The classical approach to this problem is to first take one of the sensor channels and perform power spectral analysis of the filtered time series to estimate the temporal frequency ω_0. The bearing angle can be estimated independently by performing classical spatial spectral estimation (beamforming) [14.13] on the array data. The spatial spectral estimator is scanned over bearing angle indicating the true source location at the spectral peak of maximum power. The results of applying this approach to our problem are shown in Fig. 14.17a depicting the outputs of both spectral estimators peaking at the correct frequency and angle parameters.

The MBP is implemented by incorporating the plane wave propagation, hydrophone array, and statistical noise models; however, the temporal frequency and bearing angle parameters are now unknown and must be estimated jointly along with the simultaneous enhancement of the pressure-field. The solution to this problem is performed by solving a joint (parameter/enhancement) estimation problem [14.3, 16]. This is the *parameter adaptive* form [14.17] of the MBP used in many applications [14.8]. The filter becomes nonlinear (in the measurement model) as follows

$$\hat{\theta}_{k|k} = \hat{\theta}_{k|k-1} + K_\theta e_k^\theta \,,$$
$$\hat{\omega}_{k|k} = \hat{\omega}_{k|k-1} + K_\omega e_k^\omega \,,$$
$$\hat{p}_{k|k-1} = c\left[\hat{\theta}_{k|k-1}, \hat{\omega}_{k|k-1}\right]. \qquad (14.175)$$

The results are appealing as shown in Fig. 14.17b. We see the bearing angle and temporal frequency estimates as a function of time eventually converging to the true values ($\omega_0 = 50\,\text{Hz}$, $\theta_0 = 45°$). The MBP also produces a *residual error (innovations) sequence* (shown in Fig. 14.17), which is used to determine its performance.

We summarize the classical and model-based solutions to the temporal frequency and bearing angle estimation problem. The classical approach simply performs spectral analysis temporally and spatially to extract the parameters from noisy data, while the model-based approach embeds the unknown parameters into its propagation, measurement, and noise models enabling a solution to the joint estimation problem. The MBP also monitors its performance by analyzing the statistics of its residual (or innovations) error sequence. This completes the section, next we consider a relevant extension of the MBP approach.

Wiener/Kalman Filter Equivalence

In this section, we show the equivalence of the Wiener filter as a special case of the Kalman filter. Is is well-known that there was a great conceptual stress created by the introduction of the *recursive* Kalman processor. Primarily due to the limitations of the Wiener filter which was constrained to statistically stationary (no time-varying statistics) signals. Of course, the Kalman paradigm is not constrained to stationary processes and easily handles time-varying models and statistics as

well as multivariable problems (vector-matrix) making it an extremely powerful methodology in its versatility and application. Therefore, in order to demonstrate the equivalence we must limit the discussion to stationary processes and resort to the power spectral domain where the Wiener solution evolved.

In order to show the relationship between the Wiener filter and its state-space counterpart, the Kalman filter, we state the Wiener solution and then show that the steady-state Kalman (staionary) filter provides a unique solution with all the necessary properties. We use frequency-domain techniques to show the equivalence using Z-transforms. We choose the frequency domain for historical reasons, since the classical Wiener solution has more intuitive appeal.

The Wiener filter solution in the frequency domain can be solved by spectral factorization, since

$$H(z) = P_{sy}(z) \times P_{yy}^{-1}(z) , \qquad (14.176)$$

where $H(z)$ has all its poles and zeros within the unit circle (stable). The classical approach to Wiener filtering can be accomplished in the frequency domain by factoring the power spectral density (PSD) of the measurement sequence; that is,

$$P_{yy}(z) = H(z)H^{T}(z^{-1}) . \qquad (14.177)$$

The factorization is unique, stable, and minimum-phase [14.15, 18].

Now we must show that the *steady-state Kalman filter* (ignoring the deterministic input) given by

$$\hat{s}_{k+1} = A\hat{s}_k + Ke_k ,$$
$$y_k = C\hat{s}_k + e_k = \hat{y}_k + e_k , \qquad (14.178)$$

where e is the zero-mean, white innovations with covariance R_{ee}, is stable and minimum-phase and therefore, in fact, the *Wiener solution*. The *transfer function* of the innovations model is obtained by taking Z-transforms of (14.178) as

$$T(z) = \frac{Y(z)}{E(Z)} = C(zI - A)^{-1}K . \qquad (14.179)$$

Let us calculate the measurement covariance of (14.178),

$$R_{\hat{y}\hat{y}}(\ell) = \text{Cov}[y_{k+\ell}y_k]$$
$$= R_{\hat{y}\hat{y}}(\ell) + R_{\hat{y}e}(\ell) + R_{e\hat{y}}(\ell) + R_{ee}(\ell) , \qquad (14.180)$$

where $\hat{y}_k := C\hat{s}_k$. Taking Z-transforms, we obtain the measurement PSD as

$$P_{yy}(z) = P_{\hat{y}\hat{y}}(z) + P_{\hat{y}e}(z) + P_{e\hat{y}}(z) + P_{ee}(z) . \qquad (14.181)$$

Using linear system theoretical relations [14.3], we see that

$$P_{\hat{y}\hat{y}}(z) = CP_{\hat{s}\hat{s}}(z)C^{T} = T(z)P_{ee}(z)T^{T}(z^{-1}) ,$$
$$P_{ee}(z) = R_{ee}$$
$$P_{\hat{y}e}(z) = CP_{\hat{s}e}(z) = T(z)P_{ee}(z) ,$$
$$P_{e\hat{y}}(z) = P_{ee}(z)T^{T}(z^{-1}) . \qquad (14.182)$$

Thus, the measurement PSD is given by

$$P_{yy}(z) = T(z)P_{ee}(z)T^{T}(z^{-1})$$
$$+ T(z)P_{ee}(z) + P_{ee}(z)T^{T}(z^{-1}) + P_{ee}(z) . \qquad (14.183)$$

Since $P_{ee}(z) = R_{ee}$ and $R_{ee} \geq 0$, the following factorization always exists as

$$R_{ee} = R_{ee}^{1/2}(R_{ee}^{T})^{1/2} . \qquad (14.184)$$

Thus from (14.184), $P_{yy}(z)$ of (14.183) can be written as

$$P_{yy}(z) = \left[T(z)R_{ee}^{1/2}R_{ee}^{1/2} \right] \begin{pmatrix} (R_{ee}^{T})^{1/2}T^{T}(z^{-1}) \\ (R_{ee}^{T})^{1/2} \end{pmatrix}$$
$$:= T_{e}(z) \times T_{e}^{T}(z^{-1}) , \qquad (14.185)$$

which shows that the innovations model indeed admits a spectral factorization of the type desired. To show that $T_e(z)$ is the unique, stable, minimum-phase spectral factor, it is necessary to show that $|T_e(z)|$ has all its poles within the unit circle (stable). It has been shown [14.15, 18], that $T_e(z)$ does satisfy these constraints. Therefore

$$T_{e}(z) \equiv H(z)$$

is the Wiener solution. This completes the discussion on the equivalence of the steady-state Kalman filter and the Wiener filter.

Matched–Field Processing
One of the most popular methods of solving a large suite of problems in a wide variety of acoustic applications is the model-based *matched-field processor* (MFP) [14.19–21]. The MFP can be considered a combination of spatial power spectral estimation, matched-filtering and model-based signal processing.

The matched-field processor uses a propagation model with an assumed location of a flaw for non-destructive evaluation (NDE) or a target for sonar or a tumor for medical by transmitting a pulse that interrogates the medium (material, ocean, tissue). Matched field propagates the pulse acoustically through the
Fig. 14.18a,b MFP of component part with three flaws at (200 mm, 300 mm), (500 mm, 900 mm), (900 mm, 500 mm): **(a)** MFP power image. **(b)** Flaw detection and localization: (207 mm, 297 mm), (498 mm, 898 mm) and (903 mm, 502 mm)

medium to known sensor position(s) generating a replicant field (m) synthesized at each assumed target (source) location to *match* the measured field (y) at the sensor(s). The total power is estimated from the source to the sensor(s)

$$\hat{P}(r) = |m'(r)y|^2 = m^\dagger(r)R_{yy}m(r), \qquad (14.186)$$

where $m(r)$ is the propagated field at r for each predicted source location and y is the measured field at each sensor. A matrix or grid (or image) of power estimates at each source coordinate is created during the search with the maximum peaks above a threshold selected as the estimates of flaw, target, or tumor location

$$\max_r \quad \hat{P}(r). \qquad (14.187)$$

Consider the following NDE example to illustrate this approach. There exists a large critical part of a homogeneous material that must be inspected for any potential flaws. We would like to: (1) detect the presence of any flaws; and (2) determine their location. We assume a simple homogeneous (geometric spreading and time delay) material model in two dimensions.

The transmitted pulse is $p(t)$ and the receiving array consists of 64 sensors. The flaws are located at

xy-positions (200 mm, 300 mm), (500 mm, 900 mm), and (900 mm, 500 mm) from the array center. The space-time signals arriving at the array are governed by spherical wave propagation in the homogeneous medium (material) and satisfy

$$s(r_{\ell jk}; t) = \frac{1}{|\Delta r_{\ell jk}|} \times p(t - \tau_{\ell jk}) \quad \text{for} \quad \Delta r_{\ell jk}$$
$$= |r_\ell - r_{jk}|; \tau_{\ell jk} = \frac{|\Delta r_{\ell jk}|}{v},$$

for τ the propagation delay, Δr the path length (source-to-sensor), ℓ the sensor element, j the x-position index, k the y-position index and v the sound speed in the material. The signals are contaminated by white Gaussian noise at a SNR of 40 dB.

The MFP is implemented in Cartesian coordinates with the unknown (source) position given by

$$\Delta r_{\ell jk} = |r_\ell - r_{jk}| = \sqrt{(x_\ell - x_{jk})^2 + (y_\ell - y_{jk})^2}$$

and corresponding matching function

$$m(x_{\ell jk}, p_{\ell jk}; t) = \frac{1}{|\Delta r_{\ell jk}|} p_{\text{model}_\ell}(t - \tau_{\ell jk}),$$

with the power at each pixel given by

$$P(x_{\ell jk}, p_{\ell jk}) = |\boldsymbol{m}'(\boldsymbol{r}; t)\boldsymbol{p}(t)|^2$$
$$= \sum_{\ell jk} |m(x_{\ell jk}, y_{\ell jk}; t)p_\ell(t)|^2 .$$

Using the MFP approach, flaw locations are estimated by:

1. *Varying* the assumed flaw positions (location parameter vector).
2. *Calculating* the matching vector (propagation model).

3. *Calculating* the corresponding power at the specified pixel location, a power image can be generated over desired range of pixels, $j = 1, \cdots, N_x$; $k = 1, \cdots, N_y$.
4. *Thresholding* the image and selecting the dominant peaks.

In this problem, the resulting power field is shown in Fig. 14.18a with the thresholded image shown in Fig. 14.18b. The estimated flaw positions are: (207 mm, 297 mm), (498 mm, 898 mm) and (903 mm, 502 mm) which are reasonable and can be attributed to the high SNR.

14.8 The Cepstrum

The cepstrum (pronounced *kepstrum*) is the inverse Fourier transform of the natural logarithm of the spectrum. Because it is the inverse transform of a function of frequency, the cepstrum is a function of a time-like variable. But just as the word *cepstrum* is an anagram of the word *spectrum*, the time-like coordinate is called the *quefrency*, an anagram of *frequency*. The field of cepstrology is full of word fun like this.

The complex cepstrum of complex spectrum $Y(\omega)$ is

$$q(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \, e^{i\omega\tau} \ln[Y(\omega)] , \qquad (14.188)$$

where τ is the quefrency. Because $Y(\omega) = |Y(\omega)| e^{i\varphi(\omega)}$,

$$q(\tau) = \frac{1}{2\pi} \int_{0}^{\infty} d\omega \, e^{i\omega\tau} [\ln |Y(\omega)| + i\varphi(\omega)]$$
$$+ \frac{1}{2\pi} \int_{0}^{\infty} d\omega \, e^{-i\omega\tau} [\ln |Y(-\omega)| + i\varphi(-\omega)] .$$
$$(14.189)$$

For a real signal $y(t)$, the magnitude $|Y(\omega)|$ is an even function of ω, and $\varphi(\omega)$ is odd. Therefore,

$$q(\tau) = \frac{1}{\pi} \int_{0}^{\infty} d\omega \, [\ln |Y(\omega)|] \cos(\omega\tau)$$
$$+ \frac{i}{\pi} \int_{0}^{\infty} d\omega \, \varphi(\omega) \sin(\omega\tau) . \qquad (14.190)$$

The real part of q comes from the magnitude, the imaginary part from the phase. The phase must be unwrapped; it cannot be artificially restricted to a 2π range.

It is common to deal only with the real part of the cepstrum q_R. It is evident that the calculation will fail if $|Y(\omega)|$ is zero. The cepstrum is not applied to theoretical objects such as periodic functions of time that have delta function spectra – hence zeros. The cepstrum is applied to measured data, where it can lead to insight into features of the underlying processes.

The cepstrum is used in the acoustical and vibrational monitoring of machinery. Bearings and other rotating parts tend to produce sounds with interleaved periodic spectra. These periodicities lead to peaks at the corresponding quefrencies, revealing features that may not be apparent in the spectrum.

The cepstrum is particularly suited to the separation of source and filter functions. If Y is a filtered version of X, where the transfer function is H, then

$$|Y(\omega)| = |H(\omega)| \, |X(\omega)| . \qquad (14.191)$$

The logarithm operation turns the product on the right-hand side into a sum, so that

$$q_R(\tau) = \frac{1}{\pi} \int_{0}^{\infty} d\omega \, [\ln |H(\omega)|] \cos(\omega\tau)$$
$$+ \frac{1}{\pi} \int_{0}^{\infty} d\omega \, [\ln |X(\omega)|] \cos(\omega\tau) . \qquad (14.192)$$

For instance, if $|Y|$ is the spectrum of a spoken vowel, then the term involving the formant filter $|H|$ leads to a low-quefrency structure, and the term involving source spectrum $|X|$ leads to a high-quefrency peak characteristic of the glottal pulse period.

The cepstrum can reveal reflections. As a simple example, we consider a direct sound X plus its reflection

Fig. 14.19 The cepstrum of an original signal to which is added a delayed version of the same signal, with a delay of 2 ms ($a = 1$). The original signal is the sum of two female talkers ▶

with relative amplitude a and delay T_D. The sum then has a spectrum Y,

$$|Y(\omega)| = [1 + a\cos(\omega T_D)]|X(\omega)| \quad (a < 1) . \tag{14.193}$$

The logarithm of the factor in square brackets is periodic in ω with period $2\pi/T_D$. The corresponding term in the cepstrum leads to a peak at quefrency $\tau = T_D$, as shown in Fig. 14.19. The addition of more reflections with other delays will lead to additional peaks. Main-

taining the anagram game, the separation of peaks along the quefrency axis is sometimes called *liftering*.
14.9 Noise

Noise has many definitions in acoustics. Commonly, noise is any unwanted signal. In the context of communications, it is an excitation that competes with the information that one wishes to transmit. In signal processing, noise is defined as a random signal that can only be defined in statistical terms with no long-term predictability.

14.9.1 Thermal Noise

Thermal noise, or Johnson noise, is generated in a resistor. An electrical circuit that describes this source of noise is a resistor R in series with a voltage source that depends on R, such that the RMS voltage is given by the equation

$$V = \sqrt{4Rk_B T\Delta f} , \tag{14.194}$$

where R is the resistance in ohms, k_B is Boltzmann's constant, T is the absolute temperature, and Δf is the bandwidth over which the noise is measured.

The corresponding noise power can be defined by measuring the maximum power that is transferred to a load resistor connected across the series circuit above. Maximum power occurs when the load resistor also has a resistance R and has zero temperature so that the load resistor produces no Johnson noise of its own. Then the thermal noise power is given by

$$P = k_B T\Delta f . \tag{14.195}$$

Because $k_B T$ has dimensions of Joules and Δf has dimensions of inverse seconds, the quantity P has di-

mensions of watts, as expected. Boltzmann's constant is 1.38×10^{-23} J/K, and room temperature is 293 K. Therefore, the noise power density is 4×10^{-21} W/Hz. Because the power is proportional to the first power of the bandwidth, the noise is white. Johnson noise is also Gaussian.

14.9.2 Gaussian Noise

A noise is Gaussian if its instantaneous values form a Gaussian (normal) distribution. A noise distribution is illustrated in an experiment wherein an observer makes hundreds of instantaneous measurements of a noise voltage and plots these instantaneous values as a histogram. Unless there is some form of bias, the measured values are equally often positive and negative, and so the mean of the distribution is zero. The noise is Gaussian if the histogram derived in this way is a Gaussian function. The more intense the noise, the larger is the standard deviation of the Gaussian function. Because of the central limit theorem, there is a tendency for noise to be Gaussian. However, non-Gaussian noises are easily generated. Random telegraph noise, where instantaneous values can only be $+1$ or -1, is an example.

14.9.3 Band–Limited Noise

Band-limited noise can be written in terms of Fourier components,

$$x(t) = \sum_{n=1}^{N} A_n \cos(\omega_n t) + B_n \sin(\omega_n t) . \tag{14.196}$$

The amplitudes A_n and B_n are defined only statistically. According to a famous paper by *Einstein* and *Hopf* [14.22], these amplitudes are normally distributed with zero mean, and the distributions of A_n and B_n have the same variance σ_n^2. The distributions themselves can be thought of as representative of an ensemble of noises, all of which are intended by the creator to be the same: same duration and power, same frequency range and bandwidth.

Because the average power in a sine or cosine is 0.5, the average power in band-limited noise is

$$P = \sum_{n=1}^{N} \sigma_n^2 \,. \tag{14.197}$$

An alternative description of band-limited noise is the amplitude and phase form

$$x(t) = \sum_{n=1}^{N} C_n \, \cos(\omega_n t + \varphi_n) \,, \tag{14.198}$$

where φ_n are random variables with a rectangular distribution from 0 to 2π, and $C_n = \sqrt{A_n^2 + B_n^2}$.

Given that A_n and B_n follow a Gaussian distribution with variance σ_n, the amplitude C_n follows a Rayleigh distribution f_{Rayl}

$$f_{\text{Rayl}}(C_n) = \frac{C_n}{\sigma_n^2} \, \mathrm{e}^{-C_n^2/(2\sigma_n^2)} \quad (C_n > 0) \,. \tag{14.199}$$

The peak of the Rayleigh distribution occurs at $C_n = \sigma$. The zeroth moment is 1.0 because the distribution is normalized. The first moment, or $\overline{C_n}$, is $\sigma_n \sqrt{\pi/2}$. The second moment is $2\sigma_n^2$, and the fourth moment is $8\sigma_n^4$.

The cumulative Rayleigh distribution can be calculated in closed form,

$$F_{\text{Rayl}}(C_n) = \int_0^{C_n} \mathrm{d}C_n' \, f_{\text{Rayl}}(C_n') = 1 - \mathrm{e}^{-C_n^2/(2\sigma_n^2)} \,. \tag{14.200}$$

14.9.4 Generating Noise

To generate the amplitudes A_n and B_n with normal distributions using a computer random-number generator,

one can add up twelve random numbers and subtract 6. On the average, the amplitudes will have a normal distribution, because of the central limit theorem, with a mean of zero and a variance of 1.0.

To generate the amplitudes C_n with a Rayleigh distribution, one can transform the random numbers r_n that come from a computer random-number generator, according to the formula

$$C_n = \sigma \sqrt{-2 \ln(1 - r_n)} \,. \tag{14.201}$$

14.9.5 Equal–Amplitude Random–Phase Noise

Equal-amplitude random-phase (EARP) noise is of the form

$$x(t) = C \sum_{n=1}^{N} \cos(\omega_n t + \varphi_n) \,, \tag{14.202}$$

where φ_n is again a random variable over the range 0 to 2π.

The advantage of EARP noise is that every noise sample has the same power spectrum. A possible disadvantage is that the amplitudes A_n and B_n are no longer normally distributed. Instead, they are distributed like the probability density functions for the sine or cosine functions, with square-root singularities at $A_n = \pm C$ and $B_n = \pm C$. However, the actual values of noise are normally distributed as long as the number of noise components is more than about five.

14.9.6 Noise Color

White noise has a constant spectral density, which means that the power in white noise is proportional to the bandwidth. On the average, every band with given bandwidth Δf has the same amount of power. Pink noise has a spectral density that decreases inversely with the frequency. Consequently, pink noise decreases at a rate of 3 dB per octave. On the average, every octave band has the same amount of power.

14.10 Sampled Data

Converting an analog signal, such as a time-dependent voltage, into a digital representation dices the signal in two dimensions, the dimension of the signal voltage and the dimension of time. Dicing the signal voltage is known as quantization, dicing with respect to time is known as sampling.

14.10.1 Quantization and Quantization Noise

It is common for an analog-to-digital converter (ADC) to represent the values of input voltages as integers. The range of the integers is determined by the number of bits per sample in the conversion process. A conversion into an M-bit sample (or word) allows the voltage value to be represented by 2^M bits. For instance, a 10-bit ADC that is restricted to converting positive voltages would represent 0 V by the number 0 and $+10$ V by $2^{10} - 1$ or 1023.

A 16-bit ADC would allow 2^{16} or 65 536 different values. A 16-bit ADC that converts voltages between -10 and $+10$ V would represent -10 V by $-32\,768$ and $+10$ V by $+32\,767$. Conversion is linear. Thus 0.3052 V would be converted to the sample value 1000 and 0.3055 V to the value 1001. A voltage of 0.3053 would also be converted to a value of 1000, no different from 0.3052. The discrepancy is an error known as the quantization error or *quantization noise*.

Quantization noise referenced to the signal is a signal-to-noise ratio. Standard practice makes this ratio as large as possible by assuming a signal with the maximum possible power. For the positive and negative ADC described above, maximum power occurs for a square wave between a sampled waveform value of $-2^{(M-1)}$ and $+2^{(M-1)}$. The power is the square of the waveform or $\frac{1}{4} \times 2^{2M}$.

For its part, the noise is a random variable that represents the difference between an accurately converted voltage and the actual converted value as limited by the number of bits in the sample word. This error is never more than 0.5 and never less than -0.5. The power in noise that fluctuates randomly over the range -0.5 to $+0.5$ is 1/12. Consequently the signal-to-noise (S/N) ratio is 3×2^{2M}. Expressed in decibels, this value is $10\log(3 \times 2^{2M})$, or $20M\log(2) + 4.8$ dB, or $6M + 4.8$ dB. For a 16-bit word, this would be $96 + 4.8$ or about 101 dB. An alternative calculation would assume that the maximum power is the power for the largest sine wave that can be reproduced by such a system. This sine has half the power of the square, and the S/N ratio is then about $6M$ dB.

