag{8.153}$$

The third derivative in (8.153) can be estimated using the approximation of a freely oscillating bubble

$$\frac{\partial^2 \tilde{R}}{\partial t^2} \approx -\frac{\left(p_0 + \frac{2\sigma}{R_0}\right) \frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2}}{\rho_{10} R_0} \tilde{R}. \tag{8.154}$$

Substituting (8.154) in the third-derivative term of (8.153) we get

$$\tilde{p} = -\left[\left(p_0 + \frac{2\sigma}{R_0}\right) \frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2}\right] \tilde{R} - \frac{4\mu_{\text{eff}}}{R_0} \frac{\partial \tilde{R}}{\partial t}$$
$$- \rho_{10} R_0 \frac{\partial^2 \tilde{R}}{\partial t^2} , \tag{8.155}$$

where

$$\mu_{\text{eff}} = \mu_1 + \mu_r, \quad \mu_r = \frac{(3\kappa - 1)\sigma}{2C_1} + \frac{3\kappa p_0}{4C_1} R_0 . \tag{8.156}$$

It is easy to see from (8.156) that acoustic radiation may lead to a very large dissipation. For example, for
Fig. 8.13 The dispersion relation for water with air bubbles (the liquid is treated as compressible, dissipation is ignored): $C_l = 1500$ m/s, $p_0 = 10^5$ Pa, $\kappa = 1.4$, $\sigma = 0.0725$ N/m, $\rho_{l0} = 10^3$ kg/m, $\alpha_{g0} = 10^{-4}$, $R_0 = 10^{-4}$ m

air bubbles of $R_0 = 10^{-4}$ m in water, effective viscosity due to acoustic radiation μ_r may be about seven times larger than the viscosity of water, μ_l.

Equation (8.135), and eventually its linearized form (8.137), are valid in the case of a compressible liquid. However, the linearized form of (8.122) changes. Now instead of (8.138) we have

$$\tilde{\rho} = \tilde{\rho}_l - 4\pi R_0^2 \rho_0 n_0 \tilde{R} \tag{8.157}$$

or, accounting for the liquid equation of state (8.150),

$$\tilde{\rho} = C_l^{-2} \tilde{p} - 4\pi R_0^2 \rho_0 n_0 \tilde{R} . \tag{8.158}$$

Substituting (8.158) into (8.147) we have

$$C_l^{-2} \frac{\partial^2 \tilde{p}}{\partial t^2} - \nabla^2 \tilde{p} = 4\pi R_0^2 n_0 \rho_0 \frac{\partial^2 \tilde{R}}{\partial t^2} . \tag{8.159}$$

Equation (8.159) together with (8.155) leads to the following wave equation for a bubbly fluid in the case of a compressible liquid

$$\frac{\partial^2 \tilde{p}}{\partial t^2} - C_b^2 \left(1 + \frac{2\delta_{\text{eff}}}{\omega_b^2} \frac{\partial}{\partial t} + \frac{1}{\omega_b^2} \frac{\partial^2}{\partial t^2} \right)$$
$$\times \left(\nabla^2 - C_l^{-2} \frac{\partial^2}{\partial t^2} \right) \tilde{p} = 0 . \tag{8.160}$$
Fig. 8.14 The phase velocity for water with air bubbles (the liquid is treated as compressible, dissipation is ignored): $C_l = 1500$ m/s, $p_0 = 10^5$ Pa, $\kappa = 1.4$, $\sigma = 0.0725$ N/m, $\rho_{l0} = 10^3$ kg/m, $\alpha_{g0} = 10^{-4}$, $R_0 = 10^{-4}$ m

Here ω_b and δ_{eff} are calculated according to (8.141) and (8.144) in which α_{g0} is taken to be zero, and C_b is calculated according to (8.140). It is easy to see that (8.160) reduces to (8.148) in the case when $C_l \to \infty$.

The linear wave equation (8.160) admits the harmonic wave-train solution

$$\tilde{p} = p_a \exp\left[\mathrm{i}(kx - \omega t) \right] , \tag{8.161}$$

in which the frequency ω and wave number k are related through the following dispersion relation

$$k^2 = \omega^2 \left(\frac{1}{C_l^2} + \frac{1}{C_b^2 \left(1 + \mathrm{i}\frac{2\omega\delta_{\text{eff}}}{\omega_b^2} - \frac{\omega^2}{\omega_b^2} \right)} \right) . \tag{8.162}$$

The graph of this dispersion relation is shown in Fig. 8.13. The corresponding phase velocity is given in Fig. 8.14.

8.10.3 Low–Frequency Waves: The Korteweg–de Vries Equation

In order to analyze the low-frequency nonlinear acoustics of a bubbly liquid the low-frequency limit of the

dispersion relation (8.162) is first considered,

$$\omega = Ck + i\alpha_1 k^2 - \alpha_2 k^3 , \qquad (8.163)$$

where

$$\frac{1}{C^2} = \frac{1}{C_1^2} + \frac{1}{C_b^2} , \quad \alpha_1 = \frac{\delta_{\text{eff}} C^4}{\omega_b^2 C_b^2} , \quad \alpha_2 = \frac{C^5}{2 C_b^2 \omega_b^2} . \qquad (8.164)$$

Noting that

$$\omega = -i\frac{\partial}{\partial t} , \quad k = i\frac{\partial}{\partial x} , \qquad (8.165)$$

(8.163) can be treated as the Fourier-space equivalent of an operator equation which when operating on $\tilde{p}$, yields

$$\frac{\partial \tilde{p}}{\partial t} + C\frac{\partial \tilde{p}}{\partial x} - \alpha_1 \frac{\partial^2 \tilde{p}}{\partial x^2} + \alpha_2 \frac{\partial^3 \tilde{p}}{\partial x^3} = 0 . \qquad (8.166)$$

Equation (8.166) should be corrected to account for weak nonlinearity. A systematic derivation is normally based on the *multiple-scales* technique [8.123]. Here we show how this derivation can be done less rigorously, but more simply. We assume that the nonlinearity in bubbly liquids comes only from bubble dynamics. Then (8.155) for weakly nonlinear bubble oscillations has an additional nonlinear term and becomes

$$\tilde{p} = -B_1 \tilde{R} + B_2 \tilde{R}^2 - \frac{4\mu_{\text{eff}}}{R_0}\frac{\partial \tilde{R}}{\partial t} - \rho_{l0} R_0 \frac{\partial^2 \tilde{R}}{\partial t^2} . \qquad (8.167)$$
Fig. 8.15 The potential well used to illustrate the *soliton* solution for the KdV equation

$$B_1 = \left(p_0 + \frac{2\sigma}{R_0} \right)\frac{3\kappa}{R_0} - \frac{2\sigma}{R_0^2} ,$$

$$B_2 = \left(p_0 + \frac{2\sigma}{R_0} \right)\frac{3\kappa(3\kappa + 1)}{2R_0^2} - \frac{2\sigma}{R_0^3} . \qquad (8.168)$$

Equation (8.167) has to be combined with the linear wave equation (8.159), which in the case of plane waves can be written

$$C_1^{-2}\frac{\partial^2 \tilde{p}}{\partial t^2} - \frac{\partial^2 \tilde{p}}{\partial x^2} = 4\pi R_0^2 n_0 \rho_0 \frac{\partial^2 \tilde{R}}{\partial t^2} . \qquad (8.169)$$

Taking into account that all the terms except the first one on the right-hand side of (8.167) are small, i.e., of the second order of magnitude, one can derive the following nonlinear wave equation for pressure perturbations in a bubbly liquid,

$$C^{-2}\frac{\partial^2 \tilde{p}}{\partial t^2} - \frac{\partial^2 \tilde{p}}{\partial x^2}$$
$$= 4\pi R_0^2 n_0 \rho_0$$
$$\times \left(\frac{B_2}{B_1^3}\frac{\partial^2 \tilde{p}^2}{\partial t^2} + \frac{4\mu_{\text{eff}}}{R_0 B_1^2}\frac{\partial^3 \tilde{p}}{\partial t^3} + \frac{\rho_{l0} R_0}{B_1^2}\frac{\partial^4 \tilde{p}}{\partial t^4} \right) . \qquad (8.170)$$

Equation (8.170) is derived for plane weakly nonlinear pressure waves traveling in a bubbly liquid in both directions. Namely, the left part of this equation contains a classic wave operator when applied to a pressure perturbation function describes waves traveling left to right and right to left. The right part of this equation contain terms of second order of smallness and is therefore responsible for a slight change of these waves. Thus, (8.170) may be structured as follows,

$$\left(C^{-1}\frac{\partial}{\partial t} + \frac{\partial}{\partial x} \right)\left(C^{-1}\frac{\partial}{\partial t} - \frac{\partial}{\partial x} \right)\tilde{p} = O\left(\varepsilon^2\right) . \qquad (8.171)$$

If one considers only waves traveling left to right then

$$C^{-1}\frac{\partial}{\partial t} + \frac{\partial}{\partial x} = O\left(\varepsilon\right) , \qquad (8.172)$$

and we can use the following derivative substitution (see [8.10])

$$\frac{\partial}{\partial t} \approx -C\frac{\partial}{\partial x} . \qquad (8.173)$$

Then, after one time integration over space, and translation to the frame moving left to right with a speed

of sound C, (8.170) leads to the Burgers–Korteweg–de Vries (BKdV) equation for a pressure wave [8.115–117, 124],

$$\frac{\partial \tilde{p}}{\partial t} + \alpha_0 \tilde{p} \frac{\partial \tilde{p}}{\partial \xi} - \alpha_1 \frac{\partial^2 \tilde{p}}{\partial \xi^2} + \alpha_2 \frac{\partial^3 \tilde{p}}{\partial \xi^3} = 0,$$
$$\xi = x - Ct , \qquad (8.174)$$

where

$$\alpha_0 = \frac{C^3}{C_b^2} \cdot \frac{B_2}{B_1^2} \qquad (8.175)$$

and the parameters α_1, α_2, and C are presented in (8.164).

Let us first discuss a nondissipative case, $\alpha_1 = 0$. Then (8.174) is called the Korteweg–de Vries (KdV) equation. The low-frequency dispersion relation (8.163) shows that every Fourier component of initial arbitrary pressure perturbation propagates with its own speed, and the shape of the acoustic signal changes. Since $\alpha_2 > 0$, the long-wavelength waves propagate with higher speed than lower-wavelength waves. This means that dispersion may begin to compete with nonlinearity, which stops shock-wave formation. The competition between dispersion and nonlinearity leads to the formation of a so-called *soliton*.

In order to derive the shape of soliton, here we consider a steady solution of (8.174) in the moving frame

$$\eta = \xi - Wt . \qquad (8.176)$$

Then, assuming that there is no pressure perturbation at infinity, (8.174) can be reduced as follows,

$$\alpha_2 \frac{d^2 \tilde{p}}{d\eta^2} = -\frac{\partial \Pi}{\partial \tilde{p}} , \quad \Pi(\tilde{p}) = -\frac{W \tilde{p}^2}{2} + \frac{\alpha_0 \tilde{p}^3}{6} . \qquad (8.177)$$

It is instructive to use the analogy that (8.177) is similar to the equation of a point-like particle in a potential well shown schematically in Fig. 8.15. The structure of the pressure *solitary* wave can be viewed as follows: initially the particle is at point O, which corresponds to the fact that far away the pressure perturbation is equal to zero; then the particle slides down to the bottom of the potential well, point A, and due to a conservation law climbs up to point B; at point B it stops and moves all the way back to point O. The solution of (8.177) represents the shape of the soliton, which in the immovable frame is

$$\tilde{p} = \frac{3W}{\alpha_0} \cosh^{-2} \left\{ \sqrt{\frac{W}{4\alpha_2}} [x - (C + W)t] \right\} . \qquad (8.178)$$

It was mentioned above that a soliton may be interpreted as a result of the balance between two competitors: nonlinearity and dispersion. To consider this competition in more detail the KdV equation is considered in the frame moving with the speed of sound in a bubbly liquid

$$\frac{\partial \tilde{p}}{\partial t} + \alpha_0 \tilde{p} \frac{\partial \tilde{p}}{\partial \xi} + \alpha_2 \frac{\partial^3 \tilde{p}}{\partial \xi^3} = 0, \quad \xi = x - Ct . \quad (8.179)$$

Then the solitary wave has the following shape,

$$\tilde{p} = \frac{3W}{\alpha_0} \cosh^{-2} \left\{ \sqrt{\frac{W}{4\alpha_2}} (\xi - Wt) \right\} \qquad (8.180)$$

with a pressure amplitude equal to $3W/\alpha_0$ and a thickness of about $\sqrt{\alpha_2/W}$.

In order to evaluate the effect of nonlinearity let us consider the simple nonlinear equation

$$\frac{\partial \tilde{p}}{\partial t} + \alpha_0 \tilde{p} \frac{\partial \tilde{p}}{\partial \xi} = 0 . \qquad (8.181)$$

The factor $\alpha_0 \tilde{p}$ stands for the velocity of transportation of pressure perturbations. Thus, part of the pressure profile which has higher pressure will be translated faster than the part which has lower pressure. According to the solitary solution (8.180) the maximum translation velocity is equal to $3W$. The time needed for the pressure peak to be translated the distance of about the thickness of the pressure wave can be estimated as $t_{nl} \approx \alpha_2^{1/2} W^{-3/2}$. This amount of time would be needed to transform the smooth solitary shape to a shock wave.

In order to evaluate the effect of dispersion let us consider the simple dispersive equation

$$\frac{\partial \tilde{p}}{\partial t} + \alpha_2 \frac{\partial^3 \tilde{p}}{\partial \xi^3} = 0 . \qquad (8.182)$$

This equation admits harmonic wave-train solutions of the form $\exp(ik\xi + i\alpha_2 k^3 t)$. The characteristic wave numbers contributing to the wave shape of thickness $\sqrt{\alpha_2/W}$ are $k \approx \sqrt{W/\alpha_2}$. Such wave numbers will gradually change the wave phase on π and thus lead to a substantial deformation of the wave shape. The time interval needed for this, t_d, is calculated as follows: $\alpha_2 \left(\sqrt{W/\alpha_2} \right)^3 t_d = \pi$, thus, $t_d \approx \alpha_2^{1/2} W^{-3/2}$, which is $\approx t_{nl}$. So, the time that is needed for nonlinearity to transform the solitary wave into a shock wave is equal to the time taken for dispersion to smooth out this wave.

One of the most important results obtained from the BKdV equation is the prediction of an oscillatory shock wave. In order to derive the shape of an oscillatory shock wave we again consider the steady-state solution

of (8.174) in the moving frame (8.176). Then, assuming that there is no pressure perturbation at infinity, (8.174) can be reduced to

$$\alpha_2 \frac{d^2 \tilde{p}}{d\eta^2} - \alpha_1 \frac{d\tilde{p}}{d\eta} = -\frac{\partial \Pi}{\partial \tilde{p}} \,,$$
$$\Pi(\tilde{p}) = -\frac{W \tilde{p}^2}{2} + \frac{\alpha_0 \tilde{p}^3}{6} \,. \qquad (8.183)$$

Equation (8.183) represents the equation of a point-like particle in a potential well shown schematically in Fig. 8.15 with friction. Here $\tilde{p}$ stands for the coordinate of the particle, minus ξ stands for the time (time passes from $-\infty$ to $+\infty$), α_2 is the mass of the particle, and α_1 is the friction coefficient. An oscillatory shock wave corresponds to motion of the particle from point O to the bottom of potential well (point A) with some decaying oscillations around the bottom. Thus, the amplitude of the shock wave is equal to $2W/\alpha_0$. Eventually oscillations take place only for relatively small values of the friction coefficient α_1. To derive a criterion for an oscillatory shock wave one should investigate a solution of (8.183) in close vicinity to point A. Assuming that

$$\tilde{p} = \frac{2W}{\alpha_0} + \psi(\xi) \,, \qquad (8.184)$$

where ψ is small, and linearizing (8.183) we get

$$\alpha_2 \frac{d^2\psi}{d\xi^2} - \alpha_1 \frac{d\psi}{d\xi} + W\psi = 0 \,. \qquad (8.185)$$

Equation (8.185) has a solution

$$\psi = A_1 \exp(-\lambda\xi) + A_2 \exp(\lambda\xi),$$
$$\lambda = \frac{\alpha_1}{2\alpha_2} \pm \sqrt{\frac{\alpha_1^2}{4\alpha_2^2} - \frac{W}{\alpha_1}} \,. \qquad (8.186)$$

It is easy to see that the shock wave has an oscillatory structure if

$$\alpha_1 < \sqrt{4\alpha_2 W} \,. \qquad (8.187)$$

In terms of the bubbly fluid parameters, (8.187) gives a critical effective viscosity

$$\mu_{\text{eff}} < \mu_{\text{crit}} = \rho_l R_0^2 \omega_b \frac{C_b}{C} \sqrt{\frac{1}{2} \frac{W}{C}} \,. \qquad (8.188)$$

The KdV equation for describing the evolution of long-wavelength disturbances in an ideal liquid with adiabatic gas bubbles was first proposed in [8.124]. The solitons and shock waves in bubbly liquids were systematically investigated in [8.116] in the framework of the BKdV equation. Good correlation with experimental data was obtained. In [8.115] wave-propagation

phenomena in bubbly liquids were analyzed using a more advanced and complete mathematical model that is valid for higher intensities of pressure waves. In [8.125] the effect of polydispersivity on long small-amplitude nonlinear waves in bubbly liquids was considered. It was shown that evolution equations of BKdV type can be applied for modeling of such waves. In particular, it was shown that for polydisperse bubbly liquids an effective monodisperse liquid model can be used with the bubble sizes found as ratios of some bubble size-distribution moments and corrections to the equation coefficients.

8.10.4 Envelopes of Wave Trains: The Nonlinear Schrödinger Equation

When the amplitude of an acoustic wave in a fluid is small enough the respective linearized system of equations will admit the harmonic wave-train solution

$$u = a \exp\{i[kx - \omega(k)t]\} \,. \qquad (8.189)$$

If the amplitude is not small enough the nonlinearity cannot be neglected. The nonlinear terms produce higher harmonics, which react back on the original wave. Thus, the effect of nonlinearity on this sinusoidal oscillation is to cause a variation in its amplitude and phase in both space and time. This variation can be considered as small (in space) and slow (in time) for off-resonant situations. To account for a variation of amplitude and phase it is convenient to consider the amplitude as a complex function of space and time A.

Here we follow [8.126] to show what kind of equation arises as the evolution equation for a carrier-wave envelope in a general dispersive system. A linear system has a dispersion relation which is independent of the wave amplitude

$$\omega = \omega(k) \,. \qquad (8.190)$$

However, it is instructive to assume that the development of a harmonic wave in a weakly nonlinear system can be represented by a dispersion relation which is amplitude dependent

$$\omega = \omega(k, |A|^2) \,. \qquad (8.191)$$

Such a situation was initially uncovered in nonlinear optics and plasma where the refractive index or dielectric constant of a medium may be dependent on the electric field. That same situation occurs in bubbly liquids as well.

Let us consider a carrier wave of wave number k_0 and frequency $\omega_0 = \omega(k_0)$. A Taylor expansion of the dispersion relation (8.191) around k_0 gives

$$\Omega = \left(\frac{\partial\omega}{\partial k}\right)_0 K + \frac{1}{2}\left(\frac{\partial^2\omega}{\partial k^2}\right)_0 K^2 + \left(\frac{\partial\omega}{\partial(|A|^2)}\right)_0 |A|^2 , \tag{8.192}$$

where $\Omega = \omega - \omega_0$ and $K = k - k_0$ are the frequency and wave number of the variation of the wave-train amplitude. Equation (8.192) represents a dispersion relation for the complex amplitude modulation. Noting that

$$\Omega = -\mathrm{i}\frac{\partial}{\partial t}, \quad K = \mathrm{i}\frac{\partial}{\partial x} , \tag{8.193}$$

(8.192) can be treated as the Fourier-space equivalent of an operator equation that when operating on A yields

$$\mathrm{i}\left[\frac{\partial}{\partial t} + \left(\frac{\partial\omega}{\partial k}\right)_0 \frac{\partial}{\partial x}\right] A + \frac{1}{2}\left(\frac{\partial^2\omega}{\partial k^2}\right)_0 \frac{\partial^2 A}{\partial x^2}$$
$$- \left(\frac{\partial\omega}{\partial(|A|^2)}\right)_0 |A|^2 A = 0 . \tag{8.194}$$

In the frame moving with group velocity

$$\xi = x - C_\mathrm{g} t, \quad C_\mathrm{g} = (\partial\omega/\partial k)_0 , \tag{8.195}$$

(8.194) represents the classical nonlinear Schrödinger (NLS) equation

$$\mathrm{i}\frac{\partial A}{\partial t} = \beta_\mathrm{d}\frac{\partial^2 A}{\partial\xi^2} + \gamma_\mathrm{n}|A|^2 A , \tag{8.196}$$

$$\beta_\mathrm{d} = -\frac{1}{2}\left(\frac{\partial^2\omega}{\partial k^2}\right)_0 , \quad \gamma_\mathrm{n} = \left(\frac{\partial\omega}{\partial(|A|^2)}\right)_0 , \tag{8.197}$$

which describes the evolution of wave-train envelopes.

Here A is a complex amplitude that can be represented as follows

$$A(t, \xi) = a(t, \xi)\exp[\mathrm{i}\varphi(t, \xi)] , \tag{8.198}$$

where a and φ are the (real) amplitude and phase of the wave train. A spatially uniform solution of (8.196) corresponds to an unperturbed wave train. To analyze the stability of this uniform solution let us represent (8.196) as a set of two scalar equations,

$$-a\frac{\partial\varphi}{\partial t} = \beta_\mathrm{d}\left[\frac{\partial^2 a}{\partial\xi^2} - a\left(\frac{\partial\varphi}{\partial\xi}\right)^2\right] + \gamma_\mathrm{n}a^3 , \tag{8.199}$$

$$\frac{\partial a}{\partial t} = \beta_\mathrm{d}\left(2\frac{\partial a}{\partial\xi}\frac{\partial\varphi}{\partial\xi} + a\frac{\partial^2\varphi}{\partial\xi^2}\right) . \tag{8.200}$$

It is easy to verify that a spatially uniform solution $(\partial/\partial\xi \equiv 0)$ of (8.199) and (8.200) is

$$a = a_0, \quad \varphi = -\gamma_\mathrm{n}a_0^2 t . \tag{8.201}$$

The evolution of a small perturbation of this uniform solution

$$a = a_0 + \tilde{a}, \quad \varphi = -\gamma_\mathrm{n}a_0^2 t + \tilde{\varphi} , \tag{8.202}$$

is given by the following linearized equations

$$a_0\frac{\partial\tilde{\varphi}}{\partial t} + \beta_\mathrm{d}\frac{\partial^2\tilde{a}}{\partial\xi^2} + 2\gamma_\mathrm{n}a_0^2\tilde{a} = 0 . \tag{8.203}$$

$$\frac{\partial\tilde{a}}{\partial t} - \beta_\mathrm{d}a_0\frac{\partial^2\tilde{\varphi}}{\partial\xi^2} = 0 . \tag{8.204}$$

Now let us consider the evolution of a periodic perturbation with wavelength $L = 2\pi/K$ that can be written as

$$\begin{pmatrix}\tilde{a} \\ \tilde{\varphi}\end{pmatrix} = \begin{pmatrix}a_1 \\ \varphi_1\end{pmatrix}\exp(\sigma t + \mathrm{i}K\xi) . \tag{8.205}$$

The stability of the uniform solution depends on the sign of the real part of the growth-rate coefficient σ. To compute σ we substitute the perturbation (8.205) into the linearized equations (8.203) and (8.204) and obtain the following formula for σ

$$\sigma^2 = \beta_\mathrm{d}^2 K^2\left(\frac{2\gamma_\mathrm{n}}{\beta_\mathrm{d}}a_0^2 - K^2\right) . \tag{8.206}$$

This shows that the sign of the $\beta_\mathrm{d}\gamma_\mathrm{n}$ product is crucial for wave-train stability. If $\beta_\mathrm{d}\gamma_\mathrm{n} < 0$ then σ is always an imaginary number, and a uniform wave train is stable to small perturbations of any wavelength; if $\beta_\mathrm{d}\gamma_\mathrm{n} > 0$ then in the case that

$$K < K_\mathrm{cr} = \sqrt{\frac{2\gamma_\mathrm{n}}{\beta_\mathrm{d}}}a_0 \tag{8.207}$$

σ is real, and a long-wavelength instability occurs.

This heuristic derivation shows how the equation for the evolution of the wave-train envelope arises. The NLS equation has two parameters: β_d, γ_n. Eventually, the parameter β_d can be calculated from the linear dispersion relation discussed in detail earlier. However, the parameter γ_n has to be calculated from more-systematic, nonlinear arguments.

The general method of derivation is often given the name of the *method of multiple scales* [8.123]. A specific multiscale technique for weakly nonlinear oscillations of bubbles was developed in [8.127,128]. This technique has been applied to analyze pressure-wave propagation in bubbly liquids.

In [8.129] the NLS equation describing the propagation of weakly nonlinear modulation waves in bubbly liquids was obtained for the first time. It was derived using the multiple asymptotic technique from the

governing continuum equations for bubbly liquids presented in detail in this chapter. The NLS equation was applied for determination of the regions of modulation stability/instability in the parametric plane for mono- and polydisperse bubbly liquids.

To understand the behavior of the coefficients of the NLS equation one can consider the simplified model of a monodisperse system presented before. For this we note that the dispersion relation for bubbly liquids with compressible carrier liquid has two branches (Fig. 8.13). The low-frequency branch is responsible for bubble compressibility, and the high-frequency branch is due to liquid compressibility.

The first (low-frequency) branch corresponds to frequencies from zero to ω_b, which is the resonance frequency for bubbles of given size, the second (high-frequency) branch corresponds to frequencies from some $\omega_\star$ to infinity. There are no solutions in the form of spatially oscillating waves for frequencies between ω_b and $\omega_\star$; in this range there are exponentially decaying solutions only. This region is known as the *window of acoustic non-transparency*.

The coefficient β_d is calculated as shown in (8.197). For bubbly liquids this quantity is always positive for the low-frequency branch and always negative for the high-frequency branch.

The coefficient γ_n (see (8.197)) represents the nonlinearity of the system and is a complicated function of frequency ω. If it is positive, then long-wavelength modulation instability occurs. An important region of instability appears near the frequency ω_s, where $C_g(\omega_s) = C_e$, with C_e being the equilibrium speed of sound ($C_e = \omega/k$ for $\omega \to 0$).

For such frequencies the coefficient γ_n has a singularity and changes sign when the frequency is changing around this point. Physically this corresponds to the Benjamin–Feir instability, and can be explained by transfer of energy from mode 0 (DC mode, or mode of zero frequency, for which perturbations propagate with velocity C_e) to the principal mode of the wave train, which moves with the group velocity C_g.

Accounting for a small dissipation in bubbly liquids leads to the Landau–Ginzburg equation, which describes how the wave amplitude should decay due to dissipation. This part includes the dissipation effect due to viscosity and due to internal bubble heat transfer. The difference between the viscous and thermal effects for bubbles is that for an oscillating bubble there is a $\pi/2$ shift in phase between the bubble volume and the heat flux, while the loss of energy due to viscous dissipation occurs in phase with bubble oscillation. This phase

shift results in the effect that the pressure in the mixture has some additional shift in phase relative to the mixture density (determined mainly by the bubble volume). This, in fact, can be treated as a weak dispersive effect and included to the dispersion relation in the third-order approximation.

It is interesting to note that the system of governing equations presented can be also obtained as Euler equations for some Lagrangian [8.130, 131]. The variation formulation might be very useful for the analysis of nonlinear acoustics phenomena in bubbly liquids.

8.10.5 Interaction of Nonlinear Waves: Sound–Ultrasound Interaction

The nature of the interactions among individual wave components is quite simple and can be explained by considering the nature of dispersive waves in general.

Suppose u represents some property of the fluid motion, for example the fluid velocity. Then infinitesimal (linear) plane one-dimensional sound waves in a pure liquid are governed by the classical linear wave equation

$$\frac{\partial^2 u}{\partial t^2} - c^2 \frac{\partial^2 u}{\partial x^2} = 0 , \tag{8.208}$$

where c is the speed of sound. This equation has elementary solutions of the type

$$u = A \exp[i(kx \pm \omega t)], \quad \omega = ck , \tag{8.209}$$

describing the propagation of a sinusoidal wave with a definite speed c independent of the wavelength ($\lambda = 2\pi/k$, k is the wavenumber). These waves are called nondispersive.

However, many of the waves encountered in fluids do not obey the classical wave equation, and their phase velocity may not be independent of the wavenumber. An example is wave propagation in bubbly liquids.

More generally, for an infinitesimal disturbance, the governing equation is of the type

$$L(u) = 0 , \tag{8.210}$$

where L is a linear operator involving derivatives with respect to position and time. The form of this operator depends upon the fluid system and the particular type of wave motion considered. Again, this linear equation admits solutions of the form

$$u = A \exp[i(kx \pm \omega t)] , \tag{8.211}$$

provided that ω and k satisfy a so-called dispersion relation

$$D(\omega, k) = 0 \tag{8.212}$$

that is characteristic for the fluid system and of the type of wave motion considered.

These infinitesimal wave solutions are useful since in many circumstances the nonlinear effects are weak. Thus, the infinitesimal amplitude solution in many cases represents a very useful first approximation to the motion. The interaction effects can be accounted for by considering an equation of the form

$$L(u) = \epsilon N(u) , \tag{8.213}$$

where N is some nonlinear operator whose precise nature again depends upon the particular fluid system considered, and ϵ is a small parameter characterizing the amplitude of the motion. Solutions to this equation can be built by successive approximation.

Let us consider two interacting wave trains, given to a first approximation by solutions to the linear equation (8.210)

$$u_1 = A_1 \exp[i(k_1 x - \omega_1 t)] ,$$
$$u_2 = A_2 \exp[i(k_2 x - \omega_2 t)] , \tag{8.214}$$

where the individual wave numbers and frequencies are related by the dispersion relation (8.212): $D(\omega_i, k_i) = 0$; $i = 1, 2$. These expressions are to be substituted into the small nonlinear term $\epsilon N(u)$ of (8.213).

If the lowest-order nonlinearity is quadratic, this substitution leads to expressions of the type

$$\approx \exp i[(k_1 \pm k_2)x - (\omega_1 \pm \omega_2)t] . \tag{8.215}$$

These terms act as a small-amplitude forcing function to the linear system and provide an excitation at the wave numbers ($k_3 = k_1 \pm k_2$) and frequencies ($\omega_3 = \omega_1 \pm \omega_2$). In general, the response of the linear system to this forcing is expected to be small ($\approx \epsilon$). However, if the wavelength and frequency of the forcing are related by the dispersion relation (8.212) as well: $D(\omega_3, k_3) = 0$, then we have a case which normally is referred to as nonlinear resonance wave interaction. Similarly to a well-known resonance behavior of a linear oscillator, the amplitude of the third component

$$u_3 = A_3 \exp[i(k_3 x - \omega_3 t)] \tag{8.216}$$

grows linearly at the beginning. Later the energy drain from the first two components begins to reduce their amplitudes and consequently the amplitude of the forcing function.

Let us now consider a set of three wave trains undergoing resonant interactions. The solutions representing these wave trains would be expected to look like the solutions of the linear problem, although the amplitudes

A_i ($i = 1, 2, 3$) may possibly vary slowly with time

$$u = \sum_{i=1}^{3} \left\{ A_i(\epsilon t) \exp[i(k_i x - \omega_i t)] \right.$$
$$\left. + A_i^*(\epsilon t) \exp[-i(k_i x - \omega_i t)] \right\} . \tag{8.217}$$

Here it is used that u is necessarily real. Substitution of this set into (8.213) with subsequent averaging over a few wavelengths leads to a system of equations for the amplitudes of the interacting wave trains. This system basically describes the energy balance between these wave components.

Thus, the existence of energy transfer of this kind clearly depends upon the existence of these resonance conditions. The classic example of dispersion relations which allow for such resonance conditions are capillary gravity waves on the surface of deep water [8.132]. This example, however, is far from the scope of the present section.

In this section the nonlinear acoustics of liquids with bubbles is discussed as an example of a multiphase fluids with complicated and pronounced nonlinearity and dispersion. The dispersion encountered there may also lead to a special nonlinear wave interaction called *long-wave–short-wave resonance* in this context.

In [8.133] it was suggested a new form of triad resonance between three waves of wave numbers k_1, k_2, and k_3 and frequencies ω_1, ω_2, and ω_3, respectively, such that

$$k_1 = k_2 + k_3, \quad \omega_1 = \omega_2 + \omega_3 . \tag{8.218}$$

It was suggested to consider k_1 and k_2 to be very close: $k_1 = k + \varepsilon$, $k_2 = k - \varepsilon$ and $k_3 = 2\varepsilon$ ($\varepsilon \ll k$). The resonance conditions (8.218) are automatically achieved if

$$\omega(k + \varepsilon) - \omega(k - \varepsilon) = \omega_3 \tag{8.219}$$

or

$$2\varepsilon \frac{d\omega}{dk} = \omega_3 . \tag{8.220}$$

That means the group velocity of the short wave (wave number k) equals the phase velocity of the long wave (wave number 2ε). It is called the long-wave–short-wave resonance. At first sight this resonance would appear hard to achieve but it is clearly possible from Fig. 8.13.

Let us identify the lower (or low-frequency) and upper (or high-frequency) branches of the dispersion relation with subscripts "−" and "+", respectively. The

long-wave asymptotics of the low-frequency branch, $\omega_l(k_l) = \omega_- |_{k \to 0}$, and the short-wave asymptotics of the high-frequency branch, $\omega_s(k_s) = \omega_+ |_{k \to \infty}$, can be written as follows,

$$\omega_l = c_e k_l + O(k_l^3) , \quad \omega_s = c_f k_s + O(k_s^{-1}) , \quad (8.221)$$

where

$$c_e = \frac{\omega_l}{k_l} |_{k_l \to 0} , \quad c_f = \frac{d\omega_s}{dk_s} |_{k_s \to \infty} , \quad (8.222)$$

are the *equilibrium* and the *frozen* speeds of sound in the bubbly mixture.

It is easy to see that dispersion relation (8.162) allows the existence of the long-wave–short-wave resonance. Since $c_f > c_e$, there is always some wave number k_s and frequency ω_s (Fig. 8.13) such that its group velocity is equal to the equilibrium velocity of the mixture.

It should be noted that the long-wave–short-wave resonance in bubbly liquids has nothing to do with the resonance of bubble oscillations. Suppose we consider water with air bubbles of radius $R_0 = 0.1\,\text{mm}$ under normal conditions ($p_0 = 0.1\,\text{MPa}$, $\rho_{l0} = 10^3\,\text{kg/m}^3$) and with a volume gas content $\alpha_{g0} = 2.22 \times 10^{-4}$. The wavelengths of the short and long waves are then $\lambda_s \approx 0.67\,\text{cm}$ and $\lambda_l \approx 6.7\,\text{m}$, respectively. The equilibrium speed of sound is $c_e \approx 730\,\text{m/s}$. Thus, the frequency of the long wave is $f_l = c_e/\lambda_l \approx 110\,\text{Hz}$ (audible sound). Obviously, the short-wave frequency $f_s \geq 35.6\,\text{kHz}$ lies in the ultrasound region. Moreover, a decrease in the bubble radius R_0 leads to

increasing the short-wave frequency f_s. Hence, the long-wave–short-wave interaction in a bubbly fluid can be considered as the interaction of ultrasound and audible sound propagating in this medium.

The long-wave–short-wave resonance interaction for pressure waves in bubbly liquids was investigated in [8.134–137] using the method of multiple scales. In particular, it was shown that in a nondissipative bubbly medium this type of resonance interaction is described by the following equations [8.138]

$$\frac{\partial L}{\partial \tau} + \frac{\alpha}{2c_e} \frac{\partial |S|^2}{\partial \xi} = 0 , \quad i\frac{\partial S}{\partial \tau} + \beta \frac{\partial^2 S}{\partial \xi^2} = \delta LS , \quad (8.223)$$

where L and S are normalized amplitudes of the long- and short-wave pressure perturbations, τ is the (slow) time and ξ is the space coordinate in the frame moving with the group velocity; α and β are parameters of interaction.

It turns out that in bubbly fluids, parameters of interaction can vanish simultaneously at some specific ultrasound frequency [8.137]. The interaction between sound and ultrasound is then *degenerate*, i.e., the equations for interaction are separated. However, such a degeneracy does not mean the absence of interaction. The quasi-monochromatic ultrasonic signal will still generate sound but of much smaller intensity than in the nondegenerate case.

8.11 Sonoluminescence

Sound waves not only give rise to self-steepening and shock waves but may even become the driving agent to the emission of light, a phenomenon called sonoluminescence. It is mediated by bubbles in the liquid that are driven to strong oscillations and collapse [8.22–32, 40–51]. The detection of the conditions when a single bubble can be trapped in the pressure antinode of a standing sound wave [8.139] has furthered this field considerably.

The trapping of a bubble in a sound field is due to the acoustic radiation forces acting on objects in a sound field (primary Bjerknes force) [8.140–145]. In the case of a spherical bubble in a harmonic standing sound field of frequency f_a and amplitude $p_a(\boldsymbol{x})$,

$$p_{ac}(\boldsymbol{x}, t) = p_a(\boldsymbol{x}) \sin(2\pi f_a t) , \quad (8.224)$$

the net force is given by

$$\boldsymbol{F}_B(\boldsymbol{x}) = -\langle V(t) \nabla p_{ac}(\boldsymbol{x}, t) \rangle_\tau , \quad (8.225)$$

where $V(t) = (4\pi/3 R^3(t))$ is the volume of the oscillating bubble, $\nabla p_{ac}(\boldsymbol{x}, t)$ is the gradient of the sound field and $\langle \ldots \rangle_\tau$ denotes averaging over a time interval τ (often one period of the sound field). The bubble is located at $\boldsymbol{x}$, where it encounters the pressure amplitude $p_a(\boldsymbol{x})$ modulated in time harmonically. The force on the bubble is a second-order effect, i.e. nonlinear, but strong enough to trap bubbles under appropriate conditions. For small amplitude (linear) bubble oscillations (appropriate $V(t)$ in (8.225)) bubbles driven below their resonance frequency move toward the pressure antinode, whereas bubbles driven above their resonance frequency move away from it to the pressure node. The
Fig. 8.16 Positional stability diagram for bubbles in water in a standing sound field of $f_a = 20$ kHz. Attractive (*green area*) and repelling (*red area*) Bjerknes force with respect to the pressure antinode in the standing sound field for different bubble sizes normalized to the resonance bubble size at 20 kHz of $R_{n0} = 176.8$ μm. $p_{stat} = 100$ kPa, $\sigma = 0.072$ N/m, $\gamma = 1.67$

Fig. 8.17 Bubble habitat diagram for bubbles in water in a standing sound field of $f_a = 20$ kHz. Bubble habitat (*green area*), dissolving bubbles (*lower white area*), shape unstable bubbles (*upper white area*). Above the *thin red line* in the middle of the diagram the bubble is positionally unstable (compare Fig. 8.16 for the complete positional unstability region), in the *red areas* being solely positionally unstable, in the *white areas above the line* being additionally shape unstable. Resonance bubble radius at 20 kHz is $R_{n0} = 176.8$ μm. $p_{stat} = 100$ kPa, $\sigma = 0.072$ N/m, $\gamma = 1.67$

linear resonance frequency, f_0, of a bubble with radius at rest of R_{n0}, when surface tension σ is included, is given by

$$f_0 = \frac{1}{2\pi R_{n0}\sqrt{\rho_l}}\sqrt{3\gamma\left(p_{stat} + \frac{2\sigma}{R_{n0}} - p_v\right) - \frac{2\sigma}{R_{n0}}},$$

(8.226)

with the further parameters density of the liquid ρ_l, static pressure p_{stat}, and (constant) vapor pressure p_v.

For nonlinear bubble oscillations the situation gets more complex. A bubble trapped at low driving may be expelled from the pressure antinode at high driving [8.146–149]. This is due to the nonlinearity of bubble oscillations of finite amplitude that enter (8.225) via $V(t)$. For getting an overview which bubbles can be trapped for a given driving frequency, *positional stability diagrams* may be calculated. Figure 8.16 gives an example for a driving frequency of 20 kHz.

For a bubble to become stably trapped further stability criteria must be fulfilled, in particular that the bubble does not go into solution or grow (diffusional stability) [8.150–152] and does not disintegrate by too strong surface oscillations (shape stability) [8.153–156]. Each of these criteria impose further restrictions on the region in parameter space, where a bubble can be stably trapped [8.157, 158]. The notion of a *bubble habitat* [8.31, 159] has been introduced for visualizing these

restrictions. More precisely, the bubble habitat is that region in parameter space, where positional and shape stability criteria are fulfilled for a nondissolving bubble.

An example of a bubble habitat diagram is given in Fig. 8.17 for bubbles in a standing sound field of frequency $f_a = 20$ kHz. The different stability/instability areas are quite involved and overlap leaving the small green area as the bubble habitat. In the habitat the bubbles grow by rectified diffusion and will finally reach one of its stability borders. The fate of the bubble then depends on the type of the border and its slope. When the bubble gets shape unstable, it will be fragmented and may start anew, when the fragment or fragments fall into the green area. When it encounters the positional stability border, it will be expelled from the pressure antinode with unknown fate. The dissolution border can be reached from within the habitat only at positive slope of the border; the negative slope border is an unstable equilibrium. At the positive slope border the bubble must stop as it simultaneously wants to grow and to dissolve. At this bubble size and driving amplitude of the sound field the bubble then is stable and settles in the pressure antinode.

It is seen from Fig. 8.17 that the regions of positive slope are very small at normal conditions and thus bubbles are difficult to trap [8.160]. However, when the
Fig. 8.18 Bubble habitat diagram for bubbles in water in a standing sound field of $f_a = 20\,\text{kHz}$ with reduced gas content. Bubble habitat (*green area*), dissolving bubbles (*lower white area below the green line*), shape unstable bubbles (*upper white area above the green line*; plunging into the lower white area not shown). Above the *red line* in the middle of the diagram the bubble is positionally unstable, in the red areas being solely positionally unstable, in the *white areas* above the *red line* being additionally shape unstable. The *white shape* unstable region between the *green and red line* eliminates part of the habitat. Resonance bubble radius at 20 kHz is $R_{n0} = 176.8\,\mu\text{m}$. $p_{\text{stat}} = 100\,\text{kPa}$, $\sigma = 0.072\,\text{N/m}$, $\gamma = 1.67$, 0.00001 of the saturation gas content

Fig. 8.19 Photograph of a rectangular container with light-emitting bubble. There is only one transducer glued to the bottom plate of the container (dimensions: $50\,\text{mm} \times 50\,\text{mm} \times 60\,\text{mm}$). The piezoelectric transducer (dimensions: height 12 mm, diameter 47 mm) sets up a sound field of high pressure (approx. 1.3 bar) at a frequency of approx. 21 kHz (courtesy of R. Geisler)

content of noncondensable gas is lowered, the habitat changes and opens up a connected window for bubbles to be stably trapped. This is shown in Fig. 8.18, where the gas content has been lowered to 0.00001 of its saturation concentration and again $f_a = 20\,\text{kHz}$ is taken as the sound field frequency. An extended positive slope of the habitat–diffusion border (green line) is found that is cut by shape instability. Thus shape instability confines sonoluminescence to small bubbles in the trapping case. More habitat diagrams can be found in [8.159].

In Fig. 8.19 a basic arrangement for single-bubble sonoluminescence (SBSL) is shown where a bubble is trapped in a rectangular container filled with water. The sound field is produced by a circular disc of piezoelectric material glued to the bottom of the container. The bright spot in the upper part of the container is the light from the bubble. It is of blueish white color. The needle sticking out into the container in the upper left part of the figure is a platinum wire for producing a bubble via a current pulse. The bubble is then driven via acoustic radiation forces into its position where it is

trapped almost forever. The bubble exerts large oscillations that can be photographed [8.161]. Figure 8.20 shows a sequence of the bubble oscillation of a light-emitting bubble. A full cycle is shown after which the oscillation repeats. Indeed, this repetition has been used to sample the series of photographs by shifting the instant of exposure by 500 ns from frame to frame with respect to the phase of the sound wave. The camera is looking directly into the illuminating light source (back illumination). The bubble then appears dark on a bright background because the light is deflected off its surface. The white spot in the middle of the bubble results from the light passing the spherical bubble undeflected.

Upon the first large collapse a shock wave is radiated (Fig. 8.21). At the 30 ns interframe time the 12 frames given cover 330 ns, less than one interframe time in Fig. 8.20. The shock wave becomes visible via deflection of the illuminating light at the density variation in the shock wave. The bubble expands on a much slower time scale than the speed of the shock wave and is seen as a tiny black spot growing in the middle of the ring of the shock wave. Measurements of the shock velocity near the bubble at collapse (average from 6 to 73 μm) leads to about 2000 m/s, giving a shock pressure

of about 5500 bar [8.162]. Higher-resolution measurements have increased these values to about 4000 m/s and 60 kbar [8.163].

The bubble oscillation as measured photographically can be compared with theoretical models for the motion of a bubble in a liquid. A comparison is shown in Fig. 8.22. The overall curve is reproduced well, although the steep collapse is not resolved experimentally. For details the reader is referred to [8.32].

There is the question whether shock waves are also emitted into the interior of the bubble [8.164–167]. Theoretically, shock waves occur in certain models, when the collapse is of sufficient intensity. Recently, the problem has been approached by molecular dynamics calculations [8.168–175]. As the number of molecules in a small bubble is relatively small, around 10^9 to 10^{10} molecules, this approach promises progress for the question of internal shock waves. At present molecular dynamics simulations are feasible with several million particles inside the bubble. Figure 8.23 gives a graphical view on the internal temperature distribution inside a collapsing sonoluminescence bubble with near-adiabatic conditions (reflection of the molecules at the inner boundary of the bubble) for six different times around maximum compression. The liquid motion and the inner molecular dynamics calculations are coupled via the gas pressure (at the interface), which is determined from the molecular dynamics of the 10^6 particles and inserted into the Rayleigh–Plesset equation giving the motion of the bubble wall. A strong focusing of energy inside the bubble is observed under these conditions. An inward-traveling compression wave focuses at the center and yields a core temperature of more than 10^5 K. This temperature is an overestimate as no energy-consuming effects are included.

The temperature variation inside the bubble with time can be visualized for spherical bubbles in a sin-
Fig. 8.20 Photographic series of a trapped, sonoluminescing bubble driven at 21.4 kHz and a pressure amplitude of 132 kPa. The interframe time is 500 ns. Picture size is 160×160 μm (courtesy of R. Geisler)

gle picture in the following way (Fig. 8.24). The vertical axis represents the radial direction from the bubble center, the horizontal axis represents time and the color gives the temperature in Kelvin according to the color-coded scale (bar aside Fig. 8.24). The upper solid line in Fig. 8.24 depicts the bubble wall; the blue part is water. In this case an argon bubble with water vapor is taken and chemical reactions are included. Then the temperature is lowered significantly by the endothermal processes of chemical species formation, for instance of

Fig. 8.22 Radius-time curve of a trapped bubble in a water-glycerine mixture derived from photographic observations. A numerically calculated curve (Gilmore model) is superimposed on the experimental data points (*open circles*). The calculation is based on the following parameters: driving frequency $f_0 = 21.4$ kHz, ambient pressure $p_0 = 100$ kPa, driving pressure $p_0 = 132$ kPa, vapor pressure $p_v = 0$, equilibrium radius $R_n = 8.1$ μm, density of the liquid $\rho = 1000$ kg/m^3, viscosity $\mu = 0.0018$ Ns/m^2 (measured) and surface tension $\sigma = 0.0725$ N/m. The gas within the bubble is assumed to obey the adiabatic equation of state for an ideal gas with $\kappa = 1.2$ (measured points courtesy of R. Geisler) ◄

OH$^-$ radicals. The temperature drops to about 40 000 K in the center [8.171].

Experimental investigations suggest that an increase of the driving frequency may lead to stronger col-

lapses and higher temperatures [8.176, 177]. Therefore molecular dynamics calculations have been done with a driving frequency of 11 MHz for a small argon bubble with a radius at rest of 250 nm. Driving pressure amplitude is 100 bar, necessary to expand a small bubble to larger radii for storing energy. In this case, the bub-

ing. Figure 8.25 gives the results for the evolution of temperature, argon density, water vapor density and the radiated light flash in a small interval around bubble collapse (≈ 10 ps). A hot spot at the bubble center is formed shortly before the bubble minimum with a maximum core temperature of 396 000 K and about 2 ps flash duration (Fig. 8.25a). In a collapsing bubble species are separated according to their molecular weight called vapor trapping or more generally species segregation [8.169, 173–175, 178, 179], whereby the lighter species accumulate in the bubble center region and the heavier particles near the bubble wall. This can be seen in Fig. 8.25b,c with the argon molecules accumulating at the bubble wall (Fig. 8.25b) and the vapor molecules being driven to the bubble center (Fig. 8.25c).

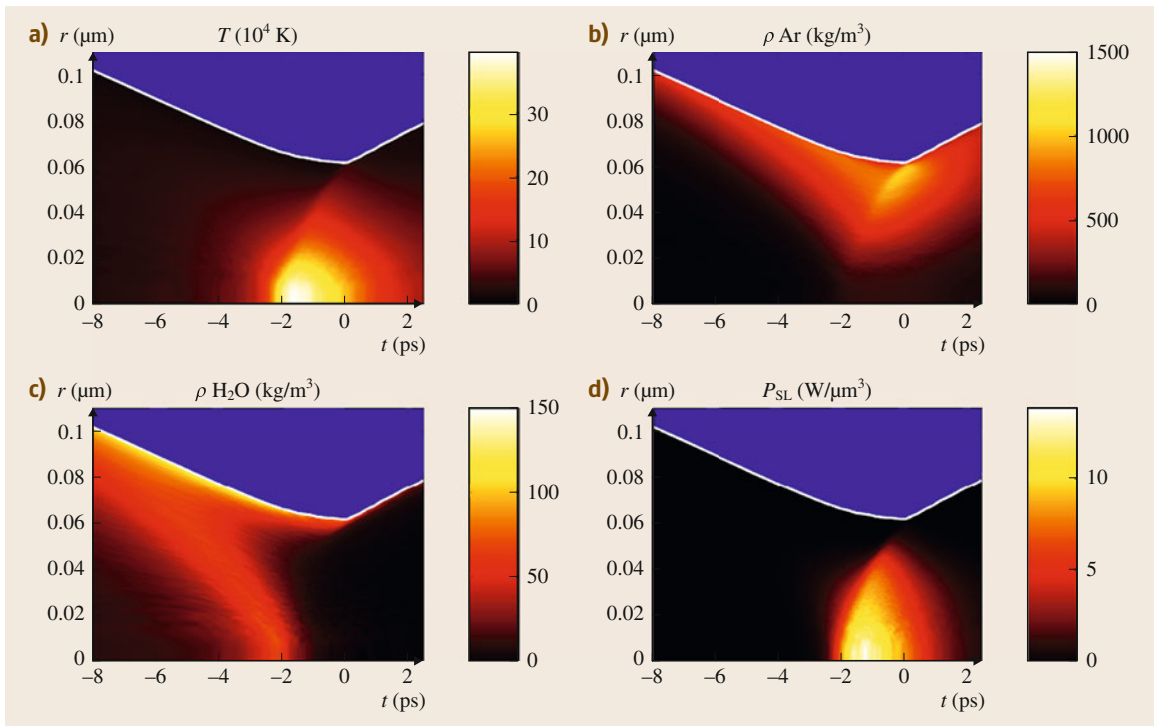
ble oscillates (ultra)subharmonically with one strong collapse occurring once every two cycles of the driv-


Fig. 8.25a–d Bubble collapse diagrams for a small argon bubble in water in a standing sound field of frequency $f_a =$ 11 MHz. Space-time evolution of (a) temperature, (b) argon density, (c) H_2O vapor density an (d) light emission power density in the final stages of collapse and the first stages of rebound. Bubble contents: argon and water vapor including vapor chemistry. About 700 000 initial ensemble particles. Bubble radius at rest $R_n = 250$ nm, $p_a = 100$ bar, $T_{water} =$ 290 K (courtesy of D. Schanz)

The water vapor is decomposed as soon as the temperature reaches values above $\approx 8500\,\mathrm{K}$ and is almost gone shortly after the onset of the hot spot and the start of the light emission (Fig. 8.25d). A density wave is running to the bubble center, best seen in Fig. 8.25c, arriving there about 2 ps before the bubble minimum. The bubble collapse is stopped, when the reflected, backward running density wave reaches the bubble wall, best seen in Fig. 8.25b. The light emission (Fig. 8.25d) is calculated according to a Bremsstrahlung model [8.165], assuming an optically thin plasma. As expected, the light emission is restricted in its duration to the hot spot and is of similar duration, $\approx 1.9\,\mathrm{ps}$. The spatial extension of the light emission ($\approx 100\,\mathrm{nm}$ in diameter) is slightly extended toward the wall because of the larger shell volume at larger distances from the center contributing to the emission.

The highest core temperature so far reached in molecular dynamics calculations for an argon bubble in water including water vapor and vapor chemistry is $1\,180\,000\,\mathrm{K}$ [8.173]. It is attained for a bubble radius at rest of 70 nm, a driving frequency of 11 MHz and a driving pressure of 100 bar.

In the quest for even higher temperatures (inertial confinement fusion in mind), the conditions for reaching high temperatures under the conditions of single bubble (sono)luminescence must be discussed. Water vapor with its endothermic decomposition and reaction products uses up part of the available energy during bubble compression leading to lower core temperatures [8.180] as do volatile additives (alcohols) to the water [8.181]. The basic idea, therefore, is straightforward: put as few as possible decomposable and endothermically reacting molecules into the bubble. There are two solutions to the problem, either working with ever smaller bubbles for a given liquid (see before, 70 nm bubble) or use a liquid with lower vapor pressure. The best solution will make use of both approaches. Additionally, the new liquid should be transparent in a large range of wavelengths for ease of access to the light emission. This excludes mercury, for instance.

The first solution has been tested experimentally [8.176, 177] for noble gas bubbles in water and by molecular dynamics calculations [8.173–175] and is shown to work, i. e., to lead to higher temperatures. The small bubbles, however, need high acoustic pressure amplitudes to drive them into expansion and high frequencies to keep the maximum bubble radius sufficiently small for not to accumulate too many vapor molecules by evaporation in the expansion phase. Thus, there will be a natural frontier, albeit not yet finally explored, by the small bubble sizes and the high frequencies.

The second solution has led to essentially two liquids with low vapor pressure that are presently intensely studied, sulfuric acid [8.182–204] and phosphoric acid [8.183, 184, 201, 205–211]. A strong increase in emitted light intensity has been found compared to water (up to three orders of magnitude [8.185, 186]), whereas the (spectroscopic) emission temperatures do not change in magnitude. This can be explained by the much larger bubbles that form and are trapped or almost trapped (for sulfuric acid [8.188, 197]) and the stronger emission for larger bubbles ([8.32, Fig. 38], where it is shown for bubbles in water). Simultaneously the pulse duration is much larger [8.188, 197] as it is positively correlated with the maximum bubble radius ([8.31, Fig. 85], where it is shown for laser-induced bubbles and trapped bubbles in water). Therefore the emission temperatures may stay the same and yet the brightness increases [8.205].

For single bubble collapse in water spectroscopic temperatures (fitted to an assumed blackbody) range from ≈ 6000 to $\approx 20\,000\,\mathrm{K}$ [8.212], whereas emission temperatures between $\approx 8000\,\mathrm{K}$ and $\approx 15\,000\,\mathrm{K}$ have been observed in 85 wt % H_2SO_4 (aq.) at 30 kHz driving, albeit for moving bubbles [8.185] prone to a finally aspherical collapse. Up to $\approx 10\,000\,\mathrm{K}$ are reported for phosphoric acid, again for a moving bubble [8.206], and under water hammer conditions, conditions also leading to aspherical bubble collapse [8.210]. Aspherical bubble collapse diminishes light emission (presumably along with lowering the temperature), as has been demonstrated with laser-induced bubbles [8.213]. The reason, why bubbles in sulfuric and phoshoric acid cannot be stabilized so easily in position for spherical collapse (and higher temperatures), has to be sought for in their relatively high viscosity. Viscosity introduces a history force [8.214] with the tendency to lower the positional stability of a bubble in a standing sound field [8.215]. However, windows of positional stability have been found, although not for all aequous concentrations of sulfuric acid [8.192, 195, 197].

The spectroscopic data are from the visible part of the bubble and there are speculations about a dense core inside the collapsed bubble with a high degree of ionization [8.200, 208, 211] and possibly higher temperatures. This may limit the observable temperatures as with the stars, supposed to have much higher core temperatures. Moreover, the spectroscopic data usually are averages over the flash duration. Time resolved spectra of the flashes ($\approx 10\,\mathrm{ns}$ duration) from single krypton bubbles

in sulfuric acid (85 wt %) driven at 26.3 kHz and 1.4 bar reveal a changing spectrum strongly going from red to violet in 10 ns and ending in the violet region [8.196].

Fitting blackbody curves to the spectra gives an average temperature of 11 800 K, but a peak temperature of $\approx 100\,000$ K [8.196].

8.12 Acoustic Chaos

Nonlinearity in acoustics not only leads to shock waves and, as just demonstrated, to light emission, but to even deeper questions of nonlinear physics in general [8.4]. In his curiosity, man wants to know the future. Knowledge of the future may also be of help to master one's life by taking proper provisions. The question therefore arises: how far can we look into the future and where are the difficulties in doing so? This is the question of predictability or unpredictability. In the attempt to solve this question we find deterministic systems, stochastic systems and, nowadays, chaotic systems [8.216–219]. The latter are special in that they combine deterministic laws that nevertheless give unpredictable output. They thus form a link between deterministic and stochastic systems.

8.12.1 Methods of Chaos Physics

A description of the methods developed to handle chaotic systems, in particular in acoustics, has been given in [8.54]. The main question in the context of experiments is how to connect the typically one-dimensional measurements (a time series) with the high-dimensional state space of theory (given by the number of variables describing the system). This is done by what is called *embedding* (Fig. 8.26 and [8.220–222]) and has led to a new field called *nonlinear time-series analysis* [8.223–225].

The embedding procedure runs as follows. Let $\{p(kt_s), k = 1, 2, \ldots, N\}$ be the measured time series,

then an embedding into a n-dimensional state space is achieved by grouping n elements each of the time series to vectors $\boldsymbol{p}_k^{(n)} = [p(kt_s), p(kt_s + t_l), \ldots, p(kt_s + (n-1)t_l)]$, $k = 1, 2, \ldots, N - n$, in the n-dimensional state space. There t_s is the sampling interval at which samples of the variable p are taken. The delay time t_l is usually taken as a multiple of t_s, $t_l = lt_s$, $l = 1, 2, \ldots$, to avoid interpolation. The sampling time t_s, the delay time t_l and the embedding dimension n must all be chosen properly according to the problem under investigation. Figure 8.27 demonstrates the effect of different delay times with experimental data from a chaotically oscillating periodically driven pendulum. When the delay time t_l is too small then from one embedding vector to the next there is little difference and the embedded points all lie along the diagonal in the embedding space (Fig. 8.27a). On the other hand, when the delay time t_l is too large, the reconstructed trajectory obtained by connecting successive vectors in the embedding space becomes folded and the reconstruction becomes fuzzy (Fig. 8.27c). The embedding dimension n is usually not known beforehand when an unknown system is investigated for its properties. Therefore the embedding is done for increasing n until some criterion is fulfilled. The basic idea for a criterion is that a structure in the point set obtained by the embedding should appear. Then some law must be at work that generates it. The task after embedding is therefore to find and characterize the structure and to find the laws behind it. The characterization of the point set
Fig. 8.26 Visualization of the embedding procedure
Fig. 8.27a–c Three embeddings with different delay times t_l for experimental data obtained from a chaotically oscillating, periodically driven pendulum (courtesy of U. Parlitz)

obtained can be done by determining its static structure (e.g., its dimension) and its dynamic structure (e.g., its expansion properties via the dynamics of nearby points).

The dimension easiest to understand is the pointwise dimension. It is defined at a point P of a point set M by $N(r) \approx r^D$, $r \to 0$, where $N(r)$ is the number of points of the set M inside the ball of radius r around P (Fig. 8.28). Examples for a line and a surface give the right integer dimensions of one and two (Fig. 8.29), because for a line we have $N(r) \approx r^1$ for $r \to 0$ and thus $D = 1$, and for a surface we have $N(r) \approx r^2$ for $r \to 0$ and thus $D = 2$.

Chaotic or strange attractors usually give a fractal (noninteger) dimension. The pointwise dimension may not be the same in this case for each point P. The distribution of dimensions then gives a measure of the inhomogeneity of the point set. Figure 8.30 gives an example of a fractal point set. It has been obtained by sampling the angle and the angular velocity of a pen-

dulum at a given phase of the periodic driving for parameters in a chaotic regime.

To investigate the dynamic properties of a (strange or chaotic) set the succession of the points must be retained. As chaotic dynamics is brought about by a stretching and folding mechanism and shows sensitive dependence on initial conditions [8.54] the behavior of two nearby points is of interest: Do they separate or approach under the dynamics? This behavior is quantified by the notion of the *Lyapunov exponent*. In Fig. 8.31 the calculation scheme [8.226] is depicted. It gives the maximum Lyapunov exponent via the formula

$$\lambda_{\max} = \frac{1}{t_m - t_0} \sum_{k=1}^{m} \log_2 \frac{L'(t_k)}{L(t_{k-1})} \quad \left[\frac{\text{bit}}{\text{s}} \right]. \quad (8.227)$$

When the largest Lyapunov exponent is positive, the system is said to be chaotic. A whole set of Lyapunov exponents can be defined, the *Lyapunov spectrum* of a dynamical system, giving the expansion properties in suitably defined eigenspaces. A comparison of methods for calculation of the Lyapunov spectrum can be found in [8.227]. When the Lyapunov spectrum from embedded experimental data is to be calculated, routinely the problem of spurious Lyapunov exponents arises,

Fig. 8.28 Notations for the definition of the pointwise dimension
Fig. 8.29 Example of pointwise dimensions for one-dimensional (a curve) and two-dimensional (a surface) point sets

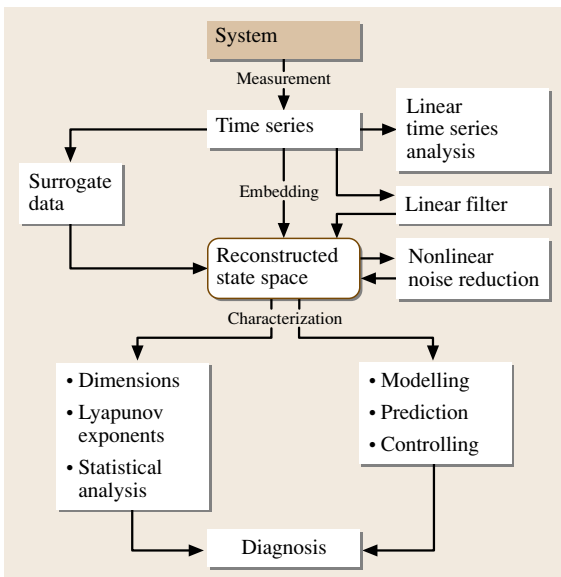
Fig. 8.30 The point set of a strange attractor of an experimental, driven pendulum (courtesy of M. Kaufmann)
Fig. 8.31 Notations for the definition of the largest Lyapunov exponent


Fig. 8.32 Operations in nonlinear time-series analysis (courtesy of U. Parlitz)

when the dimension of the embedding space is getting larger than the dimension of the embedded attractor. The extra, superfluous Lyapunov exponents are not necessarily the lowest ones. The problem can be solved by the method of time reversal of the data [8.228]. The true Lyapunov exponents then change sign due to their connection with the inverted dynamics, whereas the spurious ones do not as they are not connected with a real dynamics. The more Lyapunov exponents are positive, the more chaotic the system behaves. A system with a large number of positive Lyapunov exponents approaches a stochastic behavior.

As space does not permit us to dig deeper into the operations possible with embedded data, only a graph depicting the possible operations in nonlinear time-series analysis is given in Fig. 8.32. Starting from the time series obtained by some measurement, the usual approach is to do a linear time-series analysis, for instance by calculating the Fourier transform or some correlation. The new way for chaotic systems proceeds via embedding to a reconstructed state space. There may be some filtering involved in between, but this is a dangerous operation as the results are often difficult to predict. For the surrogate data operation and nonlinear noise reduction the reader is referred to [8.223–225]. From the characterization operations we have mentioned here the dimension estimation and the largest Lyapunov exponent or Lyapunov spectrum. Various statistical analyses can be done and the data can also be used for modeling, prediction and controlling the sys-
Fig. 8.33 Cylindrical transducer submerged in water for bubble oscillation, cavitation noise, and sonoluminescence studies
Fig. 8.34 Example of the filamentary bubble pattern (acoustic Lichtenberg figure) inside the cylinder in the projection along the axis of the transducer (courtesy of A. Billo)

tem. Overall, nonlinear time series analysis is a new diagnostic tool for describing (nonlinear) systems.

8.12.2 Chaotic Sound Waves

One of the first examples of chaotic dynamics and where these methods were first applied was acoustic cavitation [8.4, 53, 229]. To investigate this phenomenon, the rupture of liquids by sound waves and the phenomena associated with it, an experimental arrangement as depicted in Fig. 8.33 was used. A cylindrical transducer of piezoelectric material is used to generate a strong sound field in water. A typical transducer was of 76 mm length, 76 mm inner diameter, and 5 mm wall thickness submerged in a water-filled glass container. Cylinders of different size were available driven at different frequencies between 7 kHz and 23 kHz. A standing acoustic wave is set up inside the cylinder having its maximum pressure amplitude along the axis of the transducer. A hydrophone monitors the sound output of the liquid. Some electronics and a computer

Fig. 8.35 Power spectra of cavitation noise taken at a driving frequency of $f_0 = 23$ kHz, marked in the figures by small triangle. The driving pressure was increased from one graph to the next, giving first a periodic, anharmonic signal (*top*), then subharmonic motion with lines at multiples of $f_0/2$ (period 2 motion, *top next*), then period 4 motion with lines at multiples of $f_0/4$ (*third plot*) and finally a broadband spectrum indicative of chaotic behavior (*bottom*) ▶

surround the experiment to drive the cylinder and to store the sampled pressure data from the hydrophone. When cavitation is fully developed, a dentritic filamentary bubble pattern is set up in the cylinder (Fig. 8.34).

When the sound field amplitude is raised the whole bubble field undergoes a period-doubling cascade to chaos [8.31, 32, 230], a strong indication that chaotic dynamics has been reached and that the broadband sound spectrum then encountered after successive period doubling (Fig. 8.35) is not of stochastic origin. It
should be noted, however, that the noise floor may have a stochastic part from fluctuating conditions actually being present in the bubble cloud as given in Fig. 8.34. The series of sound spectra as given in Fig. 8.35 can be visualized in a single diagram, called *spectral bifurcation diagram*, where the spectral amplitude is color coded and plotted versus some parameter, then called control parameter [8.53]. Figure 8.36 gives an example of the onset of cavitation inside the cylinder with the successive generation of period doubled subharmonic lines in the spectrum together with their harmonics. Period doubling sequences and chaotic oscillations have also been observed in connection with sonoluminescence experiments, i. e., when working with single bubbles [8.231–236].

The cascade of period-doubled sound in the liquid has its origin in the cascade of period-doubled oscillations to chaos of the nonlinearly oscillating bubbles [8.31, 32, 54, 237–239], and thus shows chaotic sound at the end of the cascade. An example of a period doubling sequence of bubble oscillations is given in Fig. 8.37 for a bubble with a radius at rest of $10\,\mu m$
driven at 275 kPa with the frequency of the sound field as control parameter. The oscillation is represented by sampling the radius of the bubble at a specified phase of the sound field. A bubble oscillation with the period of the sound field then is represented by one dot at the respective frequency, a period doubled oscillation repeating after two periods of the sound field by two dots and so on, a chaotic oscillation being represented by a given, sufficiently large number of sample points. Two period doubling cascades are to be seen from low frequencies upwards (left) and from high frequencies downwards (right) meeting in a zone of chaotic oscillations. The corresponding sequence of diagrams when coming successively from lower driving amplitudes starts from incomplete period doubling sequences, i. e., meeting in the middle at period 2, at higher driving at period 4, etc., until both sequences meet with chaotic oscillations [8.239] as in Fig. 8.37. This scenario is called *period bubbling*, also in contexts not pertaining to bubbles. Spherical bubble clusters with many interacting bubbles have been investigated numerically for their dynamics. Again period doubling sequences to chaos are found [8.240].

Embedding of the experimental (chaotic) time series data from acoustic chaos into spaces of increasing dimension [8.241, 242] yields a structure with low fractal dimensions between two and three (Fig. 8.38) and only just one positive Lyapunov exponent [8.242]. This is a quite surprising result in view of the thousands of oscillating bubbles of different sizes. Indeed, new theoretical results on the superposition of the sound output

Fig. 8.39 Different types of use of the thermoacoustic oscillator (TAO) as a musical instrument. *From top to bottom*: moving the hand for opening and closing the open end of the TAO, TAO trombone, TAO flute, TAO organ (courtesy of G. Müller)

of a population of driven bubbles have indicated that the low dimensionality may be a result of the (weak) synchronization of their motion from the periodic driving and the scale of observation [8.243]. Synchronization has been found to be a universal concept that abounds in nonlinear science [8.244]. It has directly been observed between two bubble populations in numerical calculations [8.240].

Bifurcations and chaotic sound waves also appear in other contexts [8.55]. In musical acoustics bifurcations are long known under the name of *multiphonics* in woodwind instruments [8.245, 246] and as the *wolf note* in bowed string instruments [8.247]. Recently, also bowed-string multiphonics have been investigated [8.248]. These oscillations are quasiperiodic motions, i.e. contain at least two incommensurable frequencies in their Fourier spectrum. Several musical instruments are susceptible to bifurcations and chaotic sound emission [8.249]. Examples are the bowed string [8.250–255], the clarinet [8.256–260], gongs and cymbals [8.261], and the trombone, crumhorn and bassoon [8.262, 263].

The human speech production process is intrinsically nonlinear. To produce voice sounds the vocal cords

are set into vibration through the air flow between them. The cords are a coupled system of nonlinear oscillators giving rise to bifurcations and chaos [8.264]. They play some role in modern vocal music [8.265].

Sound can be generated by heat. This research area is called thermoacoustics. When a gas-filled tube, closed at one end and open at the other is heated at the closed end and/or cooled at the open end, sound waves are emitted at a sufficiently high temperature difference (Sondhauss and Taconis oscillation). This phenomenon has been used to study its quasiperiodic route to chaos [8.266, 267]. Also shock waves have been observed in a looped tube [8.268]. Upon suitable construction a thermoacoustic oscillator (TAO) can be built that can be used as a musical instrument [8.269, 270]. In Fig. 8.39 a few of the musical operations tried are demonstrated: moving a hand in front of a TAO, altering the length of the oscillating air column for gliding sounds, fitting holes to the tube like in a flute, and using TAOs of different length that can be played like an organ. The main use of thermoacoustic engines, however, is as a new type of refrigerator and heat pump [8.271] and the principles and construction details are described in a separate chapter of this Handbook.

Architect Part C

Part C Architectural Acoustics

9. Acoustics in Halls for Speech and Music

Anders C. Gade

This chapter deals specifically with concepts, tools, and architectural variables of importance when designing auditoria for speech and music. The focus will be on cultivating the useful components of the sound in the room rather than on avoiding noise from outside or from installations, which is dealt with in Chap. 11. The chapter starts by presenting the subjective aspects of the room acoustic experience according to consensus at the time of writing. Then follows a description of their objective counterparts, the objective room acoustic parameters, among which the classical *reverberation time* measure is only one of many, but still of fundamental value. After explanations on how these parameters can be measured and predicted during the design phase, the remainder of the chapter deals with how the acoustic properties can be controlled by the architectural design of auditoria. This is done by presenting the influence of individual design elements as well as brief descriptions of halls designed for specific purposes, such as drama, opera, and symphonic concerts. Finally, some important aspects of loudspeaker installations in auditoria are briefly touched upon.

Current knowledge about room acoustic design is based on several centuries of practical (trial-and-error) experience plus a single century of scientific research. Over the last couple of decades scientific knowledge has matured to a level where it can explain to a usable degree:

1. The subjective aspects related to how we perceive the acoustics of rooms
2. How these subjective aspects are governed by objective properties in the sound fields
3. How these objective properties of the sound field are governed by the physical variables in the architectural design.

This chapter is organized in the same manner. The various subjective acoustic aspects will form the basis for our discussion and be a guide through most aspects of relevance in room acoustic design. However, some trends in current design practice based on the experience and intuition of individual acoustical designers will also be commented on. It is hoped that this approach will also have the advantage of stimulating the reader's ability to judge a room from her/his own listening experience, an ability which is important not only for designers of concert halls, but also for those responsible for creating and enjoying the sound in these halls: musicians, sound-system designers, recording engineers and concert enthusiasts.

9.1 Room Acoustic Concepts

In order to help the reader maintain a clear perspective all the way through this chapter, Fig. 9.1 illustrates the universe of architectural acoustics.

In the upper half of the figure, we have the phenomena experienced in the real world. Going from left to right, we have the auditoria, in which we can experience objective sound fields causing subjective impressions of the acoustic conditions. In all of these three domains, we find a huge number of degrees of freedom: halls can differ in a myriad of ways (from overall dimensions

to detailed shaping of small details like door handles), the sound fields which we describe by the impulse response concept – as explained in a moment – contain a wealth of individual sound components (reflections), each being a function of time, level, direction and frequency. Also, every individual may have his/her own way of expressing what the room does to the sound heard.

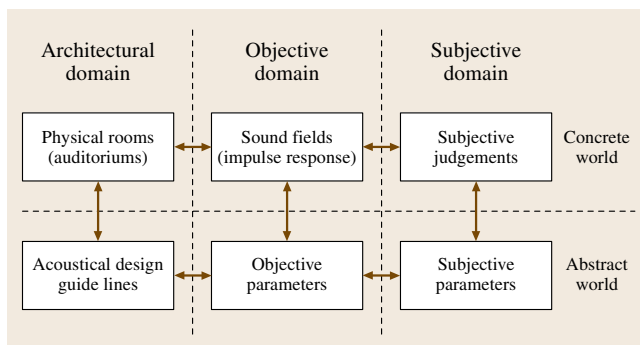
In other words, like in many other aspects of life, the real world is so complex that we need to simplify the problem – reduce the degrees of freedom – through definition of abstract, well-formulated and meaningful concepts and parameters in all three domains (the lower row of boxes). First, we must try to define a vocabulary to describe the subjective acoustic impression: we will isolate a set of subjective acoustic parameters that are valid to most people's listening experience (as indicated by the box in the lower-right corner), then we will try to deduce those properties from the sound fields that are responsible for our experience of each of the subjective aspects: we will define a set of objective, measurable parameters that correlate well with the subjective parameters, and finally – in order to be able to guide the architect – we must find out which aspects of the design govern the important objective and in turn the subjective


Fig. 9.1 Overview of concepts related to subjective room acoustics (after [9.1])

parameters, so we can assist in building halls meeting the specific needs of their users.

A rough historical overview: systematic search for objective acoustic parameters peaked in the 1960s and 1970s, while the relationships between the objective parameters and design variables were the topic of many research efforts in the 1980s and 1990s. However, we cannot yet claim to have the answers to all questions regarding the acoustic design of auditoria. Hopefully, there will always be room for intuition and individual judgment, not only in room acoustic design; but also as a source of inspiration for continued research efforts. Still it should be clear that room acoustic design today is based on solid research; it is not a snake-oil business.

9.2 Subjective Room Acoustics

9.2.1 The Impulse Response

The basic source of information regarding the audible properties of the sound field in a room is the impulse response signal. Actually, this signal – when recorded with a multichannel technique preserving the information about direction of incidence – can be shown to contain all information about the acoustics of a room between two specific source and receiver positions.

Consider a short sound impulse being emitted by the source on the stage, as shown in Fig. 9.2. A spherical wave propagates away from the source in all directions and the sound first heard in the listener position originates from that part of the wave that has propagated directly from the source to the receiver, called *the direct sound*. This is shown on the left in the lower part of Fig. 9.2, which shows the received signal versus time at a given position in the room.

This component is soon followed by other parts of the wave that have been reflected one or more times by the room boundaries or by objects in the room before reaching the receiver, called *the early reflections*. Besides arriving later than the direct sound, normally these reflections are also weaker because the intensity is reduced as the area of the spherical wavefront increases with time (spherical distance attenuation) and because a fraction of the energy is being absorbed each time the wave hits a more or less sound-absorbing room boundary or object in the room.

The sound wave will continue to be reflected and to pass the receiver position until all the energy has been absorbed by the boundaries/objects or by the air. The density of these later reflections increases with time (proportional to t^2), but the attenuation due to absorption at the room boundaries ensures that eventually all sound dies out. This decay is often heard as reverberation in the room, as Sabine did, when he carried out his famous experiment in the Fogg Art Museum more than 100 years ago [9.2]. This event marked the start of subjective room acoustics as a science.

9.2.2 Subjective Room Acoustic Experiment Techniques

With each of the reflections specified in time, level, spectrum and direction of incidence, the impulse response contains a huge amount of information. Now, the question is how we can reduce this to what is necessary for an explanation of why we perceive the acoustics in different rooms as being different.

Experiments trying to answer this question have mainly been carried out in the second half of the 20th century when electro-acoustic means for recording, measurement and simulation of sound fields had become available. Such experiments take place in the four rightmost boxes in Fig. 9.1: A number of impulse responses – or rather, music or speech convolved (filtered) through these responses – are presented to a number of subjects. The subjective evaluations are collected either as simple preferences between the sound fields presented in pairs or as scalings along specific subjective parameters suggested by the experimenter. The experimenter will also choose a number of different objective parameters, and calculate their values for each of the impulse responses presented. The level of correlation between these objective values and the objective scalings will then indicate which of the parameters and therefore which properties of the impulse responses are responsible for the subjective evaluations.

As can be imagined, the results of such experiments will be strongly dependent on the range of variation and degree of realism of the impulse responses presented – as well as by the sound quality of the equipment used for the presentation. Besides, the results will always be limited by the imagination of the experimenter regarding his/her:

1. Suggestions of proper semantic descriptors for the subjects' evaluation (except in cases where the subjects are only asked to give preferences) and

2. Suggestions of calculation of parameters from the impulse response.

In other words, before the experiments, the experimenter must have some good hypotheses regarding the contents of the lower-mid and lower-right boxes in Fig. 9.1.

Over the years, a variety of different techniques have been applied for presenting room sound fields to test subjects:

1. Collection of opinions about existing halls recalled from the memory of qualified listeners
2. Listening tests in different halls or in a hall with variable acoustics

3. Listening tests with presentation of recordings from existing halls or of *dry* speech/music convolved with impulse responses recorded in existing halls
4. Listening tests with sound fields synthesized in anechoic rooms (via multiple loudspeakers in an anechoic room) or impulse responses generated/modified by computer convolved with *dry* speech/music and presented over headphones.

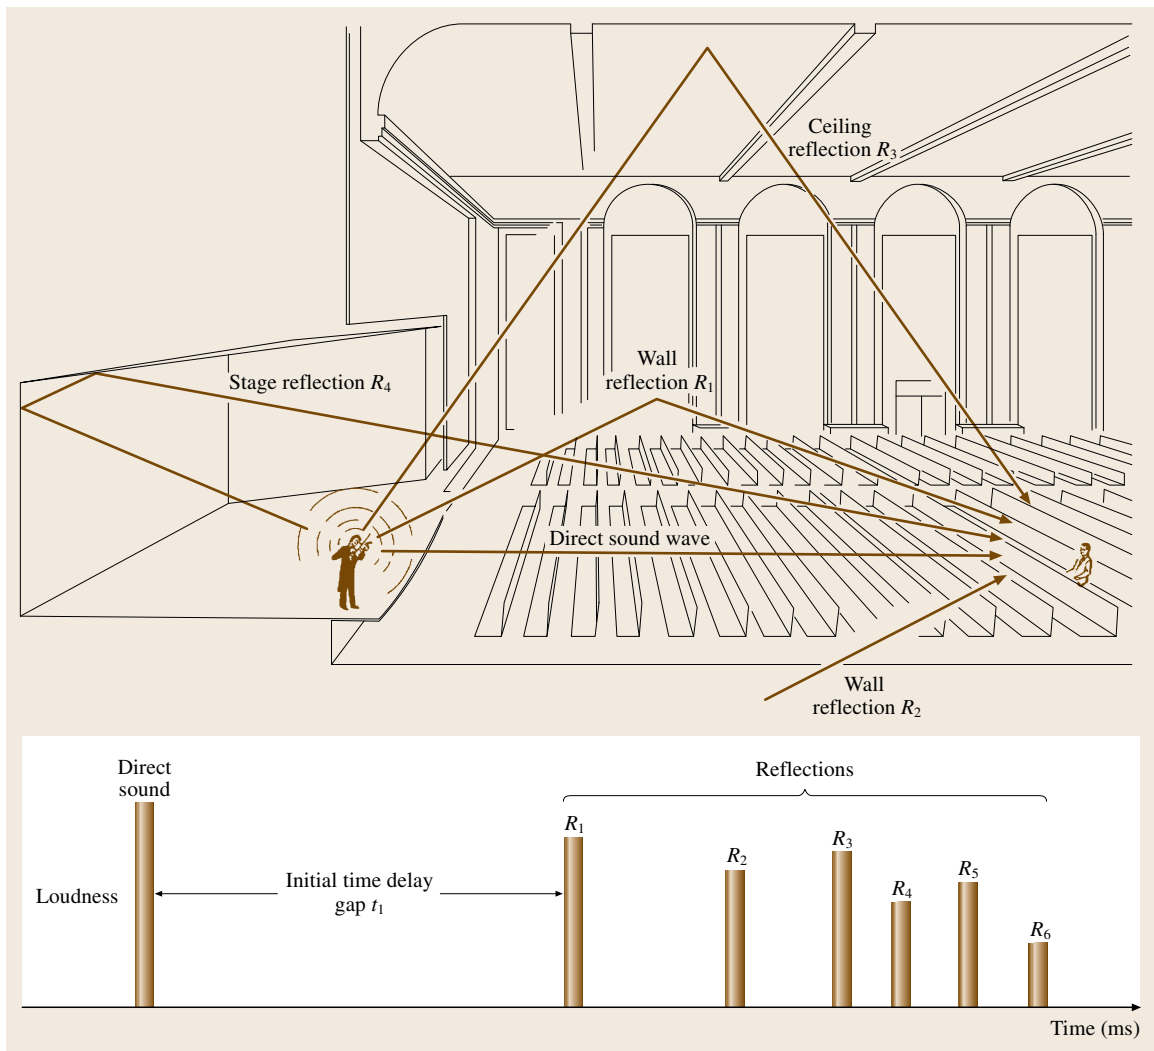
It should be mentioned here that our acoustic memory is very short. Therefore, unless the subjects are highly experienced in evaluating concert hall acoustics, comparison of acoustic experiences separated by days,


Fig. 9.2 Diagram illustrating the generation of an impulse response in a room (after [9.3])

weeks or even years is less reliable than comparison in the lab, where different recordings can be presented immediately one after the other. On the other hand, it is often difficult to get really qualified people to come to the lab to participate in scientific tests. Therefore, results from interview surveys can still be highly relevant.

These different techniques for presenting the sound fields all have different limitations. Experiments in the lab involving electro-acoustic reproduction or the generation of sound fields may lack fidelity, while listening in a real hall to a real orchestra will normally lack flexibility and control of the independent variables. Another important difference between these two methods is the absence of realistic visual cues in the lab. Enjoyment of a performance is a holistic experience, a fact which is now given increased scientific attention. In all cases elaborate statistical analysis of the results are needed in order to separate the significant facts from the error variance present in any experiment involving subjective judgements. Since the 1960s, multidimensional statistical tool such as factor analysis and multidimensional scaling have been very useful in distinguishing between the different subjective parameters which are present – consciously or not – in our evaluation. In any case, published results are more likely to be close to the truth, if they have been verified by several experiments – and experimenters – using different experimental approaches.

9.2.3 Subjective Effects of Audible Reflections

As the impulse response consists of the direct sound followed by a series of reflections, the simplest case possible would be to have only the direct sound plus a single reflection (and perhaps some late, artificial reverberation). Many experiments in simulated sound fields have been conducted using such a simple setup, and in spite of the obvious lack of realism, we can still learn a lot about the subjective effects of reflections from these experiments.

First of all, due to the psycho-acoustic phenomenon called forward masking, the reflection will be inaudible if it arrives very soon after the direct sound and/or its level is very low relative to the direct sound. Thus, there exists a level threshold of audibility depending on delay and direction of incidence relative to the direct sound. Only if the level of the reflection is above this threshold will the reflection have an audible effect, which again depends on its level, delay and direction of incidence. The possible effects are (at least):

- Increased level (energy addition).
- Increased clarity, if it arrives within 50–80 ms after the direct sound.
- Increased spaciousness, if the reflection direction in the horizontal plane is different from that of the direct as this causes the signals received at the two ears to be different. (If the angle between the direct and reflected sounds differs in the vertical plane only, the effect is rather a change in *timbre* or coloration of the sound.)
- Echo, typically observed for delays beyond. 50 ms and at high reflection levels. If the delay is very long, say 200 ms, then the echo may even be detected at a much lower level.
- Coloration. If the delay is short, say below 30 ms, and the level is high, phase addition of the direct sound and the reflection will create a *comb filter* effect, which severely deteriorates the original frequency spectrum.
- Change in localization direction, in cases where the reflection is louder than the direct sound. This may happen either due to amplification of the reflection via a concave surface or due to excess attenuation of the direct sound, for instance by an orchestra pit rail.

Audibility thresholds, echo risk and other effects also depend on spectral and temporal properties of the signal itself. Thus, with speech and fast, staccato played music (not to speak of artificial, impulsive *click* sounds), echoes are much easier to detect than when the signal is
Fig. 9.3 Various audible effects of a single reflection arriving from the side. The signal used was music (after [9.4])
Fig. 9.4 Thresholds of perception of a new reflection (*circles and horizontal lines*) being added to impulse responses already containing one, two, three, or four other reflections with delay and relative levels, as indicated by the *vertical lines* (after [9.5])

slow, legato music. On the other hand, these slower signals are more sensitive for the detection of coloration effects.

The temporal properties of sounds are sometimes described by the autocorrelation function. According to *Ando* (Chap. 10) not only the thresholds of audibility but also the preferred delay of early reflections and the preferred reverberation time depend strongly on the autocorrelation of the signal. However, such a strong effect on concert hall preference – derived from listening experiments in rather simplified simulated sound fields in the lab – is not in accordance with everyday listening experiences in concert halls, in which we gladly accept listening to different music pieces of different tempo from different seats (different reflection delays) in the same hall (fixed reverberation time).

Figure 9.3 illustrates the various audible effects of a single reflection arriving from a 40° angle relative to a frontal direct sound. In this experiment music was used as the stimulus signal. Below the lower threshold (reflection level below about -20 dB and almost independent of the delay), the reflection is inaudible. In the upper-right region it causes a distinct echo, while in the shaded area we experience *spatial impression* or a broadening of the area from which the sound seem to originate. For delays lower than about 30 ms, this single reflection also causes an unpleasant change in *timbre* or *tonal color*, which is due to the combination of the direct and reflected signal forming a comb filter giving systematic changes in the spectrum. If the level of the reflection is increased to be louder than the direct sound (above 0 dB) while the delay is still below say 50 ms, we experience an *image shift* or a change in localization from the direction of the direct sound towards the direction from which the reflection is coming.

In practice, of course, the impulse response from a room contains many reflections, and we therefore need to know how the threshold of perceptibility of the incoming reflection changes in cases where the impulse response contains other reflections already. As seen from Fig. 9.4, the threshold level increases substantially in the delay range already occupied by other reflections. This phenomenon is primarily due to masking.

From this we can conclude that many of the details in a complex impulse response will be masked and only some of the dominant components or some of its overall characteristics seriously influence our perception of the acoustics. This is the reason why it is possible to create rather simple objective room acoustic parameters, as listed in the following section, which still describe the main features of the room acoustic experience. Thus, we seem to have some success describing the complex real world (the upper-middle and right boxes in Fig. 9.1) by simpler, abstract concepts. Also, it will be seen that the subjective effects caused by a single reflection remain important in the evaluation of more-realistic and complicated impulse responses.

9.3 Subjective and Objective Room Acoustic Parameters

From a consensus of numerous subjective experiments in real rooms and in simulated sound fields (representing all of the previously mentioned subjective research techniques), we now have a number of subjective parameters and corresponding objective measures available. Most of these are generally recognized as relevant descriptors of major aspects in our experience of the acoustics in rooms. This situation has promoted standardization of measurement methods and many of the objective parameters are now described in an appendix to the International Organization for Standardization (ISO) standard [9.6]. In order to maintain a clear distinction between the subjective and objective parameters in the following, the names for the subjective parameters will be printed in italics.