14.10.2 Binary Representation

Digitized data, like a sampled waveform are represented in binary form by numbers (or words) consisting of digits 0 and 1. For example, an eight-bit word consisting of two four-bit bytes and representing the decimal number 7, would be written as

0 0 0 0   0 1 1 1 .

This number has 1 in the ones column, 1 in the twos column, 1 in the fours column, and nothing in any other column. One plus two plus four is equal to 7, which is what was desired.

An eight-bit word ($M = 8$) could represent decimal integers from 0 to 255. It cannot represent 2^M, which is decimal 256. If one starts with the decimal number 255 and adds 1, the binary representation becomes all zeros, i.e. $255 + 1 = 0$. It is like the 100 000-mile odometer on an automobile. If the odometer reads 99 999 and the car goes one more mile, the odometer reads 00 000.

Signals are generally negative as often as they are positive, and that leads to a need for a binary representation of negative numbers. The usual standard is a representation known as *twos-complement*. In twos-complement representation, any number that begins with a 1 is negative. Thus, the leading digit serves as a *sign bit*.

In order to represent the number $-x$ in an M-bit system one computes $2^M - x$. That way, if one adds x and $-x$ one ends up with 2^M, which is zero.

A convenient algorithm for calculating the twos-complement of a binary number is to reverse each bit, 0 for 1 and 1 for 0, and then add 1. Thus, in an eight-bit system the number -7 is given by

1 1 1 1   1 0 0 1 .

14.10.3 Sampling Operation

The sampling process replaces an analog signal, which is a continuous function of time, by a sequence of points. The operation is equivalent to the process shown
Fig. 14.20a–c An analog signal (**a**) $x(t)$ is multiplied by a train of delta functions $s(t)$ (**b**) to produce a sampled signal $y(t)$ (**c**)

in Fig. 14.20, where the analog signal $x(t)$ is multiplied by a train of evenly spaced delta functions to create a sequence of sampled values $y(t)$.

Intuitively, it seems evident that this operation is a sensible thing to do if the delta functions come along rapidly enough – rapid compared to the speed of the temporal changes in the waveform. That concept is most clearly seen by studying the Fourier transforms of functions x, s and y.

The Fourier transform of the analog signal is $X(\omega)$, with a spectrum that is limited to some highest frequency ω_{max}. By contrast, the Fourier transform of the train of delta functions is, itself, a train of delta functions, $S(\omega)$ that extends over the entire frequency axis. Because the delta functions in time have period T_s, the delta functions in $S(\omega)$ are separated by ω_s, equal to $2\pi/T_s$. Because $y(t)$ is the product of the time-dependent analog signal and the train of delta functions, the Fourier transform $Y(\omega)$ is the convolution of $X(\omega)$ and $S(\omega)$, as shown in part (b) of Fig. 14.21. Because of the convolution operation, $Y(\omega)$ includes multiple images of the original spectrum.

It is evident from Fig. 14.21b that, if the ω_{max} is less than half of ω_s, the multiple images will not overlap. That observation has the status of a theorem known as the *sampling theorem*, which says that the sampled signal is an adequate representation of an analog signal if the sample rate is more than twice the highest frequency in the analog signal, i.e., $\omega_s > 2\omega_{max}$.

As an example of a failure to apply the sampling theorem, suppose that a 600 Hz sine tone is sampled at
Fig. 14.21 **(a)** The spectrum of the analog signal $X(\omega)$ is bounded in frequency. **(b)** The spectrum of the sampled signal, $Y(\omega)$, is the convolution of $X(\omega)$ and the Fourier transform of the sampling train of delta functions. Consequently, multiple images of $X(\omega)$ appear. Frequencies that are allowed by the sampling theorem are included in the *dashed box*. A particular frequency (*circled*) is followed through the multiple imaging

a rate of 1000 Hz. The spectrum of the sampled signal will contain 600 Hz as expected, and it will also contain a component at $1000 - 600 = 400$ Hz. The 400 Hz component was not present in the original spectrum; it is an alias, an unwanted image of the 600 Hz tone.

14.10.4 Digital–to–Analog Conversion

In converting a signal from digital to analog form, one can begin with the train of delta functions that is signal $y(t)$ as shown in Fig. 14.20c. An electronic device to do that is a digital-to-analog converter (DAC). However, as shown in Fig. 14.21b, this signal includes many high frequencies that are unwanted byproducts of the sampling process. Consequently, one needs to low-pass filter the signal so as to pass only the frequencies less than half the sample rate, i.e., the frequencies in the dashed box. Such a low-pass filter is called a *reconstruction* filter.

Practical DACs do not produce delta-function voltage spikes. Instead, they produce rectangular functions with durations pT_s, where p is a fraction of a sample period $0 < p \leq 1$. If $p = 1$, the output of the DAC resembles a staircase function. Mathematically, replacing the delta function train of Fig. 14.20c by the train of rectangles is equivalent to convolving the function $y(t)$ with a rectangular function. The consequence of this convolution is that the output is filtered, and the transfer function of the filter is the Fourier transform of the rectangle. The magnitude of the transfer function is

$$|H(\omega)| = \frac{\sin(\omega pT_s/2)}{\omega pT_s/2} \ . \tag{14.203}$$

The phase shift of the filter is a pure delay and consequently unimportant. The effective filtering that results from the rectangles, known as *sin(x)-over-x* filtering, can be corrected by the reconstruction filter.

14.10.5 The Sampled Signal

This brief section will introduce a notation that will be useful in later discussions of sampled signals. It is supposed at the outset that one begins with a total of N samples, equally spaced in time by the sampling period T_s. By convention, the first sample occurs at time $t = 0$ and the last sample occurs at time $t = (N - 1)T_s$. Consequently, the signal duration is $T_D = (N - 1)T_s$.

In dealing with sampled signals, it is common to replace the time variable with a discrete index k. Thus,

$$x(t) = x(kT_s) = x_k \ , \tag{14.204}$$

where the equation on the left indicates that the original data exist only at discrete time values.

14.10.6 Interpolation

The discrete-time values of a sampled waveform can be used to compute an approximate Fourier transform of the original signal. This Fourier transform is valid up to a frequency as high as half the sample rate, i. e., as high as $\omega_s/2$, or π/T_s. The Fourier transform can then be used to estimate the values of the original signal $x(t)$ at times other than the sample times. In this way, the Fourier transform computed from the samples serves to interpolate between the samples. Such an interpolation scheme proceeds as follows.

First, the Fourier transform is

$$X(\omega) = T_s \sum_k x_k \exp(-i\omega T_s k) , \qquad (14.205)$$

where, as noted above, x_k is the signal $x(t)$ at the times $t = T_s k$, and the leading factor of T_s gets the dimensions right.

Then the inverse Fourier transform is

$$x(t) = \frac{T_s}{2\pi} \int\limits_{-\omega_s/2}^{\omega_s/2} d\omega \, e^{i\omega t} \sum_k x_k \, e^{-i\omega T_s k} . \qquad (14.206)$$

Reversing the order of sum and integral and using the fact that $T_s\omega_s/2 = \pi$, we find that

$$x(t) = \sum_k x_k \frac{\sin \pi (t/T_s - k)}{\pi (t/T_s - k)} . \qquad (14.207)$$

The sinc function is 1.0 whenever $t = T_s k$, and is zero whenever t is some other integer multiple of T_s. Therefore, the sum on the right only interpolates; it does not change the values of $x(t)$ when t is equal to a sample time.

14.11 Discrete Fourier Transform

The Fourier transform of a signal with finite duration is well defined in principle. The finite signal itself can be regarded as some base function that is multiplied by a rectangular window to limit the duration. Then the Fourier transform proceeds by convolving with the transform of the window. For example, a truncated exponentially decaying sine function can be regarded as a decaying sine, with the usual infinite duration, multiplied by a rectangular window. Then the Fourier transform of the truncated function is the Fourier transform of the decaying sine convolved with a sinc function – the Fourier transform of the rectangular window. Such a Fourier transform is a function of a continuous frequency, and it shows the broad spectrum associated with the abrupt truncation.

In digital signal processing the frequency axis is not continuous. Instead, the Fourier transform of a signal is defined at discrete frequencies, just as the signal itself is defined at discrete time points. This kind of Fourier transform is known as the discrete Fourier transform (DFT).

To compute the DFT of a function, one begins by periodically repeating the function over the entire time axis. For example, the truncated decaying sine in Fig. 14.22a is repeated in Fig. 14.22b where it should be imagined that the repetition precedes indefinitely to the left and right.

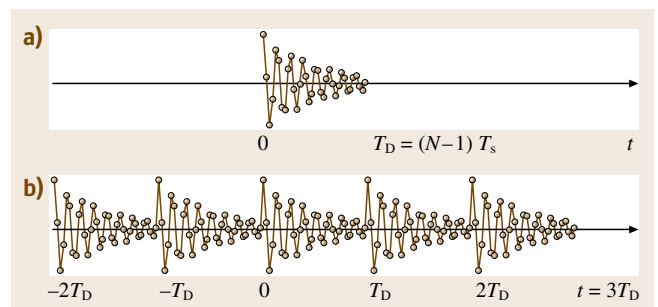
Then the Fourier transform of the periodically repeated signal becomes a Fourier series. The fundamental frequency of the Fourier series is the reciprocal of the duration, $f_0 = 1/T_D$, and the spectrum becomes a set of discrete frequencies, which are the harmonics of f_0. For instance, if the signal is one second in duration, the spectrum consists of the harmonics of 1 Hz, and if the duration is two seconds then the spectrum has all the harmonics of 0.5 Hz. As expected, the highest harmonic is limited to half the sample rate. That Fourier series is the DFT. Using x_k to define the periodic repetition of the original discrete function, x_k, the DFT $\underline{X}(\omega)$ is defined for $\omega = 2\pi n/T_D$, where n indicates the n-th har-


Fig. 14.22a,b A decaying function in part (**a**) is periodically repeated in part (**b**) to create a periodic signal with period T_D

monic. In terms of the fundamental angular frequency $\omega_0 = 2\pi/T_D$, the DFT is

$$\underline{X}(n\omega_0) = T_s \sum_{k=0}^{N-1} x_k \, e^{-in\omega_0 k T_s} \,, \tag{14.208}$$

where the prefactor T_s keeps the dimensions right. The product $\omega_0 T_s$ is equal to $\omega_0 T_D/(N-1)$ or $2\pi/(N-1)$, and so

$$\underline{X}(n\omega_0) = T_s \sum_{k=0}^{N-1} x_k \, e^{-i2\pi n k/(N-1)} \,. \tag{14.209}$$

Both positive and negative frequencies occur in the Fourier transform. Because the maximum frequency is equal to $[1/(2T_s)]/(1/T_D)$ times the fundamental frequency, the number of discrete positive frequencies is $(N-1)/2$, and the number of discrete negative frequencies is the same. Consequently the inverse DFT can be written

$$\underline{x}_k = \frac{1}{T_D} \sum_{n=-(N-1)/2}^{(N-1)/2} X(n\omega_0) \, e^{i2\pi n k/(N-1)} \,, \tag{14.210}$$

or

$$\underline{x}(t) = \frac{1}{T_D} \sum_{n=-(N-1)/2}^{(N-1)/2} X(n\omega_0) \, e^{in\omega_0 t} \,. \tag{14.211}$$

A virtue of the DFT is that the information in the DFT is exactly what is needed to create the original truncated function $x(t)$ – no more and no less. The fact that the DFT spectrum actually creates the periodically repeated function $\underline{x}_k$ and not the original x_k is not a problem if we agree in advance to ignore $\underline{x}_k$ for k outside the range of the original time-limited signal. However, it should be noted that certain operations,

such as time translations, products, and convolution, that have familiar characteristics in the context of the Fourier transform, retain those characteristics only for the periodically extended signal $\underline{x}_k$ and its Fourier transform $\underline{X}(n\omega_0)$ and not for the finite-duration signal.

14.11.1 Interpolation for the Spectrum

It is possible to estimate the Fourier transform at values of frequency between the harmonics of ω_0. The procedure begins with the definition of the Fourier transform of a finite function,

$$X(\omega) = \int_{0}^{T_D} dt \, x(t) e^{-i\omega t}. \tag{14.212}$$

Next, the function $x(t)$ is replaced by the inverse DFT from (14.211), and the variable of integration t is replaced by t', which has symmetrical upper and lower limits,

$$\begin{aligned} X(\omega) \\ = \frac{1}{T_D} \int_{-T_D/2}^{T_D/2} dt' \, e^{-i\omega t'} \\ \times \sum_{n=-(N-1)/2}^{(N-1)/2} X(n\omega_0) \, e^{in\omega_0 t'} \, e^{-i\omega T_D/2} \, e^{in\omega_0 T_D/2} \,, \end{aligned} \tag{14.213}$$

which reduces to

$$\begin{aligned} X(\omega) = \sum_{n=-(N-1)/2}^{(N-1)/2} X(n\omega_0) \frac{\sin[(\omega - n\omega_0)T_D/2]}{(\omega - n\omega_0)T_D/2} \\ \times e^{-i\omega T_D/2} \, e^{i\pi n} \,. \end{aligned} \tag{14.214}$$

14.12 The *z*-Transform

Like the discrete Fourier transform, the z-transform is well suited to describing sampled signals. We consider $x(t)$ to be a sampled signal so that it is defined at discrete time points $t = t_k = kT_s$, where T_s is the sampling period. Then the time dependence of x can be described by an index, $x_k = x(t_k)$. The z-transform of x is

$$X(z) = \sum_{k=-\infty}^{\infty} x_k z^{-k} \,. \tag{14.215}$$

The quantity z is complex, with amplitude A and phase φ,

$$z = A \, e^{i\varphi} = A \, e^{i\omega T_s} \,, \tag{14.216}$$

where φ is the phase advance in radians per sample.

In the special case where $A = 1$, all values of z lie on a circle of radius 1 (the *unit circle*) in the complex z plane. In that case the z-transform is equivalent to the discrete Fourier transform. An often-overlooked alter-

Table 14.2 z-Transform pairs

x_k	$X(z)$	Radius of convergence
δ_{k,k_0}	z^{-k_0}	all z
$a^k u_k$	$z/(z-a)$	$|z| > a$
$ka^k u_k$	$az/(z-a)^2$	$|z| > a$
$a^k \cos(\omega_o T_s k) u_k$	$\dfrac{z^2 - az\cos(\omega_o T_s)}{z^2 - 2az\cos(\omega_o T_s) + a^2}$	$|z| > a$
$a^k \sin(\omega_o T_s k) u_k$	$\dfrac{az\sin(\omega_o T_s)}{z^2 - 2az\cos(\omega_o T_s) + a^2}$	$|z| > a$

native view is that the z-transform is an extension of the Fourier transform wherein the angular frequency ω becomes complex,

$$\omega = \omega_R + i\omega_I , \tag{14.217}$$

so that

$$z = e^{-\omega_I T_s} e^{i\omega_R T_s} . \tag{14.218}$$

The extended Fourier transform will not be pursued further in this chapter.

A well-defined z-transform naturally includes a function of variable z, but the function itself is not enough. In order for the inverse transform to be unique, the definition also requires that the region of the complex plane in which the transform converges must also be specified. To illustrate that point, one can consider two different functions x_k that have the same z-transform function, but different regions of convergence (Table 14.2).

Consider first the function

$$x_k = 2^k \qquad \text{for} \quad k \geq 0 , \tag{14.219}$$
$$x_k = 0 \qquad \text{for} \quad k < 0 .$$

This two-line function can be written as a single line by using the discrete Heaviside function u_k. The function u_k is defined as zero when k is a negative integer and as $+1$ when k is any other integer, including zero. Then x_k above becomes

$$x_k = 2^k u_k . \tag{14.220}$$

The z-transform of x_k is

$$X(z) = \sum_{k=0}^{\infty} (2/z)^k . \tag{14.221}$$

The sum is a geometric series, which converges to

$$X(z) = \frac{1}{1 - 2/z} = z/(z-2) \tag{14.222}$$

if $|z| > 2$. The region of convergence is therefore the entire complex plane except for the portion inside and on a circle of radius 2.

Next consider the function

$$x_k = -2^k u_{-k-1} . \tag{14.223}$$

The z-transform of x_k is

$$X(z) = -\sum_{k=-\infty}^{-1} (2/z)^k \quad \text{or} \quad -\sum_{k=1}^{\infty} (z/2)^k . \tag{14.224}$$

The sum converges to

$$X(z) = -\frac{(z/2)}{1 - z/2} = \frac{z}{z-2} \tag{14.225}$$

if $|z| < 2$. The function is identical to the function in (14.222), but the region of convergence is now the portion of the complex plane entirely inside the circle of radius 2.

The inverse z-transform is given by a counterclockwise contour integral circling the origin

$$x_k = \frac{1}{2\pi i} \oint_C dz\, X(z) z^{k-1} . \tag{14.226}$$

The contour C must lie entirely within the region of convergence of x and must enclose all the poles of $X(z)$.

The regions of convergence when the functions x and y are combined in some way are at least the intersection of the regions of convergence for x and y separately. Scaling and time reversal lead to regions of convergence that are scaled and inverted, respectively. For instance, if $X(z)$ converges in the region between radii r_1 and r_2, them $X(1/z)$ converges in the region between $1/r_2$ and $1/r_1$.

14.12.1 Transfer Function

The output of a process at time point k, namely y_k, may depend on the inputs x at earlier times and also on the outputs at earlier times. In equation form,

$$y_k = \sum_{q=0}^{Nq} \beta_q x_{k-q} - \sum_{p=1}^{Np} \alpha_p y_{k-p} . \tag{14.227}$$

This equation can be z-transformed using the time-shift property in Table 14.3,

$$\sum_{q=0}^{Nq} \beta_q z^{-q} X(z) = \sum_{p=0}^{Np} \alpha_p z^{-p} Y(z) , \tag{14.228}$$

Table 14.3 Properties of the z-transform

Property	Signal	z-transform
Definition	x_k	$X(z)$
Linearity	$ax_k + by_k$	$aX(z) + bY(z)$
Time shift	x_{k-k_0}	$z^{-k_0} X(z)$
Scaling z	$a^k x_k$	$X(z/a)$
Time reversal	x_{-k}	$X(1/z)$
Derivative w.r.t. z	kx_k	$-z\, dX(z)/dz$
Convolution	$x_k * y_k$	$X(z)Y(z)$
Multiplication	$x_k y_k$	$\frac{1}{2\pi i} \oint_C dz'/z'\ X(z')Y(z/z')$

where $\alpha_0 = 1$. The transfer function is the ratio of the transformed output over the transformed input,

$$H(z) = Y(z)/X(z)\,, \tag{14.229}$$

which is

$$H(z) = \frac{\sum_{q=0}^{Nq} \beta_q z^{-q}}{\sum_{p=0}^{Np} \alpha_p z^{-p}}\,. \tag{14.230}$$

From the fundamental theorem of algebra, the numerator of the fraction above has Nq roots and the denominator has Np roots, so that $H(z)$ can be written as

$$H(z) = \frac{(1 - q_1 z^{-1})(1 - q_2 z^{-1})\ldots(1 - q_{Nq} z^{-1})}{(1 - p_1 z^{-1})(1 - p_2 z^{-1})\ldots(1 - p_{Np} z^{-1})}\,. \tag{14.231}$$

This equation and its development are of central importance to digital filters, also known as linear time-invariant systems. If the system is recursive, outputs from a previous point in time are sent back to the input. Therefore, some values of the coefficients α_p are finite for $p > 1$ and so are the values of some poles, such

as p_2. Such filters are called *infinite impulse response* (IIR) filters because it is possible that the response of the system to an impulse put in at time zero will never entirely die out. Some of the output is always fed back into the input. A similar conclusion is reached by recognizing that the expansion of $1/(1 - pz^{-1})$ in powers of z^{-1} goes on forever. Because the system has poles, there are concerns about stability.

If the system is nonrecursive, no values of the output are ever sent back to the input. Therefore, the denominator of $H(z)$ is simply the number 1. Such filters are called *finite impulse response* (FIR) filters because their response to a delta function input will always die out eventually as long as Nq is finite. The system is said to be an *all-zero* system. The order of the filter is established by Nq or Np, the number of time points back to the earliest input or output that contribute to the current output value.

The formal z-transform,

$$H(z) = \sum_{k=-\infty}^{\infty} h_k z^{-k} \tag{14.232}$$

leads to conclusions about causality and stability.

A filter is causal if the current value of the output does not depend on future inputs. For a causal filter h_k is zero for $k < 0$. Then this sum has no terms with positive powers of z, and the region of convergence of $H(z)$ includes $|z| = \infty$.

A filter is stable if

$$S = \sum_{k=-\infty}^{\infty} |h_k| \tag{14.233}$$

is finite. It follows, that $H(z)$ is finite for $|z| = 1$, i.e., for z on the unit circle. Thus, if the region of convergence includes the unit circle, the filter is stable.

14.13 Maximum Length Sequences

A maximum length sequence (MLS) is a train of ones and zeros that makes a useful signal for measuring the impulse response of a linear system. An MLS can be generated by a bit-shift register, which resembles a bucket brigade. To make an N-bit MLS, one needs an N-stage shift register. Each stage can hold either a one or a zero. The register is imagined to have a clock which synchronizes the transfer of bits from each stage to the next. On every clock tick the content of each stage of the register is transferred to the next stage down the line.

The content of the last stage is regarded as the output of the register, and it is also fed back into the first stage. In addition, the output can be fed back into one or more of the other stages, and when that occurs the stage receiving the output, in addition to the content of the previous stage, performs an exclusive OR (XOR) operation on those two inputs. The XOR operation obeys the truth table shown in Table 14.4. In words, the XOR of inputs A and B is zero if A and B are the same and is 1 if A and B are different.

Table 14.4 Truth table for the exclusive or (XOR) operation

A	B	A XOR B
0	0	0
0	1	1
1	0	1
1	1	0
Fig. 14.23 A three-stage shift register [3: 1, 2] in which the output is fed back into the first and second stages

Table 14.5 Successive values in the shift register of Fig. 14.12

Step			
0	1	1	1
1	1	0	1
2	1	0	0
3	0	1	0
4	0	0	1
5	1	1	0
6	0	1	1
7	1	1	1
8	1	0	1
9	1	0	0

A shift register with three stages is shown in Fig. 14.23. With three stages and feedback *taps* to stages 1 and 2, it is defined as [3: 1,2].

At the instant shown in the figure, the register holds the value 1,1,1. The subsequent development of the register values is given in Table 14.5. The sequence repeats after seven steps. The table shows that every possible pattern of *ones* and *zeros* occurs once, and only once, before the pattern repeats. There are $2^N - 1 = 2^3 - 1 = 7$ such patterns. There is one exception, namely the pattern 0,0,0. If this pattern should ever appear in the register then the process gets stuck forever. Therefore, this pattern is not allowed. The output sequence is the contents of the stage on the right, here, 1,1,0,0,1,0,1. Because all seven register patterns appear before repetition, this output is a maximum length sequence. There is nothing special about the starting register value, 1,1,1. Therefore, any cyclic permutation of the MLS is also an MLS. For instance, the sequence, 1,0,0,1,0,1,1 is the same sequence.
Fig. 14.24 A three-stage shift with feedback into all the stages does not produce an MLS

Table 14.6 Successive values in the shift register of Fig. 14.13

Step			
0	1	1	1
1	1	0	0
2	0	1	0
3	0	0	1
4	1	1	1
5	1	0	0
6	0	1	0

An example of a three-bit shift register that does not produce an MLS is [3: 1,2,3], shown in Fig. 14.24. The pattern for this shift register is shown in Table 14.6. The pattern of register values begins to repeat after only four steps. Therefore, the sequence of output values, namely 1,0,0,1,1,0,0,1,1,0,0,1, is not an MLS.

14.13.1 The MLS as a Signal

To make a signal from an MLS requires only one step: every 0 in the sequence is replaced by -1. Therefore, the MLS for the shift register in Fig. 14.23 becomes: 1, 1, -1, -1, 1, -1, 1. For this three-stage register (N = 3) the MLS has a length of seven; there are four $+1$ values and three -1 values. These results can be generalized to an N-stage register which has $2^N - 1$ values; $2^{(N-1)}$ are $+1$ values and $2^{(N-1)} - 1$ are -1 values. The average value is therefore $1/(2^N - 1)$.

14.13.2 Application of the MLS

The key fact about an MLS is that its autocorrelation function is very nearly a delta function. To express that idea, one can write the autocorrelation function in the form appropriate for discrete samples,

$$c_k = \frac{1}{2^N - 1} \sum_{k1} x_{k1} \, x_{k1+k} \, . \tag{14.234}$$

This sum, and all sums to follow, are over the $2^N - 1$ values of the MLS sequence x. Because the sequence is cyclical, it does not matter where one starts the sum.

An MLS has the property that

$$c_k = \left(1 + \frac{1}{2^N - 1}\right) \delta_{k,0} - \frac{1}{2^N - 1} \ . \tag{14.235}$$

Therefore, c_k is approximately a Kronnecker delta function

$$c_k \approx \delta_{k,0} \ . \tag{14.236}$$

If we would like to know the impulse response h of a linear system, we can excite the system with the MLS x, and record the output y. As for filters, the linear response y is the convolution of x and h, i.e.,

$$y_k = x * h = \sum_{k1} x_{k1+k} \, h_{k1} \ . \tag{14.237}$$

To find the impulse response, one can form the quantity d, by convolving the recording y with the original MLS x, i.e.,

$$d_k = \frac{1}{2^N - 1} \sum_{k2} x_{k2+k} \, y_{k2} \tag{14.238}$$

or from (14.237)

$$d_k = \frac{1}{2^N - 1} \sum_{k1,k2} x_{k2+k} \, x_{k1+k2} \, h_{k1} \ . \tag{14.239}$$

Only $x * x$ involves the index $k2$, and doing the sum over $k2$ leads to

$$d_k = \sum_{k1} \delta_{k,k1} \, h_{k1} \tag{14.240}$$

so that $d_k = h_k$. In this way, we have found the desired impulse response.

As applied in architectural acoustics, the MLS is an alternative to recording the response to a popping balloon or gun shot. Because the MLS is continuous, it avoids the dynamic-range problem associated with an impulsive test signal, and by repeating the sequence one can achieve remarkable noise immunity.

Similarly, the MLS is an alternative to recording the response to white noise (the MLS is white). However, digital white noise, such as random telegraph noise, has an autocorrelation function that is zero only for a long-term or ensemble average. In practice, the white-noise response of a linear system is much noisier than the MLS response.

14.13.3 Long Sequences

Table 14.7 gives the taps for some MLSs generated by shift registers with 2–20 stages, i.e., orders 2–20. The longest sequence has a length of more than one million bits,

Table 14.7 Taps for maximum length sequences

Number of stages	Length (bits)	Number of taps	Number of sets	Set
2	3	2	1	[2: 1,2]
3	7	2	1	[3: 1,3]
4	15	2	1	[4: 1,4]
5	31	2	1	[5: 1,4]
6	63	2	1	[6: 1,6]
7	127	2	2	[7: 1,7], [7: 1,5]
8	255	4	6	[8: 1,2,7,8]
9	511	2	1	[9: 1,6]
10	1023	2	1	[10: 1,8]
11	2047	2	1	[11: 1,10]
12	4095	4	9	[12: 1,6,7,9]
13	8191	4	33	[13: 1,7,8,9]
14	16383	4	21	[14: 1,6,9,10]
15	32767	2	3	[15: 1,9], [15: 1,12], [15: 1,15]
16	65535	4	26	[16: 1,7,10,11]
17	131071	2	3	[17: 1,12], [17: 1,13], [17: 1,15]
18	262143	2	1	[18: 1,12]
19	524287	4	79	[19: 1,10,11,14]
20	1048575	2	1	[20: 1,18]

For orders 2, 3, and 4, there is only one possible set of taps. These sets have two taps, including the feedback to stage 1. For orders 7, 15, and 17 there is more than one set with two taps, and all of them are shown in the table.

Beginning with order 5 there are four-tap sets as well as two-tap sets, except that for some orders, such as 8, there are no two-tap sets. For every order the table gives a set with the smallest possible number of taps.

Beginning with order 7 there are six-tap sets. As the order increases the number of sets also increases. For order 19, there are 79 four-tap sets.

14.14 Information Theory

Information theory provides a way to quantify information by computing information content. The information content of a message depends on the context, and the context determines the initial uncertainty about the message. Suppose, for example, that we receive one character, but we know in advance that the context is one in which the character must be a digit between 0 and 9. Our uncertainty before receiving that actual character is described by the number of possible outcomes, which is $\Omega = 10$ in this case. Suppose instead, that the context is one in which the character must be a letter of the alphabet. Then our initial uncertainty is greater because the number of possible outcomes is now $\Omega = 26$. The first step of information theory is to recognize that, when we actually receive and identify a character, the information content of that character is greater in the second context than in the first because in the second context the character has eliminated a greater number of a priori possibilities.

The second step in information theory is to consider a message with two characters. If the context of the message is decimal digits then the number of possibilities is the product of 10 for the first digit and 10 for the second, namely $\Omega = 100$ possibilities. Compared to a message with one character, the number of possibilities has been multiplied by 10. However, it is only logical to expect that two characters will give twice as much information as one, not 10 times as much. The logical problem can be solved by quantifying information in terms of entropy, which is the logarithm of the number of possibilities

$$H = \log \Omega \,. \tag{14.241}$$

Because log 100 is just twice log 10, the logical problem is solved. The information measured in bits is obtained by using a base 2 logarithm.

A few simple features follow immediately. If the number of possible messages is $\Omega = 1$ then the message provides no information, which agrees with $\log 1 = 0$. If the context is binary, where a character can be only 1 or 0 ($\Omega = 2$), then receiving a character provides 1 bit of information, which agrees with $\log_2 2 = 1$.

If the context is an alphabet with M possible symbols, and all of the symbols are equally probable, then a message with N characters has $\Omega = M^N$ possible outcomes and the information entropy is

$$H = \log M^N = N \log M \,, \tag{14.242}$$

illustrating the additivity of information over the characters of the message.

14.14.1 Shannon Entropy

Information theory becomes interesting when the probabilities of different symbols are different. *Shannon* [14.23, 24] showed that the information content per character is given by

$$H_c = - \sum_{i=1}^{M} p_i \log p_i \,, \tag{14.243}$$

where p_i is the probability of symbol i in the given context.

The rest of this section proves Shannon's formula. The proof begins with the plausible assumption that, if the probability of symbol i is p_i, then in a very long message of N characters, the number of occurrences of character i, m_i will be exactly $m_i = N p_i$.

The number of possibilities for a message of N characters in which the set of $\{m_i\}$ is fixed by the corresponding $\{p_i\}$ is

$$\Omega = \frac{N!}{m_1! \, m_2! \, \ldots \, m_M!} \,. \tag{14.244}$$

Therefore,

$$H = \log N! - \log m_1! - \log m_2! - \ldots \log m_M! \,. \tag{14.245}$$

One can write $\log N!$ as a sum

$$\log N! = \sum_{k=1}^{N} \log k \qquad (14.246)$$

and similarly for $\log m_i!$.

For a long message one can replace the sum by an integral,

$$\log N! = \int_{1}^{N} dx \log x = N \log N - N + 1 \qquad (14.247)$$

and similarly for $\log m_i!$.

Therefore,

$$H = N \log N - N + 1$$
$$- \sum_{i=1}^{M} m_i \log m_i + \sum_{i=1}^{M} m_i - \sum_{i=1}^{M} 1 . \qquad (14.248)$$

Because $\sum_{i=1}^{M} m_i = N$, this reduces to

$$H = N \log N + 1 - \sum_{i=1}^{M} m_i \log m_i - M . \qquad (14.249)$$

The information per character is obtained by dividing the message entropy by the number of characters in the message,

$$H_c = \log N - \sum_{i=1}^{M} p_i \log m_i + (1 - M)/N , \qquad (14.250)$$

where we have used the fact that $m_i/N = p_i$.

In a long message, the last term can be ignored as small. Then because the sum of probabilities p_i is equal to 1,

$$H_c = - \sum_{i=1}^{M} p_i (\log m_i - \log N) , \qquad (14.251)$$

or

$$H_c = - \sum_{i=1}^{M} p_i \log p_i , \qquad (14.252)$$

which is (14.243) as advertised.

If the context of written English consists of 27 symbols (26 letters and a space), and if all symbols are equally probable, then the information content of a single character is

$$H_c = -1.443 \sum_{i=1}^{27} \frac{1}{27} \ln \frac{1}{27} = 4.75 \text{ (bits)} , \qquad (14.253)$$

where the factor $1/\ln(2) = 1.443$ converts the natural log to a base 2 log. However, in written English all symbols are not equally probable. For example, the most common letter, E, is more than 100 times more likely to occur than the letter J. Because equal probability of symbols always leads to the highest entropy, the unequal probability in written English is bound to reduce the information content – to about 4 bits per character. An even greater reduction comes from the redundancy in larger units, such as words, so that the information content of written English is no more than 1.6 bits per character.

The concept of information entropy can be extended to continuous distributions defined by a probability density function

$$h = - \int_{-\infty}^{\infty} dx \, \text{PDF}(x) \, \log[\text{PDF}(x)] . \qquad (14.254)$$

14.14.2 Mutual Information

The mutual information between sets of variables $\{i\}$ and $\{j\}$ is a measure of the amount of uncertainty about one of these variables that is eliminated by knowing the other variable. Mutual information H_m is given in terms of the joint probability mass function $p(i, j)$

$$H_m = \sum_{i=1}^{M} \sum_{j=1}^{M} p(i, j) \log \frac{p(i, j)}{p(i) p(j)} . \qquad (14.255)$$

Using written English as an example again, $p(i)$ might describe the probability for the first letter of a word and $p(j)$ might describe the probability for the second. It is convenient to let the indices i and j be integers, e.g., $p(i = 1)$ is the probability that the first letter is an 'A', and $p(j = 2)$ is the probability that the second letter is a 'B'. Then $p(1, 2)$ is the probability that the word starts with the two letters 'AB'. It is evident that in a context where the first two letters are completely independent of one another so that $p(i, j) = p(i) p(j)$ then the amount of mutual information is zero because $\log(1) = 0$. In the opposite limit the context is one in which the second letter is completely determined by the first. For instance, if the second letter is always the letter of the alphabet that immediately follows the first letter then $p(i, j) = p(j) = p(i)\delta(j, i + 1)$, and

$$H_m = \sum_{i=1}^{M} p(i) \log \frac{p(i)}{p(i) p(i)} \qquad (14.256)$$

which simply reduces to (14.243) for H_c, the information content of the first letter of the word.

In the general case, the mutual information is a difference in information content. It is equal to the information provided by the second letter of the word given no prior knowledge at all, minus the information provided by the second letter of the word given knowledge of the first letter. Mathematically, $p(i, j) = p(i)p(j|i)$, where $p(j|i)$ is the probability that the second letter is j given that the first letter is i. Then

$$
\begin{aligned}
H_{\mathrm{m}} = {} & \sum_{j=1}^{M} p(j) \log \frac{1}{p(j)} \\
& - \sum_{i=1}^{M} \sum_{j=1}^{M} p(i, j) \log \frac{1}{p(j|i)} \; .
\end{aligned} \tag{14.257}
$$

The information transfer ratio T is the degree to which the information in the first letter predicts the information in the second. Equivalently, it describes the transfer of information from an input to an output

$$
T = \frac{-H_{\mathrm{m}}}{\sum_{i=1}^{M} p(i) \log p(i)} \; . \tag{14.258}
$$

This ratio ranges between 0 and 1, where 1 indicates that the second letter, or output, can be predicted from the first letter, or input, with perfect reliability. The mutual information is the basis for the calculation of the information capacity of a noisy communications channel.

15. Musical Acoustics

Colin Gough

This chapter provides an introduction to the physical and psycho-acoustic principles underlying the production and perception of the sounds of musical instruments. The first section introduces generic aspects of musical acoustics and the perception of musical sounds, followed by separate sections on string, wind and percussion instruments.

In all sections, we start by considering the vibrations of simple systems – like stretched strings, simple air columns, stretched membranes, thin plates and shells. We show that, for almost all musical instruments, the usual text-book description of such systems is strongly perturbed by material properties, geometrical factors and acoustical coupling between the drive mechanism, vibrating system and radiated sound.

For stringed, woodwind and brass instruments, we discuss excitation by the bow, reed and vibrating lips, which all involve strongly non-linear processes, even though the vibrations of the excited system usually remains well within the linear regime. However, the amplitudes of vibration of very strongly excited strings, air columns, thin plates and membranes can sometimes exceed the linear approximation limit, resulting in a number of interesting non-linear phenomena, often of significant musical importance.

Musical acoustics therefore provides an excellent introduction to the physics of both linear and non-linear acoustical systems, in a context of rather general interest to professional acousticians, teachers and students, at both school and college levels.

The subject continues its long tradition in advancing the frontiers of experimental, computational and theoretical acoustics, in an area of wide general appeal and contemporary relevance.

By discussing the theoretical models and experimental methods used to investigate the acoustics of many musical instruments, we have

aimed to provide a useful background for professional acousticians, students and their teachers, for whom musical acoustics provides an exceedingly rich area for original research projects at all educational levels.

Because the subject is ultimately about the sounds produced by musical instruments, a large number of audio illustrations have been provided, which can be accessed on the Springer EXTRAS server. The extensive list of references is intended as a useful starting point for entry to the current research literature, but makes no attempt to provide a comprehensive list of all important research.

This chapter highlights the acoustics of musical instruments. Other related topics, such as the human voice, the perception and psychology of sound, architectural acoustics, sound recording and reproduction, and many experimental, computational and analytic techniques are described in more detail elsewhere in this volume.

Musical acoustics is one the oldest of all the experimental Sciences (see *Levenson* [15.1] for an informative account of the interactions between Music and Science over the ages). The observation of the relationship between the notes produced by the exact fraction divisions of a stretched string and consonant musical intervals like the octave (2 : 1), perfect fifth (3 : 2) and fourth (4 : 3), resulted in the first physical law to be expressed in mathematical terms. It also led to the idea of a divinely created cosmos based on exact fractions, filled with the *music of the spheres* (see, for example, Kepler's account of the ellipticity of the planetary orbits described as notes on a musical scale, in *Harmonies of the World* (1618) [15.2]). Ultimately, such observations led to Newton's discovery of celestial dynamics and the laws of gravity leading to the modern view of the universe subject to physical laws rather than numerical relationships.

In the nineteenth century, musical acoustics continued to occupy a central scientific role. This culminated in Lord Rayleigh's monumental two volumes on the *Theory of Sound* [15.3], which still provide the foundations for almost every branch of modern acoustics. The 19th century advances in understanding waves in acoustics also laid the mathematical framework for quantum wave mechanics in the early part of the 20th century. More recently, the physics of vibrating strings can be said to have come full circle, with the suggestion that string-like vibrations of the quantum field equations account for the mass to the elementary particles (*Hawkins* [15.4]).

Musical acoustics still remains a challenging and exciting field of research and continues to advance mainstream acoustics in many ways. Examples include nonlinear physics and the use of laser holography and both modal and finite-element analysis to investigate complicated vibrating systems. Such developments are described in this chapter and in more detail in other chapters of this Handbook and in the *Physics of Musical Instruments* by *Fletcher* and *Rossing* [15.5], which will often be cited, as an authoritative text and source of additional references for most topics discussed. The *Science of Sound* by *Rossing* et al. [15.6] covers an even wider range of topics at a somewhat less mathematical

level. An informative overview of the history, technology and performance of western musical instruments has recently been published by *Campbell*, *Greated* and *Myers* [15.7].

The first section of this chapter deals with the generic properties of the vibrations and sounds of musical instruments. A brief description is first given of the properties of both simple and coupled resonators, typifying the vibrational modes of stringed, wind and percussion instruments, where the sound is generated by vibrating strings, air columns, plates, membranes and shells. The radiation of sound by such structures is then described in terms of multipole sources. This is followed by a brief description of the envelopes, waveforms and spectra of the sounds that characterize the sound of individual instruments. The section ends with a consideration of the way the listener perceives such sounds.

The section on stringed instruments first considers the general properties of string vibrations and their excitation by plucking, bowing and striking. Large amplitude vibrations are shown to provide a particular interesting illustration of nonlinearity of much wider applicability than to musical acoustics alone. The coupling of the vibrating string via the bridge to the acoustically radiating surfaces of the instrument is then discussed in some detail, followed by a more detailed discussion of excitation of a string via the bowed slip-stick mechanism. The vibrational modes of the main shell of the instrument and the importance of the bridge and soundpost in determining the efficiency of energy transfer to the radiating surfaces of the instrument are then discussed. The section ends with a description of some of the experiment and computational techniques used to describe the vibrational modes, followed by a brief description of the radiated sound and the subjective assessment of the quality of stringed instruments.

The section on woodwind and brass instruments starts with a consideration of oscillating air columns and sound radiation from cylindrical and conical tubes and the more complicated shapes used for woodwind and brass instruments. This is followed by sections on the highly nonlinear processes involved in the excitation of such vibrations by reed and lip vibrations and air-jets.

The section concludes with a brief description of the acoustical properties of various wind instruments.

The final section on percussion instruments describes the acoustical properties of a range of instruments based on the vibrations of stretched membranes, bars, plates and shells. Typical waveform envelopes and time-dependent spectra are used to illustrate the relationship between the vibrational modes of such instruments and the radiated sound. Non-linearity at large amplitude excitation is again shown to be important and accounts for the characteristic sounds of certain instruments like gongs and cymbals.

15.1 Vibrational Modes of Instruments

15.1.1 Normal Modes

All musical instruments produce sound via the excitation of a vibrating structure. Woodwind, brass and percussion instruments radiate sound directly. However, stringed instruments radiate sound indirectly, because the vibrating string itself radiates an insignificant amount of energy. Energy from the vibrating string therefore has to be transferred to the much larger area, acoustically efficient, radiating surfaces of the body of the instrument. The resultant modes of vibration are complex and involve the interactions and vibrations of all the component parts, such as the strings, bridge, front and back plates, soundpost, neck, and even the air inside the volume of the violin body.

Any vibrating structure, however complicated, will have a number of what are called normal modes of vibration (Chap. 22). The important influence of damping on the nature of the normal modes will be described in the section on stringed instruments. The normal modes satisfy exactly the same equations of motion as a simple damped mass–spring resonator. The displacement ξ_n of a given excited mode measured at any chosen point p on the structure is given by

$$m_n \left(\frac{\partial^2 \xi_n}{\partial t^2} + \frac{\omega_n}{Q_n} \frac{\partial \xi_n}{\partial t} + \omega_n^2 \xi_n \right) = F(t) , \qquad (15.1)$$

where the effective mass m_n at the point p is defined in terms of the kinetic energy of the excited mode, $\frac{1}{2} m_n (\partial \xi_n / \partial t)_p^2$, $\omega_n = 2\pi f_n$ is the eigenfrequency (the angular frequency) of free vibration of the excited mode in the absence of damping and Q_n is the quality factor describing its damping. Initially, we consider a local driving force $F(t)$ at the point p, though it could be applied at any chosen point on the structure or distributed over the whole surface.

The effective mass of a one-dimensional string, solid bar or air column, at the point of maximum displacement, is half the mass of the vibrating system, the factor half resulting from averaging the kinetic energy over the sinusoidal spatial displacement. Likewise, the effective mass of a two-dimensional vibrating object at maximum displacement, like a violin plate or drum skin, is of order 1/4 its mass. The effective mass is very large close to nodal positions, where the displacement is small, and is small at antinodes, where the displacement is large.

Typical driving forces are those acting on the bridge of a bowed or plucked string instrument and the pressure fluctuations at the input end of the air column of a blown woodwind or brass instrument. Such forces are generated by highly nonlinear excitation mechanisms. In contrast, the vibrations of the vibrating structure are generally linear with displacements proportional to the driving force. However, there are important exceptions for almost all types of instruments, when nonlinearity becomes significant at sufficiently strong excitation, as discussed later.

In any continuously bowed or blown musical instruments, feedback from the vibrating system results in a periodic driving force, which will not in general be sinusoidal. Nevertheless, by the Fourier theorem, any periodic force can always be represented as a superposition of sinusoidally varying, harmonic, partials with frequencies that are integer multiple of the periodic repetition frequency. We can therefore consider the induced vibrations of any musical instruments in terms of the induced response of its vibrational modes to a harmonic series of sinusoidal driving forces.

Resonance and Admittance

In the harmonic approach, the applied forces and induced motions are assumed to vary sinusoidally as $e^{i\omega t}$. We will generally use this complex notation for notational and algebraic simplicity, where $\mathrm{Re}(e^{i\omega t}) = cos\omega t$ and $\mathrm{Im}(e^{i\omega t}) = \sin \omega t$. The resonant response, with displacement $\xi_n e^{i\omega t}$ and velocity $i\omega \xi_n e^{i\omega t}$ at the driving point p, for an applied sinusoidal force $F e^{i\omega t}$, is then given by

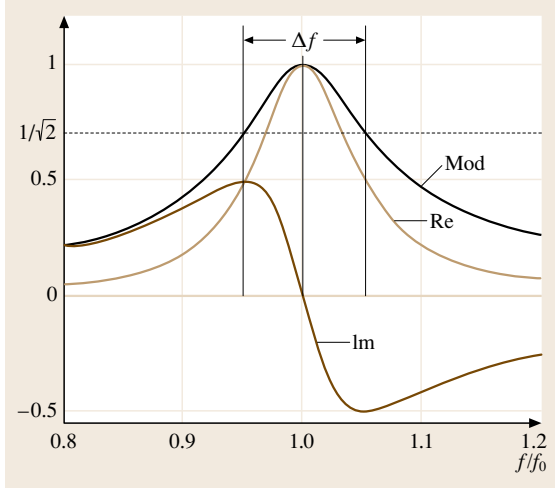
$$\frac{\partial \xi_n}{\partial t} = i\omega \xi_n = \frac{F}{m_n} \frac{i\omega}{(\omega_n^2 - \omega^2 + i\omega \omega_n / Q_n)} . \qquad (15.2)$$


Fig. 15.1 Normalised real (Re) and imaginary (Im) components and the modulus (Mod) of the induced velocity of a simple harmonic resonator driven by a constant amplitude sinusoidal force for a Q-factor of 10

The ratio of induced velocity to driving force is known as the local admittance at the driving point p, and is plotted in normalised form in Fig. 15.1 for a Q-value of 10. The admittance has both real and imaginary components. The real part describes the component of the induced velocity in phase with the driving force, while the imaginary part describes the component in phase quadrature (with phase leading that of the force by 90° degrees).