9.3.1 Reverberation Time

Reverberance is probably the best known of all subjective room acoustic aspects. When a room creates too much *reverberance*, speech loses intelligibility because important details (consonants) are masked by louder, lingering speech sounds (the vowels). For many forms of music, however, *reverberance* can add an attractive fullness to the sound by bonding adjacent notes together and blending the sounds from the different instruments/voices in an ensemble.

The reverberation time T which is the traditional objective measure of this quality, was invented 100 years ago by W. C. Sabine. T is defined as the time it takes for the sound level in the room to decrease by 60 dB after a continuous sound source has been shut off. In practice, the evaluation is limited to a smaller interval of the decay curve, from -5 dB to -35 dB (or -5 dB to -25 dB) below the start value; but still relating to a 60 dB decay (Fig. 9.5), i. e.

$$T = 60\,\text{dB}\,\frac{(t_{-35}) - (t_{-5})}{(-5\,\text{dB}) - (-35\,\text{dB})}. \tag{9.1}$$

In this equation, t_{-x} denotes the time when the decay has decreased to X dB below its start value, or, if we let $R(t)$ represent the squared value of the decaying sound pressure and shut off the sound source at time $t = 0$

$$10 \log_{10}\left(\frac{R(t_{-X})}{R(0)}\right) = -X\,\text{dB}. \tag{9.2}$$

With the fluctuations always present in decay curves, T should rather be determined from the decay rate, A dB/s, as found from a least-squares regression line (determined from the relevant interval of the decay curve). Hereby we get for T

$$T = \frac{60\,\text{dB}}{A\,\frac{\text{dB}}{\text{s}}} = \frac{60}{A}\,\text{s}. \tag{9.3}$$

Ways to obtain the decay curve from the impulse response will be further explained in the section on measurement techniques.

Due to masking, the entire decay process is only perceivable during breaks in the speech or music. Besides, the rate of decay is often different in the beginning and further down the decay curve. During running music or speech, the later, weaker part of the reverberation will be masked by the next syllable or musical note. Therefore an alternative measure, early decay time (EDT) has turned out to be better correlated with the *reverberance* perceived during running speech and music. This pa-
Fig. 9.5 The definition of reverberation time (after [9.4])

rameter, like T, also measures the rate of the decay; but now evaluated from the initial part, the interval between 0 and -10 dB, only. Thus,

$$\text{EDT} = 6(t_{-10}) \quad \text{or} \quad \text{EDT} = \frac{60}{A_{(0\,\text{dB} \to -10\,\text{dB})}}\,\text{s}. \tag{9.4}$$

The detailed behavior of the early part of the reverberation curve is influenced by the relative levels and distribution in time of the early reflections, which in turn vary depending on the positions of the source and receiver in the room. Likewise, the value of EDT is often found to vary throughout a hall, which is seldom the case with T.

In spite of the fact that EDT is a better descriptor of *reverberance* than T, T is still regarded the basic and most important objective parameter. This is mainly due to the general relationship between T and many of the other room acoustic parameters and because a lot of room acoustic theory relates to this concept, not least diffuse field theory, which is the basis for measurements of sound power, sound absorption, and sound insulation. T is also important by being referred to in legislation regarding room acoustic conditions in buildings.

Talking about diffuse field theory, it is often of relevance to compare the measured values of certain objective parameters with their expected values according to diffuse field theory and the measured or calculated reverberation time. As diffuse field theory predicts the decay to be purely exponential, the distribution in time of the impulse response squared should follow the

function:

$$h^2(t) = A \exp\left(\frac{-13.8}{T}t\right) , \tag{9.5}$$

in which the constant -13.8 is determined by the requirement that for $t = T$

$$10 \log_{10}\left(\exp\left(\frac{-13.8}{T}t\right)\right) = 60\,\text{dB} . \tag{9.6}$$

With an exponential decay, the decay curve in dB becomes a straight line. Consequently, the expected value of EDT, EDT_{exp}, equals T.

When evaluating measurement results, it is also relevant to compare differences with the smallest change that can be detected subjectively. For EDT, this so-called subjective difference limen is about 5% [9.7].

9.3.2 Clarity

Clarity describes the degree to which every detail of the performance can be perceived as opposed to everything being blurred together by later-arriving, reverberant sound components. Thus, *clarity* is to a large extent a property complementary to *reverberance*.

When reflections are delayed by no more than 50–80 ms relative to the direct sound, the ear will integrate these contributions and the direct sound together, which means that we mainly perceive the effect as if the clear, original sound has been amplified relative to the later, reverberant energy. Thus, an objective parameter that compares the ratio between energy in the impulse response before and after 80 ms has been found to be a reasonably good descriptor of *clarity*

$$C = 10 \log_{10}\left[\int_0^{80\,\text{ms}} h^2(t)\,\text{d}t \Big/ \int_{80\,\text{ms}}^{\infty} h^2(t)\,\text{d}t\right] . \tag{9.7}$$

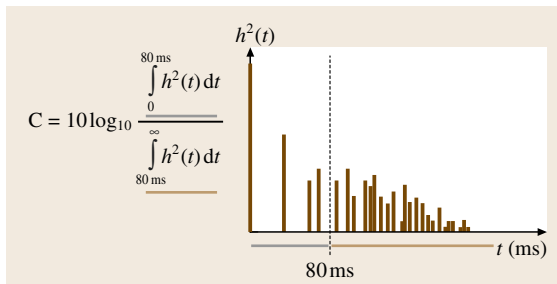
The higher the value of C, the more the early sound dominates, and the higher the impression of *clarity*.


Fig. 9.6 The definition of C: the ratio between early and late energy in the impulse response

With exponential decay, the expected value of C becomes a function of T alone

$$C_{\text{exp}} = 10 \log_{10}\left[\exp\left(\frac{1.104}{T}\right) - 1\right]\,\text{dB} . \tag{9.8}$$

The subjective difference limen for C (the equal best difference perceivable) is about 0.5 dB.

The definition of C is illustrated in Fig. 9.6.

Another parameter, which is also used to describe the balance between early and late sound or the balance between *clarity* and *reverberance*, is the center time t_s, which describes the center of gravity of the squared impulse response:

$$t_s = \int_0^{\infty} t h^2(t)\,\text{d}t \Big/ \int_0^{\infty} h^2(t)\,\text{d}t . \tag{9.9}$$

A low value of t_s corresponds to a clear sound, whereas higher values indicate dominance of the late, reverberant energy. The main advantage of t_s is that it does not contain a sharp time limit between early and late energy, since this sharp distinction is not justified by our knowledge about the functioning of our hearing system. The subjective difference limen for t_s is about 10 ms, and the expected diffuse field value is simply given by

$$t_{s,\text{exp}} = \frac{T}{13.8} . \tag{9.10}$$

9.3.3 Sound Strength

The influence of the room on the perceived *loudness* is another important aspect of room acoustics. A relevant measurement of this property is simply the difference in dB between the level of a continuous, calibrated sound source measured in the room and the level the same source generates at 10 m distance in anechoic surroundings. This objective measure called the (relative) strength G can also be obtained from impulse response recordings from the ratio between the total energy of the impulse response and the energy of the direct sound with the latter being recorded at a fixed distance (10 m) from the impulsive sound source

$$G = 10 \log_{10} \frac{\int_0^{\infty} h^2(t)\,\text{d}t}{\int_0^{t_{\text{dir}}} h_{10\,\text{m}}^2(t)\,\text{d}t} . \tag{9.11}$$

Here the upper integration limit in the denominator t_{dir} should be limited to the duration of the direct sound pulse (which in practice will depend on the bandwidth selected). A distance different from 10 m can be used,

if a correction for the distance attenuation is applied as well.

The expected value of G according to diffuse field theory becomes a function of T as well as of the room volume V

$$G_{\exp} = 10 \log_{10} \left(\frac{T}{V} \right) + 45 \, \text{dB} . \tag{9.12}$$

The subjective difference limen for G is about $1.0 \, \text{dB}$. The definition of G is illustrated in Fig. 9.7.

9.3.4 Measures of Spaciousness

Spaciousness is the feeling that the sound is arriving from many different directions in contrast to a monophonic impression of all sound reaching the listener through a narrow opening. It is now clear that there are two aspects of *spaciousness*, both of which are attractive, particularly when listening to music:

- *Apparent source width* (ASW): the impression that the sound image is wider than the visual, physical extent of the source(s) on stage. This should not be confused with localization errors, which of course should be avoided.

and

- *Listener envelopment* (LEV): the impression of being inside and surrounded by the reverberant sound field in the room.

Both aspects have been found to be dependent on the direction of incidence of the impulse response reflections. When a larger portion of the early reflection energy (up to about 80 ms) arrives from lateral directions (from the sides) the ASW increases. When the level of the late, lateral reflections is high, strong LEV results.

The lateral components of the impulse response energy can be recorded using a figure-of-eight microphone with the sensitive axis held horizontal and perpendicular to the direction towards the sound source (so that the source lies in the deaf plane of the microphone). For measurement of the lateral energy fraction (LEF), the early part (up to 80 ms) of this lateral sound energy is compared with the energy of the direct sound plus all early reflections picked up by an ordinary omnidirectional microphone

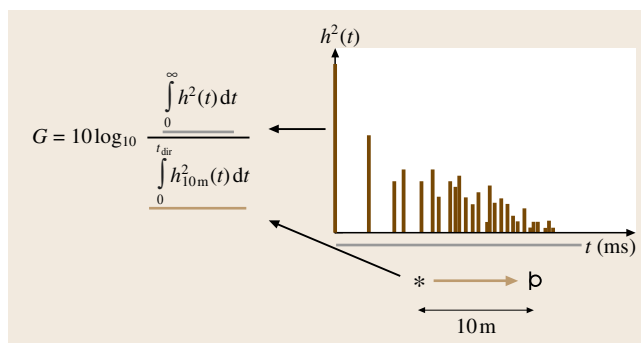
$$\text{LEF} = \int_{t=5\,\text{ms}}^{t=80\,\text{ms}} h_1^2(t)\,\text{d}t \bigg/ \int_{t=0\,\text{ms}}^{t=80\,\text{ms}} h^2(t)\,\text{d}t , \tag{9.13}$$


Fig. 9.7 The definition of strength G: the total energy in the impulse response measured relative to the direct sound level at 10 m distance from the source

where h_1 is the impulse response pressure recorded with a figure-of-eight microphone, whereas h is captured through the (usual) omnidirectional microphone.

It is mainly the energy at low and mid frequencies that contribute to the *spaciousness*. Consequently, LEF is normally averaged over the four octaves 125–1000 Hz. The higher the value of LEF, the wider the ASW. The literature contains many data on LEF values in different, existing concert halls.

LEF does not have an expected value related to T. In a completely diffuse field, LEF would be constant with a value of 0.33, which is higher than that normally found in real halls. The subjective difference limen for LEF is about 5%.

The definition of LEF is illustrated in Fig. 9.8.

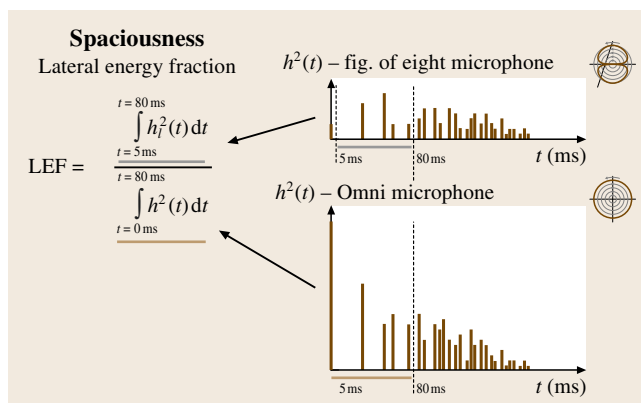
The ASW aspect of *spaciousness* is not only dependent on the ratio between early lateral and total early


Fig. 9.8 The definition of lateral energy fraction (LEF): the ratio between early reflection energy arriving from the sides and total early energy

sound; but also on the total level of the sound. The higher the G value (and the louder the sound source), the broader the acoustic image of the source. However, at the time of writing, there is no solid way of incorporating the influence of level into the objective measure.

Listener envelopment seems to be determined mainly by the spatial distribution and the level of the late reflections (arriving after 80 ms). A parameter called *late lateral strength* (LG) relating the late lateral energy to the direct sound at 10 m distance from the source has been proposed to measure this quality [9.8]

$$\text{LG} = \int\limits_{t=80\,\text{ms}}^{t=\infty} h_1^2(t)\,\mathrm{d}t \Big/ \int\limits_{t=0\,\text{ms}}^{t=t_\text{dir}} h_{10\,\text{m}}^2(t)\,\mathrm{d}t \;. \qquad (9.14)$$

LG is likely to be included in the ISO 3382 standard (from 2007); but so far LG has only been found correlating with subjective responses in laboratory experiments using synthetic sound fields. Therefore, it may be wise not to put too much emphasis on this parameter until its value has also been confirmed by experiments in real halls.

In contrast to reflections arriving in the median plane, lateral reflections will cause the instantaneous pressure at the two ears of the listener to be different. Such a dissimilarity of the signals at the two ears can also be measured by means of the interaural cross-correlation coefficient IACC

$$\text{IACC}_{t_1,t_2} = \max \left| \frac{\int_{t_1}^{t_2} h_\text{L}(t)h_\text{R}(t+\tau)\,\mathrm{d}t}{\sqrt{\int_{t_1}^{t_2} h_\text{L}^2(t)\,\mathrm{d}t \int_{t_1}^{t_2} h_\text{R}^2(t)\,\mathrm{d}t}} \right| \quad (9.15)$$

in which t_1 and t_2 define the time interval of the impulse response within which the correlation is calculated, h_L and h_R represent the impulse response measured at the entrance of the left and right ear, respectively, and τ is the interval within which we search for the maximum of the correlation. Normally, the range of τ is chosen between -1 and $+1$ ms, covering roughly the time it takes for sound to travel the distance from one ear to the other. As the correlation is normalized by the product of the energy of h_L and h_R, the IACC will take a value between 0 and 1. Results are often reported as $1 - \text{IACC}$ in order to obtain a value increasing with increasing dissimilarity, corresponding to an increasing impression of *spaciousness*. If the time interval for the calculation (t_1, t_2) is (0 ms, 100 ms), then the IACC will measure the ASW, while a later interval $(t_1, t_2) = $ (100 ms, 1000 ms) may be used to describe the LEV. The literature on measured values in halls

mainly contain data on IACC related to the 0–100 ms time interval.

Although the LEF and IACC parameters relate to the same subjective quality, they are not highly correlated in practice. Another puzzling fact is that LEF and IACC emphasize different frequency regions being of importance. LEF is primarily measured in the four lowest octaves, 125 Hz, 250 Hz, 500 Hz and 1000 Hz while IACC should rather be measured in the octave bands above 500 Hz. IACC values would always be high in the lower octaves, because the distance between the ears (< 30 cm) is small compared to 1/4 of the wave length (≈ 70 cm at 125 Hz).

9.3.5 Parameters Relating to Timbre or Tonal Color

Timbre describes the degree to which the room influences the frequency balance between high, middle and low frequencies, i. e. whether the sound is *harsh*, *bright*, *hollow*, *warm*, or whatever other adjective one would use to describe *tonal color*. Traditionally, a graph of the frequency variation of T (per 1/1 or 1/3 octave) has been used to indicate this quality; but a convenient single-number parameter intended to measure the warmth of the hall has been suggested [9.9]: the bass ratio (BR) given by

$$\text{BR} = \frac{T_{125\,\text{Hz}} + T_{250\,\text{Hz}}}{T_{500\,\text{Hz}} + T_{1000\,\text{Hz}}} \;. \qquad (9.16)$$

Likewise, a *treble ratio* (TR) can be formed as

$$\text{TR} = \frac{T_{2000\,\text{Hz}} + T_{4000\,\text{Hz}}}{T_{500\,\text{Hz}} + T_{1000\,\text{Hz}}} \;. \qquad (9.17)$$

However, in some halls, a lack of bass sound is experienced in spite of high T values at low frequencies. Therefore EDT or perhaps G versus frequency would be a better – and intuitively more logical – parameter for measurement of *timbre*. Likewise, BR or TR could be based on G rather than T values.

Besides the subjective parameters mentioned above, a quality called *intimacy* is also regarded as being important when listening in auditoria. *Beranek* [9.9] originally suggested this quality to be related to the initial time delay gap ITDG; but this has not been experimentally verified (At the time of writing, Beranek no longer advocates this idea but mentions the observation that, if the ITDG exceeds 45 ms, the hall has no intimacy [9.10]). It is likely that *intimacy* is related to a combination of some of the other parameters already mentioned, such as a high sound level combined

with a clear and enveloping sound, as will naturally be experienced fairly close to the source or in small rooms.

9.3.6 Measures of Conditions for Performers

In rooms for performance of music it is also relevant to consider the acoustic conditions for the musicians, partly because it is important to ensure that the musicians are given the best working conditions possible and partly because the product as heard by the audience will also be better if the conditions are optimal for the performers.

Musicians will be concerned about *reverberance* and *timbre* as mentioned above; but also about at least two aspects which are unique for their situation: *ease of ensemble* and *support* [9.11] and [9.12].

Ease of ensemble relate to how well musicians can hear – and play together with – their colleagues. If ensemble is difficult to achieve, the result – as perceived by musicians and listeners alike – might be less precision in rhythm and intonation and a lack of balance between the various instruments. *Ease of ensemble* has been found to be related to the amount of early reflection energy being distributed on the stage. So far, the only widely recognized objective parameter suggested for objective measurement of this quality is *early support* ST_{early}.

ST_{early} is calculated from the ratio between the early reflection energy and the direct sound in an impulse response recorded on the stage with a distance of only one meter between the source and receiver

$$ST_{early} = 10 \log_{10} \frac{\int_{20\,ms}^{100\,ms} h_{1\,m}^2(t)\,dt}{\int_{0\,ms}^{t_{dir}} h_{1\,m}^2(t)\,dt} \ . \qquad (9.18)$$

Support relates to the degree to which the room supports the musicians' efforts to create the tone on their own instruments, whether they find it easy to play or whether they have to force their instruments to fill the room. Having to force the instrument leads to playing fatigue and inferior quality of the sound.

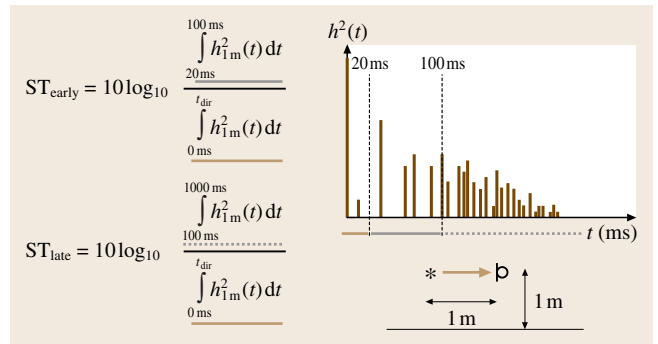
Support is also related to the amount of reflected energy on the stage measured using only a one meter source/microphone distance. For measurement of *support*, however, one needs to consider also the later reflections. This is because for many types of instruments, (especially strings), the early reflections will be masked by the strong direct sound from the instrument itself. Consequently, it seems relevant to define a mea-


Fig. 9.9 The definition of early support ST_{early} and late support ST_{late}, the ratio between early and late reflection energy respectively and the direct sound in the impulse response. Both are measured at 1 m distance from the source

sure such as *late support*, ST_{late}

$$ST_{late} = 10 \log_{10} \frac{\int_{100\,ms}^{1000\,ms} h_{1\,m}^2(t)\,dt}{\int_{0\,ms}^{t_{dir}} h_{1\,m}^2(t)\,dt} \qquad (9.19)$$

which relates to late response (after 100 ms) from the room to the sound emitted.

ST_{early} and ST_{late} are typically measured in the four octaves 150 Hz, 500 Hz, 1000 Hz, 2000 Hz. The lowest octave is omitted primarily because it is not possible to isolate the direct sound from the early reflections in a narrow band measurement. The definitions of early and late support are illustrated in Fig. 9.9.

Also the support parameters are planned to be included in the ISO 3382 standard (from 2007); but like LG the experiences and amount of data available from existing halls are still rather limited.

The amount of *reverberance* on the stage may be measured by means of EDT, (with a source–receiver distance of, say, 5 m or more).

9.3.7 Speech Intelligibility

All the objective parameters mentioned above (except the basic *T* parameter), are mainly relevant in larger auditoria intended for performance of music. In auditoria used for speech, such as lecture halls or theaters, the influence of the acoustics on intelligibility is a major issue.

Currently, the most common way to assess objectively *speech intelligibility* in rooms is by measurement of the speech transmission index STI.

As illustrated in Fig. 9.10, this measure is based on the idea that speech can be regarded as an amplitude-

Theory:
Modulation reduction function of T and S/N

$$m(F) = \frac{1}{\sqrt{1 + \left(2\pi F \dfrac{T}{13.8}\right)}} \; \frac{1}{1 + 10^{(-S/N)/10}}$$

$$(S/N)_{\text{app}} = 10\log_{10}\left(\frac{m}{1-m}\right)$$

$$\text{RASTI} = \left((S/N)_{\text{app}} + 15\right)/30$$

RASTI value	<0.30	0.30–0.45	0.45–0.60	0.60–0.75	>0.75
Intelligibility	Bad	Poor	Fair	Good	Excellent

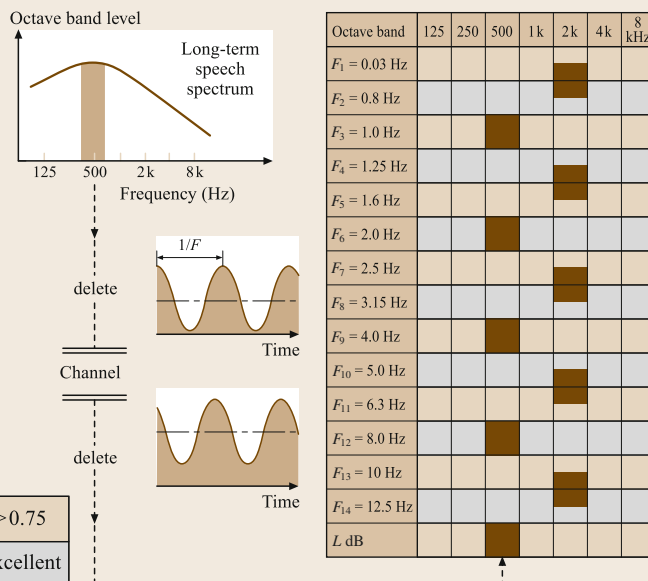
$F_{12} = 8.0$ Hz			■				
$F_{13} = 10$ Hz					■		
$F_{14} = 12.5$ Hz					■		
L dB			■				


Fig. 9.10 Illustration of the theory and principle in the measurement of STI or RASTI. The scale for the evaluation of RASTI values is shown at the bottom (after [9.13])

modulated signal in which the degree of modulation carries the speech information. If the transmission path adds noise or reverberation to the signal, the degree of modulation in the signal will be reduced, resulting in reduced intelligibility.

The modulation transfer is tested by emitting noise in seven octave bands, each modulated with 14 different modulation frequencies as listed in the table in Fig. 9.10 and then calculating the ratio between the original and the received degree of modulation, the modulation reduction factor, in each of these 98 combinations. A weighted average of the modulation reduction factor then results in a number between 0 and 1, corresponding to very poor and excellent conditions respectively.

A faster measurement method using only two carrier bands of noises and four plus five modulation frequencies (indicated by the dark squares in Fig. 9.10) is called rapid STI (RASTI). The STI/RASTI method is described in an International Electrotechnical Commission (IEC) standard: IEC 286-16.

Although the original method of STI or RASTI measurement employs modulated noise signals, it is also possible to calculate the modulation reduction factor from the impulse response. Thus, the modulation reduction factor versus modulation frequency F, which is called the modulation transfer function (MTF), can be found as the Fourier transform of the squared impulse response normalized by the total impulse response energy.

According to *Bradley* [9.14], a simpler parameter, called the *useful-to-detrimental sound ratio U_{80}* is equally suitable for measurement of speech intelligibility. U_{80} is simply a modified version of the clarity parameter defined in Sect. 9.3.2, in which a correction is made according to the ratio between the levels of speech and background noise.

9.3.8 Isn't One Objective Parameter Enough?

It is important to notice that all the parameters mentioned above – apart from T – may show large differences between different seats within the same hall. Actually, differences within a single hall are sometimes as large (both objectively and subjectively) as the differences between two different halls.

It should also be mentioned that the objective parameters related to the three subjectively different aspects: *reverberance/clarity*, *loudness* and *spaciousness* show low mutual correlation when measured in different seats or in different halls. In other words, they behave as orthogonal factors and do not monitor the

same properties of the sound fields. Consequently, it is obviously necessary to apply one objective parameter for each of these subjective aspects.

It is also clear that different listeners will judge the importance of the various subjective parameters differently. While some may base their judgment primarily on *loudness* or *reverberance* others may be more concerned about *spaciousness* or *timbre*.

For these reasons, one should be very sceptical when people attempt to rank concert halls along a single, universal, one-dimensional quality scale or speak about the best hall in the world. Fortunately, the diversity of room acoustic design and the complexity of our perception does not justify such simplifications.

9.3.9 Recommended Values of Objective Parameters

In view of the remarks above, it may be regarded risky to recommend values for the various objective acoustic parameters. On the other hand, there is a long tradition of suggesting optimal values for reverberation time T as a function of hall volume and type of performance. Besides, most of the other parameters will seldom deviate drastically from the expected value determined by T. As we shall see later, this deviation is primarily influenced by how we shape the room to control early reflections. Designing for strong early reflections can increase *clarity*, *sound strength* and *spaciousness*. Current taste regarding concert hall acoustics for classical music seems to be in favor of high values for these factors in addition to strong *reverberance*. This could lead to suggested ranges for the various parameters in small and large halls, as shown in Table 9.1. These values relate to empty halls with well-upholstered seating,

assuming that, when fully occupied with musicians and audience, the T values will drop by no more than say 0.2 s. The reason for relating the values to the unoccupied condition is that it is seldom possible to make acoustic measurements in the occupied state and almost all reference data existing regarding parameters other than T are from unoccupied halls. On the other hand, suggesting well-upholstered seats is a sound recommendation in most cases, which will ensure only small changes depending on the degree of occupancy. This will also justify extrapolation of the unoccupied values of the other parameters to the occupied condition, as mentioned later in this section.

The values listed in the table were arrived at by first choosing values for T ensuring high *reverberance*, while the correlative values for EDT, G and C stem from the diffuse field expected values; but these have been slightly changed to promote high *clarity* and high *levels*. As this is particularly important in larger halls, it has been suggested to use an EDT value 0.1 s lower than T ($=$ EDT$_{exp}$) and C values 1 dB higher than C_{exp} in a 2500 m^3 hall, but 0.2 s less than T and 2 dB higher than C_{exp}, respectively, in the 25 000 m^2 hall. Likewise, it is suggested to use G values 2 dB less than G_{exp} in the small halls; but only 1 dB less than or even equal to G_{exp} in large halls. For halls of size between the 2500 and 25 000 m^3 listed in the table, one may of course interpolate to taste. Please note that, in general, G is found to be 2–3 dB lower that G_{exp} (Sect. 9.5.6) so the G values suggested here are actually 1–2 dB higher than those found in *normal* halls.

In the occupied condition, one may expect EDT, C and G to be reduced by amounts equal to the difference between the expected values calculated using T for the empty and occupied conditions respectively. In any case,

Table 9.1 Suggested position-averaged values of objective room acoustic parameters in unoccupied concert halls for classical music. It is assumed that the seats are highly absorptive, so that T will be reduced by no more than 0.2 s when the hall is fully occupied. 2.4 s should be regarded as an upper limit mainly suitable for terraced arena or DRS halls with large volumes per seat (Sect. 9.7.3), whereas 2.0 s will be more suitable for shoe-box-shaped halls, which are often found to be equally reverberant with lower T values and lower volumes per seat

Parameter	Symbol	Chamber music	Symphony
Hall size	V/N	2500 m^3/300 seats	25 000 m^3/2000 seats
Reverberation time	T	1.5 s	2.0–2.4 s
Early decay time	EDT	1.4 s	2.2 s
Strength	G	10 dB	3 dB
Clarity	C	3 dB	−1 dB
Lateral energy fraction	LEF	0.15–0.20	0.20–0.25
Interaural cross correlation	$1-$ IACC	0.6	0.7
Early support	ST$_{early}$	−10 dB	−14 dB

if the empty–occupied difference in T is limited to 0.2 s, as suggested here, then the difference in these parameters will be fairly limited, with changes in both C and G being less than one dB – given that the audience does not introduce additional grazing incidence attenuation of direct sound and early reflections (Sect. 9.6.2).

For opera, one may aim towards the same relationships between the diffuse field expected and the desired values of EDT, C and G, as mentioned above for symphonic halls; but the goal for the reverberation time will normally be set somewhat lower, 1.4–1.8 s in order to obtain a certain intelligibility of the libretto and perhaps to make breaks in the music sound more dramatic (Sect. 9.7.2).

For rhythmic music, T values of 0.8–1.5 s, depending on room size, are appropriate, and certainly the value should not increase towards low frequencies in

this case. In very large rock venues such as sports arenas, it may actually be very difficult to get T below 3–5 s; but even then the conditions can be satisfactory with a properly designed sound system. The reason is that in such large room volumes the level of the reverberant sound can often be controlled, if highly directive loudspeakers are being used. In these spaces, the biggest challenge is often to avoid highly delayed echoes, which are very annoying. For amplified music, only recommendations for T are relevant, because the acoustic aspects related to the other parameters will be determined primarily by the sound system (Sect. 9.7.5).

In order to ensure adequate speech intelligibility in lecture halls and theaters, values for STI/RASTI should be at least 0.6. In reverberant houses of worship values higher than 0.55 are hard to achieve even with a well-designed loudspeaker system.

9.4 Measurement of Objective Parameters

Whenever the acoustic specifications of a building are of importance we need to be able to predict the acoustic conditions during the design process as well as document the conditions after completion. Therefore, in this and the following sections, techniques for measurement and prediction of room acoustic conditions will be presented.

In Sect. 9.2.1 it was claimed that the impulse response contains all relevant information about the acoustic conditions in a room. If this is correct, it must also be true that all relevant acoustic parameters can be derived from impulse response measurements. Fortunately, this has also turned out to be the truth.

9.4.1 The Schroeder Method for the Measurement of Decay Curves

Originally, reverberation decays were recorded from the decay of the sound level following the termination of a stationary sound source. However, *Schroeder* [9.15] has shown that the reverberation curve can be measured with increased precision by *backwards* integration of the impulse response, $h(t)$, as follows

$$R(t) = \int_t^\infty h^2(t)\,dt = \int_0^\infty h^2(t)\,dt - \int_0^t h^2(t)\,dt \quad (9.20)$$

in which $R(t)$ is equivalent to the decay of the squared pressure decay. The method is called backwards integration because the fixed upper integration limit, *infinite time*, is not known when we start the recording. There-

fore, in the days of magnetic tape recorders, the integration was done by playing the tape backwards. In this context *infinite time* means the duration of the recording, which should be comparable with the reverberation time. Traditional noise decays contain substantial, random fluctuations because of interference by the different eigenmodes present within the frequency range of the measurement (normally 1/3 or 1/1 octaves). These fluctuations will be different each time the measurement is carried out because the modes will be excited with random phase by the random noise (and the random time of the noise interruption). When, instead, the room is exited by a repeatable impulse, the response will be repeatable as well without such random fluctuations. In fact, Schroeder showed that the ensemble average of interrupted noise decays (recorded in the same source and receiver positions) will converge towards $R(t)$ as the number of averages goes towards infinity.

In (9.20), the right-hand side indicates that the impulse response decay can be derived by subtracting the running integration (from time zero to t) from the total energy. Contrary to the registration of noise decays, this means that the entire impulse response must be stored before the decay function is calculated. However, with modern digital measurement equipment, this is not a problem. From the $R(t)$ data, T is calculated by linear regression as explained in Sect. 9.3.1. As the EDT is evaluated from a smaller interval of the decay curve than T, the EDT is more sensitive to random decay fluctuations than is T. Therefore, EDT should never

be derived from interrupted noise decays – only from integrated impulse responses.

9.4.2 Frequency Range of Measurements

T may be measured per 1/3 octave; but regarding the other objective parameters mentioned in this chapter, it makes no sense to use a frequency resolution higher than 1/1 octave. The reason is that the combination of narrow frequency intervals and narrow time windows in the other parameters will lead to extreme fluctuations with position of the measured values due to the acoustic relation of uncertainty. Such fluctuations have no parallel in our subjective experience. *Bradley* [9.16] has shown that, with 1/1 octave resolution, a change in microphone position of only 30 cm can already cause fluctuations in the clarity C and strength G of about 0.5–1 dB, which is equal to the subjective difference limen. Higher fluctuations would not make sense, as normally we do not experience an audible change when moving our head 30 cm in a concert hall.

The frequency range in which room acoustic measurements are made is normally the six octaves from 125 to 4000 Hz, but it may be extended to 63–8000 Hz when possible. Particularly for reverberation measurements in halls for amplified music, the 63 Hz octave is important.

9.4.3 Sound Sources

With the possibility of deriving all of the objective parameters described above from impulse response measurements, techniques for creating impulses are described briefly in the following.

Basically, the measurements require an omnidirectional sound source emitting short sound pulses (or other signals that can be processed to become impulses) covering the frequency interval of interest, an omnidirectional microphone and a medium for the storage of the electrical signal generated by the microphone.

Impulsive sources such as pistols firing blank cartridges, bursting balloons, or paper bags and electrical spark sources may be used; but these sources are primarily used for noncritical measurements, as their directivity and acoustic power are not easy to control.

For measurements requiring higher precision and repeatability, omnidirectional loudspeakers are preferable, as the power and directivity characteristics of loudspeakers are more stable and well defined. Omnidirectional loudspeakers are often built as six units placed into the sides of a cube, 12 units placed into a dodecahedron or 20 units in an icosahedron, see Fig. 9.11. The

requirements regarding omnidirectivity of the source are described in the ISO 3382 standard.

Loudspeakers, however, cannot always emit sufficient acoustic power if an impulsive signal is applied directly. Therefore, special signals of longer duration such as maximum-length sequences or tone sweeps have been developed, which have the interesting property that their autocorrelation functions are band-limited delta pulses. This means that the loudspeaker can emit a large amount of energy without challenging its limited peak-power capability while impulse responses with high time resolution can still be obtained afterwards through postprocessing (a correlation/convolution process) of the recorded noise or sweep responses.

In certain cases, other source directivity patterns than omnidirectional can be of interest. For example, a directivity like that of a human talker may be relevant if the measurement is related to the intelligibility of speech or to measurements on the stage in an opera house. A suitable talker/singer directivity can be obtained by using a small loudspeaker unit (membrane diameter about three to four inches) mounted in a closed box of size comparable to that of the human head. Using only one of the loudspeakers in a cube or dodecahedron speaker of limited size is another possibility.

9.4.4 Microphones

For most of the parameters mentioned, the microphone should be omnidirectional, while omni plus figure-of-eight directivity and dummy heads are used when the impulse responses are to be used for the calculation of LEF and IACC.

Three-dimensional intensity probes, sound field microphones or microphone arrays have also been suggested in attempts to obtain more-complete information about the amplitude and direction of incidence of individual reflections [9.17] or for wave field analysis [9.18]. However, such measurements are mainly for research or diagnostic purposes. As such, they do not fulfill the goal set up in Sect. 9.1 of reducing the information to what is known to be subjectively relevant. A selection of relevant microphones are shown in Fig. 9.12.

9.4.5 Signal Storage and Processing

For the storage of the impulse responses the following choices appear:

- The hard disk on a personal computer (PC) equipped with a sound card or special analog-to-digital (A/D) converter card.

- Real-time (1/3 and 1/1 octave) analyzers or sound level meters with sufficient memory for storage of a series of short time-averaged root-mean-square (RMS) values.
- Fast Fourier transform (FFT) analysers capable of recording adequately long records.
- Tape recorders, preferably a digital audio tape (DAT) recorder, or even MP3 recorders given that the data reduction does not deteriorate the signal.

Of these, real-time analyzers and sound level meters will process the signal through an RMS detector before storage, which means that not the full signal,

but only energy with a limited time resolution will be recorded.

Today, calculation of the objective parameters will always be carried out by a PC or by a computer built into a dedicated instrument. A large number of PC-based systems and software packages particularly suited for room acoustic measurements are available. Some systems come with a specific analog-to-digital (A/D), digital-to-analog (D/A) and signal-processing card, which must be installed in or connected to the PC, while others can use the sound card already available in most PCs as well as external sound cards for hobby music use.

9.5 Prediction of Room Acoustic Parameters

Beyond theoretical calculation of the reverberation time, the prediction techniques presented in this section range from computer simulations and scale model measurements to simple linear models based on empirical data collected from existing halls.

In all cases, the main objective is the prediction of the acoustic conditions described in terms of the acoustic parameters presented in Sect. 9.3. Just as we can record the sound in a hall, both scale models and numerical computer simulations can also provide *auralizations*, which are synthesized audible signals that allow the client and architect to listen to and participate in the acoustic evaluation of proposed design alternatives. Such audible simulations will often have much greater impact and be more convincing than the acoustician's verbal interpretation of the numerical results. Therefore, the acoustician must be very careful to judge the fidelity and the degree of realism before presenting auralizations.

9.5.1 Prediction of Reverberation Time by Means of Classical Reverberation Theory

Reverberation time as defined in Sect. 9.3.1 is still the most important objective parameter for the characterization of the acoustics of a room. Consequently, the prediction of T is a basic tool in room acoustic design. Calculation of reverberation time according to the Sabine equation was the first attempt in this direction and today is still the most commonly used. However, during the 100 years since its invention, several other reverberation time formulae have been suggested (by Eyring, Fitzroy, Millerton and Sette, Metha and Mulholland Kuttruff and

others), all with the purpose of correcting some obvious shortcomings of the Sabine method.

The Sabine equation has been described in Sect. 11.1.4. In larger rooms, the absorption in the air plays a major role at high frequencies. If we include this factor, the Sabine equation reads

$$T = \frac{0.161V}{S\alpha^* + 4mV} \, , \tag{9.21}$$

where V is the room volume, S is the total area of the room surfaces, α^* is the area-weighted average absorption coefficient of the room surfaces

$$\alpha^* = \overline{\alpha} = \frac{1}{S} \sum_i S_i \alpha_i \tag{9.22}$$

and m accounts for the air absorption, which is a function of the relative humidity and increases rapidly with

Fig. 9.11 Two types of omnidirectional sound sources for room acoustic measurements: blank pistol (in the *raised hand of the seated person*) and an omnidirectional loudspeaker (icosahedron with 20 units)

Table 9.2 Air absorption coefficient m for different frequencies and relative humidity; valid for an air temperature of 20 °C (after [9.19])

Relative humidity (%)	0.5 kHz	1 kHz	2 kHz	4 kHz	8 kHz	Air absorption
40	0.4	1.1	2.6	7.2	23.7	$10^{-3}\,\text{m}^{-1}$
50	0.4	1.0	2.4	6.1	19.2	$10^{-3}\,\text{m}^{-1}$
60	0.4	0.9	2.3	5.6	16.2	$10^{-3}\,\text{m}^{-1}$
70	0.4	0.9	2.1	5.3	14.3	$10^{-3}\,\text{m}^{-1}$
80	0.3	0.8	2.0	5.1	13.3	$10^{-3}\,\text{m}^{-1}$

frequency [9.19]. Values of m versus frequency and relative humidity are listed in Table 9.2.

The Sabine equation assumes the absorption to be evenly distributed on all surfaces, and that the sound field is *diffuse*, which means that in each point of the room:

1. The energy density is the same, and
2. There is equal probability of the sound propagating in all directions.

Among the alternative reverberation formulae, only the Eyring method will be described here, as it may give more-accurate predictions in cases where the room is highly absorptive.

In contrast to Sabine, the Eyring theory assumes that the sound field is composed of plane sound waves that lose a fraction of their energy equal to the absorption coefficient of the surface whenever the wave hits a surface in the room. Thus, after n reflections, the energy in all wavefronts and the average energy density in the room has been reduced to $(1 - \overline{\alpha})^n$ times the original value. The average distance of propagation during this process is $l_m n = ct$, in which l_m is the *mean free path*,

Fig. 9.12 A selection of microphones types used for recording impulse responses in rooms. *From left*: artificial head (with both internal and external microphones), *sound field microphone* (with four capsules for 3-D recordings of reflections) and a two-channel (stereo) microphone with omnidirectional and figure-of-eight capsules

equal to the average distance traveled by the wave between two reflections, and t is the time elapsed since the wave propagation started. *Kosten* [9.20] has shown, that regardless of the room shape, l_m equals $4V/S$, if all directions of propagation are equally probable. These assumptions lead to the Eyring formula, which can be expressed by substituting α^* in (9.21) by

$$\alpha^* = \alpha_e = \ln\left(\frac{1}{1 - \overline{\alpha}}\right). \tag{9.23}$$

For low values of α^*, $\overline{\alpha}$ and α_e are almost identical, causing the Sabine and the Eyring formulae to give nearly identical results; but the difference becomes noticeable when $\overline{\alpha}$ exceeds about 0.3. In general, α_e will always be larger than $\overline{\alpha}$, leading to $T_{\text{Sabine}} > T_{\text{Eyring}}$. In the extreme case of the mean absorption approaching 1, α_e converges towards ∞, whereby $T_{\text{Eyring}} \to 0$ as one would expect for a totally absorbing room. However, T_{Sabine} converges towards the finite positive value $0.16\,V/S$, which of course is unrealistic.

Both the Sabine and the Eyring theories suffer from at least two shortcomings. Neither of them consider the actual distribution of the free paths (see the comments on the *mean free path* above), which is highly dependent on the room shape, nor the often very uneven distribution of the absorption in the room, which causes different directions of sound propagation not to be equally probable. Typical situations where these factors become important are rooms with highly absorbing acoustic ceilings and hard walls and floors – or the reverse situation of an auditorium, where almost all absorption is found in the seating. In these situations the energy is certainly not evenly distributed, there is a considerable distribution of the path lengths, and there is a much higher probability for sound energy to travel towards the absorbing surface than away from it.

A common example in which the Sabine and Eyring theories fall short is the simple case of a rectangular room with plane walls, absorbing ceiling and low height compared to length and width. In such a room the main part of the late reverberant energy will be stored in
Fig. 9.13 Strength versus distance measured in the Boston Symphony Hall; values averaged over the four octaves 250–2000 Hz. The reverberation distance in this hall is about 5 m

one- and two-dimensional horizontal room modes with long free paths, whereas the three-dimensional modes with shorter free paths will soon have lost their energy by interacting with the absorbing ceiling. Hereby, different modes end up having very different decay rates, leading to bent or double-sloped decay curves and to measured T values often longer than calculated. In fact, only the unnatural situation with an even absorption distribution and all free paths of equal length will result in a straight-line decay and a well-defined T value.

From practical measurements of the distribution of G values, it is also clear that the assumption of an even distribution of the energy density is not met in large auditoria. Contrary to the Sabine theory, which predicts a constant level beyond the reverberation distance (Fig. 11.6), we observe that the level continues to decrease with distance from the source – even far beyond the reverberation distance, where the contribution of the direct sound is negligible. An example of this is seen in Fig. 9.13. (Based on empirical data, simple equations predicting this attenuation of G with distance as a function of room geometry have been derived as described in Sect. 9.5.6.)

Still, rather than relying on another of the reverberation formulas to provide a more correct result, today it may be wiser just to apply the Sabine and perhaps the Eyring equations, keeping in mind their limitations. Thus, *Beranek* [9.21] has suggested that, for Sabine calculations in concert halls, one should apply different sets of seat absorption values depending on the room shape. These values should be measured in nearly the same type of room as the hall in question.

When higher prediction accuracy is required, it is recommended to carry out simulations in a computer model as described in Sect. 9.5.4. However, also with this calculation approach, the question about which absorption values to use is relevant.

9.5.2 Prediction of Reverberation in Coupled Rooms

Auditoria with coupled spaces form another situation in which the decay curve may end up being nonlinear and the energy density will be different in different areas of the room. Typical of such cases are open-plan office floors coupled to an atrium covering several storeys, seating areas in auditoria subdivided by (deep) balconies, theaters with proscenium openings between the auditorium and the stage house, churches subdivided into main and side naves and concert halls with reverberation chambers. Diffuse field theory can be used to illuminate important properties of the reverberation conditions in coupled rooms.

We consider a sound source placed in a room, room 1, with volume V_1 and physical absorption area A_{10}. This room is coupled by an opening with area S to another room, room 2, with volume V_2 and absorption area A_{20}. From diffuse field theory (the energy balance equations) we find that the apparent absorption area of room 1, A_1, depends on the ratio between the absorption area of the attached room A_{20} and the area of the opening S

$$A_1 = A_{10} + \frac{A_{20}S}{A_{20} + S} \ . \tag{9.24}$$

It is seen that for small openings, $S \ll A_{20}$, $A_1 \approx A_{10} + S$, and for large openings, $S \gg A_{20}$, $A_1 \approx A_{10} + A_{20}$, as we would expect.

As for the reverberation curve, a double slope may be observed, particularly if both source and receiver are placed in the less reverberant of the two rooms. The two reverberation times T_I and T_{II} defining the double slope can be described in terms of the reverberation times for each of the two rooms separately if we consider the opening to be totally absorbing

$$T_1 = \frac{0.161 V_1}{A_{10} + S} \quad \text{and} \quad T_2 = \frac{0.161 V_2}{A_{20} + S} \ . \tag{9.25}$$

However, for our purpose the math gets simpler if we apply damping coefficients: $\delta_1 = 6.9/T_1$ and $\delta_2 = 6.9/T_2$ instead of the reverberation times. Then, with coupling, the two damping coefficients, δ_I and δ_{II}, corresponding to the slope in the first and second part of

the decay, respectively, can be calculated from

$$\delta_{\text{I,II}} = \frac{\delta_1 + \delta_2}{2}$$

$$\pm \sqrt{\frac{(\delta_1 - \delta_2)^2}{4} + \frac{S^2 \delta_1 \delta_2}{(A_{10} + S)(A_{20} + S)}} \quad (9.26)$$

upon which

$$T_{\text{I}} = \frac{6.9}{\delta_{\text{I}}} \quad \text{and} \quad T_{\text{II}} = \frac{6.9}{\delta_{\text{II}}} \,. \quad (9.27)$$

Another important feature of the double-slope decay is how far down the knee point appears. If the opening area is large and/or the source or receiver is placed close to the opening, then a substantial exchange of energy can occur and the knee point may appear so early that even the EDT can be influenced by the decay from the coupled room with longer T. If the opening area is small, then the knee point appears late and far down on the curve, in which case the influence of the coupled room can only be perceived after final cords. This is the case with some of the existing concert halls equipped with coupled reverberation chambers. Further descriptions of coupled spaces can be found in [9.5].

9.5.3 Absorption Data for Seats and Audiences

Regardless of which reverberation formula is used, the availability of reliable absorption values is fundamental for the accurate prediction of T as well as of most other room acoustic parameters. Beyond the absorption values of various building materials (as listed in Table 11.1), realistic figures for the absorption of the chairs and seated audience are of special concern, be-

cause these elements normally account for most of the absorption in auditoria. The absorption of chairs – both with and without seated people – depends strongly on the degree of upholstery. Average values of absorption for three different degrees of chair upholstery have been published by *Beranek* [9.22] and quoted in Table 9.3. As mentioned earlier, chair absorption values for use specifically in Sabine calculations and for different types of hall geometries can be found in [9.21].

Sometimes audience absorption data are quoted as absorption area per chair or per person. However, as demonstrated by *Beranek* [9.3], the use of absorption coefficients multiplied by the area covered by the seats plus an exposed perimeter correction is more representative than absorption area per person, because audience absorption tends to vary proportionally with the area covered, while the absorption coefficient does not change much if the density of chairs is changed within that area.

Minimizing the total sound absorption area is often attempted in auditoria for classical music in order to obtain a strong, reverberant sound field. One way to achieve this is not to make the row-to-row distance and the width of the chairs larger than absolutely necessary. Another factor is the seat design itself. Here one should aim at a compromise between minimum absorption and still a minimum difference between the absorption of the occupied and empty seat. This is facilitated by back rests not being higher than the shoulders of the seated person and only the surfaces covered by the person being upholstered. The rear side of the back rest should be made from a hard material like varnished wood. On the other hand, a minimum difference between the occupied and empty chair implies that the upholstery on the seat

Table 9.3 Absorption coefficients of seating areas in concert halls for three different degrees of upholstery; both empty and occupied (after [9.22])

Octave centre frequency (Hz)	125	250	500	1000	2000	4000
Heavily upholstered chairs Unoccupied	0.70	0.76	0.81	0.84	0.84	0.81
Heavily upholstered chairs Occupied	0.72	0.80	0.86	0.89	0.90	0.90
Medium upholstered chairs Unoccupied	0.54	0.62	0.68	0.70	0.68	0.66
Medium upholstered chairs Occupied	0.62	0.72	0.80	0.83	0.84	0.85
Lightly upholstered chairs Unoccupied	0.36	0.47	0.57	0.62	0.62	0.60
Lightly upholstered chairs Occupied	0.51	0.64	0.75	0.80	0.82	0.83

and back rest should be fairly thick (e.g., 80 mm on the seat and 50 mm on the back rest), the bottom of the tip-up seats should be perforated or otherwise absorptive, and when the seat is in its vertical position, there should be a wide opening between the seat and the back rest so that the sound can still access the upholstered areas.

9.5.4 Prediction by Computer Simulations

Computer simulations take into account the geometry and actual distribution of the absorption materials in a room as well as the actual source and receiver positions. The results provided are values for all relevant acoustic parameters as well as the generation of audio samples for subjective judgments. Computer simulation is useful not only for the design of concert halls and theaters, but also for large spaces such as factories, open-plan offices, atria, traffic terminals, in which both reverberation, intelligibility and noise-mapping predictions are of interest. Besides, they can be used in *archaeological acoustics* for virtual reconstruction of the acoustics of ancient buildings such as Roman theaters (http://server.oersted.dtu.dk/www/oldat/erato/).

The first computer models appeared in the 1960s, and today a number of commercially available software packages are in regular use by acoustic consultants as well as by researchers all over the world.

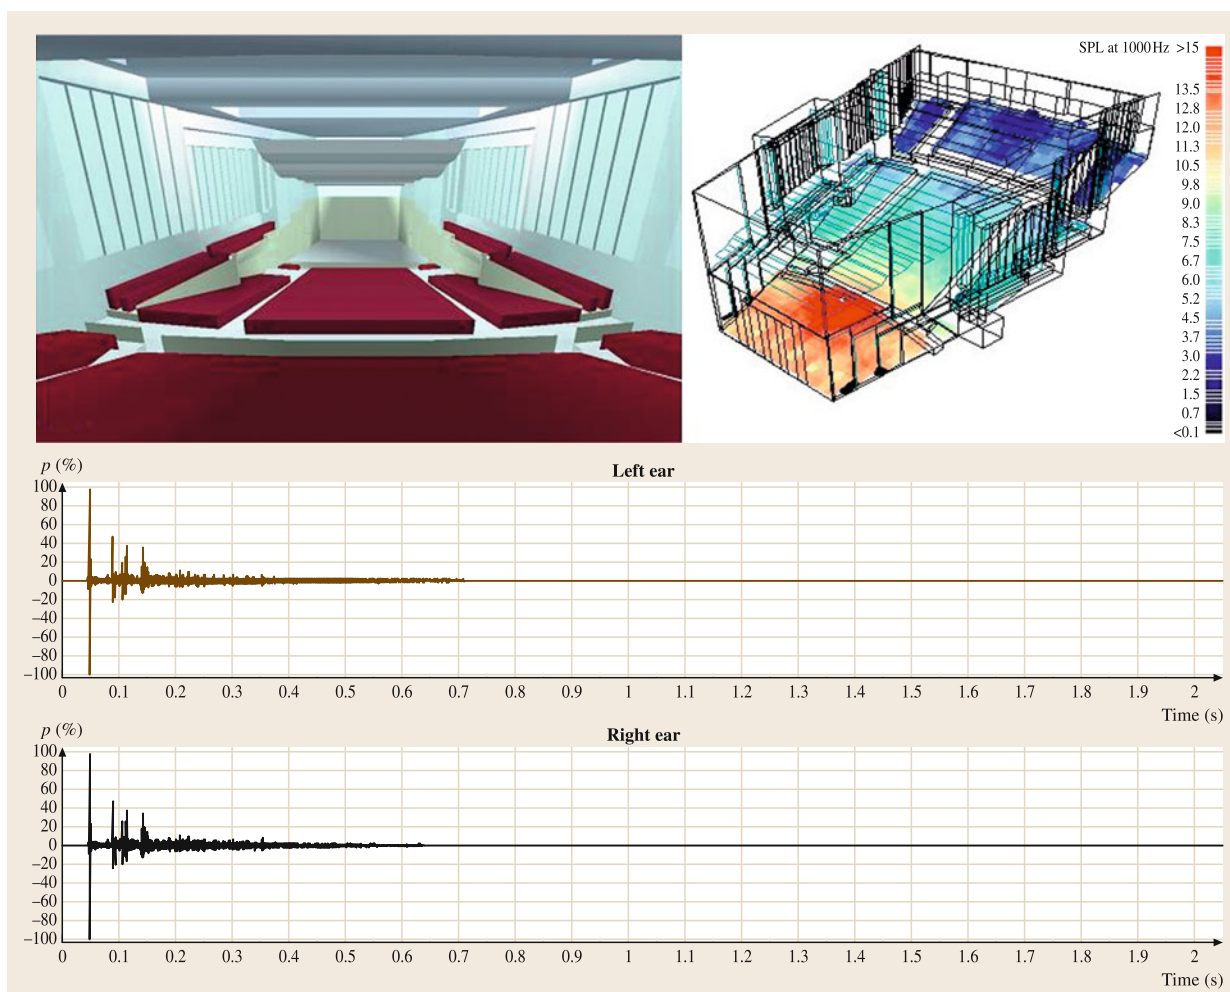
In computer simulations the room geometry is represented by a three-dimensional (3-D) computer-aided design (CAD) model. Thus, the geometry information can often be imported from a 3-D model file already created by the architects. However, one needs to break up


Fig. 9.14 Examples of output from a room acoustic simulation software package (ODEON); see text for explanation

eventual curved surfaces into plane elements and often it is also advisable to simplify details in the geometry provided by the architect. Alternatively, the acoustician can build the room model by writing a file of coordinate points or mathematical expressions for all surface corners. Of course this will be more time consuming in cases of complex room geometry, but some programs offer intelligent programming routines for the modeling of geometric elements.

When the geometry has been completed, the absorption values for each octave band, the scatter, and the eventual degree of acoustic transparency have to be assigned to each surface. In addition, the source and receiver characteristics (power and directivity versus frequency, position and orientation) must also be entered.

In the calculation of sound propagation, most models disregard phase properties and use an energy approximation. The sound propagation is studied by means of rays (up to millions depending on the room complexity) being traced from the source position through reflections until their energy has been reduced below the dynamic range of interest (often determined by T or the signal-to-noise ratio in auralizations). Reflection directions are chosen so that angle of reflection equals angle of incidence or with more or less random angles depending on the scatter value attributed to the surface. For the calculation of early reflections, some models also apply image source theory, which actually makes phase considerations possible if the complex impedances of the various surface materials and not just their energy absorption coefficients are known. However, the late reverberation part is normally calculated by some kind of ray method, as image source calculations become impractical after a few orders of reflection. Recently, however, attempts to carry out complete calculations inspired by finite-element (FEM) or boundary-element (BEM) methods have been reported even for rather complex rooms [9.23], whereby phase and diffraction phenomena can be handled.

As a result of tracing the history of all rays emitted in the room model, source and receiver specific impulse responses are produced with detailed information about the direction of incidence, delay and level versus frequency of each reflection component. From these, all the parameters mentioned in Sect. 9.3 can be calculated. Most programs can generate a grid of receiver point over selected audience areas and code the numeric results using a color scale to facilitate a fast overview of the detailed position results for any of the parameters. Also, automatic plots of relevant statistics regarding the distribution with frequency and position are provided.

Impulse responses suitable for use in *auralization* can be generated by applying available head-related transfer functions, which have been recorded as a function of direction of sound incidence on an artificial head. Such transfer functions not only represent the directivity of the human receiver, but are also important for correct perception of direction of incidence of sound field components when listening through headphones. Alternatively, the directional information of the individual reflections making up the impulse response can be coded into a surround-sound format for listening via a multiple-loudspeaker setup.

Figure 9.14 shows a view of a room model as well as two binaural impulse responses and a color mapping of a calculated parameter (generated by the ODEON software).

9.5.5 Scale Model Predictions

Acoustic scale models have been used since the 1930s [9.24] to study the behavior of sound in rooms. With proper care in detailing the geometry and the choice of materials for building the model, this technique can provide quite accurate predictions of impulse responses and acoustic parameters. Actually, scale modeling is still regarded as more reliable than computer models in cases where the room contains a lot of irregular surfaces or objects that diffuse or diffract sound waves. However, the use of physical scale models is limited to larger, acoustically demanding projects, as building and testing the model is far more time consuming and costly than computer modeling.

The diffusion and diffraction caused by an object or surface in a room depends on the ratio between the linear dimensions and the wavelength of the sound: l/λ. Therefore, in a $1 : M$ scale model, the diffraction/diffusion conditions will be modeled correctly if the wavelengths of the measurement signals in the model are chosen such that

$$\frac{l}{\lambda} = \frac{l_{\mathrm{M}}}{\lambda_{\mathrm{M}}} = \frac{l/M}{\lambda/M} \quad \Rightarrow \quad f_{\mathrm{M}} = fM . \qquad (9.28)$$

This means that we should increase the frequency used in the model measurements by the factor M. Fortunately, sound sources and microphones exist that are capable of handling frequencies up to around $100\,\mathrm{kHz}$, whereby the frequency range up to $10\,\mathrm{kHz}$ can be handled in a $1 : 10$ scale model or $2\,\mathrm{kHz}$ in a $1 : 50$ scale model. The sources may be small loudspeaker units (piezoelectric or electro magnetic) and the microphones $1/4''$ or even $1/8''$ condenser types.

Ideally, the absorption coefficient α_M of the materials chosen for building each surface in the hall model should fulfil the equation

$$\alpha_M(fM) = \alpha(f) . \tag{9.29}$$

In practice, however, we need only to distinguish between mainly reflecting and mainly absorptive materials. The reflecting surfaces are quite easy, as these can be made of any hard material (plywood, plaster) with a couple of layers of varnish if necessary. It is far more important to build the seats/audience so that both head diffraction and absorption is correct for the scale chosen. In the end it is often necessary to fine-tune the reverberation time in the model by applying absorption to some secondary surfaces (surfaces that do not generate primary early reflections).

Another important issue is to compensate for the excessive air absorption at high frequencies in the model. This can be achieved either by drying the air in the model, by exchanging the air for nitrogen, or simply as a calculated compensation since the attenuation is a simple linear function of time once the, frequency, humidity and temperature have been specified. However, in the case of compensation the signal-to-noise ratio at high frequencies will be severely limited, which reduces the decay range for the estimation of T and the sound quality if auralization is attempted. Figures 9.15 and 9.16 show an example of a 1 : 10 scale model and its audience respectively.

9.5.6 Prediction from Empirical Data

In the 1980s, when most of the current objective acoustic parameters had been defined, several researchers started making systematic measurement surveys of concert, opera and multipurpose halls. Many of these measured data were published in [9.3]. Combining acoustic data with data on the geometry of the halls has made it possible to derive some simple rules of thumb regarding how, and how much, acoustic parameters are affected by the choice of gross room shape and dimensions.

Through statistical multiple linear-regression analysis of data from more than 50 halls, a number of relationships between acoustical and geometrical properties have been found [9.25]. A number of the linear regression models derived are shown in Table 9.4. In these models, the variations in the acoustic parameters are described as functions of the expected value according to diffuse field theory (G_{exp} and C_{exp}, Sect. 9.3) plus various geometrical variables such as: average room height H, average width W, room volume V, number

of seats N, number of rear balcony levels *no. rear balc.* etc. When the models were derived, the measured reverberation time (T) was used to calculate the expected values of strength G_{exp} and clarity C_{exp}. When using these models for prediction of the values in a hall not yet built, the expected values could be based on a Sabine calculation of T instead. It should be mentioned that, apart from $\Delta G(10\,\text{m})$, the attenuation in strength per 10 m increase in source–receiver distance, the predicted values should be considered as representing the position average of values to be found in the hall.

The three rightmost columns in Table 9.4 contain information about how well each prediction formula matched the measured data. When comparing the amounts of variance explained by the different models, it is seen that the diffuse field prediction is responsible for the largest portion of the variance. This may be interpreted as hall volume and total absorption area being the most important factors governing the behavior of C and G. However, as all the independent variables listed gave a significant improvement of the model accuracy, this also demonstrated that consideration of the geometrical factors can improve the prediction accuracy. Equally importantly, the acoustic effects of changes in certain design variables can be quantified quickly.

Prediction of Clarity
The first C-model illustrates that absorption and volume, as reflected in T, are responsible for the main part of the variation in C. The other three models all illustrate the positive, but sometimes unwanted, effect of average hall width on clarity. Moreover, it is seen that introducing a moderate $15°$ slope of the main audience floor (without changing the other variables: average width-to-height ratio, volume and absorption area) causes C to increase by about 0.5 dB on average. Similarly, changing the basic design from rectangular to a $70°$ fan shape makes C increase by about 1 dB. The last C-model illustrates the effect of tilting the angle of the stage ceiling towards the audience. Changing the slope from horizontal to $20°$ results in about 0.5 dB higher C values.

Predictions of Strength
The G model only considering G_{exp} is rather accurate. The constants in both G-models illustrate the fact that G is always a few dB lower than G_{exp}, as also predicted by *Barron's revised theory* [9.26].

The second G-model contains an independent variable: the ratio between the volume and the number of seats. The positive influence of this ratio is not immediately evident because V/N, which is strongly correlated

Table 9.4 Regression models for the relationships between room acoustic parameters and room design variables as derived from a database containing data from more than 50 halls (after [9.25])

Room acoustic parameter	Regression models: $f(\text{PAR}_\text{expected}, \text{geometry})$	Correlation coefficient	% of variance	STD residuals
C (dB)	$-0.1 + 1.0C_\text{exp}$	0.76	58	1.0 dB
	$-1.4 + 0.95C_\text{exp} + 0.47W/H + 0.031$ floor slope	0.83	68	0.9 dB
	$-1.2 + 1.03C_\text{exp} + 0.43W/H + 0.013$ wall angle	0.84	70	0.9 dB
	$-1.77 + 1.10C_\text{exp} + 0.055W + 0.027$ stage ceil. angle	0.86	74	0.8 dB
G (dB)	$-2.0 + 0.94G_\text{exp}$	0.91	83	0.9 dB
	$-5.61 + 1.06G_\text{exp} + 0.17V/N + 0.04$ distance	0.94	89	0.9 dB
$\Delta G(10\,\text{m})$ (dB)	$-1.85 + 0.42$ no. rear balc.	0.50	25	0.7 dB
	$-1.41 + 0.35$ no. rear balc. $- 3.93$ distance$/(HW)$	0.55	31	0.6 dB
LEF (–)	$0.39 - 0.0061$ width	0.70	49	0.05
	$0.37 - 0.0051$ width $- 0.00069$ wall angle	0.72	53	0.05

with T, is expected to be incorporated into the variable G_exp already (although this result has also been confirmed by other researchers [9.27]).

As mentioned earlier, G shows a steady and significant decrease with distance in most halls, as was also found by *Barron* [9.26]. This phenomenon is described quantitatively by the two models for estimation of the rate of decrease in G per 10 m source–receiver distance $\Delta G(10\,\text{m})$.

Both listed $\Delta G(10\,\text{m})$ models indicate a reduced distance attenuation when the number of rear balconies is increased. This may be related to the fact that the level is increased in the more-distant seats when these are placed on a balcony, whereby they are closer to the stage and to the reflecting ceiling.

In the second $\Delta G(10\,\text{m})$ model, distance$/HW$ appears as an independent variable. This variable equals the distance from the stage to the rearmost seat divided by the product of the average room height H and average hall width W. As the coefficient to this variable is

negative, the natural result appears to be that attenuation with distance will increase if the hall is long, narrow or has a low ceiling.

Predictions of Lateral Energy Fraction

At the bottom of Table 9.4 are listed two models for LEF as a function of hall geometry only, as diffuse field theory has no effect on LEF variation. The effects of the width and angle between the side walls are understandable.

Simple prediction formulae as listed in Table 9.4 are particularly useful in the very early phases of the design process, in which it is natural for the architect to produce and test many different sketches in short succession, leaving no time to carry out computer simulation of each proposal. The importance of the knowledge embedded in these rule-of-thumb equations is highlighted by the fact that many aspects of the acoustics of a new hall are settled when one of these sketches is selected for the further development of the project.

9.6 Geometric Design Considerations

With the connections between room acoustic parameters and hall geometry described in the previous section, we have made the first approach to the third question set up in the introduction to this chapter, which is of real interest to the acoustic designer: how do we control the acoustic parameters by the architectural design variables? Referring again to Fig. 9.1, we are beginning to fill the lower-left box with architectural parameters and establish the relationship between these and the objective parameters. The major geometric factors of importance in auditorium design will be dealt with in

the present section: seating layout in plan (determining the gross plan shape of the room) and in section (determining sight lines), use of balconies, choice of wall structure, room height, ceiling shape and use of free-hanging reflectors.

9.6.1 General Room Shape and Seating Layout

When people stop to watch or listen to a spontaneous performance, for instance in an open square in the city,

Fig. 9.15 A 1 : 10 scale model of the Danish Broadcasting concert hall in Ørestad, Copenhagen. The model is fitted with audience and orchestra (acoustic design by Nagata Acoustics, Japan)
Fig. 9.16 Model audience used in a 1 : 10 scale model of the Danish Broadcasting concert hall shown in Fig. 9.15. *Upper-left corner*: Close view of model orchestra musicians and spark sound source. *Lower left*: close-up view of model chairs and polystyrene audience with hollow chest. Dress and hair is made from wool felt. *Right*: model audience and chairs placed in model reverberation chamber for absorption testing (reverberation room designed by Nagata Acoustics)

Fig. 9.17 *Organic* formations of audience depending on the type of performance
Fig. 9.18 Basic room shapes (after [9.4])

the way they arrange themselves depends on the type of performance. It will be governed by the fact that any newcomer will look for the best position available relative to his/her need to see or hear properly. The choice will be a compromise between choosing a position close to the performer(s) and next to other members of the audience or farther away but close to an eventual main center line for vision and sound radiation. In Fig. 9.17, such organic audience arrangements are shown for two different types of performances:

1. Action or dialogue theater such as dancing, fighting, debating, circus performance, for which the visual and acoustic emission are more or less omnidirectional and
2. Monologue or proscenium stage theater performance and concerts with acoustic instruments – all of which have a more-limited visual and/or acoustic directivity.

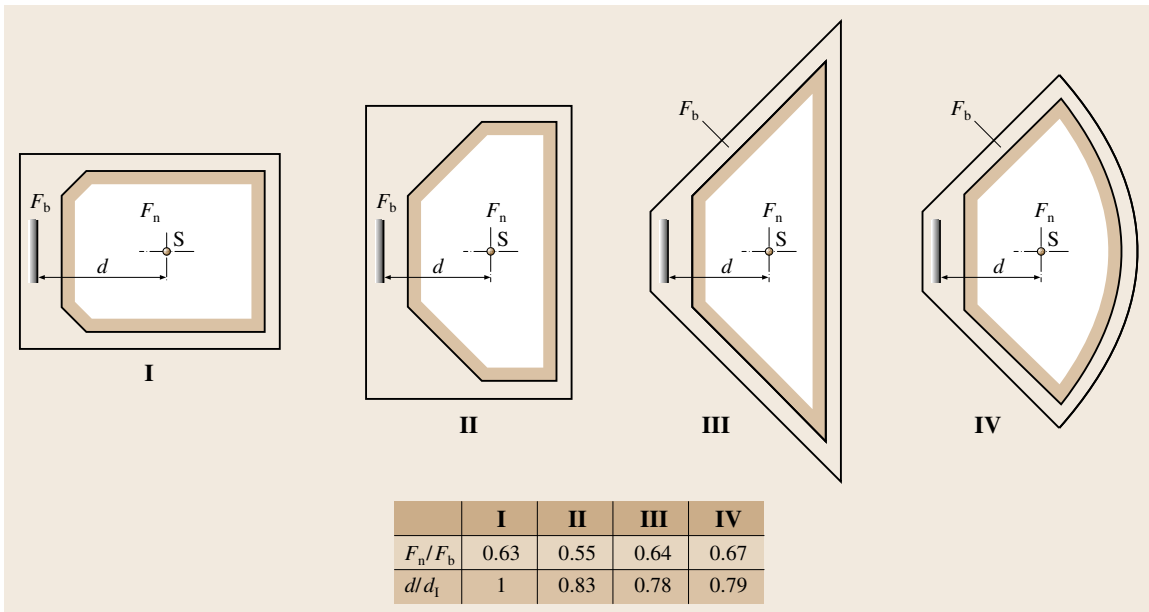
When we set up walls around the gathered people, we arrive at two classical plan shapes of auditoria developed early during our cultural history. These are shown at the top of Fig. 9.18: the fan-shaped Greek/Roman theater (left), and the amphitheater, circus or arena (right). Both were originally open theaters; but the shapes were maintained in roofed buildings. In the bottom of Fig. 9.18, later, basic forms are shown: the horseshoe, the Italian opera plan and the rectangular concert hall. The latter form was originally a result of traditional


Fig. 9.19 Mean stage–listener distance and net efficiency of floor area for four different room shapes. F_n is the net area occupied by the audience, F_b is the total floor area, d is the average source–listener distance; $d_I = d$ for case I (after [9.28])

	I	**II**	**III**	**IV**
F_n/F_b	0.63	0.55	0.64	0.67
d/d_I	1	0.83	0.78	0.79
Fig. 9.20 Calculated distributions of early lateral reflection levels in rooms of different plan shape: fan, hexagon, rectangular and reverse fan. *Darker areas* represent higher LEF levels (after [9.5])

building forms and limitations in roof span with wooden beams.

When building an auditorium, efficient use of the available floor space and the average proximity of the audience to the performers are very important parameters. Depending on the plan shape of the room different values appear as shown in Fig. 9.19.

Low average distance is the main reason for the frequent use of the fan shape (III and IV in Fig. 9.19), although the directivity of sound sources (like the hu-

man voice) as well as the quality of lines of sight sets limits on the opening angle of the fan.

Another limitation of the fan shape is that it does not generate the strong lateral reflections so important in halls for classical music. This was already seen in the empirical equations in Sect. 9.5.6 and confirmed in Fig. 9.20, showing the calculated distributions of early lateral reflection levels in rooms of different plan shapes.

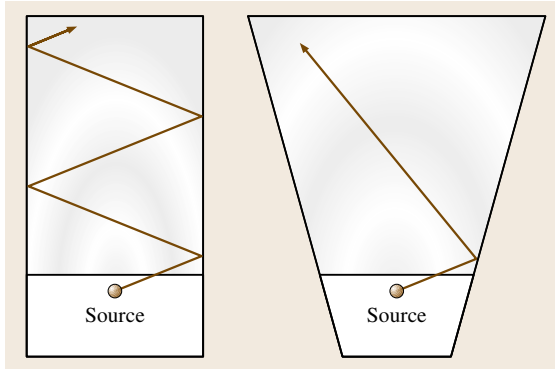
The reason is that sound waves from the source hitting the side walls will produce reflections that will run


Fig. 9.21 Directions of side-wall reflections depending on room shape (after [9.4])

Fig. 9.22 Relevant parameters for the calculation of the necessary angle α for a constantly sloping floor section. a: distance from the source to the first seating row, b: distance from the source to the last seating row, d: distance between the seat rows, e: source height above the head of listeners in the first row (determined by the height of the stage floor over the stalls floor), h: line-of-sight clearance at the last row. Rows closer to the source will have clearance values larger than h (after [9.28])

almost parallel to the direct sound and so hit the listener from an almost frontal direction, therefore not contributing to the LEF or causing dissimilarity between the two ear signals. This is also illustrated in Fig. 9.21. In addition, many of the side-wall reflections will not reach the center of the hall at all.

9.6.2 Seating Arrangement in Section

When several rows of seated audience are placed on a flat floor, the direct sound from a source on the stage and the reflection off the audience surface will hit a receiver in this audience area after having traveled almost identical distances, and the reflection will hit the audience surface at a very small angle relative to the surface plane. At this grazing angle of incidence, all the energy will be reflected regardless of the diffuse absorption value of the surface, but the phase of the pressure in the reflected wave will also be shifted 180°. Hereby the direct sound and the grazing incidence reflection will almost cancel each other over a wide frequency range. Typical attenuation values found at seats beyond the tenth row can amount to 10–20 dB in the range 100–800 Hz relative to an unobstructed direct sound. Moreover, the higher frequencies above 1000 Hz will also be attenuated by 10 dB or more due to scattering of the sound by the heads of people sitting in the rows in front.

The same values of attenuation mentioned above for the direct sound are likely also to be valid for first-order reflections off vertical side walls. The result will be weaker direct sound and early reflections in the horizontal stalls area and subjective impressions of reduced *clarity*, *intimacy* and *warmth* in the stalls seats.

To avoid this grazing incidence attenuation, the seating needs to be sloped relative to the direction towards the source. The vertical angle of the audience floor can be designed to be constant or to vary gradually with distance. If a constant slope is planned, the angle α necessary to obtain a certain clearance h at the last row (equal to the vertical distance between sight lines from this and the preceding row) can be calculated from the variables indicated in Fig. 9.22

$$\tan \alpha = \frac{hb}{da} - \frac{e}{a} \ . \tag{9.30}$$

In particular, it is of interest to use this formula to see how far away from the source it is possible to maintain a certain slope (one obvious example being $\alpha = 0$, corresponding to a horizontal floor)

$$b = \frac{d}{h} \left(e + a \tan \alpha \right) \ . \tag{9.31}$$

Normally, a clearance value of minimum 8 cm will be sufficient to avoid grazing-incidence attenuation; but sight lines will still be unsatisfactory unless staggered seating is applied so that each listener is looking towards the stage between two other heads and not over a person sitting directly in front. However, if the clearance is increased to about 12 cm, then both the acoustic and visual conditions will be satisfactory, but this implies a steeper floor slope.

In rows closer to the sound source a linear slope will cause the clearance to be higher than the design goal – and so higher than necessary. Often this is not desirable as it may cause the last row to be elevated high
Fig. 9.23 Relevant parameters for the calculation of a floor slope with constant clearance. The variables are explained in the text (after [9.29])

above the source and the steeply sloped floor will reduce the effective volume of the room. Therefore, it can be relevant to consider instead a curved floor slope with constant clearance, as illustrated in Fig. 9.23.

In Fig. 9.23, the height of a person's head in the n-th row H_n relative to the height of the head in the first row is calculated according to the formula (derived from a logarithmic spiral)

$$H_n = d_0 \gamma + d (\theta - \gamma)$$
$$= \gamma \left[d_n \log_e \left(\frac{d_n}{d_0} \right) - (d_n - d_0) \right] . \quad (9.32)$$

In this expression d_0 is the distance from the source to the first row, d_n the distance to the n-th row and γ the desired angle between the tangent to the seating plane and the line of sight to the source. For a one meter row-to-row distance, an angle γ of $8°$ will correspond to a clearance of about 12 cm.

A curved slope can also be obtained by simply applying the linear-slope formula to each of smaller sections of seat rows successively (e.g. for every five rows). In this case the variables a and e in (9.30) should refer to the first row in the relevant section.

As mentioned earlier, a steep slope will reduce the volume and so the reverberation time T. Besides, geometric factors may reduce T beyond what a Sabine calculation may predict. The reason is that the elevated seating – and its mirror image in the ceiling – will cover a larger solid angle as seen from the source. Hereby a larger part of the emitted sound energy will quickly reach the absorbing seating and leave less for fueling a reverberant sound field in the room. The result is higher *clarity* and less *reverberance* in halls with steeply raked seating. This is in line with the empirical equation for clarity as a function of T ($C_{\exp}$) and floor slope listed in Table 9.4, Sect. 9.5.6. Consequently, it is a good idea to limit the clearance/angle in halls for

classical music to about 8 cm or $6°$, whereas for speech auditoriums and drama theaters, in which both intelligibility and good visual sight lines have priority, values closer to $12-15$ cm or $8-10°$ may be preferable.

9.6.3 Balcony Design

The introduction of balconies allows a hall with a larger seat count to be built where a limited footprint area is available; but often balconies are introduced simply in order to avoid longer distances between stage and listeners. The average stage–listener distance can be reduced significantly by elevating the rearmost seat rows and moving them forward on rear or side balconies above parts of the audience in the stalls. In this way not only is the direct sound increased by shortening the direct sound path, but the elevated seats also become closer to a possibly reflecting ceiling. The result is higher strength as well as higher clarity in the balcony seats compared to the alternative placement of seats at the back of an even deeper hall.

Since the line-of-sight and clearance criteria still have to be fulfilled for balcony seats, the slope often becomes quite steep on balconies, as illustrated in Fig. 9.24 showing a long section in a hall with constant clearance on main floor and balcony seats. For safety reasons the slope must be limited to no more than about $35°$.

When balconies are introduced, the acoustics in the seats below the balconies need special attention. It is important to ensure sufficient opening height below balcony fronts relative to the depth of the seating under the balcony (Fig. 9.25). Otherwise, particularly the level of the reverberant energy in the overhung seats will be reduced, causing the overall sound level to be weak and lacking in fullness. Rules of thumb in design are $H \geq 2D$ for theaters (in which reverberant sound is less important) and $H \geq D$ for concert halls (in which full-
Fig. 9.24 Section of a hall with a rear balcony and constant clearance. The result is an increased slope for the elevated balcony (after [9.30])
Fig. 9.25 Important parameters for maintaining proper sound in seats overhung by balconies (after [9.9])
Fig. 9.26a,b Poor (**a**) and good (**b**) design of balcony profile (after [9.29])
Fig. 9.27 A half cross section of a hall with side balconies that, in combination with the side wall, return early reflection energy towards the stalls area from a lateral angle (after [9.4])

ness is more important) [9.9]. The criteria may also be stated in terms of the vertical viewing angle from the seat to the main hall volume. Recently, *Beranek* [9.3] has suggested this be a minimum of 45°.

Sometimes, the requirement for limited depth of balcony overhangs is also specified as a percentage of the ceiling area needed to be visible from the last row of seating or as a vertical opening angle β between the balcony soffit and the head of listener below the balcony front as seen from the last row. In the latter case, Barron has suggested 25° as suitable for drama halls and 35° for concert halls.

As illustrated in Fig. 9.26, it is often advantageous to let the soffit be sloped, so that it will help distribute reflected sound to the overhung seats. If a diffusing profile is added to the balcony soffit, the reflection off this surface may even gain a lateral component, so that *spaciousness* will not be reduced. The drawing also illustrates how the otherwise vertical balcony front and the right angle between the rear wall and balcony soffit have been modified to avoid sound being reflected back to the stage where it could generate an echo. However, in a rectangular hall with balconies along the side walls, vertical soffits in combination with the side-wall surface can increase the early and lateral reflection energy in the stalls area as shown in the half cross section in Fig. 9.27.

In general, as large-scale modulations in the hall geometry, balconies also provide low-frequency diffusion, which is considered an advantage.

9.6.4 Volume and Ceiling Height

As the people present are often the main source of sound absorption in an auditorium, the ratio between the volume and area covered by the audience and performers is an important factor for the reverberation time achievable. The general relationship valid for concert halls is shown in Fig. 9.28.

Because the variation in area per person does not vary significantly between halls, the volume per seat is also used as a rule of thumb for the calculation of the required volume. For speech theaters, a volume per seat of $5-7\,\mathrm{m^3}$ will result in a reverberation time around 1 s, whereas at least $10\,\mathrm{m^3}$ per seat is needed to obtain a T value of 2 s.

Since the audience normally occupies most of the floor area, the volume criterion can also be translated to a ceiling height criterion. In such cases, the abscissa in Fig. 9.28 can be interpreted as roughly equal to the required room height. A ceiling height of about 15 m is required if a T value of 2 s is the target, whereas a height of just $5-6\,\mathrm{m}$ will result in an auditorium with a reverberation time of about 1 s. It should be emphasized that, in the discussion above, we have assumed the other room surfaces to be reflective.
Fig. 9.28 Reverberation time T in occupied concert halls versus the ratio between the volume V and area occupied by the audience and orchestra S_T (including aisle space up to 1 m width). Derived from empirical data (after [9.9])

Fig. 9.29 Echo ellipses drawn over the plan of an auditorium (after [9.4])

receiver point in question by means of simple geometrical studies of plan and sectional drawings as seen in Fig. 9.29. Ellipses are drawn so that the source and relevant receiver positions are placed at the focal points and so that the sum of distances from the focal points to any point on the ellipse equals the distance between the focal points plus 17 m (times the scale of the drawing). Then, if a surface outside the ellipse marked "m" in the figure directs sound towards seats near point M, this surface must be made absorbing, diffusing or be reoriented so that the reflection is directed towards areas farther away from the source than M.

In particular, it is important to check the risk of echoes being generated by the rear wall behind the audience and from a high ceiling.

9.6.6 Room Shape Details Causing Risks of Focusing and Flutter

Concave surfaces can cause problems as they may focus the sound in certain areas while leaving others with too little sound. Thus, vaulted ceilings as seen in Fig. 9.30 are only acceptable if the radius of curvature is less than half the height of the room (or rather half the distance from peoples' heads to the ceiling) so that the focus center is placed high above the listeners. Situations with

These guidelines on volume should be regarded as rough rules of thumb only, as room shape, floor slope, the presence of balconies and the distribution of absorption on other surfaces can cause significant variations in the objective values obtained for T and other parameters. In smaller halls (say below 1500 seats) for symphonic concerts, it is better to start with a volume slightly larger than required rather than the opposite, as one can always add a little absorption – but not more volume – to a hall near completion. On the other hand, in larger halls, where maintaining a suitably high G value is also of concern, a better strategy is to limit the volume and minimize the absorption instead. One way of minimizing absorption is to place some of the seats under balcony overhangs, where they are less exposed to the reverberant sound field. However, the other side of the coin is the poor conditions in these seats, as explained in Sect. 9.6.3.

9.6.5 Main Dimensions and Risks of Echoes

In order for early reflections to contribute to the *intelligibility* of speech or to the *clarity* of music, they must not be delayed more than about 30 ms and 80 ms, respectively, relative to the direct sound. If the first reflection arrives later than 50 ms, it is likely to be perceived as a disturbing echo when impulsive sounds are emitted (Sect. 9.2).

In large rooms it is a challenge to shape the surfaces so that reflections from the main reflecting areas arrive within 50 ms at all seats. It is possible to identify which surfaces are able to generate echoes at the

Fig. 9.30 Focusing by concave ceilings (after [9.31])
Fig. 9.31a,b Circular room with focused and creeping waves (**a**), and with the surface shape modified (**b**) so that these phenomena are avoided

Fig. 9.32a–c Room shapes causing risk of flutter echoes

a slight curvature, $r \geq 2h$, may also be acceptable if the floor is covered with absorptive seating so that multiple reflections between floor and ceiling will not arise.

Circular rooms are also unfavorable both due to the risk of focusing and the risk of a whispering-gallery effect (boundary waves creeping along the wall). Modifications of the concave wall within the overall circular shape as shown in Fig. 9.31 can solve the problem, at least at mid and high frequencies.

Another frequent problem is regular, repeated reflections, so-called flutter echoes, which arise between parallel, smooth reflecting walls or along other simple reflection paths that can repeat themselves as shown in Fig. 9.32. Particularly in small rooms such reflections may cause strong coloration of the sound (through comb filtering as explained in Sect. 9.2.3) while in larger

rooms they may be perceived as a long series of distinct echoes evenly spaced in time.

In any case, the flutter can be avoided by simple absorptive or diffusive treatment of at least one of the opposite reflecting surfaces, as shown in Fig. 9.33. Besides, if it is possible to change the angle between the opposite walls just by a few degrees (3−5°), the problem will also disappear.

9.6.7 Cultivating Early Reflections

In most rooms accommodating more than say 25 listeners, it is of relevance to consider how early reflections can help distribute the sound evenly from the source(s) to the audience. This will increase the early reflection energy and so improve *clarity/intelligibility* and perhaps even reduce the reverberation time by directing more sound energy towards the absorbing audience.

In rooms for speech, the ceiling height should be moderate (Sect. 9.6.4) so that this surface becomes the main surface for the distribution of early reflection energy to the audience. Figure 9.34 shows examples of how this can be accomplished in rooms with both low and high ceilings.

In this figure the two situations at the top need improvement. In the low-ceiling room to the left the echo from the rear wall/ceiling combination can be removed by introducing a slanted reflector covering the corner. In this way the sound is redirected to benefit the last rows, which may need this to compensate for the weak direct sound at this large distance. Alternatively, the energy from this rear corner may simply be attenuated by one or both surfaces near the corner being supplied with absorption.

If the ceiling is so high that echoes can be generated in the front part of the room, as shown to the right, the front part may likewise be treated with slanted reflectors that redirect the sound to the remote seat rows, or this ceiling area may simply be made sound absorbing. The lower-right section in the figure also illustrates how the

Fig. 9.33a–c Room with flutter echoes (**a**), and measures against this by means of diffusion (**b**) or absorption (**c**) (after [9.28])

floor can be tilted to reduce volume and allow the rear seats benefit from being closer to the reflecting ceiling.

If for architectural reasons the ceiling is higher than necessary in a room for speech or rhythmic music, substantial areas of the room surfaces must be treated with sound-absorbing material to control the reverberation time. However, more sound absorption will reduce the overall sound level in the room so this is only recommended if the sound can be amplified.

If the ceiling is to be partly absorbing, the ceiling area that should be kept reflecting in order to distribute useful first-order reflections to all listeners can be generated geometrically by drawing the image of the source in the ceiling surface and connecting lines from this image point to the boundaries of the seating area. Where these lines cross the actual ceiling we find the boundaries for the useful reflecting area, as shown in Fig. 9.35.

In larger auditoria, a more-detailed shaping of the ceiling profile may be needed to ensure even distribution of the reflected sound to the listeners. Notice in Fig. 9.36 that the concave overall shape of the ceiling can be maintained if just the size of the ceiling panel segments is large enough to redirect the reflections at suitably low frequencies.

Local reshaping of surfaces while maintaining the overall form is also illustrated in Fig. 9.37, in which the weak lateral reflections in a fan-shaped hall are improved by giving the walls a zigzag shape with almost parallel sets of smaller areas along the splayed side walls. In the example shown in the photo, the panels are even separated from the wall surface and tilted downward.

9.6.8 Suspended Reflectors

In many cases it is advantageous to reduce the delay and increase the level of a reflection without changing the room volume. In this case it is obvious to suggest individual reflecting surfaces suspended within the room boundaries, as shown to the right in Fig. 9.38. If the reflector is placed over an orchestra pit, it can improve mutual hearing among the musicians in the pit as well as increase the early energy from the singing on the stage to the seating primarily in the stalls area.

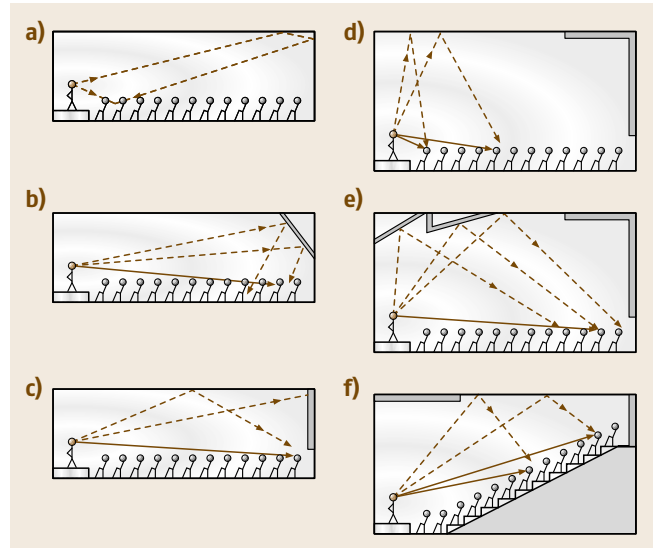
Suspended reflectors are also suitable for acoustic renovation of existing, listed buildings, because the main building structure is not seriously affected (as in the case of the Royal Albert Hall in London [9.3]).


Fig. 9.34a–f Means of controlling early reflections in auditoria (after [9.28])
Fig. 9.35 Sketch identifying the area responsible for covering the audience area with a first-order ceiling reflection (after [9.32])
Fig. 9.36 Reshaping of ceiling profile to avoid focusing and provide more-even sound distribution
Fig. 9.37 Improvement of side-wall reflections in a fan-shaped hall by local reshaping or adding of panels parallel to the long axis of the room (drawing after [9.32])

For a given source position, a small reflector will cover only a limited area of receiver positions. Therefore, how the reflector(s) influence the balance heard between different sources such as the different sections in a symphony orchestra must be thoroughly considered. With small reflectors, the balance between sections may be perceived as very different in different parts of the audience. Often it will be advantageous to give the reflector(s) a slightly convex shape to extend the area covered by the reflection and to soften its level.