Well below resonance the induced displacement is in phase with the driving force, while at resonance the phase lags behind the driving force by 90°, and well above resonance lags by 180°. The velocity $v(t)$ leads the displacement by 90° degree and is thus in phase with the driving force at resonance, which corresponds to the maximum rate of energy transfer $i\omega F\xi_n$ to the excited mode. The 180° change in the phase of the response, as the excitation frequency passes from well below to well above resonance, is especially important in interpreting the multiple resonances of any musical instrument.

Provided the damping of an excited mode is not too strong (i.e. Q_n is significantly larger than unity), the peak in the modulus or real part of the admittance occurs at $\omega_n \left(1 - 1/8Q^2\right)$, which is very close to the natural resonant frequency ω_n. The width of the resonance is $\Delta f = f_n/Q$, where Δf is defined as the difference in frequency between the points on the resonance curve when the modulus of the induced displacement has fallen to $1/\sqrt{2}$ of its maximum value

(i.e. the stored energy is half that at resonance). The displacement at resonance is $Q \times$ the static displacement.

Multi-Mode Systems

For any musical instrument having a number of vibrational modes, the admittance at the driving point p can be written as

$$A_{pp} = \sum_n \frac{1}{m_n} \frac{i\omega}{\omega_n^2 - \omega^2 + i\omega\omega_n/Q_n} \,, \tag{15.3}$$

with admittances A_{pp} of individual modes adding in series, equivalent to impedances in parallel. The vibrational response of a multi-resonant mode musical instrument can therefore be characterised by fitting the measured admittance to such a function giving the effective mass at the point of excitation, resonant frequency and Q-value for each of the excited modes. Using such a procedure, *Bissinger* [15.8] typically identifies up to around 40 vibrational modes for the violin below 4 kHz. However, at high frequencies, the width of individual resonances exceeds the spacing between them, making it increasingly difficult to identify individual modes.

It is important to recognise that damping is only important in a relatively narrow frequency range $\approx f_n/Q$ around the individual resonance peaks. Outside such regions, the reactive component associated with each vibrational mode continues to contribute significantly to the overall response. For example, well below resonance, each mode acts as a spring with effective spring constant $m_n(\omega_n^2 - \omega^2)$, while well above resonance it acts as a mass with effective mass $m_n(1 - \omega_n^2/\omega^2)$. The static displacement (at $\omega = 0$) is given by $\xi = F/K_o = \sum_n 1/(m_n\omega_n^2)$. Note that this involves contributions from all the vibrational modes of the structure, which is an important global property describing the low-frequency response of a multi-resonant structure such as the violin or guitar. If displacements are measured at a point p for an applied force at q, a *nonlocal admittance* can be expressed as

$$A_{pq} = \sum_n \frac{1}{m_{n,p}} \frac{i\omega}{\left(\omega_n^2 - \omega^2 + i\omega\omega_n/Q_n\right)} \frac{\xi_{n,p}\xi_{n,q}}{\xi_{n,p}^2} \,, \tag{15.4}$$

where $\xi_{n,p}$ and $\xi_{n,q}$ are the simultaneous displacements of the nth mode at the points p and q, with identical stored modal energy $1/2m_{n,p}\omega^2\xi_{n,p}^2 = 1/2m_{n,q}\omega^2\xi_{n,q}^2$.

Equation (15.4) illustrates the principle of reciprocity in acoustics, which states that the motion at a point p induced by a force at q is identical to the mo-

tion at q induced by the same force at p. Equation (15.4) also shows that, by applying a force at a particular position and measuring the induced motion (amplitude and phase) at a large number of different points $p(x, y, z)$ on the structure, it is possible to map out the amplitude of the modal vibrations $\xi_n(x, y, z)$ over the whole of any excited structure. Alternatively, the measurement point can be fixed and the excitation point moved across the structure. This is the basis of the powerful technique of modal analysis, which has been widely used to investigate the vibrational modes of many stringed and percussion instruments, as described by *Rossing* in Chap. 28 of this Handbook.

It also follows from (15.4) that a particular mode of vibration will never be excited if the driving force is located at a node of its vibrational state. This has important consequences for the spectrum of sound produced by bowed, plucked and struck stringed instruments and all percussion instruments.

Time-Domain Measurements
The vibrational characteristics of an instrument can also be investigated in the time domain. For example, by striking a stringed instrument with a light hammer or exciting the vibrational modes of a woodwind or brass instrument with a short puff of air, the frequencies of free vibration of the vibrational modes and their damping can be determined from their time-dependent decay. Provided the damping is not too strong ($Q \gg 1$), the modes will decay with time as

$$\xi_n(t) = \xi_0 \, e^{-t/\tau_n} \, e^{i\omega_n t}, \tag{15.5}$$

where $\tau_n = 2Q_n/\omega_n = Q_n/\pi f_n$. The frequency f_n of a given mode can be determined from its inverse period and Q_n from $\pi \times$ the number of periods for the amplitude to fall by the factor exponential e. The Q-value of strongly excited modes of a musical instrument can be estimated from $\tau_{60\mathrm{dB}} = 13.6\tau$, the Sabine decay time (Chap. 10 *Concert Hall Acoustics*). This is the perceptually significant time taken for the sound pressure to fall by a factor of 10^3 – from a very loud level to just being detectable. Hence, $Q_n = \pi f_n \tau_{60}/13.6 \approx 0.23 f_n \tau_{60}$. For example, the sound of a strongly plucked cello open A-string (220 Hz) can be heard for at least ≈ 2 s, corresponding to a Q-value of ≈ 100 or more.

Damping results in a loss of stored energy given by

$$\frac{\mathrm{d}E_n}{\mathrm{d}t} = -\frac{\omega_n}{Q_n} E_n = -2\frac{E_n}{\tau_n} \,. \tag{15.6}$$

Hence, the power P required to maintain a constant amplitude at resonance is $\frac{\omega_n}{Q_n} E_n$, where E_n is the energy stored. This tends to be the way that Q is defined and measured by physicists, whereas in acoustic spectroscopy it is more usual to define and measure Q-values from either the width of resonances in spectroscopic measurements or from decay times after transient excitation. As illustrated above, all such definitions are equivalent.

15.1.2 Radiation from Instruments

Although a large number of vibrational modes of a musical instrument may be excited simultaneously, they will not be equally important in radiating sound, which has important consequences for the quality of the sound. This section therefore provides a brief introduction to the radiation of sound from the vibrational modes of musical instruments.

Sound Waves in Air
In free space, the longitudinal displacement $\xi(x, t) = \xi_0 \, e^{i(\omega t - kx)}$ of plane sound waves satisfies the wave equation

$$\frac{\partial^2 \xi}{\partial x^2} = \frac{1}{c_0^2} \frac{\partial^2 \xi}{\partial t^2} \,. \tag{15.7}$$

The dispersionless (independent of frequency) velocity of sound $c_0 = \sqrt{\gamma P_0/\rho}$, where $\gamma (\approx 1.4)$ is the ratio of specific heats at constant pressure and volume, P_0 ($\approx 10^5$ Pa or N/m^2) is the ambient pressure and ρ (≈ 1 kg/m^3) is the density (the brackets give the values for air at ambient pressure and temperature). The ratio of acoustic pressure $p = -\gamma P_0 \partial \xi/\partial x$ to the particle velocity $v = \partial \xi/\partial t$ is referred to as the specific impedance, $z_0 = p/v = \rho c_0$.

The appearance of γ in the expression for the velocity of sound reflects the adiabatic nature of acoustic waves. This arises because acoustic wavelengths are far too long to allow any significant equalisation of the longitudinal temperature fluctuations arising from the compressions and rarefactions of a sound wave. In free space longitudinal heat flow between the fluctuating regions is only important at very high ultrasonic frequencies (MHz), where it leads to significant attenuation. The major source of attenuation of freely propagating acoustic sound waves arises from the water vapour present. However, both viscous and transverse thermal losses to the side walls of woodwind and brass instruments can result in significant attenuation, as described later.

The above expressions neglect first-order, nonlinear, corrections to the compressibility, proportional to

$\partial \xi / \partial x$, and other inertial correction terms in the nonlinear Navier–Stokes equation. This approximation breaks down at the very high intensities in the bores of the trumpet and trombone when played very loudly [15.9], which results in shockwave propagation, with a transition from a relatively smooth to a very brassy sound (*son cuivré* in French). For the present, such corrections will be neglected.

The speed of sound in air depends on the temperature θ (degrees centigrade) and, to a lesser extent, on the humidity. For 50% humidity,

$$c_0(\theta) = 332\,(1 + \theta/273)^{1/2} \approx 332(1 + 1.710^{-3}\theta)\,,$$
(15.8)

giving a value of 343 m/s at 20 °C. Note that the air inside a woodwind or brass instrument, once the instrument is *warmed up*, will always be warm and humid, which will affect the playing pitch.

Pressure and Intensity

The intensity I of sound radiated by a musical instrument is given by the flow of acoustic energy ($1/2\rho v^2$ per unit volume) crossing unit area per unit time,

$$I = \frac{1}{2}\rho c_0 v_{\max}^2 = \frac{1}{2}z_0 v_{\max}^2 = \frac{1}{2z_0}p_{\max}^2\,.$$
(15.9)

Sound pressure levels (SPL) are measured in dB relative to a reference sound pressure p_0 of 2×10^{-5} Pa or N/m², so that $\mathrm{SPL(dB)} = 20\log_{10}(p/p_0)$. The reference pressure is approximately equal to the lowest level of sound that can be heard at around $1-3$ kHz in a noise-free environment. Relative changes in sound pressure levels are given by $20\log_{10}(p_1/p_2)$ dB. A sound pressure of 2×10^{-5} Pa is very close to an intensity of $I_0 = 10^{-12}$ W/m², which is used to define the almost identical intensity level, $\mathrm{IL(dB)} = 10\log_{10}(I/I_0)$. The difference between the factor 10 and 20 arises because sound intensity is proportional to the square of the sound pressure.

Spherical Waves

In free space, sound from a localised source will propagate as a spherical wave satisfying the three-dimensional wave equation (*Fletcher* and *Rossing* [15.5, Sect. 6.2]), with pressure

$$p(r) = A\,\frac{\mathrm{e}^{\mathrm{i}(\omega t - kr)}}{r}$$
(15.10)

and particle velocity

$$v(r) = \frac{A}{z_0}\left(1 + \frac{1}{\mathrm{i}kr}\right)\frac{\mathrm{e}^{\mathrm{i}(\omega t - kr)}}{r}\,.$$
(15.11)

Near and Far Fields

Note that, unlike plane-wave solutions, the velocity and pressure differ in phase by an amount that depends on the distance from the source and the wavelength. Close to the source, in the *near field* ($kr \ll 1$), the pressure and induced velocity are in phase quadrature. Such terms therefore involve no work being done (proportional to $\int pv\,\mathrm{d}t$) and hence no radiation of sound. The near-field term describes the motion of the air that is forced to vibrate backwards and forwards with the vibrating surface of the source, which simply adds inertial mass to the vibrating mode. This term is responsible for the *end correction* ($\Delta L \approx a$, where a is the pipe radius), which extends the effective length of an open-ended vibrating air column. The additional inertial mass also lowers the vibrational frequency of the relatively light vibrating membranes of a stretched drum skin.

In contrast, in the *far field* ($kr \gg 1$), the pressure is in phase with the velocity, so that work is done on the surrounding gas. This accounts for the fact that sound radiation varies in intensity as $1/r^2$.

The transition from the near- to far-field regions occurs when $r \approx \lambda/2\pi$, where λ is the acoustic wavelength of the radiated sound. At 340 Hz, this corresponds to a distance of only ≈ 15 cm. The difference in the frequency dependencies of the near- and far-field sound means that a violinist or piccolo player, with their ears relatively close to the instrument, experiences a rather different sound from that heard by the listener in the far field. However, for most musical instruments, the distance between the source of radiated sound and the player's head is already at least $\lambda/2$, so that even the player is in the *far field* ($kr > 1$), at least for the high-frequency partials of a musical tone.

Directionality and Multipole Sources

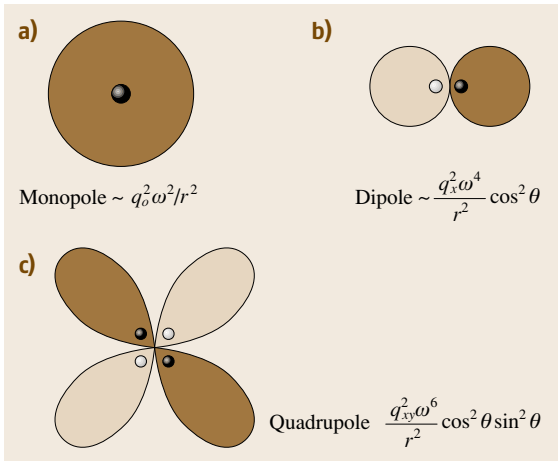
At very low frequencies, the acoustic wavelength λ is often considerably larger than the physical size of the radiating source (e.g. the open ends of woodwind and brass instrument bores and the body of most stringed instruments), which can then be considered as a point source radiating isotropically into space. However, as soon as the wavelength becomes comparable with the size of the radiating source, the radiated sound will acquire directional properties determined by the geometry of the instrument and the vibrational characteristics of the excited modes. The directional properties can then be described by treating the instrument as a superposition of monopole, dipole, quadrupole and higher-order multipole acoustic sources, with the directional radiating properties shown schematically in Fig. 15.2.


Fig. 15.2a–c Typical radiation patterns and intensities for (**a**) monopole, (**b**) dipole and (**c**) quadrupole sources. The *two colours* represent monopole sources and sound pressures of opposite signs

A monopole source can be considered as a pulsating sphere of radius a with surface velocity $v\mathrm{e}^{\mathrm{i}\omega t}$ resulting in a pulsating volume source $4\pi a^2 v\mathrm{e}^{\mathrm{i}\omega t} = Q\,\mathrm{e}^{\mathrm{i}\omega t}$. Equations (15.10) and (15.11) describe the sound field generated by such a source. Equating the velocities on the surface of the sphere to that of the induced air motion gives, at low frequencies such that $ka \ll 1$,

$$p(r, t) = \frac{\mathrm{i}\omega\rho}{4\pi r} Q\,\mathrm{e}^{\mathrm{i}(\omega t - kr)} \ . \tag{15.12}$$

The radiated power P is then given by $\frac{1}{2}p^2/\rho c_0$ integrated over the surface of a sphere at radius r, so that

$$P(ka \ll 1) = \frac{\omega^2 \rho Q^2}{8\pi c_0} \ . \tag{15.13}$$

In the high-frequency limit ($ka \gg 1$), when the acoustic wavelength is much less than the size of the sphere,

$$P(ka \gg 1) = \frac{\rho c_0}{8\pi a^2} Q^2 = 4\pi a^2 \frac{1}{2} z_0 v^2 \ . \tag{15.14}$$

Equation (15.12) is a special case of the general result that, at sufficiently high frequencies such that the size of the radiating object $\gg \lambda$, the radiated sound is simply $\frac{1}{2}z_0 v^2$ per unit area, though the sound at a distance also has to take into account the phase differences from different parts of the vibrating surface. Note that

$$\frac{P(ka \ll 1)}{P(ka \gg 1)} = (ka)^2 \ . \tag{15.15}$$

The radiated sound intensity from a monopole source therefore initially increases with the square of the fre-

quency but becomes independent of frequency above the crossover frequency when $ka > 1$. Hence members of the violin family and guitar families are rather poor acoustic radiators for the fundamental component of notes played on their lowest strings, as are wind and brass instruments, which radiate sound from the relatively small open ends and side holes. However, it is only because of such low radiation efficiencies, that strong resonances can be excited in the air columns of brass and woodwind instruments.

A dipole source can be formed by displacing two oppositely signed monopoles $\pm Q$ a short distance along the x-, y- or z-directions. For a dipole aligned along the x-axis of strength $q_x = Q\Delta x$. The sound pressure is simply the difference in pressure from monopoles of opposite sign a distance Δx apart, so that in the far field ($kr \gg 1$)

$$p(\theta)_{\mathrm{dipole}} = p(\theta)_{\mathrm{monopole}} \times (\mathrm{i}k\Delta x)\cos\theta \ . \tag{15.16}$$

A polar plot of the sound pressure from a dipole is illustrated schematically in Fig. 15.2, with intensity and radiated power now proportional to ω^4 and q_x^2. In general, any radiating three-dimensional object will involve three dipole components (p_x, p_y and p_z), with radiation lobes along the three directions.

A quadrupole source is generated by two oppositely signed dipole sources displaced a small distance along the x-, y-, or z-directions (e.g. of the general form $q_{xy} = Q\Delta x\Delta y$). The pressure is now given by the differential of the dipole radiation in the newly displaced direction, so that, for example, the pressure from a quadrupole source q_{xy} in the xy-plane is given by

$$p_{\mathrm{dipole}} = p_{\mathrm{monopole}} \times (-k^2\Delta x\Delta y)\cos\theta\sin\theta \ , \tag{15.17}$$

as illustrated in Fig. 15.2. Note that each time the order of the multipole source increases, the radiated pressure depends on one higher power of frequency, while the intensity increases by two powers of the frequency. The radiated power from multipole sources therefore decreases dramatically at low frequencies relative to that of a monopole source. At low frequencies, radiation from most musical instruments is dominated by monopole components.

In general, six quadrupole sources ($q_{xx}, \dots, q_{yz}$) would be required to describe radiation from a three-dimensional source. However, because the acoustic power radiated by a quadrupole source at low frequencies is proportional to ω^6, one need often only consider the monopole and three dipole components to describe

the low-frequency radiation pattern of instruments like the violin and guitar family, as described in a recent study of the low-frequency radiativity of a number of quality guitars by *Hill* et al. [15.10]. However, at high frequencies, when λ is comparable with or less than the size of an instrument, the above simplifications break down. The directionality of the radiated sound then has to be computed from the known velocities over the whole surface, taking into account phase differences and baffling effects from the body of the instrument.

Radiation from Surfaces

Many musical instruments produce sound from the vibrations of two-dimensional surfaces – like the plates of a violin or the stretched membrane of a drum. Imagine first a standing wave set up in the two-dimensional xy-plane with displacements in the z-direction varying as $\sin(k_x x)\,e^{i\omega t}$. We look for propagating sound waves solutions radiating from the surface of the form $\sin(k_x x)\,e^{i(\omega t - k_z z)}$, which must satisfy the wave equation and hence the relationship,

$$k_z^2 = \frac{\omega^2}{c_0^2} - k_x^2 = \omega^2\left(\frac{1}{c_0^2} - \frac{1}{c_m^2}\right), \tag{15.18}$$

where c_m is the phase velocity of transverse waves on the membrane or plate in the xy-plane. Sound will therefore only propagate away from the surface ($k_z^2 > 0$)

when $c_m > c_0$. If the sound velocity is greater than the phase velocity in the plate or membrane, energy will flow from regions of positive to negative vertical displacements and vice versa, with an exponentially decaying sound field, varying as $e^{-z/\delta}$ where $\delta = |k_z|^{-1}$.

Typical dispersionless wave velocities for the stretched drum heads of timpani are around 100 m/s (*Fletcher* and *Rossing* [15.5, Sect. 18.1.2]), so that they are not very efficient radiators of sound. This is particular relevant for asymmetrical modes, when sound energy can flow from the regions of positive to negative displacement and vice versa. However, for even modes, the cancellation between adjacent regions moving out of phase with each other can never be complete, so that such modes will radiate more effectively.

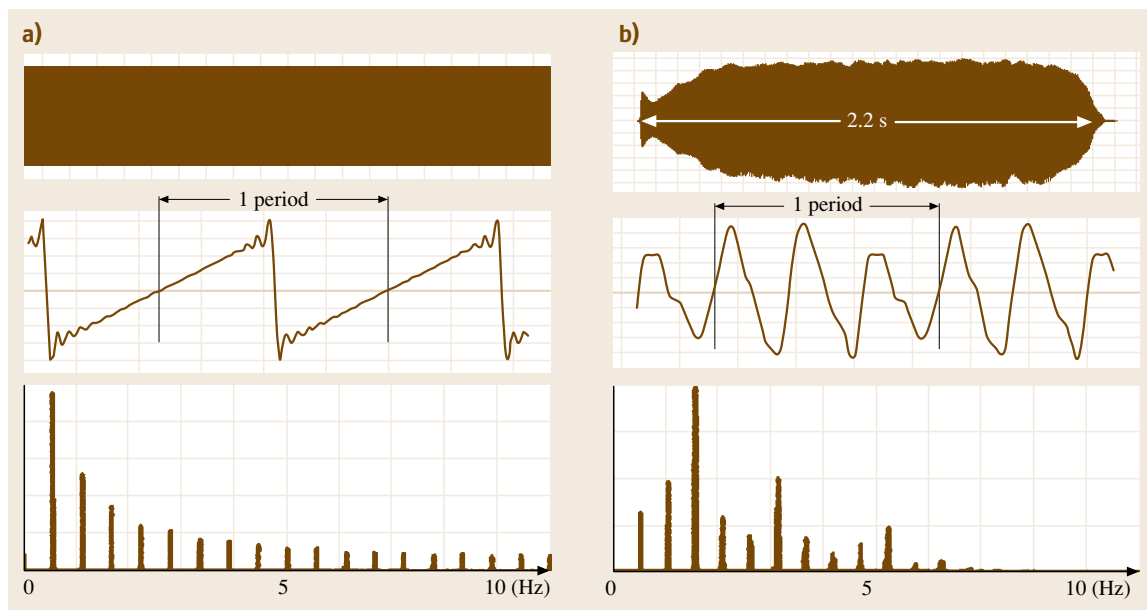
A particularly interesting case occurs for stringed instruments, where the phase velocity of the transverse vibrations of the thin front and back plates increases with frequency as $\omega^{1/2}$ (Sect. 15.2.6). Hence, below a critical crossover or coincidence frequency, when the phase velocity in the plates is less than the speed of sound in air, standing waves on the vibrating plates are relatively inefficient radiators of sound, while above the crossover frequency the plates radiate sound rather efficiently. *Cremer* [15.11] estimates the critical frequency for a 4 mm-thick cello plate as 2.8 kHz; for a 2.5 mm violin plate the equivalent frequency would be ≈ 2 kHz.