The nature of the reflection off a panel of limited size is strongly frequency dependent and may be influenced by several factors: distance to source and receiver,

absorption by the panel material, diffraction governed by the ratio between panel size and the wavelength, and focusing/diffusion due to panel curvature.

The attenuation with distance is as for a spherical wave in free field: 6 dB per doubling of the total distance from the source to the reflector a_1 plus the distance from the reflector to the receiver a_2. Normally, the attenuation due to absorption is negligible, as reflectors should obviously be made from a reflective material. The only exception could be when a thin, lightweight material is used, such as plastic foil or coated canvas. In this case the attenuation ΔL_{abs} can be calculated from the mass law

$$\Delta L_{abs} = -10 \log_{10}\left[1 + \left(\frac{\rho c}{\pi f m \cos\theta} \right)^2 \right] \quad (9.33)$$

where ρc equals the specific impedance of air ($\approx 414\,\mathrm{kg\,m^{-2}\,s^{-1}}$), f is the frequency in Hz, m is the mass per square meter of the material and θ is the angle of incidence relative to the normal direction.

As a simple design guide, diffraction can be said to cause the specular reflection to be attenuated by 6 dB per octave below a limiting frequency f_g given by

$$f_g = \frac{ca^*}{2S\cos\theta} \quad (9.34)$$

where a^* is the weighted *characteristic distance* of the reflector from the source and receiver

$$a^* = \frac{2a_1 a_2}{a_1 + a_2}, \quad (9.35)$$

S is the area of the reflector, and θ is the angle of incidence as before. Above the frequency specified in (9.34), the influence of diffraction can be neglected.

If the reflector is curved, the attenuation ΔL_{curv} can be calculated as

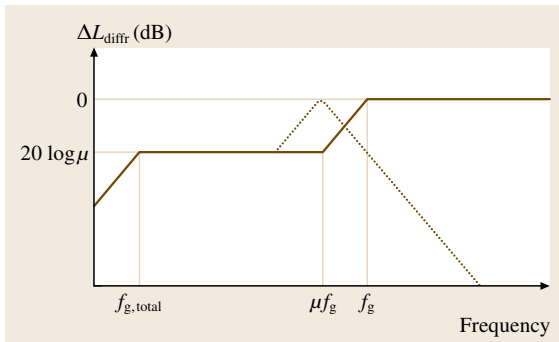
$$\Delta L_{curv} = -10 \log_{10}\left| 1 + \frac{a^*}{R\cos\theta} \right|. \quad (9.36)$$
Fig. 9.38 The influence on reflection paths of a reflecting panel suspended in front of a stage (after [9.33])
Fig. 9.39 Attenuation of a reflection caused by concave and convex reflectors (after [9.34])


Fig. 9.40 Approximate attenuation due to diffraction from a reflector array. All non-horizontal lines have a slope of 6 dB per octave. See text for further explanation (after [9.34])

Here, the only new variable R is the radius of curvature. R should be entered positive for convex surfaces and negative for concave surfaces. When the reflector is concave, strong focussing occurs when $R = -a^*/\cos\theta$. In Fig. 9.39, graphs of ΔL_{curv} are shown for both the concave and convex cases. It is noted that the values can be both positive and negative. In the case where the surface is curved in both the x- and y-directions of the reflecting plane, the ΔL_{curv} correction should be applied twice using the appropriate radii of curvature in the two directions.

In certain cases an array of (identical) reflectors are suspended as an alternative to having one large reflector. Such an array can be characterized by the area of each element, S, the total area covered by the array S_{total} and the degree of coverage, μ, equal to the ratio between the total area of the n reflector elements nS and S_{total}. In this case, the attenuation due to diffraction depends on frequency as shown in Fig. 9.40.

Here, f_g is the limit frequency of the individual elements calculated according to (9.34), while $f_{g,total}$ is the lower-limit frequency related to the entire array area S_{total}

$$f_{g,total} = \frac{ca^*}{2S_{total}\cos\theta} \ . \tag{9.37}$$

First we look at the situation above the frequency f_g in Fig. 9.40. As in the case of the single reflector, the attenuation is zero as long as the specular reflection point falls on one of the reflector elements. If the specular point falls between two elements, the attenuation can be approximated by the dotted line, according to which we have an attenuation of 6 dB per octave as frequency increases. In the frequency range between $f_{g,total}$ and μf_g, the attenuation is roughly frequency independent and governed by the array density μ, and below $f_{g,total}$ the level again rolls off by 6 dB per octave. It is seen that, in order to obtain a wide range of frequency-independent reflection, one should aim to use many small reflectors rather than fewer, larger elements. Fortunately, the strong position-dependent variation in reflection level at high frequencies can be reduced by making the individual elements slightly convex.

It should be remembered that whenever surfaces are shaped with the purpose of efficiently directing sound energy from the source towards the absorbing audience, this energy is no longer available for the creation of the reverberant sound field. In other words, the more we try to improve the *clarity* and *intelligibility*, the more we reduce reverberation in terms of T and EDT (regardless of the physical absorption area), and the more the sound field will deviate from the diffuse field predicted by any simple reverberation formula. If substantial reverberation is needed as well, the solution may be to increase the volume per seat beyond the 10 m^3 as already suggested for large halls in Table 9.1. As seen in Sect. 9.7.3 this is in line with the current trend in concert hall design.

9.6.9 Sound-Diffusing Surfaces

It is often stated that diffusion of sound from irregular surfaces adds a pleasant, smooth character to the sound in a concert hall. It is a fact that reflections from large smooth surfaces can produce an unpleasant harsh sound. It is also a fact that most of the surfaces in famous old and highly cherished halls such as

the Musikvereinsaal break up and scatter the reflected sound in many directions due to rich ornamentation, many window and door niches and the coffered ceiling (Fig. 9.45). Even the large chandeliers in this hall break up the sound waves.

Many present-day architects are influenced by modernism and are less enthusiastic about filling their designs with rich ornamentation. Therefore, close cooperation is often needed between architect and acoustician in order to reach a surface structure that will scatter the sound sufficiently, although this is difficult to define exactly as good guidelines do not exist for what percentage of the wall/ceiling area one should make diffusive.

Schroeder [9.35] has done pioneering work on creating algorithms for the design of surface profiles that will ensure uniform distribution of scattered sound within a well-defined frequency range. These algorithms are based on number theory using the maximum length, quadratic residue or primitive root number sequences. However, in most cases of practical auditorium design, perfectly uniform scattering is not needed, and good results can be obtained even after a relaxed architectural adaptation of the ideas, as shown in Fig. 9.41.

The primary requirement to achieve diffusion is that the profile depth of the relief is comparable with a quarter of the wavelength and the linear extension of the diffusing element (before it is eventually repeated) is
Fig. 9.41 Diffusion treatment by means of wooden sticks screwed on an otherwise plane, wooden wall surface

comparable with the wavelength at the lowest frequency of interest to be diffused. Given this, many different solutions can be imagined such as soft, curved forms cast in plaster, broken stone surfaces, wooden sticks, irregular brick walls etc.

Finally, it should be mentioned that strict periodic structures with sharp edges equally spaced along the surface can cause problems of harsh sound at frequencies above the design frequency range. Actually, it is safer to apply more-organic, chaotic structures, or to ask the workers not to be too careful with the ruler.

9.7 Room Acoustic Design of Auditoria for Specific Purposes

This section will present some examples showing how the principles outlined in Sect. 9.5 are implemented in the current design of different types of auditoria. The main focus will be on concert halls for classical music as well as drama and opera theaters. It will also be shown that design choices are not only compromises between acoustic and other concerns, but sometimes even between different room acoustic aspects. This is often the case with multipurpose auditoria. In any case, the compromises are more serious the larger the seating capacity.

9.7.1 Speech Auditoria, Drama Theaters and Lecture Halls

In the Western world, rooms for spoken drama as well as for opera have their roots in the Greek and Roman theaters in which the audience is arranged in sloping concentric rows, the *cavea*. In Roman times, this audience area covered a 180° an-

gle around the orchestra or apron stage. The advantage of such an arrangement is of course the possibility to accommodate a large audience within a limited maximum distance from the stage. Many modern theaters and speech auditoria have adopted this layout – perhaps extended with one or more sets of balconies.

An example of such a modern speech auditorium (the lecture hall at Herlev Hospital, Denmark) is seen in Fig. 9.42 along with a Roman theater for comparison.

In a drama theater, a moderate reverberation time around 1 s will provide a good compromise between high intelligibility and a high strength value, as both are needed for unamplified speech. The T value may be reduced to about 0.5 s in small rooms for 50–100 people and also increased slightly for audiences above 1000. To obtain a high strength value in a large theater, it is important to choose a modest volume per seat (about 5 m^3) rather than to control the reverberation in an unnecessarily large volume by applying additional absorption
Fig. 9.42a,b Photos of Roman theater (in Aspendos, Turkey) **(a)** and of a modern speech auditorium (Herlev Hospital, Denmark) **(b)**

beyond that provided by the audience chairs. Thus, the height of the ceiling should be chosen fairly low – which is also advantageous for its ability to distribute early reflections to the audience. According to diffuse field theory, the steady-state energy density equivalent to G_{exp} is inversely proportional to the total absorption area A in the room.

High *clarity* and sound *level* are also promoted by careful shaping of the reflecting ceiling and a substantial sloping of the audience floor. Due to the directivity of the human voice, a reflecting rear wall (or stage scenery in a theatre) is of less importance, unless an actor should turn his back to the audience. Also the wall surfaces close to the stage opening are important, because they will send sound across the room so that sound also reaches people behind the speaker when he turns the head towards one side. The rear wall/balcony soffits behind/over the rear part of the audience should diffuse or redirect the sound to benefit nearby listeners.

As *spaciousness* is not a quality of particular importance in a speech auditorium, reflections from the side walls farther from the stage are often given lower priority than a low average stage-to-audience distance, which is promoted by a fan-shaped floor plan. However, as indicated by the problems encountered in the Olivier Theater in London [9.4], there should be limits to the opening angle of large fan-shaped theaters.

In a modern theater, the floor slope will often be more modest than seen in Fig. 9.42. In contrast to the lecture hall, a modern drama theater also needs to be highly flexible regarding the layout of stage and audience areas.

The classical proscenium frame inherited from the Italian Baroque theater is often considered to limit intimacy as well as the creativity of the stage-set de-signers and directors. If the classical proscenium stage is not needed, intimacy and audience involvement can be maximized by an arena arrangement, with audience all around the stage. In other cases, the stage can be extended into the audience chamber, for instance by removing the first rows of seats and raising the floor below to stage level. If such a flexible forestage is considered, the line-of-sight design should be adjusted accordingly, particularly if the hall features balconies.

An example of a flexible modern theater (without balcony) is seen in Fig. 9.43. In this room, the circular side/rear wall was made highly sound absorbing, leaving most of the distribution of early reflection energy to the ceiling.

Dedicated drama theaters are seldom built with a seat count higher than 500–1000, because visual as well as acoustic intimacy, including close view of facial expressions and freedom from artificial amplification, are given high priority. Thus, the maximum distance from the stage front to any seat should not exceed about 20 m for drama performances.

From this discussion it can be concluded that a reflecting ceiling of modest height is the main source of early reflection energy in theaters. However, lighting staff will often want to penetrate this surface with slots for stage lights and rigging or place light bridges across the room, which will act as possible barriers for the sound paths going via the ceiling. This challenge must always be considered in the acoustic design of drama theaters.

9.7.2 Opera Halls

There is a 350 year tradition of performing opera in halls of the Italian Baroque theater style. These are halls with
Fig. 9.43a–f Plans showing a flexible theater in Hëlsingborg, Sweden, with different layouts of the stage, orchestra pit and audience seating. (**a**) and (**b**): arena with small and large stage respectively, (**c**), (**e**), and (**f**): proscenium theater with three different sizes of orchestra pits. (**d**): proscenium theater without pit

a horse-shoe plan shape with several balcony levels running continuously from one side of the proscenium arch to the other along the curved side and rear walls. The balconies are either divided into boxes separated by thin walls or are open with long seat rows. The orchestra is placed in front of the proscenium opening that connects the auditorium with the stage house.

This tradition has undergone few changes during the past 350 years. Since the 19th century, the orchestra has been placed in a lowered pit separated from the stalls by

a closed barrier. In this arrangement, seats in the stalls and lower rear balcony experience an attenuation of the direct sound from the orchestra, because the pit rail blocks the free line of sight to the orchestra. The result may be an improved singer-to-orchestra balance in these seating areas. The pit rail will also reflect sound back and forth between the stage and pit, giving improved contact between the singers and the lowered orchestra.

Another development is that the separate boxes have been exchanged for open balconies, which improves the possibility for the now exposed side walls to help distribute the sound to seating farther backwards in the auditorium. This development is the result of advances in building technology as well as of changes in social attitudes.

The multiple levels of horseshoe-shaped balconies facilitates a short average distance between the audience and the singers, promoting both the visual and the acoustic intimacy, which is important for both parties. However, balcony seats close to the proscenium and on the upper balcony levels often have a very restricted view of the stage.

The short audience–singer distance obtained by the horseshoe form gives high levels of both strength and clarity. On the other hand, the horseshoe form and the proscenium arch also cause some acoustic problems:

- With all wall surfaces covered by balconies, only small free wall areas are left to generate the early reflections that assist an even distribution of the sound, clarity and the generation of reverberation in the room.
- Often focusing effects occur from the curved wall surfaces and a cupola-shaped ceiling which, along with the placement of the orchestra out of sight in the pit, give a high risk of false localization of certain instruments.
- Only part of the energy generated by the singer will reach the auditorium, because the singers are placed in a large stage house coupled to the auditorium via a proscenium opening of limited size, and this energy even depends on the acoustic properties of the ever-changing stage sets.

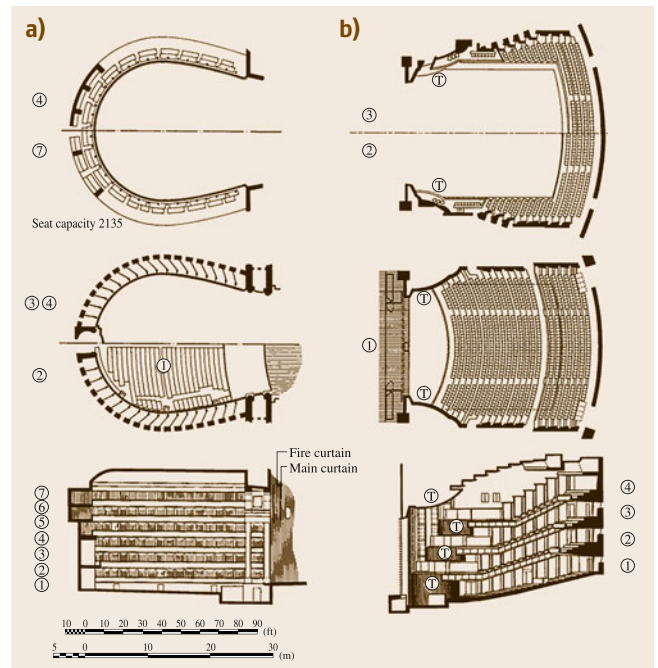
Recent developments in the acoustic design of opera halls have mainly aimed at avoiding these problems. Only a few attempts have been tried to radically change the overall shape (e.g. the Deutsche Oper in Berlin, and the Opéra Bastille in Paris) but without much success. Therefore, we are left with tradition and acoustic properties of horseshoe halls to shape the current acoustic ideals for opera, which are:


Fig. 9.44a,b Plan and section drawings of the Teatro alla Scala, Milan, Italy, from 1778 **(a)** and the New National Theatre Opera, Tokyo, Japan, from 1997 **(b)** (after [9.3])

- Sufficient level of the singers' voices relative to the orchestra,
- Some emphasis on *clarity* and *intelligibility* (although not as much as in speech auditoria),
- A certain *fullness of tone* and *reverberance*; but less than in a classical concert hall.

In recent years the trend has moved towards higher T values than found in the old halls, like Opéra Garnier, Paris (2131 seats, 1.1 s), Teatro Alla Scala, Milano (2289 seats, 1.2 s). This might well be due to the tendency to perform operas in the original language and display the translated text on a text board above the proscenium. Thus, for many recent opera halls we find T values of 1.4–1.8 s. Examples are: Göteborg (1390 seats, $T = 1.7$ s), Glyndebourne (1200 seats, $T = 1.4$ s), Tokyo (1810 seats, $T = 1.5$ s), and Semper Oper, Dresden (reconstruction, 1290 seats, $T = 1.6$ s).

As the width of the traditional horseshoe shape is about equal to its length, the lateral sound is not very pronounced and so *spaciousness* is seldom regarded a factor of particular importance in opera hall acoustics.

In order to ensure a sufficient level and *clarity* of the singers' sound, efficient sound reflections off the

proscenium frame, ceiling, balcony fronts and from the corners between balcony soffits and rear/side walls are important. Of course the scenery may also be designed to help in this respect, but generally this is out of the hands of the acoustician.

If a seat count larger than, say, 1500 is demanded it is better to extend the top balcony backwards, as seen in Covent Garden in London and the Metropolitan in New York rather than increase the overall dimensions of the horseshoe, which would give poorer acoustics for all seats. As this extended balcony is close to the ceiling surface, the acoustics here can often be very intimate, clear and loud, in spite of the physical and visual distance to the stage being very large. In the Metropolitan Opera in New York the farthest seat is about 60 m from the stage.

The culmination of the old Baroque theater tradition is represented by the Teatro alla Scala in Milan, Italy, which dates from 1778. Drawings of this theater are shown in Fig. 9.44 along with a modern opera with almost the same number of seats, the New National Opera in Tokyo from 1997.

The horseshoe-shaped Milan opera contains six levels of balconies subdivided into boxes with the openings covered with curtains so that the audience could decide whether to concentrate on the play or on socializing with their guests or family in the box. The audience in the boxes receive a rather weak sound unless they are very close to the opening.

This aspect has been improved in the modern opera with open balconies. Steeper slopes on the stalls floor and even on the side balconies have also improved the direct sound propagation to all seats. Fewer balcony levels have created higher openings at the balcony fronts,

allowing the reverberant sound to reach the seats in the last rows below the balconies, providing more early reflection energy from the walls to all seats.

In the Tokyo opera, much emphasis has been put on retracting the balconies away from the proscenium so that extensive side-wall areas close to the proscenium are available for projecting the sound from the stage into the auditorium. Along with the ceiling above the pit, these wall areas almost form a trumpet flare. In the section, it is also seen that the side balconies are tilted downwards towards the stage in order to improve lines of sight. Finally, the side-wall areas and the side-balcony fronts have been made straight to avoid focusing and improve lateral reflection energy.

9.7.3 Concert Halls for Classical Music

Public concerts with large orchestras started in Europe about 250 years ago in halls that resembled those in which the composers normally found audience for their nonreligious music such as the salons and ballrooms of the nobility and courts. It is likely that this tradition as well as the limited span of wooden beam ceilings are the main reasons why many of the old concert rooms were built in what we now call the classical shoe-box shape: a narrow rectangle with a flat floor and ceiling and with the orchestra placed on a platform at one end.

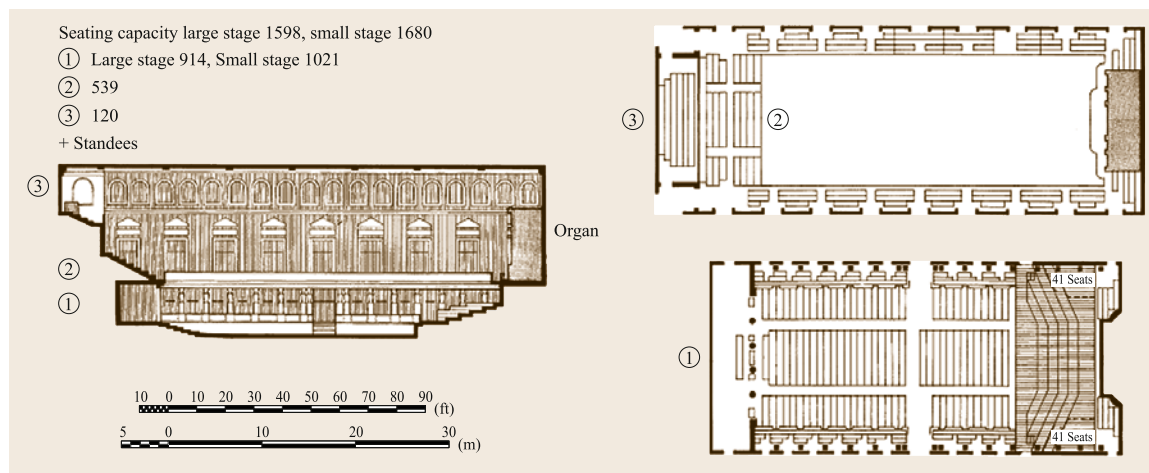
The most famous of the shoe-box-shaped halls is the Musikvereinsaal in Vienna, Austria, shown in Fig. 9.45. This hall, dating from 1870, has a volume of $15\,000\,\text{m}^3$ and seats 1670 people. Today, we understand many of the factors responsible for its highly praised acoustics:


Fig. 9.45 The Musikvereinsaal, Vienna. Balcony and floor plans and long section (after [9.3])

- The volume per seat is only 9 m^3; but T is still 2.0 s in the fully occupied hall because the seating area is relatively small (the seats are narrow and the row-to-row distance is small) and because of the flat main floor. Thus, the sound becomes both loud and reverberant.
- The reverberation also benefits from the fact that the absorbing audience (apart from a few on the top rear balcony) is placed in the lower half of the volume, whereby a *reservoir* of reverberant energy can exist in the upper part of the room.
- The close side walls create strong lateral reflections giving high *clarity* and *envelopment*, and all surfaces are modulated with rich ornamentation, which prevents echoes and causes the room reflections to sound soft and pleasant.

There are however elements of the acoustics, and lack of comfort, that we would not accept in a modern concert hall. The sound is somewhat unclear and remote in the rear part of the flat main floor due to grazing-incidence attenuation. Also, in the side balconies only people sitting close to the balcony front can see well. Other old and famous shoe-box halls (such as the Boston Symphony Hall) have too-shallow balcony overhangs, which results in weak reverberant energy below the balconies.

Because of the general and proven success of the shoe-box design, many new halls are built with this shape. However, in most of the modern shoe-box halls, the drawbacks mentioned above are avoided by a slightly sloping stalls floor and a different layout of the side balconies.

One of the modern shoe-box halls in which the above modifications have been introduced is the Kyoto Concert Hall, Japan, shown in Fig. 9.46. Comparing Fig. 9.45 and Fig. 9.46, the increased floor slope and the subdivided side balconies turned towards the stage are clearly seen.

Recalling the influence of floor slope on T (and other parameters, Sect. 9.5.6) the increased slope will result in a reduced T and higher C. In modern designs T will also tend to be reduced by more-spacious seating and less-shallow balcony overhangs, which result in a larger absorptive audience area being exposed to the sound field. All these factors call for a larger volume per seat in modern shoe-box halls than found in the classical ones, if a high T value is to be maintained. On the other hand, this might well be the reason why the newer halls seldom provide the same intensity and warmth as experienced when listening from one of the sparsely upholstered wooden chairs in Vienna.

Early in the 20th century the development of concrete building technology allowed architects to shape the halls more freely. At the same time it became popular to treat sound as light, by designing the surfaces by means of geometric acoustics and by trying to transmit the sound as efficiently as possible from the source on stage to the (absorbing) audience. Another desire was to put the audience as close as possible to the stage.

The result was the fan-shaped concert hall, which dominated modernist architecture between about 1920 and 1980. An example is seen in Fig. 9.47: Kleinhans Music Hall in Buffalo, USA. Comparison with Fig. 9.45 reveals a very wide hall with a relatively low ceiling and the stage surrounded by concave, almost parabolic, walls and with the ceiling projecting the sound into the absorbing audience area after just a single reflection. This phenomenon, as well as the low volume per seat (about 6.4 m^3), are the reasons for the resulting low reverberation time and the weak sense of *reverberance*. The audience receives most of the sound from frontal directions or from the ceiling, so the sound is clear but lacks envelopment. Other examples of modernist fan-shaped halls are, the Salle Pleyel in Paris (1927) and the old Danish Broadcasting Concert Hall (Copenhagen, 1946). In conclusion, few concert halls from the modernist era have been acoustically successful.

arena-shaped with the possibility of the audience being placed all around the orchestra platform. Even more than the fan shape, this causes the audience to come closer to the orchestra for the sake of intimacy. However, both designs are primarily relevant for larger halls, say more than 1500 seats. For halls seating more than about 2000, these designs may even be more successful than the classical rectangular shape, which, with so many seats, possess a risk of some listeners being placed too far from the stage.

The first vineyard concert hall was the Philharmonie Berlin, shown in Fig. 9.48, which opened in 1963. This hall has no balconies. Instead, the seating area is subdivided into terraces elevated relative to each other, whereby the terrace fronts and sides can act as *local* reflectors for specific seating areas. By careful design of these terraces, it is possible to provide plenty of early, and even lateral, reflections to most of the seats in an arena-shaped hall. With no seats being overhung by balconies, a large absorptive area is exposed to the sound, whereby a generous volume per seat is recommended. Thus, in the Sapporo Concert Hall in Japan (1997) as well as in the new Danish Radio Concert Hall in Copenhagen, the volume per seat is about $14\,\text{m}^3$. This is a quite high value for concert halls, as a 2 s T value should normally be obtained with just $10\,\text{m}^3$ per seat.

In *directed reflection sequence* halls such as the Christchurch Town Hall shown in Fig. 9.49, most of the

Fortunately, mainly as a result of advances in room acoustic research, two alternative and more-promising designs appeared in the 1960s and 1970s: the *vineyard* and the *directed reflection sequence* (DRS). Both are

early reflections are provided by huge, suspended and tilted reflectors. These are distinctly separate from the boundaries, which define the reverberant volume. The fronts and soffits of the sectioned balconies surrounding the main floor and stage in the elliptical plan provide additional early reflections. Because of the arena
Fig. 9.51 Three concert hall concepts with the potential of combining high clarity with long reverberation. *From left to right*: vineyard (plan), shoe box with coupled reverberation chambers (cross section), and directed reflection sequence (cross section)

layout combined with the extensive use of balconies (containing more than half of the seats) the hall is very intimate, and the large reflecting surfaces provide a stunningly clear, dynamic and almost too loud sound. Still, the reverberation is long and rich because of the significant volume without absorption above/behind the reflectors.

This aim towards a combination of high *clarity* and high *reverberance*, probably developed through our extensive listening to recorded music, requires close reflecting surfaces as well as a large volume. The natural consequence of this demand is to separate the early reflecting surfaces from the room boundaries. Both the terrace fronts in the vineyard halls and the suspended reflectors in the DRS halls offer this possibility. A third way to achieve high *clarity* as well as high *reverberance* is a narrow shoe box with added surrounding volume, as found in a number of halls since about 1990. In these halls the volume of the narrow tall shoe-box hall providing the early reflections is quite moderate; but an extra volume is coupled to the main hall through openings that can be closed by heavy doors, so that the total volume can be varied. However, in such halls one should be careful to make the coupling area large enough for the added volume to have any significant effect (unless one sits close to one of the open doors), otherwise it is hard to justify the enormous costs of the extra volume and door system. With weak coupling, a double-sloped decay curve with a knee point perhaps 20 dB down is created, whereby the added, longer reverberation becomes barely audible except during breaks in the music.

A recent design of such a rectangular hall with a coupled volume is shown in Fig. 9.50.

The sketches in Fig. 9.51 summarize the basic design of the three types of halls mentioned. It is seen that they all possess the possibility of separating the surfaces that generate the early reflections from the volume boundaries that generate the reverberation.

9.7.4 Multipurpose Halls

Many modern halls built for cultural purposes often have to accommodate a variety of different types of events, from classical to pop/rock concerts, drama and musicals, opera, conferences, banquets, exhibitions, cinema and perhaps even sports events. From an acoustical point of view, the first concern in these cases is whether a variable reverberation time will be necessary. The answer is yes in most cases where some functions primarily require intelligibility of speech while others require a substantial reverberation, such as for classical music.

A hall in which these demands have been met by means of variable absorption is Dronningesalen, at the Royal Library in Copenhagen (Fig. 9.52). For this hall both chamber-music concerts and conferences with amplified speech were given high priority. The variable absorption is provided by means of moveable panels on the side walls as well as by folded curtains and roller blinds on the end walls. Combining these measures in different ways, *T* values in the range from 1.1 to above 1.8 s can be obtained (in the empty hall) as seen in Fig. 9.52.

In many cases, stage performances with extensive scenery are also required. The most common way to accomplish this is to design a stage house, mount an orchestra shell on the stage and raise the pit to stage level for concerts. If a hall is also to be used for banquets and exhibitions requiring a flat floor, it is common to place the stalls seats on a telescopic riser system on

a flat floor instead of having a fixed, sloped seating. When not in use, this riser system is stored along the rear wall or under a balcony. If the reverberation time suits classical music concerts with the sloped seating in place, a substantial area of variable absorption is needed to reduce the T value when the chairs are absent. Another problem may be that the telescopic systems offer only a rather steep and linear slope, which is not optimal for classical concerts. If the chairs are fixed on the riser steps, the minimum step height is about 25 cm, corresponding to a rake of about 25%.

If a change in T is accomplished by means of variable absorption, G will be reduced along with lowering T. However, if instead T is lowered by reducing the volume, for instance by moving a wall or lowering the ceiling, G will remain approximately constant or perhaps even increase. This can be advantageous when the low-T setting is to be used, for instance for unamplified drama or for chamber music in a larger symphony concert hall.

An example of a hall with variable volume is found in Umeå, Sweden (Fig. 9.53). In this hall the auditorium

volume can be adjusted by moving the proscenium wall between three positions. When the proscenium is stored against the rear wall in the *concert* format, the entire volume is available for concerts with large symphonic orchestras on an open stage. In this situation, the stage tower can be closed off by horizontal panels at ceiling level. But when the proscenium is moved forward to the *opera* setting, the auditorium becomes smaller and a proscenium stage area is created, while the ceiling panels are removed for access to the fly tower above. In the third position, *drama*, the auditorium volume is further reduced to create an intimate theater. The variable elements also include a hinged side-wall section to improve the shape of the room for theater as well as moveable reflectors and variable absorption curtains above the grid ceiling level.

It should be mentioned that many of the problems related to the successful design of speech and music auditoria become more severe with increased size of the room. In other words, it is much easier to design a hall for less than 1000 people, like the two examples presented above, than for 2000 plus. The problems be-

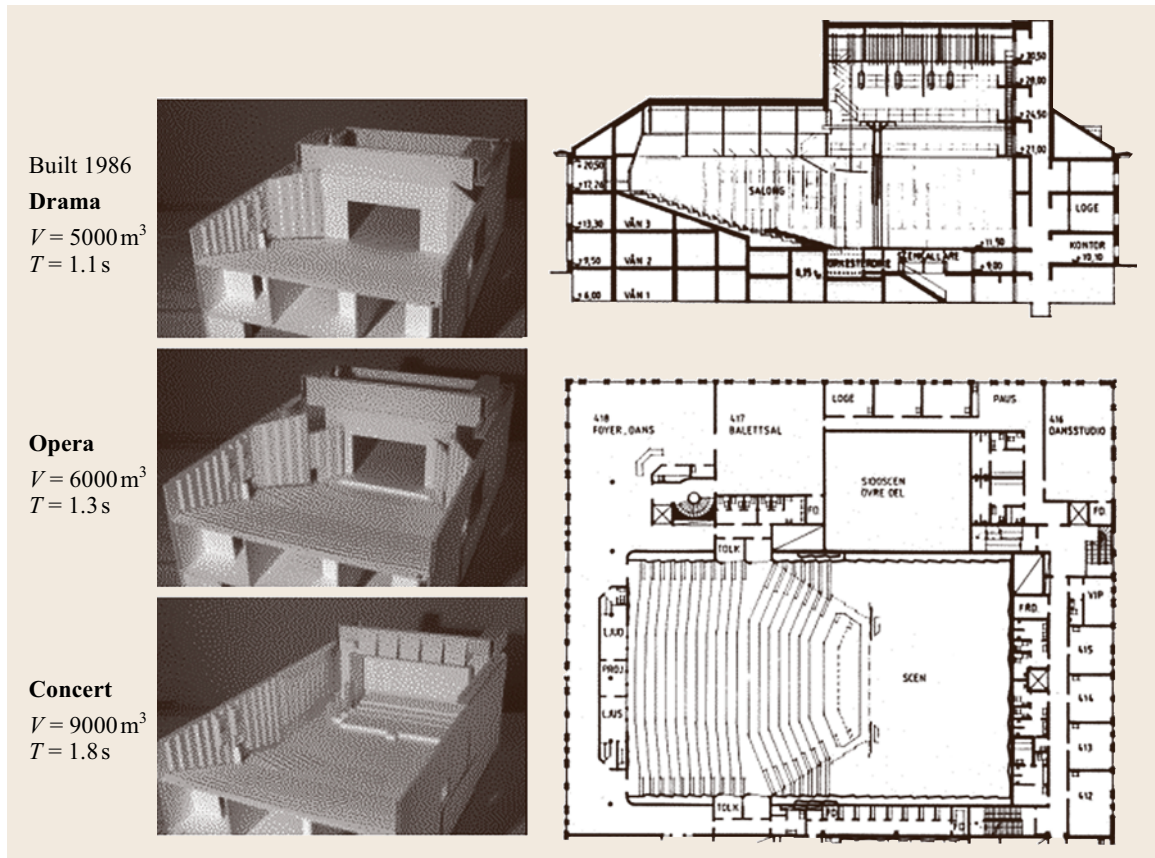
Concert
$V = 9000 \, \text{m}^3$
$T = 1.8 \, \text{s}$


Fig. 9.53 The Idun multipurpose hall in Umeå, Sweden, with variable volume and stage configurations. The hall seats up to 860 people. Brief data (*left*), photos from cardboard model, long section and plan (*right*)

come even more complicated if multipurpose function is requested.

Still, a few examples of such successful designs exist. The most innovative is probably the Segerstrom Hall in Orange County, California, USA, which is shown in Fig. 9.54. This hall features a special layout of the almost 3000 audience seats, which are distributed on four levels. Each of these forms an almost rectangular, or even reverse fan, shape. However, the orientation of each level is shifted so that the overall plan becomes a wide fan. In this way the virtues of the fan shape for audience proximity to the stage are combined with the advantages of the rectangular shape for strong, early reflections from lateral directions. Thus, although the total width is about 50 m, the lateral energy level in this hall resembles that found in rectangular, 25 m-wide concert halls with typical seating capacity up to, say, 2000 people [9.36].

9.7.5 Halls for Rhythmic Music

Halls intended for rhythmic, amplified music concerts range in size from less than 100 to perhaps more than 50 000 listeners (in roofed sports arenas). The reason for this broad range of audience capacity is that the size and number of the sound amplification loudspeakers as well as of event video screens can be chosen at will to ensure good vision and adequate (often too high) sound levels for any size of audience. In any case, the reverberation time should be close to the optimal for speech, i. e., not more than 1 s if possible.

In huge arenas, of course, the reverberation time will be higher; but if efficient absorption is applied to the critical surfaces, a higher reverberation time need not compromise clarity. This is because the reverberation level will be low compared to the direct sound from the loudspeakers. In large spaces, designed to have a mod-

erate T value, one must be careful to avoid echoes from distant, hard surfaces facing the often highly directional loudspeakers. Even small surfaces such as doors can cause echo problems if most other surfaces in the room are efficiently absorbing.

It is also very important to maintain modest low-frequency T values. A bass ratio larger than unity can create serious problems with control of the low-frequency levels. This is largely because most loud-speakers are almost omnidirectional at low frequencies, at which they willingly excite the room *reverberance*. In contrast, with high loudspeaker directivity in mid- and high-frequency range, it is easy to control the level in the audience area at these frequencies without spilling additional sound energy into the room.

Unfortunately, low-frequency reverberation control can be difficult to achieve, because low-frequency absorbers are normally less efficient (have lower α values)

than mid-/high-frequency absorbers, and in a room in which these already occupy most of the available surfaces, it can be difficult to also find spaces for dedicated low-frequency absorbers. In particular, this poses a problem in buildings made from heavy concrete or masonry (which on the other hand is favorable for insulation of low-frequency sound towards the neighbors). When the low-frequency reverberation is too high the string bass and pedal drum will sound muddy. The audience area layout should be shaped to allow an even coverage by a sensible loudspeaker set up, and in large halls, a sloping floor is not suitable if a standing audience is expected. Fortunately, a sloping floor is not always mandatory, since in larger venues, the loudspeakers can be elevated to avoid grazing-incidence attenuation and elevated video projection screens improve the visual experience. It is advantageous to design the hall as well as the loudspeaker system so that zones with lower levels are also created, whereby people can have a chance to rest their ears, for instance while picking up refreshments in the bar. This may be accomplished by placing the bar in a smaller, partly decoupled, space with a shallower room height and an efficiently absorbing ceiling.

9.7.6 Worship Spaces/Churches

The liturgies in old Christian and Muslim worship were developed in highly reverberant cathedrals and mosques, both of which have their roots in Byzantine architecture. When new churches are built for the traditional Catholic or Protestant Christian denominations, it is customary to aim at a rich reverberation, which suit the pipe organ literature and congregational singing, while the intelligibility of the words by the priests is taken care of by a distributed public address (PA) sound system.

The same is true for new large mosques, in which the speech is amplified while the long reverberation supports traditional singing by the imams. Apart form these songs music is not performed in mosques.

In contrast to this, several Christian denominations, particularly in the US, have built new churches or temples (often accommodating several thousand people) and brought in newer art forms making use of large rock-music sound systems. In these spaces, therefore, the solution is often for the acoustician to create fairly dry, natural acoustics and to install both a heavy PA sound system as well as an artificial, electronic reverberation-enhancement system. Both types of sound systems are briefly described in Sect. 9.8.

9.8 Sound Systems for Auditoria

It is important to realize that sound systems will always be installed in both new and existing halls. As these systems are often used to amplify natural sound sources appearing on the stage in the hall, they may be regarded as a means for creating variable acoustics of the space. In this regard, the following will focus on how these systems interact with the natural acoustics, rather than talking about specific details or trends in the design of the loudspeakers themselves.

In principle, one may consider two different types of loudspeaker to be installed in an auditorium: traditional PA systems intended for the modification of the early part of the impulse response of the hall, and reverberation-enhancement systems intended for modification of the later part. Below, important aspects of both types will be briefly explored.

9.8.1 PA Systems

Normally, PA sound systems are installed with the purpose of increasing the sound level and/or the intel-

ligibility of the performance. Use of the sound system for the reproduction of prerecorded sounds is of less interest in this context, as in this case it just acts like any other sound source working under the acoustic conditions provided by the natural acoustics of the room. In Sect. 9.2 we learned that, in order to improve *clarity/intelligibility* as well as the *level*, we need to increase the clarity C by adding sound components to the early part of the impulse response. (The alternative, to increase C by reducing the late part, can so far only be accomplished by adding physical absorption; but some day in the future, active systems with multiple microphones and loudspeakers integrated into *acoustic wallpaper* could be imagined as well.) Doing this requires that the main part of the sound energy leaving the loudspeakers hits the absorbing audience area. Alternatively, if substantial parts of the energy hit other, reflecting room surfaces, it may be reflected randomly and feed the reverberant field, which will reduce the clarity. For this reason, it is very important to apply loudspeakers with well-controlled directivity for this

purpose, especially in auditoria with T values larger than optimal for speech.

For the acoustician, the most important technical specification for PA loudspeakers relates to their directivity, either in terms of vertical and horizontal radiation angles or in terms of the Q factor. Sometimes, the term *directivity index* $DI = 10 \log(Q)$ is used instead. Q is defined as the ratio between

1. The intensity emitted in the axis direction of the directive loudspeaker, and
2. The averaged intensity emitted by the same loudspeaker integrated over all directions.

The higher the Q value, the more the sound emitted will be concentrated in the forward direction (or rather, within the radiation angles specified).

When the loudspeaker is placed in a room, the sound field close to the loudspeaker will be dominated by the direct sound, whereas at longer distances, this component is negligible compared to the (diffuse) reverberant sound, as illustrated in Fig. 11.6. The (squared) sound pressure as a function of distance from the source in a room can be written as follows

$$p^2(r) = \rho c \, P_{SP} \left(\frac{Q_{SP}}{4\pi r^2} + \frac{4}{A} \right) . \tag{9.38}$$

In (9.38) the first term in the parenthesis is the direct sound component and the second one, $4/A$, the diffuse, reverberant component, P_{SP} is the emitted sound power, Q_{SP} is the Q factor of the loudspeaker, and A is the total sound absorption area of the room. Notice that in (9.38), for simplification, we assume a diffuse field intensity that is constant throughout the room, although in Sect. 9.5.1 and Fig. 9.13 we demonstrated that this is seldom the case.

Equation (9.38) shows that the direct component will dominate as long as the direct term is larger than the diffuse term. This will be the case for distances below the *critical distance* or the *reverberation distance*, $r_{cr,SP}$. At this distance, the two components have equal magnitude, whereby

$$r_{cr,SP} = \sqrt{\frac{Q_{SP}A}{16\pi}} = \sqrt{\frac{Q_{SP}V}{100\pi T}} . \tag{9.39}$$

As seen from (9.39), we maximize the range within which we are able to provide the listeners with a clear sound from the speakers by increasing Q (as well as A).

One should be careful not to apply a larger number of loudspeakers than needed for coverage of the audience area, as each new loudspeaker will contribute to the generation of the reverberant diffuse field, while

only one at a time will send direct sound towards a given audience position. Likewise, the number of open microphones should be minimized (which is often done automatically by an intelligent microphone mixer), as all open microphones will pick up and amplify the unclear reverberant field in the room.

The number of active loudspeakers and microphones should also be minimized in order to reduce the risk of feedback, which is a consequence of the microphone(s) picking up the sound from the loudspeaker(s) and the amplifier gain being set to high. If the amplification through the entire closed loop (microphone–amplifier–loudspeaker–room and back to the microphone) exceeds unity, the system will start to oscillate at a random frequency, which is emitted at maximum power level into the room, a most annoying experience.

The risk of feedback can be reduced by minimizing the loudspeaker–listener distance and the source–microphone distance, whereby a suitable listening level can be obtained with a moderate amplifier gain setting. Use of head-borne microphones represents the ultimate reduction of the source–microphone distance. Consequently, with such microphones the risk of feedback is substantially reduced. Also, the microphone–loudspeaker distance should be maximized and directional microphones and loudspeakers should be used and positioned so that the transmission from the loudspeaker back into the microphone is minimized. Thus, the loudspeakers and the microphones should be placed pointing away from each other with the microphone pointing towards the stage and the loudspeaker pointing toward the audience.

Considering the factors mentioned above, we still need to choose a configuration of the loudspeakers for a given room. Often the choice is between

1. A central system, consisting of a single or a limited number of highly directional units arranged close together in a cluster over the stage, or
2. A distributed system of several smaller units placed closer to the listeners.
Fig. 9.55 Alternative solutions for loudspeaker coverage in an auditorium: a central (cluster) system H1, the same with a delayed secondary unit H2, or a highly distributed (pew back) system with small loudspeakers placed in each row of seats

These options are illustrated schematically in Fig. 9.55 as H1 and H3, respectively. H2 illustrates a compromise with a secondary unit or cluster assisting the main cluster, H1.

In meeting rooms or churches, highly distributed systems with small loudspeakers built into fixed meeting tables or pews can be very successful. With each loudspeaker being within a distance of say 1 m from the listener, each unit can be set to a very moderate level. Therefore, it is often possible to serve the listeners with a clear direct sound from such speakers without the total number of speakers exciting too much of the room reverberation. If the system is subdivided into independent sections, it is even possible to install automatic switches that only activate loudspeakers in zones where people are sitting. In this way, the reverberant field can be even further reduced in cases of fewer people attending the meeting or service. This is actually very fortunate as, especially in churches, fewer people also means less absorption and louder reverberation. The performance regarding intelligibility of pew-back systems with perhaps one hundred, moderately directive speakers is often equal to or better than when a highly directive central-cluster system is used. This is simply due to the moderate sound level needed from each of the closely placed loudspeakers compared to the much higher level needed for the cluster to reach the distant listeners. As can be imagined, the sound level distribution produced by the pew-back system will also be more uniform.

Of course, the highly distributed systems are not suitable for amplification of stage performances, where a high sound level of music is needed. For this purpose, a main cluster over the stage or a stereo system with loudspeakers on each side of the stage is preferable. For such systems, it is also more important to maintain a correct localization of the sound as coming from the performers on the stage.

In cases where some additional, distributed loudspeakers are needed to assist coverage in certain parts of the room, for instance on and under deep balconies, these are equipped with an electronic delay. If this delay is set so that the sound from the distributed assisting loudspeakers arrives 5–25 ms after the sound from the main loudspeakers, the listener will still perceive the sound as coming from the direction of the source. This is even true when the assisting loudspeakers are up to 5 dB louder than the main cluster at the listener's position. This very convenient phenomenon, called the precedence effect or Hass effect, is generally used as a guideline for the choice of level and delay settings in distributed loudspeaker systems.

9.8.2 Reverberation-Enhancement Systems

For auditoria where a long reverberation time is only needed occasionally or when the available room volume is simply inadequate, one may consider creating more reverberation by means of an electronic reverberation-enhancement system. Like the systems described in the previous section, these also consist of a number of loudspeakers and microphones connected by amplifiers; but there are many important differences.

The basic difference is that enhancement systems primarily attempt to add energy to the late part of the impulse response. Therefore, delays must be built into the signal processing between microphones and
Fig. 9.56 Example of distribution of loudspeakers for reverberation enhancement in a theatre

loudspeakers. In the first systems of this kind, *assisted resonance* (AR) and *multichannel reverberation* (MCR), which appeared in the 1960s, this delay was provided by letting the loop gain of a large number of microphone–loudspeaker channels be tuned to just below the feedback limit. By spacing the microphones and loudspeakers far apart in the room (normally close to the ceiling), the sound would spend sufficient time traveling several times between loudspeakers and microphones for an audible prolongation of the reverberation to be perceived. In more-modern systems, electronic delays and reverberators are normally used.

In order to create the illusion of diffuse reverberation coming from the room itself, a large number of loudspeakers with low directivity must be distributed over the main surfaces in the room, as illustrated in Fig. 9.56. Since many speakers are needed, each can be fairly small and with limited acoustic power capability. The density and placement of these speakers as well as the balancing of their levels is essential to prevent localization of individual loudspeakers from any seat.

Regarding the microphones, these may be highly directive, but they must be placed quite far from the sound sources (and preferably out of sight) in order to cover the stage without the reverberant level being strongly dependent on the position of the sound source.

In view of what was explained in Sect. 9.8.1 about the measures needed to reduce the risk of feedback in loudspeaker systems, it is no wonder that most reverberation-enhancement manufacturers have to implement a solid strategy against uncontrolled feedback. One very efficient approach is to introduce time-varying delays in the sound-processing equipment, as this seems to destroy sharp room resonances when they start to build up to form a hauling frequency. Still, most enhancement systems work with a loop gain close to the feedback limit (which is actually participating actively in increasing the reverberation time), which is acceptable as long as it is under control and does not cause audible coloration of the sound.

Fig. 9.57 Reverberation time values measured in a hall for different settings of the reverberation enhancement system (LARES)

It is essential for the acceptance of enhancement systems that neither audience nor performers experience the sound as coming from a loudspeaker system. Likewise, artefacts such as coloration due to feedback or the poor frequency characteristics of speakers are unacceptable.

The maximum increase in reverberation time possible with feedback-based systems like AR and MCR was typically about 50%. With modern digital reverberators, a much larger range can be achieved, as shown in Fig. 9.57. Increasing the reverberation time by a factor of three or more is not impossible. However, the illusion, when you still see the physical, much-dryer room around you, tends to break down when the value increases much above the 50%, which ironically is what the old systems could produce.

From a purist standpoint, reverberation enhancement can be regarded as an acoustic prosthesis, but in many cases a pragmatic approach to the use of these systems can increase the range of programs that a cultural venue can host.

10. Concert Hall Acoustics Based on Subjective Preference Theory

Yoichi Ando

Part C | 10

This chapter describes the theory of subjective preference for the sound field applied to designing concert halls. Special attention is paid to the process of obtaining scientific results, rather than only describing a final design method. Attention has also been given to enhancing satisfaction in the selection of the most preferred seat for each individual in a given hall. We begin with a brief historical review of concert hall acoustics and related fields since 1900.

A neurally grounded theory of subjective preference for the sound field in a concert hall, based on a model of the human auditory–brain system, is described [10.1]. Most generally, subjective preference itself is regarded as a primitive response of a living creature and entails judgments that steer an organism in the direction of maintaining its life. Brain activities relating to the scale value of subjective preference, obtained by paired–comparison tests, have been determined. The model represents *relativity*, relating the autocorrelation function (ACF) mechanism and the interaural cross–correlation function (IACF) mechanism for signals arriving at the two ear entrances. The representations of ACF have a firm neural basis in the temporal patterning signal at each of the two ears, while the IACF describes the correlations between the signals arriving at the two ear entrances. Since Helmholtz, it has been well appreciated that the cochlea carries out a rough spectral analysis of sound signals. However, by the use the of the spectrum of an acoustic signal, it was hard to obtain factors or cues to describe subjective responses directly. The auditory representations from the cochlea to the cortex that have been found to be related to subjective preference in a deep way involve these temporal response patterns, which have a very different character from those related to power spectrum analyses. The scale value of subjective preference of the sound field is well described by four orthogonal factors. Two are

temporal factors (the initial delay time between the direct sound and the first reflection, Δt_1, and the reverberation time, T_{sub}) associated with the left cerebral hemisphere, and two are spatial factors (the binaural listening level (LL) and the magnitude of the IACF, the IACC) associated with the right hemisphere. The theory of subjective preference enables us to calculate the acoustical quality at any seat in a proposed concert hall, which leads to a seat selection system.

The temporal treatment enables musicians to choose the music program and/or performing style most suited to a performance in a particular concert hall. Also, for designing the stage enclosure for music performers, a temporal factor is proposed. Acoustical quality at each seating position examined in a real hall is confirmed by both temporal and spatial factors.

	10.3.1 Individual Subjective Preference of Each Listener	386

In the first half of the 20th century, studies were mostly concentrated on temporal aspects of the sound field. In 1900 *Sabine* [10.2] initiated the science of architectural acoustics, developing a formula to quantify reverberation time. In 1949, *Haas* [10.3] investigated the echo disturbance effect from adjustment of the delay time of the early reflection by moving head positions on a magnetic tape recorder. He showed the disturbance of speech echo to be a function of the delay time, with amplitude as a parameter.

After investigations with a number of existing concert halls throughout the world, *Beranek* in 1962 [10.4] proposed a rating scale with eight factors applied to sound fields from data obtained by questionnaires on existing halls given to experienced listeners. Too much attention, however, has been given to monaural temporal factors of the sound field since Sabine's formulation of reverberation theory. For example, the Philharmonic Hall of Lincoln Center in New York, opened in 1962, was not satisfactory to listeners even after many improvements.

On the spatial aspect of the sound field, *Damaske* in 1967 [10.5] investigated subjective diffuseness by arranging a number of loudspeakers around the listener. In 1968, *Keet* [10.6] reported the variation of apparent source width (ASW) in relation to the short-term cross-correlation coefficient between two signals fed into the stereo loudspeakers as well as the sound pressure level. *Marshall* in 1968 [10.7] stressed the importance of early lateral reflections of just 90°, and *Barron* in 1971 [10.8] reported *spatial impressions* or *envelopment* of sound fields in relation to the short-term interaural cross-correlation coefficient.

As a typical spatial factor of the sound field, *Damaske* and *Ando* in 1972 [10.9] defined the IACC as the maximum absolute value of the interaural cross-correlation function (IACF) within the possible maximum interaural delay range for the human head, such that

$$\text{IACC} = |\phi_{\text{lr}}(\tau)|_{\max} \text{ , for } |\tau| < 1\,\text{ms} \qquad (10.1)$$

and proposed a method of calculating the IACF for a sound field. In 1974, *Schroeder* et al. in [10.10] re-ported results of paired-comparison tests asking listeners which of two music sound fields was preferred. In an anechoic chamber, sound fields in existing concert halls were reproduced at the ears of listeners through dummy head recordings and two loudspeaker systems, with filters reproducing spatial information. They found that two significant factors, the reverberation time and the IACC, had a strong influence on subjective preference.

In 1977, *Ando* discussed subjective preference in relation to the temporal and spatial factors of the sound field simulated with a single reflection [10.11]. In 1983, he described a theory of subjective preference in relation to four orthogonal factors consisting of the temporal and spatial factors for the sound field, which enable us to calculate the scale value of the subjective preference at each seat [10.12, 13]. *Cocchi* et al. reconfirmed this theory in an existing hall in 1990 [10.14]. In 1997, *Sato* et al. [10.15] reconfirmed this clearly by use of the paired-comparison judgment in an existing hall, switching identical loudspeakers located at different positions on the stage, instead of changing the seats of each subject. This method may avoid effects of other physical factors than the acoustic factors. In addition to the orthogonal factors, they found the interaural delay in the IACF, τ_{IACC}, as a measure of image shift of the sound source that is to be kept at zero realizes good balance in the sound field. Using this method, the dissimilarity distance has also been described by the temporal and spatial factors of the sound field in 2002 [10.16].

Thus far, the theory has been based on the global subjective attributes for a number of subjects. The theory may be applied for enhancing each individual's satisfaction by adjusting the weighting coefficient of each orthogonal factor [10.1], even though a certain amount of individual differences exist [10.17]. The seat selection system [10.18] was introduced in 1994 after construction of the Kirishima International Concert Hall.

For the purpose of identifying the model of the auditory–brain system, experiments point toward the possibility of developing the correlation between brain activities, measurable with electroencephalography (EEG) [10.19, 20]. Correspondences between

subjective preference and brain activity have been found from EEG and magnetoencephalography (MEG) studies in human subjects [10.21, 22], but details of these results are not included in this chapter due to limited space. Results show that orthogonal factors comprise two temporal factors: the initial time delay gap between the direct sound and the first reflection (Δt_1) and the subsequent reverberation time (T_{sub}) are associated with the left hemisphere, and two spatial factors: the listening level (LL) and the magnitude of the IACF (IACC) are associated with the right hemisphere. The information corresponding to subjective preference of the sound field can be found in the effective duration of the autocorrelation function (ACF) of the alpha (α) waves of both EEG and MEG. A repetitive feature in the α-wave, as measured in its ACF at the preferred condition, has been found. The evidence ensures that the basic theory of subjective preference may also be applied to each individual preference [10.21].

Since individual differences of subjective preference in relation to the IACC in the spatial factor are small enough, at the first stage of acoustic design we can determine the architectural space form of the room. The temporal factors are closely related to the dimensions of a specific concert hall, which can be altered to exhibit specific types of music, such as organ music, chamber music or choral works.

On the neural mechanism in the auditory pathway, a possible mechanism for the interaural time difference and correlation processors in the time domain was proposed by *Jeffress* in 1948 [10.23], and by *Licklider* in 1951 [10.24]. By recording left and right auditory brainstem responses (ABR), *Ando* et al. in 1991 [10.25] revealed that the maximum neural activity (wave V at the inferior colliculus) corresponds well to the magnitude of the interaural cross-correlation function. Also, the left and right waves $IV_{l,r}$ are close to the sound energies at the right- and left-ear entrances. In fact, the time-domain analysis of the firing rate of the auditory nerve of a cat reveals a pattern of ACF rather than the frequency-domain analysis as reported by *Secker-Walker* and *Searle* in 1990 [10.26]. *Cariani* and *Delgutte* in 1996 showed that pooled inter-spike interval distributions resemble the short-time or the running autocorrelation function (ACF) for the low-frequency component. In addition, pooled interval distributions for sound stimuli consisting of the high-frequency component resemble the envelope for running ACF [10.27, 28].

Remarkably, primary sensations such as the pitch of the missing fundamental [10.29], loudness [10.30], and duration sensation [10.31] can be well described by the temporal factors extracted from the ACF [10.32, 33]. *Timbre* investigated by the dissimilarity judgment [10.16] of the sound field has been described by both the temporal and spatial factors. The typical spatial attributes of the sound field, such as subjective diffuseness [10.34] and apparent source width (ASW), as well as subjective preference, are well described by the spatial factor [10.32–36].

Besides the design of concert halls, other acoustical applications such as speech identification [10.36], environmental noise measurement [10.37], and sound localization in the median plane [10.38] should benefit from guidelines derived from this model.

10.1 Theory of Subjective Preference for the Sound Field

Subjective preference judgment is the most primitive response in any subjective attribute and entails judgments that steer an organism in the direction of maintaining and/or animating *life*. Subjective preference, therefore, may relate to an aesthetic issue. It is known that judgment in an absolute manner presents a problem in reliability; rather, data is judged in a relative manner such as by paired-comparison tests. This is the simplest method, in that any person may participate, and the resulting scale value may be utilized in the wide range of applications. From the results of subjective preference studies in relation to the temporal factor and the spatial factor of the sound field, the theory of subjective preference is derived. Examples of calculating subjective preference at each listener's position are demonstrated in Sect. 10.2 for the global listener and Sect. 10.3 for the individual listener. The relationship between the resulting scale value of subjective preference in an existing hall and the physical factors obtained by calculation using architectural plan drawings, has been examined by factor analysis in Sect. 10.4.

10.1.1 Sound Fields with a Single Reflection

Preferred Delay Time of a Single Reflection
First of all, the simplest sound field, which consists of the direct sound with the horizontal angle to a listener: $\xi_0 = 0°$ (the elevation angle $\eta_0 = 0°$), and a single reflection from a fixed direction $\xi_1 = 36°$ ($\eta_1 = 9°$), was investigated. These angles were selected since they are

Table 10.1 Music and speech source signals and their minimum effective duration of the running ACF[a], $(\tau_e)_{min}$

Sound source	Title	Composer or writer	$(\tau_e)_{min}$ (ms)
Music motif A	Royal Pavane	Orlando Gibbons	125
Music motif B	Sinfonietta, opus 48; IV movement	Malcolm Arnold	40
Speech S	Poem read by a female	Doppo Kunikida	10

[a] The value of $(\tau_e)_{min}$ is the minimum value extracted from the running ACF, $2T = 2$ s, with a running interval of 100 ms. The recommended value of $2T$ is given by (10.14)
Fig. 10.1 Determination of the effective duration of the running ACF, τ_e. The value of τ_e may be obtained by the delay for which the envelope of the normalized ACF becomes 0.1 or -10 dB (10-percentile delay)

Fig. 10.2 Preference scores of the sound fields as a function of the delay time $A_1 = 1.0$ (six sound fields and 13 subjects (after [10.11]). Preference scores are directly obtained for each pair of sound fields by assigning the values $+1$ and -1, corresponding to positive and negative judgments, respectively. The normalized score is obtained by accumulating the scores for all sound fields (F) tested and all subjects (S), and then dividing by the factor $S(F-1)$ for 13 subjects. A: music motif A, Royal Pavane by Gibbons, $(\tau_e)_{min} = 125$ ms; B: music motif B, Sinfonietta, opus 48, III movement by Malcolm Arnold, $(\tau_e)_{min} = 40$ ms

typical in a concert hall. The delay time Δt_1 of the reflection was adjusted in the range of 6–256 ms. The paired-comparison test was performed for all pairs in an anechoic chamber using normal hearing subjects with two different music motifs A and B (Table 10.1). The effective duration of the ACF of the sound source defined by τ_e may be obtained by the delay at which the envelope of the normalized autocorrelation function (ACF) becomes 0.1 (10-percentile delay) as shown in Fig. 10.1. The value of $(\tau_e)_{min}$ indicated in Table 10.1 is obtained from the minimum value of the running ACF, $2T = 2$ s, with an interval of 100 ms. The recommended $2T$ is given by (10.14). As far as these source signals are concerned, values of (τ_e) extracted from the long-term ACF were similar to the minimum values from the running ACF, $(\tau_e)_{min}$.

For simplicity, the score was simply obtained, in this section, by accumulating a score giving $+1$ and -1 corresponding to positive and negative judgments, respectively, and the total score is divided by $S(F-1)$ to get the normalized score, where S is the number of subjects and F is the number of sound fields tested. The normalized scores for two motifs and the percentage of preference for speech signal as a function of the delay time are shown in Fig. 10.2.

Obviously, the most preferred delay time with the maximum score differs greatly between the two motifs. When the amplitude of reflection $A_1 = 1$, the most preferred delays are around 130 ms for music motif A, 35 ms for music motif B (Fig. 10.2a), and 16 ms for speech [10.36]. Later, it was found that this corresponds well to the minimum values of the effective durations of the running ACF [10.39] of the source signals, so that
Fig. 10.3 The relationship between the preferred delay time of the single reflection and the duration of the ACF such that its envelope becomes $0.1\,A_1$ (for $k = 0.1$ and $c = 1.0$). The ranges of the preferred delays are graphically obtained at 0.1 below the maximum score. A, B and S refer to motif A, motif B, and speech, respectively. Different symbols indicate the center values obtained at the reflection amplitudes of $+6\,\mathrm{dB}$ ($\circ$), $0\,\mathrm{dB}$ ($\bullet$), and $-6\,\mathrm{dB}$ ($\square$), respectively (13–19 subjects) (after [10.11])

the most preferred delay time were 125 ms (motif A), 40 ms (motif B) and 10 ms (speech). After inspection, the preferred delay is found roughly at certain durations of the ACF, defined by τ_p, such that the envelope of the ACF becomes $0.1 A_1$. Thus, $[\Delta t_1]_p \approx \tau_e$ only when $A_1 = 1$. As shown in Fig. 10.3, changing the amplitude A_1, collected data of $[\Delta t_1]_p$ are expressed approximately by

$$[\Delta t_1]_p = \tau_p \approx (1 - \log_{10} A_1)(\tau_e)_{\min} . \tag{10.2}$$

Note that the amplitude of reflection relative to that of the direct sound should be measured by the most accurate method (ex. the square-root value of the ACF at the origin of the delay time).

Two reasons can be given for why the preference decreases for the short delay range of reflection, $0 < \Delta t_1 < [\Delta t_1]_p$:
Fig. 10.4 Definition of the three spatial factors IACC, τ_{IACC} and W_{IACC}, extracted from the interaural cross-correlation function (IACF)

1. Tone coloration effects occur because of the interference phenomenon in the coherent time region; and
2. The IACC increases when Δt_1 is near 0. The definition of the IACC, which may be extracted from the IACF, as given by [10.1], is shown in Fig. 10.4.

On the other hand, echo disturbance effects can be observed when Δt_1 is greater than $[\Delta t_1]_p$.

Preferred Horizontal Direction of a Single Reflection to a Listener

The direction was specified by loudspeakers located at $\xi_1 = 0°$ ($\eta_1 = 27°$), and $\xi_1 = 18°, 36°, \ldots, 90°$ ($\eta_1 = 9°$), where the delay time of the reflection was fixed at 32 ms [10.11]. Results of the preference tests for the two motifs are shown in Fig. 10.5. No fundamental differences are observed between the curves of the sound source in spite of the large differences in the value of $(\tau_e)_{\min}$. The preferred score increases roughly with decreasing IACC, the typical spatial factor. The correlation coefficient between the score and the IACC is -0.8 ($p < 0.01$). The score with motif A at $\xi_1 = 90°$ drops to a negative value, indicating that the lateral reflections coming only from around $\xi_1 = 90°$, thus, are not always preferred. The figure shows that there is a preference for angles less than $\xi_1 = 90°$, and on average there may be an optimum range centered on about $\xi_1 = 55°$. Similar results can be seen in the data from speech signals [10.40]. These results are due to the spatial factor independent of the temporal factor, which consists of the source signal.
Fig. 10.5 Preference scores and the IACC of the sound fields with extreme music motifs A and B, as a function of the horizontal angle of a single reflection, $A_1 = 0$ dB (six sound fields and 13 subjects)

10.1.2 Optimal Conditions Maximizing Subjective Preference

According to a systematic investigation of simulating the sound field with multiple reflections and reverberation by the aid of a computer and the listening test, the optimum design objectives and the linear scale value

Fig. 10.6 Recommended reverberation time for several sound programs

of subjective preference may be derived. The optimum design objectives can be described in terms of the subjectively preferred sound qualities, which are related to the four orthogonal factors describing the sound signals arriving at the two ears. They clearly lead to comprehensive criteria for achieving the optimal design of concert halls as summarized below [10.11–13].

Listening Level (LL)

The listening level is, of course, the primary criterion for listening to sound in a concert hall. The preferred listening level depends upon the music and the particular passage being performed. The preferred levels obtained with 16 subjects were similar for two extreme music motifs: 77–79 dBA in peak ranges for music motif A (Royal Pavane by Gibbons) with a slow tempo, and 79–80 dBA for music motif B (Sinfonietta by Arnold) with a fast tempo Fig. 10.7a.

Early Reflection after the Direct Sound (Δt_1)

An approximate relationship for the most preferred delay time has been discovered in terms of the ACF envelope of source signals and the total amplitude of reflections A. Generally, it is expressed by $[\Delta t_1]_p = \tau_p$

$$\left|\phi_p(\tau)\right|_{\text{envelope}} \approx kA^c, \text{ at } \tau = \tau_p, \tag{10.3}$$

where k and c are constants that depend on the subjective attributes [10.1, Fig. 41]. If the envelope of ACF is exponential, then

$$[\Delta t_1]_p = \tau_p \approx \left[\log_{10}(1/k) - c \log_{10} A\right](\tau_e)_{\min}, \tag{10.4}$$

where the total pressure amplitude of reflection is given by

$$A = \left(A_1^2 + A_2^2 + A_3^2 + \dots\right)^{1/2}. \tag{10.5}$$

The relationship given by (10.2) for a single reflection may be obtained by putting $A = A_1$, $k = 0.1$ and $c = 1$.

The value of $(\tau_e)_{\min}$ is observed at the most active part of a piece of music containing artistic information such as a vibrato, a quick passage in the music flow, and/or a very sharp sound signal. Echo disturbance, therefore, may be perceived at $(\tau_e)_{\min}$. Even for a long musical composition, the minimum part of $(\tau_e)_{\min}$ of the running ACF in the whole music, which determines the preferred temporal condition, may be taken into consideration for the choice of music program to be performed in a given concert hall. A method of controlling the minimum value $(\tau_e)_{\min}$ in performance, which determines the preferred temporal condition for vocal music
has been discussed for blending the sound source and a given concert hall [10.41, 42]. If vibrato is introduced during singing, for example, it decreases $(\tau_e)_{min}$, blending the sound field with a short reverberation time.

Reverberation Time
After the Early Reflection (T_{sub})

It has been observed that the most preferred frequency response to the reverberation time is a flat curve [10.39]. The preferred reverberation time, which is equivalent to that defined by *Sabine* [10.2], is expressed approximately by

$$[T_{sub}]_p \approx 23(\tau_e)_{min} . \qquad (10.6)$$

The total amplitudes of reflections A tested were 1.1 and 4.1, which cover the usual conditions of sound fields in a room. Recommended reverberation times for several sound sources are shown in Fig. 10.6. A lecture and conference room must be designed for speech, and an opera house mainly for vocal music but also for orchestra music. For orchestral music, there may be two or three types of concert hall designs according to the effective duration of the ACF. For example, symphony no. 41 by Mozart, *Le Sacre du Printemps* by Stravinsky, and Arnold's Sinfonietta have short ACFs and fit orchestra music of type (A). On the other hand, symphony no. 4 by Brahms and symphony no. 7 by Bruckner are typical of orchestra music (B). Much longer ACFs are typical for pipe-organ music, for example, by Bach.

The most preferred reverberation times for each sound source given by (10.6) might play important roles for the selection of music motifs to be performed. Of interest is that the most preferred reverberation time expressed by (10.6) implies about four times the *reverberation time* containing the source signal itself.

Magnitude of the Interaural
Cross-Correlation Function (IACC)

All individual data indicated a negative correlation between the magnitude of the IACC and subjective preference, i. e., dissimilarity of signals arriving at the two ears is preferred. This holds only under the condition that the maximum value of the IACF is maintained at the origin of the time delay, keeping a balance of the sound field at the two ears. If not, then an image shift of the source may occur (Sect. 10.4.2). To obtain a small magnitude of the IACC in the most effective manner, the directions from which the early reflections arrive at the listener should be kept within a certain range of angles from the median plane centered on ±55°. It is obvious that the sound arriving from the

median plane ±0° makes the IACC greater. Sound arriving from ±90° in the horizontal plane is not always advantageous, because the similar detour paths around the head to both ears cannot decrease the IACC effectively, particularly for frequency ranges higher than
Fig. 10.7a–d Scale values of subjective preference obtained by the paired-comparison test for simulated sound fields in an anechoic chamber. Different symbols indicate scale values obtained from different source signals (after [10.12]). Even if different signals are used, a consistency of scale values as a function of each factor is observed, fitting a single curve. (**a**) As a function of the listening level, LL. The most preferred listening level, $[LL]_p = 0$ dB

500 Hz. For example, the most effective angles for the frequency ranges of 1 kHz and 2 kHz are centered on $\pm 55°$ and $\pm 36°$, respectively. To realize this condition simultaneously, a geometrical uneven surface has been proposed [10.43].

10.1.3 Theory of Subjective Preference for the Sound Field

Theory
Since the number of orthogonal acoustic factors of the sound field, which are included in the sound signals at both ears, is limited [10.12]; the scale value of any one-dimensional subjective response may be expressed by

$$S = g(x_1, x_2, \ldots x_i) . \tag{10.7}$$

It has been verified by a series of experiments that four objective factors act independently on the scale value when changing two of the four factors simultaneously [10.13]. Results indicate that the units of the scale value of subjective preference derived by a series of experiments with different sound sources and different subjects have appeared to be constant [10.12], so that we may add scale values to obtain the total scale value such as

$$\begin{aligned} S &= g(x_1) + g(x_2) + g(x_3) + g(x_4) \\ &= S_1 + S_2 + S_3 + S_4 , \end{aligned} \tag{10.8}$$

where S_i $(i = 1, 2, 3, 4)$ is the scale value obtained relative to each objective parameter. Equation (10.8) indicates a four-dimensional continuity.

A Common Formula for the Four Normalized Orthogonal Factors
The dependence of the scale value on each objective parameter is shown graphically in Fig. 10.7. From the nature of the scale value, it is convenient to put a zero value at the most preferred conditions, as shown in this figure. These results of the scale value of subjective preference obtained from the different test series, using different music programs, yield the following common formula

$$S_i \approx -\alpha_i |x_i|^{3/2} , \quad i = 1, 2, 3, 4 \tag{10.9}$$

where values of α_i are weighting coefficients as listed in Table 10.2, which were obtained with a number of subjects. These coefficients depend on the individual. If α_i is close to zero, then a lesser contribution of the factor x_i on subjective preference is signified.

Table 10.2 Four orthogonal factors of the sound field and their weighting coefficients α_i obtained by a paired-comparison test of subjective preference with a number of subjects in conditions without any image shift of the source sound ($\tau_{IACC} = 0$)

i	x_i	α_i	
		$x_i > 0$	$x_i < 0$
1	$20 \log P - 20 \log[P]_p$ (dB)	0.07	0.04
2	$\log(\Delta t_1/[\Delta t_1]_p)$	1.42	1.11
3	$\log(T_{sub}/[T_{sub}]_p)$	$0.45 + 0.75A$	$2.36 - 0.42A$
4	IACC	1.45	–

The factor x_1 is given by the sound pressure level (SPL) difference, measured by the A-weighted network, so that

$$x_1 = 20 \log P - 20 \log [P]_p , \qquad (10.10)$$

P and $[P]_p$ being, respectively, the sound pressure at a specific seat and the most preferred sound pressure that may be assumed at a particular seat position in the room under investigation

$$x_2 = \log \left(\Delta t_1 / [\Delta t_1]_p \right) , \qquad (10.11)$$

$$x_3 = \log \left(T_{sub} / [T_{sub}]_p \right) , \qquad (10.12)$$

$$x_4 = \mathrm{IACC} . \qquad (10.13)$$

Scale values of preference have been formulated approximately in terms of the 3/2 powers of the normalized objective parameters, expressed in the logarithm for the parameters, x_1, x_2 and x_3. Thus, scale values are not greatly changed in the neighborhood of the most preferred conditions, but decrease rapidly outside of this range. The remarkable fact is that the spatial binaural parameter x_4 is expressed in terms of the 3/2 powers of its real values, indicating a greater contribution than those of the temporal parameters.

Limitation of Theory

Since experiments were conducted to find the optimal conditions, this theory holds in the range of preferred

Table 10.3 Hemispheric specializations determined by analyses of AEP (SVR), EEG and MEG[a]

Factors changed	AEP (SVR) $A(P_1 - N_1)$	EEG, ratio of ACF τ_e values of α-waves	MEG, ACF τ_e value of α-wave

conditions obtained by the test. In order to demonstrate the independence of the four orthogonal factors, under the conditions of fixed Δt_1 and T_{sub} around the preferred conditions, scale values of subjective preference calculated by (10.8) for the LL with (10.10) and the IACC with (10.13) with constants listed in Table 10.2 are shown in Fig. 10.8. Agreement between the calculated and observed values are satisfactory [10.13]. Even though both LL and the IACC are spatial factors, which are associated with the right cerebral hemisphere (Table 10.3), these are quite independent of each other. The same is true for the temporal factors of Δt_1 and T_{sub} associated with the left hemisphere. Of course, the spatial factor and the temporal factor are highly independent.

Example of Calculating the Sound Quality at Each Seat

As a typical example, we shall discuss the quality of the sound field at each seating position in a concert hall with a shape similar to that of Symphony Hall in Boston. Suppose that a single source is located at the center, 1.2 m above the stage floor. Receiving points at a height of 1.1 m above the floor level correspond to the ear positions. Reflections with their amplitudes, delay times, and directions of arrival at the listeners are taken

Fig. 10.8 Scale values of subjective preference for the sound field with music motif A as a function of the listening level and as a parameter of the IACC (after [10.13]). *Solid line*: calculated values based on (10.8) together with (10.9) taking the two factors (10.10) and (10.13) into consideration; *dashed line*: measured values

Fig. 10.10 Recommended temporal window $(2T)_r$ for the ACF proceeding as a function of the minimum value of effective duration of the ACF $(\tau_e)_{min}$. Different symbols represent experimental results using different sound sources

into account using the image method. Contour lines of the total scale value of preference calculated for music motif B are shown in Fig. 10.9. Results shown in Fig. 10.9b demonstrate the effects of the reflection from the sidewalls adjusted to the stage, which produce decreasing values of the IACC for the audience area. Thus the preference value at each seat is increased compared with that in Fig. 10.9a. In this calculation, the reverberation time is assumed to be 1.8 s throughout the hall and the most preferred listening level, $[LL]_p = 20 \log[P]_p$ in (10.10), is set for a point on the center line 20 m from the source position.

10.1.4 Auditory Temporal Window for ACF and IACF Processing

Auditory Temporal Window for ACF Processing

In analyzing the running ACF, the so-called *auditory–temporal window* 2T must be carefully determined. The initial part of the ACF within the effective duration of the ACF contains important information about the source signal. In order to determine the auditory–temporal window, successive loudness judgments in pursuit of the running SPL have been conducted. Results shown in Fig. 10.10 indicate that the recommended signal duration $(2T)_r$ to be analyzed is approximately expressed by [10.46]

$$(2T)_r \approx 30(\tau_e)_{min} , \tag{10.14}$$

where $(\tau_e)_{min}$ is the minimum effective duration, extracted from the running ACF [10.47]. This signifies an adaptive temporal window depending on the temporal characteristics of the sound signal in the auditory system. For example, the temporal window may differ according to music pieces $((2T)_r = 0.5–5\,s)$ and to the vowels $((2T)_r = 50–100\,ms)$ and consonants $((2T)_r = 5–10\,ms)$ in continuous speech signals. It is worth noticing that the time constant represented by *fast* or *slow* of the sound level meter should be replaced by the temporal window, which depends on the effective duration of the ACF of the source signal. The running step (R_s), which signifies a degree of overlap of signal to be analyzed, is not critical. It may be selected as $K_2(2T)_r$; K_2 is chosen, say, in the range 0.25–0.5.

Auditory Temporal Window for IACF Processing

For the sound source fixed on the stage in a concert hall as usual, the value of 2T can be selected longer than 1.0 s for the measurement of the spatial factor at a fixed audience seat. But, when a sound signal is moving in the horizontal direction on the stage, we must know a suitable temporal window for 2T in analyzing the running IACF, which describes the moving image of sound localization. For a sound source moving sinusoidally in the horizontal plane with less than 0.2 Hz,

$2T$ may be selected in a wide range from 30 to 1000 ms. If a sound source is moving below and/or at 4.0 Hz, $2T = 30$–100 ms is acceptable. In order to obtain a reliable result, it is recommended that such a temporal window for the IACF covering a wide range of movement velocity in the horizontal localization be fixed at about 30 ms.

10.1.5 Specialization of Cerebral Hemispheres for Temporal and Spatial Factors of the Sound Field

The independent influence of the aforementioned temporal and spatial factors on subjective preference judgments has been achieved by the specialization of the human cerebral hemispheres [10.44]. Recording over the left and right hemispheres of the slow vertex response (SVR) with latency of less than 500 ms, electroencephalograms (EEG) and magnetoencephalograms (MEG) have revealed various pieces of evidence (Table 10.3), with the most significant results being:

1. The left and right amplitudes of the evoked SVR, $A(P_1 - N_1)$ indicate that the left and right hemispheric dominance are due to temporal factors (Δt_1) and spatial factors (LL and IACC), respectively [10.35, 48].
2. Both left and right latencies of N_2 of SVR correspond well to the IACC [10.35].
3. Results of EEGs for the cerebral hemispheric specialization of the temporal factors, i. e., Δt_1 and T_{sub} indicated left-hemisphere dominance [10.49, 50], while the IACC indicated right-hemisphere dominance [10.45]. Thus, a high degree of independence between temporal and spatial factors was indicated.
4. The scale value of subjective preference is well described in relation to the value of τ_e extracted from the ACF of α-wave signals over the left hemisphere and the right hemisphere according to changes in temporal and spatial factors of the sound field, respectively [10.45, 49, 50].

5. Amplitudes of MEGs recorded when Δt_1 was changed reconfirm the left-hemisphere specialization [10.51].
6. The scale values of individual subjective preference relate directly to the value of τ_e extracted from the ACF of the α-wave of the MEG [10.51]. It is worth noting that the amplitudes of the α-wave in both the EEG and the MEG do not correspond well to the scale value of subjective preference.

In addition to the aforementioned activities in the time domain, in both the left and right hemispheres, spatial activity waves were analyzed by the cross-correlation function of alpha waves from the EEGs and MEGs. The results showed that a larger area of the brain is activated when the preferred sound field is presented [10.52] than when a less preferred one. This implies that the brain repeats a similar temporal rhythm in the α-wave range over a wider area of the scalp under the preferred conditions.

It has been reported that the left hemisphere is mainly associated with speech and time-sequential identifications, and the right is concerned with nonverbal and spatial identification [10.53, 54]. However, when the IACC was changed using speech and music signals, right-hemisphere dominance was observed, as indicated in Table 10.3. Therefore, hemispheric dominance is a relative response depending on which factor is changed in the comparison pair, and no absolute behavior could be observed.

To date, it has been discovered that the LL and the IACC are dominantly associated with the right cerebral hemisphere, and the temporal factors, Δt_1 and T_{sub} are associated with the left. This implies that such specialization of the human cerebral hemisphere may relate to the highly independent influence of spatial and temporal criteria on any subjective attribute. It is remarkable, for example, that *cocktail party effects* might well be explained by such specialization of the human brain, because speech is processed in the left hemisphere, and spatial information is processed in the right hemisphere independently.

10.2 Design Studies

Using the scale values in the four orthogonal factors of the sound field obtained by a number of listeners, the *principle of superposition* expressed by (10.8) together with (10.9) through (10.13) can be applied to calculate the scale value of preference for each seat.

Comparison of the total preference values for different configurations of concert halls allows a designer to choose the best scheme. Temporal factors relating to its dimensions and the absorbing material on its walls are carefully determined according to the purpose of

the hall in terms of a range of specific music programs (Fig. 10.6). In this section, we discuss mainly the spatial form of the hall, the magnitude of the interaural correlation function and the binaural listening level.

10.2.1 Study of a Space–Form Design by Genetic Algorithms (GA)

A large number of concert halls have been built since the time of the ancient Greeks, but only the halls with good sound quality are well liked. In order to increase the measure of success, a genetic algorithm (GA) system [10.55], a form of evolutionary computing, can be applied to the acoustic design of concert halls [10.56, 57]. The GA system is applied here to generate the alternative scheme on the left-hand side of Fig. 10.11 for listeners.

Procedure

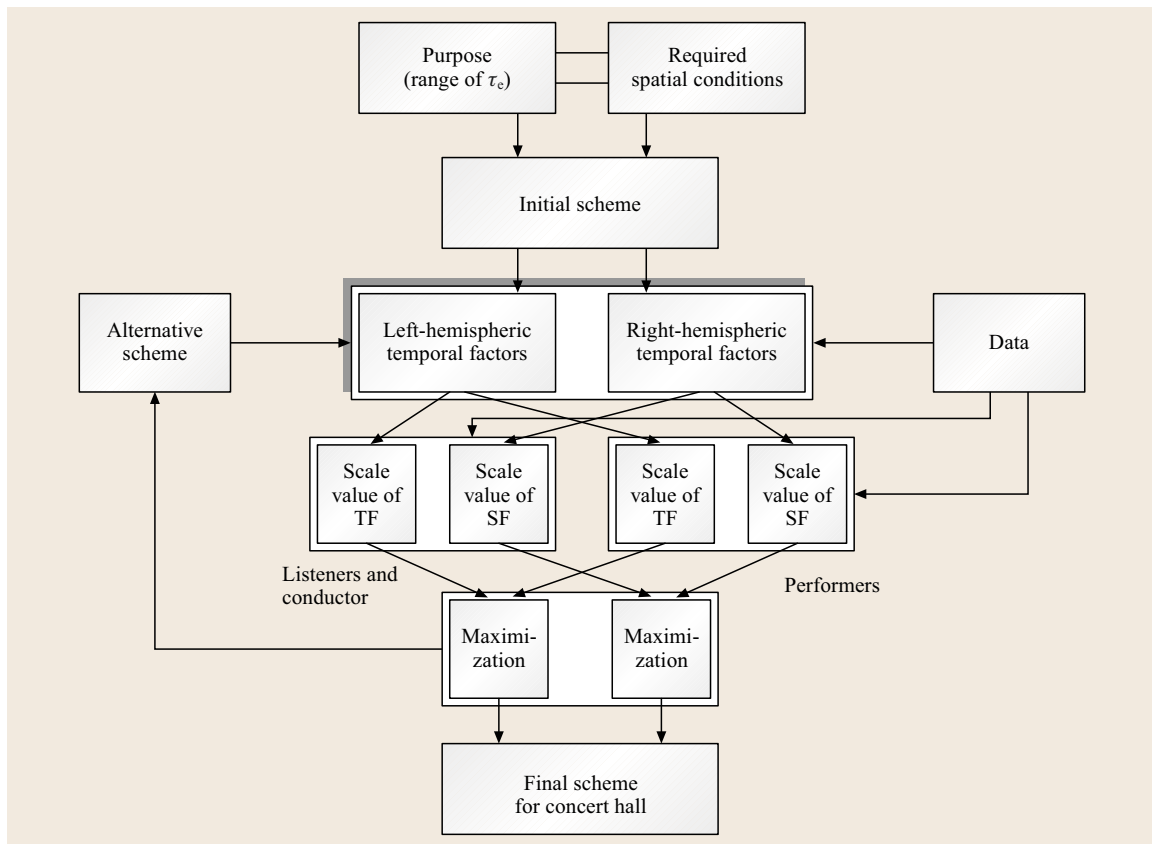
In this calculation, linear scale values of subjective preference S_1 and S_4 given by (10.9) are employed as fitting functions due to the LL and IACC, because the geometrical shape of a hall is directly affected by these spatial factors. The spatial factor for a source on the stage was calculated at a number of seating positions. For the sake of convenience, the single omnidirectional source was assumed to be at the center of the stage, 1.5 m above the stage floor. The receiving points that correspond to the ear positions were 1.1 m above the floor of the hall. The image method was used to determine the amplitudes, delay times, and directions of arrival of reflections at these receiving points. Reflections were calculated up to the second order. In fact, there was no change in the relative relationship among the factors obtained from calculations performed up to the second, third, and fourth order of reflection. The averaged val-


Fig. 10.11 The procedure for designing the sound field in a concert hall maximizing the scale values of subjective preference for a number of listeners (including a conductor) and performers. Data for global values of subjective preference may be utilized when designing a public hall

ues of the IACC for five music motifs (motifs A through E [10.13]) were used for the calculation.

Those hall shapes that produced greater scale values are selected as parent chromosomes. An example of the encoding of the chromosome is given in Fig. 10.12. The first bit indicated the direction of motion for the vertex. The other $(n-1)$ bits indicated the range over which the vertex moved. To create a new generation, the room shapes are modified and the corresponding movement of the vertices of the walls is encoded in chromosomes, i.e., binary strings. After GA operations that include crossover and mutation, new offspring are created. The fitness of the offspring is then evaluated in terms of the scale value of subjective preference. This process is repeated until the end condition of about 2000 generations is satisfied.

Shoe–Box Optimized

First of all, the proportions of the shoe-box hall were optimized (model 1). The initial geometry is shown in Fig. 10.13. In this form, the hall was 20 m wide, the stage was 12 m deep, the room was 30 m long, and the ceiling was 15 m above the floor. The point source was located at the center of the stage and 4.0 m from the front of the stage; 72 listening positions were selected. The range of motion for each sidewall and the ceiling was ±5 m from the respective initial positions, and the distance through which each was moved was coded on the chromosome of the GA. Scale values at the listening positions other than those within 1 m of the sidewalls were included in the averages ($\overline{S_1}$ and $\overline{S_4}$). These values were employed as the measure of fitness. In this calculation, the most preferred listening level $[LL]_p$ was chosen at the frontal seat near the stage. Results of optimization of the hall for $\overline{S_1}$ and $\overline{S_4}$ are shown in Fig. 10.14a,b, respectively. The width and length were almost the same in the two results, but the indicated heights were quite different. The height of the ceiling that maximizes $\overline{S_1}$ was as low as possible within the allowed range of motion to obtain a constant LL (Fig. 10.14a). The height

that maximizes $\overline{S_4}$, on the other hand, was at the upper limit of the allowed range of motion to obtain small values of the IACC (Fig. 10.14b). Table 10.4 shows the
Fig. 10.12 An example of the binary strings used in encoding of the chromosome to represent modifications to the room shape
Fig. 10.13 The initial scheme of a concert hall (model 1). The range of sidewall and ceiling variation was ±5 m from the initial scheme

Table 10.4 Comparison of proportions for the optimized spatial form of *shoe-box* type and the *Grosser Musikvereinssaal*

	Length/width	Height/width
Optimized for $\overline{S_1}$ for the listening level	2.50	0.71
Optimized for $\overline{S_4}$ for the IACC	2.57	1.43
Grosser Musikvereinssaal	2.55	0.93
Fig. 10.14a,b Results for the model 1. (**a**) Geometry optimized for $\overline{S_1}$. (**b**) Geometry optimized for $\overline{S_4}$ (after [10.56])

comparison of the proportions obtained here and those of the Grosser Musikvereinssaal, which is a typical example of an excellent concert hall. The length/width ratios are almost the same. The height/width ratio of the Grosser Musikvereinsaal is intermediate between our results for the two factors. For the ceiling of the hall, the height that maximized $\overline{S_1}$ was the lowest within the allowed range of motion (Fig. 10.14a). This is due to the fact that more energy can be provided from the ceiling to the listening position throughout the seats. To maximize $\overline{S_4}$, on the other hand, the ceiling took on the maximum height in the possible range of motion (Fig. 10.14b). Reflections from the flat ceiling did not decrease the IACC, but those from the sidewalls did.

Modification from the *Shoe–Box*

Next, to obtain even better sound fields, a little more complicated form (model 2), as shown in Fig. 10.15, was examined. The floor plan optimized according to the above results was applied as a starting point. The hall in its initial form was 14 m wide, the stage was 9 m deep, the room was 27 m long, and the ceiling was 15 m above the stage floor. The sound source was again 4.0 m from the front of the stage, but was 0.5 m to one side of the centerline and 1.5 m above the stage floor. The

front and rear walls were vertically bisected to obtain two faces, and each stretch of wall along the side of the seating area was divided into four faces. The walls were kept vertical (i. e., tilting was not allowed) to examine only the plan of the hall in terms of maximizing $\overline{S_1}$ and $\overline{S_4}$. Each wall was moved independently of the other walls. The openings between the walls, in the acoustical simulation using the image method, were assumed not to reflect the sound. Forty-nine listening positions distributing throughout the seating area on a $2\,\text{m} \times 4\,\text{m}$ grid were selected. In the GA operation, the sidewalls were moved, so that none of these 49 listening positions were excluded. The moving range of each vertex was $\pm 2\,\text{m}$ in the direction of the line normal to the surface. The coordinates of the two bottom vertices of each surface were encoded on the chromosomes for the GA. In this calculation, the most preferred listening level was set for a point on the hall's long axis (central line), 10 m from the source position.