Fig. 15.3a,b Comparison of the envelope, repetitive waveform and spectrum of **(a)** a synthesised sawtooth and **(b)** a note played on an oboe

Radiation from Wind Instruments

The holes at the ends or in the side walls of wind instruments can be considered as piston-like radiation sources. At high frequencies, such that $ka \gg 1$, where a is their radius, the holes will be very efficient radiators radiating acoustic energy $\approx 1/2 z_0 v^2$ per unit hole area. However, over most of the playing range $ka \ll 1$, so that the radiation efficiency drops off as $(ka)^2$, just like the spherical monopole source. Most of the sound impinging on the end of the instrument is therefore reflected, so that strong acoustic resonances can be excited, as discussed in the later section on woodwind and brass instruments.

15.1.3 The Anatomy of Musical Sounds

The singing voice, bowed string, and blown wind instruments produce continuous sounds with repetitive waveforms giving musical notes with a well-defined sense of musical pitch. In contrast, many percussion instruments produce sounds with nonrepetitive waveforms composed of a large number of unrelated frequencies with no definite sense of pitch, such as the side drum, cymbal or rattle. There are also other stringed instruments and percussion instruments, such as the guitar, piano, harp, xylophone, bells and gongs, which produce relatively long sounds, where the slowly decaying vibrations produce a definite sense of pitch.

In all such cases, the complexity of the waveforms of real musical instruments distinguishes their sound from the highly predictable sounds of simple electronic synthesisers. This is why the sounds of computer-generated synthesised instruments lack realism and are musically unsatisfying. In this section, we introduce the way that sound waveforms are analysed and described.

Sinusoidal Waves

The most important, but musically least interesting, waveform is the pure sinusoid. This can be expressed in several alternative forms,

$$a \cos(2\pi f t + \phi) = a \cos(\omega t + \phi) = \mathrm{Re}(a\, \mathrm{e}^{\mathrm{i}\omega t}) ,$$

(15.19)

where a is in general complex to account for phase, f is the frequency measured in Hz and equal to the inverse of the period T, $\omega = 2\pi f$ is the angular frequency measured in radians per second, t is time, and ϕ is the phase, which depends on the origin taken for time.

Any sound, however complex, can be described in terms of a superposition of sinusoidal waveforms with a spectrum of frequencies. Figure 15.3 contrasts the envelopes, waveforms and spectra of a synthesised sawtooth waveform and the much more complex and musically interesting waveform of a note played on the oboe (� **EXTRAS** provides an audio comparison). Note the much more complex fluctuating envelope and less predictable amplitudes of the frequency components in the spectrum of the oboe.

As we will show later, in defining the sound and quality of any musical instrument, the shape and fluctuations in amplitude of the overall envelope are just as important as the waveform and spectrum.

Range of Hearing and Musical Instruments

A young adult can usually hear musical sounds from around 20 Hz to 16 kHz, with the high-frequency response decreasing somewhat with age (typically down to between 10–12 kHz for 60-year olds). Audio ⏵ **EXTRAS** provides a sequence of 1 s-long sine waves starting from 25 Hz to 12.8 kHz, doubling in frequency each time. Doubling the frequency of a sinusoidal wave is equivalent in musical terms of increasing the pitch of the note by an octave. Audio ⏵ **EXTRAS** is a similar sequence of pure sine waves from 8 kHz to 18 kHz in 2 kHz steps. Any loss of sound at the low frequencies in ⏵ **EXTRAS** will almost certainly be due to the limitations of the reproduction system used, which is particularly poor below ≈ 200 Hz on most PC laptops and notebooks, while the decrease in intensity at high frequencies in ⏵ **EXTRAS** simply reflects the loss of high-frequency sensitivity of the ear (see Fig. 15.16 and Chap. 13 for more details on the amplitude and frequency response of the human ear).

The above sounds should be compared with the much smaller range of notes on a concert grand piano, typically from the lowest note A0 at 27.5 Hz to the highest note C9 at 4.18 kHz, as illustrated in Fig. 15.4. The nomenclature for musical notes is based on octave sequences of C-major scales with, for example, the note C1 followed by the white keys D1, E1, F1, G1, A1, B1, C2, D2,.... Alternatively, the octave is indicated by a subscript (e.g. A$_4$ is concert A). Where the white notes are a tone apart, a black key is inserted to play the semitone between the adjacent white keys. This is indicated by the symbol # from the note below or ♭ from the note above. Figure 15.4 also illustrates the playing range of many of the instruments to be considered in this chapter.

Frequency and Pitch

It is important to distinguish between the terms frequency and pitch. The frequency of a waveform is strictly only defined in terms of a continuous sinusoidal waveform. In contrast, the waveforms of real musical
Fig. 15.4 Notation used for notes of the musical scale and the playing range of classical western musical instruments. Subdivisions for stringed instruments represent the tuning of the open strings

instruments are in general complex, as illustrated by the oboe waveform in Fig. 15.3. However, despite such complexity, the repetition frequency and period T can still be defined provided the waveform does not vary too rapidly with time. The periodicity of a note (measured in Hz) can then be defined as the inverse of T. This is generally the note that the player reads from the written music. However, as described later, a repetitive waveform does not necessarily include a sinusoidal component at the repetition frequency, an effect referred to as the *missing fundamental*. Furthermore, depending on the strength of the various sinusoidal components present, there can often be an ambiguity in the pitch of a note perceived by the listener. The subjective pitch, when matched against a pure sinusoidal wave, can often be an octave below or above the repetition frequency.

The subjective pitch, as its name implies, can differ from person to person and within the musical context of the note being played.

Musical Intervals and Tuning

In western music the octave interval is divided into six tones (a whole-tone scale) and 12 semitones (the chromatic scale). Today, an equal temperament, logarithmic scale is used to tune a piano, with a fractional increase in frequency of $2^{1/12} = 1.059$ ($\approx 6\%$) between any two notes a semitone apart. The fractional increase between the frequencies of a given musical interval (a given number of semitones) is then always the same, whatever the starting note. Twelve successive semitones played in sequence therefore raises the frequency by an octave ($(2^{1/12})^{12} = 2$). Any music played on the piano key-

board can therefore be transposed up or down by a given number of semitones, changing the pitch but leaving the relationship between the musical intervals unchanged. Such a scale was advocated as early as 1581, in a treatise by the lutenist Vincenzo Galileo (the father of Galileo Galilei). Although it is sometimes claimed that Bach exploited such a tuning in his 48 Preludes and Fugues, which uses all possible major and minor keys of the diatonic scale, historical research now suggests that Bach used a form of mean-tone tuning, which preserved some of the characteristic qualities of music written in particular keys [15.1].

To provide a greater discrimination in the measurements of frequency, the semitone is divided into 100 further logarithmic increments called cents. The octave is therefore equivalent to 1200 cents and a quarter-tone to ≈ 50 cents, with the exact relationship between frequencies given by

$$\text{interval} = \frac{1200}{\ln 2} \ln(f_2/f_1) \text{ cents} \qquad (15.20)$$

corresponding to $\approx 1.73 \times 10^3 (\Delta f/f)$ cents for small fractional changes $\Delta f/f$.

Early musical scales were based on various variants of the natural harmonic series of frequencies, $f_n = n f_1$, where n is an integer (e.g. 200, 400, 600, ... 1600 Hz), illustrated by the audio |?⟩ EXTRAS . These notes correspond to the *harmonics* produced when lightly touching a bowed string at integral subdivisions of its length (1/2, 1/3, 1/4, etc.) |?⟩ EXTRAS . These simple divisions give successive musical intervals of the octave, perfect fifth, perfect fourth, major third and minor third, with frequency ratios 2/1, 3/2, 4/3, 5/4 and 6/5, respectively. The seventh member of the harmonic sequence has no counterpart in traditional western classical music, although it is sometimes used by modern composers for special effect [15.12].

Just temperament corresponds to musical scales based on these integer fraction intervals. The Pythagorean scale is based on the particularly consonant intervals of the octave (2/1) and perfect fifth (3/2), which can be used to generate individual intervals of the form $3^p/2^q$ or $2^p/3^q$, where p and q are positive integers. Although the Pythagorean and just-tempered scales coincide for the octave, perfect fifth and fourth, there are musically significant differences in the tuning for all other defined intervals, and all intervals other than the octave differ slightly from those of the equally tempered scale. A comparison between the musical intervals of just and equal temperament tuning is shown in Table 15.1, with the fractional mistuning indicated

Table 15.1 Principal intervals and differences between just- and equal-temperament intervals

Interval	Just	Equal	$\Delta f/f$ Just-equal cents
Octave	2/1	2.00	0
Perfect fifth	3/2	$2^{7/12} = 1.498$	+2
Perfect fourth	4/3	$2^{5/12} = 1.334$	−2
Major third	5/4	$2^{4/12} = 1.260$	−13
Minor third	6/5	$2^{3/12} = 1.189$	+15
Tone	9/8	$2^{2/12} = 1.122$	−4
Semitone	16/15	$2^{1/12} = 1.066$	+1

in cents. Because of the differences in tunings of the musical intervals, music transposed from one key to another will generally sound badly out of tune (particularly for commonly used intervals like the major and minor third) – unlike those played on a modern equal-tempered keyboard. Prior to the now almost universal practice of tuning keyboard instruments to a equal-tempered scale, many tuning schemes were devised which partially overcame the problems of tuning when playing in a succession of different keys (see *Fletcher* and *Rossing* [15.5, Sect. 17.6] and *Barbour* [15.13] for further discussion). Singers, stringed and wind instrument players can adjust the pitch of the notes they produce to optimise the tuning with other performers and for musical effect.

Figure 15.5 and audio |?⟩ EXTRAS illustrate the difference in the sounds of a major triad formed from the just intervals (1, 5/4, 3/2) and the equivalent equal-tempered scale intervals (1 : 1.260 : 1.498). The rational Pythagorean intervals give a repetitive waveform of constant amplitude, while the less-consonant, inharmonic, equal-tempered intervals have a nonrepetitive

Fig. 15.5 Wave envelope of a major triad chord based on the just tuning scale followed by the same chord on the equal-tempered scale, with pronounced beats in the amplitude arising from the departures from harmonicity in the frequencies of the major third and perfect fifth

waveform with an easily discernable periodic beat in amplitude resulting from the departures in harmonicity of its component frequencies, as illustrated in Fig. 15.5. Interestingly, the pitch of the equally tempered intervals also sounds slightly higher, though both share the same fundamental.

A sequence of upward fifths (frequency ratio 3/2) and downward octaves (ratio 1/2) can be used to fill in all the semitones of an octave scale on the piano keyboard. However, the resulting octave formed from a succession of 12 upward fifths and six downward octaves gives a frequency ratio of $(3/2)^{12}/2^6 = 2.027$, which is significantly *sharper* (higher in frequency) than a true octave. In practice, a skilled piano tuner listens to the beats produced when playing the above intervals and tunes the upward fifth slightly flat, so that the sequence returns to the exact octave. However, there are striking psychoacoustic effects, in addition to physical shifts in the frequencies of upper partials arising from the finite rigidity of the strings, which result in pianos being tuned on a slightly stretched tuning scale with the octaves purposely tuned sharp at higher frequencies and flat at lower frequencies (*Fletcher* and *Rossing* [15.5, Sect. 12.8]).

Repetitive Waveforms

Before considering the more complex waveforms of musical instruments, we consider the simple square, triangular, sawtooth and triangular repetitive waveforms (audio [?] EXTRAS) and the corresponding Fourier spectra illustrated in Fig. 15.6.

Fourier Theorem

Fourier showed that any repetitive waveform, $f(t+nT) = f(t)$, can be described as a linear combination of sinusoidal components with frequencies that are exact multiples of the inverse repetition period T or physical pitch of the wave. This is formally expressed by the Fourier theorem,

$$f(t) = \sum_{n=-\infty}^{\infty} c_n \, \mathrm{e}^{\mathrm{i} n \omega_1 t} \,, \tag{15.21}$$

where $\omega_1 = 2\pi/T$ and

$$c_n = \frac{1}{T} \int_0^T f(t) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \,, \tag{15.22}$$

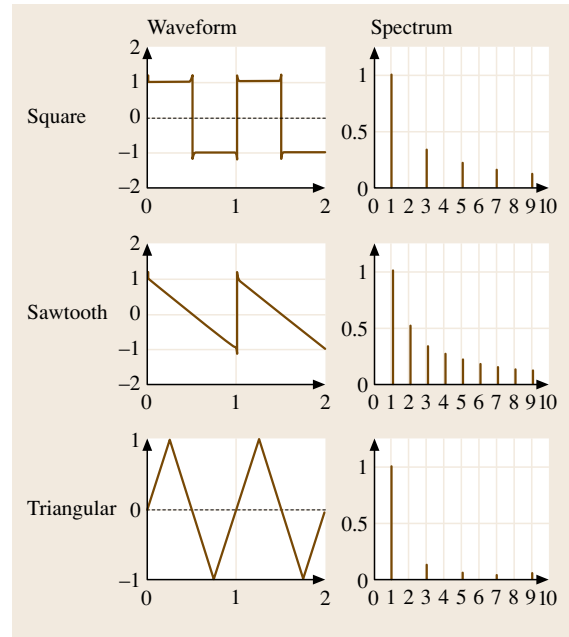
where n takes on all positive and negative integer values. The Fourier coefficients c_n can be evaluated by performing the integral over any single period of the waveform. In general, the Fourier coefficients will have


Fig. 15.6 Typical repetitive waveforms (synthesised from the first 100 components of a Fourier series) and the amplitudes of the first few partials normalised to the amplitude of the fundamental

both real and imaginary components describing both the amplitude and phase.

For simple waveforms, such as the square, sawtooth and triangular waveforms, the origin of time can be chosen to make the waveforms symmetric or antisymmetric in time. The Fourier expansion can then be expressed in terms of the even cosine or odd sine functions,

$$f(t) = \sum_{n=0}^{\infty} \left\{ \begin{array}{l} a_n \sin(n\omega_1 t) \\ \text{or} \\ b_n \cos(n\omega_1 t) \end{array} \right\} \,, \tag{15.23}$$

with corresponding coefficients given by

$$\begin{pmatrix} a_n \\ b_n \end{pmatrix} = \frac{2}{T} \int_0^T f(t) \begin{pmatrix} \sin(n\omega_1 t) \\ \cos(n\omega_1 t) \end{pmatrix} \mathrm{d}t \,, \tag{15.24}$$

where n is now restricted to positive integer values. The factor 2 is replaced by unity for the zero frequency average component b_0.

The first few terms of the square, sawtooth and triangular waveforms are listed in Table 15.2. The origin of time has been selected to make the waves odd-functions of time, as illustrated in Fig. 15.6, with the Fourier series only including sine terms. The Fourier compo-

nents at integral multiples of the fundamental repetition frequency are referred to as partials, harmonics, or overtones. The nth partial has a frequency $f_n = n f_1$. This differs from the terminology used by musicians, who refer to f_2 as the first harmonic or overtone. Interestingly, a waveform depends critically on the sign (phase) of the individual Fourier components. In contrast, the ear is largely insensitive to the phase of the individual partials, with little change in the perceived sound when the sign or phase of a component partial is changed, though the waveforms will be very different.

For an arbitrarily chosen origin of time, the Fourier expansion will include both sine and cosine terms. The energy or intensity is proportional to the resultant amplitudes squared, $a_n^2 + b_n^2$, which is independent of the origin of time. The phase ϕ_n is given by $\tan^{-1}(b_n/a_n)$. The spectrum of a waveform is often plotted in terms of the modulus of the amplitude as a function of frequency, without reference to phase, as in Fig. 15.6. However, measurements of both amplitude and phase are important in any detailed comparison with theoretical models and in analytic measurements, such as modal analysis.

The square and sawtooth waveforms are closely related to the waveforms excited on bowed and plucked

Table 15.2 Fourier expansions of the square, sawtooth and triangular waveforms

Square	$\dfrac{4}{\pi}\left(\sin \omega_1 t + \dfrac{1}{3}\sin 3\omega_1 t + \dfrac{1}{5}\sin 5\omega_1 t \dots\right)$
Sawtooth	$\dfrac{2}{\pi}\left(\sin \omega_1 t - \dfrac{1}{2}\sin 2\omega_1 t + \dfrac{1}{3}\sin 3\omega_1 t - \dfrac{1}{4}\sin 4\omega_1 t \dots\right)$
Triangular	$\dfrac{2}{\pi}\left(\sin \omega_1 t - \dfrac{1}{3^2}\sin 3\omega_1 t + \dfrac{1}{5^2}\sin 5\omega_1 t \dots\right)$

strings and loudly played notes on wind and brass instruments. The discontinuities in waveform generate a very rich harmonic spectrum with Fourier components or partials that decrease relatively slowly (as $1/n$) with increasing n. The strong higher partials give a much harsher and more penetrating sound than simple sinusoids, which is why the oboe, which has a sound that is very rich in higher partials, is used to sound concert A when an orchestra tunes up. In contrast, the partials of the triangular wave, with discontinuities in slope instead of amplitude, decrease more rapidly as $1/n^2$, with a resultant sound little different from that of a simple sinusoidal wave.

Note the large difference between the sound of a sawtooth waveform, which is closely related to the
Fig. 15.7 Short-period samples of clarinet (D#4) and bowed violin (G3) tones and the corresponding Fourier spectra. The *vertical scales* are linear

sound of an oboe in having a complete set of harmonic components, and the *hollow* sound of the square waveform, which is more like the sound of the lowest notes on a clarinet, with rather weak even-integer harmonics or overtones on its lowest notes (Fig. 15.7).

Musical Waveforms and Spectra

The waveforms produced by musical instruments are generally far more complicated than the above simple examples, as already illustrated for an oboe note in Fig. 15.3. Waveforms and associated spectra of the clarinet note D#4 (309 Hz) and the violin bowed open-G-string G3 (195 Hz) are illustrated in Fig. 15.7. These are simply representative waveforms. Unlike the impression given in some elementary textbooks, there is no such thing as a defining violin or clarinet waveform or spectrum. Both the waveforms and the spectra change significantly from one note to the next – and even within a note when played with vibrato, particularly on stringed instruments. Despite the complexity of the waveforms, any repetitive waveform can be described as a linear superposition of sine waves, with frequencies that are integer multiples of the fundamental, as illustrated by the spectra.

Plotting the amplitudes of the Fourier coefficients on a linear scale often highlights the physical processes involved in the production of the sound. For example, the relatively small amplitudes of the second harmonic or partial in the sound of the clarinet reflects the absence of even-n modes of a cylindrical tube closed at one end, which approximates to that of the clarinet. Similarly, the small amplitude of the first partial in the sound of a violin reflects the absence of efficient radiating modes at low frequencies. However, because of the very wide dynamic range of hearing (a factor of $\approx 10^{10}\text{--}10^{12}$ in intensity), it is often more appropriate to plot the Fourier coefficients in decibels on a logarithmic scale. Figure 15.8 shows the spectrum for clarinet and violin notes re-plotted on a dB scale, which illustrates the strength of all the partials over a very wide dynamical range. For bowed instruments such as the cello, well over 40 harmonic partials can be identified below 8 kHz. The sound of an instrument will be determined by all such components and not simply by the fundamental, which may make a relatively small contribution to the perceived sound. This is illustrated for a scale played on the violin with each note first played as recorded and then with the fundamental component removed by a digital filter (audio |?⟩ **EXTRAS**). The lowest notes of the scale, for which the fundamental component is already very weak, are little affected by the removal of the fundamental com-
Fig. 15.8 Typical spectra for a clarinet and violin note plotted on a dB scale illustrating the large number of harmonics or overtones excited by bowed and blown instruments

ponent; however, the sound gets progressively *thinner* in the second half of the scale for notes for which the fundamental partial makes an increasingly significant contribution to the *richness* or *warmth* of the sound.

Transient and Non-Repetitive Tones

No musical note lasts for ever, so that musical sounds are all, to some extent, transient. Moreover, the sound of many percussion instruments is composed of many strongly inharmonic partials, with no regime in which the waveforms can be considered even quasi-repetitive. Nevertheless, one can still use the Fourier theorem to extract the spectrum of such a note, by considering each transient signal as one of a sequence of such transients repeated, say, every second, minute or even year. The spectrum of such a repeated waveform will therefore involve frequency components at integer multiples of the inverse repetition period, which we can make as long as we choose. In the limit of infinitely long repetition times, the Fourier series of a nonrepeating waveform can therefore be replaced by a continuous spectral dis-

tribution over all possible frequencies, known as the Fourier transform $F(\omega)$,

$$f(t) = \int_{-\infty}^{\infty} F(\omega) e^{i\omega t} \, dt \, , \qquad (15.25)$$

where

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) e^{-i\omega t} \, dt \, . \qquad (15.26)$$

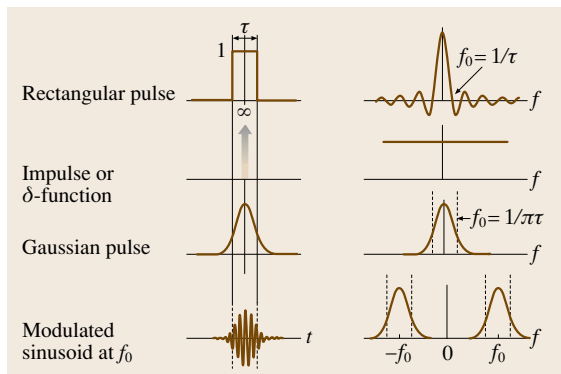
The Fourier transform spectra of important nonrepetitive waveforms are shown in Fig. 15.9. In all cases,


Fig. 15.9 Fourier transforms of transient waveforms

the width Δf of the Fourier spectrum is inversely proportional to the length τ of the input waveform, with $\Delta f \tau \approx 1$. For a rectangular pulse, the spectrum extends over a rather wide frequency range with the first zero when $f\tau = 1$, but with many ripples of decreasing amplitude extending to higher frequencies. For an impulse of negligible width (the delta-function), the spectrum is flat out to very high frequencies. The spectrum of a Gaussian waveform varying as $\exp[-(t/\tau)^2]$ is also a Gaussian proportional to $\exp[-(\pi f \tau)^2]$, with a width $\Delta f = 1/\pi\tau$. Similarly, the spectrum of a sinusoidal waveform with a Gaussian envelope of width τ is broadened by $\Delta f = 1/\pi\tau$.