Leaf–Shape Concert Hall

The result of optimizing the hall for $\overline{S_1}$ is shown in Fig. 10.16 and the contour lines of equal $\overline{S_1}$ values are shown in Fig. 10.17. To maximize $\overline{S_1}$, the rear wall of the stage and the rear wall of the audience area took on concave shapes. The result of optimizing for $\overline{S_4}$ is shown in Fig. 10.18 and contour lines of equal $\overline{S_4}$ values are shown in Fig. 10.19. To maximize $\overline{S_4}$, on the other hand, the rear wall of the stage and the rear wall
Fig. 10.15 Initial scheme of the concert hall (model 2). The rear wall of the stage and the rear wall of the audience area were divided into two. Sidewalls were divided into four
Fig. 10.16 A result for the model 2 optimized for $\overline{S_1}$

of the audience area took on convex shapes. With regard to the sidewalls, both $\overline{S_1}$ and $\overline{S_4}$ were maximized by the *leaf-shaped* plan, which is discussed in the following section. As for the conflicting requirements for S_1 and S_4, the maximization of S_4 may take priority over that of S_1, because the preference increases with decreasing IACC without exception [10.1], while there is a large individual difference in the preferred LL [10.58]. It is worth noting that listeners themselves can usually choose the best seat with respect to the preferred LL in a real concert hall.

A conductor and/or music director must be aware of the sound field characteristics of a concert hall. One is then able to select a program of music so that the sound is best in that hall in terms of the temporal factors (Fig. 10.6).

10.2.2 Actual Design Studies

After testing more than 200 listeners, a small value of the IACC, which corresponds to different sound signals arriving at two ears, was demonstrated to be the preferred condition for individuals without exception. A practical application of this design theory was done in the Kirishima International Concert Hall (Miyama Conceru), which was characterized by a *leaf shape* (Fig. 10.20).

Temporal Factors of the Sound Field for Listeners

When the space is designed for pipe-organ performance, the range of $(\tau_e)_{min}$, which may be selected to be centered on 200 ms, determines the typical temporal factor of the hall: $[T_{sub}]_p \approx 4.6$ s (10.6). When designed for the performance of chamber music, the range is selected to be near the value of 65 ms ($[T_{sub}]_p \approx 1.5$ s). The conductor and/or the sound coordinator select suitable musical motifs with a satisfactory range of effective duration of the ACF to achieve a music performance that blends the music and the sound field in a hall (Fig. 10.6). To adjust the preferred condition of Δt_1, on the other hand, since the value of $(\tau_e)_{min}$ for violins is usually shorter than that of contrabasses in the low-frequency range, the position of the violins is shifted closer to the left wall on the stage, and the position of the contrabasses is shifted closer to the center, as viewed from the audience.

Spatial Factors of the Sound Field for Listeners

The IACC should be kept as small as possible, maintaining $\tau_{IACC} = 0$. This is realized by suppressing the
Fig. 10.17 Contour lines of equal $\overline{S_1}$ values calculated for the geometry shown in Fig. 10.16

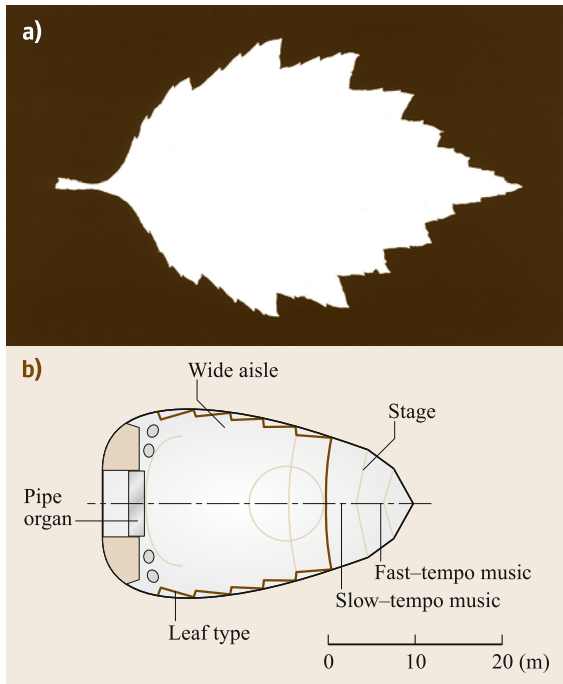

Fig. 10.20a,b A leaf shape for the plan proposed for the Kirishima International Concert Hall. (**a**) Original leaf shape. (**b**) Proposed shape for the plan. As usual, the sound field in *circled seating area* close to the stage must be carefully designed to obtain reflections from the walls on the stage and tilted sidewalls

strong reflection from the ceiling, and by appropriate reflections from the sidewall at certain angles. When the source signal mainly contains frequency components around 1 kHz, the reflection from the side walls is adjusted to be centered roughly 55° to each listener, measured from the median plane. Under actual hearing conditions, the perceived IACC depends on whether or not the amplitudes of reflection exceed the hearing threshold level. This may be one of the reasons why a more diffuse sound field can be perceived with increasing power of the sound source. When the source is weak enough, that only the direct sound is heard, the actual IACC being processed in the auditory–brain system approaches unity, resulting in no diffuse sound impression. Thus, the IACC should be small enough with only strong early reflections.

Sound Field for Musicians

For music performers, the temporal factor is considered to be much more critical than the spatial factor (Sect. 10.3.2). Since musicians perform over a sequence of time, reflections with a suitable delay in terms of the value of $(\tau_e)_{min}$ of the source signals are of particular importance. Without any spatial subjective diffuseness, the preferred directions of reflections are in the median plane of music performers, resulting in IACC $\approx$ 1.0 [10.61, 62]. In order to satisfy these acoustic conditions, some design iterations are required, maximizing scale values for both musicians and listeners and leading to the final scheme of the concert hall as shown in Fig. 10.11.

Sound Field for the Conductor

It is recommended that the sound field for the conductor on the stage should be designed as that of a listener with appropriate reflections from the sidewalls on the stage [10.63].

Acoustic Design with Architects

From the historical viewpoint, architects have been more concerned with spatial criteria from the visual
Fig. 10.21a–f Scheme of the Kirishima International Concert Hall, Kagoshima, Japan designed by the architect Maki and associates (1997) (after [10.59, 60]). (**a**) Longitudinal section

standpoint, and less so from the point of view of temporal criteria for blending human experience and the environment with design. On the other hand, acousticians have mainly been concerned with temporal criteria, represented primarily by the reverberation time, from the time of *Sabine* [10.2] onward. No comprehensive theory of design including the spatial criterion as represented by the IACC existed before 1977, so that discussions between acousticians and architects were rarely on the same subject. As a matter of fact, both temporal and spatial factors are deeply interrelated with both acoustic design and architectural design [10.64, 65].

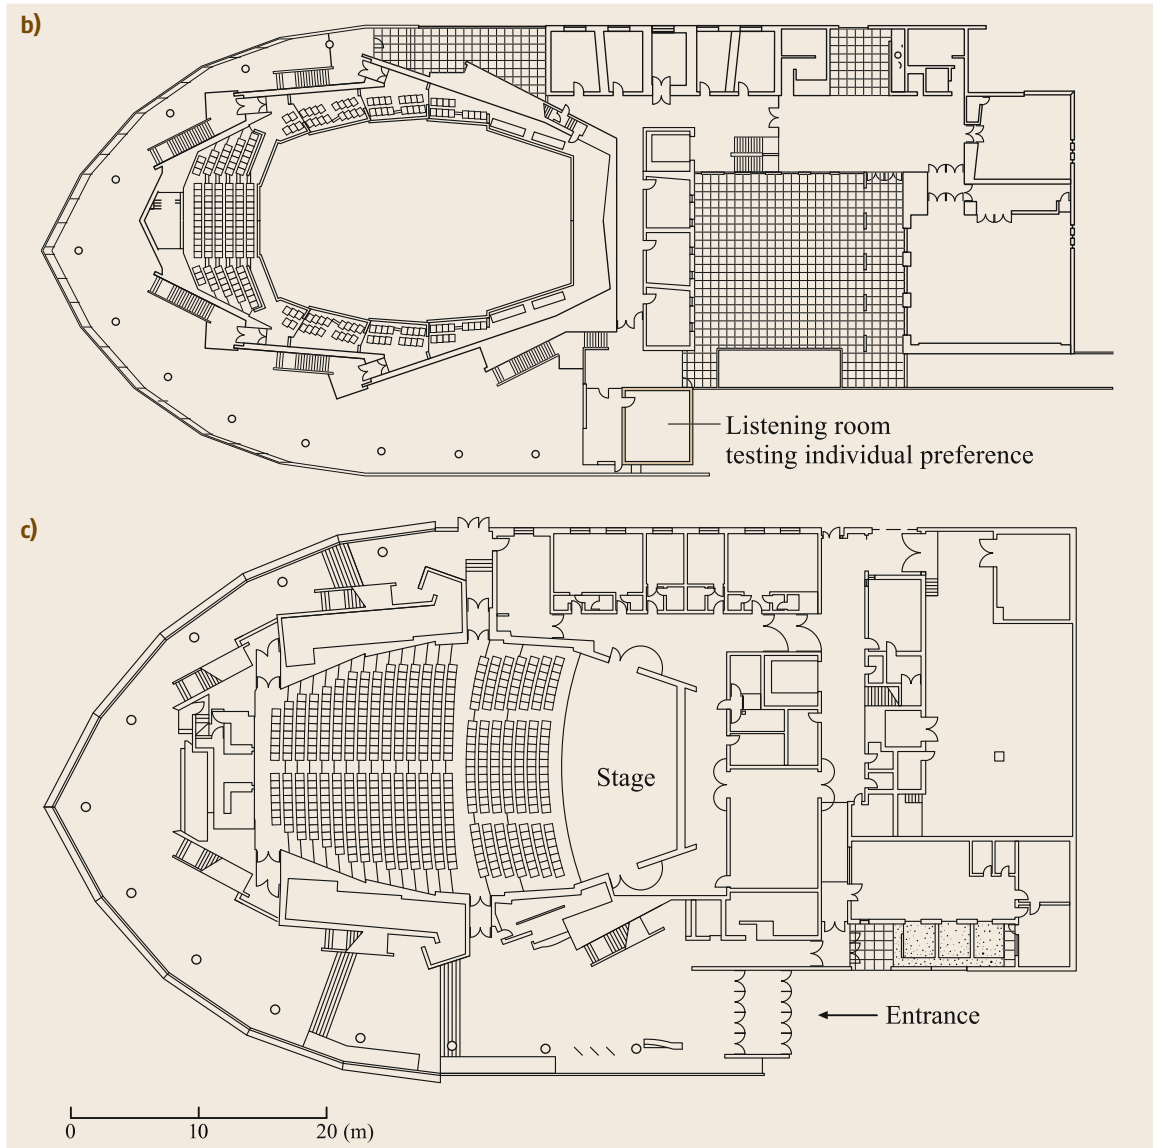
As an initial design sketch of the Kirishima International Concert Hall, a plan shape like a leaf (Fig. 10.20a) was presented at the first meeting for discussion with the architect Fumihiko Maki and associates with the explanation of the temporal and spatial factors of sound field.


Fig. 10.21 (b) Plan of balcony level; **(c)** Plan of audience level
Fig. 10.21 (d) Cross section; **(e)** Tilt sidewalls and triangular ceilings after construction of the hall

After some weeks, Maki and Ikeda indicated a scheme of the concert hall as shown in Fig. 10.21 [10.59, 60]. Without any change of plan and cross sections, the calculated results indicated the excellent sound field as shown in Fig. 10.22 [10.66, 67].

The final architectural schemes, together with the special listening room for testing individual preference

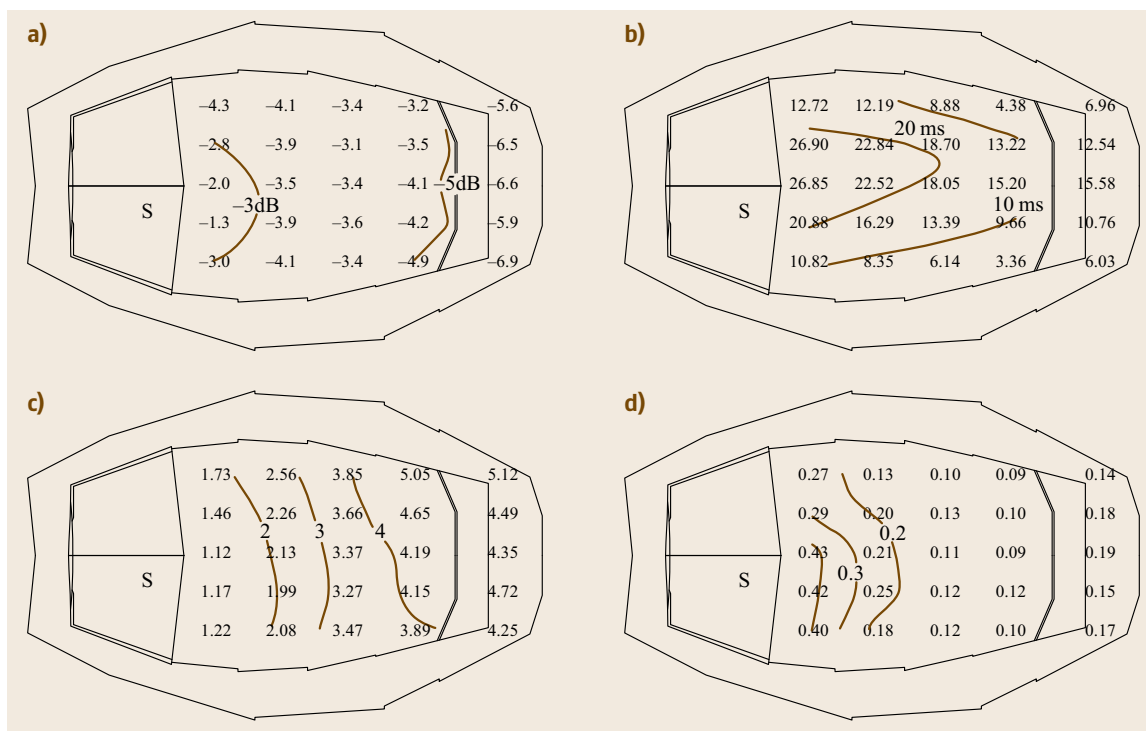
of sound field and selecting the appropriate seats for maximizing individual preference of the sound field, are shown in Fig. 10.21b. In these figures, the concert courtyard, the small concert hall, several rehearsal rooms and dressing rooms are also shown. The concert hall under construction is shown in Fig. 10.21e, in which the leaf shape may be seen; it was opened in 1994 (Fig. 10.21f).


Fig. 10.22a–d Calculated orthogonal factors at each seat with a performing position *S* for an initial design of the hall. Details of Acoustic Design

For Listeners on the Main Floor. In order to obtain a small value of the IACC for most of the listeners, ceilings were designed using a number of triangular plates with adjusted angles, and the side walls were given a 10% tilt with respect to the main audience floor, as are shown in Fig. 10.21d and Fig. 10.23. In addition, diffusing elements were designed on the sidewalls to avoid the image shift of sound sources on the stage caused by the strong reflection in the high-frequency range above 2 kHz. These diffusers on the sidewalls were designed as a modification of the Schroeder diffuser [10.68] without the wells, as shown by the detail of Fig. 10.24.

For Music Performers on Stage. In order to provide reflections from places near the median plane of each of the performers on the stage, the back wall on the
Fig. 10.24 Detail of the diffusing sidewalls effective for the higher-frequency range above 1.5 kHz, avoiding image shift of the sound source on the stage. The surface is deformed from the Schroeder diffuser by removal of the well partitions (after [10.68])

Fig. 10.25 Detail of the triangular joist arrangement for the stage floor, avoiding anomalous radiation due to the normal modes of vibration from certain music instruments that touch the floor

stage is carefully designed as shown in the lower left in Fig. 10.23. The tilted back wall consists of six sub-walls with angles adjusted to provide appropriate reflections within the median plane of the performer. It is worth noting that the tilted sidewalls on the stage provide good reflections to the audience sitting close to the stage, at the same time resulting in a decrease of the IACC. Also, the sidewall on the stage of the left-hand side looking from the audience may provide useful reflections arriving from the back for a piano soloist.

Stage Floor Structure. For the purpose of suppressing the vibration [10.69] of the stage floor and anomalous sound radiation from the stage floor during a performance, the joists form triangles without any neighboring parallel structure, as shown in Fig. 10.25. The thickness of the floor is designed to be relatively thin (27 mm) in order to radiate sound effectively from the vibration of instruments such as the cello and contrabass. During rehearsal, music performers may control the radiation power somewhat by adjusting their position or by the use of a rubber pad between the floor and the instrument.

10.3 Individual Preferences of a Listener and a Performer

The minimum unit of society to be satisfied by the environment is one individual, which leads to a unique personal existence. Here, we demonstrate that the individual subjective preferences of each listener and each cellist may be described by the theory in Sect. 10.1, which resulted from observing a number of subjects.

10.3.1 Individual Subjective Preference of Each Listener

In order to enhance individual satisfaction for each listener, a special facility for seat selection, testing each listener's own subjective preference [10.58, 70], was first introduced at the Kirishima International Concert Hall in 1994. The sound simulation system employed multiple loudspeakers. It used arrows for testing the subjective preference of four listeners at the same time. Since the four orthogonal factors of the sound field influence the preference judgment almost independently [10.1], each single factor is varied, while the other three are fixed at the preferred condition for the average listener. Results of testing acousticians who participated in the International Symposium on Music and Concert Hall Acoustics (MCHA95), which was held in Kirishima in May 1995, are presented here [10.1].

Individual Preference and Seat Selection

The music source was orchestral, the *Water Music* by Händel; the effective duration of the ACF was 62 ms [10.11]. The total number of listeners partici-

IACC
Fig. 10.26a–d Scale values of preference obtained by paired-comparison tests for the four orthogonal factors, subject BL. **(a)** The most preferred listening level was 83 dBA, the individual weighting coefficient in (10.9): $\alpha_1 = 0.06$; **(b)** the preferred initial time delay gap between the direct sound and first reflection was 26.8 ms, the individual weighting coefficient in (10.9): $\alpha_2 = 1.86$, where $[\Delta t_1]_p$ calculated by (10.4) with $(\tau_e)_{min} = 62$ ms for the music used ($A = 4$) is 24.8 ms; **(c)** the preferred subsequent reverberation time is 2.05 s, the individual weighting coefficient in (10.9): $\alpha_3 = 1.46$, where $[T_{sub}]_p$ calculated by (10.6) with $(\tau_e)_{min} = 62$ ms for the music used, is 1.43 s; **(d)** individual weighting coefficient in (10.9) for IACC: $\alpha_4 = 1.96$.

pating was 106. Typical examples of the test results for listener BL as a function of each factor are shown in Fig. 10.26. Scale values of this listener were rather close to the averages for subjects previously collected: the most preferred $[LL]_p$ was 83 dBA, the value $[\Delta t_1]_p \approx [(1 - \log_{10} A)(\tau_e)_{min}]$ was 26.8 ms (the global preferred value calculated by (10.4) with the total sound pressure as was simulated $A = 4.0$ is 24.8 ms. And the most preferred reverberation time is 2.05 s (the global preferred value calculated by (10.6) is 1.43 s). Thus, as was designed, the center area of seats was preferred for listener BL (Fig. 10.27). With regard to the IACC, the result for all listeners was that the scale value of preference increased with decreasing the IACC value. Since listener KH preferred a very short delay time of Δt_1, his preferred seats were located close to the boundary wall, as shown in Fig. 10.28. Listener KK in-

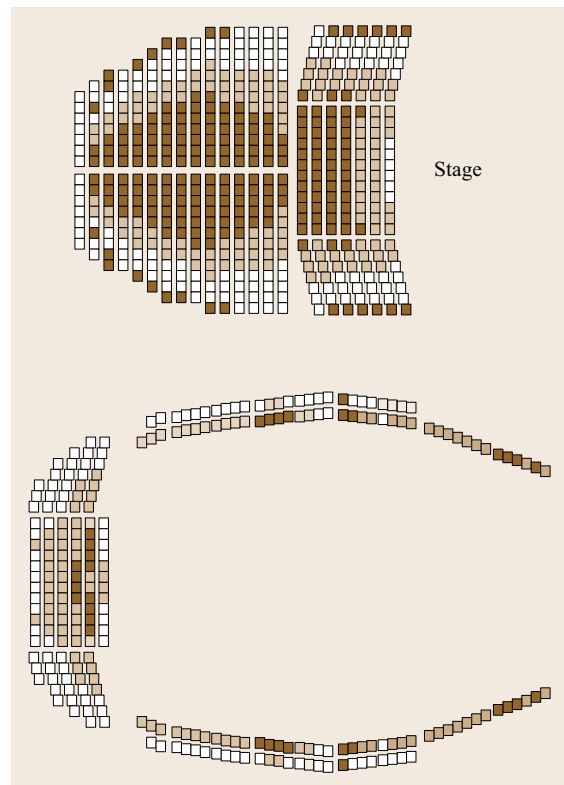
Stage


Fig. 10.27 Preferred seating area calculated for subject BL. The seats are classified in three parts according to the scale value of subjective preference calculated by the summation of S_1–S_4 (10.8) together with (10.9). Black indicates preferred seating areas, about one third of all seats in this concert hall, for subject BL

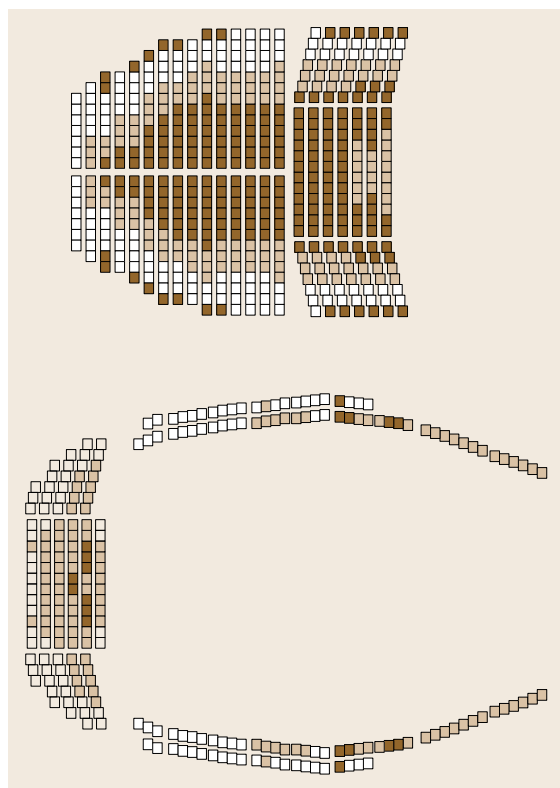

Fig. 10.29 Preferred seating area calculated for subject KK

dicated a preferred listening level exceeding 90 dBA. For this listener, the front seating area close to the stage was preferable, as shown in Fig. 10.29. For listener DP, whose preferred listening level was rather weak (76.0 dBA) and the preferred initial delay time was

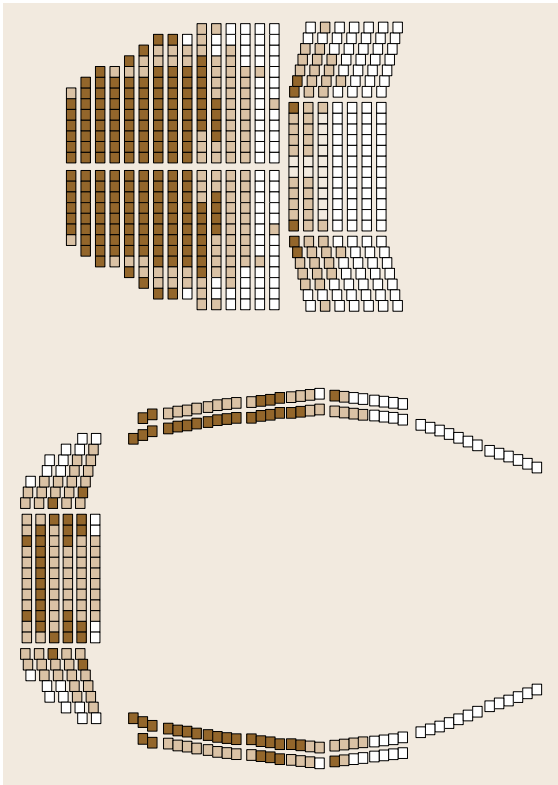
short (15.0 ms), the preferred seat was in the rear part of hall, as shown in Fig. 10.32. The preferred initial time delay gap for listener CA exceeds 100.0 ms, but was
Fig. 10.30 Cumulative frequency of preferred listening level $[LL]_p$ (106 subjects). About 60% of subjects preferred the range of 80–84.9 dBA
Fig. 10.31 Cumulative frequency of the preferred initial time delay gap between the direct sound and the first reflection $[\Delta t_1]_p$ (106 subjects). About 45% of subjects preferred the range of 20–39 ms. The value of $[\Delta t_1]_p$ calculated using (10.4) is 24.8 ms with $c = 1$ and $k = 0.1$


Fig. 10.32 Preferred seating area calculated for subject DP

Fig. 10.33 Preferred seating area calculated for subject CA

not critical. Thus, any initial delay times were acceptable, but the IACC was critical. Therefore, the preferred areas of seats were located as shown in Fig. 10.33.

Cumulative Frequency of Preferred Values

Cumulative frequencies of the preferred values with 106 listeners are shown in Fig. 10.30 through Fig. 10.34 for three factors. As indicated in Fig. 10.30, about 60% of listeners preferred the range 80–84.9 dBA when listening to music, but some listeners indicated that the most preferred LL was above 90 dBA, and the total range of the preferred LL was scattered, exceeding a 20 dB range. As shown in Fig. 10.31, about 45% of listeners preferred initial delay times of 20–39 ms, which were around the calculated preference of 24.8 ms (10.4) with $k = 0.1$, $c = 1$ and $A = 4.0$; however, some listeners indicated 0–9 ms and others more than 80 ms. With regard to the reverberation time, as shown in Fig. 10.34, about 45% of listeners preferred 1.0–1.9 s, which is centered on the preferred value of 1.43 s calculated by (10.6), but some listeners indicated preferences lower than 0.9 s or more than 4.0 s.

Independence of the Preferred Conditions

It was thought that both the initial delay time and the subsequent reverberation time appear to be mutually related, due to a kind of *liveness* of the sound field. Also,
Fig. 10.34 Cumulative frequency of the preferred subsequent reverberation time $[T_{sub}]_p$ (106 subjects). About 45% of subjects preferred the range 1.0–1.9 s. The value of $[T_{sub}]_p$ calculated using (10.6) is 1.43 s

it was assumed that there is a strong interdependence between these factors for each individual. However, as shown in Fig. 10.35, there was little correlation between preference values of $[\Delta t_1]_p$ and $[T_{sub}]_p$ (the correlation
Fig. 10.35 The relationship between the preferred values of $[\Delta t_1]_p$ and $[T_{sub}]_p$ for each subject. No significant correlation between values was achieved

Fig. 10.36 Three-dimensional illustration of the three preferred orthogonal factors for the sound field for each individual subject (*squares*). All 106 listeners tested indicated that a smaller value of the IACC was preferred, and these data are not included in this figure. Preferred conditions are distributed in a certain range of each factor, so that subjects could not be classified into any specific groups

is 0.06). The same is true for the correlation between values of $[T_{sub}]_p$ and $[LL]_p$ and for that between values of $[LL]_p$ and $[\Delta t_1]_p$, a correlation of less than 0.11. Figure 10.36 shows the three-dimensional plots of the preferred values of $[LL]_p$, $[\Delta t_1]_p$ and $[T_{sub}]_p$ for the 106 listeners. Looking at a continuous distribution in preferred values, no specific groupings of individuals can be classified from the data.

Another important fact is that there was no correlation between the weighting coefficients α_i and α_j, $i \neq j$ (i, $j = 1, 2, 3, 4$) in (10.9) for each individual listener [10.1]. A listener indicating a relatively small value of one factor will not always indicate a relatively small value for another factor. Thus, a listener can be critical about a preferred condition as a function of a certain factor, while insensitive to other factors, resulting in characteristic differences from other listeners.

10.3.2 Individual Subjective Preference of Each Cellist

To realize an excellent concert, we need to know the optimal conditions not only in the stage enclosure design for performers, but also in the style of the performance. The primary issue is that the stage enclosure is designed to provide a sound field in which performers can play easily. *Marshall* et al. [10.71] investigated the effects of stage size on the playing of an ensemble. The parameters related to stage size in their study were the delay time and the amplitude of reflections. *Gade* [10.72] performed a laboratory experiment to investigate the preferred conditions for the total amplitude of the reflections of performers. *Nakayama* [10.61] showed a relationship between the preferred delay time and the effective duration of the long-time ACF of the source signal for alto-recorder soloists (data was rearranged [10.1]). When we listen to a wide range of music signals containing a large fluctuation, it is more accurately expressed by the minimum value of the effective duration $(\tau_e)_{min}$ of the running ACF of the source signals [10.39]. For individual singers, *Noson* et al. [10.73, 74] reported that the most preferred condition of the single reflection for an individual singer may be described by $(\tau_e)_{min}$ and a modified amplitude of reflection according to the overestimate and bone conduction effects (for control of $(\tau_e)_{min}$ see [10.41, 42]).

Preferred Delay Time of the Single Reflection for Cellists

As a good example, the preferred delay time of the single reflection for individual cello soloist is de-

Table 10.5 Judged and calculated preferred delay times of a single reflection for each cello soloist. Calculated values of $[\Delta t_1]_p$ are obtained by (10.15) using the amplitude of the reflection A'_1 and $(\tau_e)_{min}$ for music signals performed by each cellist

A (dB)	A' (dB) (= A + 10)	A'	Cellist	Judged $[\Delta t_1]_p$ (ms)		Calculated $[\Delta t_1]_p$ (ms)	
				Motif I	Motif II	Motif I	Motif II
−15	−5	0.56	A	16.2	47.9	16.3	38.5
			B	<12.0	73.8	35.2	62.7
			C	<12.0	60.8	211.3	51.3
			D	22.6	38.2	35.1	53.9
			E	17.6	63.6	17.3	35.2
			Global	18.0	48.3	24.3	47.5
−21	−11	0.28	A	18.1	48.4	21.8	51.5
			B	61.2	105.0	59.3	105.6
			C	–	77.9	–	80.6
			D	74.6	86.8	56.9	87.4
			E	<14.0	42.2	24.8	50.2
			Global	30.4	71.8	37.6	73.4

scribed by the minimum value of the effective duration of the running ACF of the music motifs played by that cellist [10.75]. The same music motifs (motifs I and II) used in the experiment by Nakayama were applied here [10.61]. The tempo of motif I was faster than that of motif II, as shown in Fig. 10.37. A microphone in front of the cellist picked up the music signals performed three times by each of five cellists.

Figure 10.38 shows an example of the regression curve for the scale value of preference fitted by (10.9). The peak of this curve denotes the most preferred delay time $[\Delta t_1]_p$. The values for individual cellists are listed in Table 10.5. Global and individual results (except for that of subject E) for music motif II were longer than those for music motif I.

The most preferred delay time of a single reflection is approximately expressed by the duration τ'_p of the ACF as similar to that of listeners (10.4), so that

$$[\Delta t_1]_p = \tau'_p \approx \left[\log_{10}(1/k') - c' \log_{10} A'\right](\tau_e)_{min} ,$$
$$(10.15)$$

where the values k' and c' are constants that depend on the individual performer and musical instrument used. A substantial difference from (10.4) of listeners is that the amplitude of the reflection A' is defined by $A' = 1$ relative to -10 dB of the direct sound as measured at the ear's entrance. This is due to the phenomenon of *missing reflection* (i.e., a performer overestimating the reflection) [10.1].

Individual Subjective Preference

Using the quasi-Newton method, the resulting constants on average were $k' \approx 1/2$ and $c' \approx 1$ for the five cellists. (It is worth noting that the coefficients k' and c' for alto-recorder soloists were 2/3 and 1/4, respectively [10.1].) After setting $k' = 1/2$, the coefficient c' for each individual was figured out as listed in Table 10.6. The average value of the coefficient c' for the five cellists obtained was 1.03. The relationship between the most preferred delay time $[\Delta t_1]_p$ obtained by the judgment

the five cellists as a function of the delay time of the single reflection normalized by the calculated $[\Delta t_1]_p$ are shown in Fig. 10.40.

Subjective Responses as a Function of $[\Delta t_1]_p/(\tau_e)_{\min}$

Figure 10.41 shows the relative amplitude of the single reflection to that of the direct sound for the preference of cello soloists as a function of the delay time of the single reflection normalized by the minimum value of the effective duration $(\tau_e)_{\min}$ of the running ACF of the source signal. Several other subjective responses in terms of the amplitude are shown together as a function of the delay time of the single reflection normalized by the value of the effective duration τ_e of the long-time ACF. All these values can generally be expressed by (10.4) in relation to the effective duration of the ACF with the constants k and c, which depend on different subjective responses. An alto-recorder soloist's preference is also plotted in this

and the duration τ'_p ($= [\Delta t_1]_p$) of the ACF calculated by (10.15) is shown in Fig. 10.40. Different symbols indicate values obtained in different test series with two music motifs. The correlation coefficient between calculated values of $[\Delta t_1]_p$ and measured values is 0.91 ($p < 0.01$). The scale values of preference for each of

Fig. 10.41 Relative amplitude of the single reflection for the subjective preference of cello soloists as a function of the delay time of a single reflection normalized by the value of $(\tau_e)_{min}$. Also, the amplitudes of several subjective responses as a function of the delay time of the single reflection normalized by the value of τ_e of the source signal. Note that threshold has been rearranged using the typical ACF of the speech signal (after [10.1])

figure [10.1]. The values for performers are below or close to the threshold of perception of listeners [10.76]. These reconfirm the phenomenon of *missing reflection* for performers.

In order to blend the source music under performance and the sound field in a given concert hall, a performer, to some extent, can control the value of $(\tau_e)_{min}$ by introducing vibrato. Such an introduction of vibrato may decease the value of $(\tau_e)_{min}$ to obtain a more preferred condition for listeners as well, even though there is a short reverberation time in a given concert hall [10.41, 42].
10.4 Acoustical Measurements of the Sound Fields in Rooms

Acoustical measurements were made in an existing hall for the purpose of testing acoustic factors that were calculated using the architectural scheme at the design stage. Also, subjective preference judgments for different source locations on the stage were performed by the paired-comparison test at each set of seats. The relationship between the resulting scale values of subjective preference and the physical factors obtained by simulation using architectural plan drawings was examined by factor analysis. The accumulation and understanding of the field data, in turn, may improve details of future methods for calculating acoustic factors.

10.4.1 Acoustic Test Techniques

Binaural Impulse Response

A diagnostic system for measuring the impulse response at the two ear entrances determining the four orthogonal factors, and for further evaluation of the subjective attributes of sound field at each seat in a hall is shown in Fig. 10.42. A test signal is radiated from the loudspeaker to measure impulse responses using two small microphones placed at the ear entrances of a real head (1.1 m above the floor). Then spatial factors associated with the right-hemisphere specialization (LL and IACC) and the temporal factors of left-hemisphere specialization (Δt_1

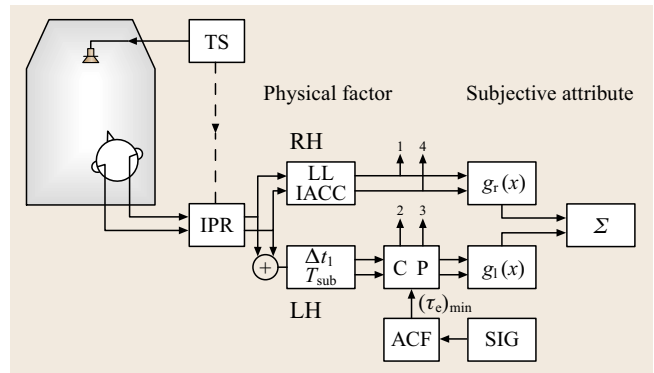
and T_{sub}) are analyzed. When the effective duration of the ACF of the source signal (τ_e) is calculated, the total scale value may be obtained by adding the scale values


Fig. 10.42 A system for measuring the four orthogonal factors of sound fields and evaluating subjective qualities at each seat in a room. TS: test signal (maximum-length sequence signal); IPR: impulse response analyzer; RH: right-hemispheric factors (listening level and the IACC); LH: left-hemispheric factors (Δt_1, T_{sub}, and the A value); CP: comparators with the most preferred condition based on the effective duration of ACF, $(\tau_e)_{min}$; ACF: autocorrelation function; SIG: source signals; $g_r(x)$: scale values from the right-hemispheric factors; $g_l(x)$: scale values from the left-hemispheric factors; Σ: total scale value of subjective preference
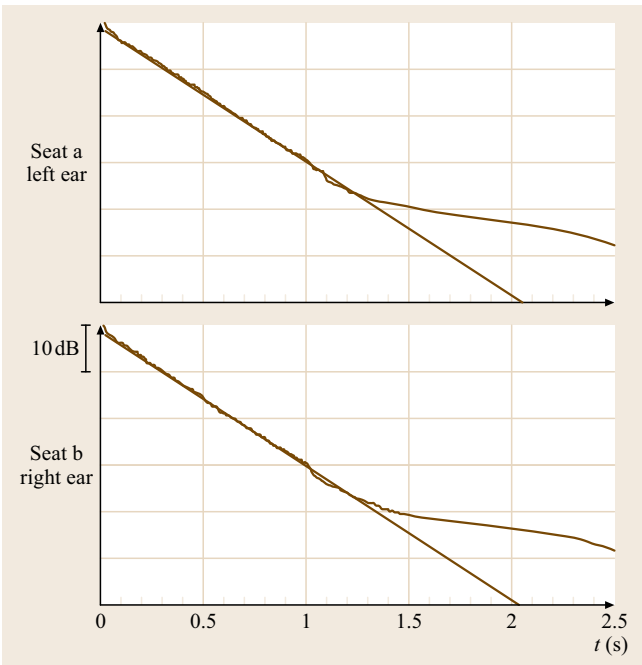
Fig. 10.43a,b Examples of the impulse response measured at seats: (**a**) (near to the stage) and (**b**) (far from the stage) in the Kirishima International Concert Hall. The amplitude of the impulse response measured at seat a is attenuated because of a strong direct sound


of the orthogonal factors referred to the most preferred conditions. The value of $(\tau_e)_{min}$ is used to determine the most preferred temporal values for $[\Delta t_1]_p$ and $[T_{sub}]_p$ (Sect. 10.1.2). If the source signal is fed into the ACF processor, then outputs (numbered 1−4) may be used to control the sound field simultaneously with an electro-acoustic system, without any manual adjustment, preserving the preferred conditions of the four factors.

Examples of measuring binaural impulse responses at a seat close to the stage (seat a, left ear) and at a rear seat b (right ear) in the Kirishima International Concert Hall are demonstrated in Fig. 10.43. In this measurement, an omnidirectional dodecahedron loudspeaker with 12 full-range drivers was placed on the stage 1.5 m above the floor for a sound source. The total amplitude of reflections A at a seat close to the stage is usually smaller than that at seat far from the stage.

Another powerful signal to be radiated from the loudspeaker to measure the impulse binaural responses is the pulse signal generated by inverse Fourier transformation [10.77].

Reverberation Time

After the impulse response is obtained, the reverberation time is measured by *Schroeder's* method [10.78, 79]. The integrated decay curve as a function of time may be obtained by squaring and integrating the impulse response of the sound field in a room, such that

$$\langle s^2(t)\rangle = \mathrm{K}\int_{t+T}^{t} h^2(x)\,\mathrm{d}x \qquad (10.16)$$

where the time T should be chosen sufficiently longer than the reverberation time.

For the 500 Hz octave band, examples of the measured decay curve and the decay rate of both left and right ears at seating position a are shown in Fig. 10.47. The reverberation times measured are both 2.07 s. The measured reverberation times with octave band filters in the Kirishima International Concert Hall (without audience) are plotted as filled circles in Fig. 10.45. The empty circles are estimated values of the reverberation time for a full audience. It is worth noticing that *Jordan* [10.80] showed that the values of the early decay time (EDT) measured over the first 10 dB of decay are close to values of the reverberation time averaged with the interval of −5 to −35 dB.

where ε signifies a small delay time just large enough to cover the duration of the direct sound.

Measurement of Acoustic Factors at Each Seat in a Concert Hall

In Sect. 10.3.1 we discussed the seat selection system, designed for the purpose of enhancing individual satisfaction. To begin with, four orthogonal factors are measured at each seat in a concert hall [10.66, 67]. Measured values of the listening level (LL), the total amplitude of reflection (A), the initial time delay gap (Δt_1) between the direct sound and the first reflection excluding the reflection from the floor, and the IACC at each seat in the Kirishima International Concert Hall are shown in Fig. 10.46. The reverberation times at all the seats had almost the same value, about 2.05 s for the 500 Hz band.

The total amplitude of reflection A, defined by (10.5), is obtained as its square

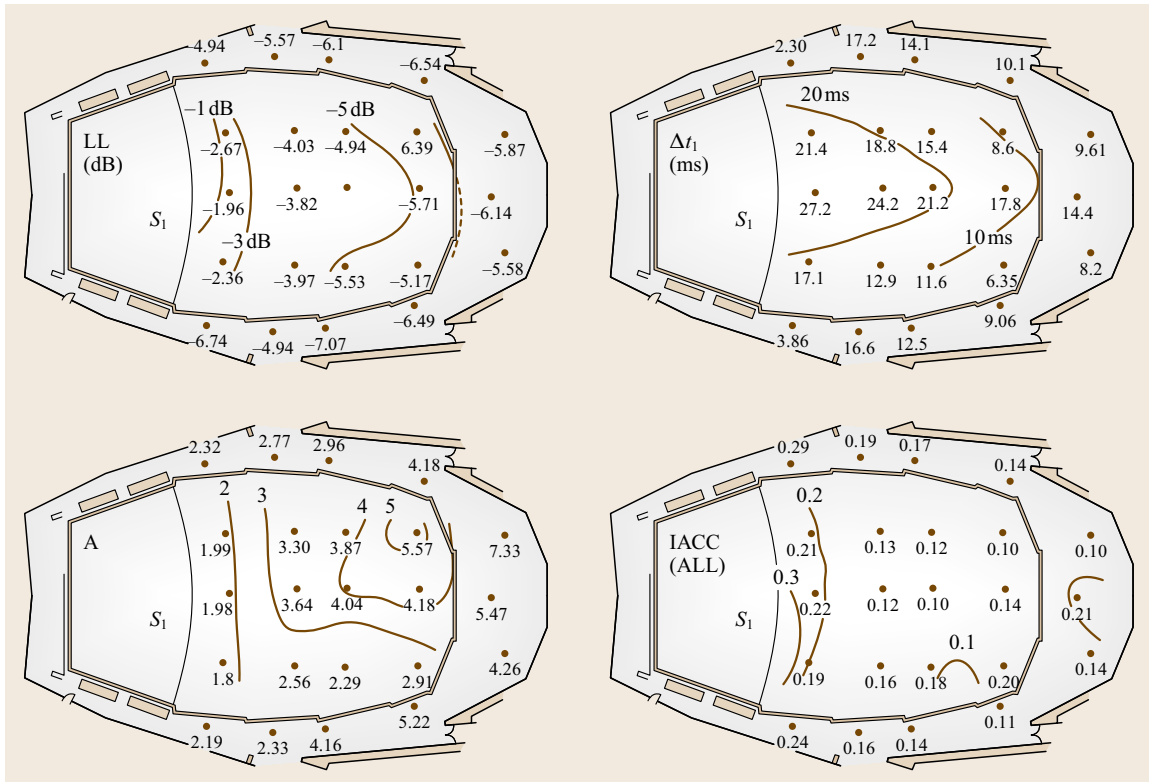
$$A^2 = \frac{\int_\infty^\varepsilon h^2(x)\,\mathrm{d}x}{\int_\varepsilon^0 h^2(x)\,\mathrm{d}x}\,, \tag{10.17}$$


Fig. 10.46a–d Orthogonal factors measured at each seat in the Kirishima International Concert Hall, other than the reverberation time, which is almost constant throughout the hall: (a) listening level; (b) Δt_1; (c) A value, the total amplitude of reflections; (d) IACC
Fig. 10.47 Measured IACC as a function of the integration interval $2T$ of the impulse responses for each octave band range. The value of IACC converged for $2T > 200$ ms (after [10.81])

Even though the final scheme of the concert hall was changed in terms of the width of the hall (one meter wider) from the scheme at the design stage, values of each physical factor measured as shown in Fig. 10.46 are not very different from the values calculated (Fig. 10.22).

Recommended Method for IACC Measurement

There are two purposes for measuring IACC, as needed for subjective evaluations and acoustic comparison of existing halls:
Fig. 10.48 Measured IACC and τ_{IACC} as a function of head direction relative to the sound source in a narrow hotel atrium (after [10.82])

1. In order to evaluate the subjective quality of the sound field in an existing hall, the IACF (with values of IACC, τ_{IACC} and W_{IACC} defined in Fig. 10.4 as well as LL) together with the other three factors Δt_1, T_{sub} and A are measured. Without any octave band filtering, measurements must be performed after passage of the music or the speech signal through an A-weighting network, under identical conditions with subjective judgment.
2. In order to compare values of the IACC as well as T_{sub} for the sound field in existing halls, measurements with octave band filtering are performed. With a fixed sound source on the stage, the IACC is defined by a long integration interval, which includes the effects of the direct sound and all reflections, including reverberation, without any temporal subdivisions.

A typical example of measuring the IACC as a function of the integration interval, which was performed in Symphony Hall, Boston, is shown in Fig. 10.47 [10.81]. It is remarkable that the measured values of IACC almost converged for $2T \approx 200$ ms, and the values are not so different for longer intervals.

If a room is used for performing dance, ice-skating or a party, then the listeners face in various directions. In this case, the values of IACC and τ_{IACC} are measured as a function of the direction of the head. The measured results with the 500 Hz octave band noise in an oblong atrium of a hotel at the distance 10 m from the source position are demonstrated in Fig. 10.48 [10.82]. When the listener is facing the sound source, then IACC = 0.41, and $\tau_{IACC} = 0$, and thus no image shift occurs. These values are nearly unchanged for head directional angles less than 30° when the listener is facing the lateral side at 90°, then the IACC is greater than 0.50, and τ_{IACC} is about 600 μs, due to the interaural delay time.

10.4.2 Subjective Preference Test in an Existing Hall

The subjective preference judgments for different source locations on the stage at Uhara Hall, Kobe, were performed by a paired-comparison test at each set of seats. The relationship between the resulting scale value of subjective preference and the physical factors obtained by calculation, using architectural plan drawings, was examined by factor analysis [10.15]. Calculated scale values of subjective preference were reconfirmed for the Uhara Hall (Fig. 10.49). The physical factors at
Fig. 10.49 (a) Plan; **(b)** and **(c)** cross sections of the Uhara Hall, Kobe. Four source positions, 1, 2, 3 and 4 on the stage, which were switched in the paired-comparison test of subjective preference without moving subjects from seat to seat. There were 21 listening positions including neighboring seats

each set of seats for four source locations on the stage were calculated. In the simulation, the directional characteristics of the four loudspeakers used in preference tests were not taken into consideration for the sake of convenience. The simulation calculation was performed up to the third order of reflection. Due to a floor structure with a fair amount of acoustic transparency, the floor reflection was not taken into account for the calculation, and part of the diffuser ceiling was regarded as a nonreflective plane for the sake of convenience. In the calculation of the IACC, the listeners faced toward the center of the stage, so that the IACC was not always a maximum at the interaural time delay $\tau = 0$.

The hall contains 650 seats with a volume of 4870 m^3. Four identical loudspeakers with the same characteristics were placed 0.8 m above the stage floor, and sixty-four listeners, divided into 21 groups, were seated in the specified set of seats. Without moving from seat to seat and excluding the effects of other physical factors such as visual and tactual senses on judgments, subjective preference tests by the paired-comparison method were conducted, switching only the loudspeakers on the stage. As a source signal, music motif B was selected in the tests. Scale values of preference were obtained by applying the law of comparative judgment and were reconfirmed by the goodness of the fit [10.83, 84]. The session was repeated five times, exchanging seats, and thus data for 14−16 subjects in total were obtained for each set of seats.

Results of Multiple-Dimensional Analyses

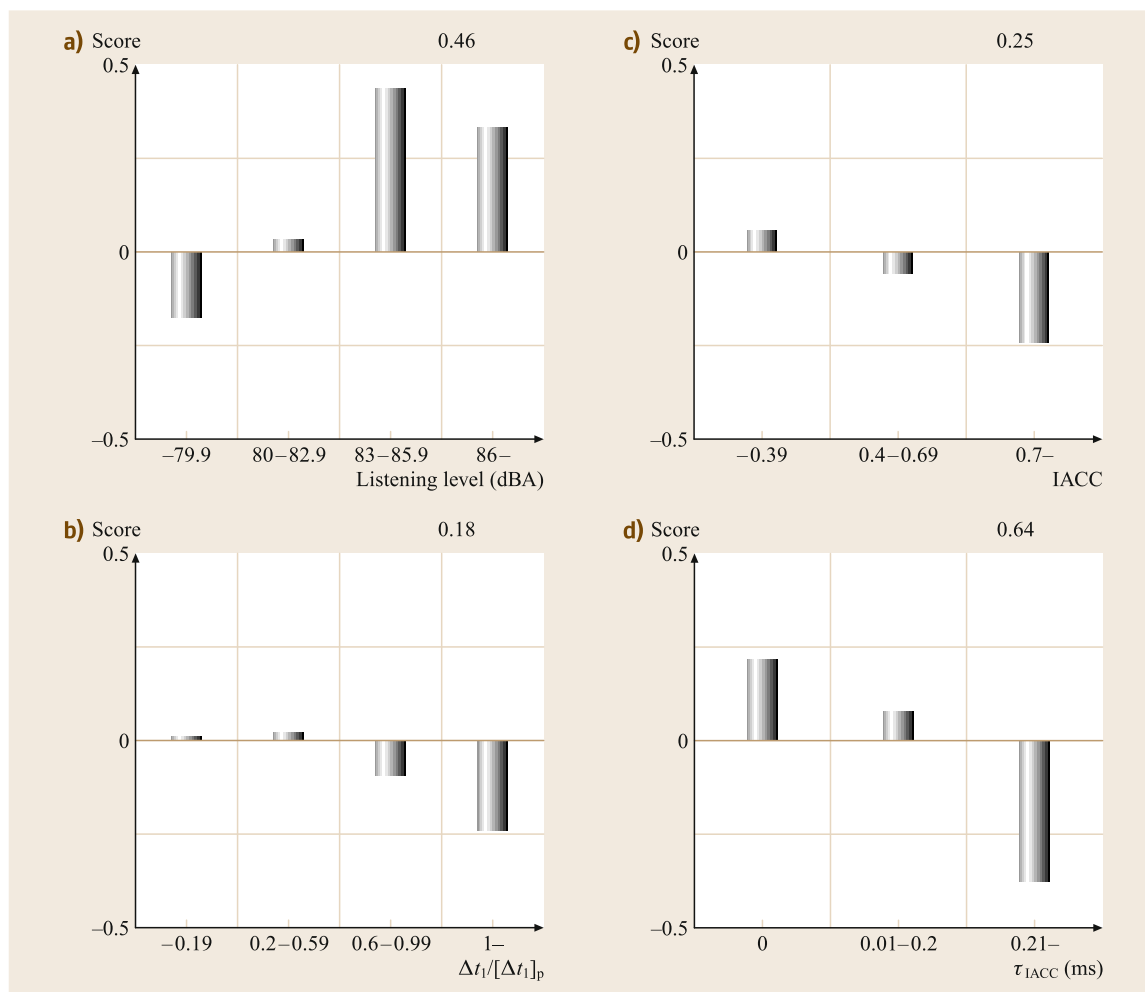
In order to examine the relationship between scale values of subjective preference and physical factors ob-


Fig. 10.50a–d Scores for each category of four physical factors obtained by the factor analyses. The number indicated at the upper left part of each figure signifies the partial correlation coefficient between the score and each factor. **(a)** Listening level; **(b)** normalized initial time delay gap between the direct sound and the first reflection; **(c)** IACC; **(d)** interaural time delay of the IACC, τ_{IACC}, found as the most significant factor in this investigation with loudspeaker reproductions on the stage. Tendencies obtained here are similar to those of the scale value shown in Fig. 10.7, which were obtained from the simulated sound field

tained by simulation of an architectural scheme, the data were analyzed by factor analysis [10.78, 79, 85].

Of the four orthogonal factors, the reverberation time was almost constant for the source location and the seat location throughout the hall, and thus was not involved in the analysis. As previously discussed, as a condition for calculating the scale value of preference, the maximum value of the interaural cross-correlation function must be maintained at $\tau_{IACC} = 0$ to ensure frontal localization of the sound source. However, the IACC was not always maintained at $\tau = 0$ due to the loudspeaker locations, because the subjects were facing the center of stage. In this analysis, therefore, the effect of the interaural time delay of the IACC was added as an additional factor. Thus, the outside variable to be predicted with factor analysis was the scale value obtained by subjective judgments, and the explanatory factors were: (1) the listening level, (2) the initial time delay gap, (3) the IACC, and (4) the interaural time delay (τ_{IACC}).

Scores for Each Factor

The scores for each category of the factors obtained from the factor analysis are shown in Fig. 10.50. As shown in Fig. 10.50a, the scores for the listening level indicate a peak at the subcategory of $83-85.9$ dB, with decreasing scores moving away from the preferred listening level. For the IACC, the preference score increases with a decrease in the IACC (Fig. 10.50c). It is worth noting that the scores for the aforementioned two factors are in good agreement with preference scale values obtained from preference judgments for a simulated sound field (Fig. 10.7a and 10.7d). The scores of the initial time delay gap normalized to the optimum value ($\Delta t_1/[\Delta t_1]_p$) peaked at smaller values (Fig. 10.50b) than the most preferred value of the initial time delay gap obtained from the simulated sound fields (Fig. 10.7b). It is considered that, due to the limited range of the Δt_1 in the existing concert hall and the limited data for the short range of the Δt_1, the effects of the Δt_1 of the sound fields was rather minor in this investigation. Concerning τ_{IACC}, as shown in Fig. 10.50d, the score decreases monotonically as the delay is increased. This may be caused by an image shift without balancing of the sound field.

Measured and Calculated Subjective Preference Values

The relationship between the scale value obtained by subjective judgments and the total score at each center of three or four seats is shown in Fig. 10.51. The scale values of preference are well predicted with the total score for four loudspeaker locations ($r = 0.70$, $p < 0.01$). In some cases there is a certain degree of apparent coherence between physical factors, for example, the calculated listening level and the IACC for sound fields in existing concert halls. However, these factors are theoretically orthogonal, and therefore the preference scores obtained were in good agreement with the calculated preference scale values obtained by the simulation.

So far the subjective preference of source locations on the stage has been examined at each set of seats. The rear source position (#4) on the stage is more preferred than that of the other source locations. The side source position (#3) indicates a low preference, due to the interaural time delay. The initial time delay gap resulted in a small influence on the total score because of its limited range.
Fig. 10.51 Relationship between the scale value of subjective preference obtained by the paired-comparison test in the existing hall and the total score calculated by using the scores shown in Fig. 10.50. The correlation coefficient was $r = 0.70$ ($p < 0.01$)

10.4.3 Conclusions

Results of the analysis demonstrate that the theory of calculating subjective preference by the use of orthogonal parameters obtained in the laboratory is supported by experiments in a real hall. This may hold only when the maximum value of the interaural cross-correlation is maintained at $\tau = 0$. However, this condition is usually realized by introducing certain diffusing elements on the sidewalls in a real concert hall when the listeners face a performer.

Cerebral hemisphere specialization in the human brain may play an important role for the independent effects of temporal and spatial factors on preference as discussed in Sect. 10.1.5. The scale values of subjective preference of both the sound field and the visual field have been described by both temporal and spatial factors [10.86]. Accordingly, a generalized theory of environmental planning incorporating the temporal and spatial values for the left and right cerebral hemispheres, respectively, has been proposed by blending the built environment and nature [10.87]. In particular, examples of temporal design associated with the left hemisphere are opened for discussed introducing the third stage of human life [10.88].

11. Building Acoustics

James Cowan

This chapter summarizes and explains key concepts of building acoustics. These issues include the behavior of sound waves in rooms, the most commonly used rating systems for sound and sound control in buildings, the most common noise sources found in buildings, practical noise control methods for these sources, and the specific topic of office acoustics. Common noise issues for multi-dwelling units can be derived from most of the sections of this chapter. Books can be and have been written on each of these topics, so the purpose of this chapter is to summarize this information and provide appropriate resources for further exploration of each topic.

11.1 Room Acoustics

When a sound wave in a room encounters a boundary surface, some of its energy is reflected back into the room, as illustrated in Fig. 11.1. The physical laws regarding reflected sound energy are analogous to those for the laws of optics. Just as light bounces off a mirror at the same angle as its angle of incidence, sound waves have equal angles of incidence and reflection. Acoustically reflective surfaces are typically smooth and hard.

Some common room acoustics problems caused by reflection are echoes and room resonance. Echoes result from the limitations of our hearing mechanisms to process sounds. When the difference in arrival times between two sounds is less than 60 ms, we hear the combination of the two sounds as a single sound. However, when this difference exceeds 60 ms, we hear the two distinct sounds (Fig. 11.2). When these two sounds are generated by the same source, this effect (which
Fig. 11.1 Reflection of a sound wave off a hard, smooth surface

is called an echo) can cause difficulty in understanding speech, especially when arrival times differ by more than 100 ms. These kinds of delays occur when a person hears a sound wave coming directly from a source and

another coming from a reflecting surface. Given that the speed of sound in air is roughly 300 m per second, the 100 ms delay translates to a distance of roughly 30 m. Therefore, a difference in sound travel path of more than 30 m between a sound wave traveling directly from a source to a listener and a sound wave traveling from a source to a reflecting surface and then to a listener causes an echo.

When parallel reflective surfaces are tall and more than 10 m from each other, a rapid succession of mid-frequency echoes can occur, known as flutter echo, resulting in a flapping sound similar to that generated by birds or bats. When these surfaces are fairly close to each other, as in a narrow hallway or stairwell, flutter echo sounds more like a high-pitched buzzing since the smaller spacing accommodates higher frequencies (shorter wavelengths).

Echoes are normally perceived as discrete reflections that can be clearly heard and identified, but many reflections off all surfaces within a room can combine to produce the phenomenon known as reverberation. Reverberation can raise the sound level in a room and can also reduce speech intelligibility, but it is desirable for certain types of music. More discussion on reverberation and its control can be found later in this chapter.

11.1.1 Room Modes

Room modes occur at specific frequencies when two reflective walls are parallel to each other. Since the surfaces reflect the sound, their mirror images

Fig. 11.2 Generation of an echo
Fig. 11.3 Generation of a standing wave between parallel, reflective surfaces
Fig. 11.4 Pressure patterns of the lowest axial standing wave modes in a room with parallel reflective surfaces

reflect off each wall to set up a stationary pressure pattern in a room. This phenomenon is called a single-dimensional (or axial) standing wave, as shown in Fig. 11.3, and it is the simplest form of room modes.

Axial standing waves occur at frequencies described by the equation below:

$$f_n = nc/2d \, , \tag{11.1}$$

where $n = 1, 2, 3, \ldots$, c is the speed of sound, and d is the distance between the parallel reflective surfaces. This means that axial standing wave room modes occur at integer multiples of specific 1/2-wavelengths of sound, as is shown in Fig. 11.4. Standing waves can become more complex in two and three dimensions, where they are known as tangential and oblique modes, respectively.

A design problem with standing waves is that they generate uneven sound distribution patterns. Some areas will have higher levels of sound (because a standing wave is reinforcing the pressure at those locations) and some areas will have lower levels of sound (because the standing wave is canceling much of the pressure at those locations), but only at specific frequencies.

The topic of building acoustics stresses the importance of controlling sound. When one talks about controlling sound, it is often assumed that one is referring to the reduction of sound. However, there are cases (e.g., auditorium or concert hall design) in which we want to preserve the sound energy but we would like to control its spatial spreading characteristics. The primary ways to reduce sound are through absorption and insulation. Using absorption on an auditorium's side walls may eliminate unwanted reflections but may also eliminate the possibility of some people hearing sound coming from the stage. We therefore must clarify how we plan to control the sound. Redirection and diffusion can have favorable acoustic results for even sound distribution in large rooms.

Discussions about noise control usually refer to the reduction of sound (since noise is defined as unwanted sound). Figure 11.5 shows what happens to a sound wave that interacts with a room's surface. Part is absorbed, part is redirected, and the rest is transmitted through the surface.
Fig. 11.5 The interaction of a sound wave with a partition

11.1.2 Sound Fields in Rooms

Several different fields, or acoustic environments, exist in all rooms. The size of these fields depends on the dimensions of the room, the reflective qualities of the room's surfaces, and the frequency of interest. The near field is the region within 1/4-wavelength (of the lowest frequency of interest) of a sound source or large reflective surface. Sound pressure levels can fluctuate dramatically in the near field of a source and sound pressures cancel and enhance each other near large reflective surfaces, so sound pressure level measurements should be avoided in near fields.

The far field is the region beyond the near field. It is contrasted with the near field to designate the region that is appropriate for recording sound pressure level measurements from a sound source. As one moves out of the near field and into the far field, sound pressure levels drop off at a rate of 6 dB per doubling of distance, for a point source, in accordance with the inverse square law that is simplified in the following equation:

$$\mathrm{SPL}_2 = \mathrm{SPL}_1 - [20 \times \log(d_2/d_1)] , \tag{11.2}$$

where SPL_1 is the sound pressure level at the location closer to the sound source, SPL_2 is the sound pressure level at the location farther from the sound source, d_1 is the distance from the source at which SPL_1 is measured, and d_2 is the distance from the source at which SPL_2 is measured.

The region in which (11.2) is valid is known as the free field. Free-field conditions exist in large open outdoor spaces or in rooms having highly absorptive surfaces, in which there are no obstructions in the sound travel path between the source and listener. The free field is sometimes referred to as the direct field when source measurements are taking place that only consider the sound wave traveling from the source to the listener with no influence by reflected sound coming from room surfaces.
As sound pressure levels decay from sources within a room, they eventually drop to a relatively constant level which is determined by the amount of reflected sound within a room. This lower limit is known as the reverberant or diffuse field. The size of the reverberant field depends on the size of the room and the size and characteristics of its reflective surfaces. Within the reverberant field, sound pressures are similar independent of location. Figure 11.6 puts all of the fields described above into perspective.

11.1.3 Sound Absorption

Absorption converts sound energy into heat energy. It is useful for reducing sound levels *within* rooms but not *between* rooms. Each material with which a sound wave interacts absorbs some sound. The most common measurement of that is the absorption coefficient, typically denoted by the Greek letter α. The absorption coefficient is a ratio of absorbed to incident sound energy. If a material does not absorb any sound incident upon it, its absorption coefficient is 0. In other words, a material with an absorption coefficient of 0 reflects all sound incident upon it. In practice, all materials absorb some sound, so this is a theoretical limit. If a material absorbs all sound incident upon it, its absorption coefficient is 1. As with the lower limit for absorption coefficients, all materials reflect some sound, so this is also a theoretical limit. Therefore, absorption coefficients range between 0 and 1.

Absorption coefficients vary with frequency. Typical absorptive materials are porous and characterized by absorption coefficients that increase with frequency. They therefore have limited effectiveness for lower frequencies, especially below 250 Hz. There are absorbers that have been designed to absorb these lower frequencies, and these will be discussed shortly. However, for typical cases, it is convenient to use a single number (incorporating multiple frequency components) to describe the absorption characteristics of a material. This value has been defined by the American Society for Testing and Materials (ASTM) in Standard C 423 as the noise reduction coefficient (NRC). The NRC is the arithmetic (as opposed to the logarithmic) average of a material's absorption coefficients at 250, 500, 1000, and 2000 Hz, rounded to the closest 0.05.

Fig. 11.6 Sound fields in rooms

Table 11.1 lists absorption coefficients and NRC values for common materials. Note that the values listed in Table 11.1 are for general reference purposes only, and specific values should be based on manufacturers specifications. Also note that absorption coefficients and NRC values have no units associated with them. In general, materials with NRC values less than 0.20 are considered to be reflective while those with NRC values greater than 0.40 are considered to be absorptive. When significant sound energy must be absorbed, as may be the case for eliminating echoes or standing waves, materials having higher absorption coefficients are usually recommended.

A few cautionary notes apply. NRC values are convenient to use for rating the absorption characteristics of a material. However, they should only be used when the sound sources of interest are within the 200–2000 Hz range. For sources outside of this range, and especially below this range, materials effective for the specific frequency of interest must be used. Also note that some manufacturers specify NRC and absorption coefficient values that are greater than 1.0. Methods used to measure absorption coefficients can artificially raise their values above 1.0; yet such values inaccurately imply that more energy is absorbed by a material than is incident upon it, which is a physical impossibility. Therefore, any published absorption coefficient or NRC values greater than 1.0 should be not be considered as greater than 1.0.

Another absorption metric gaining increasing application is the sound absorption average (SAA). The SAA is a single number rating that is the average, rounded off
Fig. 11.7 The general effect of an air space between absorptive material and its mounting surface

Absorption coefficient α
Fig. 11.8 The general effect of non-acoustically transparent facings on absorption

to the nearest 0.01, of the sound absorption coefficients of a material for the twelve one-third octave bands from 200 through 2500 Hz. Although the SAA replaces the NRC rating, as directed by the ASTM C 423 since the year 2000, most product literature still uses NRC values.

The method by which these materials are mounted affects their sound absorption effectiveness, especially for low frequencies (below 500 Hz). Figure 11.7 shows the effect of air spaces between an absorptive material and a mounting surface.

Facings on absorptive materials can degrade their absorptive properties, especially for higher frequencies (above 2000 Hz). Acoustically transparent facings, such as grill cloth and open-weave fabrics, will have little effect on absorption properties, but facing materials that are not acoustically transparent, such as perforated metal and wood slats, can produce the kind of effects shown in Fig. 11.8.

Of critical importance with these facings is the open area ratio. Since there are so many perforated metal designs, it is best to check with the manufacturer for the most appropriate opening ratio and design for the situation. Figure 11.9, however, offers some guidelines for wood-slat ceiling designs.

As Table 11.1 shows, the absorption coefficients of most porous materials increase with increasing frequency. This means that they are not as effective at low frequencies as at higher ones. If absorption is required for frequencies below 250 Hz, special materials must be used. Each of these materials has an air space behind its light or open surface to provide the extra absorption. Two common materials used for this purpose are Helmholtz resonators and diaphragmatic absorbers. Helmholtz resonators have narrow openings that lead to the outside on one end and into a larger air cavity on the other, as is shown in Fig. 11.10.

As viewed by an incoming sound wave, the air in the narrow neck functions as a mass and the air in the larger cavity functions as a spring. A mass on a spring will resonate at a frequency appropriate to that mass and spring stiffness. Thus, at and near the resonant frequency of such an acoustic chamber, sound will be absorbed from an incoming sound wave, as is shown in Fig. 11.11.

Such devices incorporated in wall constructions are usually resonant below 250 Hz, depending on the dimensions of the neck and size of the cavity. There are commercially available products that incorporate this design into concrete masonry units. When viewing these products installed as partitions, the wall surfaces have slots in them, as are shown in Fig. 11.12. Table 11.1 has a listing for these products which shows their superior absorption in a narrow low-frequency range. The
Fig. 11.9 General design guidelines for absorptive wood-slat ceilings
Fig. 11.10 Cross section of a Helmholtz resonator concrete masonry unit. The absorptive material helps to spread the absorptive properties over a larger frequency range than would otherwise occur

Fig. 11.11 General absorption characteristics of Helmholtz resonators not filled with absorptive material

porous and coarse nature of the surface provides modest absorption at higher frequencies also.

Diaphragmatic absorbers work according to similar principles to Helmholtz resonators, except they are comprised of an air space behind a lightweight wall, as shown in Fig. 11.13.

Reverberant Field Noise Reduction

Adding absorptive materials to a room's surfaces, in addition to reducing or eliminating echoes and standing waves, can reduce the overall reverberant field noise level within a room. The mathematical basis for this is to determine the total absorption for all of a room's surfaces using the following equation:

$$A = \sum_{i=1}^{n} \alpha_i S_i = \alpha_1 S_1 + \alpha_2 S_2 + \ldots + \alpha_n S_n , \quad (11.3)$$

where α_1, α_2, etc., are the absorption coefficients of each surface material in the room while S_1, S_2, etc. are the surface areas corresponding to the surfaces having the same subscript value as those for the absorption coefficients. The total absorption (A) is in units of sabins, for which one sabin is defined as the total absorption provided by a one square foot piece of material having an absorption coefficient of 1.

The reverberant field noise reduction (NR) is defined as

$$\text{NR} = 10 \times \log(A_2/A_1) , \quad (11.4)$$

Fig. 11.12 Wall built from Helmholtz resonator concrete masonry units

where A_1 is the total absorption within a room before absorptive treatment is applied and A_2 is the total absorption within that same room after absorptive treatment is applied. The practical limits of NR are 12–15 dBA with typical cases yielding 6–8 dBA of noise reduction within a room from the proper use of absorptive materials. Bear in mind that this will not reduce sound pressure levels close to a source but will only reduce reflected sound pressure levels, which limits the effectiveness of the noise reduction to locations in a room's reverberant field.
Fig. 11.13 Cross section of a generalized diaphragmatic absorber

11.1.4 Reverberation

Absorption is useful in reducing or eliminating unwanted reflections off surfaces. The standing waves discussed in Sect. 11.1.1 can be eliminated by covering one of the parallel surfaces with absorptive material. Absorption can also be used to eliminate echoes. The rear walls of auditoriums are prime candidates for absorptive materials since rear walls have the greatest potential to cause echoes. The most common use of absorption, however, is to control reverberation.

Reverberation is the build up of sound within a room resulting from repeated sound wave reflections off all of its surfaces. Reverberation can increase sound levels within a room by up to 15 dBA, as well as distort speech intelligibility. Reverberation is desirable for rooms in which music is being played, especially classical and cathedral-style music, to add a pleasant persistence to the sounds. Therefore, there are different reverberation characteristics that would be appropriate for different room uses.

Reverberation is described by a parameter known as the reverberation time (denoted RT_{60}). RT_{60} can be defined in two ways – physically and mathematically. Physically, RT_{60} is the time (in seconds) that it takes for a sound source to reduce in sound pressure level (within a room) by a factor of 60 dB after that sound source has been silenced. Mathematically, in what is known as the sabine equation, RT_{60} is directly proportional to the volume of a room and inversely proportional to the absorption of the materials in the room, as follows:

$$RT_{60} = 0.161 \cdot V/A \,, \tag{11.5}$$

where V is the room volume in cubic meters and A is the total absorption of the room's surfaces in metric sabins.

Table 11.2 Optimum mid-frequency RT_{60} values for various occupied facilities

Type of facility	Optimum mid-frequency RT_{60} (s)
Broadcast studio	0.5
Classroom	1.0
Lecture/conference room	1.0
Movie/drama theater	1.0
Multipurpose auditorium	1.3 to 1.5
Contemporary church	1.4 to 1.6
Rock concert hall	1.5
Opera house	1.4 to 1.6
Symphony hall	1.8 to 2.0
Cathedral	3.0 or higher

This means that RT_{60} increases as the size of a room increases and as the absorption of the room's surfaces decreases. Conversely, RT_{60} decreases as the size of a room decreases and as the absorption of the room's surfaces increases. There are then two principal ways to control RT_{60}: (1) by changing a room's size and (2) by changing the amount of absorption on its surfaces. Although it is possible to reduce a large room's volume by dividing the space with walls, it is more practical to adjust RT_{60} by adding sound absorptive materials.

Since the absorption performance of materials varies with frequency, so does RT_{60}. Table 11.2 offers generally accepted ranges of RT_{60} for different uses in the mid-frequency (500–1000 Hz) range. As you can see from the table, lower RT_{60} values are desirable for rooms used mainly for human speech and higher RT_{60} values are desirable for rooms used mainly for music. The optimum mid-frequency RT_{60} for a fully occupied room is different for various types of music. Because contemporary orchestral repertoires emphasize late classical and romantic music, the optimum mid-frequency RT_{60} for a fully occupied concert hall is usually stated as 1.8–2.0 s.

Optimum RT_{60} values generally increase by 10% of the values in Table 11.2 for each halving of frequency below 500 Hz and decrease by 10% of the values in Table 11.2 for each doubling of frequency above 1000 Hz. A room with a low (less than 0.8 s) RT_{60} is called a *dead* room and a room with a high (greater than 1.7 s) RT_{60} is called a *live* room. Multipurpose facilities should have RT_{60} values between the live and dead range limits.

Note that the sabine equation is based on the assumption that the absorptive properties of the surface materials are spread evenly throughout the room. When

this is clearly not the case, other (more complex) RT_{60} calculation methods would be more appropriate.

11.1.5 Effects of Room Shapes

Although absorption is necessary in many circumstances, eliminating reflections is not always useful. This is of key importance in rooms where an audience is listening to a performance or lecture. In this type of room, it is desirable that all audience members hear the sound not only clearly, but without preference to seating location. Without an electronic sound system, this can only be accomplished by reflections off side walls and ceilings. Discrete echoes can be eliminated by avoiding smooth, flat reflective surfaces and by having irregular and convex surfaces to diffuse the sound evenly throughout the audience. For smaller rooms such as recording studios that require diffusion, commercially available sound-diffusing panels called quadratic residue diffusers are available. These panels can also be used for larger spaces, as well as irregularly shaped surfaces.

Concave reflective surfaces focus sound in certain areas and defocus sound from others, causing hot spots where sound is concentrated and dead spots where sound cannot be heard. Concave reflective surfaces should be avoided for this reason. If aesthetics dictate the need for a concave surface, it would be best to install an absorptive or diffusive surface (as needed) and cover it with acoustically transparent fabric in the concave shape.

Reflective rear walls in auditoriums are notorious for generating echoes because of their associated large sound travel path differences. For this reason, reflective surfaces should be avoided for rear walls. Reflective surfaces are beneficial, especially for concert halls, when they are close to the stage and along side walls. Reflective surfaces close to the stage assist in several ways, by sending sound into the audience rather than allowing it to be lost behind the stage and by enhancing the sound through lateral reflections off side walls to spread the sound more evenly throughout an audience. Another benefit of reflective surfaces near the stage is that they permit the performers to hear each other, something that is critical to concert performances. These so-called early reflections are usually generated by shells on the stage or by hanging reflective panels.

11.1.6 Sound Insulation

The description of the insulation of sound is similar in many ways to the description of the absorption of sound.

As with absorption, there is a transmission coefficient that ranges from the ideal limits of 0 to 1. The transmission coefficient, denoted by the Greek letter τ, is the unitless ratio of transmitted to incident sound energy. Unlike the absorption coefficient, however, the limit of $\tau = 1$ is possible in practice since a transmission coefficient of 1 implies that all of the sound energy is transmitted through a partition. This would be the case for an open window or door, where the sound energy has no obstruction to its path. The other extreme of $\tau = 0$ (implying no sound transmission), however, is not a practical value since some sound will always transmit through a partition.

Unlike absorption, the principal descriptor for sound insulation is a decibel level based on the transmission coefficient. This value is known as the transmission loss (TL), and is based on the following equation:

$$TL = 10 \cdot \log(1/\tau) . \tag{11.6}$$

The transmission loss can be loosely defined as the amount of sound reduced by a partition between a sound source and a listener. The complete sound reduction of a partition between two rooms also takes into account the absorptive characteristics of the listener's room, as follows:

$$SPL_S - SPL_L = TL + 10 \cdot \log(A_L/S) , \tag{11.7}$$

where SPL_S is the average sound pressure level in the room enclosing the sound source, SPL_L is the average sound pressure level in the adjacent listener's room, A_L is the total absorption in the listener's room, TL is the transmission loss of the partition between the two rooms, and S is the surface area of the partition between the two rooms. Note that TL is the quantity that is typically reported in manufacturers' literature since it is measured in a laboratory independent of the installation.

Since the logarithm of 1 is 0, the condition in which the transmission coefficient is 1 translates to a TL of 0 dB. This concurs with the notion that an open air space in a wall allows the free passage of sound. Although an open air space itself would have a TL value of 0 dB associated with it, a wall with an open air space in it would have a TL value greater than 0 (up to 10) dB, depending on the size of the opening and the location with respect to the wall. The practical upper limit of TL is roughly 70 dB.

As for absorption, TL is frequency dependent. Typical partitions have TL values that increase with increasing frequency, as is shown in Fig. 11.14, with the exception of a dip in TL around a bending wave resonance frequency, known as the critical frequency. This
Fig. 11.14 General characteristics of the transmission loss spectrum

Table 11.3 Critical frequencies for common building materials

Material	Thickness (cm)	Critical frequency (Hz)
Concrete	8	100
Plywood	1.2	1700
Gypsum wall board	1.2	3100
Steel or aluminum	0.3	4100

Glass	0.3	4900
Plexiglass	0.3	9800

Fig. 11.15 The standard STC calculation curve, from ASTM E 413. STC values are derived by plotting the TL spectrum on this curve and determining the highest curve shape that meets the criteria of: (1) the sum of the differences between individual TL values and the *solid line* is less than 32 dB and (2) no individual 1/3-octave band TL value is more than 8 dB below the *solid line*. The TL value at 500 Hz corresponding to this spectrum is the STC value

effect is known as the coincidence dip. The extent of this dip depends on the vibrational damping of the partition and the frequency at which it occurs depends on the density and thickness of the material.

Table 11.3 lists critical frequencies for common building materials. Critical frequencies generally decrease at the same rate as the material thickness increases. Therefore, a doubling in material thickness translates to cutting the critical frequency in half for the same homogeneous material. Coincidence effects can be minimized by using multilayered partitions with different materials and different material thicknesses combined into a single partition.

There is a single-number rating for TL that takes the entire frequency spectrum into account, established by ASTM standard E413. This value, known as the sound transmission class (STC), is not derived by the simple averaging method used for NRC values. Instead, the TL frequency spectrum is matched to a standard curve within the limits imposed by the ASTM standard. Figure 11.15 shows how STC is calculated from the TL spectrum. Note that STC values have no units associated

with them, but they are based on decibels. Similar to NRC, STC is useful to describe the sound insulation efficiency of a partition over the human speech frequency range of roughly 500–2000 Hz. If sound insulation outside of that frequency range (especially for frequencies below 250 Hz) is required, the TL values relevant to the frequency range of interest must be used.

Table 11.4 lists TL and STC values for common partitions. As with Table 11.1, these values are for general reference purposes only, and specific values should be based on manufacturers' specifications. Table 11.5 gives some meaning to the numbers by listing speech privacy ratings for different ranges of STC values. Notice that the same wall design with metal studs has a higher STC rating than one with wooden studs. Stud spacing can also make a difference in TL and STC values. A wall having a 400 mm stud spacing can have a 3–4 unit lower STC rating than one having a 600 mm stud spacing. The gauge of metal can also make a difference of up to 5 STC units when comparing 16-gauge studs with 25-gauge studs, with walls having 25-gauge studs having the higher values [11.1].

Table 11.4 Transmission loss and STC values for common partitions

Partition	125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	STC
1/2 inch drywall on both sides of wooden studs	17	31	33	40	38	36	33

Corrugated steel roof with 1 inch of sprayed cellulose	17	22	26	30	35	41	30

As with any construction system, the actual in-field performance seldom matches the theoretical or laboratory STC rating for the construction. This is most often caused by flanking paths, poor construction practices, and/or lack of sealing cracks, gaps and openings. The noise isolation class (NIC) is the metric that considers these conditions. NIC is determined using the same method and template as is used for determining STC (shown on Fig. 11.15), using measured field data instead of using controlled laboratory data. The NIC value is typically 5–10 points less than the STC rating of a given partition design.

STC does not effectively consider the transmission of impact noise on floors from foot traffic as it may affect floors below. For this purpose the impact insulation class (IIC) was established by ASTM standard E 989. The IIC stresses the low-frequency range, as is shown in Fig. 11.16, but note that IIC does not address very low (below 100 Hz) frequencies, which may be associated with resonances of a building's structural components.

One other single-number rating worth noting here is the outdoor–indoor transmission class (OITC), established in ASTM E 1332. The OITC is a single-number rating for the effectiveness of a building façade in reducing noise to interior spaces. The calculation of OITC is based on an A-weighted source spectrum of typical transportation (aircraft, rail, and traffic) sources in the 80–4000 Hz range and the façade's transmission loss spectrum in the same frequency range.

Non-Homogeneous Partitions

Up to this point we have been discussing homogeneous partitions. Actual designs, however, include walls composed of different materials, such as those with windows and doors. Each of these wall components has different associated TL characteristics. Wall components having lower TL characteristics than the rest of the wall can

Table 11.5 Speech privacy associated with STC ratings[a]

STC range	Sound privacy
0 to 20	No privacy (voices heard clearly between rooms)
20 to 40	Some privacy (voices heard in low[b] background noise)
40 to 55	Adequate privacy (only raised voices heard in low background noise)
55 to 65	Complete privacy (only high level noise heard in low background noise)
70	Practical limit

significantly degrade a wall's sound reduction effectiveness. This can be calculated using the composite transmission coefficient, which is defined as:

$$\tau_{\mathrm{comp}} = \left(\sum_{i=1}^{n} \tau_i S_i \right) / S$$
$$= (\tau_1 S_1 + \tau_2 S_2 + \ldots + \tau_n S_n)/S , \qquad (11.8)$$

where τ_1, τ_2, etc., are the transmission coefficients of each wall component while S_1, S_2, etc. are the surface areas corresponding to the surfaces having the same subscript value as those for the transmission coefficients, and S is the surface area of the entire partition. The composite transmission coefficient that is calculated using (11.8) can then be replaced in (11.6) to yield the composite transmission loss for the partition.

Air gaps (e.g., around doors, windows or penetrations) are notorious for compromising the sound reduction effectiveness of walls. Table 11.6 shows the TL degradation caused by varying sizes of air gaps in a wall originally rated at a TL of 45 dB. As the table shows, an air gap just one tenth of one percent the size of a wall can lower the TL rating from 45 to 30 dB. Figure 11.17 offers a graphical method for making this determination, not only for openings but also for doors and windows that have lower TL values than the walls in which they are installed. This emphasizes the importance of sealing walls, avoiding air gaps, and placing airtight seals around doors.

A rule that governs most of the TL spectrum of homogeneous partitions, known as the mass law, states that TL increases at a rate of 6 dB with each doubling of mass and with each doubling of frequency (shown in Fig. 11.14). This rule can make it impractical to solve

SPL in increments of 10 dB

Fig. 11.16 The standard IIC calculation curve, from ASTM E 989. IIC values are derived by plotting the SPL spectrum (from a tapping machine specified in ASTM E 492) on this curve and determining the lowest curve shape that meets the criteria of: (1) the sum of the differences between individual SPL values and the *solid line* is less than 32 dB and (2) no individual 1/3-octave band TL value is more than 8 dB above the *solid line*. The SPL value at 500 Hz corresponding to this spectrum, subtracted from 110, is the IIC value

sound privacy issues with homogeneous partitions. For example, if a 1/2 meter-thick concrete wall does not provide enough sound insulation for a specific situ-
Fig. 11.17 Chart for determining the reduction in TL wall rating by the installation of a door, window, or opening ◄

ation, doubling the thickness of that wall to 1 meter would only offer an additional 6 dB of sound reduction. A more practical way of avoiding this kind of issue is by using multilayered partitions.

Multilayered partitions are comprised of layers of different materials. Each time sound passes through a different material, its level is reduced. Therefore, this method can be used to reduce costs, weight and space restrictions while providing adequate sound reduction. A sharp change in density of material is most effective in raising TL. Air spaces between wall sections and materials are effective by setting up such environments and also breaking any rigid connections between sides of a partition. A rigid connection can provide a vibration channel for sound to pass through with little reduction. For example, the noise reduction effectiveness of a studded wall filled with fiber insulation between studs can be short-circuited because sound may travel unim-
Fig. 11.18a–d Examples of multilayered partition and floor/ceiling designs that result in high TL

Approximate improvement in TL (dB)

Airspace in cm   16

Octave band center frequency (Hz)
Fig. 11.19 General TL improvement that can be expected from air spaces in partitions ◄

Figure 11.19 shows the TL benefit of different air spaces in partitions. In general, the TL of a partition increases at a rate of 5 dB with each doubling of air space (within a partition) beginning with an air space of 5 cm.

As is mentioned above, transmission loss generally increases with frequency. If significant sound reduction is required for frequencies below 250 Hz, it is most practical to use multilayered partitions with air spaces and staggered studs or resilient channels between components. Resilient channels are shaped metal bars (the S shape is common) or resilient clips that connect two wall components. Only one side of their shape touches each side of the wall, and they effectively reduce vibrational energy from traveling through them. Resilient clips resemble isolation hangers, and can be more effective than resilient channels because short-circuiting their isolation properties during installation is easier with resilient channels. Another option for greater transmission loss at low frequencies is massive concrete slabs.

peded through the studs to the other side of the wall. Figure 11.18 shows examples of multilayered partitions that are effective for sound insulation.

11.2 General Noise Reduction Methods

Noise can be controlled at its source, in the path between the source and the listener, or at the listener. Table 11.7 summarizes the general options available. If the noise can be controlled sufficiently well at its source, it is unnecessary to consider the path or listener locations. Likewise, if the noise can be controlled sufficiently well in the path between the source and listener, it is unnecessary to consider the listener's location for noise control measures.

The options for noise control at the source are generally self-explanatory. Most often, due to economic or logistic issues, noise control options are limited to the

path between the source and the listener. Given many misconceptions about these options, it is useful to discuss some of them further.

11.2.1 Space Planning

The most effective noise control method for buildings is space planning. This is true both for room layout within a building and for the placement of the building itself with respect to exterior noise sources. Inherently noisy spaces adjacent to spaces inherently requiring quiet should be avoided as much as possible. The noisiest indoor spaces tend to be mechanical rooms, restrooms, and elevator shafts.

For placement with respect to loud exterior sources, buildings should be as far as possible from noisy streets or rail lines, taking advantage of shielding from other buildings and topographical features. If building placement near noisy outdoor sources is unavoidable, special attention should be paid to the design of the façade(s) facing the noisy sources, avoiding operable windows, doors, and penetrations.

Another aspect to consider for outdoor sound is the potential effect of a building's noise sources on the surrounding community. Rooftop mechanical units are

Table 11.7 Generalized noise reduction options

Control at the source	Control in the path	Control at the listener
Maintenance	Enclosure(s)	Relocate listener
Avoid resonance	Barrier(s)	Enclose listener
Relocate source/ space planning	Muffler(s)	Hearing protection
Remove unnecessary sources	Absorptive treatment	Masking
Use quieter model(s)	Vibration isolation	
Redesign source to be quieter	Active noise control	

the most common noise sources that may need to be insulated from community intrusions, especially when municipal codes are involved. The community noise aspect of a building is often considered in the building's permitting process.

11.2.2 Enclosures

Enclosures can be effective at reducing noise levels as long as they are properly designed. The following points should be considered when designing noise enclosures (also illustrated in Fig. 11.20a–d).

1. The enclosure must completely surround the noise source, with no air gaps. As mentioned earlier in this chapter, air gaps can significantly compromise the noise reduction effectiveness of partitions. An enclosure with any side open is not an enclosure but a barrier, and the noise reduction effectiveness of barriers is limited by diffraction to 15 dBA, independent of the barrier material (as long as the material would provide at least 20 dBA of noise reduction on its own). Enclosures, on the other hand, can provide up to 70 dBA of reduction.

2. The enclosure must be isolated from floors or any structural members of a building. An enclosure covering the sides and top of a noise source but not the bottom (since the source is sitting on the floor or ground) can compromise its effectiveness for several reasons. First, the chances of the sides of the enclosure perfectly sealing to the ground are slim, and therefore, air gaps would result. Second, vibrations will be carried along the ground or floor since the source is in direct contact with it. The only way to reduce these vibrations is to vibrationally isolate the source from the ground or floor using tuned springs (appropriate for the source), pads, or a floating floor.

3. The enclosure should be constructed using nonporous materials. Sound absorptive material can be effective in reducing noise when it is used as part of a multilayered enclosure (on the inside); how-

Fig. 11.20a–d Noise reduction effectiveness of enclosures sitting on a solid surface (**a**) enclosing the source on five sides with absorptive material only, (**b**) enclosing the source on five sides with one layer of rigid, nonporous material, (**c**) completely enclosing the source with absorptive material only, and (**d**) surrounding the source in an isolated, multilayered enclosure ▶
ever, absorptive material by itself is not effective in reducing noise.