Any waveform that involves variations on a time scale τ will have Fourier components extending out to frequencies $\approx 1/\tau$. To reproduce such waveforms faithfully, the bandwidth of any recording or reproduction system must therefore extend to frequencies of at least $1/\tau$. Examples of nonrepetitive waveforms and their associated spectra are illustrated in Fig. 15.10 for an orchestral rattle, a cymbal crash and timpani.

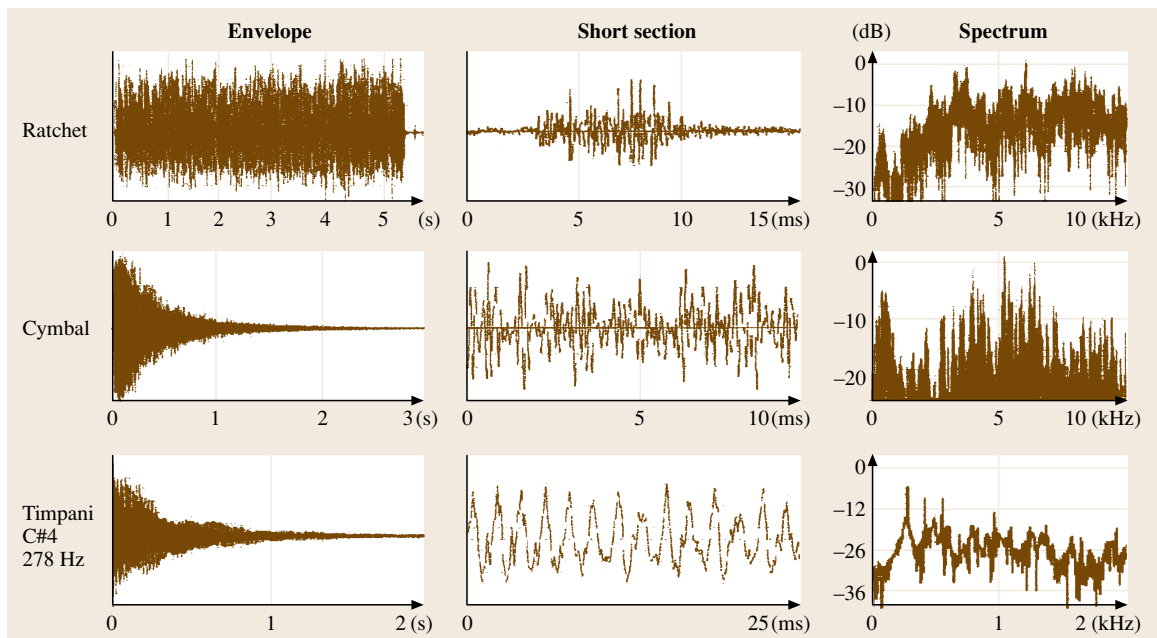
The ratchet sound consists of a sequence of short *clicks* illustrated by the selected short-section waveform. The spectrum is very broad with no individual frequencies particularly dominant. The crash of a cymbal generates a very large number of very closely spaced resonances, which appear as a fairly random set of


Fig. 15.10 Envelope, typical short-period waveform and spectrum for the sounds of a ratchet, cymbal and timpani

peaks giving an overall broadband spectrum. The timpani spectrum shows a small number of large peaks corresponding to the prominent modes of vibration of the drum head, superimposed on a very wide-band spectrum largely associated with the initial transients involving sound from all parts of drum.

Digital Recording

Nowadays almost all sound is recorded digitally using an analogue-to-digital converter (ADC). This converts the continuously varying analogue input signal into a stream of numbers, which can be recorded digitally on a computer or compact disc. Audio signals are typically recorded at a sampling rate of 44.1 kHz with 16-bit resolution corresponding to 1 part in 2^{16}. This allows signals to be recorded in 65 536 equally divided levels between the maximum positive and negative input signals (i. e. between ± 32.8 k levels).

For the highest-quality digital recordings, even faster recording rates with higher-bit resolution are used (typically 24-bit sampling at 96 kHz). This allows for over-sampling of the recorded signal, so that signals can be averaged, any errors detected and eliminated, and filtered more easily. As already noted, the dynamic range of human hearing can be as large as 100 dB. To exploit such a large range and to capture the details of both loud and soft sounds from a large orchestra accurately requires the recording system to have a large dynamic range. Table 15.3 shows the dynamic range in terms of the number of bits used to record the sound. Audio |?⟩ EXTRAS illustrates the greatly enhanced signal-to-noise ratio and hence increased dynamic range when sound is recorded at 16-bit rather than 8-bit resolution.

Aliasing

When sound is recorded digitally, ambiguities can arise when any of the input frequencies is larger than half the sampling rate f_D. This is known as the Nyquist limit $f_{Nyquist} = f_D/2$. For example, if a 2 kHz sine wave were to be sampled at 2 kHz, the digital signal would be recorded at exactly the same point of the waveform each cycle. The recorded digital signal would then be

indistinguishable from a DC signal. It can easily be shown that sinusoidal inputs at $f_{Nyquist} + \Delta f$ give the same digital output as at $f_{Nyquist} - \Delta f$ and that the recorded signal is the same for all frequencies differing in frequency by the digitising frequency, $2 f_{Nyquist}$. Thus for a steadily increasing input frequency the digital output is equivalent to that of a frequency which first increases up to $f_{Nyquist}$ then decreases to zero when $f_{in} = f_D = 2 f_{Nyquist}$, with the process repeating for higher input frequencies, as illustrated in Fig. 15.11. In any replay system, an analogue output is generated that assumes a smooth curve between the sampled points. Hence, recorded frequencies above the Nyquist limit will be misinterpreted and will produce sounds below $f_{Nyquist}$ with no harmonic relevance to the original input.

This ambiguity is illustrated in audio |?⟩ EXTRAS , in which a sinusoidal input is swept in frequency from 200 Hz to 6 kHz. This is first recorded at 22.05 kHz, when aliasing is not a problem, and then at 6 kHz, when halfway through the increasing frequency signal, at 3 kHz, the replayed sound starts to descend to zero frequency at the end of the sweep, when the input signal has the same frequency as the sampling rate. The single-frequency sweep is then followed by an ascending major triad (with intervals in the ratios $1 : 5/4 : 3/2$) recorded at 6 kHz, which illustrating the severe problems of aliasing in terms of musical harmonies, as soon as any of the higher-frequency components in a signal exceed the Nyquist limit, with the frequency of some partials ascending while others are descending.

To avoid such problems, a high-frequency cut-off input filter is generally used, with a cut-off frequency slightly below the Nyquist frequency (see Chap. 14 by *Hartmann* for further details).

Fig. 15.11 Ambiguity of digital output for a steadily increasing frequency exceeding the Nyquist limit

Table 15.3 Dynamic range of an analogue-to-digital converter (ADC)

N-bit ADC	Dynamic range $\pm 2^{n-1}$	Dynamic range (dB)
8 bit	128	42
16 bit	32.8 k	90
24 bit	8.39 M	138

Table 15.4 Decoded WAVE file information

Data provided	Typical example
Mono (1), stereo (2)	2
Data acquisition rate	2.205×10^4
Resolution in bits	16
Data per second	4.41×10^4
First measurement from left channel	237
Simultaneous measurement from right channel	-1356
Second measurement from left channel	456
Simultaneous measurement from right channel	-1972
Repeated sequence until end of recorded sound	. . .

Sound File Formats

A sound signal is frequently recorded and stored as an encoded WAVE file of the generic form *.wav, which includes additional information on data acquisition rate, stereo or mono format and bit resolution. The decoded structure of a WAVE file is shown in Table 15.4.

Recording audio signals as WAVE files is very expensive in memory, with 1 hour of stereo music recorded at 22 kHz requiring ≈ 300 MB. Music files on CDs are encoded so that the input is redistributed over time and therefore over the surface of the disc. This enables the original signal to be reproduced even in the presence of dust, scratches and other small imperfections on the disc surface, eliminating the clicks that were a familiar feature of older vinyl records. More sophisticated, adaptive, encoding schemes can be used to significantly reduce the amount of memory used, such as the now widely used mp3 format. An algorithm is used, based on physical principles and on the way the ear responds to musical sounds, to continuously analyse and process the incoming data. The input data can then be recorded using a much reduced number of bits, in much the same sort of way that digital pictures are encoded more efficiently in ZIP files and compact image formats. The information used to encode the digital signal is also recorded, so that the processed data can be unscrambled on playback with relatively little loss in perceived quality.

Discrete Fourier Transform

The digital form of the recorded data allows certain computational efficiencies in calculating the Fourier spectrum. Consider a recorded sample of N measurements, corresponding to a sample of length $T_s = N/f_D$. To calculate the spectrum, this data set is assumed to repeat indefinitely, to form a continuous waveform with a repetition frequency. From the Fourier theorem, the resulting spectrum is composed of Fourier components that are exact multiples of the repetition frequency, so that $f_n = n/T_s$. Hence, a 1 s set of data points will give a discrete Fourier spectrum with frequencies at $1, 2, \ldots n \ldots$ Hz. In practice, the number of Fourier components is limited to $N/2$, because each component has both an amplitude and a phase, which requires at least two independent measurements to be made per Fourier component.

Windowing Functions

Using the sampled waveform to form a continuously repeating waveform will, in general, introduce a repeating discontinuity Δ at the beginning and end of each repeated data set, since the start and end values will not usually be the same. Any such discontinuity will generate spurious contributions to the spectrum, with additional Fourier coefficients with amplitudes proportional to Δ/n. To circumvent this problem, a *windowing function* is used. This applies a smooth envelope to the data set, which reduces the values at the start and end to zero, thus eliminating the discontinuities. However, as described above, the application of such an envelope will give an extra width $\Delta f \approx 1/T_s$ to the spectral features.

A typical windowing function is the Hanning function $\sin^2(2\pi t/T_s)$. A number of other windowing functions are illustrated in Fig. 15.12, each of which has advantages for specific applications [15.14]. The Hanning windowing is widely used for general-purpose measurements, while the Hamming function is used to separate closely spaced sine waves. In general there is a trade-off between the accuracy that can be achieved in
Fig. 15.12 Representative windowing functions (after [15.14])

determining the frequency of individual spectral components and the width of the low-amplitude side lobes generated by application of a windowing function. Various forms of the Blackman–Harris windowing function can be used to optimise the fast Fourier transform (FFT) for specific measurements. Windowing need not be used for the accurate measurements of widely separated sinusoidal waves with similar amplitudes, though one should be aware of the existence of the rather wide side lobes generated unless the sampling period is an exact integer multiple of the period of the waveform being measured.

Fast Fourier Transform (FFT)

To determining the amplitude and phase of the $N/2$ Fourier components from N input measurements requires the inversion of an $N \times N$ matrix, requiring a computation time proportional to N^2. However, if N is an integral power of 2 (e.g. $2^8 = 256$, $2^{16} = 65\,536$), the FFT computing algorithm can be used to reduce the computing time by many orders of magnitude (by

Fig. 15.13 A typical digital sampling and FFT analysis scheme
Fig. 15.14 Time sequence of delayed FFTs illustrating the decay of excited modes of a violin, when the A-string is plucked, with an expanded section of the frequency scale for the lowest resonances excited. The time between successive traces is 10 ms

a factor $\approx N/\log N$). The speed of modern computers is such that FFT spectra of the sound of musical instruments can be calculated and displayed with delays of only a few milliseconds, though any such delay will always be limited by the length and hence frequency resolution of the data set being analysed.

A typical implementation of the FFT method for spectral analysis is shown schematically in Fig. 15.13. An input anti-aliasing filter is first used to remove frequency components above the Nyquist limit $f_D/2$; an ADC then converts the incoming signal to a digital output to give a data set of $N = 2^n$ measurements over a time $T = N/f_D$. A windowing function removes problems from discontinuities at the start and end of the recorded set of data, and the computer evaluates the FFT giving the amplitudes and phases of the Fourier components at $N/2$ discrete frequencies spaced $1/T = f_D/N$ Hz apart.

A sequence of FFTs from data taken over successive short periods of time can be used to illustrate the decay of individual partials in transient and decaying waveforms, such as those of a plucked string, a piano note or struck bell, as illustrated for the sound of a plucked violin A-string in Fig. 15.14.

Envelopes of Sound Waveforms

The time dependence or envelope of the amplitude of a sound signal is just as important a factor in the recognition of any musical instrument as the spectrum of the sound produced. In general, the envelope has a starting transient, a period with a quasi-constant amplitude for a continuously bowed or blown instrument, and a period of free decay, when the instrument is no longer being excited. The sound produced by musical instruments is also significantly affected by the acoustic environment in which the instrument is played, but this will be ignored for the moment. Typical initial transients and overall envelopes of single notes played on a violin, clarinet and trumpet are shown in Fig. 15.15.

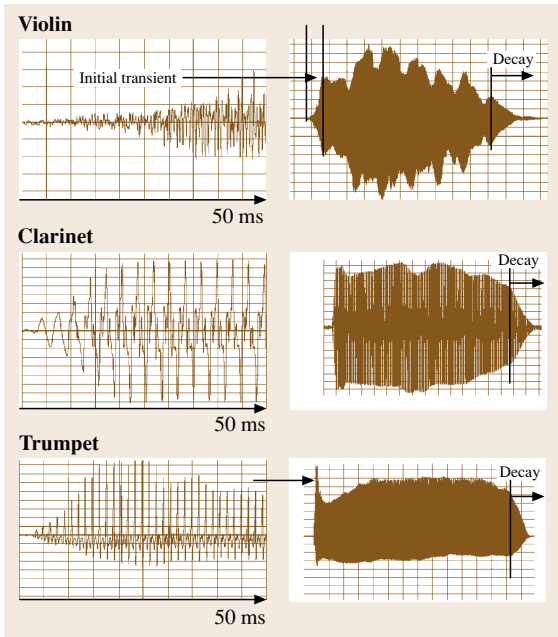
The starting transient provides an immediate clue to the ear enabling the listener to recognise the instrument being played quickly. However, the characteristic fluctuations in frequency and amplitude within the overall envelope and noise associated with the method of excitation (e.g. bowing and blowing) are just as important in the recognition of specific instruments. This can easily be shown by removing the starting transient from a musical sound altogether, as illustrated in |?〉 **EXTRAS** . In this example comparisons are made between the sounds of a violin, flute, trombone and oboe played first with the initial 200 ms transient removed and then


Fig. 15.15 Typical wave envelopes for a violin, clarinet and trumpet with a 50 ms expanded view of the initial starting transient

with the transient reinserted. In each case the instrument can immediately be identified even in the absence of the starting transient. The audio example ends with a constant amplitude sawtooth waveform having an unvarying sound quite unlike the sound of any real musical instrument.

Nevertheless, the starting transient and subsequent decay of sound are extremely important in the identification of the sounds of plucked or hammered strings and all percussion instruments, where the waveform and spectral content changes very rapidly with time after the start of the note. This is illustrated by the dramatic difference in the unrecognisable sound of a piano when played backwards and then replayed in the normal direction (⏸️ **EXTRAS**).

Noise

There are several potential sources of fluctuations in the envelope of musical instruments, which help to characterise their characteristic sounds, such as the breathiness induced by the noise of turbulent air passing over the sound hole in a recorder, flute or organ pipe (*Verge* and *Hirschberg* [15.15]) and irregularities in the sound of any bowed instrument due to inherent noise in the slip–stick bowing mechanism (*McIntyre* et al. [15.16]).

Amplitude and Frequency Modulation

Another important source of fluctuations is vibrato, which involves periodic changes in the amplitude, frequency, or spectral content of a note and often all three (*Meyer* [15.17], *Gough* [15.18]). Vibrato is produced on a stringed instrument by periodically changing the length of the bowed string by rocking the finger stopping the string backwards and forwards. In singing (*Prame* [15.19]) and wind instruments (*Gilbert* et al. [15.20]) vibrato is produced by periodic modulations of the pressure exerted by the lungs or mouth on the exciting reed or air passage.

Amplitude modulation of a sinusoidal frequency component can be expressed as

$$y(t) = (1 + a_m \cos \Omega t) \sin \omega t$$
$$= \sin \omega t + \frac{a_m}{2} [\sin(\omega + \Omega)t + \sin(\omega - \Omega)t] ,$$
(15.27)

where Ω is the modulation frequency and a the modulation parameter. Amplitude modulation introduces two *side-bands* with amplitude $a_m/2$ at frequencies Ω above and below that of the principal central component. The side-bands have a net resultant that remains in phase with the central component giving a fractional change in amplitude $[1 + a_m \cos \Omega t]$.

Frequency modulation should more strictly be referred to as phase modulation, with the phase varying as

$$\phi(t) = \omega t + a_f \cos \Omega t .$$
(15.28)

where a_f is frequency-modulation index. The time-varying frequency can then be defined by the rate of change of phase, such that

$$\frac{d\phi}{dt} = \omega - a_f \Omega \sin \Omega t ,$$
(15.29)

with a fractional shift in frequency varying as

$$\frac{\Delta\omega(t)}{\omega} = -a_f \frac{\Omega}{\omega} \sin \Omega t .$$
(15.30)

For small modulation index, a phase-modulated wave can be written as

$$y(t) = \sin \omega t + \frac{a_f}{2} [\cos(\omega + \Omega)t + \cos(\omega - \Omega)t] ,$$
(15.31)

which again results in equally spaced side-bands about the central frequency with amplitude $a_f/2$, but with a resultant now in phase-quadrature with that of the central frequency giving the above phase modulation.

Because of the multi-resonant frequency response of all musical instruments, changes in driving frequency

also induce significant fluctuations in amplitude. Such fluctuations are particularly important for the strongly peaked multi-resonant instruments of the violin family, as illustrated in Fig. 15.15.

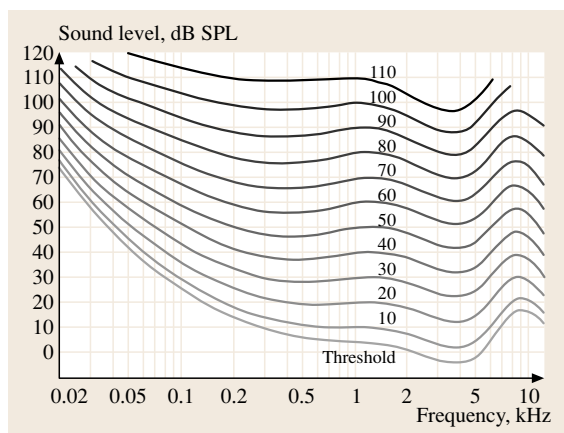
15.1.4 Perception and Psychoacoustics

In this section, we briefly highlight a number of psychoacoustic aspects of particularly importance in any discussion of musical acoustics. See also Chap. 13 on Psychoacoustics by *Brian Moore*.

Sensitivity of Hearing

We have already commented that the brain interprets both frequency and intensity on a logarithmic scale. The recognition of familiar intervals such as the octave, perfect fifth, irrespective of the absolute frequencies, provide an immediate example, as is the use of the dB scale in the measurement of sound levels.

In the 1930s, *Fletcher* and *Munson* [15.22] undertook a survey of a large population of subjects to investigate how the sensitivity of the ear varies with frequency and intensity (and age). These measurements were later refined by *Robinson* and *Dadson* [15.21]. Their published values for normal equal-loudness level contours, shown in Fig. 15.16, were adopted by the International Standards Organization, as the original ISO 226 standard for audio sensitivity, with data recently refined to define the new ISO 226:2003 standard.

The plotted curves show population-averaged equal loudness contours for sinusoidal sound waves measured in phons on a dB scale, which equate to sound pressure level (SPL) measurements in dB at 1 kHz. The SPL dB scale is based on a reference root-mean-square pressure of $20\,\mu\text{Pa}$ (equivalent to $2\times10^{-5}\,\text{Nm}^{-2}$), which is very close to an qintensity of $10^{-12}\,\text{Wm}^{-2}$. The threshold contour is the population-averaged minimum sound pressure that can be just detected under the quietest environmental conditions. Above sound pressures of $\approx 120\,\text{dB}$, the ear experiences pain and potential permanent damage.


The equal subjective sound level contours reflect the dynamics of the ear's detection system. There is a rapid fall-off in sensitivity at low frequencies, where the efficiency of the outer ear drum considered as a piston detector falls off as ω^4. The fall-off at high frequencies is due to the increasing inertial impedance of the ear drum and bones in the inner ear. However, the fall-off is partially compensated by peaks in sensitivity from the resonances of the outer air channel between the ears and ear-drum. Older people experience a considerable loss in sensitivity at high frequencies, which is strongly correlated with age. Fortunately, the losses are at relatively high frequencies and are generally not too important for the appreciation of music.

The sensitivity of the ear is particularly strong in the frequency range 2–6 kHz, which is important for recognising the consonants in speech. One would therefore expect such frequencies to be equally important in the identification and assessment of sound quality of musical instruments. Below around 200–400 Hz there is an increasingly rapid fall-off in sensitivity, which will differentially affect the subjective loudness of the lower partials of any complex musical sound at these and lower frequencies. At low frequencies the contours of equal amplitude are more closely spaced, so that the effect of increasing the SLP by 20 dB increases the subjective loudness by considerably more. Turning up the volume on any reproduction system changes the perceived quality from a rather thin sound to a more exciting sound with a much stronger bass and a somewhat stronger high-frequency response.

From a musical acoustics viewpoint, it is often sensible to invert the equal contour plot, as the inverted plot essentially acts as a subjective, mid-frequency band filter, de-emphasising the perceived intensities of the lowest and highest-frequency partials in a complex waveform.

Loudness levels will clearly vary with distance from any source. Sounds levels exceed 120 dB close to an aeroplane on take off or close to a loudspeaker in a noisy rock concert, resulting in potential permanent damage

Fig. 15.16 *Robinson–Dadson* curves (after [15.21]) with contours of perceived equal loudness measured in phons on a dB scale

to the ear. Sound levels close to a heavily used motorway are typically around 90 dB, around 70 dB inside a car, about 50 dB in an office, 30 dB inside a quiet house at night, 20 dB in a very quiet recording studio and 0 dB inside an anechoic chamber. At the quietest levels, one begins to hear the beating of the heart and workings of other internal organs, which can be a somewhat disquieting experience. There would clearly be no evolutionary reason to have developed a more sensitive hearing system.

Audio |?〉 EXTRAS is a short orchestral excerpt played at successively decreasing 6 dB steps (half the amplitude or a quarter the intensity). Musicians indicate the loudness with which music should be played using the dynamic markings *pp*, *p*, *mp*, *mf*, *f* and *ff*, which roughly correspond to a subjective doubling of intensity between each level. Such levels are clearly only relative, since absolute values will vary strongly with the distance of the listener from the source with a 12 dB decrease in intensity on doubling the distance in free space. Although the dynamic range of an individual note on a musical instrument rarely exceeds 20 dB, with only about six distinguishable dynamic levels within this range, the total dynamic range of an instrument is more like 45 dB (*Patterson* [15.23]). However, there is a much larger range of sounds produced by different instruments (e.g. the trombone and violin. The carrying power, penetration and prominence of musical sounds is not simply a matter of absolute intensity, but also depends on the harmonic content and transient structures of the complex tones produced. This helps to explain how a solo violinist can still be heard over the massive sound of a large orchestra.