4. The enclosure designer must consider that some sources require ventilation. This cannot translate to leaving an opening in the enclosure without compromising the noise control effectiveness of the enclosure. Ventilation systems must be developed that minimize noise transmission.

5. The enclosure should be constructed using multi-layered construction for maximum efficiency. As is mentioned earlier in this chapter, doubling the mass of an enclosure would add 6 dB to its noise reduction effectiveness. This can easily lead to excessive weight for an effective homogeneous enclosure. As for single partitions, multilayered enclosures can add more than 20 dB of effectiveness (under similar space requirements) to massive enclosures with a fraction of the weight.

11.2.3 Barriers

A barrier is contrasted from an enclosure by being open to the air on at least one side. Because of diffraction, noise barriers are limited to 15 dBA of noise reduction capability, independent of the material. This limited effectiveness is compromised even more if there are reflective ceilings above the barrier because sound reflected off the ceiling minimizes the barrier's effectiveness. Therefore, wherever noise barriers are used indoors, an absorptive ceiling should be installed above them. It is also important to have no air spaces within or under the barriers, since this will compromise their already limited effectiveness.

The noise reduction effectiveness of barriers is typically rated by the insertion loss (denoted by IL). The IL is the reduction in sound pressure level, at a specific location, resulting from the installation of a barrier. The IL is then the difference between conditions with and without a barrier.

To provide any insertion loss, a barrier must break the line of sight between the sound source and listener. In other words, if you can see a sound source on the other side of a barrier, that barrier is providing no sound reduction (from that source) for you. Breaking this line of sight typically provides a minimum of 3–5 dBA of insertion loss, with insertion loss increasing as one goes further into the shadow zone of the barrier.

Bear in mind that a row of trees is ineffective for outdoor noise control. Only solid walls or earth berms breaking the line of sight between the noise source and building occupants will produce any meaningful noise reduction.

11.2.4 Mufflers

Mufflers are devices that are inserted in the path of ductwork or piping with the specific intention of reducing sound traveling through that conduit. The effectiveness of mufflers is typically rated using insertion loss. Mufflers must be designed for each purpose to preserve the required static or back pressure characteristics of the equipment and to reduce noise in the appropriate frequency range(s). For that reason, each muffler is unique to its installation.

11.2.5 Absorptive Treatment

Absorptive treatment within a room can reduce reverberation and, in this process, reduce noise levels by up to 10 dBA. Bear in mind, though, that absorptive treatment is only effective for reducing reverberation within a room and not for reducing transmission of sound between rooms.

11.2.6 Direct Impact and Vibration Isolation

Mechanical equipment can generate vibration that can travel through a building's structural members to affect remote locations within a building. It is therefore prudent to isolate any heavy equipment from any structural members of buildings. This can be accomplished by mounting the equipment on springs, pads, and/or inertia blocks; however, the selection of specific isolating devices (especially springs) should be performed by a specialist trained in vibration analysis. The main reason for this is that each vibration isolation device is tuned to a specific frequency range. If this is not matched properly with the treated equipment, the devices can amplify the vibration and cause more of a problem than would have occurred without any treatment.

Mechanical equipment and, to a lesser degree, footfalls generate direct impacts that should also be addressed by properly isolating floors from building structures.

11.2.7 Active Noise Control

Passive noise control involves all of the noise control methods discussed above, in which the sound field is not directly altered. Active noise control involves electronically altering the character of the sound wave to reduce
Fig. 11.21 Typical characteristics of effective masking systems (frequency response range in *shaded area*)

its level. In this case, a microphone measures the noise and a processor generates a mirror image of (180° out of phase from) that source. This mirror image is then reproduced by a loudspeaker in the path of the original sound. This new sound cancels enough of the original signal to reduce levels by up to 40 dB under the appropriate conditions. Although this is a very powerful noise control tool, active noise control is only practical in local environments and for tones below 500 Hz. Ventilation ducts provide ideal environments for active noise control systems because they are enclosed environments and their noise is often dominated by low frequency tones (associated with the fan characteristics).

11.2.8 Masking

As long as background sound levels are low in a building, one way of easing a noise problem is to add a more pleasing sound to the environment to make the noise less noticeable. This is especially desirable in open-plan offices where people can clearly hear activities in other offices and areas (since their offices are not completely enclosed). Any desirable sound can provide masking, but most often electronic masking systems are used, comprised of loudspeakers
Fig. 11.22 NC curves (after [11.2])

placed between dropped ceilings and structural ceilings. These loudspeakers are connected to signal processors that are set to generate sounds similar to those generated by typical heating, ventilating and air conditioning (HVAC) systems. Although many people think of masking system sounds as white noise, which has an equal amount of energy in all audible frequencies, a typical masking system frequency response is more like that shown in Fig. 11.21, where less emphasis is placed on higher frequencies. Whatever the response, it is advisable to have an electronic masking system installed by a contractor with experience in this area. If the system is set at too high a level or with a harsh frequency response, the resulting environment may be more unpleasant with the masking system than without.

11.3 Noise Ratings for Steady Background Sound Levels

There are two standardized methods for rating the background sound levels inside rooms. Each of these methods is referenced in ANSI standard S12.2 and the

American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Handbooks [11.3, 4]. These are the balanced noise criterion (NCB) and
Fig. 11.23 NCB curves (after [11.5]). Sound in the *region labeled A* can cause perceptible noise-induced vibration such as rattling of doors, windows, or fixtures. Sound in the *region labeled B* may generate lower levels of these noise-induced vibrations

Fig. 11.24 RC curves (after [11.6, 7]). The *A and B regions* have the same meanings as the NCB curves in Fig. 11.23. The LF, MF, and HF regions are designated as low-frequency (rumble), medium-frequency (roar), and high-frequency (hiss) ranges, respectively

the room criterion (RC) curves. The NCB curves are updated versions of the widely used noise criterion (NC) curves, different in that they are extended down to the 16 and 31.5 Hz octave bands. Figure 11.22 shows the NC curves and Fig. 11.23 shows the NCB curves.

As for the room criterion (RC) method, the NCB method was developed to better consider low-frequency noise generated by HVAC systems. In each case, standardized curves are used in conjunction with measured noise levels in a room to yield a single-number rating for HVAC noise. The NC and NCB rating values result from plotting the measured octave band sound pressure level spectrum on each chart and noting the lowest standard curve that is not exceeded by the measured values. This single number is then rated against design guidelines established in the two references above. Determining the RC rating is more complicated, based on the 1000 Hz value of the standard RC curve (in Fig. 11.24) that matches the arithmetic average of

the 500, 1000, and 2000 Hz values of the SPL room spectrum. The quality of the sound is also rated by the RC method, based on the deviations of the measured SPL spectrum from the standard RC curve. A *neutral* spectrum, designated by *N* and used in most RC specifications, implies that levels below 500 Hz do not exceed an RC curve by more than 5 dB and levels above 1000 Hz do not exceed an RC curve by more than 3 dB. When deviations greater than these exist, the RC rating is given the designation of the frequency range (from Fig. 11.24) in which the greatest deviations occur. The levels in the octave bands below 125 Hz are much lower for RC curves than those for the NCB curves. The purpose of this lower limit is to consider fluctuations or surges at the ventilation outlets better. These fluctuations are not considered for NCB ratings.

Table 11.8 lists generally recommended NC, NCB and RC(N) ranges for common spaces.

Table 11.8 Recommended background noise criteria for common spaces

Category of space	Specific uses	NC, NCB or RC(N) range	dBA limit
Sensitive listening spaces	Broadcast and recording studios, concert halls	15 to 20	25 dBA
Performance spaces	Theaters, churches, video and teleconferencing	20 to 25	30 dBA
Presentation spaces	Large conference rooms, small auditoriums, movie theaters, courtrooms, meeting and banquet rooms, executive offices	25 to 30	35 dBA
Private spaces	Offices, small conference rooms, classrooms, private residences, hospitals, hotels, libraries	30 to 35	40 dBA
Public spaces	Restaurants, lobbies, open-plan offices, clinics	35 to 40	45 dBA
Service and support spaces	Computer equipment rooms, public circulation areas, arenas, convention centers	40 to 45	50 dBA

11.4 Noise Sources in Buildings

The most common noise sources in buildings, other than the inhabitants, are related to HVAC systems, plumbing systems, electrical systems, and exterior sources. Figure 11.25 shows the most common paths for intrusive noise in buildings.

Although there is legislation that often deals with outdoor noise disturbances directly related to people as sources, these indoor sources are typically unregulated and their associated noise levels are governed by the desires of developers, builders, and occupants.

11.4.1 HVAC Systems

Noise sources associated with HVAC systems can be separated into two general categories – mechanical equipment and duct-borne/airflow noise.

Mechanical Equipment

Common mechanical equipment associated with HVAC systems includes pumps, compressors, chillers, generators, and air handlers. Rotating components of these pieces of equipment, such as gears and fans, generate most of the noise that causes concerns in buildings. Rotating mechanical equipment typically generate tones, their frequencies being associated with their rotational speeds. When mechanical equipment is housed in rooms within buildings, its associated noise can affect rooms throughout a building. When mechanical equipment is placed on rooftops or slabs outside buildings, its associated noise can also affect the surrounding communities. Figure 11.26 shows noise sources and paths for a typical rooftop HVAC unit.

Mechanical equipment not only generates noise in buildings, but also generates vibrations that can propagate throughout a building's structural members if not properly isolated. These vibrations can excite building members far from the sources and cause remote building components to rattle and generate their own noise.

Duct–Borne/Airflow Noise

Air is typically carried throughout a building using a system of ductwork. Ducts carry the tones generated by fans and they cause additional noise by inducing turbulence in the airflow. Some of this noise is carried through the ductwork to rooms in buildings (out of grilles in each room) and some of it is radiated directly from the duct walls (known as breakout noise).

11.4.2 Plumbing Systems

The most common plumbing system noise sources are water flowing through pipes and noise radiating from the walls of pipes.

11.4.3 Electrical Systems

The most common electrical system noise sources are transformers and noise radiated from associated conduit (by carrying vibrations that excite walls).

11.4.4 Exterior Sources

The most common exterior noise sources that affect building inhabitants are those associated with transportation (such as vehicular traffic, rail, and aircraft), industrial operations, and mechanical equipment from nearby buildings or mounted outside the same building. Figure 11.27 shows an average spectrum shape for
Fig. 11.25 Common noise leaks occur through these nine paths
Fig. 11.26 Common noise paths for a typical rooftop HVAC unit
Fig. 11.27 Average transportation noise spectrum shape (adapted from data in ASTM E 1332)

transportation noise sources used by ASTM E 1332. This shows the concentration of sound in the low frequency (below 500 Hz) range, emphasizing the need for exterior-wall noise control design measures that effectively address low frequencies.

11.5 Noise Control Methods for Building Systems

The principles discussed in Sect. 11.2 can be put into practice using the general design concepts listed in this section. Specific dimensions and sound ratings have intentionally been omitted from the drawings in this section because these drawings stress the design principles rather than specific installations. These design concepts can be used to develop specific designs for each project.

11.5.1 Walls, Floor/Ceilings, Window and Door Assemblies

A key issue with all of these designs is to stop the path of sound and vibration through rigid connections between building components. Generous use of air spaces and resilient materials is the most effective method for this to occur. Another key issue is avoiding openings in and around partitions (for the reasons stated in Sect. 11.1.6). All openings must therefore be completely sealed. These two themes will be repeated in most of the designs listed in this section.

Walls

The most effective wall system for noise reduction is a double-wall system, in which wall sections (including studs) are separated by an air space. The larger the depth of the air space, the more effective the wall will be in controlling sound. Double walls can be especially effective for controlling low-frequency sound, as long as the walls are properly sealed and isolated from the building structure. It is important to have absorptive insulation in any wall system to avoid cavity resonance. This insulation should not be tightly packed.

Figure 11.28 shows the general concept of a double-studded wall that is effective for noise control. Although metal studs are shown in the drawing, wooden studs would provide comparable results in this design because of the air gap. Figure 11.29 shows

a full floor-to-structural-ceiling double-wall construction concept.

Note that the wall must be sealed with a non-hardening material at its perimeter to avoid any sound leakage through air gaps (since a hardening material may crack and leave gaps). Figure 11.30 shows a double-wall concept using a concrete masonry unit (CMU) and studded component.

All of these double-wall designs will provide STC values in excess of 55; however, if low-frequency noise control is an issue, the STC rating does not address that and larger air spaces between wall components will increase the low-frequency noise control effectiveness.

Double-wall constructions are often impractical because of space restrictions. In these cases, an alternative to the CMU construction in Fig. 11.30 would be that shown in Fig. 11.31, in which the air space is replaced by a resilient element.

When working with gypsum board, Fig. 11.32 shows a design concept that will provide an STC of at least 50 as long as it is sealed properly. Note that a fluted structural deck may provide air gaps at the top of the wall that would need to be sealed to preserve the noise reduction effectiveness of the system.

When a room needs to be isolated from the building structure (which would be the case when structure-borne vibrations cause unwanted noise and vibration in certain rooms in which sensitive activities are taking place), Fig. 11.33 shows the conceptual design for a resiliently mounted wall. Figure 11.34 shows appropriate designs for intersections of double-studded walls.

A common path for sound leaks between rooms in buildings with large windows as facades is the connection between walls and those windows. Figures 11.35 and 11.36 show designs that effectively minimize sound transmission between rooms having this situation, Fig. 11.35 with a permanent installation and Fig. 11.36 with a curtain wall design.

Floor/Ceilings

Noise control design for floor/ceiling assemblies typically involves a significant amount of vibration isolation to minimize the transmission of footfall and other impact noise between floors. The design concepts that
Fig. 11.31 Cross section of alternate construction to a double-wall design in Fig. 11.30 (courtesy of Acentech Inc., Cambridge MA)

minimize vibration between floors can also be used to minimize sound transmission between floors.

The most common noise control design for floors is the floating floor system, in which a layer of resilient material is placed between the floor structure and the subflooring. More complicated measures are required for effective control of the high vibration and noise levels that can be associated with mechanical equipment in buildings. Figures 11.37–11.43 offer design concepts for resiliently mounted ceilings for mechanical rooms or other noisy spaces. Figure 11.44 shows a sound isolating design for a metal roof deck and Fig. 11.45 shows a sound isolating design for a concrete roof deck.

Windows and Doors

Windows and doors often have the lowest TL ratings of a wall system and are therefore often the sources of noise leaks through partitions. In addition to their lower TL ratings than the main wall, installation with air gaps
Fig. 11.32 Cross section of a single-studded sound insulating wall meeting a fluted metal structural deck (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.38 Cross section of a sound insulating gypsum board ceiling framed from I-beams (courtesy of Acentech Inc., Cambridge MA)

around them can significantly compromise their noise control effectiveness.

Many window manufacturers provide models that offer significant sound insulation and each of these manufacturers offers its own acoustical test data and design parameters. As for walls, larger air spaces between double-paned designs will provide better sound insulation than single-paned windows of the same thickness. For those wishing to manufacture custom sound-insulating windows, Fig. 11.46 shows some design guidelines for high-TL interior windows and Fig. 11.47 shows design guidelines for high-TL exterior windows.

Fig. 11.45 Cross section of a sound isolating sandwich design for a concrete roof deck (courtesy of Acentech Inc., Cambridge MA)

As for windows there are many door manufacturers that provide sound insulation data for their prefabricated products. In general, solid-core doors are more effective than hollow-core doors for noise reduction. To maximize the effectiveness of these doors, they should be gasketed around their perimeters and they should either have drop seals or rubber skirts on their undersides, which should contact solid floor thresholds.

11.5.2 HVAC Systems

ASHRAE publishes thorough discussions on HVAC noise sources and their control in their *Fundamentals and Applications Handbooks* [11.3, 4]. The basic principles to bear in mind for minimizing HVAC noise are minimizing airflow turbulence and isolating vibrations, each of which is able to carry noise far from the source to remote locations in buildings.

Airflow Turbulence
Airflow turbulence noise can be minimized by

- Lowering flow rates as much as possible,
- Distributing the flow as evenly as possible throughout the ducted system,
Fig. 11.46 Cross section of a high-TL interior window in a double-wall design (courtesy of Acentech Inc., Cambridge MA)

- Providing long ducted passages and transitions that avoid sharp changes in direction or discontinuities in cross-sectional area,
- Installing properly designed silencers and absorptive lining in the flow path that do not unduly compromise the efficiency of the HVAC system,
- Wrapping ductwork with lagging materials, and
- Enclosing ductwork and HVAC equipment.

Figures 11.48 through 11.50 offer effective noise control designs for duct and hanging HVAC equipment enclosures.

Fig. 11.48 Cross section of a double-layer gypsum-board duct enclosure (courtesy of Acentech Inc., Cambridge MA) ▶
Fig. 11.47 Cross section of an upgraded exterior window for high-TL design (courtesy of Acentech Inc., Cambridge MA)

Another issue to consider with ductwork is sound leaks through wall and ceiling duct penetrations. If these penetrations are not sealed properly, they will diminish the noise reduction effectiveness of the wall or ceiling
Fig. 11.49 Cross section of a duct enclosure resiliently mounted to a metal deck (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.50 Sections of a ducted terminal box enclosure mounted to a structural deck (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.51 Cross section of a duct penetrating a gypsum-board partition near a deck (courtesy of Acentech Inc., Cambridge MA)

that they are penetrating. Figure 11.51 shows an effective design for a single duct penetrating a wall and Fig. 11.52 shows an effective design for multiple duct

penetrations. Figure 11.53 shows design considerations for the placement of a duct silencer near a wall penetration.

Vibration Isolation

Springs and pads are the most common tools used to minimize the transfer of vibration from HVAC units to the building structure. The key here is to eliminate any rigid connections between the units and the structure. Figure 11.54 shows a typical spring isolator properly mounted to reduce this transfer of vibrations effectively.

These benefits, however, will become short-circuited if improper or misaligned isolators are installed. Figure 11.55 shows improperly loaded spring isolators supporting a piece of equipment, one being overcompressed and the other being undercompressed.

Figure 11.56 shows an example of a spring isolating pipe hanger that is misaligned. The rigid connections
Fig. 11.52 Cross section of sealed multiple duct penetrations in a partition (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.53a,b Cross section of a duct penetration with appropriate silencer locations. (a) Preferred location; (b) alternate location (courtesy of Acentech Inc., Cambridge MA)

established by this misalignment compromise the effectiveness of the system.

Figure 11.57 shows a common design in which pipe supports are rigidly attached to a floor. Figure 11.58 shows an effective design to reduce the transfer of vibrations between the piping and the floor using neoprene pads and spring hangers. Note that any spring hangers must be appropriately sized for each situation. When lateral restraints are required for large equipment, Fig. 11.59 offers a general design for effective vibration isolation.

Enclosures for Floor–Based Equipment

When barriers and source treatments do not provide enough noise control, the only practical noise control option for many floor-based units may be a full enclosure. Key issues for enclosures of HVAC equipment are access (for maintenance) and ventilation. A practical design for indoor environments is shown in Fig. 11.60, in which a heavy curtain system (which can be drawn

Fig. 11.54 A properly mounted spring isolator

along tracks for access) surrounds the equipment. There are hoods built into the sliding curtains to provide the necessary ventilation for the equipment.

Exterior enclosures are discussed in Sect. 11.5.5 below.
Fig. 11.55 Examples of misaligned and misloaded spring isolators

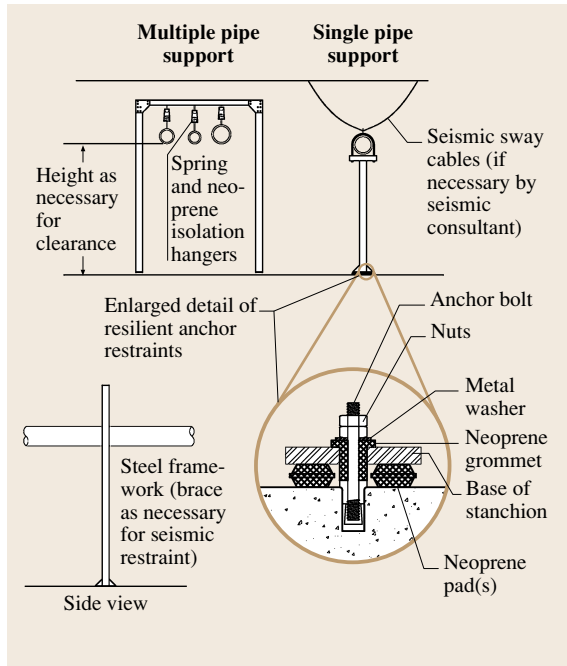
Fig. 11.57 Pipe supports rigidly attached to a structural floor. This can channel vibrations through the building structure


Fig. 11.58 Pipe floor supports with resilient anchors (courtesy of Acentech Inc., Cambridge MA)

11.5.3 Plumbing Systems

As for HVAC systems, the most common plumbing-system noise issues are related to reducing flow turbulence and vibration isolation. For plumbing systems we are dealing with liquid flow rather than air
Fig. 11.59 Cross section of a lateral restraint for an equipment base on neoprene pads (courtesy of Acentech Inc., Cambridge MA)
Fig. 11.60 A heavy curtain enclosure system for floor-based equipment

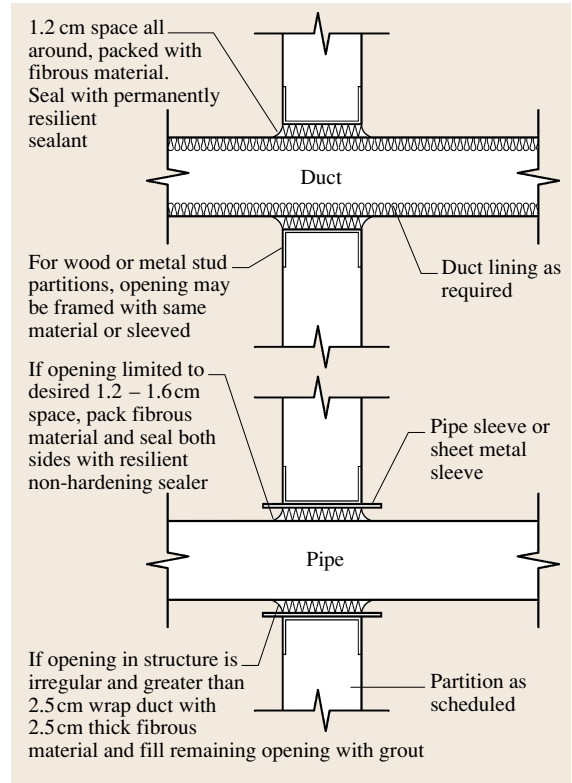
flow and pipe noise and vibration isolation rather than duct noise and vibration isolation. As for ducted systems, pipes can be wrapped with lagging materials to reduce breakout noise radiated from the pipe walls. Figures 11.61 and 11.62 show the general design principles to bear in mind for pipe penetrations through common walls and Fig. 11.63 shows these principles in practice


Fig. 11.61 Cross sections of sealed wall penetrations with a duct and a pipe (courtesy of Acentech Inc., Cambridge MA)

in an installation. As much as possible, it is best to keep active pipes, especially for toilets, out of common walls with acoustically sensitive spaces.

11.5.4 Electrical Systems

Electrical system noise control issues typically deal with transformer noise control and the vibration channel set up by rigid conduit between noise and vibration sources and noise-sensitive spaces. When transformers cause noise issues, they are most commonly addressed by enclosing and vibrationally isolating the transformers. Conduit issues can be addressed by using a flexible conduit that is not stretched. Figure 11.64 shows an example of stretched electrical conduit, which provides a clear vibration channel from the source to remote locations.

An air space between an electrical box and other equipment will break any vibration channel that
Fig. 11.62 General considerations for sealing pipe penetrations (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.63 Examples of sealed pipe and duct penetrations

Fig. 11.64 An example of stretched flexible conduit

Fig. 11.65 An example of separating an electrical box from mechanical equipment to isolate vibrations

would otherwise have been established, as is shown in Fig. 11.65.

11.5.5 Exterior Sources

Environmental noise sources, such as transportation or industrial sources, can only be controlled in buildings by using exterior-wall designs that effectively reduce noise in the frequency ranges of those sources. Exterior noise sources, such as rooftop mechanical equipment or

mechanical equipment in lots beside buildings (associated with the operations of the building in question) can be controlled by appropriately designed enclosure systems. Figure 11.66 shows an enclosure for a rooftop HVAC unit and Fig. 11.67 shows an enclosure for a rooftop chiller unit.

Note in Fig. 11.66 the relief hoods that provide ventilation while directing the sound away from the community. When designing these types of enclo-

sures, it would be prudent to face any ventilation openings away from noise-sensitive locations, including skylights on the roof of the building supporting the unit. Figure 11.68 shows a chiller enclosure at ground level next to a building near a residential community.

11.6 Acoustical Privacy in Buildings

Privacy issues can be a concern for spaces in which speech is a predominant source. A partial list of these areas includes offices, dwelling units, classrooms, health care facilities, libraries, hotels, and motels. The office environment provides a good example of privacy concerns and how they are handled. These solutions can be used for sound privacy in most situations.

Fig. 11.66 An example of a rooftop HVAC unit enclosure (courtesy of Acentech Inc., Cambridge MA)

Fig. 11.67 An example of a rooftop chiller enclosure (courtesy of Acentech Inc., Cambridge MA)

11.6.1 Office Acoustics Concerns

The most common concerns related to office acoustics are privacy and distractions. Distractions can affect productivity. The concern for privacy has recently received much broader attention due to the passage of numerous privacy-protection laws by the US federal government and the European Parliament. Current legislation in the USA requires that the transfer of health records, in whatever format, conforms with requirements for privacy (through the Health Insurance Portability and Accounting Act of 1996). This includes privacy for digital transfer of health records between health care providers and presumably aural privacy as well. Similar concerns are also entering the realm of potential legislation for the financial world (through the Gramm Leach Bliley Financial Services Modernization Act of 1999, relating to privacy of financial transactions).

11.6.2 Metrics for Speech Privacy

Many metrics are available for rating office environments, particularly those related to speech privacy. Listed below are the most popular.
Fig. 11.68 An example of a ground-level chiller enclosure (courtesy of Acentech Inc., Cambridge MA)
Fig. 11.69 Correlation between articulation index and speech privacy (adapted from [11.8])

Articulation Index

Speech intelligibility and acoustics in open-plan offices have been rated in terms of the articulation index (AI) until recently (through ANSI S3.5), but AI is still being used by many consultants. AI is a measure of the ratio between a voice level and steady background noise (background noise from mechanical equipment, traffic, or electronic sound masking). AI was originally developed to evaluate communication systems, and has been widely used to assess conditions for speech intelligibility in rooms. AI values range from near 0 (low speech level and relatively high background noise resulting in poor intelligibility and good speech privacy) to 1.0 (high voice level and low background noise resulting in excellent communication and no speech privacy). When privacy is desired, it is necessary to have a low AI. When communication is desired, it is necessary to have a high AI so people can clearly understand speech.

Figure 11.69 shows how AI relates to speech privacy. This graph provides general guidelines from experience. Speech privacy goals are divided into three categories – minimal distraction, normal speech privacy, and confidential speech privacy. Minimal distraction corresponds to an AI of 0.35 or less. Normal speech privacy, in which the average person can work without distraction although occasional parts of outside conversations can be heard, corresponds to an AI of 0.20 or less. Confidential privacy, where the average person can carry on discussions with assurance that he or she will
Fig. 11.70a,b The most common paths for sound leakage between closed offices. (**a**) Plan view; (**b**) cross section (1-diffraction between openings, 2-transmission through partitions, 3-structure-borne transmission, 4-transmission through air gaps in wall seals, 5-diffraction through plenum when partition does not seal to structural deck, and 6-transmission through ductwork)

not be understood by neighbors, corresponds to an AI of 0.05 or less. There is no privacy when AI exceeds 0.40.

Speech Intelligibility Index

AI has been replaced by the speech intelligibility index (SII) in recent versions of ANSI S3.5. SII is still, like AI, a weighted speech-to-noise ratio. However, it is somewhat more complex to calculate than AI and includes revised frequency weightings and the masking effect of one frequency band on nearby frequency bands. Like AI, it has values that range between 0 and 1, but for the same conditions SII values are slightly higher than AI values.

Privacy Index

Low AI values indicate a higher degree of privacy. Since this may be confusing to laypersons who want to focus on better privacy conditions, a metric called privacy index (PI) has been published in ASTM E 1130. The

Table 11.9 AI, SII and PI for open plan offices

AI	SII	PI	Privacy condition	Office environment
> 0.65	> 0.75	< 35%	Good communication	Necessary when communication is desirable (conference rooms, classrooms, auditoriums, etc.)
> 0.40	> 0.45	< 60%	No privacy	Clear intelligibility of conversations and distraction
0.35	0.45	65%	Freedom from distraction	Reasonable work conditions not requiring heavy concentration or speech privacy; can hear and understand neighboring conversations
0.20	0.27	80%	Normal speech privacy	Only occasional intelligibility from a neighbor's conversation; work patterns not interrupted
< 0.05	< 0.10	> 95%	Confidential speech privacy	Aware of neighbor's conversation but it is not intelligible

Privacy Index (PI) is defined as:

$$PI = (1 - AI) \times 100 , \qquad (11.9)$$

presented as a percentage. Higher PI values indicate more privacy; lower PI values indicate less privacy. For example, an AI of 0.10 corresponds to a PI of 90%.

Generally accepted practice for the design of open-plan offices refers to two levels of speech privacy. *Confidential privacy* is defined as a condition in which speech may be detected but not understood. *Normal privacy* allows modest amounts of intelligibility, but normal work patterns are usually not interrupted. These terms are standardized in ASTM E 1374.

Table 11.9 compares AI, SII, and PI for the same types of communication and privacy conditions.

Articulation Class

In an open-plan office, the effectiveness of the ceiling in determining noise reduction is partially related to the height of the barrier that separates two workstations, the distance between a talker and listener, and the absorption characteristics. Therefore, another metric has been developed to describe a ceiling's contribution to noise reduction between typical work areas. This is the articulation class (AC), measured in an office mock-up environment in accordance with ASTM E 1110 and E 1111. The AC is the sum of the weighted sound attenuation numbers in a series of 15 test bands for a carefully specified office layout, barrier height, and ceiling height. AC values usually exceed 100 and typically range from about 150 to 220, with higher values indicating more privacy and less speech intelligibility. AC only considers the effects of noise reduction while AI, SII, and PI also consider the effects of speech level and spectrum characteristics, and background level and spectrum characteristics. Subjective ratings of AC for levels of privacy (like those listed in Table 11.9) have not been analyzed at this time.

Speech Interference Level

The international community uses the speech interference level (SIL), as defined in ISO 9921-1, to rate speech communication environments. SIL is defined as the arithmetic average of sound pressure levels in the ambient environment at the 500, 1000, 2000, and 4000 Hz octave-band frequencies. SIL can also be approximated by subtracting 8 dB from the overall dBA ambient level. Speech intelligibility is rated by the difference between the SIL and the A-weighted sound pressure level of speech at the listener's location. If this signal-to-noise ratio exceeds 10 dB, that indicates satisfactory speech communication. Table 11.10 shows general characteristics of assessing speech intelligibility against this signal-to-noise ratio.

Speech Transmission Index

While the metrics above are typically used for office environments to rate privacy between spaces, there is another metric that is widely used to describe speech intelligibility within performance and lecture spaces. This metric, known as the speech transmission index (STI), can be measured with commercially available instruments, often in terms of the metric known as the rapid speech transmission index (RASTI) to stream-

Table 11.10 ISO 9921-1 speech intelligibility ratings based on SIL

Signal-to-noise ratio at listener's position (dBA-SIL)	Speech intelligibility rating
< −6	Insufficient
−6 to −3	Unsatisfactory
−3 to 0	Sufficient
0 to 6	Satisfactory
6 to 12	Good
12 to 18	Very good
> 18	Excellent

line the monitoring effort. STI measurements consider octave-band levels between 125 and 8000 Hz while RASTI measurements only consider octave-band levels at 500 and 2000 Hz. STI measurement procedures are standardized in the International Electrotechnical Commission (IEC) standard IEC 60268-16. STI, as AI and SII, ranges from 0 to 1 and, unlike AI and SII, STI takes room reverberation into account in its calculations. The meanings of STI ratings are generally similar to those for SII, with higher values being good for speech intelligibility and bad for privacy, and low values representing the opposite. While STI can be measured directly with instruments, AI and SII cannot.

Ceiling Attenuation Class

With current lightweight construction, walls often do not extend to the structure. In these cases, the path for sound through the ceiling plenum is the weakest sound path between offices. This sound path is rated with a ceiling attenuation class (CAC) that is analogous to an STC rating. The CAC value is measured in accordance with ASTM E 1414 and measures the sound transfer from one standard-sized office through an acoustic tile ceiling, then into a standard plenum, and then back into the neighboring office again through an acoustic tile ceiling. Mineral fiber acoustic tiles typically have a rating of CAC 35–39. Fiberglass tiles have significantly lower CAC values. In cases where there is a return air grille in the ceiling so air can be exhausted through the plenum, the field performance will also be significantly degraded.

11.6.3 Fully Enclosed Offices

If confidential privacy is required, employees must be located in closed offices with sealed doors and walls that extend to the structural ceiling. This point needs to be stressed because many closed offices are designed with unsealed doors and walls extending to suspended, nonstructural ceilings, allowing space for HVAC and electrical equipment. Typical suspended ceilings provide acoustic absorption for reflected sound but provide little in the way of transmission loss. This means that sound will travel through suspended ceiling panels and over walls as if the walls are barriers, thus limiting the acoustic privacy of these offices almost to the open-plan condition. Figure 11.70 shows the most common sound leakage paths between closed offices.

Speech privacy between two rooms, in general, is a function of two key parameters – noise reduction and background noise level. One must not only reduce the sound level of the unwanted source, but one must also generate sufficient background noise to mask the unwanted source, making it less intelligible and less distracting. Confidential speech privacy can be achieved in closed offices by using walls having a high transmission loss. If these types of walls are used, the background sound levels can remain low. However, for normal speech privacy in an open-plan office, one must strike a balance between a lower transmission loss (because of the limited effectiveness of barriers) and a higher background noise level (that can often be set using an electronic masking system).

For typical contemporary offices, the range of construction options is often limited to just the number of layers of gypsum board on the wall, the type of stud framing, and whether or not there will be insulation in the cavity of the wall. A single metal stud with a single layer of gypsum board on each side of the stud and no insulation in the cavity will have a performance in the range of STC 40. If the layers of gypsum board are doubled (that is, two layers on each side), then the overall STC value will increase by about 5 STC points. There is negligible difference between the performance of the wall with gypsum board that is 1.2 cm thick or 1.6 cm thick. Insulation in the cavity of a wall with a single stud may provide an additional 3–5 STC points performance. Wood studs instead of metal studs can provide a more rigid path for the transfer of sound (in a single-wall design), and may degrade the performance by 3–5 STC points. Further improvements above STC 50 require the use of resilient channels or staggered stud framing, as discussed in Sect. 11.5.1.

11.6.4 Open-Plan Offices

The open-plan office design has become very popular through the latter half of the 20th century and into the 21st. This design scheme saves money, promotes teamwork, and improves flexibility for future renovations. Many employees, however, view this design as a series of compromises in terms of space, prestige, and (most of all) privacy. As employees consider changing from the traditional closed office to open-plan cubicles, they often have concerns about their abilities to work productively in what they anticipate to be a noisier, more distracting workplace. The overwhelming complaint about open-plan office design is the lack of acoustic privacy.

The first step in the acoustic design of an office is to determine the needs of the employees in each area. Employees in some companies may need to communicate freely as part of their jobs. These workers
Fig. 11.71 Acoustic considerations for open-plan office design in cross section
Fig. 11.72 Acoustic considerations for open-plan office design in plan view

Fig. 11.73 Acoustical considerations for open-plan office layout

would not need any acoustic privacy. Some may need visual privacy (using barriers that block their line of sight with others) but need only a minimal amount of speech privacy. Some may require an environment free from distractions for the performance of detailed work. It is often this last category of employees that feels most compromised by being moved into cubicles. This category of employee needs normal speech privacy, in which conversations in adjacent areas can be understood but are not distracting to concentration on tasks. Normal speech privacy is attainable for open-plan offices with the proper acoustic design.

Confidential speech privacy, in which no part of a conversation can be understood from an adjacent space, cannot be expected from open-plan office designs.

Assuming a goal of normal speech privacy, there are three acoustic design principles that must be addressed to achieve that goal in an open-plan office. These three principles are to absorb, block and cover speech in

nearby workstations. These three principles are briefly discussed below.

Absorption

It is critical to have as much absorption as possible in rooms designed for open-plan offices. This will stop sound from reflecting off room surfaces to travel appreciable distances and from causing remote distractions. If one has to choose surfaces for absorptive treatment, the ceiling is the most critical surface to start with. This is because reflections off ceilings significantly compromise the already limited noise reduction capabilities of barriers. Ceiling finishes should have NRC ratings of at least 0.90 or an AC of at least 180. Ceiling treatments can be part of suspended ceilings or surface-applied. Hard, sound-reflecting lighting fixtures can degrade the performance of the ceiling finish, so it is ideal to use indirect floor lighting to keep the ceiling as absorbing as possible. If ceiling fixtures must be used, parabolic fixtures are more appropriate than others because they diffuse the sound more evenly. Figure 11.71 shows ceiling considerations. Absorptive finishes are also important on the interior of workstation panels and on any walls that may reflect sound from one cubicle to another. Figure 11.72 shows how to place absorptive materials strategically on walls to eliminate reflected paths between cubicles. Carpeting is important for floors to control impact noise (such as footfalls, dropped objects and furniture movement) as well as to absorb reflected sound energy.

Blocking

Sound is blocked in open-plan offices by cubicle barriers. To be most effective, these barriers must be designed to minimize the compromises caused by diffraction. In this regard, barriers should be at least 1.5 m tall and should have STC ratings of at least 25. The amount by which STC ratings exceed 25 will not make a difference in barrier performance (because of diffraction). They should be arranged to block the line of sight between workers (as is shown in Fig. 11.73) and should be flush with floors, window sills, and side walls.

Masking

A typical contemporary office, with sealed windows and properly maintained HVAC systems, often has too low of a background noise level to allow for normal speech privacy. The most practical way to improve privacy under these conditions is to increase the background noise level by adding an electronic sound masking system. These systems can include loudspeakers distributed throughout ceiling plenums, hanging unobtrusively from ceilings, or in each cubicle. These systems, when set up properly, sound like typical HVAC noise to employees. Figure 11.21 shows a typical spectrum for sound masking systems.

11.6.5 LEED Participation

The U.S. Green Building Council has established a rating system for the environmental friendliness of buildings through Leadership in Energy and Environmental Design (LEED) criteria. The LEED certification process has minimum requirements and potential for advanced credits for acoustics in the design of educational and health care facilities, both through the indoor environmental quality (IEQ) category.

The LEED schools guidelines offer minimum performance requirements [11.9] and the potential for an extra point of credit for enhanced acoustical performance [11.10]. Both of these are meant to optimize the learning environment by offering learning spaces with clear communications free of limiting reverberation or background noise. In each case, the limits are based on criteria listed in ANSI Standard S12.60 for all core learning spaces. Reverberation requirements can be satisfied by using absorptive materials on the ceiling having a minimum NRC of 0.70. Background noise is rated in terms of HVAC noise and the STC ratings of perimeter walls of core learning spaces. For the minimum performance category, HVAC noise must be 45 dBA or less in all core learning spaces and for an extra credit point for enhanced acoustical performance, HVAC noise is limited to 40 dBA or less.

The LEED healthcare facilities requirements are based on the premise of providing environments free of intrusive or disruptive sound to promote the healing process. Similar issues to those for schools, such as reverberation, background noise, and sound insulation, are the bases for this rating as well, but the criteria are based on the latest version of the Facility Guidelines Institute (FGI) Guidelines and associated Sound and Vibration Design Guidelines for Health Care Facilities [11.11]. In this rating system, there are two credit points available, one point for minimum sound insulation, speech privacy, and background room noise requirements, and another point for meeting the minimum requirements plus minimizing reverberation and considering exterior noise sources in building designs. This second point includes performing measurements to ensure compliance with the criteria. The requirements and associated methods are spelled out in the LEED [11.12] and FGI guidelines.

11.7 Relevant Standards

The following standards are referenced in this chapter:

US Standards

ANSI (American National Standards Institute)

S3.5 Standard Methods for Calculation of the Speech Intelligibility Index
S12.2 Standard Criteria for Evaluating Room Noise
S12.60 Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools

ASTM (American Society of Testing and Materials)

C 423 Standard Test Method for Sound Absorption and Sound Absorption Coefficients by the Reverberation Room Method
E 90 Standard Test Method for Laboratory Measurement of Airborne Sound Transmission Loss of Building Partitions and Elements
E 413 Classification for Rating Sound Insulation
E 492 Standard Test Method for Laboratory Measurement of Impact Sound Transmission Through Floor-Ceiling Assemblies Using the Tapping Machine
E 989 Standard Classification for Determination of Impact Insulation Class (IIC)
E 1041 Standard Guide for Measurement of Masking Sound in Open Offices
E 1110 Standard Classification for Determination of Articulation Class
E 1111 Standard Test Method for Measuring the Interzone Attenuation of Ceiling Systems

E 1130 Standard Test Method for Objective Measurement of Speech Privacy in Open Offices Using Articulation Index
E 1179 Standard Specification for Sound Sources Used for Testing Open Office Components and Systems
E 1332 Standard Classification for Determination of Outdoor–Indoor Transmission Class

Part D Hearing and Signal Processing

12. Physiological Acoustics

Eric D. Young

The analysis of sound in the peripheral auditory system solves three important problems. First, sound energy impinging on the head must be captured and presented to the transduction apparatus in the ear as a suitable mechanical signal; second, this mechanical signal needs to be transduced into a neural representation that can be used by the brain; third, the resulting neural representation needs to be analyzed by central neurons to extract information useful to the animal. This chapter provides an overview of some aspects of the first two of these processes. The description is entirely focused on the mammalian auditory system, primarily on human hearing and on the hearing of a few commonly used laboratory animals (mainly rodents and carnivores). Useful summaries of non-mammalian hearing are available [12.1]. Because of the large size of the literature, review papers are referenced wherever possible.

12.1 The External and Middle Ear

The external and middle ears capture sound energy and couple it efficiently to the cochlea. The problem that must be solved here is that sound in air is not efficiently absorbed by fluid-filled structures such as the inner ear. Most sound energy is reflected from an interface between air and water, and terrestrial animals gain up to 30 dB in auditory sensitivity by virtue of their external and middle ears.

Comprehensive reviews of the external and middle ears are available [12.2, 3]. Figure 12.1 shows an anatomical picture of the ear (Fig. 12.1a) and a schematic showing the important signals in this part of the system (Fig. 12.1b). The external ear collects sound from the ambient field (p_F) and conducts it to the eardrum where sound pressure fluctuations (p_T) are converted to mechanical motion of the middle-ear bones, the malleus (with velocity v_M), the incus, and the stapes; the velocity of the stapes (v_S) is the input sig-

nal to the cochlea, producing a pressure p_V in the scala vestibuli. The following sections describe the properties of the transfer function from p_F to p_V.

12.1.1 External Ear

The acoustical properties of the external ear transform the sound pressure (p_F) in the free field to the sound pressure at the eardrum (p_T). Two main aspects of this transformation important for hearing are:

1. Efficient capture of sound impinging on the head; and
2. The directional sensitivity of the external ear, which provides a cue for localization of sound sources.

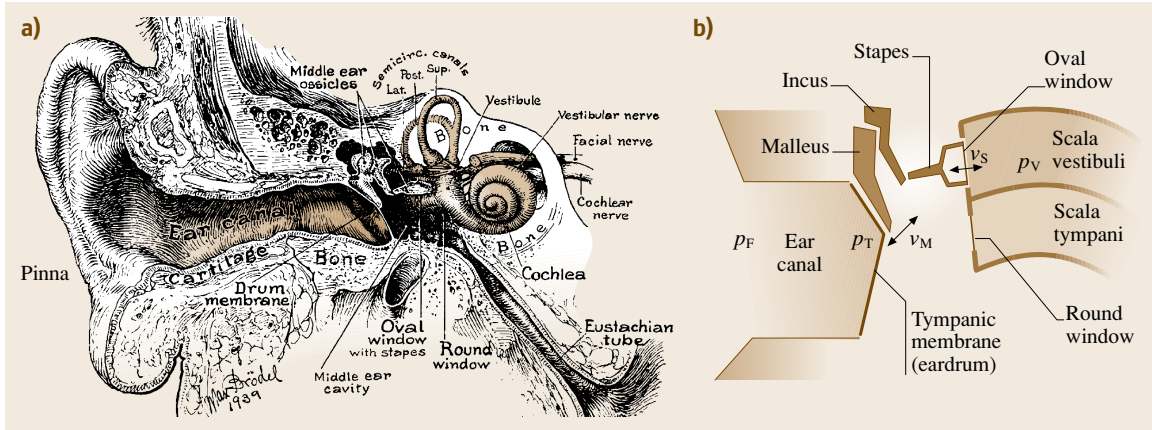
Figures 12.2a and 12.2b show external-ear transfer functions for the human and cat ear, These are the dB ratio of the sound pressure near the eardrum p_T (see


Fig. 12.1 (a) Drawing of a cross section of the human ear, showing the pinna, the ear canal, eardrum (drum membrane), middle-ear bones (ossicles), and the labyrinth. The latter contains the vestibular organs of balance and the cochlea, or inner ear (after [12.8]). **(b)** Schematic of the mammalian external and middle ears showing the signals referred to in the text. The middle-ear bones are the malleus, incus, and stapes. The stapes terminates on the cochlea, on a flexible membrane called the oval window. The velocity of the stapes (v_S) is the input signal to the cochlea; it produces a pressure variation p_V in the fluids of the scala vestibuli, one of the chambers making up the cochlea. The structure of the cochlea and definitions of the scala vestibuli and scala tympani are shown in a later figure. The function of the external and middle ears is to capture the energy in the external sound field p_F and transfer it to stapes motion v_S or equivalently, sound pressure p_V in the scala vestibuli

the caption) to the sound in free field (p_F). The free-field sound p_F is the sound pressure that would exist at the approximate location of the eardrum if the subject were removed from the sound field completely. Thus the transformation from p_F to p_T contains all the effects of putting the subject in the sound field, including those due to refraction and reflection of sound from the surfaces of the body, the head, and the ear and the effects of propagation down the ear canal. In each case several transfer functions are shown. The dotted lines show p_T/p_F for sound originating directly in front of the subject [12.4, 5]; these curves are averaged across a number of ears. The solid lines show transfer functions measured in one ear from different locations in space [12.6, 7]. These have a fixed azimuth (i. e., position along the horizon, with 0° being directly in front of the subject) and vary in elevation (again 0° is directly in front) in the median plane. Elevations are given in the legends. External-ear transfer functions differ in detail from animal to animal. In particular, the large fluctuations at high frequencies, above 3 kHz in the human ear and 5 kHz in the cat ear, differ from subject to subject. These fluctuations are not seen in the averaged ears because they are substantially reduced by averaging across subjects, although some aspects of them remain [12.7]. However, the general features illustrated here are typical.

Capture of Sound Energy by the External Ear

Over most of the range of frequencies, the sound pressure is higher at the eardrum than in the free field in both the human (Fig. 12.2a) and the cat (Fig. 12.2b) subjects. The amplification results from resonances in the external ear canal and in the cavities of the pinna; the resonances produce the broad peak between 2 and 5 kHz [12.2]. Although this seems to be an amplification of the sound field, the pressure gain is not by itself sufficient to specify fully the sound-collecting function of the external ear, because it is really the power collection that is important and sound power is the product of pressure and velocity. A useful summary measure of power collection is the effective cross-sectional area of the ear a_{ETM} [12.2, 9]. a_{ETM} measures the ear's ability to collect sound from a diffuse pressure field incident on the head, in the sense that the sound power into the middle ear is equal to a_{ETM} multiplied by the power density in the sound field. If a_{ETM} is larger (smaller) than the anatomical area of the eardrum, for example, it means that the external ear is more (less) efficient at collecting sound than a simple eardrum-sized membrane located on the surface of the head.

Figure 12.2c shows calculations of the magnitude of a_{ETM} for the cat and human ear [12.2]. For comparison,

b) p_T/p_F (dB)

c) a_{ETM} (cm^2)

Frequency (kHz)

Fig. 12.2a–c Transformation of sound pressure by the external ear, considered as the ratio p_T/p_F for the human ear (**a**) and the cat ear (**b**). p_T is the pressure measured by a probe microphone in the ear canal, within 2 mm of the eardrum for all cases except the *solid curves* in (**a**), which show the pressure at the external end of the ear canal, with the ear canal blocked. The *dashed curves* are averaged across many ears, with the sound originating straight ahead, and the *solid curves* are data from one ear at various sound-source directions. The *numbers* next to the curves or in the legend identify the elevation of the sound source relative to the head. In both cases, the azimuth of the source is fixed. (**c**) Capture of sound energy by the external ear, considered as the effective cross-sectional area of the ear, mapped to the eardrum and plotted versus frequency. Curves for the cat and human ear are shown. The *shaded bar* shows the range of cross-sectional areas of the ear canal, for comparison. (Fig. 12.2a after [12.4,7]; Fig. 12.2b after [12.5,6]; Fig. 12.2c after [12.2]) ◄

3. Increase in the impedance of the middle ear at low frequencies, decreasing the ability of the ear to absorb sound.

Figure 12.2c shows that the external ear can be considered as an acoustical horn that captures sound and couples it to the eardrum. A feeling for the effectiveness of the external ear's sound collection can be gotten by comparing the values of a_{ETM} to the cross-sectional area of the ear canal, which is $0.2-0.4$ cm^2 in cat, shown by the shaded bar [12.10].

Directional Sensitivity

Directional sensitivity means that the transfer function of the external ear depends on the direction to the sound source. As a result, the spectra of broadband sounds (like noise) will be different, depending on the direction in space from which they originate. Listeners, both humans and non-human mammals, are sensitive to these differences and are able to extract sound localization information from them. For example, human observers use these so-called *spectral cues* to localize sounds in elevation and to disambiguate binaural difference cues, helping to distinguish sounds in front and behind the listener [12.11]. Cats depend on spectral cues to localize sounds in the frontal plane, both in azimuth and elevation [12.12].

The directional sensitivity of the external ear is generated by sound reflecting off the structures of the pinna. In humans the pinna is the cartilaginous structure attached to the external ear canal on the side of the head,

the horizontal line shows the cross-sectional area of the external opening of the cat's pinna. Around $2-3$ kHz, a_{ETM} equals the pinna area for the cat. The dotted line marked *ideal* is the maximum possible value of a_{ETM}, based on the power incident on a sphere in a diffuse field [12.2, 9]. At frequencies above 2 kHz, the cat ear is close to this maximum and the human ear is somewhat lower. At these frequencies, the external ear is collecting the sound power in a diffuse field nearly as efficiently as is possible. At lower frequencies, the efficiency drops rapidly; *Shaw* [12.9] attributes the drop off to three effects:

1. Loss of pressure gain below the canal resonance
2. Increase in the wavelength of sound compared to the size of the ear

and includes the cavities that lead to the entrance of the ear canal [12.13, 14]. In the cat, the pinna is a collection of similar cartilaginous shapes and cavities leading to the ear canal, most of which are located on the surface of the head at the ear canal opening. The external auricle, which forms the movable part of the cat's ear, serves as an additional sound collector and a way for the cat to change the directionality of its ear under voluntary control [12.15]. The nature of spectral cues in human and cat are shown in Figs. 12.2a,b. The most prominent spectral cue is the notch at mid frequencies (3–10 kHz in human and 7–20 kHz in cat). The notch is created as an interference pattern when sound propagates through the pinna. Essentially, there are multiple sound paths through the pinna due to reflections. These echoed sounds reach the ear canal after variable delays, depending on the path taken. At the ear canal, sounds can cancel at frequencies where the delays are approximately a half-cycle. The interference patterns so generated produce the notches shown in Fig. 12.2. The notches occur at relatively high frequencies, where the wavelength of sound is comparable to the lengths of the reflection paths in the pinna. In cats, the notch moves toward higher frequencies as the elevation (or the azimuth, not shown) increases [12.6, 16]. At higher frequencies, above 10 kHz in humans and 20 kHz in cat, there are additional complex changes in the transfer function of the external ear that are not easily summarized. Cats appear to be sensitive to spectral cues at all frequencies, but use the notch for localizing sounds and the higher-frequency characteristics for discriminating the locations of two sounds [12.17].

12.1.2 Middle Ear

The function of the middle ear is to transfer sound from the air to the fluids of the cochlea (e.g., from p_T to p_V in Fig. 12.1b). The process can be considered as an impedance transformation [12.18]. The specific acoustic impedance of a medium is the ratio of the sound pressure to the particle velocity of a plane wave propagating through the medium and is a property of the medium itself. When sound impinges on an interface between two media with different impedances, such as an air–water interface, energy is reflected from the boundary. In the case of air and water, the air is a low-impedance medium (low pressure, large velocity) and the water is high impedance medium (high pressure, low velocity). At the boundary, the pressure and velocity must be continuous, i.e. equal across the boundary.

If the pressure is equal across the boundary, then the velocities must be different, larger in air than in water because of the differing impedances. A reflection occurs to allow both boundary conditions to be satisfied, i.e., the boundary conditions can only be satisfied by creating a third reflected wave at the boundary. The reflected wave, of course, takes energy away from the wave that propagates through the boundary. Maximum energy transfer across the boundary occurs when the impedance of the source medium equals that of the second medium (no reflection). In the middle ear, the challenge is to transform the low impedance of air to the high impedance of the cochlea, so as to couple as much energy as possible into the cochlea.

The function of the middle ear as a impedance transformer is schematized in Fig. 12.3a which shows a drawing of the eardrum and the ossicles in approximately the anatomically correct position. In this model, the eardrum and oval window are assumed to act as pistons and the ossicles are assumed to act as a lever system, rotating approximately in the plane of the figure around the axis shown by the white dot in the head of the malleus [12.3]. The area of the eardrum (A_{TM}) is larger than the area of the oval window (A_{OW}), which increases the pressure by the ratio $p_V/p_T = A_{TM}/A_{OW}$. The difference in the lengths of the malleus and incus further increases the pressure by the lever ratio L_M/L_I, and decreases the velocity by the same amount. Thus the net pressure ratio is $A_{TM}L_M/A_{OW}L_I$. The area ratio amounts to a factor of 10–40 and the lever ratio is about 1.2–2.5 in mammalian ears [12.3]. For the cat, the pressure ratio should be about 36 dB. The impedance change is the ratio of the pressure and velocity ratios, $A_{TM}/A_{OW}(L_M/L_I)^2$, which is about 29 for the human ear [12.18]. This is less than the ideal value of 3500 for an air–water interface or 135 estimated for an air–cochlea interface, but is still a significant improvement (about 15 dB).

In reality, the motion of middle-ear components is more complex than is assumed in this model [12.2]. First, the eardrum does not displace as a simple piston; second the malleus and incus undergo a more complex motion than the one-dimensional rotation assumed in Fig. 12.3a; and third, there are losses in the motion of the ossicles that are not included in the model. Figure 12.3b shows a comparison of the actual pressure transformation in the middle ear of a cat, given as p_V/p_T. The dashed line is the prediction of the transformer model (36 dB). The cat ear gives a smaller pressure p_V than the transformer model for the rea-

a)

d) a_{EOW} (cm^2)

Fig. 12.3 **(a)** Schematic drawing of the mammalian middle ear from the eardrum (TM on the *left*) to the oval window (OW on the *right*). The malleus, incus, and stapes are shown in their approximate anatomical arrangement. The areas of the TM and OW are shown along with the lever arms of the malleus (L_M) and incus (L_I). These lever arms are drawn as if the malleus and incus rotate in the plane of the paper around an axis indicated by the *white dot*. In reality, the motion is more complex. **(b)** Ratio of the sound pressure in scala vestibuli (p_V) to the sound pressure at the eardrum (p_T) as a function of frequency, from measurements by *Décory* (unpublished doctoral thesis, 1989 [12.2]). The *dashed line* is the prediction of the model in **(a)** for typical dimensions of the cat middle ear. **(c)** Transfer admittance of the middle ear in human and cat, given as the velocity at the stapes (v_S) divided by the pressure at the eardrum (p_T). **(d)** Performance of the external and middle ears in sound collection plotted as the effective area of the ear, referenced to the oval window. This is the cross-sectional area across which the ear collects sound power in a diffuse sound field, plotted against frequency; the *shaded bar* shows the range of cross sectional areas of the oval window for comparison. Comparing with Fig. 12.2c shows the effect of the middle ear (after [12.2]) ◄

as a transfer admittance from the eardrum pressure p_T to the velocity in the cochlea v_S.

The overall function of the external and middle ears in collecting sound from a diffuse field in the environment and delivering it to the cochlea is shown in Fig. 12.3d [12.2]. This figure plots the effective area of the ear as a sound collector as in Fig. 12.2c, except now it refers to the sound power delivered to the oval window. Again, the dashed line shows the performance of an ideal spherical receiver and is the same line as in Fig. 12.2c. The effective area has a bandpass shape, as in Fig. 12.2c, with a maximum at 3 kHz. The sharp drop off in performance below 3 kHz was seen in the external ear analysis and occurs because energy is not absorbed at the eardrum at low frequencies. At higher frequencies the effective area tracks the ideal receiver, but is about 10−15 dB smaller than the performance at the eardrum, which approximates the ideal for the cat. This decrease reflects the losses in the middle ear discussed above. Although the external and middle ear do not approach ideal performance, they do serve to couple sound into the cochlea. As a comparison to the effective area in Fig. 12.3d, the cross-sectional area of the oval window is about 0.01−0.03 cm^2 in the cat and human (shaded

sons listed above, along with the fact that additional impedances in the middle ear must be considered when doing this calculation, such as the middle-ear cavity behind the eardrum, whose air is compressed and expanded as the eardrum moves [12.2]. Figure 12.3c shows the transfer function as it is usually displayed,

bar). Thus the effective area is larger than the area of the oval window over the mid frequencies. Moreover, if there were no middle ear, the collecting cross section of the oval window would be smaller by about 15–30 dB because of the impedance mismatch between the air and cochlear fluids [12.19].

12.2 Cochlea

The cochlea contains the ear's transduction apparatus, by which sound energy is converted into electrical activity in nerve cells. The conversion occurs in transduction cells, called inner hair cells, and is transferred to neurons in the auditory nerve (AN) that connect to the brain. However the function of the cochlea is more than a transducer. The cochlea also does a frequency analysis, in which a complex sound such as speech or music is separated into its component frequencies, a process not unlike a Fourier or wavelet transform. Auditory perception is largely based on the frequency content of sounds; such features as the identity of sounds (which speech sound?), their pitches (which musical note?), and the extent to which they interact in the ear (e.g., to make it hard to hear one sound because of the presence of another) are determined by the mixture of frequencies making them up (Chap. 13).

In this section, the steps in the transduction process in the inner ear or cochlea are described. The problems solved in this process include frequency analysis, mentioned above, but also regulating the sensitivity of process. Transduction must be very sensitive at low sound levels, so that sounds can be detected near the limit imposed by Brownian motion of the components of the cochlea [12.20]. At the same time, the cochlea must function over the wide dynamic range of sound intensities (up to 100 dB or more) that we encounter in the world. Responses to this wide dynamic range must be maintained in neurons with much more limited dynamic ranges, 20–40 dB [12.21]. In part this is accomplished by compressing the sound in the transduction process, so that acoustic sound intensities varying over a range of 60–100 dB are mapped into neural excitation over a much more limited dynamic range. Thus cochlear sensitivity must be high at low sound levels to allow soft sounds to be heard and must be reduced at high sound levels to maintain responsiveness without saturation. Both frequency tuning and dynamic-range adjustment depend on the same cochlear element, the second set of transducer cells called outer hair cells. Whereas inner hair cells convey the representation of sound to the AN, the outer hair cells participate in cochlear transduction itself, making the cochlea more sensitive, increasing its frequency selectivity, and compressing its dynamic range. These processes are described in more detail below.

The remainder of this chapter assumes some knowledge of neural excitation and synaptic transmission. These subjects are too extensive to review here, but can be quickly grasped from an introductory text on neurophysiology or neuroscience.

12.2.1 Anatomy of the Cochlea

The inner ear consists of the cochlea and the AN. The cochlea contains the transduction apparatus; it is a coiled structure, as shown in Fig. 12.1a. A cross-sectional view of a cochlea is shown in Fig. 12.4a. This figure is a low-resolution sketch that is provided to show the locations of the major parts of the structure. The section is cut through the center of the cochlear coil and shows approximately 3.5 turns of the coil. The cochlea actually consists of three fluid-filled chambers (or scalae) that coil together. A cross section of one turn of the spiral showing the three chambers is in Fig. 12.4b. The scala tympani (ST) and scala media (SM) are separated by the basilar membrane, a complex structure consisting of connective tissue and several layers of epithelial cells. The scala vestibuli (SV) is separated from the SM by Reissner's membrane, a thin epithelial sheet consisting of two cell layers. Reissner's membrane is not important mechanically in the cochlea and is usually ignored when discussing cochlear function. In the following, the mechanical properties of the basilar membrane are discussed without reference to the Reissner's membrane and it is usual to speak of the basilar membrane as if it separated the SV and ST.

What Reissner's membrane does do is to separate the fluids of the SV from the SM. The fluids in the SV and ST are typical of the fluids filling extracellular spaces in the body; this fluid, called *perilymph* is basically a dilute NaCl solution, with a variety of other constituents but with low K^+ concentration. In contrast, the fluid in SM, called *endolymph*, has a high K^+ concentration with low Na^+ and Ca^{2+} concentrations. Such a solution is rare in extracellular spaces, but is commonly found bathing the apical surfaces of hair cells in sensory organs from insects to mammals, suggesting

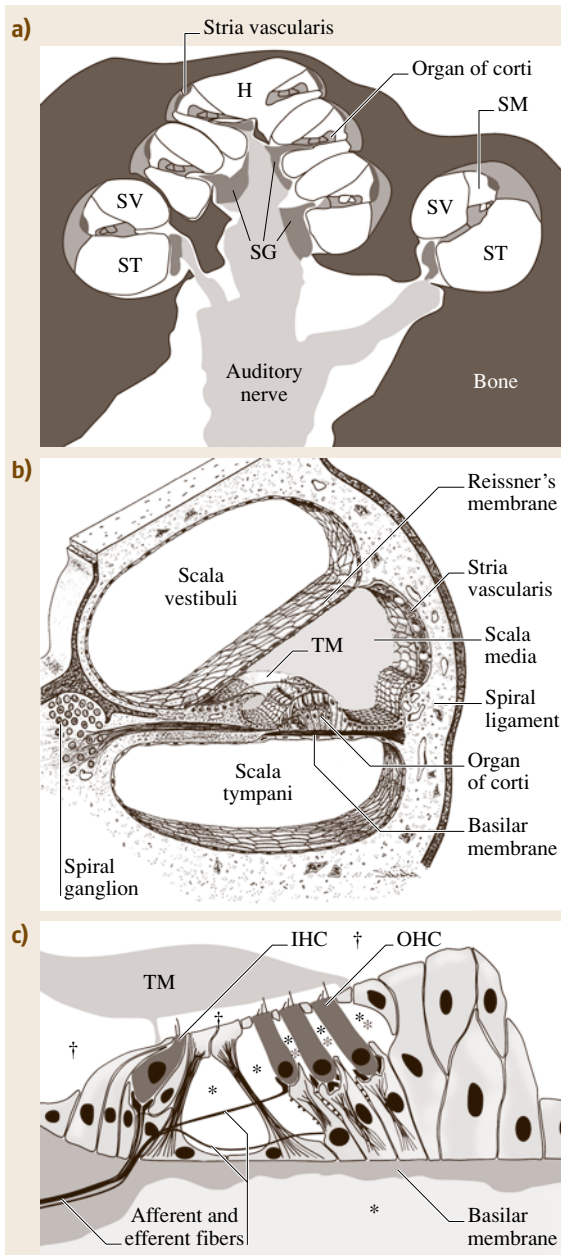

Fig. 12.4 (a) Sketch of a cross section of the cochlea, cut through the center of the coil. The cochlear spirals are cut in cross section, shown at higher resolution in (b). The cochlea consists of three fluid-filled chambers that spiral together: [ST1]ST – scala tympani, SV – scala vestibuli, and SM – scala media. H is the helicotrema, a connection between the SV and ST at the apex of the cochlea. The cochlear transducer has three essential functional parts: 1 – the basilar membrane which separates the SM and ST; 2 – the organ of Corti, which contains the hair cells, and 3 – the stria vascularis which secretes the fluid in the SM and provides an energy source to the transducer. The AN fibers have their cell bodies in the spiral ganglion (SG); their axons project to the brain in the AN. (b) Cross section of the cochlear spiral showing the three scalae. The scalae are fluid-filled; the SV and ST contain perilymph. The SM contains endolymph. (c) Schematic drawing of the organ of Corti showing the inner (IHC) and outer hair cells (OHC) and several kinds of supporting cells. The spaces containing perilymph are marked with *asterisks* and the spaces containing endolymph with *daggers* (†). TM is the tectorial membrane, which lies on the organ of Corti and is important in stimulating the hair cells. Nerve fibers enter the organ from the SG (off to the left). Both afferent and efferent fibers are present. Afferents are the SG neurons that are connected synaptically to hair cells, mainly IHCs, and carry information to the brain. Efferents are the axons of neurons located in the brain which connect to OHCs and to the afferents under the IHCs (Fig. 12.5) (after [12.23]) ◀

apparatus, shown in more detail in Fig. 12.4c. The organ of Corti consists of supporting cells and hair cells. There are two types of hair cells, called inner (IHC) and outer (OHC), because of their positions. The AN fibers and their cell bodies in the spiral ganglion (SG in Fig. 12.4a) occupy the center of the cochlear coil. Spiral ganglion cells have two processes: a distal process that invades the organ of Corti and innervates one or more hair cells, usually an IHC, and a central process that travels in the AN to the brain.

The arrangement of the nerve fibers in the cochlea is reviewed in detail by *Ryugo* [12.24] and by *Warr* [12.25] and is summarized in Fig. 12.5. Both afferent and efferent fibers are present. The afferents are the neurons mentioned above with their cell bodies in the SG which carry information from the hair cells to the brain. The efferents are the axons of neurons in the brain that terminate in the cochlea and allow central control of cochlear transduction.

Considering the afferents firsts, there are two groups of SG neurons, called type I and type II. Type I neurons

that the high potassium concentration is important for hair-cell function. The endolymph is generated in the stria vascularis, a specialized epithelium in the lateral wall of the SM by a complex multicellular active-transport system [12.22].

Mounted on the basilar membrane is the organ of Corti, which contains the actual cochlear transduction
Fig. 12.5 A schematic of the wiring diagram of the mammalian cochlea. The hair cells are on the left. Afferent terminals on hair cells, those in which the hair cell excites an AN fiber, are shown *lightly shaded*; efferent terminals, in which an axon from a cell body in the central nervous system contacts a hair cell or another terminal in the organ of Corti, are shown *heavily shaded*. All the synapses in the cochlea are chemical. Inner hair cells (IHC) are contacted by the distal processes of AN fibers. These fibers have bipolar cell bodies in the spiral ganglion; their axons are myelinated and travel centrally (type I fibers) to innervate principal neurons in the cochlear nucleus (CN). Outer hair cells (OHC) are innervated by a small population of type II spiral ganglion cells whose axons terminate in granule cell regions in the CN. The efferent fibers to the cochlea are called olivocochlear neurons; they originate in the superior olivary complex (SOC, box at lower right), another part of the central auditory system. There are two kinds of efferents: the medial olivocochlear system (MOC), originates near the medial nucleus of the SOC and innervates OHCs. The lateral olivocochlear system (LOC) originates near the lateral nucleus of the SOC and innervates afferent terminals of type I afferent fibers under the IHCs. The MOC and LOC contain fibers from both sides of the brain, although most LOC fibers are ipsilateral and most MOC fibers are contralateral, as drawn. The exact ratios vary with the animal

make up about 90–95% the population; their distal processes travel directly to the IHC in the organ of Corti. Each type I neuron innervates one IHC, and each hair cell receives a number of type I fibers; the exact number varies with species and location in the cochlea, but is typically 10–20. The connection between the IHC

and type I hair cells is a standard chemical synapse, by which the hair cell excites the AN fiber. Type I AN fibers project into the core areas of the cochlear nucleus, the first auditory structure in the brain; the type I fibers plus the neurons in the core of the cochlear nucleus make up the main pathway for auditory information entering the brain.

The remaining 5–10% of the spiral ganglion neurons, type II, innervate OHCs. The fibers cross the fluid spaces between the IHC and the OHC (shown by the asterisks in Fig. 12.4c) and spiral along the basilar membrane beneath the OHCs toward the base of the cochlea (toward the stapes, not shown) innervating a few OHCs along the way. Although the type II fibers are like type I fibers in that they connect hair cells (in this case OHC) to the cochlear nucleus, there are some important differences. The axons of type II SG neurons are unmyelinated, unlike the type I fibers; their central processes terminate in the granule-cell areas of the cochlear nucleus, where they contact interneurons, meaning neurons that participate in the internal circuitry of the nucleus but do not contribute their axons to the outputs of the nucleus. Finally, type II fibers do not seem to respond to sound [12.26–28], even though they do propagate action potentials [12.29,30]. It is clear that the type I fibers are the main afferent auditory pathway, but the role of the type II fibers is unknown. In the remainder of this chapter, the term *AN fiber* refers to type I fibers only.

The efferent neurons have their cell bodies in an auditory structure in the brain called the superior olivary complex; for this reason, they are called the olivocochlear bundle (OCB). The anatomy and function of the OCB efferents are reviewed by *Warr* [12.25] and by *Guinan* [12.31]. Anatomically, there are two groups of OCB neurons. So-called lateral efferents (LOC) travel mainly to the ipsilateral cochlea and make synapses on the dendrites of type I afferents under the IHC. Thus they affect the afferent pathway directly. The second group, medial efferents (MOC), travel to both the ipsilateral and contralateral ears and make synapses on the OHCs. Their effect on the afferent pathway is thus indirect, in that they act through the OHC's effects on the transduction process in the cochlea.

12.2.2 Basilar-Membrane Vibration and Frequency Analysis in the Cochlea

An overview of the steps in cochlear transduction is shown in Fig. 12.6a. The sound pressure at the eardrum (p_T) is transduced into motion of the middle-ear ossicles, ultimately resulting in the stapes velocity (v_S),
Fig. 12.6 (a) Summary of the steps in direct cochlear transduction. **(b)** Schematic diagram showing the basilar membrane in an unrolled cochlea and the nature of cochlear frequency analysis. A snapshot of basilar-membrane displacement (greatly magnified) by a tone with frequency near 3 kHz is shown. The frequency *left scale* shows the location of the maximum membrane displacement at various frequencies for a cat cochlea. For a human cochlea, the frequency scale runs from about 20 Hz to 15 kHz. The array of AN fibers is shown by the *parallel lines on the right*. Each fiber innervates a hair cell at one place on the basilar membrane, so the fiber's sensitivity is maximal at the frequency corresponding to that place, as shown by the *left scale*. In other words, the separation of frequencies done by the basilar membrane is preserved in the AN fiber array (after [12.32] with permission)

which couples sound energy into the SV. The transformations in this part of the system have mainly to do with acoustical mechanics and were described in the first section above. The stapes motion produces a sound pressure signal in the cochlea that results in vibration of the basilar membrane, which is the topic of this section. The vibration results in stimulation of hair cells, through opening and closing of transduction channels built into the cilia that protrude from the top of the hair cell, de-

scribed in a later section. The hair cells are synaptically coupled to AN fibers, so that basilar-membrane vibration is eventually coupled to activation of the nerve.

A key aspect of cochlear function is frequency analysis. The nature of cochlear frequency analysis is illustrated in Fig. 12.6b, which shows the cochlea uncoiled, with the basilar membrane stretching from the base, the end near the stapes, to the apex (the helicotrema). As described above, the basilar membrane lies between (separates) the ST and the SM/SV. The sound entering the cochlea through the vibration of the stapes is coupled into the fluids of the SV and SM at the base, above the basilar membrane in Fig. 12.6. The sound energy produces a pressure difference between the SV/SM and the ST, which causes vertical displacement of the basilar membrane. The displacement is tuned, in that the motion produced by sound of a particular frequency is maximum at a particular place along the cochlea. The resulting place map is shown by the frequency scale on the left in Fig. 12.6. Basilar-membrane displacement was first observed and described by *von Békésy* [12.33]; more recent data are reviewed by *Robles* and *Ruggero* [12.34].

Basilar–Membrane Motion

The displacement of any single point on the basilar membrane is an oscillation vertically (perpendicular to the surface of the membrane); the relative phase (or timing) of the oscillations of adjacent points is such that the overall displacement looks like a traveling wave, frequently described as similar to the waves propagating away from an object dropped into a pool of water. Essentially, the motion of the basilar membrane is delayed in time as the observation point moves from base to apex. Figure 12.7a shows an estimate of the cochlear traveling wave on the guinea-pig basilar membrane, based on electrical potentials recorded across the membrane [12.35]. The horizontal dimension in this figure is distance along the basilar membrane, with the base at left and the apex at right. The vertical dimension is the estimate of displacement, shown at a greatly expanded scale. The oscillations marked "2 kHz" show membrane deflections in response to a 2 kHz tone at five successive instants in time (labeled 1–5). The wave appears to travel rightward, from the base toward the apex; as it does so, its amplitude changes. When the stimulus is a tone, the displacement envelope (i. e., the maximum amplitude of the displacement at each point along the basilar membrane) has a single peak at a location that depends on the tone frequency (approximately at point 2 in this case). In Fig. 12.7a, displacement envelopes are

Fig. 12.7 (**a**) An estimate of the instantaneous displacement of the basilar membrane in the guinea-pig cochlea for a 2 kHz tone (*solid lines*) and estimates of the envelope of the displacement for two lower-frequency tones (*dashed lines*). Distance along the basilar membrane runs from left (*base*) to right (*apex*) and the displacement of the membrane is plotted vertically. The estimates were obtained by measuring the cochlear microphonic at three sites, indicated by the three vertical lines, and then interpolating or extrapolating to other locations using an informal method [12.35]; this method can be expected to produce only qualitatively correct results. The 2 kHz estimates are shown at 0.1 ms intervals. Waveforms at successive times are identified with the numbers 1 through 5. The *dashed curves* were drawn through the maximum displacements of similar data for 0.5 and 0.15 kHz tones, which were scaled to have the same maximum displacement as the 2 kHz data. The cochlear microphonic is produced by hair cells, mainly OHCs, and is roughly proportional to basilar-membrane displacement. The ordinate scale has been left as microvolts of cochlear microphonic. The scale markers at lower left show distance from the origin. (**b**) Measurements of the gain of the basilar membrane (root mean square displacement divided by pressure at the eardrum) for two data sets. In each case, basilar-membrane displacement at one place was measured with an interferometer. Both frequency (abscissa) and sound level (symbols) were varied. The curves peaking near 9–10 kHz are from the chinchilla cochlea [12.36] and the curves peaking near 20 kHz are from the guinea pig cochlea [12.37] (after [12.34]). (**c**) Basilar-membrane input–output curves, showing the velocity of membrane displacement (*ordinate*) versus sound intensity (*abscissa*), at various frequencies, marked on the plots (kHz). The *dashed line at right* shows the linear growth of basilar-membrane motion (velocity proportional to sound pressure). The curve for 10 kHz is extrapolated to low sound levels (*dashed line at left*) under the assumption of linear growth at low sound levels (Fig. 12.7a after [12.35], Fig. 12.7b after [12.34], and Fig. 12.7c after [12.36]) ◄

shown by dashed lines for 0.5 kHz and 0.15 kHz tones; these envelopes peak at more apical locations, compared to 2 kHz. The locations of the envelope peaks are given by the cochlear frequency map for the cat cochlea, shown by the scale running along the basilar membrane in Fig. 12.6b. Notice that the scale is logarithmic: the position along the basilar membrane corresponds more closely to log than to linear frequency. The logarithmic frequency organization corresponds to a number of phenomena in the perception of sound, such as the fact that musical notes are spaced logarithmically in frequency.

The basilar-membrane responses in Fig. 12.7a illustrate the property of tuning, in that the displacement in response to a tone is confined to a region of the membrane centered on a place of maximal displacement. Tuning can be further understood by plotting basilar-membrane displacement as in Fig. 12.7b. This plot shows the displacement plotted against frequency at a fixed location, thus providing a direct measure of the frequency sensitivity of a place on the membrane. Data are shown at two locations from separate

experiments (in different species). The ordinate actually shows basilar-membrane *gain*, defined as membrane displacement divided by sound pressure at the eardrum. At low sound levels (20 dB, plotted with empty circles), the gain peaks at a particular best frequency (BF) and decreases at adjacent frequencies. If such measurements could be repeated at multiple locations along the basilar membrane (which is difficult because of the restricted anatomical access to the basilar membrane), these gain functions would move toward higher frequencies at more basal locations in the cochlea, as predicted by the displacement functions in Fig. 12.7a.

Notice that the gain and tuning of the basilar-membrane response near the BF varies with sound level. At low sound levels (20 dB in Fig. 12.7b), gain is high and the tuning is sharp (i.e. the width of the gain functions is small), giving a clear BF; at high sound levels (100 dB), the gain is substantially reduced, especially in the vicinity of the low-sound-level BF, and the frequency at which the gain is maximum moves to a lower frequency, often about a half-octave lower. The tuning also becomes much broader.

Basilar Membrane and Compression

The fact that basilar-membrane gain changes with sound level was first described by *Rhode* [12.38]; this finding revolutionized our understanding of the auditory system, most importantly by introducing the idea of an active cochlea, meaning one in which the acoustic energy entering through the middle ear is amplified by an internal energy-utilizing process to produce cochlear responses [12.39–44]. The existence of amplification has been demonstrated by calculations of energy flow in the cochlea. However, a simpler evidence for cochlear amplification is the change in cochlear gain functions with death. The dependence of gain on sound level seen in Fig. 12.7b occurs only in the live, intact cochlea; after death, the cochlear gain functions resemble those at the highest sound levels in living animals (e.g. at 100 dB in Fig. 12.7b). Most important, the post-mortem gain functions are linear, meaning that the gain is constant, regardless of stimulus intensity, at all frequencies. In the live cochlea, as shown in Fig. 12.7b, the gain functions are linear only at low frequencies (below 6 kHz or 12 kHz for the two sets of data shown). Presumably, the post-mortem gain functions are the result of passive basilar-membrane mechanics, i.e., the result of the mechanical properties of the cochlea without any energy sources. The difference between the gain at the highest sound levels in Fig. 12.7b and those at low sound levels thus re-

flects an amplification process, often called the cochlear amplifier.

Additional evidence for a cochlear amplifier comes from the study of otoacoustic emissions, OAE [12.45, 46]. OAEs are sounds produced in the cochlea that can be measured at the eardrum, after propagating in the backwards direction through the middle ear. OAEs can be produced by reflection of the cochlear traveling wave from irregularities in the cochlea [12.47, 48] or from nonlinear distortion in elements of the cochlea [12.49]. In either case amplification of the sound is necessary to explain the characteristics of the emitted sound [12.46], but see also [12.50]. There are several different kinds of OAEs, varying in the mode of production. Most relevant for the present discussion are the spontaneous emissions, sounds that are present in the ear canal without any external sound source. Such sounds necessitate an acoustic energy source in the cochlea, of the type postulated for the cochlear amplifier.

A variety of evidence suggests that cochlear amplification depends on the OHCs. When these cells are destroyed, as by an ototoxic antibiotic, the sharply tuned high-sensitivity portion of the tuning of auditory-nerve fibers is lost [12.51]; presumably this change reflects a similar change at the level of the basilar membrane, i.e., loss of the high-gain sharply tuned portion of the basilar-membrane response. Electrical stimulation of the MOC (Fig. 12.5), which affects only the OHC, produces similar losses in both basilar-membrane motion [12.52] and neural responses [12.53, 54]. Finally, stimulation of the MOC reduces OAE [12.55, 56]. In each case, a neural input to a cellular element of the cochlea, the OHC, affects mechanical processes in the cochlea. These data suggest that the OHCs participate in producing basilar-membrane motion. The possible mechanisms for this effect are discussed in Sect. 12.2.4.

The sound-level dependence of gain observed in Fig. 12.7b shows that the sensitivity of the cochlea is regulated across sound levels. The gain is high at low sound levels and decreases at higher sound levels; as a result, the output varies over a narrower dynamic range than the input, which is compression. A different view of compression is shown in Fig. 12.7c, which plots basilar-membrane input/output functions at various frequencies for a 10 kHz site on a chinchilla basilar membrane [12.36]. Basilar-membrane response is measured as velocity, instead of displacement as in previous figures. However, velocity and displacement are proportional for a fixed frequency, so in terms of input/output functions it does not matter which variable is plotted. Figure 12.7c has logarithmic axes, so a linear

growth of response, in which the output is proportional to the input, corresponds to a line with slope 1, as for the dashed line at right. At low sound levels ($< 40\,\text{dB}$), the response is largest at 10 kHz, as it should be for the BF. The response to 10 kHz is roughly linear at very low sound levels ($< 20\,\text{dB}$), but has a lower slope at higher levels. Over the range of input sound levels from 20–80 dB SPL, the output velocity increases only 10-fold or 20 dB, a compression factor of about 0.3. At lower frequencies (8 and 2 kHz), the slope is closer to 1, as expected from the constant gain at low frequencies in Fig. 12.7b. At higher frequencies (11 kHz), the growth of response is also compressive, but with a lower gain. Finally, at very high frequencies (16 kHz), the growth is again approximately linear.

The behavior shown in Fig. 12.7b,c is typical of cochleae that are judged to be in the best condition during the measurements. As the condition of the cochlea deteriorates, the input/output functions become more linear and their gain decreases [12.57], reflecting a loss of cochlear amplification. Although such data are not available for the example in Fig. 12.7c, the typical post-mortem behavior of input/output functions at BF is something like the dashed line used to illustrate linear growth. Post-mortem functions have a slope of 1 at all sound levels and typically intercept the compressive BF input/output function at levels of 70–100 dB. Assuming that the cochlear amplifier is not functioning post-mortem, the gain of the amplifier can be defined as the horizontal distance between the linear-growth portion of the BF curve in the normal ear and the post-mortem curve. With this definition of gain, the compression region of the input/output function can be understood as resulting from a gradual decrease in amplification as the sound grows louder.

The compression of basilar-membrane response shown in Fig. 12.7c has a number of perceptual correlates [12.58]. The degree of compression can be measured in human observers using a masking technique, motivated by the behavior of basilar-membrane data like Fig. 12.7 [12.59, 60]; the compression measured in these studies is comparable to that measured in basilar-membrane data. Moreover, compression can be used to explain a number of perceptual phenomena, including aspects of temporal processing and loudness growth. In hearing-impaired persons, compression is lost to varying degrees, consistent with the effects of loss of OHCs on basilar-membrane responses discussed above (i. e., the slopes of basilar-membrane input/output functions steepen). Some of the effects of hearing impairment can be explained by a change in compression

ratio from 0.2–0.3 to a value near 1. An important example is loudness recruitment. If loudness is somehow proportional to the overall degree of basilar-membrane motion, then a steepening of the growth of basilar-membrane motion with sound intensity should lead to a steepening of loudness growth with intensity. This is the major effect observed on loudness growth with hearing impairment.

Mechanisms Underlying Basilar-Membrane Tuning

The current understanding of how the properties of basilar-membrane motion arise is incomplete. Work on this subject has proceeded along two lines:

1. Collection of evermore accurate data on the motion of the basilar membrane and the components of the organ of Corti; and
2. Models of the observed motion of the basilar membrane based on physical principles of mechanics and fluid mechanics.

Progress in this field has been limited by the difficulty of obtaining data, however, and modelers have generally responded vigorously to each new advance in observing and measuring basilar-membrane motion. At present, the major impasse in this work seems to be the difficulty of observing the independent motion of the components of the organ of Corti. Such data are necessary to resolve questions about the mode of stimulation of hair cells by the motion of the basilar membrane and questions about the effects of OHC and stereociliary movements on the basilar membrane.

Modeling of basilar-membrane motion has been approached with a variety of methods in an attempt to account for the properties of the motion. Comprehensive reviews of this literature and its relationship to important aspects of data on basilar-membrane motion are available [12.61, 62]. The next paragraphs provide a rough summary of the current understanding of this topic.

Tuning or the separation of frequencies in basilar-membrane motion is usually attributed to the variation in the stiffness and (sometimes) the mass of the basilar membrane along its length. In most basilar-membrane models, the points on the basilar membrane are assumed to move independently; that is, the longitudinal stiffness coupling adjacent points on the membrane is assumed to be small. With this assumption, the resonant frequency of a point on the basilar membrane should vary approximately as the square root of its stiffness divided by its mass, using the usual formula for the resonant frequency of a mass–spring oscillator. In so-

called long-wave models, it is this resonant frequency that determines the mapping of frequency into place in the cochlea. Experimentally, the stiffness of the basilar membrane varies from high near the base to low at the apex [12.33, 63]. Thus the stiffness gradient is qualitatively consistent with the observed place–frequency map; however, whether the stiffness gradient is sufficient to fully account for tuning in the cochlea is not settled, because of the difficulty of making measurements.

Recent efforts in cochlear modeling have been devoted to micromechanical models, i.e., models of the detailed mechanics of the organ of Corti and the tectorial membrane [12.49, 62]. Movement of the basilar membrane is coupled to the hair cells through the organ of Corti, particularly through the relative movement of the top surface of the organ (the reticular lamina) in which the hair cells are inserted and the overlying tectorial membrane (refer to Fig. 12.4c). Mechanical feedback from the OHCs is similarly coupled into the basilar membrane through the same structures. The structure of the organ of Corti is complex and heterogeneous, with considerable variation in the stiffness of its different parts [12.64]. Thus a full account of the properties of the basilar membrane awaits an adequate micromechanical model, based on accurate data on the mechanical properties of its components.

In both models and measurements, the sound pressure difference across the basilar membrane drops rapidly to zero past the point of resonance. This behavior is illustrated by the high-frequency part of the data in Fig. 12.7b and the lack of deflection beyond the peak of the responses in Fig. 12.7a. This fact means that there is no pressure difference across the basilar membrane at the apical end of the cochlea, so the helicotrema does not affect basilar-membrane mechanics (in particular it does not *short out* the pressure difference driving the basilar membrane) except at very low frequencies, where the displacement is large near the apex. The role of the helicotrema is presumably to prevent the generation of a constant pressure difference across the basilar membrane; such a difference would interfere with the delicate transducer system in the organ of Corti.

The frequency analysis done by the basilar membrane is preserved by the arrangement of hair cells and nerve fibers in the cochlea (Fig. 12.6b). A particular hair cell senses only the local motion of the basilar membrane, so that the cochlear place map is recapitulated in the population of hair cells spread out along the basilar membrane. Moreover, each AN fiber innervates only one IHC, so the cochlear place map is again recapitulated in the AN fiber array. As a result, AN fibers that innervate, say, the 3 kHz place on the basilar membrane are maximally activated by 3 kHz energy in the sound and it is the level of activation of those fibers that provides information to the brain about the 3 kHz energy in the sound. The representation of sound in an array of neurons tuned to different frequencies is the basic organizing principle of the whole auditory system and is called *tonotopic* organization.

12.2.3 Representation of Sound in the Auditory Nerve

Before discussing cochlear transduction in hair cells, it is useful to introduce some properties of the responses to sound of AN fibers. Of course, the properties of AN fibers derive directly from the properties of the basilar membrane and the transduction process in IHCs. AN fibers encode sound using trains of action potentials, which are pulses fired by a fiber when stimulated by a hair-cell synapse. Information is encoded in the rate at which the fiber discharges action potentials or by the temporal pattern of action potentials. Fibers are active spontaneously at rates that vary from near 0 to over 100 spikes/s. When stimulated by an appropriate sound, the fiber's discharge rate increases and the temporal patterning of action potentials often changes as well. Figure 12.8 shows some basic features of the encoding process. Reviews of the representation of sound by auditory neurons are provided by *Sachs* [12.65], *Eggermont* [12.66] and *Moore* [12.67]. Another view is provided by recent attempts to model comprehensively the responses of AN fibers [12.68–70] or to analyze the information encoded using theoretical methods [12.71].

The tuning of the basilar membrane is reflected in the tuning of AN fibers as is shown by the tuning curves in Fig. 12.8a. This figure shows tuning curves from 11 AN fibers with different BFs. Each curve shows how intense a tone has to be (ordinate) in order to produce a criterion change in discharge rate from a fiber, as a function of sound frequency (abscissa). The tuning curves qualitatively resemble the basilar-membrane response functions shown in Fig. 12.7b for the lowest sound levels (after being turned upside down). The comparison should not be exact because the data are from different species and the tuning curves in Fig. 12.8a are constant-response contours whereas the basilar-membrane functions in Fig. 12.7b are constant-input-level response functions. However, a quantitative comparison of threshold functions for the basilar membrane and AN fibers from the same species yields a good agreement, and it is generally considered that
Fig. 12.8a–c Basic properties of responses to sound in AN fibers. (**a**) Tuning curves, showing the threshold sound level for a response plotted versus frequency. the *dashed line* shows the lowest thresholds across a population of animals. (**b**) Rate versus sound-level plots for responses to BF tones in three AN fibers. Rate in response to a 200 ms tone is shown by the *solid lines* and SR by the *dashed lines*, which actually plot the SR during the 400 ms immediately preceding each stimulus. The fibers had similar BFs (5.36, 6.18, and 5.74 kHz) but different spontaneous rates and were recorded successively in the same experimental preparation. The fluctuations in the curves derive from the randomness in the responses remaining after three-point smoothing of the curves. (**c**) Strength of phase-locking in a population of AN fibers to a BF tone plotted as a function of BF. Phase-locking is measured as the synchronization index, equal to the magnitude of the Fourier transform of the spike train at the stimulus frequency divided by the average rate. The *inset* illustrates phase-locked spike trains (Fig. 12.8a after [12.72], Fig. 12.8c after [12.73])

AN tuning is accounted for by basilar-membrane tuning [12.34]. The AN consists of an array of fibers tuned across the range of frequencies that the animal can hear. The frequency content of a sound is conveyed by which fibers are activated, the tonotopic representation discussed in the previous section.

The perceptual sense of sound frequency, of the highness or lowness of a simple sound like a tone, is strongly correlated with stimulus frequency and, therefore, with the population of AN fibers activated by the sound. However, the pitch of a complex sound, as for musical sounds or speech, is a more complex attribute both in terms of the relationship of pitch to the physical qualities of the sound [12.74] and in terms of the representation of pitch in the AN. A discussion of this issue is provided by *Cariani* and *Delgutte* [12.75].

The intensity of a sound is conveyed by the rate at which fibers respond. AN fibers increase their discharge rates as sound intensity increases (Fig. 12.8b). In mammalian ears, fibers vary in their threshold sensitivity, where threshold means the sound level at which the rate increases from the spontaneous rate. The threshold variation is correlated with spontaneous discharge rate (SR), so that very sensitive fibers, those with the lowest thresholds, have relatively high SR and less-sensitive fibers have lower SR [12.76]. Fibers are

broken into three classes, low, medium, and high, using the somewhat arbitrary criteria of 0.5–1 spikes/s to divide low from medium and 15–20 spikes/s to divide medium from high, depending on the experimenters. Figure 12.8b shows plots of discharge rate versus sound level for an example fiber in each SR group, labeled on the figure. Fibers of all SRs have similar rate-level functions; for tones, these increase monotonically with sound level (except for the effect of noisy fluctuations) from spontaneous rate to a saturation rate. In high-SR fibers, the dynamic range, the range over which sound intensity increases produce rate increases, is narrow and the saturation of discharge rate at high sound levels is clear. In low- and medium-SR fibers, the saturation is gradual (sloping) and the dynamic range is wider.

The sloping saturation in low- and medium-SR fibers is thought to reflect compression in basilar-membrane responses [12.21, 77]. High-SR fibers do not show sloping saturation because the fiber reaches its maximum discharge rate at sound levels where growth of the basilar-membrane response is linear (e.g. below 20 dB in Fig. 12.7). By contrast, the low- and medium-SR fibers sample both the linear and compressed portion of the basilar-membrane input/output function. The vertical dashed line in Fig. 12.8 shows the approximate

threshold for basilar-membrane compression inferred for these fibers.

The relationship of AN responses to the perceptual sense of loudness is an apparently simple problem that has not been fully solved. While it is generally assumed that loudness is proportional to the overall increase in discharge rate across all BFs [12.78], this calculation does not predict important details of loudness growth [12.79–81], especially in ears with damage to the hair cells. Presumably there are additional transformations in the central auditory system that determine the final properties of loudness growth.

A property of AN discharge that is important for many sounds is the ability to represent the temporal waveform. Sounds such as speech have information encoded at multiple levels of temporal precision [12.82]; these include:

1. Syllables and other aspects of the envelope at frequencies below 50 Hz;
2. Periodicity (pitch) in sounds such as vowels at frequencies from 50–500 Hz; and
3. The fine structure of the actual oscillations in the acoustic waveform at frequencies above 500 Hz.

AN fibers represent the waveform of sounds (the fine structure) by phase-locking to the stimulus. A schematic example is shown in the inset of Fig. 12.8c, which shows a sinusoidal acoustic waveform (a tone) and four examples of AN spike trains in response to the stimulus. The important point is that the spikes in the responses do not occur at random, but rather at a particular stimulus phase, near the positive peak of the stimulus waveform in this example. The phase-locking is not perfect, in that a spike does not occur on every cycle of the stimulus, and the alignment of spikes and the waveform varies somewhat. However, a histogram of spike-occurrence times shows a strong locking to the stimulus waveform and the Fourier transform of the spike train generally has its largest component at the frequency of the stimulus.

Phase-locking occurs at stimulus frequencies up to a few kHz, depending on the animal. The main part of Fig. 12.8c shows the strength of phase-locking in terms of the synchronization index (defined in the caption) plotted against the frequency of the tone. These data are from the cat ear [12.73] where phase-locking is strongest below 1 kHz and disappears by about 6 kHz. Phase-locking always shows this low-pass property of being strong at low frequencies and nonexistent at high frequencies. The highest frequency at which phase-

locking is seen varies in different species, being lower in rodents than in cats [12.83].

AN phase-locking is essential for the perception of sound localization. The relative time of occurrence of spikes from the two ears is used to compute the delays in the stimulus waveform across the head that provide information about the azimuth of a sound source [12.84]. Phase-locking has also been suggested as a basis for processing of speech and other complex stimuli [12.71, 85]. Examples of the usefulness of phase-locking in analyzing responses to complex stimuli are given in Sect. 12.3.1.

12.2.4 Hair Cells

The transduction of basilar-membrane motion into electrical signals occurs in the IHCs. The OHCs participate in the generation of sensitive and sharply tuned basilar-membrane motion. In this section, the physiology of IHCs and OHCs are described with reference to these tasks. At the time of this writing, hair-cell research is one of the most active areas in auditory neuroscience and many of the details of hair-cell function are just being worked out. Useful recent reviews of the literature are available [12.86–89].

IHCs and Transduction

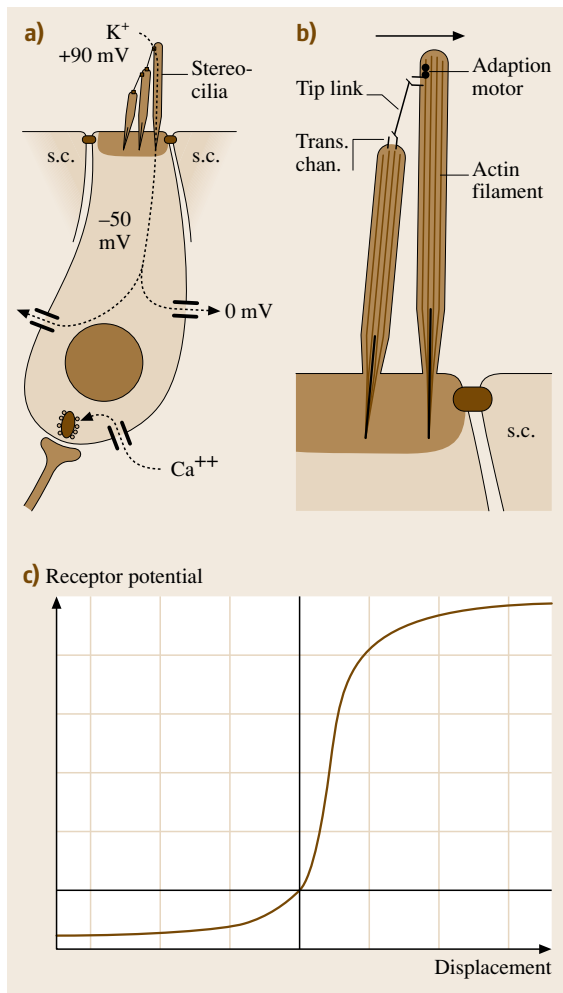
Both IHCs and OHCs transduce the motion of the basilar membrane. This section describes transduction with reference to the IHCs, but transduction works in essentially the same fashion in OHCs. The transduction apparatus depends on the arrangement of stereocilia on the apical surface of hair cells. Stereocilia are structures that protrude from the hair cells into the endolymphatic space of the SM (Fig. 12.9a). They consist of bundles of actin filaments anchored in an actin/myosin matrix just under the apical surface of the cell. The membrane of the cell wraps the actin rods so that they are intracellular and the membrane potential of the cell appears across the membranes of the stereocilia. The structure of stereocilia is intricate and involves a number of structural proteins that are important for organizing the development of the cilia and for maintaining them in proper position on the cell [12.90]. The stereocilia form a precisely organized bundle; in the cochlea, the bundle consists of several roughly V- (IHCs) or W-shaped (OHCs) rows of cilia (typically three, as in Fig. 12.9) of graded length, so that the cilia in the row nearest the lateral edge of the hair cell are the longest and those in the adjacent rows are successively shorter. Each row consists of 20–30 cilia precisely aligned with the cilia in


Fig. 12.9a–c Transduction in IHCs. (**a**) Schematic of an IHC showing the components important for transduction. The stereocilia protrude into the endolymphatic space (*top*), containing mainly K$^+$; the extracellular potential here is about +90 mV (the endolymphatic potential). The transduction apparatus consists of tip links and channels near the tips of the cilia. The *dashed lines* show the transduction current. It enters the cell through the transduction channel and exits through K$^+$ channels in the basolateral membrane of the cell into the perilymphatic space. The intracellular and extracellular potentials of the cell and the perilymphatic space are given. There is a mechanically stiff and electrically insulating boundary between the endolymphatic and perilymphatic spaces, formed by tight junctions between the apical surfaces of hair cells and supporting cells (s.c.), indicated by the *small black ovals*. The synapse, at the base of the cell, is a standard chemical synapse, in which voltage-gated Ca^{2+} channels open in response to the depolarization caused by the transduction current and admit Ca^{2+} to activate neurotransmitter release. (**b**) Detailed view of two stereocilia with a tip link connecting ion channels in the membrane of each. The upper ion channel is connected to an adaptation motor that moves up and down along the actin filaments to tension the tip link. (**c**) Transduction function showing the receptor potential (the depolarization or hyperpolarization) of a hair cell versus the displacement of the stereocilia tips. Typical axis scales would be 0.01–1 μm per tick on the abscissa and ≈ 2 mV per tick on the ordinate ◄

adjacent rows. The tips of the cilia are connected by tip links [12.91], a string-like bundle of protein that connects the tip of a shorter cilium to the side of the taller adjacent cilium (Fig. 12.9b).

Transduction occurs when vertical motion of the basilar membrane is converted into a shearing motion of the stereocilia (the arrow in Fig. 12.9b). It has long been known that hair cells are functionally polarized, in the sense that they respond most strongly to displacement of the cilia in the direction of the arrow, are inhibited by displacement in the opposite direction, and respond weakly to displacement of the cilia in lateral directions [12.92, 93]. In fact, hair cells are depolarized when the stereocilia are displaced in the direction that stretches the tip links. Further evidence to associate the tip links to the transduction process is that when

the tip links are destroyed by lowering the extracellular calcium concentration, transduction disappears and reappears as the tip links are regenerated [12.94].

The mechanical connection between basilar-membrane motion and cilia motion is not fully understood. As shown in Fig. 12.4c, the stereocilia bundles are oriented so that lateral displacement of the cilia (i. e., displacement away from the central axis of the cochlea) should be excitatory. Furthermore the tips of the OHC cilia are embedded in the tectorial membrane, whereas those of the IHC are not. Based on the geometry of the organ, upward motion of the basilar membrane (i. e., away from the ST and toward the SM and SV) results in lateral displacement of the cilia through the relative motions of the organ of Corti and the tectorial membrane. Presumably the coupling to the OHC is a direct mechanical one, whereas the coupling to the IHC is via fluid movements, so the IHC stereocilia are bent through viscous drag of the endolymph in the space between the organ of Corti and the tectorial membrane. While this model is commonly offered and is proba-

bly basically correct, it is not consistent in detail with the phase relations between the stimulus (or basilar-membrane motion) and action potential phase locking in AN fibers [12.95]. Presumably the inconsistencies reflect complexities in the motions of the organ of Corti that connect basilar-membrane displacement to stereociliary displacement.

The current model for the tip link and transduction channel is shown in Fig. 12.9b. The tip link connects (probably) two transduction channels, one in each cilium. When the bundle moves in the excitatory direction (the direction of the arrow), the tension in the tip link increases, which opens the transduction channels and allows current flow into the cell. Movement in the opposite direction relaxes the tension in the tip link and allows the channels to close. The current through the transduction channels is shown by the dashed line in Fig. 12.9a. Outside of the stereociliary membrane is the endolymph of the SM. The transduction channels are nonspecific channels which allow small cations to pass; in the cochlea, these are mainly Na^+, K^+, and Ca^{2+}. However, the predominant ion in both the extracellular (endolymph) and intracellular spaces is K^+, so the transduction current is mostly K^+. The energy source producing the current is the potential difference between the SM (the endolymphatic potential, approximately $+90$ mV) and the intracellular space in the hair cell (approximately -50 mV). The endolymphatic potential is produced by the active transport of K^+ into the endolymph and Na^+ out of the endolymph in the stria vascularis (Fig. 12.4b). This transport process also produces the endolymphatic potential [12.22]. The negative potential inside the hair cell is produced by the usual mechanisms in which active transport of K^+ into the cell and Na^+ out of the cell produces a negative diffusion potential through the primarily K^+ conductances of the hair cell membrane. Because the transduction current is primarily K^+, it does not burden the hair cell with the necessity for additional active transport of ions brought into the hair cell by transduction.

When the transduction channels open, the hair cell is depolarized by the entry of positive charge into the cell. The transduction current flows out of the cell through the potassium channels in its membrane. Figure 12.9c shows the typical transduction curve for a cochlear hair cell, as the depolarization of the membrane (ordinate) produced by a certain displacement of the stereociliary bundle (abscissa). At rest (zero displacement), some transduction channels are open, so that both positive and negative displacements of the bundle can be signaled. However, hair cells generally have only a fraction of channels open at rest so that a much larger depolarization is possible than hyperpolarization, i.e., more channels are available for opening than for closing. The transduction curve saturates when all channels are closed or all channels are open.

The transduction process is completed by the opening of voltage-gated Ca^{2+} channels in the hair cell membrane, which allows Ca^{2+} ions to enter the cytoplasm (dotted line at the bottom of Fig. 12.9a) and activate the synapse. The hair-cell synapse has an unusual morphology, containing a synaptic ribbon surrounded by vesicles [12.96,97]. This ribbon presumably reflects molecular specializations that allow the synapse to be activated steadily over a long period of time without losing its effectiveness and also to produce an action potential in the postsynaptic fiber on each release event, so that summation of postsynaptic events is not necessary, as is required for phase-locking at kilohertz frequencies. The synapse appears to be glutamatergic [12.98] with specializations for fast recovery from one synaptic release, also necessary for high-frequency phase-locking.

The final component of the transduction apparatus is the adaptation motor, shown as two black circles in Fig. 12.9b [12.99]. Presumably the transduction channel and the adaptation motor are mechanically linked together so that when the motor moves, the channel moves also. The sensitivity of the transduction process depends on having an appropriate tension in the tip link. If the tension is too high, the channels are always open; if the tip link is slack, then the threshold for transduction will by elevated because larger motions of the cilia will be required to open a transduction channel. The tip-link tension is adjusted by a myosin motor that moves upward along the actin filaments when the transduction channel is closed. When the channel opens, Ca^{2+} flows into the stereocilium through the transduction channel and causes the motor to slip downward. Thus the adaptation motor serves as a negative feedback system to set the resting tension in the tip link. The zero-displacement point on the transduction curve in Fig. 12.9c is set by an equilibrium between the motor's tendency to climb upward and the tension in the tip link, which causes the channel to open and admit Ca^{2+}, pulling it downward. Adaptation also regulates the sensitivity of the transduction process in the presence of a steady stimulus.

There is a second, fast, mechanism for adaptation in which Ca^{2+} entering through an open transduction channel acts directly on the channel to close it, thus moving the transduction curve in the direction of the applied stimulus [12.88]. This mechanism is discussed

again in a later section, because it also can serve as a kind of cochlear amplifier.

IHC Transduction and the Properties of AN Fibers

The description of transduction in the previous section suggests that the stimulus to an AN fiber should be approximately the basilar-membrane motion at the point in the cochlea where the IHC innervated by the fiber is located. It follows that the tuning and rate responses of the fiber should be similar to the tuning and response

amplitude of the basilar membrane, discussed in connection with Fig. 12.7.

The receptor potentials in an IHC responding to tones are shown in Fig. 12.10 [12.83]. The traces are the membrane potentials recorded in an IHC, each trace at a different stimulus frequency. These potentials are the driving force for the Ca^{2+} signal to the synapse, and thus indirectly for the AN fibers connected to the cell. The properties of these potentials can be predicted from Fig. 12.9c by the thought experiment of moving a stimulus sinusoidally back and forth on the abscissa and following the potential traced out on the ordinate. The potential should be a distorted sinusoid, because depolarizing responses are larger than hyperpolarizing ones, and it should have a steady (DC) offset, also because of the asymmetry favoring depolarization. At low frequencies, both components can be seen in Fig. 12.10; the response is a distorted sinusoid riding on a steady depolarization. At high frequencies (>1000 Hz), the sinusoidal component is reduced by low-pass filtering by the cell's membrane capacitance and only the steady component is seen. The transition from sinusoidal receptor potentials at low frequencies to rectified DC potentials at high frequencies corresponds to the loss of phase-locking at higher frequencies in AN fibers (Fig. 12.8c). At low frequencies, the IHC/AN synapse releases transmitter on the positive half cycles of the

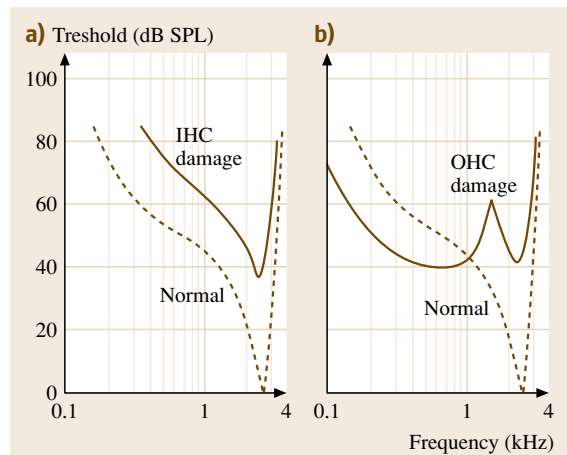
Fig. 12.10 Receptor potentials in an IHC in the basal turn of a guinea-pig cochlea. The stimulus level was set at 80 dB SPL so that the cell would respond across a wide range of frequencies. Stimulus frequency is given at right. Notice the change in ordinate scale between the 900 Hz and 1000 Hz traces (after [12.83], with permission)


Fig. 12.11a,b Schematic summary of AN tuning curves in normal ears and in ears with damaged cochleae. **(a)** In regions of the cochlea with remaining OHCs but damaged IHCs tuning curves mainly show a threshold elevation. **(b)** In regions with missing OHCs but intact IHCs there is an elevation of threshold at frequencies near BF and a substantial broadening of tuning (after [12.51])

receptor potential and the AN fiber is phase-locked; at high frequencies, there is a steady release of neurotransmitter and the AN fiber responds with a rate increase but without phase-locking.

OHCs and the Cochlear Amplifier

In the discussion of the basilar membrane, the need for a source of energy in the cochlea, a cochlear amplifier, was discussed. At present, two possible sources of the amplification have been suggested. The first is OHC motility [12.86, 100] and the second is hair bundle motility [12.101]. Although hair bundle motility could function in both IHCs and OHCs, it seems likely that the OHC is the principal element of the cochlear amplifier. The evidence for this is that the properties of the cochlea change in a way consistent with modification of cochlear mechanics when the OHC are damaged or otherwise manipulated, but not the IHC. For example, electrical stimulation of the MOC, which projects only to the OHCs (Fig. 12.5), modifies otoacoustic emissions [12.31] and reduces the amplitude of motion of the basilar membrane [12.102, 103].

Figure 12.11 shows tuning curves in AN fibers for intact ears (*normal*) and for ears with IHC or OHC damage [12.51, 104]. These tuning curves are schematics that summarize the results of studies in ears with damage due to acoustic trauma or ototoxic antibiotics. Complete destruction of IHCs, of course, eliminates AN activity entirely. However, it is possible to find regions of the cochlea with surviving IHCs that have damaged stereocilia and OHCs that appear intact. The sensitivity of AN fibers in such regions is reduced, reflected in the elevated threshold in Fig. 12.11a, but the tuning is still sharp and appears to be minimally altered. By contrast, in regions with intact IHCs and OHCs that are damaged or missing, the tuning curves are dramatically altered, as in Fig. 12.11b. There is a threshold shift reflecting a loss of sensitivity but also a substantial broadening of tuning. These are the effects that are expected from the loss of the cochlear amplifier. Note that the thresholds well below BF (<1 kHz in Fig. 12.11b) can actually be lower than normal with OHC damage. This phenomenon is not fully understood and seems to reflect the existence of two modes of stimulation of IHCs [12.105].

Some properties of OHCs are shown in Fig. 12.12. These cells have a transduction apparatus similar to that in IHCs, but Fig. 12.12 focuses on unique aspects of OHC anatomy and physiology. The OHCs are located in an unusual system of structural or supporting cells. Unlike virtually all tissues, the OHC are surrounded by a fluid space containing perilymph for distances compa-

rable to the cells' widths (asterisks in Fig. 12.4c). The OHC are held by supporting cells called Deiter's cells that form a cup around the base of the cell and have a stiff extension up to the top surface of the organ of Corti. The extension terminates next to the apical surface of the OHC, where a system of tight junctions similar to that in the IHC region holds the OHCs and Deiter's cells to form a mechanically stiff and electrically insulating barrier between the endolymph and perilymph.

In response to depolarization of their membranes, say in response to a transduction current, OHCs shorten, a process called electromotility [12.106, 107]. Electromotility does not use a direct chemical energy source (such as adenosine triphosphate (ATP)) as do other cellular motility processes. It is also very fast, responding to frequencies of 10 kHz or above, limited mainly by the limits of the experimental observations. This unusual motile process is produced by a molecule called prestin ("P" in Fig. 12.12a) found in a dense array in the lateral wall of the OHCs [12.108–110], where it is associated with a complex mechanical matrix that forms the cell's skeleton [12.111]. Prestin causes the cell to shorten in response to electrical depolarization of its membrane, so the energy source for electromotility is the electrical membrane potential. The mechanism of electromotility is shown schematically in Fig. 12.12b. The prestin molecule is similar to anion transporters, molecules that normally move anions through the cell membrane. It is thought that prestin is a modified transporter that can bind an anion, but the ion moves only part of the way through the membrane. In OHCs, the relevant anion is Cl^- because electromotility is blocked by removing Cl^- from the cytoplasm [12.112]. When a Cl^- ion binds to a prestin molecule, the cross-sectional area of the molecule increases, thus increasing the membrane area and lengthening the cell (indicated by the double-headed arrow). Cl^- ions are driven into the membrane by negative membrane potentials, so depolarization pulls them out and decreases the membrane area, shortening the cell.

When a Cl^- ion binds to a prestin molecule, it moves part way through the cell's electrical membrane potential (ΔV in Fig. 12.12b). This movement behaves like charging a capacitance in the cell's membrane and appears in electrical recordings as an additional membrane capacitance. However the extent of charge movement depends on the membrane potential, making the capacitance nonlinear. At very negative membrane potentials, all the prestin molecules have a bound Cl^- and no charge movement can occur; similarly, at positive potentials, the Cl^- is unlikely to bind to

Fig. 12.12 (a) Schematic picture of an OHC showing elements important for OHC function. The diagram is labeled as for Fig. 12.9a except for the following: DC – Deiter's cell extensions that are linked to OHCs by tight junctions to form the top surface of the organ of Corti; Na^+ – the extracellular spaces around the lateral membranes of the OHCs are filled with perilymph, a high-Na^+, low-K^+ fluid; P – prestin molecules in the lateral membrane; eff. – efferent terminal of a MOC neuron on the OHC; s.c. subsynaptic cistern associated with the efferent synapse. K^+ and Ca^{2+} currents activated by the synapse are shown by dashed and dotted lines, respectively. **(b)** Schematic of prestin molecules in the lateral membrane of the cell. When the membrane potential ΔV is negative, Cl^- ions are driven into the prestin molecule, increasing its membrane area (as indicated by the *double-headed arrow*). **(c)** The *top plot* shows the length of an isolated OHC as a function of membrane potential showing the amplitude of the electromotility. The *bottom plot* shows the nonlinear capacitance of the same cell. (Fig. 12.12c after [12.113] with permission) ◄

Prestin is found essentially only in OHCs and, in particular, is not seen in IHCs [12.110]. When expressed by genetic methods in cells that normally do not contain it, prestin confers electromotility on those cells. In addition, when the prestin gene was knocked out, the morphology of the cochlea and the hair cells was not affected (except that the OHCs were shorter), but electromotility was not observed and the sensitivity of auditory neurons was decreased; otoacoustic emissions were also decreased [12.114]. These are the effects expected if prestin is the energy source for the cochlear amplifier.

The means by which OHC motility amplifies basilar-membrane motion is somewhat uncertain. Models that use physiologically accurate OHC motility to produce cochlear amplification have been suggested and analyzed, e.g., [12.115]. However, such models require assumptions about the details of the mechanical interactions within the organ of Corti, assumptions that have not been tested experimentally. For example, the OHCs lie at an angle to the vertical extensions of the Deiter's cells, so that successive locations along the basilar membrane are coupled to one another [12.107]. The mechanical effects of structures like this are quite important in models of basilar-membrane movement that incorporate OHC electromotility [12.62]. An additional major uncertainty at present about a prestin-derived cochlear amplifier is the fact that prestin depends on the membrane potential as its driving signal [12.88]. Because the membrane potential is low-pass filtered by the cell's membrane capacitance, in the fashion seen in

prestin and again no charge movement can occur. Thus the nonlinear capacitance is significant only over the range of membrane potentials where the prestin molecules are partially bound to Cl^-. The bottom part of Fig. 12.12c shows the nonlinear capacitance as a function of membrane potential, showing the predicted behavior [12.113]. The top part of Fig. 12.12c shows the electrically produced change in cell length; as expected, changes in cell length are observed only over the range of membrane potentials where the nonlinear membrane capacitance is observed.

Fig. 12.10, it is not clear that a prestin-based mechanism can generate sufficient force at high frequencies.

The second possible mechanism for the cochlear amplifier is by stereocilia bundle movements that can amplify hair-cell stimulation either through nonlinearities in the compliance of the bundle or through active hair-bundle movements [12.89, 101]. Essentially these mechanisms work by moving the bundle further in the direction of its displacement, which would amplify the stimulation of the hair cell. Calculations suggest that the speed of bundle movement is sufficient and that the stiffness of the bundles is a significant fraction of the basilar-membrane stiffness, both necessary conditions for a stereociliary-bundle motor to be the cochlear amplifier. Of course both the prestin and stereociliary-bundle mechanisms may operate.

The final aspect of OHC physiology shown in Fig. 12.12a is the efferent synapse made by the MOC neuron on the OHC. This synapse activates an unusual cholinergic postsynaptic receptor which admits a significant Ca^{2+} current (dotted line), along with other cations, to the cytoplasm. The Ca^{2+} current activates a calcium-dependent potassium channel producing a larger potassium current (dashed line) [12.116]. The efferent synapse inhibits OHC function, decreasing the sensitivity of AN fibers and broadening their tuning, effects consistent with a decrease in cochlear amplification [12.31]. The mechanism is thought to be an increase in the membrane conductance of the OHC, from opening the calcium-dependent K^+ channel, which hyperpolarizes the cell and shorts the transducer current, producing a smaller receptor potential.

12.3 Auditory Nerve and Central Nervous System

In a previous section, the basic properties of AN fiber responses to acoustic stimuli were described. These properties can be related directly to the properties of the basilar membrane and hair cells. The auditory system does not usually deal with the kinds of simple stimuli that have been considered so far, i.e., tones of a fixed frequency. When multiple-tone complexes or other stimuli with multiple frequency components are presented to the ear, there are interactions among the frequency components that are important in shaping the responses. This section describes two such interactions and then provides an overview of the tasks performed by the remainder of the auditory system.

12.3.1 AN Responses to Complex Stimuli

Many of the features of responses of AN fibers to complex stimuli can be seen from the responses to a two-tone complex. An example is shown in Fig. 12.13 which shows responses of AN fibers to 2.17 and 2.79 kHz tones (called f_1 and f_2, respectively) presented simultaneously and separately [12.117]. In this experiment a large population of AN fibers were recorded in one animal and the same set of stimuli were presented to each fiber. Because fibers were recorded across a wide range of BFs, this approach allows the construction of an estimate of the response of the whole AN population. Responses are plotted in Fig. 12.13 as the strength of phase-locking to various frequency components of the stimulus. Phase-locking is used here to

allow the complex responses of the fibers to be separated into responses to the various individual frequency components. The abscissa is plotted as BF, on a reversed frequency scale, and also in terms of the distance of the fibers' points of innervation from the stapes.

The distribution of responses to the f_1 frequency component (2.17 kHz) presented alone is shown in Fig. 12.13a by the solid line. The response peaks near the point of maximum response to f_1, indicated by the arrow labeled f_1 at the top of the plot. The dotted line shows the phase-locking to f_1 when the stimulus is a simultaneous presentation of f_1 and f_2. The response to f_1 is similar in both cases, except near the point of maximum response to f_2 (at the arrow marked f_2) where the response to f_1 is reduced by the addition of f_2 to the stimulus. This phenomenon is called two-tone suppression [12.118, 119]; it can be suppression of phase-locking as in this case or it can be a decrease of the discharge rate in response to an excitor tone when a suppressor tone is added. Suppression can be seen on the basilar membrane as a reduction in the membrane motion at one frequency caused by the addition of a second frequency [12.34], and is usually explained as resulting from compression in the basilar-membrane input/output relationship.

The importance of suppression for responses to complex stimuli is that it improves the tonotopic separation of the components of the stimulus. In Fig. 12.13a, for example, f_1 presented by itself (solid line) gives a broad response that spreads away from the f_1 place

Fig. 12.13a,b Responses of a population of AN fibers to a two-tone complex consisting of $f_1 = 2.17$ kHz and $f_2 = 2.79$ kHz at 65 dB SPL. The *ordinates* show the strength of the phase-locked response as the synchronized rate divided by the spontaneous rate. Synchronized rate is the Fourier transform of the spike train at the appropriate frequency normalized to have units of spikes/s. Responses of a representative sample of fibers of different BFs were recorded. The lines are smoothed versions of the data computed as a moving-window average of the responses of individual fibers, for fibers with SR > 15 /s. **(a)** Phase-locking to f_1 for responses to the f_1 stimulus tone alone (*solid line*) and to both f_1 and f_2 (*dashed line*). The arrows at top show the BF places for the two frequencies. **(b)** The *top plots* and *left ordinate* show phase-locking to the combination frequencies $2f_1 - f_2$ (*dashed*) and $f_2 - f_1$ (*solid*) when the stimulus was f_1 and f_2. The *bottom plots* and the *right ordinate* show phase-locking to f_1 (*solid*) and f_2 (*dashed*). For both plots, data were taken only from fibers to which all the stimuli shown were presented. Thus the f_1 phase-locking in **(a)** (*dashed line*) and in the bottom part of **(b)** (*solid line*) differ slightly, even though they estimate the same response to the same stimulus, because they were computed from somewhat different populations of fibers (after [12.117] with permission) ◄

component is produced in the cochlea and is a prominent part of otoacoustic emissions for two-tone stimuli. It is used for both diagnostic and research purposes as a measure of OHC function [12.46]. In the cochlea, phase-locking at the frequency $2f_1 - f_2$ is seen, as shown by the dotted curve in the top part of Fig. 12.13b. It is important that the response to $2f_1 - f_2$ peaks at the place appropriate to the frequency $2f_1 - f_2$ (indicated by the arrow). The distribution of phase-locking to $2f_1 - f_2$ is similar to the distribution of phase-locking to a single tone at the frequency $2f_1 - f_2$, when account is taken of suppression effects and of sources of distortion in the region near the f_1 and f_2 places [12.117]. This behavior has been interpreted as showing that cochlear nonlinearities in the region of the primary tones (f_1 and f_2) lead to the creation of energy at the frequency $2f_1 - f_2$, which propagates on the basilar membrane in a fashion similar to an acoustic tone of that frequency presented at the ear. The phase of the responses (not shown) is consistent with this conclusion.

There is also a distortion tone at the frequency $f_2 - f_1$ (solid line in the top part of Fig. 12.13b), which appears to propagate on the basilar membrane and shows a peak of phase-locking at the appropriate place. This difference tone can also be heard by observers; how-

and encompasses the f_2 place. In the presence of f_2, the f_1 response is confined to points near the f_1 place, thus improving the effective *tuning* of the fibers for f_1. The bottom part of Fig. 12.13b shows that the responses at the f_2 place are dominated by phase-locking to f_2 when f_1 and f_2 are presented simultaneously (dashed curve). The suppression effect is symmetric and a dip in the response to f_2 is observed at the f_1 place (at the asterisk in the bottom plot of Fig. 12.13b) which represents suppression of f_2 by f_1.

The top part of Fig. 12.13b shows responses to combination tones, another phenomenon that can be important in responses to complex stimuli. When two tones are presented simultaneously, observers can hear distortion tones, most strongly at the cubic distortion frequency $2f_1 - f_2$ (1.55 kHz here). This distortion

ever, there are differences in the rate of growth of the percept of $f_2 - f_1$ versus $2f_1 - f_2$, such that the former grows nonlinearly and the latter linearly as the level of f_1 and f_2 are increased. As a result, $f_2 - f_1$ is audible at high sound levels only.

Responses to a somewhat more complex stimulus are shown in Fig. 12.14, in this case an approximation to the vowel /eh/, as in *met* [12.65]. The magnitude spectrum of the stimulus is shown in Fig. 12.14a. It consists of the harmonics of a 125 Hz fundamental with their amplitudes adjusted to approximate the spectrum of /eh/. The actual vowel has peaks of energy at the resonant frequencies of the vocal tract, called formants; these are indicated by F1, F2, and F3 in Fig. 12.14a. Again the experimental approach is to record from a large population of AN fibers in one animal and present the same stimulus to each fiber. The response of the whole population is estimated by a moving average of the data points for individual fibers. This stimulus contains many frequency components, so the responses are quite complex. However, the data show that formant frequencies dominate the responses. Note that combination tones always occur at the frequency of a real acoustic stimulus tone for a harmonic series like this, so it is not possible to analyze combination tones without making assumptions that allow the responses to combination and real tones to be separated [12.121].

The distribution of phase-locking in response to the formants and to one non-formant frequency are shown in Figs. 12.14b and 12.14c; these show responses at two sound levels. At 58 dB (Fig. 12.14b), the formant responses are clearly separated into different populations of fibers, so that the response to a formant is largest among fibers with BFs near the formant frequency. There are significant responses to all three formants, but there is little response to frequency components between the formants, such as the response to 1.152 kHz (dotted line). These results demonstrate a clear tonotopic representation of the vowel.

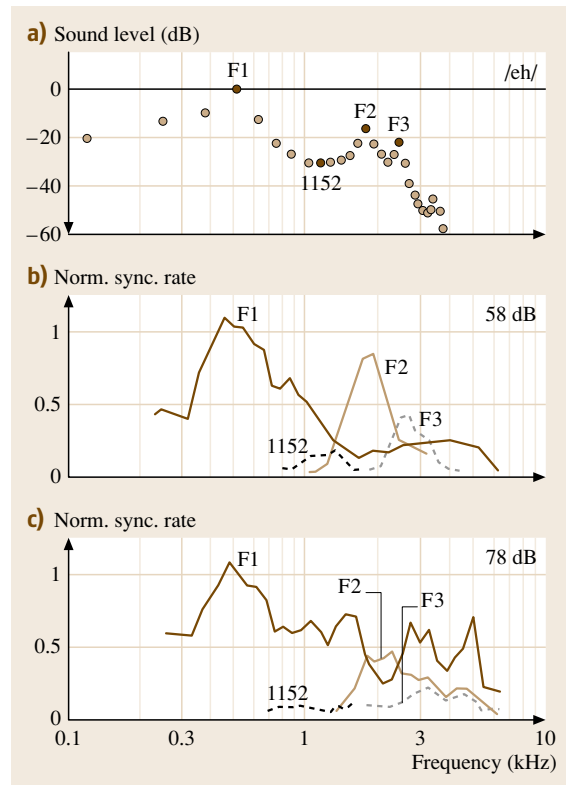
At 78 dB (Fig. 12.14c), the responses to F2 and F3 decrease in amplitude and the response to F1 spreads to occupy almost the entire population. This behavior is typically observed at high sound levels, where the phase-locking to a large low-frequency component of the stimulus spreads to higher BFs in the population [12.122]. Suppression plays two roles in this process. First, the spread of F1 and the decrease in response to F2 and F3 behave quantitatively like suppression of a tone at F2 or F3 by a tone at F1 and therefore seem to represent suppression of F2 and F3 by


Fig. 12.14a–c Responses to a stimulus similar to the vowel /eh/ presented at two sound levels in a population of AN fibers. (**a**) The magnitude spectrum of the stimulus. It is periodic and consists of harmonics of a 125 Hz fundamental. There are peaks of energy at the formant frequencies of a typical /eh/, near 0.5 (F1), 1.75 (F2), and 2.275 kHz (F3). The 1.152 kHz component in the trough between F1 and F2 is used for comparison in parts (**b**) and (**c**). (**b**) Distribution of phase-locking to four frequency components of the vowel when presented at 58 dB SPL, as labeled. These are moving-window averages of the phase-locking of individual fibers. Phase-locking here is the magnitude of the Fourier transform of the spike train at the frequency of interest normalized by the maximum discharge rate of the fiber. Maximum rate is the rate in response to a BF tone 50 dB above threshold. (**c**) Same for responses to the vowel at a sound level of 78 dB SPL (after [12.120, 121])

F1 [12.120]. Second, the response to F1 is suppressed among fibers with BFs near F2, as shown by dips in the phase-locking to F1 near the F2 place. Suppression acts to improve the representation in the latter case, but has the opposite effect in the former case.

12.3.2 Tasks of the Central Auditory System

The discussion so far concerns only the most basic aspects of physiological acoustics. The representation of sound in the AN is the input to a complex of neural pathways in the central auditory system. Discussion of specifics of the central processing of auditory stimuli is beyond the scope of this chapter. However, several recent books provide comprehensive coverage of the anatomy and physiology of this system, e.g., [12.123–126].

The representation of the auditory stimulus provided to the brain by the AN is a spectrotemporal one. That is, the responses of AN fibers provide an accurate representation of the moment-by-moment distribution of energy across frequency for the sound entering the ear. In terms of processing sound, the major steps taken in the cochlea are frequency analysis, compression, and suppression. Frequency analysis is essential to all of the processing that follows in the brain. Indeed central auditory centers are all organized by frequency and most properties of the perception of sound appear to include frequency analysis as a fundamental component. Compression is important for extending the dynamic range of hearing. Its importance is illustrated by the problems of loudness abnormality and oversensitivity to loud sounds in persons with damaged cochleae that are missing compression [12.127]. Suppression is important for maintaining the quality of the spectrotemporal representation, at least at moderate sound levels, and is the first example of interaction across frequencies in the auditory system. In the following paragraphs, some of the central nervous system's secondary analyses on the cochlear spectrotemporal representation are described.

The first function of the central auditory system is to stabilize the spectrotemporal representation provided in the AN. As shown in Fig. 12.14, the representation changes across sound level and the quality of the representation is generally lower at high sound levels and at low sound levels. In the cochlear nucleus the representation is more stable as sound level changes, e.g., for speech [12.128]. Presumably the stabilization occurs through optimal combination of information across SR groups in the AN and perhaps also through inhibitory interactions.

A second function of the lower central auditory system is binaural interaction. The location of sound sources is computed by the auditory system from small differences in the sounds at the two ears [12.84, 129]. Essentially, a sound is delayed in reaching the ear on the side of the head away from the source and is less intense there. Differences in interaural stimulus timing are small and require a specialized system of neurons in the first and second stages of the central auditory system to allow accurate representation of the interaural timing cues. A similar system is present for interaural differences in sound level. The representation of these cues is elaborated in higher levels, where neurons show response characteristics that might explain perceptual phenomena like binaural masking level differences [12.130] and the precedence effect [12.131].

A third aspect of central processing is that the representation of sound switches away from a spectrotemporal description of the stimulus, as in the AN, and moves to derived representations, such as one that represents auditory objects [12.132]. For example, the representation of speech in the auditory cortex does not take a recognizable tonotopic form, in that peaks of activity at BFs corresponding to the formant frequencies are not seen [12.133]. The nature of the representation used in the cortex is unknown; it is clearly based on a tonotopic axis, but neurons' responses are not determined in a straightforward way by the amount of energy in their tuning curves, as is observed in lower auditory nuclei [12.134]. In some cases, neurons specialized for particular auditory tasks have been found; neurons in one region of the marmoset cortex are tuned to pitch, for example [12.135]. Perhaps the best-studied cases are neurons that respond specifically to species-specific vocalizations in marmosets [12.136] and songbirds [12.137, 138].

12.4 Summary

Research on the auditory system has defined the means by which the system efficiently captures sound and couples it into the cochlea, how the frequency analysis of the cochlea is conducted, how transduction occurs, how nonlinear mechanisms involving the OHCs sharpen the frequency tuning, increase the sensitivity, and compress the stimulus intensity, and how suppression acting at the level of AN fibers maintains the sharpness of the frequency analysis for complex, multicomponent stimuli. Over the next dec-

ade, research on the auditory system will increasingly be focused on the organization and function of the central auditory system, with particular reference to the way in which central neurons derive information from the spectrotemporal display received from the AN.

Psychoacoust

13. Psychoacoustics

Brian C. J. Moore

Psychoacoustics is concerned with the relationships between the physical characteristics of sounds and their perceptual attributes. This chapter describes: the absolute sensitivity of the auditory system for detecting weak sounds and how that sensitivity varies with frequency; the frequency selectivity of the auditory system (the ability to resolve or *hear out* the sinusoidal components in a complex sound) and its characterization in terms of an array of auditory filters; the processes that influence the masking of one sound by another; the range of sound levels that can be processed by the auditory system; the perception and modeling of loudness; level discrimination; the temporal resolution of the auditory system (the ability to detect changes over time); the perception and modeling of pitch for pure and complex tones; the perception of timbre for steady and time-varying sounds; the perception of space and sound localization; and the mechanisms underlying *auditory scene analysis* that allow the construction of percepts corresponding to individual sounds sources when listening to complex mixtures of sounds.

13.1 Absolute Thresholds

The absolute threshold of a sound is the lowest detectable level of that sound in the absence of any other sounds. In practice, there is no distinct sound level at which a sound suddenly becomes detectable. Rather, the probability of detecting a sound increases progressively as the sound level is increased from a very low value. Hence, the absolute threshold is defined as the sound level at which an individual detects the sound with a certain probability, such as 75% (in a two-alternative forced-choice task, where guessing leads to 50% correct, on average). Typically, results are averaged across many listeners with normal hearing (i. e., with no known history of hearing disorders and no obvious signs of hearing problems) to obtain representative results.

The absolute threshold for detecting sinusoids is partly determined by the sound transmission through the outer and middle ear (Chap. 12); to a first approximation, the inner ear (the cochlea) is equally sensitive to all frequencies, except perhaps at very low frequencies and very high frequencies [13.3, 4]. Figure 13.1 shows esti-

mates of the absolute threshold, measured in two ways. For the curve labeled MAP, standing for minimum audible pressure, the sound level was measured at a point close to the eardrum [13.2]. For the curve labeled MAF, standing for minimum audible field, the measurement of sound level was made after the listener had been removed from the sound field, at the point which had been occupied by the center of the listener's head [13.1]. For the MAF curve, the sound was presented in free field (in an anechoic chamber) from a direction directly in front of the listener. Note that the MAP estimates are for monaural listening and the MAF estimates are for binaural listening. On average, thresholds are about 2 dB lower when two ears are used as opposed to one, al-

Fig. 13.1 The minimum audible sound level as a function of frequency. The *brown curve* shows the minimum audible field (MAF) for binaural listening published in an International Standards Organization (ISO) standard (after [13.1]). The *grey curve* shows the minimum audible pressure (MAP) for monaural listening (after [13.2])
Fig. 13.2a,b Comparison of a clinical audiogram for a 50 dB hearing loss at all frequencies (**a**) and the absolute threshold curve for the same hearing loss plotted in terms of the MAP (**b**)

though the exact value of the difference varies across studies from 0 to 3 dB, and it can depend on the interaural phase of the tone [13.5–7]. Both curves represent the average data from many young listeners with normal hearing. It should be noted, however, that individual people may have thresholds as much as 20 dB above or below the mean at a specific frequency and still be considered as normal.

The MAP and MAF curves are somewhat differently shaped, since the head, the pinna and the meatus have an influence on the sound field. The MAP curve shows only minor peaks and dips (±5 dB) for frequencies between about 0.2 kHz and 13 kHz, whereas the MAF curve shows a distinct dip around 3–4 kHz and a peak around 8–9 kHz. The difference derives mainly from a broad resonance produced by the meatus and pinna. The sound level at the eardrum is enhanced markedly for frequencies in the range 1.5–6 kHz, with a maximum enhancement at 3 kHz of about 15 dB.

The highest audible frequency varies considerably with age. Young children can often hear tones as high as 20 kHz, but for most adults the threshold rises rapidly above about 15 kHz. The loss of sensitivity with increasing age (presbyacusis) is much greater at high frequencies than at low, and the variability between different people is also greater at high frequencies. There seems to be no well-defined low-frequency limit to hearing, and very intense low-frequency tones can sometimes be felt as vibration as well as being heard. The lowest frequency that evokes a pitch sensation is about 20–30 Hz [13.8].

A third method of specifying absolute thresholds is commonly used when measuring hearing in clinical situations, for example, when a hearing impairment is suspected; thresholds are specified relative to the average threshold at each frequency for young, healthy listeners with normal hearing. In this case, the sound level is usually specified relative to standardized values produced by a specific earphone in a specific coupler. A coupler is a device that contains a cavity or series of cavities and a microphone for measuring the sound produced by the earphone. The preferred earphone varies from one country to another. For example, the Telephonics TDH49 or TDH50 is often used in the UK and USA, while the Beyer DT48 is used in Germany. Thresholds specified in this way have units of dB HL (hearing level) in Europe or dB HTL (hearing threshold level) in the USA. For example, a threshold of 40 dB HL at 1 kHz would mean that the person had a threshold that was 40 dB higher than normal at that frequency. In psychoacoustic work, thresholds are normally plotted with threshold increasing upward, as in Fig. 13.1. However, in audiology, threshold elevations are shown as hearing losses, plotted downward. The average normal threshold is represented as a horizontal line at the top of the plot, and the degree of hearing loss is indicated by how much the threshold falls below this line. This type of plot is called an audiogram. Figure 13.2 compares an audiogram for a hypothetical hearing-impaired person with a flat hearing loss, with a plot of the same thresholds expressed as MAP values. Notice that, although the audiogram is flat, the corresponding MAP curve is not flat. Note also that thresholds in dB HL can be negative. For example, a threshold of −10 dB simply means that the individual is 10 dB more sensitive than the average.

The absolute thresholds described above were measured using tone bursts of relatively long duration. For durations exceeding about 500 ms, the sound level at threshold is roughly independent of duration. However, for durations less than about 200 ms, the sound level necessary for detection increases as duration decreases, by about 3 dB per halving of the duration [13.9]. Thus, the sound energy required for threshold is roughly constant.

13.2 Frequency Selectivity and Masking

Frequency selectivity refers to the ability to resolve or separate the sinusoidal components in a complex sound. It is a key aspect of the analysis of sounds by the auditory system, and it influences many aspects of auditory perception, including the perception of loudness, pitch and timbre. It is often demonstrated and measured by studying masking, which has been defined as: *The process by which the threshold of audibility for one sound is raised by the presence of another (masking) sound* [13.10]. It has been known for many years that a signal is most easily masked by a sound having frequency components close to, or the same as, those of the signal [13.11]. This led to the idea that our ability to separate the components of a complex sound depends, at least in part, on the frequency analysis that takes place on the basilar membrane (Chap. 12).

13.2.1 The Concept of the Auditory Filter

Fletcher [13.13], following *Helmholtz* [13.14], suggested that the peripheral auditory system behaves as if it contains a bank of bandpass filters, with overlapping passbands. These filters are now called the auditory filters. Fletcher thought that the basilar membrane provided the basis for the auditory filters. Each location on the basilar membrane responds to a limited range of frequencies, so each different point corresponds to a filter with a different center frequency. When trying to detect a signal in a broadband noise background, the listener is assumed to make use of a filter with a center frequency close to that of the signal. This filter passes the signal but removes a great deal of the noise. Only the components in the noise that pass through the filter have any effect in masking the signal. It is usually assumed that the threshold for detecting the signal is determined by the amount of noise passing through the auditory filter; specifically, threshold is assumed to correspond to a certain signal-to-noise ratio at the output of the filter. This set of assumptions has come to be known as the *power spectrum model* of masking [13.15], since the stimuli are represented by their long-term power spectra, i. e., the short-term fluctuations in the masker are ignored.

The question considered next is: What is the shape of the auditory filter? In other words, how does its relative response change as a function of the input frequency? Most methods for estimating the shape of the auditory filter at a given center frequency are based on the assumptions of the power spectrum model of masking. The threshold of a signal whose frequency is fixed is measured in the presence of a masker whose spectral content is varied. It is assumed, as a first approximation, that the signal is detected using the single auditory filter that is centered on the frequency of the signal, and that threshold corresponds to a constant signal-to-masker ratio at the output of that filter. The methods described below both measure the shape of the filter using this technique.

13.2.2 Psychophysical Tuning Curves

One method of measuring the shape of the auditory filter involves a procedure that is analogous in many ways to the determination of a neural tuning curve (Chap. 12), and the resulting function is often called a psychophysical tuning curve (PTC). To determine a PTC, the signal is fixed in level, usually at a very low level, say, 10 dB above absolute threshold (called 10 dB sensation level, SL). The masker can be either a sinusoid or a noise with a small bandwidth.
Fig. 13.3 Psychophysical tuning curves (PTCs) determined in simultaneous masking, using sinusoidal signals at 10 dB SL. For each curve, the *circle* below it indicates the frequency and level of the signal. The masker was a sinusoid which had a fixed starting phase relationship to the 50 ms signal. The masker level required for threshold is plotted as a function of masker frequency on a logarithmic scale. The *dashed line* shows the absolute threshold for the signal (after *Vogten* [13.12])

For each of several masker center frequencies, the level of the masker needed just to mask the signal is determined. Because the signal is at a low level it is assumed that it produces activity primarily at the output of a single auditory filter. It is assumed further that at threshold the masker produces a constant output from that filter, in order to mask the fixed signal. Thus the PTC indicates the masker level required to produce a fixed output from the auditory filter as a function of frequency. Normally a filter characteristic is determined by plotting the output from the filter for an input varying in frequency and fixed in level. However, if the filter is linear the two methods give the same result. Thus, assuming linearity, the shape of the auditory filter can be obtained simply by inverting the PTC. Examples of some PTCs are given in Fig. 13.3.

One problem in interpreting PTCs is that, in practice, the listener may use the information from more than one auditory filter. When the masker frequency is above the signal frequency the listener might do better to use the information from a filter centered just below the signal frequency. If the filter has a relatively flat top, and sloping edges, this will considerably attenuate the masker at the filter output, while only slightly attenuating the signal. By using this off-center filter the listener can improve performance. This is known

as *off-frequency listening*, and there is now good evidence that humans do indeed listen off-frequency when it is advantageous to do so [13.16, 17]. The result of off-frequency listening is that the PTC has a sharper tip than would be obtained if only one auditory filter were involved [13.18].

13.2.3 The Notched–Noise Method

Patterson [13.19] described a method of determining auditory filter shape that limits off-frequency listening. The method is illustrated in Fig. 13.4. The signal (indicated by the bold vertical line) is fixed in frequency, and the masker is a noise with a bandstop or notch centered at the signal frequency. The deviation of each edge of the noise from the center frequency is denoted by Δf. The width of the notch is varied, and the threshold of the signal is determined as a function of notch width. Since the notch is symmetrically placed around the signal frequency, the method cannot reveal asymmetries in the auditory filter, and the analysis assumes that the filter is symmetric on a linear frequency scale. This assumption appears not unreasonable, at least for the top part of the filter and at moderate sound levels, since PTCs are quite symmetric around the tips. For a signal symmetrically placed in a bandstop noise, the optimum signal-to-masker ratio at the output of the auditory filter is achieved with

a filter centered at the signal frequency, as illustrated in Fig. 13.4.

As the width of the spectral notch is increased, less noise passes through the auditory filter. Thus the threshold for detecting the signal drops. The amount of noise passing through the auditory filter is proportional to the area under the filter in the frequency range covered by the noise. This is shown as the dark shaded areas in Fig. 13.4. Assuming that threshold corresponds to a constant signal-to-masker ratio at the output of the filter, the change in signal threshold with notch width indicates how the area under the filter varies with Δf. The area under a function between certain limits is obtained by integrating the value of the function over those limits. Hence by differentiating the function relating threshold to Δf, the relative response of the filter at that value of Δf is obtained. In other words, the relative response of the filter for a given deviation, Δf, from the center frequency is equal to the slope of the function relating signal threshold to notch width, at that value of Δf.

A typical auditory filter derived using this method is shown in Fig. 13.5. It has a rounded top and quite steep skirts. The sharpness of the filter is often specified as the bandwidth of the filter at the points where the response has fallen by a factor of two in power, i. e., by 3 dB. The 3 dB bandwidths of the auditory filters derived using the notched-noise method are typically between 10%
Fig. 13.4 Schematic illustration of the technique used by *Patterson* [13.19] to determine the shape of the auditory filter. The threshold of the sinusoidal signal (indicated by the *vertical line*) is measured as a function of the width of a spectral notch in the noise masker. The amount of noise passing through the auditory filter centered at the signal frequency is proportional to the *dark shaded areas*
Fig. 13.5 A typical auditory filter shape determined using Patterson's method. The filter is centered at 1 kHz. The relative response of the filter (in dB) is plotted as a function of frequency

and 15% of the center frequency. An alternative measure is the equivalent rectangular bandwidth (ERB), which is the bandwidth of a rectangular filter that has the same peak transmission as the filter of interest and that passes the same total power for a white noise input. The ERB of the auditory filter is a little larger than the 3 dB bandwidth. In what follows, the mean ERB of the auditory filter determined using young listeners with normal hearing and using a moderate noise level is denoted ERB_N (where the subscript N denotes normal hearing). An equation describing the value of ERB_N as a function of center frequency, F (in Hz), is [13.20]:

$$ERB_N = 24.7(0.00437F + 1) \,. \tag{13.1}$$

Sometimes it is useful to plot psychoacoustical data on a frequency scale related to ERB_N, called the ERB_N-number scale. For example, the value of ERB_N for a center frequency of 1 kHz is about 132 Hz, so an increase in frequency from 934 to 1066 Hz represents a step of one unit on the ERB_N-number scale. The units of ERB_N-number are *Cams*. A formula relating ERB_N number in Cams to frequency is [13.20]:

$$ERB_N\text{-number} = 21.4 \log_{10}(0.00437F + 1) \,, \tag{13.2}$$

where F is frequency in Hz. This scale is conceptually similar to the Bark scale proposed by *Zwicker* and coworkers [13.22], although it differs somewhat in numerical values.

The notched-noise method has been extended to include conditions where the spectral notch in the noise is placed asymmetrically about the signal frequency. This allows the measurement of any asymmetry in the auditory filter, but the analysis of the results is more difficult, and has to take off-frequency listening into account [13.23]. It is beyond the scope of this chapter to give details of the method of analysis; the interested reader is referred to [13.15, 20, 24, 25]. The results show that the auditory filter is reasonably symmetric at moderate sound levels, but becomes increasingly asymmetric at high levels, the low-frequency side becoming shallower than the high-frequency side. The filter shapes derived using the notched-noise method are quite similar to inverted PTCs [13.26], except that PTCs are slightly sharper around their tips, probably as a result of off-frequency listening.

13.2.4 Masking Patterns and Excitation Patterns

In the masking experiments described so far, the frequency of the signal was held constant, while the masker was varied. These experiments are most appropriate for estimating the shape of the auditory filter at a given center frequency. However, many of the early experiments on masking did the opposite; the masker was held constant in both level and frequency and the signal threshold was measured as a function of the signal frequency. The resulting functions are called masking patterns or masked audiograms.

Masking patterns show steep slopes on the low-frequency side (when the signal frequency is below that of the masker), of between 55 and 240 dB/octave. The slopes on the high-frequency side are less steep and depend on the level of the masker. A typical set of results is shown in Fig. 13.6. Notice that on the high-frequency side the curve is shallower at the highest level. Around the tip of the masking pattern, the growth of masking is approximately linear; a 10 dB increase in masker level leads to roughly a 10 dB increase in the signal threshold. However, for signal frequencies in the range from about 1300 to 2000 Hz, when the level of the masker is increased by 10 dB (e.g., from 70 to 80 dB SPL), the masked threshold increases by more than 10 dB; the amount of masking grows nonlinearly on the high-frequency side. This has been called the *upward spread of masking*.

The masking patterns do not reflect the use of a single auditory filter. Rather, for each signal frequency the listener uses a filter centered close to the signal frequency. Thus the auditory filter is shifted as the sig-
Fig. 13.6 Masking patterns for a narrow-band noise masker centered at 410 Hz. Each curve shows the elevation in threshold of a pure-tone signal as a function of signal frequency. The overall noise level for each curve is indicated in the figure (after *Egan* and *Hake* [13.21])

nal frequency is altered. One way of interpreting the masking pattern is as a crude indicator of the excitation pattern of the masker [13.27]. The excitation pattern is a representation of the effective amount of excitation produced by a stimulus as a function of characteristic frequency (CF) on the basilar membrane (BM; see Chap. 12), and is plotted as effective level (in dB) against CF. In the case of a masking sound, the excitation pattern can be thought of as representing the relative amount of vibration produced by the masker at different places along the basilar membrane. The signal is detected when the excitation it produces is some constant proportion of the excitation produced by the masker at places with CFs close to the signal frequency. Thus the threshold of the signal as a function of frequency is proportional to the masker excitation level. The masking pattern should be parallel to the excitation pattern of the masker, but shifted vertically by a small amount. In practice, the situation is not so straightforward, since the shape of the masking pattern is influenced by factors such as off-frequency listening, and the detection of beats and combination tones [13.28].

Moore and *Glasberg* [13.29] have described a way of deriving the shapes of excitation patterns using the concept of the auditory filter. They suggested that the excitation pattern of a given sound can be thought of as the output of the auditory filters plotted as a function of their center frequency. To calculate the excitation pattern of a given sound, it is necessary to calculate the output of each auditory filter in response to that sound, and to plot the output as a function of the filter center frequency. The characteristics of the auditory filters are determined using the notched-noise method described earlier. Figure 13.7 shows excitation patterns calculated in this way for 1000 Hz sinusoids with various levels. The patterns are similar in form to the masking patterns shown in Fig. 13.6. Software for calculating excitation patterns can be downloaded from [13.30].
13.2.5 Forward Masking

Masking can occur when the signal is presented just before or after the masker. This is called non-simultaneous masking and it is studied using brief signals, often called *probes*. Two basic types of non-simultaneous masking can be distinguished: (1) backward masking, in which the probe precedes the masker; and (2) forward masking, in which the probe follows the masker. Although many studies of backward masking have been published, the phenomenon is poorly understood. The amount of backward masking obtained depends strongly on how much practice the subjects have received, and practiced subjects often show little or no backward masking [13.31, 32]. The larger masking effects found for unpracticed subjects may reflect some sort of confusion of the signal with the masker. In the following, I will focus on forward masking, which can be substantial even in highly practiced subjects. The main properties of forward masking are as follows:

1. Forward masking is greater the nearer in time to the masker that the signal occurs. This is illustrated in the upper panel of Fig. 13.8. When the delay D of the signal after the end of the masker is plotted on a logarithmic scale, the data fall roughly on a straight line. In other words, the amount of forward masking, in dB, is a linear function of log D.
2. The rate of recovery from forward masking is greater for higher masker levels. Regardless of the initial amount of forward masking, the masking decays to zero after 100–200 ms.
3. A given increment in masker level does not produce an equal increment in amount of forward masking. For example, if the masker level is increased by 10 dB, the masked threshold may only increase by 3 dB. This contrasts with simultaneous masking,

Fig. 13.7 Calculated psychoacoustical excitation patterns for a 1 kHz sinusoid at levels ranging from 20 to 90 dB SPL in 10 dB steps
Fig. 13.8a,b Panel (**a**) shows the amount of forward mask-ing of a brief 4 kHz signal, plotted as a function of the time delay of the signal after the end of the noise masker. Each curve shows results for a different noise level, specified as the level in a one-ERB$_N$-wide band centered at 4 kHz. The results for each level fall roughly on a straight line when the signal delay is plotted on a logarithmic scale, as here. Panel (**b**) shows the same thresholds plotted as a function of masker level. Each curve shows results for a different signal delay time (17.5, 27.5, or 37.5 ms). Note that the slopes of these growth of masking functions decrease with increasing signal delay. The *dashed line* indicates a slope of 1 (after *Moore* and *Glasberg* [13.33])

where, at least for wide-band maskers, threshold corresponds approximately to a constant signal-to-masker ratio. This effect can be quantified by plot-ting the signal threshold as a function of the masker level. The resulting function is called a growth of masking function. Several such functions are shown in the lower panel of Fig. 13.8. In simultaneous

masking such functions would have slopes close to one, as indicated by the dashed line. In forward masking the slopes are usually less than one, and the slopes decrease as the value of *D* increases.
4. The amount of forward masking increases with in-creasing masker duration for durations up to at least 50 ms. The results for greater masker dura-tions vary somewhat across studies. Some studies show an effect of masker duration for durations up to 200 ms [13.34, 35], while others show little effect for durations beyond 50 ms [13.36].
5. Forward masking is influenced by the relation be-tween the frequencies of the signal and the masker (just as in the case of simultaneous masking).

The basis of forward masking is still not clear. Four factors may contribute:

1. The response of the BM to the masker contin-ues for some time after the end of the masker, an effect known as *ringing*. If the ringing overlaps with the response to the signal, then this may con-tribute to the masking of the signal. The duration of the ringing is less at places tuned to high fre-quencies, whose bandwidth is larger than at low frequencies. Hence, ringing plays a significant role only at low frequencies [13.37–39]. For frequencies above 200–300 Hz, the amount of forward mask-ing for a given masker level and signal delay time is roughly independent of frequency [13.40].
2. The masker produces short-term adaptation or fa-tigue in the auditory nerve or at higher centers in the auditory system, which reduces the response to a signal presented just after the end of the masker [13.41]. However, the effect in the auditory nerve may be too small to account for the forward masking observed behaviorally [13.42].
3. The neural activity evoked by the masker persists at some level in the auditory system higher than the auditory nerve, and this persisting activity masks the signal [13.43].
4. The masker may evoke a form of inhibition in the central auditory system, and this inhibition persists for some time after the end of the masker [13.44].

Oxenham and *Moore* [13.45] have suggested that the shallow slopes of the growth of masking func-tions, as shown in the bottom panel of Fig. 13.8, can be explained, at least qualitatively, in terms of the com-pressive input–output function of the BM (Chap. 12). Such an input–output function is shown schematically
Fig. 13.9 Illustration of why growth of masking functions in forward masking usually have shallow slopes. The *solid curve* shows a schematic input–output function on the basilar membrane. The relative response is plotted on a dB scale with an arbitrary origin. When the masker is increased in level by ΔM, this produces an increase in response of ΔO. To restore signal threshold, the response to the signal also has to be increased by ΔO. This requires an increase in signal level, ΔS, which is markedly smaller than ΔM

in Fig. 13.9. It has a shallow slope for medium input levels, but a steeper slope at very low input levels. Assume that, for a given time delay of the signal relative to the masker, the response evoked by the signal at threshold is directly proportional to the response evoked by the masker. Assume, as an example, that a masker with a level of 40 dB produces a signal threshold of 10 dB. Consider now what happens when the masker level is increased by 30 dB. The increase in masker level, denoted by ΔM in Fig. 13.9, produces a relatively small increase in response, ΔO. To restore the signal to threshold, the signal has to be increased in level so that the response to it also increases by ΔO. However, this requires a relatively small increase in signal level, ΔS, as the signal level falls in the range where the input–output function is relatively steep. Thus, the growth of masking function has a shallow slope.

According to this explanation, the shallow slope of the growth of masking function arises from the fact that the signal level is lower than the masker level, so the masker is subject to more compression than the signal. The input–output function on the BM has a slope that decreases progressively with increasing level over the range 0 to about 50 dB SPL. Hence the slope of the growth of masking function should decrease with

increasing difference in level between the masker and signal. This can account for the progressive decrease in the slopes of the growth of masking functions with increasing delay between the signal and masker (see the right-hand panel of Fig. 13.8); longer delays are associated with greater differences in level between the signal and masker. Another prediction is that the growth of masking function for a given signal delay should increase in slope if the signal level is high enough to fall in the compressive region of the input–output function. Such an effect can be seen in the growth of masking function for the shortest delay time in Fig. 13.8; the function steepens for the highest signal level.

In summary, the processes underlying forward masking are not fully understood. Contributions from a number of different sources may be important. Temporal overlap of patterns of vibration on the BM may be important, especially for small delay times between the signal and masker. Short-term adaptation or fatigue in the auditory nerve may also play a role. At higher neural levels, a persistence of the excitation or inhibition evoked by the masker may occur. The form of the growth of masking functions can be explained, at least qualitatively, in terms of the nonlinear input–output functions observed on the BM.

13.2.6 Hearing Out Partials in Complex Tones

A complex tone, such as a tone produced by a musical instrument, usually evokes a single pitch; pitches corresponding to the frequencies of individual partials are not usually perceived. However, such pitches can be heard if attention is directed appropriately. In other words, individual partials can be *heard out*. *Plomp* [13.46] and *Plomp* and *Mimpen* [13.47] used complex tones with 12 equal-amplitude sinusoidal components to investigate the limits of this ability. The listener was presented with two comparison tones, one of which was of the same frequency as a partial in the complex; the other lay halfway between that frequency and the frequency of the adjacent higher or lower partial. The listener had to judge which of these two tones was a component of the complex. Plomp used two types of complex: a harmonic complex containing harmonics 1 to 12, where the frequencies of the components were integer multiples of that of the fundamental; and a nonharmonic complex, where the frequencies of the components were mistuned from simple frequency ratios. He found that for both kinds of complex, partials could only be heard out if they were sufficiently far in frequency from neighboring

partials. The data, and other more recent data [13.48], are consistent with the hypothesis that a partial can be heard out (with 75% accuracy) when it is separated from neighboring (equal-amplitude) partials by 1.25 times the ERB_N of the auditory filter. For harmonic complex tones, only the first (lowest) five to eight harmonics can be heard out, as higher harmonics are separated by less than 1.25 ERB_N.

It seems likely that the analysis of partials from a complex sound depends in part on factors other than the frequency analysis that takes place on the basilar membrane. *Soderquist* [13.49] compared musicians and non-musicians in a task very similar to that of Plomp, and found that the musicians were markedly superior. This result could mean that musicians have smaller auditory filter bandwidths than non-musicians. However, *Fine* and *Moore* [13.50] showed that auditory filter bandwidths, as estimated in a notched-noise masking experiment, did not differ for musicians and non-musicians. It seems that some mechanism other than peripheral filtering is involved in hearing out partials from complex tones and that musicians, because of their greater experience, are able to make more efficient use of this mechanism.

13.3 Loudness

The human ear is remarkable both in terms of its absolute sensitivity and the range of sound intensities to which it can respond. The most intense sound that can be heard without damaging the ear has a level about 120 dB above the absolute threshold; this range is referred to as the dynamic range of the auditory system and it corresponds to a ratio of intensities of 1 000 000 000 000 : 1.

Loudness corresponds to the subjective impression of the magnitude of a sound. The formal definition of loudness is: that intensive attribute of auditory sensation in terms of which sounds can be ordered on a scale extending from soft to loud [13.10]. Because loudness is subjective, it is very difficult to measure in a quantitative way. Estimates of loudness can be strongly affected by bias and context effects of various kinds [13.51, 52]. For example the impression of loudness of a sound with a moderate level (say, 60 dB SPL) can be affected by presenting a high level sound (say, 100 dB SPL) before the moderate level sound.

13.3.1 Loudness Level and Equal-Loudness Contours

It is often useful to be able to compare the loudness of sounds with that of a standard, reference sound. The most common reference sound is a 1000 Hz sinusoid, presented binaurally in a free field, with the sound coming from directly in front of the listener. The loudness level of a sound is defined as the intensity level of a 1000 Hz sinusoid that is equal in loudness to the sound. The unit of loudness level is the phon. Thus, the loudness level of any sound in phons is the level (in dB SPL) of the 1000 Hz sinusoid to which it sounds equal in loudness. For example, if a sound appears to be as loud as a 1000 Hz sinusoid with a level of 45 dB SPL, then the sound has a loudness level of 45 phons. To determine the loudness level of a given sound, the subject is asked to adjust the level of a 1000 Hz sinusoid until it appears to have the same loudness as that sound. The 1000 Hz sinusoid and the test sound are presented alternately rather than simultaneously.
Fig. 13.10 Equal-loudness contours for loudness levels from 10 to 100 phons for sounds presented binaurally from the frontal direction. The absolute threshold curve (the MAF) is also shown. The curves for loudness levels of 10 and 100 phons are *dashed*, as they are based on interpolation and extrapolation, respectively

In a variation of this procedure, the 1000 Hz sinusoid is fixed in level, and the test sound is adjusted to give a loudness match, again with alternating presentation. If this is repeated for various different frequencies of a sinusoidal test sound, an equal-loudness contour is generated [13.53, 54]. For example, if the 1000 Hz sinusoid is fixed in level at 40 dB SPL, then the 40 phon equal-loudness contour is generated. Figure 13.10 shows equal-loudness contours as published in a recent standard [13.54]. The figure shows equal-loudness contours for binaural listening for loudness levels from 10–100 phons, and it also includes the absolute threshold (MAF) curve. The listening conditions were similar to those for determining the MAF curve; the sound came from a frontal direction in a free field. The equal-loudness contours are of similar shape to the MAF curve, but tend to become flatter at high loudness levels.

Note that the subjective loudness of a sound is not directly proportional to its loudness level in phons. For example, a sound with a loudness level of 80 phons sounds much more than twice as loud as a sound with a loudness level of 40 phons. This is discussed in more detail in the next section.

13.3.2 The Scaling of Loudness

Several methods have been developed that attempt to measure directly the relationship between the physical magnitude of sound and perceived loudness [13.55]. In one, called magnitude estimation, sounds with various different levels are presented, and the subject is asked to assign a number to each one according to its perceived loudness. In a second method, called magnitude production, the subject is asked to adjust the level of a sound until it has a loudness corresponding to a specified number.

On the basis of results from these two methods, Stevens suggested that loudness, L, was a power function of physical intensity I,

$$L = kI^{0.3} , \tag{13.3}$$

where k is a constant depending on the subject and the units used. In other words, the loudness of a given sound is proportional to its intensity raised to the power 0.3. Note that this implies that loudness is *not* linearly related to intensity; rather, it is a *compressive* function of intensity. An approximation to this equation is that the loudness doubles when the intensity is increased by a factor of 10, or, equivalently, when the level is increased by 10 dB. In practice, this relationship only
Fig. 13.11 The relationship between loudness in sones and loudness level in phons for a 1000 Hz sinusoid. The curve is based on the loudness model of *Moore* et al. (after [13.3])

holds for sound levels above about 40 dB SPL. For lower levels than this, the loudness changes with intensity more rapidly than predicted by the power-law equation.

The unit of loudness is the *sone*. One sone is defined arbitrarily as the loudness of a 1000 Hz sinusoid at 40 dB SPL, presented binaurally from a frontal direction in a free field. Fig. 13.11 shows the relationship between loudness in sones and the physical level of a 1000 Hz sinusoid, presented binaurally from a frontal direction in a free-field; the level of the 1000 Hz tone is equal to its loudness level in phons. This figure is based on predictions of a loudness model [13.3], but it is consistent with empirical data obtained using scaling methods [13.56]. Since the loudness in sones is plotted on a logarithmic scale, and the decibel scale is itself logarithmic, the curve shown in Fig. 13.11 approximates a straight line for levels above 40 dB SPL. The slope corresponds to a doubling of loudness for each 10 dB increase in sound level.

13.3.3 Neural Coding and Modeling of Loudness

The mechanisms underlying the perception of loudness are not fully understood. A common assumption is that
Fig. 13.12 Block diagram of a typical loudness model

loudness is somehow related to the total neural activity evoked by a sound, although this concept has been questioned [13.57]. In any case, it is commonly assumed that loudness depends upon a summation of loudness contributions from different frequency channels (i. e., different auditory filters). Models incorporating this basic concept have been proposed by *Fletcher* and *Munson* [13.58], by *Zwicker* [13.59, 60] and by *Moore* and coworkers [13.3, 61]. The models attempt to calculate the average loudness that would be perceived by a large group of listeners with normal hearing under conditions where biases are minimized as far as possible. The recent models have the basic form illustrated in Fig. 13.12. The first stage is a fixed filter to account for the transmission of sound through the outer and middle ear. The next stage is the calculation of an excitation pattern for the sound under consideration. In most of the models, the excitation pattern is calculated from psychoacoustical masking data, as described earlier. From the excitation-pattern stage onwards, the models should be considered as multichannel; the excitation pattern is sampled at regular intervals along the ERB_N-number scale, each sample value corresponding to the amount of excitation at a specific center frequency.

The next stage is the transformation from excitation level (dB) to specific loudness, which is a kind of *loudness density*. It represents the loudness that would be evoked by the excitation within a small fixed distance along the basilar membrane if it were possible to present that excitation alone (without any excitation at adjacent regions on the basilar membrane). In the model of *Moore* et al. [13.3], the distance is 0.89 mm, which corresponds to one ERB_N, so the specific loudness represents the loudness per ERB_N. The specific loudness plotted as a function of ERB_N-number is called the *specific loudness pattern*. The specific loudness cannot be measured either physically or subjectively. It is a theoretical construct used as an intermediate stage in the loudness models. The transformation from excitation level to specific loudness involves a compressive nonlinearity. Although the models are based on psychoacoustical data, this transformation can be thought of as representing the way that physical excitation is

transformed into neural activity; the specific loudness is assumed to be related to the amount of neural activity at the corresponding CF. The overall loudness of a given sound, in sones, is assumed to be proportional to the total area under the specific loudness pattern. In other words, the overall loudness is calculated by summing the specific loudness values across all ERB_N numbers (corresponding to all center frequencies).

Loudness models of this type have been rather successful in accounting for experimental data on the loudness of both simple sounds and complex sounds [13.3]. They have also been incorporated into loudness meters, which can give an appropriate indication of the loudness of sounds even when they fluctuate over time [13.27,61,62]. Software for calculating loudness using the model of *Moore* et al. [13.3] can be downloaded from [13.30]. The American National Standards Institute (ANSI) standard for calculating loudness [13.63] is based on this model.

13.3.4 The Effect of Bandwidth on Loudness

Consider a complex sound of fixed energy (or intensity) having a bandwidth W. If W is less than a certain bandwidth, called the critical bandwidth for loudness, CB_L, then the loudness of the sound is almost independent of W; the sound is judged to be about as loud as a pure tone or narrow band of noise of equal intensity lying at the center frequency of the band. However, if W is increased beyond CB_L, the loudness of the complex begins to increase. This has been found to be the case for bands of noise [13.27, 64] and for complex sounds consisting of several pure tones whose frequency separation is varied [13.65, 66]. An example for bands of noise is given in Fig. 13.13. The CB_L for the data in Fig. 13.13 is about 250–300 Hz for a center frequency of 1420 Hz, although the exact value of CB_L is hard to determine. The value of CB_L is similar to, but a little greater than, the ERB_N of the auditory filter. Thus, for a given amount of energy, a complex sound is louder if its bandwidth exceeds one ERB_N than if its bandwidth is less than one ERB_N.
Fig. 13.13 The level of a 210 Hz-wide noise required to match the loudness of a noise of variable bandwidth is plotted as a function of the variable bandwidth; the bands of noise were geometrically centered at 1420 Hz. The number by each curve is the overall noise level in dB SPL (after *Zwicker* et al. [13.64])

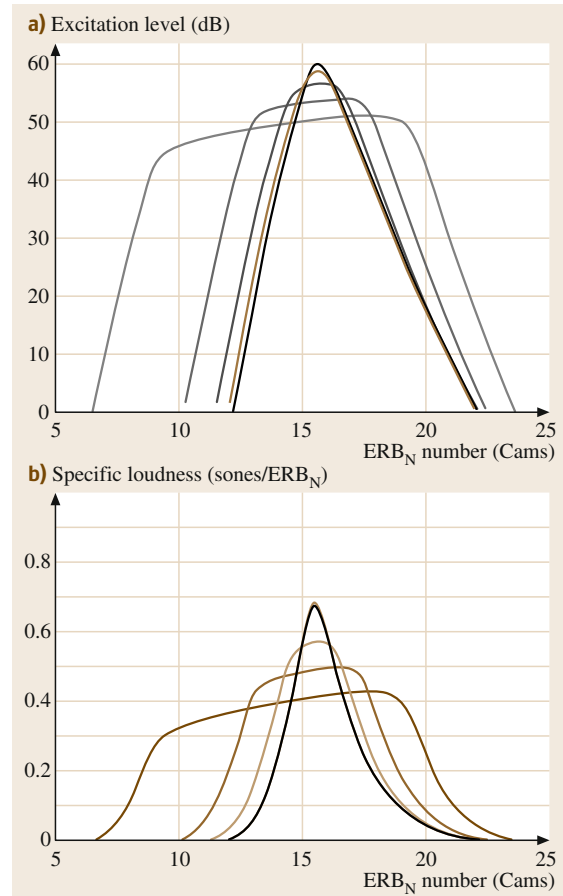
The pattern of results shown in Fig. 13.13 can be understood in terms of the loudness models described above. First, a qualitative account is given to illustrate the basic concept. When a sound has a bandwidth less than one ERB_N at a given center frequency, the excitation pattern and the specific loudness pattern are roughly independent of the bandwidth of the sound [13.67]. Further, the overall loudness is dominated by the specific loudness at the peak of the pattern. Consider now the effect of increasing the bandwidth of a sound from one ERB_N to N ERB_N, keeping the overall power, $P_{overall}$, constant. The power in each one-ERB_N-wide band is now $P_{overall}/N$. However, the peak specific loudness evoked by each band decreases by much less than a factor of N, because of the compressive relationship between excitation and specific loudness. For example, if $N = 10$, the peak specific loudness evoked by each band decreases by a factor of about two. Thus, in this example, there are ten bands each about half as loud as the original one-ERB_N-wide band, so the overall loudness is about a factor of five greater for the ten-ERB_N-wide than for the one-ERB_N-wide band. Generally, once the bandwidth is increased beyond one ERB_N, the loudness goes up because the decrease in loudness per ERB_N is more than offset by the increase in the number of channels contributing significantly to the overall loudness.


Fig. 13.14a,b Panel (a) shows excitation patterns for a 1 kHz sinusoid with a level of 60 dB SPL (the narrowest pattern with the highest peak) and for noise bands of various widths, all centered at 1 kHz and with an overall level of 60 dB SPL. The frequency scale has been transformed to an ERB_N number scale. The noise bands have widths of 20, 60, 140, 300, 620 and 1260 Hz. As the bandwidth is increased, the patterns decrease in height but spread over a greater number of Cams. Panel (b) shows specific loudness patterns corresponding to the excitation patterns in the upper panel. For bandwidths up to 140 Hz, the area under the specific loudness patterns is constant. For greater bandwidths, the total area increases

This argument is illustrated in a more quantitative way in Fig. 13.14, which shows excitation patterns (top) and specific loudness patterns (bottom) for a sinusoid and for bands of noise of various widths (20, 40, 60, 140, 300 and 620 Hz), all with a level of 60 dB SPL, calculated using the model of *Moore* et al. [13.3]. With

increasing bandwidth, the specific loudness patterns become lower at their tips, but broader. For the first three bandwidths, the small decrease in area around the tip is almost exactly canceled by the increase on the skirts, so the total area remains almost constant. When the bandwidth is increased beyond 140 Hz, the increase on the skirts is greater than the decrease around the tip, and so the total area, and hence the predicted loudness, increases. The value of CB_L in this case is a little greater than 140 Hz. Since the increase in loudness depends on the summation of specific loudness at different center frequencies, the increase in loudness is often described as loudness summation.

At low sensation levels (around 10–20 dB SL), the loudness of a complex sound is roughly independent of bandwidth. This can also be explained in terms of the loudness models described above. At these low levels, specific loudness changes rapidly with excitation level, and so does loudness. As a result, the total area under the specific loudness pattern remains almost constant as the bandwidth is altered, even for bandwidths greater than CB_L. Thus, loudness is independent of bandwidth. When a narrow-band sound has a very low sensation level (below 10 dB), then if the bandwidth is increased keeping the total energy constant, the output of each auditory filter becomes insufficient to make the sound audible. Accordingly, near threshold, loudness must decrease as the bandwidth of a complex sound is increased from a small value. As a consequence, if the intensity of a complex sound is increased slowly from a subthreshold value, the rate of growth of loudness is greater for a wide-band sound than for a narrow-band sound.

13.3.5 Intensity Discrimination

The smallest detectable change in intensity of a sound has been measured for many different types of stimuli by a variety of methods. The three main methods are:

1. Modulation detection. The stimulus is amplitude modulated (i. e., made to vary in amplitude) at a slow regular rate and the listener is required to detect the modulation. Usually, the modulation is sinusoidal.
2. Increment detection. A continuous background stimulus is presented, and the subject is required to detect a brief increment in the level of the background. Often the increment is presented at one of two possible times, indicated by lights, and the listener is required to indicate whether the increment occurred synchronously with the first light or the second light.

3. Intensity discrimination of gated or pulsed stimuli. Two (or more) separate pulses of sound are presented successively, one being more intense than the other(s), and the subject is required to indicate which pulse was the most intense.

In all of these tasks, the subjective impression of the listener is of a change in loudness. For example, in method 1 the modulation is heard as a fluctuation in loudness. In method 2 the increment is heard as a brief increase in loudness of the background, or sometimes as an extra sound superimposed on the background. In method 3, the most intense pulse appears louder than the other(s). Although there are some minor discrepancies in the experimental results for the different methods, the general trend is similar. For wideband noise, or for bandpass-filtered noise, the smallest detectable intensity change, ΔI, is approximately a constant fraction of the intensity of the stimulus, I. In other words, $\Delta I/I$ is roughly constant. This is an example of Weber's Law, which states that the smallest detectable change in a stimulus is proportional to the magnitude of that stimulus. The value of $\Delta I/I$ is called the Weber fraction. Thresholds for detecting intensity changes are often specified as the change in level at threshold, ΔL, in decibels. The value of ΔL is given by

$$\Delta L = 10 \log_{10}[(I + \Delta I)/I] \, . \qquad (13.4)$$

As $\Delta I/I$ is constant, ΔL is also constant, regardless of the absolute level, and for wide-band noise has a value of about 0.5–1 dB. This holds from about 20 dB above threshold to 100 dB above threshold [13.68]. The value of ΔL increases for sounds with levels close to the absolute threshold.

For sinusoidal stimuli, the situation is somewhat different. If ΔI (in dB) is plotted against I (also in dB), a straight line is obtained with a slope of about 0.9; Weber's law would give a slope of 1.0. Thus discrimination, as measured by the Weber fraction, improves at high levels. This has been termed the *near miss* to Weber's Law. The data of *Riesz* [13.69] for modulation detection show a value of ΔL of 1.5 dB at 20 dB SL, 0.7 dB at 40 dB SL, and 0.3 dB at 80 dB SL (all at 1000 Hz). The Weber fraction may increase somewhat at very high sound levels (above 100 dB SPL) [13.70]. In everyday life, a change in level of 1 dB would hardly be noticed, but a change in level of 3 dB (corresponding to a doubling or halving of intensity) would be fairly easily heard.

13.4 Temporal Processing in the Auditory System

This section is concerned mainly with temporal resolution (or acuity), which refers to the ability to detect changes in stimuli over time, for example, to detect a brief gap between two stimuli or to detect that a sound is amplitude modulated. As pointed out by *Viemeister* and *Plack* [13.72], it is also important to distinguish the rapid pressure variations in a sound (the *fine structure*) from the slower overall changes in the amplitude of those fluctuations (the *envelope*). Temporal resolution normally refers to the resolution of changes in the envelope, not in the fine structure. In characterizing temporal resolution in the auditory system, it is important to take account of the filtering that occurs in the peripheral auditory system. Temporal resolution depends on two main processes: analysis of the time pattern occurring within each frequency channel and comparison of the time patterns across channels.

A major difficulty in measuring the temporal resolution of the auditory system is that changes in the time pattern of a sound are generally associated with changes in its magnitude spectrum, for example its power spectrum (Chap. 14). Thus, the detection of a change in time pattern can sometimes depend not on temporal resolution per se, but on the detection of the change in magnitude spectrum. There have been two general approaches to getting around this problem. One is to use signals whose magnitude spectrum is not changed when the time pattern is altered. For example, the magnitude spectrum of white noise remains flat if the noise is interrupted, i.e., if a gap is introduced into the noise. The second approach uses stimuli whose magnitude spectra are altered by the change in time pattern, but extra background sounds are added to mask the spectral changes. Both approaches will be described.

13.4.1 Temporal Resolution Based on Within-Channel Processes

The threshold for detecting a gap in a broadband noise provides a simple and convenient measure of temporal resolution. Usually a two-alternative forced-choice (2AFC) procedure is used: the subject is presented with two successive bursts of noise and either the first or the second burst (at random) is interrupted to produce the gap. The task of the subject is to indicate which burst contained the gap. The gap threshold is typically 2–3 ms [13.73, 74]. The threshold increases at very low sound levels, when the level of the noise approaches the

absolute threshold, but is relatively invariant with level for moderate to high levels.

The long-term magnitude spectrum of a sound is not changed when that sound is time reversed (played backward in time). Thus, if a time-reversed sound can be discriminated from the original, this must reflect a sensitivity to the difference in time pattern of the two sounds. This was exploited by *Ronken* [13.75], who used as stimuli pairs of clicks differing in amplitude. One click, labeled A, had an amplitude greater than that of the other click, labeled B. Typically the amplitude of A was twice that of B. Subjects were required to distinguish click pairs differing in the order of A and B: either AB or BA. The ability to do this was measured as a function of the time interval or gap between A and B. *Ronken* found that subjects could distinguish the click pairs for gaps down to 2–3 ms. Thus, the limit to temporal resolution found in this task is similar to that found for the detection of a gap in broadband noise. It should be noted that, in this task, subjects do not hear the individual clicks within a click pair. Rather, each click pair is heard as a single sound with its own characteristic quality.
Fig. 13.15 A temporal modulation transfer function (TMTF). A broadband white noise was sinusoidally amplitude modulated, and the threshold amount of modulation required for detection is plotted as a function of modulation rate. The amount of modulation is specified as $20\log(m)$, where m is the modulation index (Chap. 14). The higher the sensitivity to modulation, the more negative is this quantity (after *Bacon* and *Viemeister* [13.71])

The experiments described above each give a single number to describe temporal resolution. A more comprehensive approach is to measure the threshold for detecting changes in the amplitude of a sound as a function of the rapidity of the changes. In the simplest case, white noise is sinusoidally amplitude modulated, and the threshold for detecting the modulation is determined as a function of modulation rate. The function relating threshold to modulation rate is known as a temporal modulation transfer function (TMTF). Modulation of white noise does not change its long-term magnitude spectrum. An example of the results is shown in Fig. 13.15; data are taken from *Bacon* and *Viemeister* [13.71]. For low modulation rates, performance is limited by the amplitude resolution of the ear, rather than by temporal resolution. Thus, the threshold is independent of modulation rate for rates up to about 50 Hz. As the rate increases beyond 50 Hz, temporal resolution starts to have an effect; the threshold increases, and for rates above about 1000 Hz the modulation cannot be detected at all. Thus, sensitivity to amplitude modulation decreases progressively as the rate of modulation increases. The shapes of TMTFs do not vary much with overall sound level, but the ability to detect the modulation does worsen at low sound levels.