Subjective Assessment of Pitch

We have already noted that the perceived pitch of a note is determined by the inverse period of a waveform and does not necessarily require the presence of a Fourier component at that frequency. This is illustrated in audio |?〉 EXTRAS , in which simple sinusoidal tones at 300 Hz and 200 Hz are first played in succession and then played together to produce a repeating waveform sounding an octave lower at 100 Hz, which is then followed by a pure 100 Hz tone of the same amplitude but sounding very much quieter. The final sinusoidal tone at 100 Hz may well not be heard on a typical PC laptop or notebook sound production systems, which radiate little sound below around 200 Hz. The absence of a Fourier component at the pitch of a complex tone is often referred to as the *missing fundamental* phenomenon. It is important in many stringed instruments, which produce very little sound at the actual frequency of their lowest open strings.

The missing fundamental phenomenon is a psychoacoustic rather than a nonlinear effect produced by a distortion of the waveform in the ear. It reflects the way that the ear processes sounds in the time domain at low frequencies (*Moore* [15.24] and Chap. 13).

The ability of the ear to recognise the pitch at which an instrument is playing, even though the lower partials of the sound of individual instruments may be missing is very important in sound reproduction systems. It enables the listener to recognise the distinctive sounds of all the instruments in an orchestra, even when the recording or reproduction system may have a very poor low-frequency response – as in early gramophones and the loudspeakers used in cheap radios and typical PC laptops and notebooks.

Combining tones to produce a lower tone is exploited on the *quint* combination stop on the organ to produce low-pitched sounds (e.g. a 16 ft pipe and a $16 \times 2/3 = 10.66$ ft pipe sounding a fifth above, when sounded together, reproduce the sound of a 32 ft pipe, as illustrated for the combination of 200 and 300 Hz sine waves in |?〉 EXTRAS above). Interesting, the effect is nothing like so strong in playing two bowed strings a fifth apart (e.g. open A and open E on a violin), presumably because of the very rich spectrum of higher partials and independent fluctuations of the two sounds. However, such sounds can often be heard when two flutes play well-tuned intervals together. The early 18th century virtuoso violinist Tartini recognised the existence of such mysterious tones, whenever pairs of notes were played together in exact intonation (e.g. integer ratios such as 3/2 (perfect fifth), 5/4 (major third), 6/5 (major third)), and reputedly attributed them to the devil. The effect is small, but is still used by violinists when practising playing such intervals exactly in tune.

In general, complex tones are composed of a number of spectral components which have no particular harmonic relationship to each other. One then has to consider what determines the subjective pitch of the perceived sound. This involves the way the brain processes the signal and the relative emphasis given to the spectral components present, which will depend on their frequencies and intensities. It is important to recognise that the perceived pitch is not necessarily that of the lowest-frequency component present. This is illustrated in |?〉 EXTRAS in which the fundamental and first octave are fixed in frequency, while an intermediate partial is swept upwards from the lower to the higher note. First the fundamental is sounded by itself and then with

the octave added producing a note at the same pitch but with a different timbre. An intermediate partial is then added and swept upwards in steps from the lower to the upper note, giving the sense of a note of continuously rising pitch, though the fundamental and its octave remain fixed. Although the fundamental and octave remain fixed, the rising partial gives the sense of a note of increasing pitch. In this particularly simple example, it is relatively easy to identify and follow the pitch of each harmonic component separately. However, for a musical instrument like a gong or bell, with no preconceived knowledge of the likely pitch of the individual partials, this is far more difficult. The perceived pitch of the strike note of a bell and many other percussion instruments, with an inharmonic combination of excited modes, depends in a rather complex way on the relative weighting of the partials present and the musical context.

In assessing the subjective pitch of a note there can often be an ambiguity of an octave in the apparent pitch. This is illustrated by the famous example of the apparent, ever-rising pitch of a note generated by a continuously rising comb of logarithmically spaced frequencies passing through a fixed hearing band of frequencies, |?⟩ EXTRAS [15.25], which appears to be increasing in pitch at all times though clearly repeating itself. This illustrates the *circularity* of pitch perception and is the audio equivalent of the visual illusion of continuously rising steps which return to the same point in space in an Escher drawing.

Precedence Effect

Another important time-domain phenomenon in the perception of musical sounds is the Haas precedence effect, which enables a listener to locate the source of a distant sound from the small difference in time that sound arriving at an angle to the head takes to reach the two ears. The brain gives precedence to the sound arriving first, even though later sounds from other directions may be significantly stronger. Any sound arriving within the first 20–40 ms (depending somewhat on frequency and intensity) of the first sound to arrive simply adds to the perceived intensity of the first sound. This is very important in musical performance, with reflections from close reflecting surfaces adding strongly to the intensity and definition of the music.

The precedence effect is illustrated in |?⟩ EXTRAS . This is a stereo recording of identical clicks recorded on the left and right channels with a delay of 20 ms between them, which is then reversed. Although the clicks are too close together for the ear to distinguish them separately, when replayed through a pair of stereo loudspeakers (not earphones), the sound will appear to come from the speaker providing the earlier click.

The precedence effect is one of the ways in which one can locate the origin of a particular sound within an orchestra or the sound of a particular voice in a crowded room. Once located, the brain is able to focus on the subsequent source even against a highly confusing background of other sources. It is likely that fluctuations within the characteristic sound of an individual person or musical instrument enable the brain to focus continuously on a particular source. In musical acoustics one must always recognise the formidable power of the brain's auditory processing capabilities, which is far beyond what can be achieved using present-day computers. Consequently, even very small effects on a physical measurement scale can have a very significant effect on the listener's subjective response to the sound of a particular instrument.

15.2 Stringed Instruments

In this section we describe the production of sound by the great variety of musical instruments based on the plucking, bowing and striking of stretched strings. This will include an introduction to the different modes of string vibrations excited by the player, the transfer of energy from the vibrating string to the acoustically radiating structural vibrations of the body of the instrument via the bridge, and the modification of such sound by the environment in which the instrument is played. Although the production of sound is based on the vibrations of relatively simple structures, such as strings and plates, it is the interactions between these, extending the

physics well beyond introductory text-book treatments, which results in the characteristic sounds of individual stringed instrument, as summarised in this section.

The Physics of Musical Instruments by *Fletcher* and *Rossing* [15.5, Chaps. 9–11] provides an authoritative account of the acoustics of a wide range of string instruments, and a comprehensive set of references to the research literature prior to 1998. The four volumes of research papers on violin acoustics, collated and edited by *Hutchins* [15.26, 27] and *Hutchins* and *Benade* [15.28], also includes excellent introductions to almost every aspect of the acoustics of instruments of the violin family,

much of which is just as relevant to other stringed instruments. Carleen Hutchins has been an inspirational figure in the field of violin acoustics. The Catgut Acoustical Society, which she cofounded, published a journal and an earlier newsletter [15.29] containing many important papers on violin research of interest to both professional acousticians and violin makers. Her inspiration has encouraged a world-wide school of violin makers, who use scientific measurements and plate tuning in particular as an aide to making high-quality instruments. The comprehensive monograph on the *Physics of the Violin* by *Cremer* [15.30] provides an invaluable theoretical and experimental survey of research on instruments of the violin family, with particular emphasis on the bowed string, the action of the bridge, the vibrations of the body and the radiation of sound.

The production of sound by any stringed instrument is based on the same acoustic principles. The player excites the vibrations of a stretched string by bowing, plucking or striking. Energy from the vibrating string is then transferred via the supporting bridge to the acoustically radiating structural vibrations of the instrument. The radiated sound is then conditioned by the performing environment.

There are many different types of stringed instruments formally classified as chordophones. Harp-like lyres appear in Sumerian art from around 2800 BC. However, more primitive instruments, like a plucked string stretched over a bent stick and resonated across the mouth, probably date back to soon after the emergence of man the hunter [15.31, 32].

Stokes [15.33] was the first to recognise that the vibrating string was essentially a linear dipole, which radiated a negligible amount of sound at low frequencies (see also *Rayleigh* [15.3, Vol. 2, Sect. 341]). To produce sound, the vibrating string has to excite the vibrations of a much larger area radiating surface. For bowed and plucked instruments, such as members of violin, lute and guitar families, almost all the sound is radiated by the shell of the instrument, with the acoustic output at low frequencies usually boosted by the Helmholtz resonance of the air inside the instrument vibrating in and out of the f- or rose-holes cut into the front plate. On larger instruments, such as the piano and harp, the sound is radiated by a large soundboard.

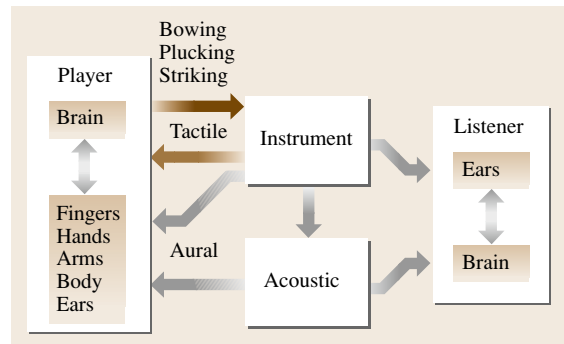
For any continuously bowed (or blown) instrument, the sound is conditioned by a complex feedback loop involving the instrument, player and surrounding acoustic, illustrated schematically for the violin in Fig. 15.17. The expert string player controls the intonation and quality of the sound produced using slight adjustments


Fig. 15.17 A schematic representation of the complex feedback and sound radiation systems involved in the generation of sound by a bowed string instrument

of the position of the left-hand fingers stopping the string, and the pressure, velocity and position of the bow on the string, in response to the sound heard from both the instrument and the surrounding acoustic. In addition, there is direct tactile feedback through the fingers of both the left hand controlling the pitch of the note and the right hand controlling the bow. A similar overall feedback system is also involved in playing woodwind or brass instrument. The perception of the sound by both player and listener is also strongly influenced by the performing acoustic and the way the brain processes the sound received by the sensory organs in the ears, as illustrated schematically in Fig. 15.17. All such factors are involved in determining the perceived quality of the sound produced by a musical instrument. However, for simplicity and physical insight into the various mechanisms involved, it is convenient to consider the acoustics of musical instruments in terms of their component parts, like the vibrating string, the supporting bridge and shell of the instrument. Nevertheless, it is important not to lose sight of the fact that the sound produced by any instrument will involve the interactions of all such subsystems and, even more importantly, the skill of the player in exciting and controlling the vibrations ultimately responsible for the sound produced.

15.2.1 String Vibrations

The transverse vibrations $\xi(x, t)$ of a perfectly flexible stretched string, of mass μ per unit length and tension T, satisfy the one-dimensional wave equation (d'Alembert, 1747)

$$\frac{\partial^2 \xi}{\partial x^2} = \frac{1}{c_\mathrm{T}^2} \frac{\partial^2 \xi}{\partial t^2} \,, \tag{15.32}$$

where the velocity of transverse waves $c_T = \sqrt{T/\mu}$. The tension $T = ES\Delta L/L$, where E is Young's modulus, S is the cross-sectional area of the string and $\Delta L/L$ is the fractional stretching of the string over its length L. For the relatively small transverse displacements of bowed and plucked strings on musical instruments, changes in tension can be ignored. However, at larger amplitudes, a number of interesting nonlinear effects can be observed, which will be described in Sect. 15.2.2.

A string can also support longitudinal and torsional modes, with velocities $c_L = \sqrt{E/\rho}$ and $c_\theta = \sqrt{E/\rho(1+v)}$, where ρ is the density and v is the Poisson ratio (≈ 0.35 for most materials). The Poisson ratio v is the ratio of transverse to longitudinal strain when the material is stretched along a given direction. For strings on musical instruments, the longitudinal and torsional wave velocities are typically an order of magnitude larger than the transverse velocity, with $c_L/c_T \approx \sqrt{L/\Delta L}$.

Although both longitudinal and torsional waves play important roles in the detailed physics of the bowed, plucked and struck string, the musically important modes of string vibration are the transverse modes – apart from unwanted squeaks from longitudinal modes, which are often excited by the beginner on the violin. Unless otherwise stated, we only consider transverse waves and drop the defining subscript, unless a distinction needs to be made.

Waves on an ideal string are dispersionless (independent of frequency), so that any wave initially excited on the string will travel along the string without change in amplitude or shape. D'Alembert obtained a general solution of the wave equation of the form

$$f(x, t) = f_1(x + ct) + f_2(x - ct), \tag{15.33}$$

corresponding to two waves of unchanging shape travelling with wave velocity c in opposite directions along the string.

If the string is supported rigidly at its ends, the propagated waves are reflected with a change in sign giving zero displacement at the nodal end-points. Each propagating wave will continue to be reflected with change of sign on reflection at each end. For a string of length L, the string displacement will therefore return to its initial state in multiples of the transit time $2L/c$. The same is also true for the velocity and acceleration waveforms, since, if f satisfies the wave equation, then so must all its temporal and spatial derivatives, $\partial^n f/\partial x^n$ and $\partial^n f/\partial t^n$. It follows that the repetition frequency of any freely propagating wave on a given length of a stretched string will always be the same, however
Fig. 15.18 Transverse motion of string induced by a localised force, with the *dotted lines* indicating the displacement at an earlier time

the string is excited (e.g. sinusoidally or by plucking, bowing or striking).

Excitation of Vibrations

First consider a string subject to a localised force F applied suddenly at a point along its length. This causes the string to move with velocity v at the point of contact exciting transverse waves travelling outwards in both directions with velocity c, as illustrated schematically in Fig. 15.18.

In a short time δt, the transverse waves travel a distance $c\delta t$ along the string while the string at the point of contact is displaced by a transverse distance $v\delta t$. For $v \ll c$, one can make the usual small-angle approximations, so that equating the applied force to the transverse force from the deformed string, we obtain

$$v = \left(\frac{c}{2T}\right) F = \frac{1}{2R_0} F, \tag{15.34}$$

where $R_0 = \mu c$ is the characteristic impedance (force/induced velocity) of the string, which for an ideal string ignoring intrinsic losses is purely resistive. The factor of two in the above equation arises because the force acts on the two semi-infinite lengths of string in parallel. In practice, any discontinuity in slope will be rounded by the finite flexibility of real strings, as discussed later.

Force on End-Supports

The characteristic resistance R_0 of the string is an important parameter, because it determines the transfer of energy from the vibrating string to the acoustically radiating modes of the instrument via the supporting bridge at the end of the string. The transverse force exerted by the string on an end-support at the origin can be written as $F_B = T(\partial \xi/\partial x)_0$. This induces a transverse velocity at the point of string support given by

$$v_B = \frac{1}{Z_B} F_B = A_B F_B, \tag{15.35}$$

where Z_B and A_B are the frequency-dependent characteristic impedance and admittance at the end-support. In

general, the induced velocity at the point of string support on the supporting bridge will differ in phase from that of the driving force, so that $Z(\omega)$ and $A(\omega)$ will be complex quantities.

The bridge on a musical instrument is never a perfect node otherwise no energy could be transferred to the radiating surfaces of the instrument. Waves on the string are reflected at the bridge with a frequency-dependent reflection coefficient r and a fractional loss of energy ε given by

$$r = \frac{R_0 - Z_B}{R_0 + Z_B} \quad \text{and} \quad \varepsilon = \frac{2R_0\left(Z_B + Z_B^*\right)}{|R_0 + Z_B|^2}, \qquad (15.36)$$

where Z_B^* is the complex conjugate of the complex impedance at the terminating bridge.

For strings on musical instruments, $R_0 \ll |Z_B|$, so that to a first approximation we can consider the bridge as a node. If this were not so, the vibrational frequencies of strings would by strongly perturbed from their harmonic values. Nevertheless, first-order corrections are important, as they determine the energy transfer from the strings to the body of the instrument and hence the intensity of the radiated sound. The coupling via the bridge also affects the string vibrations themselves, with the resistive losses at the bridge causing damping and the reactive component of the admittance perturbing their vibrational frequencies, as described in Sect. 15.2.3. Such perturbations can sometimes be so large that it is no longer possible to sustain a stable bowed note, resulting in what is known as a *wolf-note* (for an illustration of a bad wolf-note on the cello listen to |⟩ EXTRAS).

Before considering the interaction of real strings with the supporting structure, we first consider the simplest cases of sinusoidal and simple Helmholtz modes of vibration on an ideal string with perfectly rigid end-supports.

Sine–Wave Modes

An ideally flexible string stretched between rigid end-supports a distance L apart can support standing waves, or eigenmodes, with transverse string displacements given by

$$\xi_n(x, t) = a_n \sin\left(\frac{n\pi x}{L}\right) \cos\left(\omega_n t + \phi_n\right), \qquad (15.37)$$

where $\omega_n = 2\pi f_n$ and a_n is the amplitude of the nth mode with frequency $f_n = nc/2L$ and phase ϕ_n. Such modes can be considered as the sum of two sine waves of the d'Alembert form (15.33) travelling in opposite directions. For an ideal string, these solutions form a complete orthogonal set of *eigenmodes* with

a *harmonic set* of *eigenfrequencies*, which are integer multiples of the fundamental frequency $c/2L$.

The resonant response of individual modes of a metal or metal-covered string can be investigated, for example, with a photosensitive device to detect the transverse string motion induced by a sinusoidal current passing through the string placed in a magnetic field to give a transverse Lorentz force (*Gough* [15.34]).

Because the wave equation is linear, any waveform, however excited, can be described as a Fourier sum of harmonic modes, such that

$$\xi_n(x, t) = \sum_{n=1}^{\infty} \sin\left(\frac{n\pi x}{L}\right)$$
$$\times \left[A_n \cos\left(\omega_n t\right) + B_n \sin\left(\omega_n t\right)\right], \qquad (15.38)$$

where the Fourier coefficients A_n and B_n are determined by the initial transverse displacement and velocity along the length of the string, so that

$$A_n = \frac{2}{L} \int_0^L \xi(x, 0) \sin\left(\frac{n\pi x}{L}\right) dx, \qquad (15.39)$$

and

$$B_n = \frac{2}{L\omega_n} \int_0^L \frac{d\xi(x, 0)}{dt} \sin\left(\frac{n\pi x}{L}\right) dx. \qquad (15.40)$$

The transverse force on the end-support at $x = L$ is given by

$$F_{\text{end}} = -T\left(\frac{\partial \xi}{\partial x}\right)_L$$
$$= -T \sum_n \left(\frac{n\pi}{L}\right)(-1)^n$$
$$\times \left[A_n \cos\left(\omega_n t_n\right) + B_n \sin\left(\omega_n t\right)\right]. \qquad (15.41)$$

Helmholtz Modes

Although many physicists and most musicians intuitively associate waves on strings with the sinusoidal waves of textbook physics, in practice, the vibrations of a bowed, plucked or struck string are very different. Nevertheless, because such waves are repetitive, it follows from the Fourier theorem that all such solutions can be described as a sum of sinusoidal wave components. However, the motions of plucked, bowed and struck strings are much more easily described by what are known as Helmholtz solutions to the wave equation [15.35]. These are illustrated for the plucked and bowed string in Fig. 15.19a,b.

The Helmholtz solutions are made up of straight-line sections of string. There is no net force acting on
Fig. 15.19a,b Helmholtz waveforms for **(a)** a centrally plucked and **(b)** a bowed string. The *horizontal arrows* indicate the directions that the kinks are travelling in and the *vertical arrows* the directions of the moving string sections. The *different colours* represent string displacements at different times. *P* indicates a typical bowing position along the string

any small segment within any such section, because the transverse tension forces acting on its ends are equal and opposite. By Newton's laws, any such segment must therefore be either at rest or moving with constant velocity. Only where there is a *kink* or discontinuity in the slope between adjacent straight-line sections (equivalent to a δ function in the spatial double derivative) can there be any acceleration. From our earlier discussion, any such kink must travel backwards and forwards along the string at the transverse string velocity c, reversing its sign on reflection at the ends. As the kink moves past a specific position along the string, the difference in the transverse components of the tension on either side of the kink results in a localised impulse, which changes the local velocity of the string from one moving or stationary straight-line section to the next. In general, there can be any number of Helmholtz kinks travelling along the string in either direction, each kink marking the boundary between straight-line sections either at rest or moving with constant velocity. Similar solutions also exist for torsional and longitudinal waves.

We now consider the Helmholtz wave solutions for the plucked, bowed and hammered string in a little more detail.

Plucked String

Consider an ideal string initially at rest with an initial transverse displacement a at its mid-point, as illustrated in Fig. 15.19a. On release, kinks will propagate away from the central point in both directions with velocity c,

but points on the string beyond the kinks will remain at rest. When the kink arrives at a particular point along the string, the associated impulse will accelerate the string from rest to the uniform velocity of the central section of the string. After a time t, the solution therefore comprises a straight central section of the string of width $2ct$ moving downward with constant velocity c $(2a/L)$, with the outer regions remaining at rest until a kink arrives. After a time $L/2c$, the kinks separating the straight-line sections reach the ends and are reflected with change of sign. After half a single period L/c, the initial displacement will therefore be reversed and will return to the original displacement after one full period $2L/c$. In the absence of damping, the process would repeat indefinitely.

Now consider the transverse force acting on the end-support responsible for exciting sound through the induced motion of the supporting bridge and vibrational modes of the instrument. The initial transverse force on the bridge is $2Ta/L$, where we assume $a \ll L$. This force is unchanged until the first kink arrives. On reflection, the direction of the force is reversed and is reversed again when the second kink returns after reflection from the other end of the string. The two circulating kinks therefore cause a reversal in sign of the force on the end-supports every half-cycle, resulting in a square-wave waveform, as illustrated in Fig. 15.20. The spectrum of a square wave has Fourier components at odd multiples n of the fundamental frequency with amplitudes proportional to $1/n$, Fig. 15.20b.

Note that plucking a string at the mid-point excites only the odd-n modes. This is a consequence of the initial force being applied at a node of all the even-n modes. If a string is plucked at a fractional position $1/m$ along its length, any partial that is an integer multiples of m will be missing. This is illustrated in Fig. 15.21, showing the spectra of the force on the supporting bridge for a string plucked at points 1/4 and 1/7-th along
Fig. 15.20 (a) Square-wave time dependence of transverse force acting on the bridge from a string plucked at its centre and **(b)** the corresponding amplitudes of the odd Fourier components n varying as $1/n$ (*dotted curve*)
Fig. 15.21 Normalised Fourier amplitudes for the force on the bridge for a string plucked 1/4 and 1/7 of the string length from the bridge. The *dashed curves* show the $1/n$ envelope of the partials of a sawtooth waveform

its length. By selecting the plucking position along the string, the guitar or lute player can change the harmonic content of the sound produced. When plucked near the bridge, the sound of the plucked guitar string is rather bright, with nearly all the prominent partials almost equally strongly excited (audio | ⑦〉 EXTRAS).