To explore whether temporal resolution varies with center frequency, *Green* [13.76] used stimuli which consisted of a brief pulse of a sinusoid in which the level of the first half of the pulse was 10 dB different from that of the second half. Subjects were required to distinguish two signals, differing in whether the half with the high level was first or second. Green measured performance as a function of the total duration of the stimuli. The threshold, corresponding to 75% correct discrimination, was similar for center frequencies of 2 and 4 kHz and was between 1 and 2 ms. However, the threshold was slightly higher for a center frequency of 1 kHz, being between 2 and 4 ms.

Moore et al. [13.77] measured the threshold for detecting a gap in a sinusoid, for signal frequencies of 100, 200, 400, 800, 1000, and 2000 Hz. A background noise was used to mask the spectral *splatter* produced by turning the sound off and on to produce the gap. The gap thresholds were almost constant, at 6–8 ms over the frequency range 400–2000 Hz, but increased somewhat at 200 Hz and increased markedly, to about 18 ms, at 100 Hz. Individual variability also increased markedly at 100 Hz.

Overall, it seems that temporal resolution is roughly independent of frequency for medium to high fre-

quencies, but worsens somewhat at very low center frequencies.

The measurement of TMTFs using sinusoidal carriers is complicated by the fact that the modulation introduces spectral sidebands, which may be detected as separate components if they are sufficiently far in frequency from the carrier frequency. When the carrier frequency is high, the effect of resolution of sidebands is likely to be small for modulation frequencies up to a few hundred Hertz, as the auditory filter bandwidth is large for high center frequencies. Consistent with this, TMTFs for high carrier frequencies generally show an initial flat portion (sensitivity independent of modulation frequency), then a portion where threshold increases with increasing modulation frequency, presumably reflecting the limits of temporal resolution, and then a portion where threshold decreases again, presumably reflecting the detection of spectral sidebands [13.78, 79].

The initial flat portion of the TMTF extends to about 100–120 Hz for sinusoidal carriers, but only to 50 or 60 Hz for a broadband noise carrier. It has been suggested that the discrepancy occurs because the inherent amplitude fluctuations in a noise carrier limit the detectability of the imposed modulation [13.80–83]; see below for further discussion of this point. The effect of the inherent fluctuations depends upon their similarity to the imposed modulation. When a narrow-band noise carrier is used, which has relatively slow inherent amplitude fluctuations, TMTFs show the poorest sensitivity for low modulation frequencies [13.80, 81]. In principle, then, TMTFs obtained using sinusoidal carriers provide a better measure of the inherent temporal resolution of the auditory system than TMTFs obtained using noise carriers, provided that the modulation frequency is within the range where spectral resolution does not play a major role.

13.4.2 Modeling Temporal Resolution

Most models of temporal resolution are based on the idea that there is a process at levels of the auditory system higher than the auditory nerve that is sluggish in some way, thereby limiting temporal resolution. The models assume that the internal representation of stimuli is smoothed over time, so that rapid temporal changes are reduced in magnitude but slower ones are preserved. Although this smoothing process almost certainly operates on neural activity, the most widely used models are based on smoothing a simple transformation of the stimulus, rather than its neural representation.

Most models include an initial stage of bandpass filtering, reflecting the action of the auditory filters. Each filter is followed by a nonlinear device. This nonlinear device is meant to reflect the operation of several processes that occur in the peripheral auditory system such as compression on the basilar membrane and neural transduction, whose effects resemble half-wave rectification (Chap. 12). The output of the nonlinear device is fed to a smoothing device, which can be implemented either as a low-pass filter [13.84] or (equivalently) as a sliding temporal integrator [13.39, 85]. The device determines a kind of weighted average of the output of the compressive nonlinearity over a certain time interval or window. This weighting function is sometimes called the shape of the temporal window. The window itself is assumed to slide in time, so that the output of the temporal integrator is like a weighted running average of the input. This has the effect of smoothing rapid fluctuations while preserving slower ones. When a sound is turned on abruptly, the output of the temporal integrator takes some time to build up. Similarly, when a sound is turned off, the output of the integrator takes some time to decay. The shape of the window is assumed to be asymmetric in time, such that the build up of its output in response to the onset of a sound is more rapid than the decay of its output in response to the cessation of a sound. The output of the sliding temporal integrator is fed to a decision device. The decision device may use different rules depending on the task required. For example, if the task is to detect a brief temporal gap in a signal, the decision device might look for a dip in the output of the temporal integrator. If the task is to detect amplitude modulation of a sound, the device might assess the amount of modulation at the output of the sliding temporal integrator [13.84].

It is often assumed that backward and forward masking depend on the process of build up and decay. For example, if a brief signal is rapidly followed by a masker (backward masking), the response to the signal may still be building up when the masker occurs. If the masker is sufficiently intense, then its internal effects may swamp those of the signal. Similarly, if a brief signal follows soon after a masker (forward masking), the decaying response to the masker may swamp the response to the signal. The asymmetry in the shape of the window accounts for the fact that forward masking occurs over longer masker-signal intervals than backward masking.

13.4.3 A Modulation Filter Bank?

Some researchers have suggested that the analysis of sounds that are amplitude modulated depends on a specialized part of the brain that contains an array of neurons, each tuned to a different modulation rate [13.86]. Each neuron can be considered as a filter in the modulation domain, and the array of neurons is known collectively as a modulation filter bank. The modulation filter bank has been suggested as a possible explanation for certain perceptual phenomena, which are described below. It should be emphasized, however, that this is still a controversial concept.

The threshold for detecting amplitude modulation of a given carrier generally increases if additional amplitude modulation is superimposed on that carrier. This effect has been called modulation masking. *Houtgast* [13.87] studied the detection of sinusoidal amplitude modulation of a pink noise carrier. Thresholds for detecting the modulation were measured when no other modulation was present and when a masker modulator was present in addition. In one experiment, the masker modulation was a half-octave-wide band of noise, with a center frequency of 4, 8, or 16 Hz. For each masker, the masking pattern showed a peak at the masker frequency. This could be interpreted as indicating selectivity in the modulation-frequency domain, analogous to the frequency selectivity in the audio-frequency domain that was described earlier.

Bacon and *Grantham* [13.88] measured thresholds for detecting sinusoidal amplitude modulation of a broadband white noise in the presence of a sinusoidal masker modulator. When the masker modulation frequency was 16 or 64 Hz, most modulation masking occurred when the signal modulation frequency was near the masker frequency. In other words, the masking patterns were roughly bandpass, although they showed an increase for very low signal frequencies. For a 4 Hz masker, the masking patterns had a low-pass characteristic, i.e., there was a downward spread of modulation masking.

It should be noted that the sharpness of tuning of the hypothetical modulation filter bank is much less than the sharpness of tuning of the auditory filters in the audio-frequency domain. The bandwidths have been estimated as between 0.5 and 1 times the center frequency [13.81, 89–91]. The modulation filters, if they exist, are not highly selective.

13.4.4 Duration Discrimination

Duration discrimination has typically been studied by presenting two successive sounds with the same power spectrum but differing in duration. The subject is required to indicate which sound had the longer duration. Both *Creelman* [13.92] and *Abel* [13.93] found that the smallest detectable increase in duration, ΔT, increased with the baseline duration T. The data of Abel showed that, for $T = 10$, 100, and 1000 ms, ΔT was about 4, 15, and 60 ms, respectively. Thus, the Weber fraction, $\Delta T/T$, decreased with increasing T. The results were relatively independent of the overall level of the stimuli and were similar for noise bursts of various bandwidths and for bursts of a 1000 Hz sine wave.

Abel [13.94] reported somewhat different results for the discrimination of the duration of the silent interval between two *markers*. For silent durations, T, less than 160 ms, the results showed that discrimination improved as the level of the markers increased. The function relating $\Delta T/T$ to T was non-monotonic, reaching a local minimum for $T = 2.5$ ms and a local maximum for $T = 10$ ms. The value of ΔT ranged from 6 to 19 ms for a base duration of 10 ms and from 61 to 96 ms for a base duration of 320 ms.

Divenyi and *Danner* [13.95] required subjects to discriminate the duration of the silent interval defined by two 20 ms sounds. When the markers were identical high-level (86 dB SPL) bursts of sinusoids or noise, performance was similar across markers varying in center frequency (500–4000 Hz) and bandwidth. In contrast to the results of *Abel* [13.94], $\Delta T/T$ was almost independent of T over the range of T from 25 to 320 ms. Thresholds were markedly lower than those reported by *Abel* [13.94], being about 1.7 ms at $T = 25$ ms and 15 ms at $T = 320$ ms. This may have been a result of the extensive training of the subjects of Divenyi and Danner. For bursts of a 1 kHz sinusoid, performance worsened markedly when the level of the markers was decreased below 25 dB SL. Performance also worsened markedly when the two markers on either side of a silent interval were made different in level or frequency.

In summary, all studies show that, for values of T exceeding 10 ms, ΔT increases with T and ΔT is roughly independent of the spectral characteristics of the sounds. This is true both for the duration discrimination of sounds and for the discrimination of silent intervals bounded by acoustic markers, provided that the markers are identical on either side of the interval.

However, ΔT increases at low sound levels, and also increases when the markers differ in level or frequency on either side of the interval.

13.4.5 Temporal Analysis Based on Across-Channel Processes

Studies of the ability to compare timing across different frequency channels can give very different results depending on whether the different frequency components in the sound are perceived as part of a single sound or as part of more than one sound. Also, it should be realized that subjects may be able to *distinguish* different time patterns, for example, a change in the relative onset time of two different frequencies, without the subjective impression of a change in time pattern; some sort of change in the quality of the sound may be all that is heard. The studies described next indicate the limits of the ability to compare timing across channels, using highly trained subjects.

Patterson and *Green* [13.96] and *Green* [13.76] have studied the discrimination of a class of signals that have the same long-term magnitude spectrum, but which differ in their short-term spectra. These sounds, called Huffman sequences, are brief, broadband click-like sounds, except that the energy in a certain frequency region is delayed relative to that in other regions. The amount of the delay, the center frequency of the delayed frequency region, and the width of the delayed frequency region can all be varied. If subjects can distinguish a pair of Huffman sequences differing, for example, in the amount of delay in a given frequency region, this implies that they are sensitive to the difference in time pattern, i.e., they must be detecting that one frequency region is delayed relative to other regions. *Green* [13.76] measured the ability of subjects to detect differences in the amount of delay in three frequency regions: 650, 1900 and 4200 Hz. He found similar results for all three center frequencies: subjects could detect differences in delay time of about 2 ms regardless of the center frequency of the delayed region.

It should be noted that subjects did not report hearing one part of the sound after the rest of the sound. Rather, the differences in time pattern were perceived as subtle changes in sound quality. Further, some subjects required extensive training to achieve the fine acuity of 2 ms, and even after this training the task required considerable concentration.

Zera and *Green* [13.97] measured thresholds for detecting asynchrony in the onset or offset of complex

signals composed of many sinusoidal components. The components were either uniformly spaced on a logarithmic frequency scale or formed a harmonic series. In one stimulus, the standard, all components started and stopped synchronously. In the signal stimulus, one component was presented with an onset or offset asynchrony. The task of the subjects was to discriminate the standard stimulus from the signal stimulus. They found that onset asynchrony was easier to detect than offset asynchrony. For harmonic signals, onset asynchronies less than 1 ms could generally be detected, whether the asynchronous component was leading or lagging the other components. Thresholds for detecting offset asynchronies were larger, being about 3–10 ms when the asynchronous component ended after the other components and 10–30 ms when the asynchronous component ended before the other components. Thresholds for detecting asynchronies in logarithmically spaced complexes were generally 2–50 times larger than for harmonic complexes.

The difference between harmonically and logarithmically spaced complexes may be explicable in terms of perceptual grouping (see later for more details). The harmonic signal was perceived as a single sound source, i.e., all of the components appeared to belong together. The logarithmically spaced complex was perceived as a series of separate tones, like many notes being played at once on an organ. It seems that it is difficult to compare the timing of sound elements that are perceived as coming from different sources, a point that will be expanded later. The high sensitivity to onset asynchronies for harmonic complexes is consistent with the finding that the perceived timbres of musical instruments are partly dependent on the exact onset times and rates of rise of individual harmonics within each musical note [13.98]. This is described in more detail later on.

13.5 Pitch Perception

Pitch is an attribute of sound defined in terms of what is *heard*. It is defined formally as *that attribute of auditory sensation in terms of which sounds can be ordered on a scale extending from low to high* [13.10]. It is related to the physical repetition rate of the waveform of a sound; for a pure tone (a sinusoid) this corresponds to the frequency, and for a periodic complex tone to the fundamental frequency. Increasing the repetition rate gives a sensation of increasing pitch. Appropriate variations in repetition rate can give rise to a sense of melody. Variations in pitch are also associated with the intonation of voices, and they provide cues as to whether an utterance is a question or a statement and as to the emotion of the talker. Since pitch is a subjective attribute, it cannot be measured directly. Often, the pitch of a complex sound is assessed by adjusting the frequency of a sinusoid until the pitch of the sinusoid matches the pitch of the sound in question. The frequency of the sinusoid then gives a measure of the pitch of the sound. Sometimes a periodic complex sound, such as a pulse train, is used as a matching stimulus. In this case, the repetition rate of the pulse train gives a measure of pitch. Results are generally similar for the two methods, although it is easier to make a pitch match when the sounds to be matched do not differ very much in timbre (Sect. 13.6.)

13.5.1 Theories of Pitch Perception

There are two traditional theories of pitch perception. One, the *place* theory, is based on the fact that different frequencies (or frequency components in a complex sound) excite different places along the basilar membrane, and hence neurons with different CFs. The place theory assumes that the pitch of a sound is related to the excitation pattern produced by that sound; for a pure tone the pitch is generally assumed to be determined by the position of maximum excitation [13.99].

An alternative theory, called the *temporal* theory, is based on the assumption that the pitch of a sound is related to the time pattern of the neural impulses evoked by that sound [13.100]. These impulses tend to occur at a particular phase of the waveform on the basilar membrane, a phenomenon called phase locking (Chap. 18). The intervals between successive neural impulses approximate integer multiples of the period of the waveform and these intervals are assumed to determine the perceived pitch. The temporal theory cannot be applicable at very high frequencies, since phase locking does not occur at such frequencies. However, the tones produced by most musical instruments, the human voice, and most everyday sound sources have fundamental frequencies in the range where phase locking occurs.

Many researchers believe that the perception of pitch involves both place mechanisms and temporal mechanisms. However, one mechanism may be dominant for a specific task or aspect of pitch perception, and the relative role of the two mechanisms almost certainly varies with center frequency.

13.5.2 The Perception of the Pitch of Pure Tones

It is important to distinguish between frequency selectivity and frequency discrimination. The former refers to the ability to resolve the frequency components of a complex sound. The latter refers to the ability to detect changes in frequency over time. Usually, the changes in frequency are heard as changes in pitch. The smallest detectable change in frequency is called the frequency difference limen (DL).

The Frequency Discrimination of Pure Tones
Place models of frequency discrimination [13.101, 102] predict that frequency discrimination should be related to frequency selectivity; both should depend on the sharpness of tuning on the basilar membrane. *Zwicker* [13.102] described a model of frequency discrimination based on changes in the excitation pattern
Fig. 13.16 Schematic illustration of an excitation-pattern model for frequency discrimination. Excitation patterns are shown for two sinusoidal tones differing slightly in frequency; the two tones have frequencies of 995 Hz and 1005 Hz. It is assumed that the difference in frequency, ΔF, can be detected if the excitation level changes anywhere by more than a criterion amount. The biggest change in excitation level is on the low-frequency side

evoked by the sound when the frequency is altered, inferring the shapes of the excitation patterns from masking patterns such as those shown in Fig. 13.6. The model is illustrated in Fig. 13.16. The figure shows two excitation patterns, corresponding to two tones with slightly different frequencies. A change in frequency results in a sideways shift of the excitation pattern. The change is assumed to be detectable whenever the excitation level at some point on the excitation pattern changes by more than about 1 dB.

The change in excitation level is greatest on the steeply sloping low-frequency (low-CF) side of the excitation pattern. Thus, in this model, the detection of a change in frequency is functionally equivalent to the detection of a change in level on the low-frequency side of the excitation pattern. The steepness of the low-frequency side is roughly constant when the frequency scale is expressed in units of ERB_N, rather than in terms of linear frequency. The slope is about 18 dB per ERB_N. To achieve a change in excitation level of 1 dB, the frequency has to be changed by one eighteenth of an ERB_N. Thus, Zwicker's model predicts that the frequency DL at any given frequency should be about one eighteenth $(= 0.056)$ of the value of ERB_N at that frequency.

To test Zwicker's model, frequency DLs have been measured as a function of center frequency. There have been two common ways of measuring frequency discrimination. One involves the discrimination of two successive steady tones with slightly different frequencies. On each trial, the tones are presented in a random order and the listener is required to indicate whether the first or second tone is higher in frequency. The frequency difference between the two tones is adjusted until the listener achieves a criterion percentage correct, for example 75%. This measure will be called the difference limen for frequency (DLF). A second measure, called the frequency modulation detection limen (FMDL), uses tones that are frequency modulated. In such tones, the frequency moves up and down in a regular periodic manner about the mean (carrier) frequency. The number of times per second that the frequency goes up and down is called the modulation rate. Typically, the modulation rate is rather low (2–20 Hz), and the change in frequency is heard as a fluctuation in pitch – a kind of *warble*. To determine a threshold for detecting frequency modulation, two tones are presented successively; one is modulated in frequency and the other has a steady frequency. The order of the tones on each trial is random. The listener is required to indicate whether the first or the second tone is modulated. The amount of modulation (also called the modulation depth) re-
Fig. 13.17 Thresholds for detecting differences in frequency between steady pulsed tones (DLFs) and for detecting frequency modulation (FMDLs), plotted relative to the ERB_N of the auditory filter at each center frequency (after *Sek* and *Moore* [13.103])

quired to achieve a criterion response (e.g. 75% correct) is determined.

It turns out that the results obtained with these two methods are quite different [13.104], although the difference depends on the modulation rate used to measure the FMDLs. An example of results obtained with the two methods is given in Fig. 13.17 (data from *Sek* and *Moore* [13.103]). For the FMDLs the modulation rate was 10 Hz. To test Zwicker's model, the DLFs and FMDLs were plotted as a proportion of the value of ERB_N at the same center frequency. According to this model, the proportion should be independent of frequency. The proportion for FMDLs using a 10 Hz modulation rate, shown as the brighter line, is roughly constant, and its value is about 0.05, close to the value predicted by the model. However, the proportion for DLFs varies markedly with frequency [13.103, 105]. This is illustrated by the dark line in Fig. 13.17. The DLFs for frequencies of 2 kHz and below are smaller than predicted by Zwicker's model, while those for frequencies of 6 and 8 kHz are larger than predicted.

The results for the FMDLs are consistent with the place model, but the results for the DLFs are not. The reason for the deviation for DLFs is probably that DLFs at low frequencies depend on the use of temporal infor-

mation from phase locking. Phase locking becomes less precise at frequencies above 1 kHz, and it becomes very weak above 5 kHz. This can account for the marked increase in the DLFs at high frequencies [13.106].

The ratio FMDL/ERB_N is not constant across center frequency when the modulation rate is very low (around 2 Hz), but increases with increasing frequency [13.103, 107]. For low center frequencies, FMDLs are smaller for a 2 Hz modulation rate than for a 10 Hz rate, while for high carrier frequencies (above 4 kHz) the reverse is true. Thus, for a 2 Hz modulation rate, the agreement between DLFs and FMDLs is better than for a 10 Hz rate, but discrepancies remain. For very low modulation rates, frequency modulation may be detected by virtue of the changes in phase locking to the carrier that occur over time. In other words, the frequency is determined over short intervals of time, using phase-locking information, and changes in the estimated frequency over time indicate the presence of frequency modulation. *Moore* and *Sek* [13.107] suggested that the mechanism for decoding the phase-locking information was sluggish; it had to sample the sound for a certain time in order to estimate its frequency. Hence, it could not follow rapid changes in frequency and it played little role for high modulation rates.

In summary, measures of frequency discrimination are consistent with the idea that DLFs, and FMDLs for very low modulation rates, are determined by temporal information (phase locking) for frequencies up to about 4–5 kHz. The precision of phase locking decreases with increasing frequency above 1–2 kHz, and it is very weak above about 5 kHz. This can explain why DLFs increase markedly at high frequencies. FMDLs for medium to high modulation rates may be determined by a place mechanism, i. e., by the detection of changes in the excitation pattern. This mechanism may also account for DLFs and for FMDLs for low modulation rates, when the center frequency is above about 5 kHz.

The Perception of Musical Intervals

If temporal information plays a role in determining the pitch of pure tones, then we would expect changes in perception to occur for frequencies above 5 kHz, at which phase locking is very weak. Two aspects of perception do indeed change in the expected way, namely the perception of musical intervals, and the perception of melodies.

Two tones that are separated in frequency by an interval of one *octave* (i. e., one has twice the frequency of the other) sound similar. They are judged to have the same name on the musical scale (for example, C3 and

C4). This has led several theorists to suggest that there are at least two dimensions to musical pitch. One aspect is related monotonically to frequency (for a pure tone) and is known as *tone height*. The other is related to pitch class (i. e., the name of the note) and is called *tone chroma* [13.108, 109]. For example, two sinusoids with frequencies of 220 and 440 Hz would have the same tone chroma (they would both be called A on the musical scale) but, as they are separated by an octave, they would have different tone heights.

If subjects are presented with a pure tone of a given frequency, f_1, and are asked to adjust the frequency, f_2 of a second tone (presented so as to alternate in time with the fixed tone) so that it appears to be an octave higher in pitch, they generally adjust f_2 to be roughly twice f_1. However, when f_1 lies above 2.5 kHz, so that f_2 would lie above 5 kHz, octave matches become very erratic [13.110]. It appears that the musical interval of an octave is only clearly perceived when both tones are below 5 kHz.

Other aspects of the perception of pitch also change above 5 kHz. A sequence of pure tones above 5 kHz does not produce a clear sense of melody [13.111]. It is possible to hear that the pitch changes when the frequency is changed, but the musical intervals are not heard clearly. Also, subjects with absolute pitch (the ability to assign names to notes without reference to other notes) are very poor at naming notes above 4–5 kHz [13.112].

These results are consistent with the idea that the pitch of pure tones is determined by different mechanisms above and below 5 kHz, specifically, by a temporal mechanism at low frequencies and a place mechanism at high frequencies. It appears that the perceptual dimension of tone height persists over the whole audible frequency range, but tone chroma only occurs in the frequency range below 5 kHz. Musical intervals are only clearly perceived when the frequencies of the tones lie in the range where temporal information is available.

The Effect of Level on Pitch

The pitch of a pure tone is primarily determined by its frequency. However, sound level also plays a small role. On average, the pitch of tones with frequencies below about 2 kHz decreases with increasing level, while the pitch of tones with frequencies above about 4 kHz increases with increasing sound level. The early data of *Stevens* [13.113] showed rather large effects of sound level on pitch, but other data generally show much smaller effects [13.114]. For tones with frequencies between 1 and 2 kHz, changes in pitch with level are generally less than 1%. For tones of lower and higher frequencies, the changes can be larger (up to 5%). There are also considerable individual differences both in the size of the pitch shifts with level, and in the direction of the shifts [13.114].

13.5.3 The Perception of the Pitch of Complex Tones

The Phenomenon of the Missing Fundamental

For complex tones the pitch does not, in general, correspond to the position of maximum excitation on the basilar membrane. Consider, as an example, a sound consisting of short impulses (clicks) occurring 200 times per second. This sound contains harmonics with frequencies at integer multiples of 200 Hz (200, 400, 600, 800 . . . Hz). The harmonic at 200 Hz is called the fundamental component. The sound has a low pitch, which is very close to the pitch of its fundamental component (200 Hz), and a sharp timbre (a buzzy tone quality). However, if the sound is filtered so as to remove the fundamental component, the pitch does not alter; the only result is a slight change in timbre. This is called the phenomenon of the missing fundamental [13.100, 115]. Indeed, all except a small group of mid-frequency harmonics can be eliminated, and the low pitch remains the same, although the timbre becomes markedly different.

Schouten [13.100, 116] called the low pitch associated with a group of high harmonics the *residue*. Several other names have been used to describe this pitch, including *periodicity pitch*, *virtual pitch*, and *low pitch*. The term *low pitch* will be used here. Schouten pointed out that it is possible to hear the change produced by removing the fundamental component and then reintroducing it. Indeed, when the fundamental component is present, it is possible to hear it out as a separate sound. The pitch of that component is almost the same as the pitch of the whole sound. Therefore, the presence or absence of the fundamental component does not markedly affect the pitch of the whole sound.

The perception of a low pitch does not require activity at the point on the basilar membrane that would respond maximally to the fundamental component. *Licklider* [13.117] showed that the low pitch could be heard when low-frequency noise was present that would mask any component at the fundamental frequency. Even when the fundamental component of a complex tone is present, the pitch of the tone is usually determined by harmonics other than the fundamental.

The phenomenon of the missing fundamental is not consistent with a simple place model of pitch based

on the idea that pitch is determined by the position of the peak excitation on the basilar membrane. However, more elaborate place models have been proposed, and these are discussed below.

Theories of Pitch Perception for Complex Tones

To understand theories of pitch perception for complex tones, it is helpful to consider how complex tones are represented in the peripheral auditory system. A simulation of the response of the basilar membrane to
Fig. 13.18 A simulation of the responses on the basilar membrane to periodic impulses of rate 200 pulses per second. The input waveform is shown at the bottom; impulses occur every 5 ms. Each number on the left represents the frequency that would maximally excite a given point on the basilar membrane. The waveform that would be observed at that point, as a function of time, is plotted opposite that number

a complex tone is illustrated in Fig. 13.18. In this example, the complex tone is a regular series of brief pulses, whose spectrum contains many equal-amplitude harmonics. The number of pulses per second (also called the repetition rate) is 200, so the harmonics have frequencies that are integer multiples of 200 Hz. The lower harmonics are partly resolved on the basilar membrane, and give rise to distinct peaks in the pattern of activity along the basilar membrane. At a place tuned to the frequency of a low harmonic, the waveform on the basilar membrane is approximately a sinusoid at the harmonic frequency. For example, at the place with a characteristic frequency of 400 Hz the waveform is a 400 Hz sinusoid. At a place tuned between two low harmonics, e.g., the place tuned to 317 Hz, there is very little response. In contrast, the higher harmonics are not resolved, and do not give rise to distinct peaks on the basilar membrane. The waveforms at places on the basilar membrane responding to higher harmonics are complex, but they all have a repetition rate equal to the fundamental frequency of the sound.

There are two main (nonexclusive) ways in which the low pitch of a complex sound might be extracted. Firstly, it might be derived from the frequencies of the lower harmonics that are resolved on the basilar membrane. The frequencies of the harmonics might be determined either by place mechanisms (e.g., from the positions of local maxima on the basilar membrane) or by temporal mechanisms (from the inter-spike intervals in neurons with CFs close to the frequencies of individual harmonics). For example, for the complex tone whose analysis is illustrated in Fig. 13.18, the second harmonic, with a frequency of 400 Hz, would give rise to a local maximum at the place on the basilar membrane tuned to 400 Hz. The inter-spike intervals in neurons innervating that place would reflect the frequency of that harmonic; the intervals would cluster around integer multiples of 2.5 ms. Both of these forms of information may allow the auditory system to determine that there is a harmonic at 400 Hz.

The auditory system may contain a pattern recognizer that determines the low pitch of the complex sound from the frequencies of the resolved components [13.118–120]. In essence the pattern recognizer tries to find the harmonic series giving the best match to the resolved frequency components; the fundamental frequency of this harmonic series determines the perceived pitch. Say, for example, that the initial analysis establishes frequencies of 800, 1000 and 1200 Hz to be present. The fundamental frequency whose harmonics

would match these frequencies is 200 Hz. The perceived pitch corresponds to this inferred fundamental frequency of 200 Hz. Note that the inferred fundamental frequency is always the highest possible value that fits the frequencies determined in the initial analysis. For example, a fundamental frequency of 100 Hz would also have harmonics at 800, 1000 and 1200 Hz, but a pitch corresponding to 100 Hz is *not* perceived. It should also be noted that when a complex tone contains only two or three low harmonics, some people, called *analytic listeners*, do not hear the low pitch, but rather hear pitches corresponding to individual harmonics [13.121, 122]. Others, called *synthetic listeners*, usually hear only the low pitch. When many harmonics are present, the low pitch is usually the dominant percept.

Evidence supporting the idea that the low pitch of a complex tone is derived by combining information from several harmonics comes from studies of the ability to detect changes in repetition rate (equivalent to the number of periods per second). When the repetition rate of a complex tone changes, all of the components change in frequency by the same *ratio*, and a change in low pitch is heard. The ability to detect such changes is better than the ability to detect changes in a sinusoid at the fundamental frequency [13.123] and it can be better than the ability to detect changes in the frequency of any of the individual sinusoidal components in the complex tone [13.124]. This indicates that information from the different harmonics is combined or integrated in the determination of low pitch. This can lead to very fine discrimination; changes in repetition rate of about 0.2% can be detected for fundamental frequencies in the range 100–400 Hz provided that low harmonics are present (e.g., the third, fourth and fifth).

The pitch of a complex tone may also be extracted from the higher unresolved harmonics. As shown in Fig. 13.18, the waveforms at places on the basilar membrane responding to higher harmonics are complex, but they all have a repetition rate equal to the fundamental frequency of the sound, namely 200 Hz. For the neurons with CFs corresponding to the higher harmonics, nerve impulses tend to be evoked by the biggest peaks in the waveform, i.e., by the waveform peaks close to envelope maxima. Hence, the nerve impulses are separated by times corresponding to the period of the sound. For example, in Fig. 13.18 the input has a repetition rate of 200 periods per second, so the period is 5 ms. The time intervals between nerve spike would cluster around in-

teger multiples of 5 ms, i.e., 5, 10 15, 20 ... ms. The pitch may be determined from these time intervals. In this example, the time intervals are integer multiples of 5 ms, so the pitch corresponds to 200 Hz.

Experimental evidence suggests that pitch can be extracted *both* from the lower harmonics and from the higher harmonics. Usually, the lower, resolved harmonics give a clearer low pitch, and are more important in determining low pitch, than the upper unresolved harmonics [13.125–127]. This idea is called the principle of dominance; when a complex tone contains many harmonics, including both low- and high-numbered harmonics, the pitch is mainly determined by a small group of lower harmonics. Also, the discrimination of changes in repetition rate of complex tones is better for tones containing only low harmonics than for tones containing only high harmonics [13.124, 128–130]. However, a low pitch can be heard when only high unresolvable harmonics are present. Although, this pitch is not as clear as when lower harmonics are present, it is clear enough to allow the recognition of musical intervals and of simple melodies [13.130, 131].

Several researchers have proposed theories in which both place (spectral) and temporal mechanisms play a role; these are referred to as spectro-temporal theories. The theories assume that information from both low harmonics and high harmonics contributes to the determination of pitch. The initial place/spectral analysis in the cochlea is followed by an analysis of the time pattern of the neural spikes evoked at each CF [13.132–136]. The temporal analysis is assumed to occur at a level of the auditory system higher than the auditory nerve, perhaps in the cochlear nucleus. In the model proposed by *Moore* [13.134], the sound is passed through an array of bandpass filters, each corresponding to a specific place on the basilar membrane. The time pattern of the neural impulses at each CF is determined by the waveform at the corresponding point on the basilar membrane. The inter-spike intervals at each CF are determined. Then, a device compares the time intervals present at different CFs, and searches for common time intervals. The device may also integrate information over time. In general the time interval that is found most often corresponds to the period of the fundamental component. The perceived pitch corresponds to the reciprocal of this interval. For example, if the most prominent time interval is 5 ms, the perceived pitch corresponds to a frequency of 200 Hz.

13.6 Timbre Perception

Almost all of the sounds that we encounter in everyday life contain a multitude of frequency components with particular levels and relative phases. The distribution of energy over frequency is one of the major determinants of the quality of a sound or its timbre. Timbre is usually defined as [13.10]

> *that attribute of auditory sensation in terms of which a listener can judge that two sounds similarly presented and having the same loudness and pitch are dissimilar.*

Differences in timbre enable us to distinguish between the same note played on, say, the piano, the violin or the flute.

13.6.1 Time–Invariant Patterns and Timbre

Timbre depends upon more than just the frequency spectrum of the sound; fluctuations over time can play an important role (see the next section). For the purpose of this section we can adopt a more restricted definition suggested by *Plomp* [13.137] as applicable to steady tones:

> *Timbre is that attribute of sensation in terms of which a listener can judge that two steady complex tones having the same loudness, pitch and duration are dissimilar.*

Timbre defined in this way depends mainly on the relative magnitudes of the partials of the tones.

Timbre is multidimensional; there is no single scale along which the timbres of different sounds can be compared or ordered. Thus, a way is needed of describing the spectrum of a sound that takes into account this multidimensional aspect, and that can be related to the subjective timbre. A crude first approach is to look at the overall distribution of spectral energy. The *brightness* or *sharpness* [13.138] of sounds seems to be related to the spectral centroid. However, a much more quantitative approach has been described by *Plomp* and his colleagues [13.137, 139]. They showed that the perceptual differences between different sounds, such as vowels, or steady tones produced by musical instruments, were closely related to the differences in the spectra of the sounds, when the spectra were specified as the levels in 18 1/3-octave frequency bands. A bandwidth of 1/3 octave is slightly greater than the ERB_N of the auditory filter over most of the audible frequency range. Thus, timbre is related to the relative level produced at the out-

put of each auditory filter. Put another way, the timbre of a sound is related to the shape of the excitation pattern of that sound.

It is likely that the number of dimensions required to characterize timbre is limited by the number of ERB_Ns required to cover the audible frequency range. This would give a maximum of about 37 dimensions. For a restricted class of sounds, however, a much smaller number of dimensions may be involved. It appears to be generally true, both for speech and non-speech sounds, that the timbres of steady tones are determined primarily by their magnitude spectra, although the relative phases of the components may also play a small role [13.140, 141].

13.6.2 Time–Varying Patterns and Auditory Object Identification

Differences in static timbre are not always sufficient to allow the absolute identification of an *auditory object*, such as a musical instrument. One reason for this is that the magnitude and phase spectrum of the sound may be markedly altered by the transmission path and room reflections [13.142]. In practice, the recognition of a particular timbre, and hence of an auditory object, may depend upon several other factors. *Schouten* [13.143] has suggested that these include: (1) whether the sound is periodic, having a tonal quality for repetition rates between about 20 and 20 000 per second, or irregular, and having a noise-like character; (2) whether the waveform envelope is constant, or fluctuates as a function of time, and in the latter case what the fluctuations are like; (3) whether any other aspect of the sound (e.g., spectrum or periodicity) is changing as a function of time; (4) what the preceding and following sounds are like.

The recognition of musical instruments, for example, depends quite strongly on onset transients and on the temporal structure of the sound envelope. The characteristic tone of a piano depends upon the fact that the notes have a rapid onset and a gradual decay. If a recording of a piano is reversed in time, the timbre is completely different. It now resembles that of a harmonium or accordion, in spite of the fact that the long-term magnitude spectrum is unchanged by time reversal. The perception of sounds with temporally asymmetric envelopes has been studied by *Patterson* [13.144, 145]. He used sinusoidal carriers that were amplitude modulated by a repeating exponential function. The envelope either increased abruptly and decayed gradually

(damped sounds) or increased gradually and decayed abruptly (ramped sounds). The ramped sounds were time-reversed versions of the damped sounds and had the same long-term magnitude spectrum. The sounds were characterized by the repetition period of the envelope, which was 25 ms, and by the half life. For a damped sinusoid, the half life is the time taken for the amplitude to decrease by a factor of two.

Patterson reported that the ramped and damped sounds had different qualities. For a half life of 4 ms, the damped sound was perceived as a single source rather like a drum roll played on a hollow, resonant surface (like a drummer's wood block). The ramped sound was perceived as two sounds: a drum roll on a non-resonant surface (such as a leather table top) and a continuous tone corresponding to the carrier frequency. *Akeroyd* and *Patterson* [13.146] used sounds with similar envelopes, but the carrier was broadband noise rather than a sinusoid. They reported that the damped sound was heard as a drum struck by wire brushes. It did not have any hiss-like quality. In contrast, the ramped sound was heard as a noise, with a hiss-like quality, that was sharply cut off in time. These experiments clearly demonstrate the important role of the temporal envelope in timbre perception.

Pollard and *Jansson* [13.147] described a perceptually relevant way of characterizing time-varying sounds. The sound is filtered in bands of width 1/3 octave. The loudness of each band is calculated at 5 ms intervals.

Loudness values are then converted into three coordinates, based on the loudness of:

1. The fundamental component,
2. A group containing partials 2–4, and
3. A group containing partials 5–*n*,

where *n* is the highest significant partial. This *tristimulus* representation appears to be related quite closely to perceptual judgements of musical sounds.

Many instruments have noise-like qualities that strongly influence their subjective quality. A flute, for example, has a relatively simple harmonic structure, but synthetic tones with the same harmonic structure do not sound flute-like unless each note is preceded by a small puff of noise. In general, tones of standard musical instruments are poorly simulated by the summation of steady component frequencies, since such a synthesis cannot produce the dynamic variation with time characteristic of these instruments. Thus traditional electronic organs (pre-1965), which produced only tones with a fixed envelope shape, could produce a good simulation of the bagpipes, but could not be made to sound like a piano. Modern synthesizers shape the envelopes of the sounds they produce, and hence are capable of more accurate and convincing imitations of musical instruments. For a simulation to be convincing, it is often necessary to give different time envelopes to different harmonics within a complex sound [13.98, 148].

13.7 The Localization of Sounds

It has long been recognized that slight differences in the sounds reaching the two ears can be used as cues in sound localization. The two major cues are differences in the time of arrival at the two ears and differences in intensity at the two ears. For example, a sound coming from the left arrives first at the left ear and is more intense in the left ear. For steady sinusoids, a difference in time of arrival is equivalent to a phase difference between the sounds at the two ears. However, phase differences are not usable over the whole audible frequency range.

13.7.1 Binaural Cues

Experiments using sounds delivered by headphones have shown that a phase difference at the two ears can be detected and used to judge location only for frequencies below about 1500 Hz. This is reasonable

because, at high frequencies, the wavelength of sound is small compared to the dimensions of the head, so the listener cannot determine which cycle in the left ear corresponds to a given cycle in the right; there may be many cycles of phase difference. Thus phase differences become ambiguous and unusable at high frequencies. On the other hand, at low frequencies our accuracy at detecting changes in relative time at the two ears is remarkably good; changes of 10–20 μs can be detected, which is equivalent to a movement of the sound source of 1–2° laterally when the sound comes from straight ahead [13.149].

Intensity differences are usually largest at high frequencies. This is because low frequencies bend or diffract around the head, so that there is little difference in intensity at the two ears whatever the location of the sound source, except when the source is very close to the head. At high frequencies, the head casts more of

a shadow, and above 2–3 kHz the intensity differences provide useful cues. For complex sounds, containing a range of frequencies, the difference in spectral patterning at the two ears may also be important.

The idea that sound localization is based on interaural time differences at low frequencies and interaural intensity differences at high frequencies, called the duplex theory of sound localization, was proposed by Lord *Rayleigh* [13.150]. However, complex sounds, containing only high frequencies (above 1500 Hz), can be localized on the basis of interaural time delays, provided that they have an appropriate temporal structure. For example, a single click can be localized in this way no matter what its frequency content. Periodic sounds containing only high-frequency harmonics can also be localized on the basis of interaural time differences, provided that the envelope repetition rate (usually equal to the fundamental frequency) is below about 600 Hz [13.151, 152]. Since most of the sounds we encounter in everyday life are complex, and have repetition rates below 600 Hz, interaural time differences can be used for localization in most listening situations.

13.7.2 The Role of the Pinna and Torso

Binaural cues are not sufficient to account for all aspects of sound localization. For example, an interaural time or intensity difference will not indicate whether a sound is coming from in front or behind, or above or below, but such judgments can clearly be made. Also, under some conditions localization with one ear can be as accurate as with two. It has been shown that reflections of sounds from the pinnae and torso play an important role in sound localization [13.153, 154]. The spectra of sounds entering the ear are modified by these reflections in a way that depends upon the direction of the sound source relative to the head. This direction-dependent filtering provides cues for sound source location. The spectral cues are important not just in providing information about the direction of sound sources, but also

in enabling us to judge whether a sound comes from within the head or from the outside world. The pinnae alter the sound spectrum primarily at high frequencies. Only when the wavelength of the sound is comparable with or smaller than the dimensions of the pinnae is the spectrum significantly affected. This occurs mostly above about 6 kHz. Thus, cues provided by the pinnae are most effective for broadband high-frequency sounds. However, reflections from other structures, such as the shoulders, result in spectral changes at lower frequencies, and these may be important for front–back discrimination [13.155].

13.7.3 The Precedence Effect

In everyday conditions the sound from a given source reaches the ears by many different paths. Some of it arrives via a direct path, but a great deal may only reach the ears after reflections from one or more surfaces. However, listeners are not normally aware of these reflections, and the reflections do not markedly impair the ability to localize sound sources. The reason for this seems to lie in a phenomenon known as the precedence effect [13.156, 157]; for a review, see [13.158]. When several sounds reach the ears in close succession (i. e., the direct sound and its reflections) the sounds are perceptually fused into a single sound (an effect called echo suppression), and the location of the total sound is primarily determined by the location of the first (direct) sound (the precedence effect). Thus the reflections have little influence on the perception of direction. Furthermore, there is little awareness of the reflections, although they may influence the timbre and loudness of the sound.

The precedence effect only occurs for sounds of a discontinuous or transient character, such as speech or music, and it can break down if the reflections have a level 10 dB or more above that of the direct sound. However, in normal conditions the precedence effect plays an important role in the localization and identification of sounds in reverberant conditions.

13.8 Auditory Scene Analysis

It is hardly ever the case that the sound reaching our ears comes from a single source. Usually the sound arises from several different sources. However, usually we are able to decompose the mixture of sounds and to perceive each source separately. An auditory object can be defined as the percept of a group of successive and/or

simultaneous sound elements as a coherent whole, appearing to emanate from a single source.

As discussed earlier, the peripheral auditory system acts as a frequency analyzer, separating the different frequency components in a complex sound. Somewhere in the brain, the internal representations of these frequency

components have to be assigned to their appropriate sources. If the input comes from two sources, A and B, then the frequency components must be split into two groups; the components emanating from source A should be assigned to one source and the components emanating from source B should be assigned to another. The process of doing this is often called perceptual grouping. It is also given the name auditory scene analysis [13.159]. The process of separating the elements arising from two or more different sources is sometimes called segregation.

Many different physical cues may be used to derive separate perceptual objects corresponding to the individual sources that give rise to a complex acoustic input. There are two aspects to this process: the grouping together of all the simultaneous frequency components that emanate from a single source at a given moment, and the connecting over time of the changing frequencies that a single source produces from one moment to the next [13.160]. These two aspects are sometimes described as *simultaneous grouping* and *sequential grouping*, respectively.

Most experiments on perceptual grouping have studied the effect of grouping on one specific attribute of sounds, for example, their pitch, their subjective location, or their timbre. These experiments have shown that a cue that is effective for one attribute may be less effective or completely ineffective for another attribute [13.161]. Also, the effectiveness of the cues may differ for simultaneous and sequential grouping.

13.8.1 Information Used to Separate Auditory Objects

Fundamental Frequency and Spectral Regularity

When we listen to two steady complex tones together (e.g., two musical instruments or two vowel sounds), we do not generally confuse which harmonics belong to which tone. If the complex tones overlap spectrally, two sounds are heard only if the two tones have different values of the fundamental frequency (F_0) [13.162]. *Scheffers* [13.163] has shown that, if two vowels are presented simultaneously, they can be identified better when they have F_0s that differ by more than 6% than when they have the same F_0. Other researchers have reported similar findings [13.164, 165].

F_0 may be important in several ways. The components in a periodic sound have frequencies that form a simple harmonic series; the frequencies are integer multiples of F_0. This property is referred to as har-

monicity. The lower harmonics are resolved in the peripheral auditory system. The regular spacing of the lower harmonics may promote their perceptual fusion, causing them to be heard as a single sound. If a sinusoidal component does not form part of this harmonic series, it tends to be heard as a separate sound. This is illustrated by some experiments of *Moore* et al. [13.166]. They investigated the effect of mistuning a single low harmonic in a harmonic complex tone. When the harmonic was mistuned sufficiently, it was heard as a separate pure tone standing out from the complex as a whole. The degree of mistuning required varied somewhat with the duration of the sounds; for 400 ms tones, a mistuning of 3% was sufficient to make the harmonic stand out as a separate tone.

Roberts and *Brunstrom* [13.167, 168] have suggested that the important feature determining whether a group of frequency components sounds fused is not harmonicity, but spectral regularity; if a group of components form a regular spectral pattern, they tend to be heard as fused, while if a single component does not fit the pattern, it is heard to pop out. For example, a sequence of components with frequencies 623, 823, 1023, 1223, and 1423 Hz is heard as relatively fused. If the frequency of the middle component is shifted to, say, 923 or 1123 Hz, that component no longer forms part of the regular pattern, and it tends to be heard as a separate tone, standing out from the complex.

For the higher harmonics in a complex sound, F_0 may play a different role. The higher harmonics of a periodic complex sound are not resolved on the basilar membrane, but give rise to a complex waveform with a periodicity equal to F_0 (Fig. 13.18). When two complex sounds with different F_0s are presented simultaneously, then each will give rise to a waveform on the basilar membrane with periodicity equal to its respective F_0. If the two sounds have different spectra, then each will dominate the response at certain points on the basilar membrane. The auditory system may group together regions with common F_0 and segregate them from regions with different F_0 [13.164]. It may also be the case that both resolved and unresolved components can be grouped on the basis of the detailed time pattern of the neural spikes [13.169].

This process can be explained in a qualitative way by extending the model of pitch perception presented earlier. Assume that the pitch of a complex tone results from a correlation or comparison of time intervals between successive nerve firings in neurons with different CFs. Only those channels that show a high correlation would be classified as belonging to the same sound.

Such a mechanism would automatically group together components with a common F_0. However, *de Cheveigné* et al. [13.170] presented evidence against such a mechanism. They measured the identification of a target vowel in the presence of a background vowel; the nominal fundamental frequencies of the two vowels differed by 6.45%. Identification was better when the background was harmonic than when it was made inharmonic (by

shifting the frequency of each harmonic by a random amount between 0 and 6.45% or by less than half of the spacing between harmonics, whichever was smaller). In contrast, identification of the target did not depend upon whether or not the target was harmonic. *De Cheveigné* and coworkers [13.170–172] proposed a mechanism based on the idea that a harmonic background sound can be canceled in the auditory system, thus enhancing the representation of a target vowel.

Onset and Offset Disparities

A cue for the perceptual separation of (near-)simultaneous sounds is onset and offset disparity. *Rasch* [13.173] investigated the ability to hear one complex tone in the presence of another. One of the tones was treated as a masker and the level of the signal tone (the higher in F_0) was adjusted to find the point where it was just detectable. When the two tones started at the same time and had exactly the same temporal envelope, the threshold of the signal was between 0 and -20 dB relative to the level of the masker (Fig. 13.19a). Thus, when a difference in F_0 was the only cue, the signal could not be heard when its level was more than 20 dB below that of the masker.

Rasch also investigated the effect of starting the signal just before the masker (Fig. 13.19b). He found that threshold depended strongly on onset asynchrony, reaching a value of -60 dB for an asynchrony of 30 ms. Thus, when the signal started 30 ms before the masker, it could be heard much more easily and with much greater differences in level between the two tones. It should be emphasized that the lower threshold was a result of the signal occurring for a brief time on its own; essentially performance was limited by backward masking of the 30 ms asynchronous segment, rather than by simultaneous masking. However, the experiment does illustrate the large benefit that can be obtained from a relatively small asynchrony.

Although the percept of his subjects was that the signal continued throughout the masker, Rasch showed that this percept was not based upon sensory information received during the presentation time of the masker. He found that identical thresholds were obtained if the signal terminated immediately after the onset of the masker (Fig. 13.19c). It appears that the perceptual system *assumes* that the signal continues, since there is no evidence to the contrary; the part of the signal that occurs simultaneously with the masker would be completely masked.

Rasch [13.173] showed that, if the two tones have simultaneous onsets but different rise times, this also can

Fig. 13.19a–c Schematic illustration of the stimuli used by *Rasch* [13.173]. Both the signal and the masker were periodic complex tones, with the signal having the higher fundamental frequency. When the signal and masker were gated on and off synchronously (**a**), the threshold for the signal was relatively high. When the signal started slightly before the masker (**b**), the threshold was markedly reduced. When the signal was turned off as soon as the masker was turned on (**c**), the signal was perceived as continuing through the masker, and the threshold was the same as when the signal did continue through the masker

give very low thresholds for the signal, provided it has the shorter rise time. Under these conditions and those of onset asynchronies up to 30 ms, the notes sound as though they start synchronously. Thus, we do not need to be consciously aware of the onset differences for the auditory system to be able to exploit them in the perceptual separation of complex tones. Rasch also pointed out that, in ensemble music, different musicians do not play exactly in synchrony even if the score indicates that they should. The onset differences used in his experiments correspond roughly with the onset asynchronies of nominally simultaneous notes found in performed music. This supports the view that the asynchronies are an important factor in the perception of the separate parts or voices in polyphonic music.

Onset asynchronies can also play a role in determining the timbre of complex sounds. *Darwin* and *Sutherland* [13.174] showed that a tone that starts or stops at a different time from a vowel is less likely to be heard as part of that vowel than if it is simultaneous with it. For example, increasing the level of a single harmonic can produce a significant change in the quality (timbre) of a vowel. However, if the incremented harmonic starts before the vowel, the change in vowel quality is markedly reduced. Similarly, *Roberts* and *Moore* [13.175] showed that extraneous sinusoidal components added to a vowel could influence vowel quality, but the influence was markedly reduced when the extraneous components were turned on before the vowel or turned off after the vowel.

Contrast with Previous Sounds

The auditory system seems well suited to the analysis of changes in the sensory input, and particularly to changes in spectrum over time. The changed aspect stands out perceptually from the rest. It is possible that there are specialized central mechanisms for detecting changes in spectrum. Additionally, stimulation with a steady sound may result in some kind of adaptation. When some aspect of a stimulus is changed, that aspect is freed from the effects of adaptation and thus will be enhanced perceptually. While the underlying mechanism is a matter of debate, the perceptual effect certainly is not.

A powerful demonstration of this effect may be obtained by listening to a stimulus with a particular spectral structure and then switching rapidly to a stimulus with a flat spectrum, such as white noise. A white noise heard in isolation may be described as colorless; it has no pitch and has a neutral sort of timbre. However, when a white noise follows soon after a stimulus with spectral structure, the noise sounds colored [13.176].

A harmonic complex tone with a flat spectrum may be given a speech-like quality if it is preceded by a harmonic complex having a spectrum that is the inverse of that of a speech sound, such as a vowel [13.177].

Another demonstration of the effects of a change in a stimulus can be obtained by listening to a steady complex tone with many harmonics. Usually such a tone is heard with a single pitch corresponding to F_0, and the individual harmonics are not separately perceived. However, if one of the harmonics is changed in some way, by altering either its relative phase or its level, then that harmonic stands out perceptually from the complex as a whole. For a short time after the change is made, a pure-tone quality is perceived. The perception of the harmonic then gradually fades, until it merges with the complex once more.

Change detection is obviously of importance in assigning sound components to their appropriate sources. Normally we listen against a background of sounds that may be relatively unchanging, such as the humming of machinery, traffic noises, and so on. A sudden change in the sound is usually indicative that a new source has been activated, and the change detection mechanisms enable us to isolate the effects of the change and interpret them appropriately.

Correlated Changes in Amplitude or Frequency

Rasch [13.173] also showed that, when the two complex tones start and end synchronously, the detection of the tone with the higher F_0 could be enhanced by frequency modulating it. The modulation was similar to the vibrato that often occurs for musical tones, and it was applied so that all the components in the higher tone moved up and down in synchrony. Rasch found that the modulation could reduce the threshold for detecting the higher tone by 17 dB. A similar effect can be produced by amplitude modulation (AM) of one of the tones. The modulation seems to enhance the salience of the modulated sound, making it appear to stand out from the unmodulated sound.

It is less clear whether the perceptual segregation of simultaneous sounds is affected by the coherence of changes in amplitude or frequency when *both* sounds are modulated. Coherence here refers to whether the changes in amplitude or frequency of the two sounds have the same pattern over time or different patterns over time. Several experiments have been reported suggesting that coherence of amplitude changes plays a role; sounds with coherent changes tend to fuse perceptually, whereas sounds with incoherent changes tend to segregate [13.178–181]. However, *Summerfield* and

Culling [13.182] found that the coherence of AM did not affect the identification of pairs of simultaneous vowels when the vowels were composed of components placed randomly in frequency (to avoid effects of harmonicity).

Evidence for a role of frequency modulation (FM) coherence in perceptual grouping has been more elusive. While some studies have been interpreted as indicating a weak role for frequency modulation coherence [13.183, 184], the majority of studies have failed to indicate such sensitivity [13.182, 185–189]. *Furukawa* and *Moore* [13.190] have shown that the detectability of FM imposed on two widely separated carrier frequencies is better when the modulation is coherent on the two carriers than when it is incoherent. However, this may occur because the overall pitch evoked by the two carriers fluctuates more when the carriers are modulated coherently than when they are modulated incoherently [13.191–193]. There is at present no clear evidence that the coherence of FM influences perceptual grouping when both sounds are modulated.

Sound Location

The cues used in sound localization may also help in the analysis of complex auditory inputs. A phenomenon that is related to this is called the binaural masking level difference (MLD). The phenomenon can be summarized as follows: whenever the phase or level differences of a signal at the two ears are not the same as those of a masker, the ability to detect the signal is improved relative to the case where the signal and masker have the same phase and level relationships at the two ears. The practical implication is that a signal is easier to detect when it is located in a different position in space from the masker. Although most studies of the MLD have been concerned with threshold measurements, it seems clear that similar advantages of binaural listening can be gained in the identification and discrimination of signals presented against a background of other sound.

An example of the use of binaural cues in separating an auditory object from its background comes from an experiment by *Kubovy* et al. [13.194]. They presented eight continuous sinusoids to each ear via earphones. The sinusoids had frequencies corresponding to the notes in a musical scale, the lowest having a frequency of 300 Hz. The input to one ear, say the left, was presented with a delay of 1 ms relative to the input to the other ear, so the sinusoids were all heard toward the right side of the head. Then, the phase of one of the sinusoids was advanced in the left ear, while its phase in the right ear was delayed, until the input to the left ear led the input to the right ear by 1 ms; this phase-shifting

process occurred over a time of 45 ms. The phase remained at the shifted value for a certain time and was then smoothly returned to its original value, again over 45 ms. During the time that the phase shift was present, the phase-shifted sinusoid appeared toward the opposite (left) side of the head, making it stand out perceptually. A sequence of phase shifts in different components was clearly heard as a melody. This melody was completely undetectable when listening to the input to one ear alone. Kubovy et al. interpreted their results as indicating that differences in relative phase at the two ears can allow an auditory object to be isolated in the absence of any other cues.

Culling [13.195] performed a similar experiment to that of *Kubovy* et al. [13.194], but he examined the importance of the phase transitions. He found that, when one component of a complex sound changed rapidly but smoothly in interaural time difference (ITD), it perceptually segregated from the complex. When different components were changed in ITD in succession, a recognizable melody was heard, as reported by Kubovy et al. However, when the transitions were replaced by silent intervals, leaving only static ITDs as a cue, the melody was much less salient. Thus, transitions in ITD seem to be more important than static differences in ITD in producing segregation of one component from a background of other components. Nevertheless, static differences in ITD do seem to be sufficient to produce segregation under some conditions [13.196].

Other experiments suggest that binaural processing often plays a relatively minor role in simultaneous grouping. *Shackleton* and *Meddis* [13.197] investigated the ability to identify each vowel in pairs of concurrent vowels. They found that a difference in F_0 between the two vowels improved identification by about 22%. In contrast, a 400 μs interaural delay in one vowel (which corresponds to an azimuth of about 45 degrees) improved performance by only 7%. *Culling* and *Summerfield* [13.198] investigated the identification of concurrent whispered vowels, synthesized using bands of noise. They showed that listeners were able to identify the vowels accurately when each vowel was presented to a different ear. However, they were unable to identify the vowels when they were presented to both ears but with different ITDs. In other words, listeners could not group the noise bands in different frequency regions with the same ITD and thereby separate them from noise bands in other frequency regions with a different ITD.

In summary, when two simultaneous sounds differ in their interaural level or time, this can contribute to the perceptual segregation of the sounds and enhance

their detection and discrimination. However, such binaural processing is not always effective, and in some situations it appears to play little role.

13.8.2 The Perception of Sequences of Sounds

Stream Segregation

When we listen to rapid sequences of sounds, the sounds may be grouped together (i. e., perceived as if they come from a single source, called fusion or coherence), or they may be perceived as different streams (i. e., as coming from more than one source, called fission or stream segregation) [13.159, 200–202]. The term streaming is used to denote the processes determining whether one stream or multiple streams are heard. *Van Noorden* [13.203] investigated this phenomenon using a sequence of pure tones where every second B was omitted from the regular sequence ABABAB ..., producing a sequence ABA ABA .... He found that this could be perceived in two ways, depending on the frequency separation of A and B. For small separations, a single rhythm, resembling a gallop, is heard (fusion). For larger separations, two separate tone sequences can be heard, one of which (A A A) is running twice as fast as the other (B B B) (fission). Components are more likely to be assigned to separate streams if they differ widely in frequency or if there are rapid jumps in frequency between them. The latter point is illustrated by a study of *Bregman* and *Dannenbring* [13.204]. They used tone sequences in which successive tones were connected by frequency glides. They found that these glides reduced the tendency for the sequences to split into high and low streams. Conditions using partial glides also showed decreased stream segregation, although the partial glides were not quite as effective as complete glides. Thus, complete continuity between tones is not required to reduce stream segregation; a frequency change pointing toward the next tone allows the listener to follow the pattern more easily.

The effects of frequency glides and other types of transitions in preventing stream segregation or fission are probably of considerable importance in the perception of speech. Speech sounds may follow one another in very rapid sequences, and the glides and partial glides observed in the acoustic components of speech may be a strong factor in maintaining the percept of speech as a unified stream.

Van Noorden found that, for intermediate frequency separations of the tones A and B in a rapid sequence, either fusion or fission could be heard, according to the instructions given and the attentional set of the subject. When the percept is ambiguous, the tendency for fission to occur increases with increasing exposure time to the tone sequence [13.205]. The auditory system seems to start with the assumption that there is a single sound source, and fission is only perceived when sufficient evidence has built up to contradict this assumption. Sudden changes in a sequence, or in the perception of a sequence, can cause the percept to revert to its initial, default condition, which is fusion [13.206, 207]; for a review, see [13.208].

For rapid sequences of complex tones, strong fission can be produced by differences in spectrum of successive tones, even when all tones have the same F_0 [13.202, 209–211]. However, when successive complex tones are filtered to have the same spectral envelope, stream segregation can also be produced by differences between successive tones in F_0 [13.211, 212], in temporal envelope [13.210, 213], in the relative phases of the components [13.214], or in apparent location [13.215]. *Moore* and *Gockel* [13.208] proposed that any salient perceptual difference between successive tones may lead to stream segregation. Consistent with this idea, *Dowling* [13.216, 217] has shown that stream segregation may also occur when successive pure tones differ in intensity or in spatial location. He presented a melody composed of equal-intensity notes and inserted between each note of the melody a tone of the same intensity, with a frequency randomly selected from the same range. He found that the resulting tone sequence produced a meaningless jumble. Making the interposed notes different from those of the melody, in either intensity, frequency range, or spatial location,
Fig. 13.20 Example of the stimuli used by *Darwin* and *Hukin* [13.199] (after [13.199, Fig. 1])

caused them to be heard as a separate stream, enabling subjects to pick out the melody.

Darwin and *Hukin* [13.199] have shown that sequential grouping can be strongly influenced by ITD. In one experiment, they simultaneously presented two sentences (Fig. 13.20). They varied the ITDs of the two sentences in the range 0 to $\pm 181 \mu s$. For example, one sentence might lead in the left ear by $45 \mu s$, while the other sentence would lead in the right ear by $45 \mu s$ (as in Fig. 13.20). The sentences were based on natural speech but were processed so that each was spoken on a monotone, i.e., with constant F_0. The F_0 difference between the two sentences was varied from 0 to 4 semitones. Subjects were instructed to attend to one particular sentence. At a certain point, the two sentences contained two different target words aligned in starting time and duration (*dog* and *bird*). The F_0s and the ITDs of the two target words were varied independently from those of the two sentences. Subjects had to indicate which of the two target words they heard in the attended sentence. They reported the target word that had the same ITD as the attended sentence much more often than the target word with the opposite ITD. In other words, the target word with the same ITD as the attended sentence was grouped with that sentence. This was true even when the target word had the same ITD as the attended sentence but a different F_0. Thus, subjects grouped words across time according to their perceived location, independent of F_0 differences. *Darwin* and *Hukin* [13.199] concluded that listeners who try to track a particular sound source over time direct attention to auditory objects at a particular subjective location. The auditory objects themselves may be formed using cues other than ITD, for example, onset and offset asynchrony and harmonicity.

It should be noted that, for discrete sequences of musical tones, the auditory system does not necessarily form streams according to perceived location, especially when that cue competes with other cues. This is illustrated by an effect, called the scale illusion, reported by *Deutsch* [13.218]. She presented two sequences of tones via headphones, one sequence to each ear. The *n*th tone in the left ear was synchronous with the *n*th tone in the right ear. The sequences were created by repetitive presentation of the C major scale in both ascending and descending form, such that when a component of the ascending scale was in one ear, a component of the descending scale was in the other, and vice versa. However, the tones from each scale alternated between ears. Within each ear there were often large jumps in frequency between successive tones. Most subjects perceived the sounds as two streams, organized by the frequency proximity of successive tones. One stream (which was often heard towards one ear) was heard as a musical scale that started high, descended and then increased again, while the other stream (which was usually heard towards the opposite ear) was heard as a scale that started low, ascended, and then decreased again. Thus, the true location of the tones had little influence on the formation of the perceptual streams.

Another example come from the opening bars of the last movement of Tchaikovsky's sixth symphony. This contains interleaved notes played by the first and second violins, who according to 19th century custom sat on opposite sides of the stage. These notes are perceived as a single stream, despite the difference in location, presumably because of the frequency proximity between successive notes.

A number of composers have exploited the fact that stream segregation occurs for tones that are widely separated in frequency. By playing a sequence of tones in which alternate notes are chosen from separate frequency ranges, an instrument such as the flute, which is only capable of playing one note at a time, can appear to be playing two themes at once. Many fine examples of this are available in the works of Bach, Telemann and Vivaldi.

Judgment of Temporal Order

It is difficult to judge the temporal order of sounds that are perceived in different streams. An example of this comes from the work of *Broadbent* and *Ladefoged* [13.219]. They reported that extraneous sounds in sentences were grossly mislocated. For example, a click might be reported as occurring a word or two away from its actual position. Surprisingly poor performance was also reported by *Warren* et al. [13.220] for judgments of the temporal order of three or four unrelated items, such as a hiss, a tone, and a buzz. Most subjects could not identify the order when each successive item lasted as long as 200 ms. Naive subjects required that each item last at least 700 ms to identify the order of four sounds presented in an uninterrupted repeated sequence. These durations are well above those that are normally considered necessary for temporal resolution.

The poor order discrimination described by Warren et al. is probably a result of stream segregation. The sounds they used do not represent a coherent class. They have different temporal and spectral characteristics, and, as for tones widely differing in frequency, they do not form a single perceptual stream. Items in different streams appear to float about with respect

to each other in subjective time. Thus, temporal order judgments are difficult. It should be emphasized that the relatively poor performance reported by *Warren* et al. [13.220] is found only in tasks requiring absolute identification of the order of sounds and not in tasks that simply require the discrimination of different sequences. Also, with extended training and feedback subjects can learn to distinguish between and idenify orders within sequences of unrelated sounds lasting only 10 ms or less [13.221].

To explain these effects, *Divenyi* and *Hirsh* [13.222] suggested that two kinds of perceptual judgments are involved. At longer item durations the listener is able to hear a clear sequence of steady sounds, whereas at shorter durations a change in the order of items introduces qualitative changes that can be discriminated by trained listeners. Similar explanations have been put forward by *Green* [13.76] and *Warren* [13.221].

Bregman and *Campbell* [13.201] investigated the factors that make temporal order judgments for tone sequences difficult. They used naive subjects, so performance presumably depended on the subjects actually perceiving the sounds as a sequence, rather than on their learning the overall sound pattern. They found that, in a repeating cycle of mixed high and low tones, subjects could discriminate the order of the high tones relative to one another or of the low tones among themselves, but they could not order the high tones relative to the low ones. The authors suggested that this was because the two groups of sounds split into separate perceptual streams and that judgments across streams are difficult. Several more recent studies have used tasks involving the discrimination of changes in timing or rhythm as a tool for studying stream segregation [13.211, 214, 223]. The rationale of these studies is that, if the ability to judge the relative timing of successive sound elements is good, this indicates that the elements are perceived as part of a single stream, while if the ability is poor, this indicates that the elements are perceived in different streams.

13.8.3 General Principles of Perceptual Organization

The Gestalt psychologists [13.224] described many of the factors that govern perceptual organization, and their descriptions and principles apply reasonably well to the way physical cues are used to achieve perceptual grouping of the acoustic input. It seems likely that the rules of perceptual organization have arisen because, on the whole, they tend to give the right answers. That is,

use of the rules generally results in a grouping of those parts of the acoustic input that arose from the same source and a segregation of those that did not. No single rule will always work, but it appears that the rules can generally be used together, in a coordinated and probably quite complex way, in order to arrive at a correct interpretation of the input. In the following sections, I outline the major principles or rules of perceptual organization. Many, but not all, of the rules apply to both vision and hearing, and they were mostly described first in relation to vision.

Similarity

This principle is that elements will be grouped if they are similar. In hearing, similarity usually implies closeness of timbre, pitch, loudness, or subjective location. Examples of this principle have already been described. If we listen to a rapid sequence of pure tones, say 10 tones per second, then tones that are closely spaced in frequency, and are therefore similar, form a single perceptual stream, whereas tones that are widely spaced form separate streams.

For pure tones, frequency is the most important factor governing similarity, although differences in level and subjective location between successive tones can also lead to stream segregation. For complex tones, differences in timbre produced by spectral differences seem to be the most important factor. Again, however, other factors may play a role. These include differences in F_0, differences in timbre produced by temporal envelope differences, and differences in perceived location.

Good Continuation

This principle exploits a physical property of sound sources, that changes in frequency, intensity, location, or spectrum tend to be smooth and continuous, rather than abrupt. Hence, a smooth change in any of these aspects indicates a change within a single source, whereas a sudden change indicates that a new source has been activated. One example has already been described; *Bregman* and *Dannenbring* [13.204] showed that the tendency of a sequence of high and low tones to split into two streams was reduced when successive tones were connected by frequency glides.

A second example comes from studies using synthetic speech. In such speech, large fluctuations of an unexpected kind in F_0 (and correspondingly in the pitch) give the impression that a new speaker has stepped in to take over a few syllables from the primary speaker. *Darwin* and *Bethell-Fox* [13.225] synthesized spectral patterns that changed smoothly and repeatedly

between two vowel sounds. When the F_0 of the sound patterns was constant they were heard as coming from a single source, and the speech sounds heard included glides (*l* as in let) and semivowels (*w* as in we). When a discontinuous, step-like F_0 contour was imposed on the patterns, they were perceived as two distinct speech streams, and the speech was perceived as containing predominantly stop consonants (e.g., *b* as in be, and *d* as in day). Apparently, a given group of components is usually only perceived as part of one stream. Thus, the perceptual segregation produces illusory silences in each stream during the portions of the signal attributed to the other stream, and these silences are interpreted, together with the gliding spectral patterns in the vowels, as indicating the presence of stop consonants. It is clear that the perception of speech sounds can be strongly influenced by stream organization.

Common Fate

The different frequency components arising from a single sound source usually vary in a highly coherent way. They tend to start and finish together, change in intensity together, and change in frequency together. This fact is exploited by the perceptual system and gives rise to the principle of common fate: if two or more components in a complex sound undergo the same kinds of changes at the same time, then they are grouped and perceived as part of the same source.

Two examples of common fate were described earlier. The first concerns the role of the onsets and offsets of sounds. Components will be grouped together if they start and stop synchronously; otherwise they will form separate streams. The onset asynchronies necessary to allow the separation of two complex tones are not large, about 30 ms being sufficient. The asynchronies that are observed in performed music are typically as large as or larger than this, so when we listen to polyphonic music we are easily able to hear separately the melodic line of each instrument. Secondly, components that are amplitude modulated in a synchronous way tend to be grouped together. There is at present little evidence that the coherence of modulation in frequency affects perceptual grouping, although frequency modulation of a group of components in a complex sound can promote the perceptual segregation of those components from an unchanging background.

Disjoint Allocation

Broadly speaking, this principle, also known as belong-ingness, is that a single component in a sound can only be assigned to one source at a time. In other words,
Fig. 13.21a–c Schematic illustration of the stimuli used by *Bregman* and *Rudnicky* [13.226]. When the tones A and B are presented alone (**a**), it is easy to tell their order. When the tones A and B are presented as part of a four-tone complex XABX (**b**), it is more difficult to tell their order. If the four-tone complex is embedded in a longer sequence of X tones (**c**), the Xs form a separate perceptual stream, and it is easy to tell the order of A and B

once a component has been used in the formation of one stream, it cannot be used in the formation of a second stream. For certain types of stimuli, the perceptual organization may be ambiguous, there being more than one way to interpret the sensory input. When a given component might belong to one of a number of streams, the percept may alter depending on the stream within which that component is included.

An example is provided by the work of *Bregman* and *Rudnicky* [13.226]. They presented a sequence of four brief tones in rapid succession. Two of the tones, labeled X, had the same frequency, but the middle two, A and B, were different. The four-tone sequence was either XABX or XBAX. The listeners had to judge the order of A and B. This was harder than when the tones AB occurred in isolation (Fig. 13.21a) because A and B were perceived as part of a longer four-tone

pattern, including the two *distracter* tones, labeled X (Fig. 13.21b). They then embedded the four-tone sequence into a longer sequence of tones, called captor tones (Fig. 13.21c). When the captor tones had frequencies close to those of the distracter tones, they captured the distracters into a separate perceptual stream, leaving the tones AB in a stream of their own. This made the order of A and B easy to judge. It seems that the tones X could not be perceived as part of both streams. When only one stream is the subject of judgment and hence of attention, the other one may serve to remove distracters from the domain of attention.

It should be noted that the principle of disjoint allocation does not always work, particularly in situations where there are two or more plausible perceptual organizations [13.227]. In such situations, a sound element may sometimes be heard as part of more than one stream.

Closure

In everyday life, the sound from a given source may be temporarily masked by other sounds. While the masking sound is present there may be no sensory evidence that can be used to determine whether the masked sound has continued or not. Under these conditions the masked sound tends to be perceived as continuous. The Gestalt psychologists called this process closure.

A laboratory example of this phenomenon is the continuity effect [13.228–230]. When a sound A is alternated with a sound B, and B is more intense than A, then A may be heard as continuous, even though it is interrupted. The sounds do not have to be steady. For example, if B is noise and A is a tone that is gliding upward in frequency, the glide is heard as continuous even though certain parts of the glide are missing [13.231]. Notice that, for this to be the case, the gaps in the tone must be filled with noise and the noise must be a potential masker of the tone (if they were presented simultaneously). In the absence of noise, discrete jumps in frequency are clearly heard.

The continuity effect also works for speech stimuli alternated with noise. In the absence of noise to fill in the gaps, interrupted speech sounds hoarse and raucous. When noise is presented in the gaps, the speech sounds more natural and continuous [13.232]. For connected speech at moderate interruption rates, the intervening noise actually leads to an improvement in intelligibility [13.233]. This may occur because the abrupt switching of the speech produces misleading cues as to which speech sounds were present. The noise serves to mask these misleading cues.

It is clear from these examples that the perceptual filling in of missing sounds does not take place solely on the basis of evidence in the acoustic waveform. Our past experience with speech, music, and other stimuli must play a role, and the context of surrounding sounds is important [13.234]. However, the filling in only occurs when one source is perceived as masking or occluding another. This percept must be based on acoustic evidence that the occluded sound has been masked. Thus, if a gap is not filled by a noise or other sound, the perceptual closure does not occur; a gap is heard.

13.9 Further Reading and Supplementary Materials

More information about the topics discussed in this chapter can be found in: A. S. Bregman: *Auditory Scene Analysis: The Perceptual Organization of Sound* (Bradford Books, MIT Press, Cambridge 1990); W. M. Hartmann: *Signals, Sound, and Sensation* (AIP Press, Woodbury 1997); B. C. J. Moore: *An Introduction to the Psychology of Hearing, 6th edn.* (Brill, Leiden 2012); R. Plomp: *The Intelligent Ear* (Erlbaum, Mahwah 2002)

A compact disc (CD) of auditory demonstrations has been produced by A. J. M. Houtsma, T. D. Rossing, W. M. Wagenaars (1987). The disc can be obtained through the Acoustical Society of America; contact asapubs@abdintl.com for details.

The following CD has a large variety of demonstrations relevant to perceptual grouping: A. S. Bregman, P. Ahad (1995). *Demonstrations of Auditory Scene Analysis: The Perceptual Organization of Sound*, (Auditory Perception Laboratory, Department of Psychology, McGill University, distributed by MIT Press, Cambridge, MA). It can be ordered from The MIT Press, 55 Hayward St., Cambridge, MA 02142, USA. Further relevant demonstrations can be found at: http://www.kyushu-id.ac.jp/~ynhome/.

A CD simulating the effects of a hearing loss on the perception of speech and music is *Perceptual Consequences of Cochlear Damage*. This may be obtained by writing to B. C. J. Moore, Department of Experimental Psychology, University of Cambridge, Downing Street, Cambridge, CB2 3EB, England, and enclosing a check for 20 dollars or a cheque for 12 pounds sterling, made payable to B. C. J. Moore.

14. Acoustic Signal Processing

William M. Hartmann, James V. Candy

Signal processing refers to the acquisition, storage, display, and generation of signals – also to the extraction of information from signals and the re-encoding of information. As such, signal processing in some form is an essential element in the practice of all aspects of acoustics. Signal processing algorithms enable acousticians to separate signals from noise, to perform automatic speech recognition, or to compress information for more efficient storage or transmission. Signal processing concepts are the building blocks used to construct models of speech and hearing. Now, in the 21st century, all signal processing is effectively digital signal processing. Widespread access to high-speed processing, massive memory, and inexpensive software make signal processing procedures of enormous sophistication and power available to anyone who wants to use them. Because advanced signal processing is now accessible to everybody, there is a need for primers that introduce basic mathematical concepts that underlie the digital algorithms. The present handbook chapter is intended to serve such a purpose.

The chapter emphasizes careful definition of essential terms used in the description of signals per international standards. It introduces the Fourier series for signals that are periodic and the Fourier transform for signals that are not. Both begin with analog, continuous signals, appropriate for the real acoustical world. Emphasis is placed on the consequences of signal symmetry and on formal relationships. The autocorrelation function is related to the energy and power spectra for finite-duration and infinite-duration signals. The chapter provides careful definitions of statistical terms, moments, and single- and multi-variate distributions. The Hilbert transform is introduced, again in terms of continuous functions. It is applied both to the development of the analytic signal – envelope and phase, and to the dispersion relations for linear, time-invariant systems. The bare essentials of filtering are presented, mostly to provide real-world examples of fundamental concepts – asymptotic responses, group delay, phase delay, etc. This introduction is followed by more advanced ideas: matched filtering and time-reversal processing. Spectral estimation in the presence of noise is treated by several techniques: parametric models, autoregressive procedures, model-based signal processing implemented as Wiener and Kalman filters, and matched-field processing. There is a brief introduction to cepstrology, with emphasis on acoustical applications. The treatment of the mathematical properties of noise emphasizes the generation of different kinds of noise. Digital signal processing with sampled data is specifically introduced with emphasis on digital-to-analog conversion and analog-to-digital conversion. It continues with the discrete Fourier transform and with the z-transform, applied to both signals and linear, time-invariant systems. Digital signal processing continues with an introduction to maximum length sequences as used in acoustical measurements, with an emphasis on formal properties. The chapter ends with a section on information theory including developments of Shannon entropy and mutual information.

14.1 Definitions

Signal processing begins with signals. The simplest signal is a sine wave with a single spectral component, i. e., with a single frequency, as shown in Fig. 14.1. It is sometimes called a pure tone. A sine wave function of time t with *amplitude C*, *angular frequency ω*, and *starting phase φ*, is given by

$$x(t) = C \, \sin(\omega t + \varphi) \, . \tag{14.1}$$

The amplitude has the same units as the waveform x, the angular frequency has units of radians per second, and the phase has units of radians.

Because there are 2π radians in one cycle

$$\omega = 2\pi \, f, \tag{14.2}$$
Fig. 14.1 A sine wave with amplitude C and period T. A little more than three and a half cycles are shown. The starting phase is $\varphi = 0$

and (14.1) can be written as

$$x(t) = C \, \sin(2\pi \, f t + \varphi) \tag{14.3}$$

or as

$$x(t) = C \, \sin\left(2\pi \frac{t}{T} + \varphi\right) \, , \tag{14.4}$$

where f is the *frequency* in cycles per second (or Hertz) and T is the *period* in units of seconds per cycle, $T = 1/f$.

A *complex wave* is the sum of two or more sine waves, each with its own amplitude, frequency, and phase. For example,

$$x(t) = C_1 \, \sin(\omega_1 t + \varphi_1) + C_2 \, \sin(\omega_2 t + \varphi_2) \tag{14.5}$$

is a complex wave with two spectral components having frequencies f_1 and f_2. The period of a complex wave is the reciprocal of the greatest common divisor of f_1 and f_2. For instance, if $f_1 = 400\,\text{Hz}$ and $f_2 = 600\,\text{Hz}$, then the period is $1/(200\,\text{Hz})$ or 5 ms. The *fundamental frequency* is the reciprocal of the period.

A general waveform can be written as a sum of N components,

$$x(t) = \sum_{n=1}^{N} C_n \, \sin(\omega_n t + \varphi_n) \, , \tag{14.6}$$

and the fundamental frequency is the greatest common divisor of the set of frequencies $\{f_n\}$.

An alternative description of the general waveform can be derived by using the trigonometric identity

$$\sin(\theta_1 + \theta_2) = \sin\theta_1 \cos\theta_2 + \sin\theta_2 \cos\theta_1 \quad (14.7)$$

so that

$$x(t) = \sum_{n=1}^{N} A_n \cos(\omega_n t) + B_n \sin(\omega_n t) , \quad (14.8)$$

where $A_n = C_n \sin\varphi_n$, and $B_n = C_n \cos\varphi_n$, are the cosine and sine partial amplitudes respectively. Thus the two parameters C_n and φ_n are replaced by two other parameters A_n and B_n.

Because of the trigonometric identity

$$\sin^2\theta + \cos^2\theta = 1 , \quad (14.9)$$

the amplitude C_n can be written in terms of the partial amplitudes,

$$C_n^2 = A_n^2 + B_n^2 , \quad (14.10)$$

as can the component phase

$$\varphi_n = \text{Arg}(A_n, B_n) . \quad (14.11)$$

The Arg function is essentially an inverse tangent, but because the principal value of the arctangent function only runs from $-\frac{\pi}{2}$ to $\frac{\pi}{2}$, an adjustment needs to be made when B_n is negative. In the end,

$$\text{Arg}(A_n, B_n) = \arctan\left(\frac{A_n}{B_n}\right) \quad (\text{for } B_n \geq 0) \quad (14.12)$$

and

$$\text{Arg}(A_n, B_n) = \arctan\left(\frac{A_n}{B_n}\right) + \pi \quad (\text{for } B_n < 0) . \quad (14.13?)$$

The remaining sections of this chapter provide a brief treatment of real signals $x(t)$ – first as continuous functions of time and then as sampled data. Readers who are less familiar with the continuous approach may wish to refer to the more extensive treatment in [14.1].

14.2 Fourier Series

The Fourier series applies to a function $x(t)$ that is periodic. Periodicity means that we can add any integral multiple m of T to the running time variable t and the function will have the same value as at time t, i. e.

$$x(t + mT) = x(t) , \quad \text{for all integral } m . \quad (14.13)$$

Because m can be either positive or negative and as large as we like, it is clear that x is periodic into the infinite future and past. Then Fourier's theorem says that x can be represented as a Fourier series like

$$x(t) = A_0 + \sum_{n=1}^{\infty} [A_n \cos(\omega_n t) + B_n \sin(\omega_n t)] . \quad (14.14)$$

All the cosines and sines have angular frequencies ω_n that are harmonics, i. e., they are integral multiples of a fundamental angular frequency ω_0,

$$\omega_n = n\omega_0 = 2\pi \frac{n}{T} , \quad (14.15)$$

where n is an integer.

The fundamental frequency f_0 is given by $f_0 = \omega_0/(2\pi)$. The fundamental frequency is the lowest frequency that a sine or cosine wave can have and still fit exactly into one period of the function $x(t)$ because $f_0 = 1/T$. In order to make a function $x(t)$ with period

T, the only sines and cosines that are allowed to enter the sum are those that fit exactly into the same period T. These are those sines and cosines with frequencies that are integral multiples of the fundamental.

The factors A_n and B_n in (14.14) are the Fourier coefficients. They can be calculated by projecting the function $x(t)$ onto sine and cosine functions of the harmonic frequencies ω_n. Projecting means to integrate the product of $x(t)$ and a sine or cosine function over a duration of time equal to a period of $x(t)$. Sines and cosines with different harmonic frequencies are orthogonal over a period. Consequently, projecting $x(t)$ onto, for example $\cos(3\omega_0 t)$, gives exactly the Fourier coefficient A_3.

It does not matter which time interval is used for integration, as long as it is exactly one period in duration. It is common to use the interval $-T/2$ to $T/2$.

The orthogonality and normality of the sine and cosine functions are described by the following equations:

$$\frac{2}{T} \int_{-T/2}^{T/2} \mathrm{d}t \; \sin(\omega_n t) \cos(\omega_m t) = 0 , \quad (14.16)$$

for all m and n;

$$\frac{2}{T} \int_{-T/2}^{T/2} \mathrm{d}t \; \cos(\omega_n t) \cos(\omega_m t) = \delta_{n,m} \quad (14.17)$$

and

$$\frac{2}{T} \int_{-T/2}^{T/2} dt \; \sin(\omega_n t) \; \sin(\omega_m t) = \delta_{n,m} \; , \quad \text{(14.18)}$$

where $\delta_{n,m}$ is the Kronecker delta, equal to one if $m = n$ and equal to zero otherwise.

It follows that the equations for A_n and B_n are

$$A_n = \frac{2}{T} \int_{-T/2}^{T/2} dt \; x(t) \; \cos(\omega_n t) \quad \text{for } n > 0 \; , \quad \text{(14.19)}$$

$$B_n = \frac{2}{T} \int_{-T/2}^{T/2} dt \; x(t) \; \sin(\omega_n t) \quad \text{for } n > 0. \quad \text{(14.20)}$$

The coefficient A_0 is simply a constant that shifts the function $x(t)$ up or down. The constant A_0 is the only term in the Fourier series (14.14) that could possibly have a nonzero value when averaged over a period. All the other terms are sines and cosines; they are negative as much as they are positive and average to zero. Therefore, A_0 is the average value of $x(t)$. It is the direct-current (DC) component of x. To find A_0 we project the function $x(t)$ onto a cosine of zero frequency, i.e. onto the number 1, which leads to the average value of x,

$$A_0 = \frac{1}{T} \int_{-T/2}^{T/2} dt \; x(t) \; . \quad \text{(14.21)}$$

14.2.1 The Spectrum

The Fourier series is a function of time, where A_n and B_n are coefficients that weight the cosine and sine contributions to the series. The coefficients A_n and B_n are real numbers that may be positive or negative.

An alternative approach to the function $x(t)$ deemphasizes the time dependence and considers mainly the coefficients themselves. This is the spectral approach. The spectrum simply consists of the values of A_n and B_n, plotted against frequency, or equivalently, plotted against the harmonic number n. For example, if we have a signal given by

$$x(t) = 5 \sin(2\pi \; 150t) + 3 \cos(2\pi \; 300t)$$
$$- 2 \cos(2\pi \; 450t) + 4 \sin(2\pi \; 450t) \quad \text{(14.22)}$$

then the spectrum consists of only a few terms. The period of the signal is $\frac{1}{150}$ s, the fundamental frequency is 150 Hz, and there are two additional harmonics: a second harmonic at 300 Hz and a third at 450 Hz. The spectrum is shown in Fig. 14.2.

a) Amplitude A

b) Amplitude B

c) Magnitude C

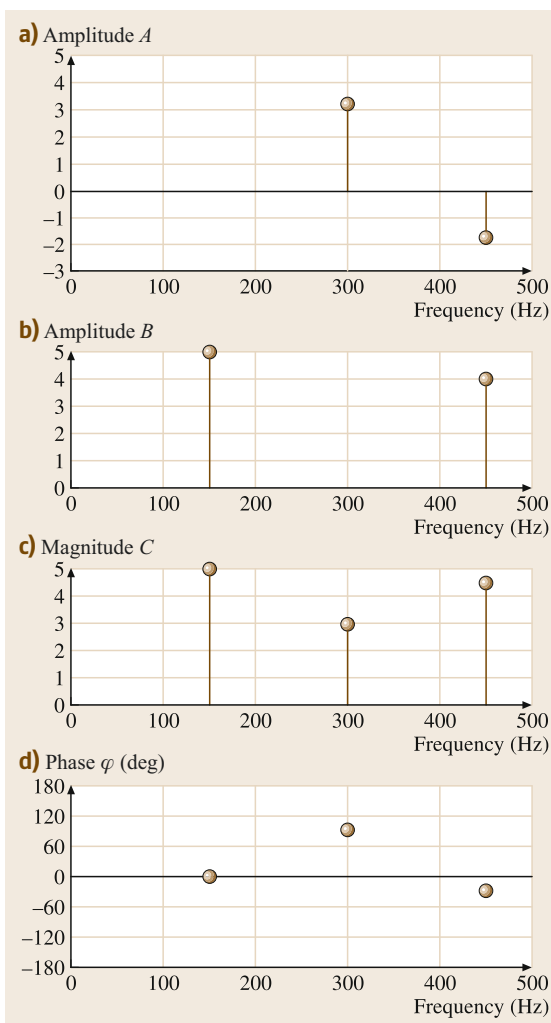
d) Phase φ (deg)


Fig. 14.2 (a,b) The amplitudes A and B for the signal in (14.22); **(c,d)** the corresponding magnitude and phases

14.2.2 Symmetry

Many important periodic functions have symmetries that simplify the Fourier series. If the function $x(t)$ is an even function $[x(-t) = x(t)]$ then the Fourier series for x contains only cosine terms. All coefficients of the sine terms B_n are zero. If $x(t)$ is odd $[x(-t) = -x(t)]$, the the Fourier series contains only sine terms, and all the coefficients A_n are zero. Sometimes it is possible to shift the origin of time to obtain a symmetrical function. Such a time shift is allowed if the physical situation at hand does not require that $x(t)$ be synchronized with some other function of time or with some other time-

Fig. 14.3 The Fourier series of an odd function like this sawtooth consists of sine terms only. The Fourier coefficients can be computed by an integral over a single period from $-T/2$ to $T/2$ ▶

referenced process. For example, the sawtooth function in Fig. 14.3 is an odd function. Therefore, only sine terms are present in the series.

The Fourier coefficients can be calculated by doing the integral over the interval shown by the heavy line. The integral is easy to do analytically because $x(t)$ is just a straight line. The answer is

$$B_n = \frac{2}{\pi} \frac{(-1)^{(n+1)}}{n} .$$ (14.23)

Consequently, the sawtooth function itself is given by

$$x(t) = \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{(-1)^{(n+1)}}{n} \sin\left(2\pi n \frac{t}{T}\right) .$$ (14.24)

A bridge between the Fourier series and the Fourier transform is the complex form for the spectrum,

$$X_n = A_n + iB_n .$$ (14.25)

Because of Euler's formula, namely

$$e^{i\theta} = \cos\theta + i\sin\theta ,$$ (14.26)

it follows that

$$X_n = \frac{2}{T} \int_{-T/2}^{T/2} dt\, x(t)\, e^{i\omega_n t} .$$ (14.27)

14.3 Fourier Transform

The Fourier transform of a time-dependent signal is a frequency-dependent representation of the signal, whether or not the time dependence is periodic. Compared to the frequency representation in the Fourier series, the Fourier transform differs in several ways. In general the Fourier transform is a complex function with real and imaginary parts. Whereas the Fourier series representation consists of discrete frequencies, the Fourier transform is a continuous function of frequency. The Fourier transform also requires the concept of negative frequencies. The transformation tends to be symmetrical with respect to the appearance of positive and negative frequencies and so negative frequencies are just as important as positive frequencies. The treatment of the Fourier integral transform that follows mainly states results. For proof and further applications the reader may wish to consult [14.1, mostly Chap. 8].

The Fourier transform of signal $x(t)$ is given by the integral

$$X(\omega) = \mathcal{F}[x(t)] = \int dt\, e^{-i\omega t}\, x(t) .$$ (14.28)

Here, and elsewhere unless otherwise noted, integrals range over all negative and positive values, i.e. $-\infty$ to $+\infty$.

The inverse Fourier transform expresses the signal as a function of time in terms of the Fourier transform,

$$x(t) = \frac{1}{2\pi} \int d\omega\, e^{i\omega t}\, X(\omega) .$$ (14.29)

These expressions for the transform and inverse transform can be shown to be self-consistent. A key fact in the proof is that the Dirac delta function can be written as an integral over all time,

$$\delta(\omega) = \frac{1}{2\pi} \int dt\, e^{\pm i\omega t} ,$$ (14.30)

and similarly

$$\delta(t) = \frac{1}{2\pi} \int d\omega\, e^{\pm i\omega t} .$$ (14.31)

Because a delta function is an even function of its argument, it does not matter if the $+$ or $-$ sign is used in these equations.

Reality and Symmetry

The Fourier transform $X(\omega)$ is generally complex. However, signals like $x(t)$ are real functions of time. In that connection (14.29) would seem to pose a problem, because it expresses the real function x as an integral

involving the complex exponential multiplied by the complex Fourier transform. The requirement that x be real leads to a simple requirement on its Fourier transform X. The requirement is that $X(-\omega)$ must be the complex conjugate of $X(\omega)$, i. e., $X(-\omega) = X^*(\omega)$. That means that

$$\mathrm{Re}\, X(-\omega) = \mathrm{Re}\, X(\omega) \qquad (14.32)$$

and

$$\mathrm{Im}\, X(-\omega) = -\mathrm{Im}\, X(\omega) \,.$$

Similar reasoning leads to special results for signals $x(t)$ that are even or odd functions of time t. If x is even $[x(-t) = x(t)]$ then the Fourier transform X is not complex but is entirely real. If x is odd $[x(-t) = -x(t)]$ then the Fourier transform X is not complex but is entirely imaginary.

The polar form of the Fourier transform is normally a more useful representation than the real and imaginary parts. It is the product of a magnitude, or absolute value, and an exponential phase factor,

$$X(\omega) = |X(\omega)|\, \exp[\mathrm{i}\varphi(\omega)] \,. \qquad (14.33)$$

The magnitude is a positive real number. Negative or complex values of X arise from the phase factor. For instance, if X is entirely real then $\varphi(\omega)$ can only be zero or 180°.

14.3.1 Examples

A few example Fourier transforms are insightful.

The Gaussian
The Fourier transform of a Gaussian is a Gaussian. The Gaussian function of time is

$$g(t) = \frac{1}{\sigma\sqrt{2\pi}}\, \mathrm{e}^{-t^2/(2\sigma^2)} \,. \qquad (14.34)$$

The function is normalized to unit area, in the sense that the integral of $g(t)$ over all time is 1.0. The Fourier transform is

$$G(\omega) = \mathrm{e}^{-\omega^2\sigma^2/2} \,. \qquad (14.35)$$

The Unit Rectangle Pulse
The unit rectangle pulse, $r(t)$, is a function of time that is zero except on the interval $-T_0/2$ to $T_0/2$. During that interval the function has the value $1/T_0$, so that the function has unit area. The Fourier transform of this pulse is

$$R(\omega) = \left[\sin\left(\omega\frac{T_0}{2}\right)\right] \Big/ \left(\omega\frac{T_0}{2}\right) \,, \qquad (14.36)$$
Fig. 14.4 The Fourier transform of a single pulse with duration T_0 as a function of frequency f expressed in dimensionless form fT_0

or, in terms of frequency

$$R(f) = \frac{\sin(\pi\, fT_0)}{\pi\, fT_0} \,,$$

as shown in Fig. 14.4.

The function of the form $(\sin x)/x$ is sometimes called the sinc function. However, $(\sin\pi x)/(\pi x)$ is also called the sinc function. Therefore, whenever the sinc function is used by name it must be defined.

Both the Gaussian and the unit rectangle illustrate a reciprocal effect sometimes called the *uncertainty principle*. The Gaussian function of time $g(t)$ is narrow if σ is small because σ appears in the denominator of the exponential in $g(t)$. Then the Fourier transform $G(\omega)$ is wide because σ appears in the numerator of the exponential in $G(\omega)$. Similarly, the unit rectangle is narrow if T_0 is small. Then the Fourier transform $R(\omega)$ is broad because $R(\omega)$ depends on the product ωT_0. The general statement of the principle is that, if a function of one variable (e.g. time) is compact, then the transform representation, that is the function of the conjugate variable (e.g. frequency), is broad, and vice versa. The extreme expression of the uncertainty principle appears in the Fourier transform of a function that is constant for all time. According to (14.30), that transform is a delta function of frequency. Conversely, the Fourier transform of a delta function is a constant for all frequency. That means that the spectrum of an ideal impulse contains all frequencies equally.

A contrast between the Fourier transforms of Gaussian and rectangle pulses is also revealing. Because the Gaussian is a smooth function of time, the transform has a single peak. Because the rectangle has sharp edges,

there are oscillations in the transform. If the rectangle is given sloping or rounded edges, the amplitude of the oscillations is reduced.

14.3.2 Time–Shifted Function

If $y(t)$ is a time-shifted version of $x(t)$, i.e.

$$y(t) = x(t - t_0) , \tag{14.37}$$

then the Fourier transform of y is related to the Fourier transform of x by the equation

$$Y(\omega) = \exp(-i\omega t_0)X(\omega) . \tag{14.38}$$

The transform Y is the same as X except for a phase shift that increases linearly with frequency. There are two important implications of this equation. First, because the magnitude of the exponential with imaginary argument is 1.0, the magnitude of Y is the same as the magnitude of X for all values of ω. Second, reversing the logic of the equation shows that, if the phase of a signal is changed in such a way that the phase shift is a linear function of frequency, then the change corresponds only to a shift along the time axis for the function of time, and not to a distortion of the shape of the wave. A general phase-shift function of frequency can be separated into the best-fitting straight line and a residual. Only the residual distorts the shape of the signal as a function of time.

14.3.3 Derivatives and Integrals

If $v(t)$ is the derivative of $x(t)$, i.e., $v(t) = dx/dt$, then the Fourier transform of v is related to the transform of x by the equation

$$V(\omega) = i\omega X(\omega) . \tag{14.39}$$

Thus, differentiating a signal is equivalent to ideal high-pass filtering with a boost of 6 dB per octave, i.e., doubling the frequency doubles the ratio of the output to the input, as processed by the differentiator. Differentiating also leads to a simple phase shift of 90° ($\pi/2$ rad) in the sense that the new factor of i equals $\exp(i\pi/2)$. The differentiation equation can be iterated. The Fourier transform of the n-th derivative of $x(t)$ is $(i\omega)^n X(\omega)$.

Integration is the inverse of differentiation, and that fact becomes apparent in the Fourier transforms. If $w(t)$ is the integral of $x(t)$, i.e.,

$$w(t) = \int_{-\infty}^{t} dt' \, x(t') , \tag{14.40}$$

then the Fourier transform of w is related to the Fourier transform of x by the equation

$$W(\omega) = \frac{X(\omega)}{i\omega} + X(0)\delta(\omega) . \tag{14.41}$$

The first term above could have been anticipated based on the transform of the derivative. The second term corresponds to the additive constant of integration that always appears in the context of an integral. The number $X(0)$ is the average (DC) value of the signal $x(t)$, and if this average value is zero then the second term can be neglected.

14.3.4 Products and Convolution

If the signal x is the product of two functions y and w, i.e. $x(t) = y(t)w(t)$ then, according to the convolution theorem, the Fourier transform of x is the convolution of the Fourier transforms of y and w, i.e.

$$X(\omega) = \frac{1}{2\pi} Y(\omega) * W(\omega) . \tag{14.42}$$

The convolution, indicated by the symbol $*$, is defined by the integral

$$X(\omega) = \frac{1}{2\pi} \int d\omega' \, Y(\omega') \, W(\omega - \omega') . \tag{14.43}$$

The convolution theorem works in reverse as well. If X is the product of Y and W, i.e.

$$X(\omega) = Y(\omega) \, W(\omega) \tag{14.44}$$

then the functions of time x, y, and w are related by a convolution,

$$x(t) = \int_{-\infty}^{\infty} dt' \, y(t') \, w(t - t') \tag{14.45}$$

or

$$x(t) = y(t) * w(t) .$$

The symmetry of the convolution equations for multiplication of functions of frequency and multiplication of functions of time is misleading. Multiplication of frequency functions, e.g. $X(\omega) = Y(\omega)W(\omega)$, normally corresponds to a linear operation on signals generally known as filtering. Multiplication of signal functions of time, e.g. $y(t)w(t)$, is a nonlinear operation such as modulation.

14.4 Power, Energy, and Power Spectrum

The instantaneous power in a signal is defined as $P(t) = x^2(t)$. This definition corresponds to the power that would be transferred by a signal to a unit load that is purely resistive, or dissipative. Such a load is not at all reactive, wherein energy is stored for some fraction of a cycle.

The energy in a signal is the accumulation of power over time,

$$E = \int dt \, P(t) = \int dt \, x^2(t) . \quad (14.46)$$

At this point, a distinction must be made between finite-duration signals and infinite-duration signals. For a finite-duration signal, the above integral exists. By substituting the Fourier transform for $x(t)$, one finds that

$$E = \frac{1}{2\pi} \int d\omega \, X(\omega) \, X(-\omega) \quad \text{or} \quad \int d\omega \, E(\omega) . \quad (14.47)$$

Thus the energy in the signal is written as the accumulation of of the energy spectral density,

$$E(\omega) = \frac{1}{2\pi} X(\omega) \, X(-\omega) = \frac{1}{2\pi} |X(\omega)|^2 . \quad (14.48)$$

The symmetry between (14.46) and (14.47) is known as Parseval's theorem. It says that one can compute the energy in a signal by either a time or a frequency integral.

The power spectral density is obtained by dividing the energy spectral density by the duration of the signal, T_D,

$$P(\omega) = \frac{E(\omega)}{T_D} . \quad (14.49)$$

For white noise, the power density is constant on average, $P(\omega) = P_0$. From (14.47) it is evident that a signal cannot be white over the entire range of frequencies out to infinite frequency without having infinite energy. One is therefore limited to noise that is white over a finite frequency band.

For pink noise the power density is inversely proportional to frequency, $P(\omega) = c/\omega$, where c is a constant. The energy integral in (14.47) for pink noise also diverges. Therefore, pink noise must be limited to a finite frequency band.

Turning now to infinite-duration signals, for an infinite-duration signal the energy is not well defined. It is likely that one would never even think about an infinite-duration signal if it were not for the useful concept of a *periodic* signal. Although the energy is undefined, the power P is well defined, and so is the power

spectrum, or power spectral density $P(\omega)$. As expected, the power is the integral of the power spectral density,

$$P = \int d\omega \, P(\omega) , \quad (14.50)$$

where $P(\omega)$ is given in terms of X from (14.27),

$$P(\omega) = \frac{\pi}{2} \sum_{n=0}^{\infty} |X_n|^2 [\delta(\omega - \omega_n) + \delta(\omega + \omega_n)] . \quad (14.51)$$

It is not hard to convert densities to different units. For instance, the power spectral density can be written in terms of frequency f instead of ω ($\omega = 2\pi f$). By the definition of a density we must have that

$$P = \int df P(f) . \quad (14.52)$$

This definition is consistent with the fact that a delta function has dimensions that are the inverse of its argument dimensions. Therefore, $\delta(\omega) = \delta(2\pi f) = \delta(f)/(2\pi)$, and

$$P(f) = \frac{1}{4} \sum_{n=0}^{\infty} |X_n|^2 [\delta(f - f_n) + \delta(f + f_n)] . \quad (14.53)$$

14.4.1 Autocorrelation

The autocorrelation function a_f of a signal $x(t)$ provides a measure of the similarity between the signal at time t and the same signal at a different time, $t + \tau$. The variable τ is called the *lag*, and the autocorrelation function is given by

$$a_f(\tau) = \int_{-\infty}^{\infty} dt \, x(t) \, x(t + \tau) . \quad (14.54)$$

When τ is zero then the integral is just the square of $x(t)$, and this leads to the largest possible value for the autocorrelation, namely E. For a signal of finite duration, the autocorrelation must always be strictly less than its value at $\tau = 0$. Consequently, the normalized autocorrelation function $a(\tau)/a(0)$ is always less than 1.0 ($\tau \neq 0$).

By substituting (14.29) for $x(t)$ one finds a frequency integral for the autocorrelation function,

$$a_f(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \, e^{i\omega t} |X(\omega)|^2 , \quad (14.55)$$

or, from (14.47),

$$a_f(\tau) = \int\limits_{-\infty}^{\infty} d\omega \; e^{i\omega\tau} E(\omega) \, . \tag{14.56}$$

Equation (14.56) says that the autocorrelation function is the Fourier transform of the energy spectral density. This relationship is known as the Wiener–Khintchine relation. Because $E(-\omega) = E(\omega)$, one can write a_f in a way that proves that it is a real function with no imaginary part,

$$a_f(\tau) = 2 \int\limits_{0}^{\infty} d\omega \; \cos(\omega\tau) E(\omega) \, . \tag{14.57}$$

Furthermore, because the cosine is an even function of its argument $[a_f(-\tau) = a_f(\tau)]$, the autocorrelation function only needs to be given for positive values of the lag.

A signal does not have finite duration if it is periodic. Then the autocorrelation function is defined as

$$a(\tau) = \lim_{T_D \to \infty} \frac{1}{2T_D} \int\limits_{-T_D}^{T_D} dt \; x(t)x(t+\tau) \, . \tag{14.58}$$

If the period is T then $a(\tau) = a(\tau + nT)$ for all integer n, and the maximum value occurs at $a(0)$ or $a(nT)$. Because of the factor of time in the denominator of (14.58), the function $a(\tau)$ is the Fourier transform of the power spectral density and not of the energy spectral density.

A critical point for both $a_f(\tau)$ and $a(\tau)$ is that autocorrelation functions are independent of the phases of spectral components. This point seems counterintuitive because waveforms depend on phases and it seems only natural that the correlation of a waveform with itself at some later time should reflect this phase

dependence. However, the fact that autocorrelation is the Fourier transform of the energy or power spectrum proves that the autocorrelation function must be independent of phases because the spectra are independent of phases.

For example, if $x(t)$ is a periodic function with zero average value, it is defined by (14.6). Then it is not hard to show that the autocorrelation function is given by

$$a(\tau) = \frac{1}{2} \sum_{n=1}^{N} C_n^2 \; \cos(\omega_n \tau) \, . \tag{14.59}$$

The autocorrelation function is only a sum of cosines with none of the phase information. Only the harmonic frequencies and amplitudes play a role.

14.4.2 Cross–Correlation

Parallel to the autocorrelation function, the cross-correlation function is a measure of the similarity of the signal $x(t)$ to the signal $y(t)$ at a different time, i. e. the similarity to $y(t+\tau)$. The cross-correlation function is

$$\rho_0(\tau) = \int dt \; x(t) \; y(t+\tau) \, . \tag{14.60}$$

In practice, the cross-correlation is usually normalized,

$$\rho(\tau) = \frac{\int dt \; x(t) \; y(t+\tau)}{\left[\int dt_1 \; x^2(t_1) \; \int dt_2 \; y^2(t_2)\right]^{1/2}} \, , \tag{14.61}$$

so that the maximum value of $\rho(\tau)$ is equal to 1.0. Unlike the autocorrelation function, the maximum of $\rho(\tau)$ does not necessarily occur at $\tau = 0$. For example, if signal $y(t)$ is the same as signal $x(t)$ except that $y(t)$ has been delayed by T_{del} then $\rho(\tau)$ has its maximum value 1.0 when $\tau = T_{del}$.

14.5 Statistics

Measured signals are always finite in length. Definitions of statistical terms for measured signals, together with their continuum limits are given in this section.

The number of samples in a measurement is N. The *duration* of the measured signal is T_D, and $T_D = N\delta t$, where δt is the inverse of the sample rate.

The sampled signal has values x_i, $(1 \le i \le N)$, and the continuum analog is the signal $x(t)$, $(0 \le t \le T_D)$.

The *average* value, or mean, is

$$\overline{x} = \frac{1}{N} \sum_{i=1}^{N} x_i \quad \text{or} \quad \frac{1}{T_D} \int\limits_{0}^{T_D} dt \; x(t) \, . \tag{14.62}$$

The *variance* is

$$\sigma^2 = \frac{1}{N-1} \sum_{i=1}^{N} (x_i - \overline{x})^2$$

or

$$\frac{1}{T_D} \int_0^{T_D} dt \, [x(t) - \overline{x}]^2 \, . \tag{14.63}$$

The *standard deviation* is the square root of the variance, $\sigma = \sqrt{\sigma^2}$.

The *energy* is

$$E = \delta t \sum_{i=1}^{N} x_i^2 \quad \text{or} \quad \int_0^{T_D} dt \, x^2(t) \, . \tag{14.64}$$

The *average power* is

$$\overline{P} = \frac{1}{N} \sum_{i=1}^{N} x_i^2 \quad \text{or} \quad \frac{E}{T_D} \, . \tag{14.65}$$

The *root-mean-square* (RMS) value is the square root of the average power, $x_{RMS} = \sqrt{\overline{P}}$.

14.5.1 Signals and Processes

Signals are the observed results of processes. A process is *stationary* if its stochastic properties, such as mean and standard deviation, do not change during the time for which a signal is observed. Signals provide incomplete glimpses into processes.

The best estimate of the mean of the underlying process is equal to the mean of an observed signal. The expected error in the estimate of the mean of the underlying process, the so-called *standard deviation of the mean*, is

$$s = \frac{\sigma}{\sqrt{N}} \, , \tag{14.66}$$

where N is the number of data points contributing to the mean of the observed signal.

14.5.2 Distributions

Digitized signals are often regarded as sampled data $\{x\}$. If the data are integers or are put into bins j then the probability that the signal has value x_j is the probability mass function $PMF(j) = N_j/N$, the ratio of the number of samples in bin j to the total number of samples. If data are continuous floating-point numbers, the analogous distribution is the probability density function $PDF(x)$. In terms of these distributions, the mean is given by

$$\overline{x} = \sum x_j PMF(j) \quad \text{or} \quad \int_{-\infty}^{\infty} dx \, x PDF(x) \, . \tag{14.67}$$

The most important PDF is the normal (Gaussian) density $G(x)$,

$$G(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[\frac{(x - \overline{x})^2}{2\sigma^2}\right] \, . \tag{14.68}$$

Like all PDFs, $G(x)$ is normalized to unit area, i.e.

$$\int_{-\infty}^{\infty} dx \, G(x) = 1 \, . \tag{14.69}$$

The probability that x lies between some value x_1 and $x_1 + dx$ is $PDF(x_1) \, dx$, and normalization reflects the simple fact that x must have *some* value.

The probability that variable x is less than some value x_1 is the cumulative distribution function (CDF),

$$CDF(x_1) = \int_{-\infty}^{x_1} dx' \, PDF(x') \, . \tag{14.70}$$

If the density is normal, the integral is the cumulative normal distribution (CND),

$$CND(x) = \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^{x} dx' \exp\left(\frac{x'^2}{2\sigma^2}\right) \, . \tag{14.71}$$

It is convenient to think of the CND as a function of x compared to the standard deviation, i.e., as a function of $y = (x - \overline{x})/\sigma$, as shown in Fig. 14.5.

$$C(y) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y} dy' \exp\left(\frac{y'^2}{2}\right) \, . \tag{14.72}$$

Because of the symmetry of the normal density,

$$C(-y) = 1 - C(y) \, . \tag{14.73}$$

Therefore, it is enough to know $C(y)$ for $y > 0$. A few important values follow.
Fig. 14.5 The *area* under the normal density is the cumulative normal. Here the area is the function $C(y)$

Table 14.1 Selected values of the cumulative normal distribution

$C(0)$	0.5000
$C(0.675)$	0.7500
$C(1)$	0.8413
$C(2)$	0.9773
$C(3)$	0.9987
$C(\infty)$	1.0000

Table 14.1 can be used to find probabilities. For example, the probability that a normally distributed variable lies between its mean and its mean plus a standard deviation, i.e., between $\overline{x}$ and $\overline{x} + \sigma$, is $C(1) - 0.5 = 0.3413$. The probability that it lies within plus or minus two standard deviations ($\pm 2\sigma$) of the mean is $2[C(2) - 0.5] = 0.9546$.

The importance of the normal density lies in the central limit theorem, which says that the distribution for a sum of random variables approaches a normal distribution as the number of variables becomes large. In other words, if the variable x is a sum

$$x = x_1 + x_2 + x_3 + \ldots x_N = \sum_{i=1}^{N} x_i , \qquad (14.74)$$

then no matter how the individual x_i are distributed, x will be normally distributed in the limit of large N.

14.5.3 Multivariate Distributions

A multivariate distribution is described by a *joint probability density* $\text{PDF}(x, y)$, where the probability that variable x has a value between x_1 and $x_1 + dx$ and simultaneously variable y has a value between y_1 and $y_1 + dy$ is

$$P(x_1, y_1) = \text{PDF}(x_1, y_1)\,dx\,dy . \qquad (14.75)$$

The normalization requirement is

$$\int dx \int dy\, \text{PDF}(x, y) = 1 . \qquad (14.76)$$

The *marginal probability density* for x, $\text{PDF}(x)$, is the probability density for x itself, regardless of the value of y. Hence,

$$\text{PDF}(x) = \int dy\, \text{PDF}(x, y) . \qquad (14.77)$$

The y dependence has been integrated out.

The *conditional probability density* $\text{PDF}(x|y)$ describes the probability of a value x, given a specific value of y, for instance, if $y = y_1$, then

$$\text{PDF}(x|y_1) = \text{PDF}(x, y_1) \bigg/ \int dx\, \text{PDF}(x, y_1) , \qquad (14.78)$$

or

$$\text{PDF}(x|y_1) = \text{PDF}(x, y_1)/\text{PDF}(y_1) . \qquad (14.79)$$

The probability that $x = x_1$ and $y = y_1$ is equal to the probability that $y = y_1$ multiplied by the conditional probability that if $y = y_1$ then $x = x_1$, i.e.,

$$P(x_1, y_1) = P(x_1|y_1)P(y_1) . \qquad (14.80)$$

Similarly, the probability that $x = x_1$ and $y = y_1$ is equal to the probability that $x = x_1$ multiplied by the conditional probability that if $x = x_1$ then $y = y_1$, i.e.

$$P(x_1, y_1) = P(y_1|x_1)P(x_1) . \qquad (14.81)$$

The two expressions for $P(x_1, y_1)$ must be the same, and that leads to Bayes' Theorem,

$$P(x_1|y_1) = P(y_1|x_1)\frac{P(x_1)}{P(y_1)} . \qquad (14.82)$$

14.5.4 Moments

The m-th moment of a signal is defined as

$$\overline{x^m} = \frac{1}{N} \sum_{i=1}^{N} x_i^m \quad \text{or} \quad \frac{1}{T_D} \int_0^{T_D} dt\, x^m(t) . \qquad (14.83)$$

Hence the first moment is the mean (14.62) and the second moment is the average power (14.65).

The m-th central moment is

$$\mu_m = \frac{1}{N} \sum_{i=1}^{N} (x_i - \overline{x})^m \quad \text{or} \quad \frac{1}{T_D} \int_0^{T_D} dt\, [x(t) - \overline{x}]^m . \qquad (14.84)$$

The first central moment is zero by definition. The second central moment is the alternating-current (AC) power, which is equal to the average power (14.65) minus the time-independent (or DC) component of the power.

The third central moment is zero if the signal probability density function is symmetrical about the mean. Otherwise, the third moment is a simple way to measure how the PDF is skewed. The *skewness* is the normalized

third moment,

$$\text{skewness} = \frac{\mu_3}{\mu_2^{3/2}} \, . \tag{14.85}$$

The fourth central moment leads to an impression about how much strength there is in the wings of a probability density compared to the standard deviation. The

normalized fourth moment is the *kurtosis*,

$$\text{kurtosis} = \frac{\mu_4}{\mu_2^2} \, . \tag{14.86}$$

For instance, the kurtosis of a normal density, which has significant wings, is 3. But the kurtosis of a rectangular density, which is sharply cut off, is only 9/5.

14.6 Hilbert Transform and the Envelope

The Hilbert transform of a signal $x(t)$ is $\mathcal{H}[x(t)]$ or function $x_{\mathrm{I}}(t)$, where

$$x_{\mathrm{I}}(t) = \mathcal{H}[x(t)] = \frac{1}{\pi} \int_{-\infty}^{\infty} dt' \, \frac{x(t')}{t - t'} \, . \tag{14.87}$$

Some facts about the Hilbert transform are stated here without proof. Proofs and further applications may be found in appendices to [14.1].

First, the Hilbert transform is its own inverse, except for a minus sign,

$$x(t) = -\mathcal{H}[x_{\mathrm{I}}(t)] = -\frac{1}{\pi} \int_{-\infty}^{\infty} dt' \, \frac{x_{\mathrm{I}}(t')}{t - t'} \, . \tag{14.88}$$

Second, a signal and its Hilbert transform are orthogonal in the sense that

$$\int dt \, x(t) \, x_{\mathrm{I}}(t) = 0 \, . \tag{14.89}$$

Third, the Hilbert transform of $\sin(\omega t + \varphi)$ is $-\cos(\omega t + \varphi)$, and the Hilbert transform of $\cos(\omega t + \varphi)$ is $\sin(\omega t + \varphi)$.

Further the Hilbert transform is linear. Consequently, for any function for which a Fourier transform exists,

$$\mathcal{H}\left[\sum_n A_n \cos(\omega_n t) + B_n \sin(\omega_n t)\right]$$
$$= \sum_n A_n \sin(\omega_n t) - B_n \cos(\omega_n t) \tag{14.90}$$

or

$$\mathcal{H}\left[\sum_n C_n \sin(\omega_n t + \varphi_n)\right]$$
$$= -\sum_n C_n \cos(\omega_n t + \varphi_n)$$
$$= \sum_n C_n \sin\left(\omega_n t + \varphi_n - \frac{\pi}{2}\right) \, . \tag{14.91}$$

Comparing the two sine functions above makes it clear why a Hilbert transform is sometimes called a 90° rotation of the signal.

Figure 14.6 shows a Gaussian pulse $x(t)$ and its Hilbert transform, $x_{\mathrm{I}}(t)$. The Gaussian pulse was made by adding up 100 cosine harmonics with amplitudes given by a Gaussian spectrum per (14.35). The Hilbert transform was computed by using the same amplitude spectrum and replacing all the cosine functions by sine functions.

Figure 14.6 illustrates the difficulty often encountered in computing the Hilbert transform using the time integrals that define the transform and its inverse. If we had to calculate $x(t)$ by transforming $x_{\mathrm{I}}(t)$ using (14.88) we would be troubled by the fact that $x_{\mathrm{I}}(t)$ goes to zero so slowly. An accurate calculation of $x(t)$ would require a longer time span than that shown in the figure.

Fig. 14.6 A Gaussian pulse $x(t)$ and its Hilbert transform $x_{\mathrm{I}}(t)$ are the real and imaginary parts of the analytic signal corresponding to the Gaussian pulse

14.6.1 The Analytic Signal

The *analytic signal* $\tilde{x}(t)$ for $x(t)$ is given by the complex sum of the original signal and an imaginary part equal

to the Hilbert transform of $x(t)$,

$$\tilde{x}(t) = x(t) + \mathrm{i}\, x_\mathrm{I}(t) . \tag{14.92}$$

The analytic signal, in turn, can be used to calculate the envelope of signal $x(t)$. The envelope $e(t)$ is the absolute value – or magnitude – of the analytic signal

$$e(t) = |\tilde{x}(t)| . \tag{14.93}$$

For instance, if $x(t) = A\cos(\omega t + \varphi)$, then $x_\mathrm{I}(t) = A\sin(\omega t + \varphi)$ and

$$\tilde{x}(t) = A[\cos(\omega t + \varphi) + \mathrm{i}\sin(\omega t + \varphi)] . \tag{14.94}$$

By Euler's theorem

$$\tilde{x}(t) = A\exp[\mathrm{i}(\omega t + \varphi)] , \tag{14.95}$$

and the absolute value is

$$e(t) = \{A\exp[\mathrm{i}(\omega t + \varphi)]A\exp[-\mathrm{i}(\omega t + \varphi)]\}^{1/2}$$
$$= A . \tag{14.96}$$

14.7 Filters

Filtering is an operation on a signal that is typically defined in frequency space. If $x(t)$ is the input to a filter and $y(t)$ is the output then the Fourier transforms of x and y are related by

$$Y(\omega) = H(\omega)X(\omega) , \tag{14.97}$$

where $H(\omega)$ is the transfer function of the filter. The transfer function has a magnitude and a phase

$$H(\omega) = |H(\omega)|\exp[\mathrm{i}\Phi(\omega)] . \tag{14.98}$$

The frequency-dependent magnitude is the amplitude response, and it characterizes the filter type – low pass, high pass, bandpass, band-reject, etc. The phase $\Phi(\omega)$ is the phase shift for a spectral component with frequency ω. The amplitude and phase responses of a filter are explicitly separated by taking the natural logarithm of the transfer function

$$\ln H(\omega) = \ln[|H(\omega)|] + \mathrm{i}\Phi(\omega) . \tag{14.99}$$

Because $\ln|H| = \ln(10)\log|H|$,

$$\ln H(\omega) = 0.1151G(\omega) + \mathrm{i}\Phi(\omega) , \tag{14.100}$$

where G is the filter gain in decibels, and Φ is the phase shift in radians.

14.7.1 One–Pole Low–Pass Filter

The one-pole low-pass filter serves as an example to illustrate filter concepts. This filter can be made from a single resistor (R) and a single capacitor (C) with a time constant $\tau = RC$. The transfer function of this filter is

$$H(\omega) = \frac{1}{1 + \mathrm{i}\omega\tau} = \frac{1 - \mathrm{i}\omega\tau}{1 + \omega^2\tau^2} . \tag{14.101}$$

The filter is called *one-pole* because there is a single value of ω for which the denominator of the transfer function is zero, namely $\omega = 1/(\mathrm{i}\tau) = -\mathrm{i}/\tau$.

The magnitude (or amplitude) response is

$$|H(\omega)| = \sqrt{\frac{1}{1 + \omega^2\tau^2}} . \tag{14.102}$$

The filter cut-off frequency is the *half-power* point (or 3-dB-down point), where the magnitude of the transfer function is $\frac{1}{\sqrt{2}}$ compared to its maximum value. For the one-pole low-pass filter, the half-power point occurs when $\omega = 1/\tau$.

Filters are often described by their asymptotic frequency response. For a low-pass filter, asymptotic behavior occurs at high frequency, where, for the one-pole filter $|H(\omega)| \propto 1/\omega$. The $1/\omega$ dependence is equivalent to a high-frequency slope of $-6\,\mathrm{dB/octave}$, i.e., for octave frequencies,

$$L_2 - L_1 = 20\log\left(\frac{\omega_1}{2\omega_1}\right) = 20\log\frac{1}{2} = -6 . \tag{14.103}$$

A filter with an asymptotic dependence of $1/\omega^2$ has a slope of $-12\,\mathrm{dB/octave}$, etc.

The phase shift of the low-pass filter is the arctangent of the ratio of the imaginary and real parts of the transfer function,

$$\Phi(\omega) = \tan^{-1}\left(\frac{\mathrm{Im}[H(\omega)]}{\mathrm{Re}[H(\omega)]}\right) , \tag{14.104}$$

which, for the one-pole filter, is $\Phi(\omega) = \tan^{-1}(-\omega\tau)$. The phase shift is zero at zero frequency, and approaches 90° at high frequency. This phase behavior is typical of simple filters in that important phase shifts occur in frequency regions where the magnitude shows large attenuation.

14.7.2 Phase Delay and Group Delay

The phase shifts introduced by filters can be interpreted as delays, whereby the output is delayed in time compared to the input. In general, the delay is different for different frequencies, and therefore, a complex signal composed of several frequencies is bent out of shape by the filtering process. Systems in which the delay is different for different frequencies are said to be *dispersive*.

Two kinds of delay are of interest. The *phase delay* simply reinterprets the phase shift as a delay. The phase delay T_φ is given by $T_\varphi = -\Phi(\omega)/\omega$. The *group delay* T_g is given by the derivative $T_g = -\mathrm{d}\Phi(\omega)/\mathrm{d}\omega$. Phase and group delays for a one-pole low-pass filter are shown in Fig. 14.7 together with the phase shift.

14.7.3 Resonant Filters

Resonant filters, or *tuned* systems, have an amplitude response that has a peak at some frequency where $\omega = \omega_0$. Such filters are characterized by the resonant frequency, ω_0, and by the bandwidth, $2\Delta\omega$. The bandwidth is specified by half-power points such that $|H(\omega_0 + \Delta\omega)|^2 \approx |H(\omega_0)|^2/2$ and $|H(\omega_0 - \Delta\omega)|^2 \approx |H(\omega_0)|^2/2$. The sharpness of a tuned system is often quoted as a Q value, where Q is a dimensionless

number given by

$$Q = \frac{\omega_0}{2\Delta\omega} . \tag{14.105}$$

As an example, a two-pole low-pass filter with a resonant peak near the angular frequency ω_0 is described by the transfer function

$$H(\omega) = \frac{\omega_0^2}{\omega_0^2 - \omega^2 + \mathrm{i}\omega\omega_0/Q} . \tag{14.106}$$

14.7.4 Impulse Response

Because filtering is described as a product of Fourier transforms, i.e., in frequency space, the temporal representation of filtering is a convolution

$$y(t) = \int \mathrm{d}t'\, h(t - t')x(t') = \int \mathrm{d}t'\, h(t')x(t - t') . \tag{14.107}$$

The two integrals on the right are equivalent.

Equation (14.107) is a special form of linear processor. A more general linear processor is described by the equation

$$y(t) = \int \mathrm{d}t'\, h(t, t')x(t') , \tag{14.108}$$

where $h(t, t')$ permits a perfectly general dependence on t and t'. The special system in which only the difference in time values is important, i.e. $h(t, t') = h(t - t')$, is a linear *time-invariant* system. Filters are time invariant.

A system that operates in real time obeys a further filter condition, namely *causality*. A system is causal if the output $y(t)$ depends on the input $x(t')$ only for $t' < t$. In words, this says that the present output cannot depend on the future input. Causality requires that $h(t) = 0$ for $t < 0$. For the one-pole, low-pass filter of (14.101) the impulse response is

$$h(t) = \frac{1}{\tau}\, \mathrm{e}^{-t/\tau} \qquad \text{for } t > 0 ,$$
$$h(t) = 0 \qquad \text{for } t < 0 ,$$
$$h(t) = \frac{1}{2\tau} \qquad \text{for } t = 0 . \tag{14.109}$$

For the two-pole low-pass resonant filter of (14.106), the impulse response is

$$h(t) = \frac{\omega_0}{\sqrt{1 - [1/(2Q)]^2}}\, \mathrm{e}^{-\frac{\omega_0}{2Q}t}$$
$$\times \sin\left\{\omega_0 t \sqrt{1 - [1/(2Q)]^2}\right\} , \quad t \geq 0 ,$$
$$h(t) = 0 , \quad t < 0 . \tag{14.110}$$

Phase shift (rad)

Fig. 14.7 The phase shift Φ for a one-pole low-pass filter can be read on the *left ordinate*. The phase and group delays can be read on the *right ordinate*

14.7.5 Dispersion Relations

The causality requirement on the impulse response, $h(t) = 0$ for $t < 0$, has implications for the transfer function. Causality means that the real and imaginary parts of the transfer function are Hilbert transforms of one another. Specifically, if the real and imaginary parts of H are defined as $H(\omega) = H_R(\omega) + iH_I(\omega)$ then

$$H_R(\omega) = \frac{1}{\pi} \mathcal{P} \int_{-\infty}^{\infty} d\omega' \frac{H_I(\omega')}{\omega - \omega'} , \tag{14.111}$$

and

$$H_I(\omega) = \frac{-1}{\pi} \mathcal{P} \int_{-\infty}^{\infty} d\omega' \frac{H_R(\omega')}{\omega - \omega'} . $$

The symbol $\mathcal{P}$ signifies that the principal value of a divergent integral should be taken. In many cases, this requires no special steps, and definite integrals from integral tables give the correct answers.

These equations are known as *dispersion relations*. They arise from doing an integral in frequency space to calculate the impulse response for $t < 0$. The fact that this calculation must return zero means that $H(\omega)$ must have no singularities in the complex frequency plane for frequencies with a negative imaginary part. Similar dispersion relations apply to the natural log of the transfer function, relating the filter gain to the phase shift as in (14.100)

$$G(\omega) = G(0) - \frac{\omega^2}{0.1151\pi} \mathcal{P} \int_{-\infty}^{\infty} d\omega' \frac{\Phi(\omega')}{\omega'(\omega'^2 - \omega^2)} \tag{14.112}$$

and

$$\Phi(\omega) = \frac{0.1151\,\omega}{\pi} \mathcal{P} \int_{-\infty}^{\infty} d\omega' \frac{G(\omega')}{\omega'^2 - \omega^2} . $$

Because $G(\omega)$ is even and $\Phi(\omega)$ is odd, both integrands are even in ω', and these integrals can be replaced by twice the integral from zero to infinity. The second equation above is particularly powerful. It says that, if we want to find the phase shift of a system, we only have to measure the gain of the system in decibels, multiply by 0.1151, and do the integral. Of course, it is in the nature of the integral that in order to find the phase shift at any given frequency we need to know the gain over a wide frequency range.

The dispersion relations for gain and phase shift also arise from a contour integral over frequencies with a negative imaginary part, but now the conditions on $H(\omega)$ are more stringent. Not only must $H(\omega)$ have no poles for $\text{Im}(\omega) < 0$, but $\ln H(\omega)$ must also have no poles. Consequently $H(\omega)$ must have no zeros for $\text{Im}(\omega) < 0$. A system that has neither poles nor zeros for $\text{Im}(\omega) < 0$ is said to be *minimum phase*. The dispersion relations in (14.112) only apply to a system that is minimum phase.

14.7.6 Matched Filtering

One of the most important problems in acoustics especially in sonar, nondestructive evaluation and medical imaging [14.2] involves the transmission of a known pulse or signal into the medium under investigation followed by its reception. The noisy, distorted, measurement is processed to extract the pulse that has been reflected or scattered back from an object (target or scatterer). For instance, sonar, much like radar, uses this information to obtain the range of the object from the transmitter by simply monitoring the round-trip travel time. In both nondestructive evaluation and medical imaging, an ultrasonic pulse is transmitted into the material or tissue medium under investigation and the received signal is processed to remove the effects of the transmitted pulse (deconvolution) to produce an image of the medium for analysis [14.3].

The basic problem to be solved is that of maximizing the output signal-to-noise ratio (SNR_{OUT}) at the receiver. The underlying system model is given by

$$y(t) = h(r, t) * x(t) + n(t) , \tag{14.113}$$

where x is the transmitted pulse, y is the received signal or measurement, h is the impulse response of the medium in both space r and time t, n is the contaminating zero-mean, uncorrelated (white) noise and $*$ is the convolution operation.

The problem is:

Problem

GIVEN a known signal $x(t)$ in additive uncorrelated (white) noise $n(t)$ of (14.113), FIND the optimum filter response, $h_m(t)$ that maximizes the output signal-to-noise ratio.

Here the output SNR is defined by

$$\max_{\text{mf}} \quad \text{SNR}_{\text{OUT}} = \frac{\xi_{\text{OUT}}}{E\{n^2(t)\}} = \frac{|h_m(t) * x(t)|^2}{\sigma_n^2}$$

$$= \frac{\left| \int_0^T d\tau\, h_m(\tau) x(t - \tau) \right|^2}{\sigma_n^2} \tag{14.114}$$

for h_m the optimum processor or *matched-filter*, ξ_{OUT}, the output signal energy and σ_n^2 the noise variance.

The solution to this problem is classical and reduces to applying the Schwartz inequality [14.4, 5] to the numerator of the previous expression, that is,

$$|h_m(t) * x(t)|^2 \leq \xi_{\mathrm{mf}} \times \xi_x \tag{14.115}$$

for ξ the respective energies. When $h_m(t)$ is related to $x(t)$ by a constant, say unity, then this relation is satisfied with equality at some time T such that its solution is

$$h_m(t) = x(T - t) \tag{14.116}$$

the time-reversed, shifted (by T) signal or *replicant*. The *matched filtering* operation applied to the received measurement is therefore

$$\rho_{xy}(T - t) = E\{h_m(t) * y(t)\} = E\{x(T - t) * y(t)\}, \tag{14.117}$$

where ρ_{xy} is the cross-correlation function of the known signal $x(t)$ and the measurement $y(t)$.

As an example, consider the problem of detecting and locating a known acoustic pulse of unity amplitude (inset) transmitted and received on a noisy sensor (0 dB SNR) as shown in Fig. 14.8. The matched-filter is the time-reversed, shifted replicant of the pulse which is
Fig. 14.8 Matched-filtering of noisy acoustic pulse: Pulse (*inset*), measurement/noise (*dashed*) at 0 dB SNR matched-filter output (*filled line*)

used to process the raw data. After processing (cross-correlation) of the data and replicant the result distinctly shows the location of the pulse in the measurement data.

14.7.7 Time–Reversal Processor

One of the more intriguing techniques in acoustic signal processing is based on the concept of time-reversal [14.2]. We have already noted in Sect. 14.7.6 that the optimum matched-filter is the *time-reversed*, shifted replicant of the transmitted pulse, $h_m(t) = x(T - t)$. In digital signal processing (e.g. MATLAB [14.6]), two-pass filter design to remove phase lag is a standard operation that actually time reverses the original filter ($f(t)$) output to achieve a *zero-phase* design, that is,

$$\mathcal{F}[f(t) * f(-t)] = [F(\omega) \times F(-\omega)]$$
$$= [F(\omega) \times F^*(\omega)] = |F(\omega)|^2, \tag{14.118}$$

where * is the conjugation operation.

In acoustics, time-reversal (T/R) is an intricate part of nondestructive evaluation (flaw detection) and medical operations (lithotripsy) [14.7]. T/R can be applied in two basic scenarios. The first is a *monostatic* operation in which a transceiver (transmitter/receiver) device transmits the signal or wave (transceiver array) into the medium and receives the reflected or scattered signal. The second is a *bistatic* operation that occurs when a signal or wave is launched into the medium by a transmitter(s) and captured by a separate receiver(s) [14.8]. The fundamental theory can be found in [14.2] and [14.8] for each case, respectively.

The *key* to the time-reversal processor evolves from the matched-filter concept in which the known signal is simply replaced by the known impulse response or Green's function of the medium in both space and time/frequency, $g(r, r_0; t)$ or $G(r, r_0; \omega)$. For time-reversal, we have that the matched-filter solution is again found by maximizing the output SNR leading to the modified numerator of (14.115)

$$|h_m(t) * g(r, r_0; t)|^2 \leq \xi_{\mathrm{mf}} \times \xi_g, \tag{14.119}$$

that is satisfied with equality at some time T, if

$$h_m(t) = g(r, r_0; T - t). \tag{14.120}$$

Thus, for T/R, the optimal matched-filter solution is the *time-reversed*, shifted Green's function. Note that in order for the time-reversal property to hold, then spatial *reciprocity* from source-to-receiver ($r_0 \rightarrow r$) must

be valid for receiver-to-source ($r \rightarrow r_0$) or, formally, $g(r, r_0; T - t) \Leftrightarrow g(r_0, r; T - t)$.

If an array is employed then these results include the ability to *focus* the beam on reversal back to the source yielding the optimal *space/time* matched-filter solution [14.5]. Optimality occurs in temporal (autocorrelation peak) and spatial (array focus) gains. For this case, T/R processing is essentially a technique to focus on a reflective object through a homogeneous or inhomogeneous medium that is excited by a broadband source. It converts a divergent wave generated from a source into a convergent wave focused on the source while compensating for all geometric distortions and reducing the associated noise [14.7].

We illustrate the basic T/R operation (bistatic) in Fig. 14.9 where we observe (1) a *point* source transmitting through the medium creating a divergent wavefront sampled spatially by the receiver array, much like dropping a pebble into a puddle, that is,

$$y(r_\ell, t) = g(r_\ell, r; \tau) * \delta(r - r_0; \tau - t) = g(r_\ell, r_0; t) . \tag{14.121}$$

The received data is (2) time-reversed

$$y(r_\ell, -t) = g(r_0, r_\ell; -t) \tag{14.122}$$

and re-transmitted propagating back through the medium focusing on the source

$$\begin{aligned}\hat{x}(r_0, t) &= g(r_\ell, r_0; t) * y(r_\ell, -t) \\ &= g(r_\ell, r_0; t) * g(r_0, r_\ell; -t) .\end{aligned} \tag{14.123}$$

Applying reciprocity, we have (3)

$$\hat{x}(r_0, t) = \left[g(r_\ell, r_0; t) * g(r_\ell, r_0; -t) \right] = \mathscr{A}_{gg}(r_\ell, t) , \tag{14.124}$$

where $\mathscr{A}_{gg}(r_\ell, t)$ is the autocorrelation function at the ℓ-th sensor. Expanding these relations across an entire L-element receiver array gives

$$\hat{x}(r_0, t) = \sum_{\ell=1}^{L} \mathscr{A}_{gg}(r_\ell, t) = L \times \overline{\mathscr{A}_{gg}}(r, t) . \tag{14.125}$$

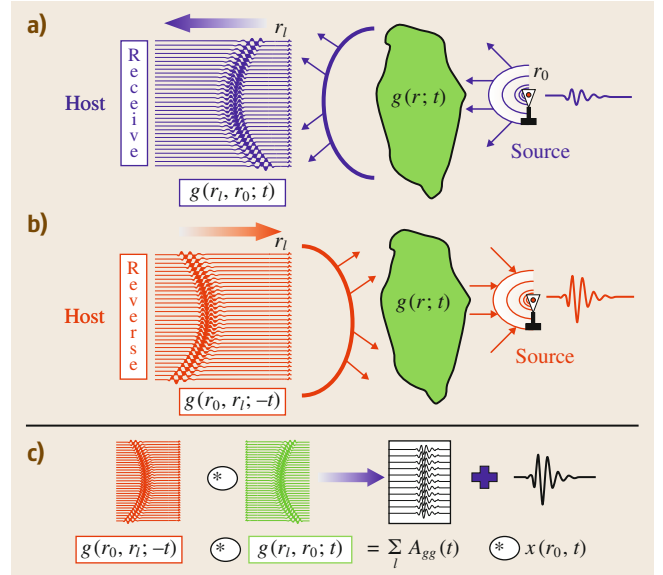
It can be observed by this example the *key* to T/R processing is to time-reverse the Green's function (replicant) in order to mitigate the effects of the medium and perform matched-filtering of Sect. 14.7.6. In practice, obtaining the Green's function in the bistatic case is obtained by *first* transmitting an impulse-like pulse from the source to the array and then performing the


Fig. 14.9a–c Time-reversal processing: (**a**) Divergent wavefront point source transmission. (**b**) Reversal convergent wavefront focusing. (**c**) Time-reversal operation: convolve and sum

T/R operations above [14.7]. The monostatic case is more complex but achieves similar results [14.2].

As an example, consider a communications problem where a coded information sequence is to be recovered from a signal transmitted through the channel medium to a client [14.8]. The *client* station first transmits a pilot signal that is a narrow pulse (impulse-like) to the *base* station receiving array establishing a link or path ($g(r_\ell, r_0; t)$). Once the link is established, the base station transmits a coded message (information) sequence $i(t)$ consisting of ones and zeros to the client along with the reversed Green's function *learned* from the received pilot

$$y(r_\ell, -t) = g(r_0, r_\ell; -t) * i(t) \tag{14.126}$$

as shown in Fig. 14.10a where we see the reversed transmission with the coded message highlighted. After propagation through the medium the data are received at the client station as

$$\begin{aligned}z_{\text{client}}(r_0, t) &= g(r_\ell, r_0; t) * y(r_\ell, -t) \\ &= \left[g(r_\ell, r_0; t) * g(r_0, r_\ell; -t) \right] * i(t)\end{aligned} \tag{14.127}$$

Again applying reciprocity and recognizing the autocorrelation (with array gain), we have

$$z_{\text{client}}(r_0, t) = L \times \overline{\mathscr{A}}(r; t) * i(t) \tag{14.128}$$

Part D | 14.7
Fig. 14.10a,b Time-reversal communications: **(a)** Reversed, transmitted information sequence. **(b)** Zoomed T/R processed data extracting the transmitted code

as shown in Fig. 14.10b where we see the original reversed transmission and the desired code along with the recovered symbols. Clearly placing a threshold at 0 and applying ($> 0 \rightarrow 1$) would recover the information perfectly. Thus, T/R establishes a unique link (path) between base and client stations using the *learned* Green's function enabling an increase in SNR, both temporal and spatial as well as establishing a secure channel.

14.7.8 Spectral Estimation

Unfortunately measured signals rarely contain readily available desired information; they are contaminated with random noise (Sect. 14.9). Deterministic processing or analysis techniques like Fourier transforms can be calculated even though theoretically the transform does not exist for this case. However, the Wiener–Khintchine relation (Sect. 14.5) relates the autocorrelation (deterministic) to the power spectrum as a Fourier transform pair. Thus, the basis of random signal processing resides in applying this relation in some form with the expectation operation incorporated to mitigate the randomness, that is, for the sampled random signal x_k we have

$$P_{xx}(z) = \mathcal{Z}\left[\rho_{xx}(\ell)\right] = E\{X(z)X^*(z)\} \quad \text{and}$$
$$\rho_{xx}(\ell) = \frac{1}{2\pi i} \oint P_{xx}(z) z^{-\ell} \, \mathrm{d}z \ . \tag{14.129}$$

where z indicates the z-transform (Sect. 14.12). Therefore, the autocorrelation and power spectrum enable a way to statistically characterize a random signal.

Classical Spectral Methods

There are a variety of methods to estimate the power spectrum from noisy measurements. Classical methods evolved with the discovery of the fast Fourier transform (FFT) techniques that led to the development of the *correlation method* of spectral estimation which is an application of the Wiener–Khintchine relation and is given by

$$\hat{P}_{xx}(z) = \mathcal{Z}\left[W(k) \times \hat{\rho}_{xx}(\ell)\right] \ , \tag{14.130}$$

where $\hat{\rho}_{xx}$ is an estimate of the autocorrelation function using lag sums or the FFT

$$\hat{\rho}_{xx}(\ell) = \frac{1}{N_x} \sum_{k=0}^{N_x} x(k)x(k+\ell) \ , \quad \ell = 0, 1, 2, \cdots \tag{14.131}$$

for lag ℓ, data length N_x and spectral window function W that must satisfy certain positivity constraints (e.g. maximum at origin) [14.9, 10].

Another well-known classical approach, especially useful when long data records are available, is the *averaged periodogram method* [14.9]. Here windowed data are sectioned, transformed (FFT) to create the periodograms that are then averaged ($\bar{P}_{xx}(z)$) to produce the

estimate,

$$\hat{P}_{xx}(z) = \bar{P}_{xx}(z) = \frac{1}{N_x} \sum_{n=1}^{N_x} |X(z; n)|^2 . \qquad (14.132)$$

Both methods suffer from the tradeoff of bias/variance. For the correlation method the spectral window choice specifies this tradeoff, while the periodogram approach enables choice of section window length and the number of averages performed.

Parametric Spectral Methods

More of the current spectral estimation techniques incorporate parametric models of the signal into the processor. We start with the discrete transfer function model of Sect. 14.12, but with a noisy input for the random case. The signal measurement $Y(z)$ is given by

$$H(z) = \frac{Y(z)}{E(z)} = \frac{B(z)}{A(z)} , \qquad (14.133)$$

where $E(z)$ is white noise with variance σ^2, $B(z) = b_0 + b_1 z^{-1} + \cdots + b_{N_b} z^{-N_b}$ and $A(z) = 1 + a_1 z^{-1} + \cdots + a_{N_a} z^{-N_a}$ are numerator and denominator polynomials and can be factored as in Sect. 14.12 into the so-called *zeros* and *poles* of $H(z)$. Thus, with this representation various models can be characterized as special cases, that is,

$$H_{\text{pole-zero}}(z) = \frac{\sigma B(z)}{A(z)} ,$$
$$H_{\text{all-pole}}(z) = \frac{\sigma}{A(z)} ,$$
$$H_{\text{all-zero}}(z) = \sigma B(z) . \qquad (14.134)$$

Taking inverse $\mathcal{Z}$-transforms of these relations and applying the delay property $z^{-q} Y(z) \rightarrow y_{k-q}$ gives the equivalent difference equation models as

$$y_k + a_1 y_{k-1} + \cdots + a_{N_a} y_{k-N_a}$$
$$= \sigma(b_0 e_k + b_1 e_{k-1} + \cdots + b_{N_b} e_{k-N_b})$$
$$\quad \text{(pole-zero)} ,$$
$$y_k + a_1 y_{k-1} + \cdots + a_{N_a} y_{k-N_a}$$
$$= \sigma b_0 e_k \quad \text{(all-pole)} ,$$
$$y_k = \sigma(b_0 e_k + b_1 e_{k-1} + \cdots + b_{N_b} e_{k-N_b})$$
$$\quad \text{(all-zero)} , \qquad (14.135)$$

where *all-pole* is called an *autoregressive* (AR) model, *all-zero* is called a *moving average* (MA) model and *pole-zero* model is called an *autoregressive-moving-average* (ARMA) model. These models prove quite useful in parametric signal processing applications as

well spectral estimators because the power spectrum can be represented as

$$P_{\text{pole-zero}}(z) = H_{\text{pole-zero}}(z) \times H_{\text{pole-zero}}(z^{-1})$$
$$= |H_{\text{pole-zero}}(z)|^2 = \frac{\sigma^2 |B(z)|^2}{|A(z)|^2} ,$$
$$P_{\text{all-pole}}(z) = H_{\text{all-pole}}(z) \times H_{\text{all-pole}}(z^{-1})$$
$$= |H_{\text{all-pole}}(z)|^2 = \frac{\sigma^2}{|A(z)|^2} ,$$
$$P_{\text{all-zero}}(z) = H_{\text{all-zero}}(z) \times H_{\text{all-zero}}(z^{-1})$$
$$= |H_{\text{all-zero}}(z)|^2$$
$$= \sigma^2 |B(z)|^2 . \qquad (14.136)$$

Parametric spectral estimation techniques require two steps: (1) estimate the parameters of the parametric model $\{\hat{a}_n\}$, $\{\hat{b}_n\}$; and (2) calculate the corresponding power spectrum as shown above varying z or using the FFT.

A wide variety of methods exist to estimate the power spectrum parametrically [14.11]. Perhaps one of the most popular techniques evolved from the processing of seismic and speech signals [14.9]. It is called *linear prediction* or equivalently the *maximum entropy method* (MEM) in which the algorithm is applied to estimate an all-pole model from noisy measurements and then used to estimate the spectrum as in (14.136). The linear predictor solves the following set of equations recursively for the unknown parameters using the well-known Levinson recursion [14.11]

$$\hat{a} = R_{xx}^{-1} \times r_{xx} , \qquad (14.137)$$

where R_{xx} is an $N_a \times N_a$ Toeplitz (covariance) matrix and r_{xx} is an $N_a \times 1$ covariance vector. Once the parameters are estimated using the recursion, the power spectrum is estimated as discussed before.

Another technique that has evolved is the minimum variance distortionless response (MVDR) processor that is considered a *data adaptive* method because it designs a set of optimal narrowband filters at each spectral frequency bin while minimizing the measurement noise variance. It is similar to the classical correlation/periodogram techniques with the exception that the narrowband filters adapt to the process. Theoretically, the MVDR processor attempts to minimize the output (noise) power at each spectral bin subject to the constraint that the narrowband filters pass center frequencies (ω_m) at each bin with unity gain, $|F(\omega_m)| = 1$. Mathematically, the formal problem is to

$$\min_{f} f^T R_{yy} f \ni |F(\omega_m)| = 1 , \qquad (14.138)$$

where $\boldsymbol{f}$ is an $N_y \times 1$ vector of filter weights, $\boldsymbol{R}_{yy}$ is the $N_y \times N_y$ covariance matrix (Toeplitz). The constraint in the Fourier domain is

$$|F(\omega_m)| = 1 = \boldsymbol{d}^T(\omega_m) \times \boldsymbol{f} \qquad (14.139)$$

for $\boldsymbol{d}^T(\omega_m) = [1e^{-i\omega_n} \cdots e^{-iN_y\omega_n}]$.

The solution to this problem is obtained by applying Lagrange multipliers to obtain ([14.11] for more details)

$$P_{MVDR}(\omega_m) = \frac{1}{\boldsymbol{d}^\dagger(\omega_m)\boldsymbol{R}_{yy}^{-1}\boldsymbol{d}(\omega_m)} \quad m = 1, 2, \cdots, \qquad (14.140)$$

where † stands for the Hermitian (conjugate) transposed operator.

In practice, the MVDR method exhibits more resolution than the classical correlation/periodogram estimators, but less than the all-pole (AR) technique. It is interesting to note that there exists a relationship between the MEM and MVDR spectral estimators called *Burg's formula* [14.11] given by

$$\frac{1}{P_{MVDR}(\omega)} = \frac{1}{N_a} \sum_{n=1}^{N_a} \frac{1}{P_{MEM}(\omega; n)}, \qquad (14.141)$$

which provides and alternate method of calculating P_{MVDR} by averaging all lower order AR models.

Subspace Spectral Methods

Another class of spectral estimators that has evolved is the *eigenvector* or *subspace* methods. It follows from the covariance matrix $\boldsymbol{R}_{yy}$ and its eigen-decomposition. An *eigenvalue* λ of a matrix $\boldsymbol{R}$ is defined as a root of $\det(R - \lambda \boldsymbol{I})$ with corresponding eigenvector $\boldsymbol{e}$ satisfying the relation $(R - \lambda \boldsymbol{I}) \times \boldsymbol{e} = 0$. The idea is based on estimating sinusoidal signals in uncorrelated noise [14.11] and was extended to the case of multiple sinusoids. The well-known multiple signal classification (MUSIC) method of spectral estimation is a special case of the eigenvector methods with the eigenvalues set to unity [14.12].

A suite of algorithms evolved with the basic idea of first finding the rank of $\boldsymbol{R}_{yy}$ or equivalently the dimension (N_e) of the *signal subspace* by eigen-decomposition. If $\boldsymbol{e}_n$ is the n-th *eigenvector* of $\boldsymbol{R}_{yy}$, then the corresponding frequency (spectral) line estimator is given by

$$P_{EIG}(\omega_m) = \frac{1}{\sum_{n=N_e+1}^{N_y} \left| \frac{1}{\lambda_n} \boldsymbol{d}^\dagger(\omega_m)\boldsymbol{e}_n \right|^2}$$
$$m = 1, 2, \cdots \qquad (14.142)$$

N_e is the number of independent signal (eigenvectors) vectors or equivalently the rank of $\boldsymbol{R}_{yy}$.

It should also be noted that the temporal spectral and frequency line estimators can be extended to the spatial domain, that is, spatial spectral (power) estimation. These techniques lead to the popular direction of arrival (DOA) or localization methods mimicking those of the time domain with the a wave space-time signal replacing the time series $x(r, t) \to x(t)$, the spatial wavenumber replacing the temporal frequency ($\kappa_m \to \omega_m$) and therefore, the spatial power spectrum replacing the spectrum $P(\kappa_m) \to P(\omega_m)$ [14.12], [14.13].

Consider an application of these methods to synthesized data consisting of sinusoids (35 Hz, 50 Hz, 56 Hz, 90 Hz) in broadband (30–70 Hz) noise at 0 dB SNR in which we:

- Constructed an *ensemble* of 100 realizations of the process;
- Selected a spectral estimation *method*: FFT, correlation, periodogram, MVDR, MEM, MUSIC;
- Performed the spectral estimation for *each* ensemble member (green in Fig. 14.11);
- Estimated the *average* power spectrum over the ensemble (red in Fig. 14.11); and
- Estimated the average *spectral peaks* (blue list in Fig. 14.11).

The results of the application are shown in Fig. 14.11. Noting the performance of each of the estimators, we see some of their interesting characteristics. In Fig. 14.11a the FFT method produced a set of very sharp spectral peaks in the correct frequency locations but unfortunately also included many extraneous peaks due to the randomness of the bandpass noise. The correlation method (Fig. 14.11b) performed the similarly but used the windowed covariance function to reduce the noise, while the periodogram (Fig. 14.11c) method smoothed the signal eliminating some of the desired peaks. The MVDR method (Fig. 14.11d) produced an enhanced spectral estimate with noise reduction capability as well. Both MEM and MUSIC frequency-line estimators (Fig. 14.11e,f) performed quite well and extracted the sinusoidal spectral line reliably with smaller variances. The completes the section on spectral estimation using classical, parametric and eigen-decomposition techniques.

Thus, classical spectral estimators fall into the all-zero (MA) category, while the parametric estimators fall into the pole-zero (ARMA) representations while the eigen-decomposition processors fall into the subspace category.

Spectrogram

An extension of spectral estimation techniques to time-varying spectra enables the development of the *spectrogram* which is a member of the time-frequency class of spectra (frequency versus time versus power). Evolving from speech and sonar (bearing-time) system developments, the spectrogram is a powerful tool [14.3, 9]. It can be calculated using both classical and parametric methods. The classical spectrogram estimator uses the short-time (or windowed) Fourier transform (STFT) in which a small (in length) data window is slid through the data record using the FFT spectral approach, while the parametric approach relies on the sequential estimation of model (AR, MA, ARMA) parameters providing an

instantaneous spectral estimate at each step (if desired) [14.3].

The spectrogram or more properly *instantaneous* power spectrum is defined by $P(z; k)$, where z is the transform (frequency) and k is the time sample (index). The classical FFT spectrogram estimator is given by

$$P(z; k) = \left| \mathcal{F} \left[W_k \times y_k \right] \right|^2 \qquad (14.143)$$

for W the short-time window function, while the parametric approach for the pole-zero (ARMA) spectral estimator is

$$\hat{P}_{\text{ARMA}}(z; k) = \left| \frac{\sigma \, \hat{B}(z; k)}{\hat{A}(z; k)} \right|^2 , \qquad (14.144)$$
Fig. 14.12 Spectrogram of sinusoids in bandpass noise at 0 dB SNR using an ARMA parametric processor

the polynomials $B(z;k)$ and $A(z;k)$ are identical to those of (14.133) but with time-varying coefficients $\{b_n \rightarrow b_n(k);\ a_n \rightarrow a_n(k)\}$.

The parameter estimation technique is sequential in that each time sample is processed individually and the ARMA parameters updated recursively (in time), that is,

$$\hat{\Theta}_k = \hat{\Theta}_{k-1} + G_k \left(y_k - \hat{y}_{k|k-1} \right) , \qquad (14.145)$$

where Θ is the joint parameter (a and b coefficients) vector, G is the weight vector and $\hat{y}$ is the one-step prediction of y based on $k-1$ samples [14.3]. Once these parameters are estimated, the spectrogram is estimated instantaneously at k (if desired) as $\hat{P}_{\mathrm{ARMA}}(z;k)$.

Reconsider the bandpass sinusoids example of the previous sections and process it with the ARMA spectrogram estimator. The results are shown in Fig. 14.12. Here we see that the spectra at the various sinusoidal frequencies appear as horizontal lines of constant frequency (red) across the spectrogram after the initial transients settle down. If at any time there were any changes in the spectrum, then the lines would indicate these changes. This approach is especially useful in condition monitoring for vibrations in machinery [14.14]. This completes the section, next we extend many of

these ideas to incorporate more direct knowledge of the underlying acoustics into the processors.

14.7.9 Model–Based Signal Processing

Inherently, it seems like the more a-priori knowledge about the measurement and its underlying acoustics that can be incorporated into the processor, the better we can expect it to perform – as long as the information that is included is correct. One strategy called the model-based approach provides the essence of *model-based signal processing*. Many believe that all of the signal processing schemes can be cast into this generic framework. Simply, the *model-based approach* is

incorporating mathematical models of both physical phenomenology and the measurement process (including noise/uncertainty) into the processor to extract the desired information.

This approach provides a mechanism to include knowledge of the underlying acoustics in the form of mathematical propagation models, measurement system models and accompanying uncertainties such as instrumentation noise or ambient noise as well as model uncertainties directly into the resulting processor [14.3]. In this way the model-based processor (MBP) enables

the interpretation of results directly in terms of the problem acoustics. The model-based processor is really an acoustic modeler's tool enabling the incorporation of any a-priori information about the particular application problem to extract the desired information. The fidelity of the model determines the complexity of the processor. These models can range from simple implied non-physical representations of the measurement data such as the Fourier or wavelet transforms to parametric models used for data prediction, to lumped mathematical physical representations characterized by ordinary differential equations to full physical partial differential equation models capturing the critical details of the acoustic wave propagation in a complex medium. The dominating factor of which model is the most appropriate is usually determined by how severe the measurements are contaminated with noise and the underlying uncertainties encompassing the philosophy of *letting the problem dictate the approach*. If the signal-to-noise ratio of the measurements is high, then simple non-physical techniques can be used to extract the desired information. Selecting the appropriate model to increase the SNR usually requires that the complexity of the model set increases to achieve the desired results.

A simple spectral estimation example of estimating sinusoids in noise as shown in Fig. 14.13 can be used to illustrate this approach. Suppose we have a noisy acoustical measurement (Fig. 14.13a) of an oscillation in random noise (SNR = 0 dB) and we would like to extract the desired information (oscillation frequency). Our first *simple* approach to analyze the measurement data would be to take its Fourier transform and investigate the various frequency bands for resonant peaks. The result is shown in (Fig. 14.13b), where we basically observe a noisy spectrum and a set of potential resonances – but nothing really conclusive. Next we apply a broadband power spectral estimator with the resulting spectrum shown in Fig. 14.13c. Here we note that the resonances have clearly been enhanced and appear in well-defined bands while the noise is attenuated by the processor, but their still remains a significant amount of uncertainty in the spectrum due to all of the resulting spectral peaks. Upon seeing these resonances in the power spectrum, we might proceed next to a model to enhance the resonances even further by using our a-priori knowledge that there is essentially one dominant resonance we seek. The results of applying this processor are shown in Fig. 14.13d.

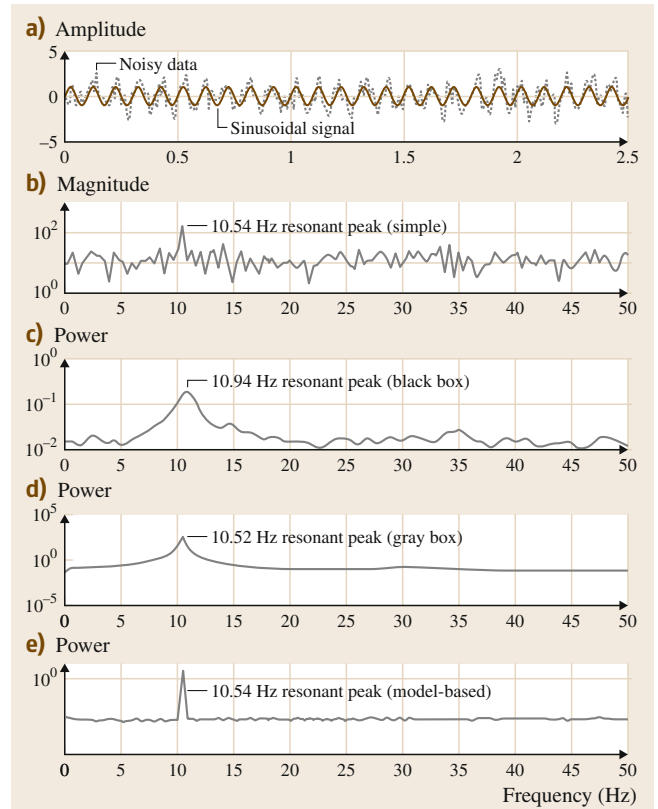
Finally, we use this extracted model to develop an explicit model-based processor (MBP) by developing


Fig. 14.13a–e Simple sinusoid in noise oscillation example. **(a)** Noisy oscillation (10.54 Hz) in noise (0 dB). **(b)** Fourier spectrum. **(c)** Correlation method spectrum. **(d)** MEM method spectrum (AR model). **(e)** Model-based method spectrum (ODE)

a set of harmonic equations for a sinusoid in noise and construct the MBP based on these relations.

$$y_k = \alpha \sin(\omega_0 k) + n_k ,$$
$$\text{(Measurement/Noise Model)}$$
$$\hat{y}_k = \hat{\alpha} \sin(\hat{\omega}_0 k) , \qquad \text{(MBP)}$$
$$\hat{P}_{\hat{y}\hat{y}}(z) = \mathcal{F}\left[\rho_{\hat{y}\hat{y}}(\ell)\right], \qquad \text{(MBP-PSD)}$$
$$(14.146)$$

where the MBP uses the knowledge of the sinusoidal model and noise statistics to estimate the parameters $(\hat{\alpha}, \hat{\omega}_0)$ and produce the enhanced spectral estimate. The results for the MBP are shown in Fig. 14.13e. So we see that once we have defined the acoustical problem, assessed the a-priori information including the underlying phenomenology, then we can proceed to incorporate more sophisticated acoustic models into the paradigm.

The Wiener Filter

Model-based signal processing requires three primary ingredients to develop a processor:

1. The model
2. The criterion
3. Algorithm.

Typically, once 1. and 2. are specified then 3. can follow.

One of the most robust input/output models available in acoustic signal processing is the finite impulse response (FIR) or equivalently moving-average (MA) model (h_k) expressed by the convolution operation of (14.45). One of the most popular applications of the FIR model is to *identify* an unknown system or black box by exciting it with a known input and measuring its output in order to provide data to estimate its impulse response. This is the original *Wiener filter* problem and solutions have been obtained in both time and frequency domains.

Suppose an unknown system is exited by an input x_k and with measured output y_k. We would like to obtain an estimate (linear) of the embedded signal s_k based on past excitation data, that is,

$$s_k = \sum_{n=0}^{N_h} h_n x_{k-n} \,. \tag{14.147}$$

If we represent the measurement y_k as

$$y_k = s_k + n_k \,, \tag{14.148}$$

where n is zero-mean, white noise of variance R_{nn}, then the optimal estimator is the solution to

$$\min_h \mathcal{J}_k = E\{e_k^2\} \,, \tag{14.149}$$

where $e_k := y_k - s_k$.

Following the standard minimization approach, we differentiate (14.149) with respect to h_j, set the result to zero and obtain the orthogonality condition

$$\frac{\partial \mathcal{J}}{\partial h_j} = 2E\left\{ e_k \frac{\partial e_k}{\partial h_j} \right\} = 0 \,. \tag{14.150}$$

The error gradient is

$$\frac{\partial e_k}{\partial h_j} = \frac{\partial}{\partial h_j}(y_k - s_k) = \frac{\partial}{\partial h_j}\left(y_k - \sum_{n=0}^{N_h} h_n x_{k-n} \right)$$

$$= x_{k-j} \,, \tag{14.151}$$

and therefore substituting (14.151) into (14.150), we obtain the *orthogonality conditions*

$$E\{e_k x_{k-j}\} = E\left\{ \left(y_k - \sum_{n=0}^{N_h} h_n x_{k-n} \right) x_{k-j} \right\}$$

$$= 0 \,, \quad j = 0, \ldots, N_h \,, \tag{14.152}$$

which yields the *normal equations* or the discrete *Wiener–Hopf equations* for the estimation problem as

$$\sum_{n=0}^{N_h} h_n R_{xx}(n-j) = r_{yx}(j) \,, \quad j = 0, \ldots, N_h \,. \tag{14.153}$$

Expanding these equations over the indices enables us to obtain

$$R_{xx} h = r_{yx} \,, \tag{14.154}$$

where $R_{xx} \in \mathcal{R}^{(N_h+1)\times(N_h+1)}$ is a Toeplitz matrix. The optimal estimate, $\hat{h}$ is obtained by inverting R_{xx} to give the *Wiener filter solution*,

$$\hat{h} = R_{xx}^{-1} r_{yx} \,. \tag{14.155}$$

We summarize the batch FIR solution as:

- Criterion: $J = E\{e_k^2\}$;
- Models:
  - Measurement: $y_k = s_k + n_k$,
  - Signal: $s_k = \sum_{n=1}^{N_h} h_n x_{k-n}$,
  - Noise: R_{nn},
- Algorithm: $\hat{h} = R_{xx}^{-1} r_{yx}$.

From this solution a variety of other problems can be solved such as the optimal *deconvolution* problem, in which the output and impulse response sequences $\{y_k\}$ and $\{h_k\}$ are *given* and the input sequence $\{\hat{x}_k\}$ is to be found. That is, the Wiener solution to this problem is

$$\hat{x} = R_{hh}^{-1} r_{yh} \,, \tag{14.156}$$

because convolution is an commutative operation ($y = h * x = x * h$).

A related application is that of time delay estimation where we assume a homogeneous medium (attenuation and delay)

$$h_k = \sum_{m=1}^{N_d} \alpha_m \delta(k - \tau_m) \,, \tag{14.157}$$

where $\alpha \leq 1$ represents the weights (attenuation), τ the delays and h_k is essentially an unequally-spaced sequence of impulses of decreasing amplitudes, that is,

Fig. 14.14a–c Optimal time delay estimation results for NDE application: **(a)** Overlay of synthesized and estimated NDE data. **(b)** Estimated impulse response (time delays) and envelope. **(c)** Squared, thresholded, peak detected impulse response for time-delay estimates

a delayed-attenuated impulse train. The objective in this delay estimation problem is to extract (estimate) the impulse train and locate the peaks corresponding to the delay times.

We apply this model-based approach to synthesized 5 MHz ultrasonic data sampled at 20 ns. The objective is NDE of material for flaw damage (pits) caused by ablation. The synthesized data are shown in Fig. 14.14a along with the resulting estimated response or *fit* using the optimal estimator of (14.156), $\hat{y}_k = \hat{h}_k * x_k$. Here the order of the FIR processor was selected to be $N_h = 2500$ weights for the 2750 simulated sample data set. Clearly, the estimated response *overlays* the data quite well providing a sanity check on the processor. In Fig. 14.14b, the estimated impulse response is shown along with its corresponding envelope. Here we note in the physical application that the ideal delayed/attenuated impulse train corresponding to the reflections from the flaws is distorted by the more realistic, highly scattering medium. However, the peaks corresponding to the delays indicating the flaw locations are clearly discernible. A practical approach is to use the squared impulse response, select a reasonable threshold for peak detection and locate the peaks. The results of this operation

along with the corresponding envelope are shown in Fig. 14.14c. The estimated delays correspond reasonably well to the known flaw locations estimated from the delay and known sound-speed of the material.

We summarize the all-zero time-delay estimation approach as follows:

- Criterion: $J = E\{\epsilon_k^2\}$;
- Models:
  - Measurement: $y_k = s_k + n_k$,
  - Signal: $s_k = h(r; k) * p_k$,
  - Noise: R_{nn},
  - Algorithm: $\hat{h} = R_{pp}^{-1} r_{yp}$,
  - Peak Detect: $\hat{\tau}_k = \max_k \hat{h}_k \ \forall k$.

The Kalman Filter

The Kalman filter is the optimal, linear, recursive, state (signal) estimator in Gaussian noise [14.3, 15]. It incorporates all of the information available. The filter processes the measurement data to provide an estimate of the parameters (states, signals, variables, etc.) by incorporating:

1. Process (acoustics) and measurement system knowledge (dynamics)

2. Statistical knowledge of process and measurement noise as well as model uncertainties
3. Any information about the initial conditions or required parameters.

It combines all of this information along with the data to provide the best estimate possible.

The Kalman filter can be thought of as a *signal reconstructor*, a *measurement filter* and a *whitening filter* all wrapped up into one processor. The mathematics become quite involved and various derivations evolve from the purely Bayesian perspective, that is, the Kalman filter can be thought of as an optimal processor recursively calculating the required conditional means and covariances of the posterior Gaussian distribution of the signals (states). It can also be thought of as an orthogonal projector via the Gram–Schmidt procedure over a random vector space or equivalently the innovations approach to orthogonal decomposition. It can also be thought of as the minimum mean-squared error processor evolving from a weighted least-squares perspective. All of these approaches lead to the same solution, the Kalman filter, only because there is one unique optimum for this estimation problem.

Perhaps the simplest way to approach the development of this model-based processor is by observing its *recursive form*. All recursive (or sequential) processors have the form

$$\hat{S}_{\text{NEW}} = \hat{S}_{\text{OLD}} + Ke , \qquad (14.158)$$

where the NEW estimate is simply the OLD estimate ($\hat{S}$) *plus* a K-weighted error (e) term. This is precisely the recursive form of the Kalman filter

$$\underbrace{\hat{s}_{k|k}}_{\text{NEW}} = \underbrace{\hat{s}_{k|k-1}}_{\text{OLD}} + \underbrace{K_k}_{\text{GAIN}} \underbrace{\left(y_k - \hat{y}_{k|k-1} \right)}_{\text{ERROR}} , \qquad (14.159)$$

where $\hat{s}_{k|k}$ is the signal or state estimate at time k given all of the data up to time k, K_k is the weight or gain and e_k is the innovation or residual error given by the difference between the measurement data y_k and its corresponding estimate $\hat{y}_{k|k-1}$. In a nutshell, (14.159) is the primary Kalman filter recursion which follows the simple recursive form of (14.158). The rest of the calculations are based on the model and conditional covariances that are also calculated recursively.

The underlying representation for this processor is the *Gauss–Markov model* in state-space form [14.3] given by

$$s_k = As_{k-1} + Bu_{k-1} + w_{k-1} ,$$
$$y_k = Cs_k + v_k , \qquad (14.160)$$

for s, u, y the N_s-signal (state), the N_u-input (deterministic) and N_y-measurement vectors, w, v the zero-mean, random Gaussian noise vectors with covariance matrices, R_{ww} and R_{vv}, and the appropriately dimensioned system and measurement matrices, A, B, C. Note that this model is a linear transformation of *Gaussian* processes causing all of the distributions to be Gaussian and has the *Markov* property that the signal at k only depends on it past value at $k-1$.

The simplest example of a Kalman filter is the recursive form for the sample mean estimator. If the sample mean is defined by

$$\hat{S}(K) = \frac{1}{K} \sum_{n=1}^{K} s_n ,$$

then removing the K-th term from the sum, and recognizing the expression for $\hat{S}(K-1)$ leads to

$$\hat{S}(K) = \frac{1}{K} s_K + \frac{K-1}{K} \hat{S}(K-1)$$

or rearranging, we obtain the desired recursive form

$$\underbrace{\hat{S}(K)}_{\text{new}} = \underbrace{\hat{S}(K-1)}_{\text{old}} + \underbrace{\frac{1}{K}}_{\text{gain}} \underbrace{\left[s_K - \hat{S}(K-1) \right]}_{\text{error}} .$$

To obtain some insight into the filter operation, we can think of it in terms of a *predictor-corrector* paradigm in which the underlying phenomenological/measurement/noise models are used to *predict* the signal in-between the arrival of a new measurement. Once the new measurement data is available, the processor *corrects* the predicted signal estimate (OLD) as in (14.159). The prediction-step embedding the dynamic model is given by

$$\hat{s}_{k|k-1} = A\hat{s}_{k-1|k-1} + Bu_{k-1} \quad \text{(Signal prediction)} , \qquad (14.161)$$

which is accompanied by its corresponding *prediction error covariance*, $\tilde{P}_{k|k-1} := \text{cov}(s_k - \hat{s}_{k|k-1})$ for

$$\tilde{P}_{k|k-1} = A\tilde{P}_{k|k-1}A^{\text{T}} + R_{ww}$$
$$\text{(Covariance prediction)} , \qquad (14.162)$$

incorporating A the process (system) matrix, $\tilde{P}$ the previous error covariance and R_{ww}, the process noise or uncertainty covariance matrix. So we see that the dynamical model (A,B) and statistics $(R_{ww},\tilde{P})$ are incorporated into this step quite naturally.

The *correction*-step (or update) incorporates the measurement data into the processor through the recursive form of (14.159) discussed earlier, that is,

$$\underbrace{\hat{s}_{k|k}}_{\text{corrected}} = \underbrace{\hat{s}_{k|k-1}}_{\text{predicted}} + \underbrace{K_k e_k}_{\text{DATA}} \quad \text{(Signal correction)},$$

(14.163)

along with the corresponding innovation (e_k) and *corrected error covariance*, $\tilde{P}_{k|k} := \text{cov}(s_k - \hat{s}_{k|k})$ given by

$$e_k = y_k - \hat{y}_{k|k-1} = y_k - C\hat{s}_{k|k-1}$$

(Error innovation),

(14.164)

and

$$\tilde{P}_{k|k} = \tilde{P}_{k|k-1} - K_k C^{\mathrm{T}} \tilde{P}_{k|k-1}$$

(Covariance correction),

(14.165)

incorporating the gain, K_k and measurement system model, C along with the predicted error covariance of the previous step. The corrected error covariance enables us to observe the quality (error) of the signal estimate. The innovation (measurement error) plays a *key* role in monitoring filter performance (on-line), since the optimal solution (in theory) requires that $\{e_k\}$ be a zero-mean and uncorrelated (white) sequence, if the processor is operating properly. Performing whiteness tests is a great advantage compared to other statistical processors. The accompanying innovations covariance is also computed as part of the scheme

$$R_{ee} = C\tilde{P}_{k|k-1}C^{\mathrm{T}} + R_{vv}$$

(Innovations covariance),

(14.166)

which incorporates both measurement system model (C) and measurement statistics (R_{vv}).

Finally, to complete the processor, the weight or *gain* (Kalman gain) is given by

$$K_k = \tilde{P}_{k|k-1}C^{\mathrm{T}}R_{ee}^{-1}, \qquad \text{(Gain)}.$$

(14.167)

We summarize the Kalman filter or state-space MBP steps in Fig. 14.15.

Next let us consider a structural vibration signal enhancement problem. The structure (one story) is governed by the dynamic equation [14.14]

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f(t),$$

(14.168)

where x is the displacement, f is the forcing function and m, c, k are the respective mass, damping and spring constants with the displacement measurement of gain G given by

$$y(t) = Gx(t).$$

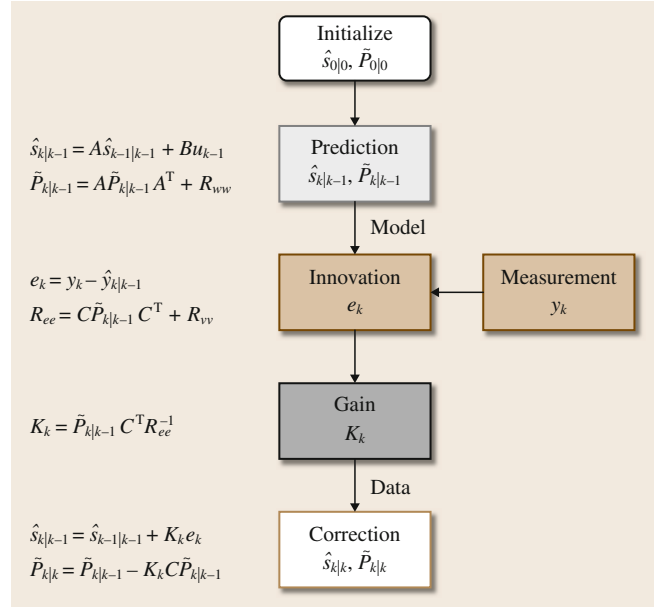
(14.169)


Fig. 14.15 Kalman Filter MBP: Predictor-Corrector Operations

The objective is to develop the Kalman filter for this problem. First, we define the state vector as $s(t) := [x(t)\dot{x}(t)]^{\mathrm{T}}$ and input $u(t) = f(t)$. Solving for the highest derivative in (14.168), we obtain the state-space relations

$$\dot{s}(t) = A_{\mathrm{c}}s(t) + B_{\mathrm{c}}u(t)$$
$$y(t) = C_{\mathrm{c}}s(t)$$

(14.170)

with continuous-time (subscript $_{\mathrm{c}}$) representations

$$A_{\mathrm{c}} = \begin{bmatrix} 0 & | & 1 \\ - & - & - \\ -\frac{k}{m} & | & -\frac{c}{m} \end{bmatrix}, \quad B_{\mathrm{c}} = \begin{bmatrix} 0 \\ \frac{1}{m} \end{bmatrix}, \quad C_{\mathrm{c}} = [G \ 0].$$

(14.171)

The data are digitized, so it is necessary to use a sampled-data representation that we develop using first differences

$$\dot{s}(t) \approx \frac{s_k - s_{k-1}}{\Delta t_k}$$

by substituting this approximation into (14.170) and extending it to a Gauss–Markov representation to obtain

$$s_k = (I + \Delta t_k A_{\mathrm{c}})\, s_{k-1} + \Delta t_k B_{\mathrm{c}} u_{k-1} + \Delta t_k w_{k-1},$$
$$y_k = C_{\mathrm{c}} s_k + v_k,$$

(14.172)

or defining discrete notation, we have

$$A := I + \Delta t_k A_c \, ,$$
$$B := \Delta t_k B_c \, ,$$
$$C := C_c \, ,$$
$$R_{ww} := \Delta t_k R_{ww} \, ,$$
$$R_{vv} := R_{vv} \, , \tag{14.173}$$

and therefore, the sampled-data system of (14.172) can be expressed simply as

$$s_k = A s_{k-1} + B u_{k-1} + w_{k-1} \, ,$$
$$y_k = C s_k + v_k \, .$$

Now the Kalman filter equations follow directly

$$\hat{s}_{k|k-1} = A \hat{s}_{k-1|k-1} + B u_{k-1} \quad \text{(Prediction)} \, ,$$
$$e_k = y_k - \hat{y}_{k|k-1} = y_k - C \hat{s}_{k|k-1} \quad \text{(Innovation)} \, ,$$
$$\hat{s}_{k|k} = s_{k|k-1} + K_k e_k \quad \text{(Correction)} \, ,$$

and the other required matrices follow. This completes the formulation.

Concluding this section, we consider the problem of the passive localization of a planar (nonlinear in parameters) source or target. This problem occurs in a variety of applications such as the seismic localization of an earthquake using an array of seismometers, the passive localization of a target in ocean acoustics or the localization of a flaw in NDE. For our problem in ocean acoustics the model-based approach incorporates the underlying physics represented by an acoustic propagation (process) model depicting how the sound propagates from a source to the sensor (measurement) array of acoustic hydrophones. The statistics of the noise from the background or ambient noise, shipping noise, or uncertainty in the model parameters provides input to both the process and measurement system models. Besides the model parameters and initial conditions, the raw measurement data is input to the processor with the output being the filtered signal and unknown parameters.

Assume that a 50 Hz (ω_0) nonlinear plane wave source (target) at a bearing angle of 45° (θ_0) is impinging on a 2-element array at a 10 dB SNR. The plane wave signal is characterized mathematically by

$$s_\ell(t) = \alpha e^{i \kappa_0 (\ell - 1) \Delta \sin \theta_0 - i \omega_0 t} \, , \tag{14.174}$$

where $s_\ell(t)$ is the space-time signal measured by the l-th sensor, α is the plane wave amplitude factor with κ_0, Δ, θ_0, ω_0 the respective wavenumber, sensor spacing, bearing angle, and temporal frequency parameters. We would we like to solve the basic ocean acoustic
Fig. 14.16a,b Plane wave propagation: (**a**) Problem geometry. (**b**) Synthesized 50 Hz, 45°, plane wave impinging on a 2-element sensor array at 10 dB SNR

processing localization problem estimating the target bearing angle θ_0 and temporal frequency, ω_0 parameters. The basic problem geometry and synthesized measurements (pressure-field) are shown in Fig. 14.16.

For the *plane wave*, we have the following models:

- Signal model:

$$s_\ell(t) = \alpha e^{i \kappa_0 (\ell - 1) \Delta \sin \theta_0 - i \omega_0 t} \, ,$$

- Measurement model

$$p_\ell(t) = s_\ell(t) + n_\ell(t) \, ,$$

- Noise model

$$n \sim \mathcal{N}(0, \sigma_n^2) \, ,$$

where $n_\ell(t)$ is zero mean, random (uncorrelated) Gaussian noise with variance, σ_n^2. We use the notation "$\mathcal{N}(m, v)$" to define a Gaussian or normal probability distribution with mean m and variance v.

In essence, this is a problem of estimating a set of parameters, $\{\theta_0, \omega_0\}$ from noisy array pressure-field measurements, $\{p_\ell(t)\}$. More formally, the *target bearing angle and frequency estimation problem* is stated as:

Problem
GIVEN a set of noisy array measurements $\{p_\ell(t)\}$, FIND the best estimates of the target bearing angle (θ_0) and temporal frequency (ω_0) parameters, $\hat{\theta}_0$ and $\hat{\omega}_0$.