In practice, the finite width of the plucking point, the finite rigidity of the string and the loss of energy at the bridge perturb the Helmholtz wave, removing the unphysical discontinuities of the idealised model. This results in a more rapid decrease in the intensities of the higher partials excited.

Bowed String

The motion of the bowed string can be described rather accurately by a simple Helmholtz wave with a single kink circulating backwards and forwards along the string. The kink now separates two straight sections moving with constant angular velocity about the nodal end-points, as illustrated in Fig. 15.19b. This is again a solution that satisfies Newton's laws of motion, with the only acceleration occurring as the kink arrives at a particular point along the string. Such a wave is just as valid a solution to the wave equation as a sine wave and once excited would continue indefinitely, if there were no damping or energy losses on reflection at the bow or supported ends.

The energy required to excite and maintain such a wave is provided by frictional forces between the moving bow hair and the string, involving what is known as the *slip–stick* excitation mechanism. For a typical bowing position, marked by the line at P in Fig. 15.19b, the friction between the bow and string forces the string to remain in contact with the bow hair moving with constant bow velocity. This is referred to as the *sticking regime* and occurs all the time the kink is travelling to the left of the bowing position. How-

ever, when the kink is between the bow and supporting bridge, the string moves in the opposite direction to the bow. This is the *slipping regime*. Such motion is possible because the sliding friction between the bow and string can be much smaller than the sticking friction, when the bow and string are in contact. In this highly idealised model, the frictional force is assumed to be infinite in the sticking regime and zero in the slipping regime.

A more detailed discussion of the slip–stick bowing mechanism will be given later (Sect. 15.2.3), taking into account more-realistic models for the frictional forces between the bow and string and the transfer of energy from the string to the vibrational modes of the structure via the bridge. However, the idealised Helmholtz motion provides a surprisingly good description of the vibrations of real strings, as confirmed in early measurements by *Raman* [15.36] and many more-recent publications to be cited later.

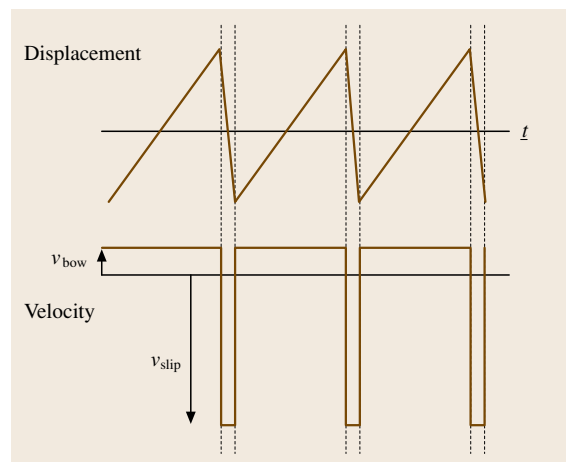
The amplitude of the Helmholtz bowed waveform is determined by the velocity of the bow v_{bow} and its distance L_B from the bridge. The transverse displacement of the kink maps out a parabolic path as it traverses the string (Fig. 15.19b). At the mid-point, the string displacement executes a triangular-wave motion with time, moving with velocity $\pm 2ca/L$ in alternate half-periods, where the maximum displacement $a = (L^2/4L_B)(v_B/c)$, for $a \ll L$. At the bowing position, the transverse string velocity alternates between v_{bow} in the sticking regime and $-v_{bow}(L - L_B)/L_B$ in the slipping regime, as illustrated in Fig. 15.22.


Fig. 15.22 Displacement and velocity of string at the bowing point. The mark-to-space ratio in the velocity is the same as the division of the string by the bow

To increase the sound, the player can therefore either use a faster bow speed or play with the bow nearer the bridge. *Schelling* [15.37] has shown that more-realistic frictional models limit the playing range, as discussed later (Fig. 15.31).

The transverse force on the bridge produced by an idealised Helmholtz bowed wave has a sawtooth-waveform time dependence, as shown in Fig. 15.23. Each time the kink is reflected at the bridge, the transverse force acting on the bridge reverses in sign. It then increases monotonically with time until the process repeats again. The sense of the sawtooth motion reverses with bow direction. The spectrum of the force acting on the bridge includes both even and odd partials, with amplitudes varying as $1/n$.

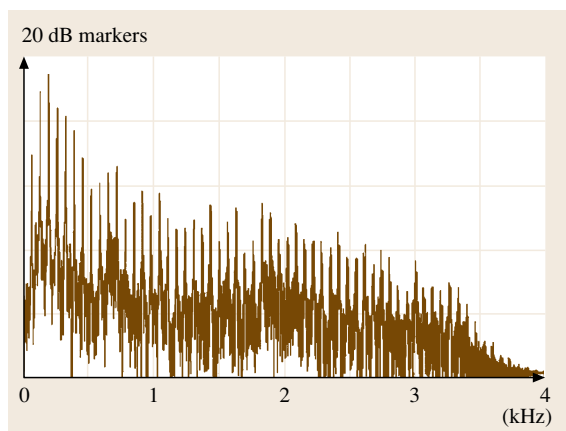
The spectrum of the sound produced by the lowest plucked and bowed notes on stringed instruments can typically involve 40 or more significant harmonic partials, as illustrated in Fig. 15.24 by the spectrum of the
Fig. 15.23 Sawtooth time-dependence of force on the end supports from Helmholtz bowed waveform and corresponding amplitudes of the normalised Fourier spectrum with partials varying as $1/n$


Fig. 15.24 The spectrum of the intensity of the lowest bowed note on a cello, illustrating the very large number of partials contributing to the sound of the instrument

sound produced by a bowed cello open C-string (C2 at $\sim 64\,\text{Hz}$, audio ⏴⏵ EXTRAS). The FFT spectrum is plotted on a dB scale to illustrate the large range of amplitudes of the partials (Fourier components) excited. The amplitudes of the individual partials depend not only on the force at the bridge exerted by the plucked or bowed strings, but also on the frequency dependent response and radiative properties of the supporting structure, as discussed later.

Struck String

Many musical instruments are played by striking the string with a hammer. The hammer can be quite light and hard, as used for playing the dulcimer, Japanese koto and many other related Asian instruments, or relatively heavy and soft, like the felted hammers on a piano. Some time after the initial impact, the striking hammer bounces away from the string, leaving the string in a free state of vibration. There are a few instruments, such as the clavichord (*Thwaites* and *Fletcher* [15.38]), where the string is struck with a metal bar (the tangent), which remains in contact with the string, defining its vibrating length and hence the note produced.

Consider first a point mass m moving with velocity v striking an ideal stretched string of infinite extent. In any small increment of time, the moving mass will generate a wave moving outwards from the point of impact. This will result in a decelerating force on the mass equal to $2Tv/c = mcv$, as illustrated in Fig. 15.18. The displacement of the mass will then be described by the following equation of motion

$$m\frac{\mathrm{d}^2\xi_\mathrm{m}}{\mathrm{d}t^2} = -\frac{2T}{c_\mathrm{T}}\frac{\mathrm{d}\xi_\mathrm{m}}{\mathrm{d}t} \, . \tag{15.42}$$

The transverse velocity of the impacting mass therefore decays exponentially with time as

$$\frac{\mathrm{d}\xi_\mathrm{m}}{\mathrm{d}t} = v_\mathrm{m}\exp\left(-t/\tau\right), \tag{15.43}$$

with $\tau = mc/2T$. The is identical to the dynamics of a trapeze artist dropping onto a stretched wire, with
Fig. 15.25a,b Time sequences of **(a)** string displacement and **(b)** string velocity for a mass striking a string
Fig. 15.26 (a) Time dependence of the upward force acting on a light hammer impacting a string in arbitrary units of time, and **(b)** amplitudes of Fourier coefficients of force acting on end supports for a hammer after hitting the string 1/7 of the length from an end-support. The *continuous line* shows the continuous spectrum for a string of semi-infinite length

waves of displacement and velocity travelling outwards in both directions away from the point of impact, as illustrated in Fig. 15.25.

In general, the string will be struck at a distance a from one of its end-supports. Hence, in a time $(a/2L)T_0$, a reflected wave will return to the mass and exert an additional force, which will tend to throw the mass back off the string. However, because the mass cannot change its velocity instantaneously, any returning wave will be partially reflected, so that the mass acts as a source of secondary reflected waves travelling outwards in both directions. The total force acting on the hammer is then given by any residual force from the first impact plus the subsequent forces created by the succession of reflections from the end-supports. This problem was first correctly solved by Hall, in the first of four seminal papers on the string–piano hammer interaction [15.39–42].

Hall showed that the first reflected wave exerts an additional decelerating force $g(t') \approx (1 - t'/\tau)e^{-t'/\tau}$ on the mass, where t' is the time after arrival of the first reflection. This is illustrated in Fig. 15.26 for a relatively light mass impacting the string at a position 1/7-th of the string length from an end. Provided the mass is sufficiently small, the force from the initial impact will have decayed significantly by the time the first reflection returns, so that the force acting on the mass will become negative (the dotted section in Fig. 15.26a), and the mass will detach itself from the string. The string will then move away from the mass and will vibrate freely, provided the hammer is prevented from falling back onto the string. An elaborate mechanism is used on the piano to prevent this from happening (see *Rossing, Fletcher* [15.5, Sect. 12.2]), while the zither or dul-

cimer player quickly lifts the hammer well away from the string after the initial impact using much the same striking action as a percussionist playing a drum, where the same considerations apply.

The heavier the mass, the longer it will remain in contact with the string. Hall showed that it may then take several reflections from both ends of the string and sometimes several periods of attachment and detachment before the mass is finally thrown away from the string. A sufficiently heavy mass will never bounce back off the string.

In general, the waveforms excited on the string will therefore be rather complicated functions of the properties of the string, hammer and striking position. However, for a very light mass ($\ll$ mass of the string), which is thrown off the string by the first reflected wave, the Fourier coefficients of the induced velocity waveform, and hence the force on the end-supports, are given by $v_n \approx \left(1 + e^{-1+in\pi\alpha}\right)\sin(n\pi\alpha)$, where $\alpha = a/L$, illustrated in Fig. 15.26b for an impact 1/7-th of the way along the string. Note that the seventh harmonic is missing, as again expected from general arguments, since no work can be transferred to a particular mode of string vibration for a force applied at a nodal position.

In practice, the spectrum is affected by the finite size of the hammer, multiple reflections occurring before the hammer is thrown from the string, and the elastic and often hysteretic properties of the hammer material [15.39].

Striking Tangent

On the clavichord (*Fletcher, Rossing* [15.5, Sect. 11.6]), a string is struck by a rising end-support, or tangent, which remains in contact with the string, exciting transverse vibrations of the string on both sides of the tangent. If we assume a simplified model in which the rising tangent moves with constant velocity until its final displacement a is reached, there is again a simple Helmholtz wave solution. In practice, the length of string on one side of the tangent is damped, so that free vibrations are only excited on one side of the striking point. We therefore need only consider the length of string between the tangent and the end connected to the soundboard. The discontinuities $\pm v$ in the tangent velocity, occurring on initial impact and on reaching its final displacement after a time Δt, generate propagating kinks and discontinuities of velocity of opposite sign separated in time by Δt. The striking therefore excites waves with kinks, velocities and displacements along the string shown in Fig. 15.27a. The solutions are again Helmholtz waves, but now with two kinks of op-
Fig. 15.27a–c Waveforms for a tangent hitting and sticking to string: **(a)** displacement and **(b)** velocity profiles along the string, at a succession of times (different colours) after the tangent hits the string, and **(c)** the spectrum of the resultant force on the end-supports for $\beta = 3/8$ (see text)

posite signs travelling around the string in the same direction.

The Fourier coefficients of the velocity waveform shown in Fig. 15.27b can be written as

$$c_n \approx \frac{1}{n}\frac{a}{L'}\left(1 - e^{in2\pi\beta}\right), \qquad (15.44)$$

where $\beta = \Delta t/T_1$ is the fraction of the period $T_1 = L'/2c$ of the freely vibrating length of string during which the striking tangent moves from its initial to final position. Figure 15.27 also includes the spectrum of the force acting on the end-supports for $\beta = 3/8$.

Very similar modes to the above will be excited during the time a heavy hammer is initially in contact with the string on instruments like the dulcimer, zither and piano. Such modes therefore contribute to the initial transient sounds of such instruments. Another related example is the use of *col legno* on stringed instruments, when the strings are struck by the wooden part of the bow. By hitting the string at specific positions along the string, pitched initial transients can be produced, creating special sound effects, *nageln*, sometimes used in avant-garde contemporary music, audio |?⟩ EXTRAS). The above simplistic model for striking a clavichord string will, in practice, be modified by the way the player depresses the key, which is directly coupled to the rising tangent, both during and after the initial impact. The player can therefore influence the initial transient and the after-sound, including the use of a small amount of vibrato on the after-note, resulting in a particularly responsive and intimate but quiet instrument, which was particularly popular in the baroque period.

Real Strings

We now consider a number of departures from the above idealised models for real strings including:

1. The finite size of the plucking or striking point
2. The finite flexibility of the string
3. Nonlinear effects.

In a subsequent section, we consider the even larger perturbations resulting from coupling to the acoustically radiating modes of the body of the instrument via the bridge.

Finite Spatial Variation

Idealised models for the string, with infinitely sharp kinks produced by plucking, bowing or striking, involve waveforms with discontinuities in amplitude and slope and an infinite number of Fourier components are clearly unphysical. In practice, physics and geometrical limitations, like the finite size of the player's finger or plectrum, will always limit the maximum curvature of the string at the point of excitation. The kinks will therefore no longer be δ-functions (infinitely narrow) but will have a finite size. For illustration, travelling kinks can be modelled as Gaussian waveforms, $\xi_\pm(x, t) \approx \exp[-(x \pm ct)^2/2\,(\Delta x)^2]$, which approximate to δ-functions when $\Delta x \to 0$, where Δx characterises the width of the kink. The Fourier transform of such a function has a Gaussian distribution of Fourier coefficients varying as $c(k) \approx \exp[-(k/\Delta k)^2/2]$, where $\Delta k \Delta x = 1$. This is analogous to the uncertainty principle in position and momentum in quantum wave mechanics. For long bending lengths, the amplitudes of the higher-frequency Fourier components will be strongly attenuated.

The sound of a guitar string played with a sharp plectrum is therefore much brighter, with many more contributing higher partials, than when played with the fleshy part of a finger, which limits the bending radius to a few mm. This is illustrated by the sound of an acoustic guitar plucked first with a plectrum and then with the thumb, both at a distance of $\approx 10\,\text{cm}$ from the bridge (audio |?⟩ EXTRAS).

Finite Rigidity

Even for an infinitely narrow plectrum, the bending at the plucking point will be limited by the finite flexibility of the string. The wave equation is then modified by an additional fourth-order bending stiffness term (*Morse* and *Ingard* [15.43, (5.1.25)]),

$$\rho S\frac{\partial^2\xi}{\partial t^2} = T\frac{\partial^2\xi}{\partial x^2} - ES\kappa^2\frac{\partial^4\xi}{\partial x^4}, \qquad (15.45)$$

where E is Young's Modulus, S is the cross-sectional area of the string (assumed homogeneous) and κ its ra-

dius of gyration. For a uniform circular wire of radius a, $S\kappa^2 = \pi a^4/4$. Using dimensional arguments, any changes in slope of the string will take place over a characteristic length $\delta \approx (ES\kappa^2/T)^{1/2} = (a^2 L/2\Delta L)^{1/2}$, where ΔL is the extension of the string required to bring it to tension. This provides an intrinsic limit to the sharpness with which the string is bent and hence to the wavelength and frequency of the highest partials contributing significantly to the sound of a plucked, bowed or struck string.

The additional stiffness energy required to bend the string will also affect wave propagation on the string and the frequencies of the excited modes. Assuming sinusoidal wave solutions varying as $e^{i(\omega t \pm kx)}$, the modified wave equation (15.45) gives modes with resonant frequencies

$$\omega_n^2 = c^2 k_n^2 \left(1 + \delta^2 k_n^2\right). \qquad (15.46)$$

Waves on a real string are therefore no longer dispersionless, but travel with a phase and group velocity that depends on their frequency and wavelength. Any Helmholtz kink travelling around a real string will therefore decrease in amplitude and will broaden with time. To maintain the Helmholtz slip–stick bowed waveform, with a well-defined single kink circulating around the string, the bow has to transfer energy to the string to compensate for such broadening each time the kink moves past the bow (*Cremer* [15.30, Chapt. 7] and Sect. 15.2.2).

If a rigidly supported string is free to flex at its ends (known as a hinged boundary condition), solutions of the form $\sin(n\pi x/L)\sin(\omega t)$. However, the mode frequencies remain are no longer harmonic;

$$\frac{\omega_n^*}{\omega_n} = \left(1 + Bn^2\right)^{1/2} \approx 1 + \frac{1}{2}Bn^2, \qquad (15.47)$$

with $B = (\pi/L)^2 \delta^2$, where the expansion assumes $Bn^2 \ll 1$.

When a string is clamped (e.g. by a circular collet), it is forced to remain straight at its ends. *Fletcher* [15.44] showed that this raises all the modal frequencies by an additional factor $\approx [1 + 2/\pi B^{1/2} + (2/\pi)^2 B]$. For a real string supported on a bridge, connected to another length of tensioned string behind the bridge, the boundary conditions will be intermediate between hinged and clamped.

Kent [15.45] has demonstrated that finite-flexibility corrections raise the frequency of the fourth partial of the relatively short C5 (an octave above middle-C) string on an upright piano by 18 cents relative to the fundamental. The inharmonicity would be even larger

for the very short, almost bar-like, strings at the very top of the piano. However, the higher partials of the highest notes on a piano rapidly exceed the limits of hearing, so that the resulting inharmonicity becomes somewhat less of a problem. The inharmonicity of the harmonics of a plucked or struck string results in dissonances and beats between partials, providing an *edge* to the sound, which helps the sound of an instrument to penetrate more easily. This is particularly true for instruments like the harpsichord and the guitar when strung with metal strings.

Finite-rigidity effects are particularly pronounced for solid metal strings with a high Young's modulus. To circumvent this problem, modern strings for musical instruments are usually composite structures using a strong but relatively thin and flexible inner core, which is over-wound with one or more flexible layers of thin metal tape or wire to achieve the required mass (*Pickering* [15.46, 47]). The difference in sound of an acoustic guitar strung with metal strings and the same instrument strung with more flexible gut or over-wound strings is illustrated in |?> EXTRAS .

15.2.2 Nonlinear String Vibrations

Large-amplitude transverse string vibrations can result in significant stretching of the string giving a time-varying component in the tension proportional to the square of the periodically varying string displacement. This leads to a number of nonlinear effects of considerable scientific interest, though rarely of musical importance.

Morse and *Ingard* [15.43] and (*Fletcher* and *Rossing* [15.5, Chap. 5]) provide theoretical introductions to the physics of nonlinear resonant systems and to nonlinear string vibrations in particular. *Vallette* [15.48] has recently reviewed the nonlinear physics of both driven and freely vibrating strings.

The Nonlinear Wave Equation

Transverse displacements of a string result in a fractional increase of its length L by an amount $\frac{1}{L_0}\int_0^L \frac{1}{2}(\partial\xi/\partial x)^2\,dx$ and hence to a similar fractional increase in tension and related frequency of excited modes. For a spatially varying sinusoidal wave, the induced strain and hence tension will vary with both position and time along the string. Any spatially localised changes in the tension will propagate along the string with the speed of longitudinal waves. As this is typically an order of magnitude larger than for transverse waves, $c_L/c_T \approx \sqrt{L/\Delta L}$, where ΔL is the amount that

the string is stretched to bring it to tension, such perturbations will propagate backwards and forwards along the string many times during a single cycle of the transverse waves. Hence, as pointed out by *Morse* and *Ingard* [15.43], to a rather good approximation, transverse wave propagation is determined by the spatially averaged perturbation of the tension.

Consider a stretched string vibrating with large amplitude in its fundamental mode with transverse displacement $u = a \sin(\pi x / L) \cos \omega t$. The spatially averaged increase in tension is given by

$$\left(1 + \frac{\pi^2}{4} \frac{a^2}{\Delta L L} \cos^2 \omega_1 t\right)$$
$$= \left[1 + \beta(1 - \cos 2\omega_1 t)a^2\right], \qquad (15.48)$$

where $\beta = \frac{\pi^2}{8} \frac{1}{L \Delta L}$. Inserting this change in tension into the equation of motion for transverse string vibrations coplanar with a localised external driving force $f(t)$, we can write

$$\frac{\partial^2 u}{\partial t^2} + \frac{\omega_1}{Q} \frac{\partial u}{\partial t} + \omega_1^2 \left[1 + \beta \left(1 - \cos 2\omega_1 t\right) a^2\right] u$$
$$= \frac{2}{m} f(t). \qquad (15.49)$$

Mode Conversion

Nonlinearity results in an increase in the static tension by the factor $(1 + \beta a^2)$ and hence an increase in frequency of all the string modes. In addition, the term varying as $\cos 2\omega_1 t$, at double the frequency of the principal mode excited, will interact with any other modes present to excite additional with frequencies $f_n \pm 2f_1$. Of special note is the effect of this term on the principal mode of vibration itself, exciting a new mode at three times the fundamental frequency $3f_1$ and an additional parametric term (acting on itself) from the $f_1 - 2f_1 = -f_1$ contribution. The parametric term causes an additional increase in frequency of the principal mode excited, so that in total

$$\omega_{1*}^2 = \omega_1^2 \left(1 + \frac{3}{2} \beta a^2\right), \qquad (15.50)$$

where ω_1 is the small-amplitude resonant frequency.

Nonlinear effects depend on the square of the amplitude of the strongly excited mode and inversely on the amount by which the string has been stretched to bring it to tension. To investigate nonlinear effects, it is therefore advantageous to use weakly stretched strings at low initial tension. Conversely, because the tension of strings on musical instruments tends to be rather high, nonlinear effects are not in general important within a musical context.
Fig. 15.28 Nonlinear excitation of the third partial of a stretched string plucked 1/3 of the way along its length; the graticule divisions are 50 ms apart (after *Legge* and *Fletcher* [15.49])

Figure 15.28 shows measurements by *Legge* and *Fletcher* [15.49], which illustrate the nonlinear excitation and subsequent decay of the third partial of a guitar string plucked one third of the way along its length, so that the third partial was initially absent.

In general, bowed, plucked and struck waveforms have many Fourier components, each of which will contribute a term proportional to a_n^2 to the nonlinear increase in tension. However, in most cases, the fundamental will be the most strongly excited mode and will therefore dominate the nonlinearity.

The inharmonicity and changes in frequency associated with nonlinearity at large amplitudes can give a strongly plucked string an initial rather *twangy* sound. Nonlinear effects can also raise the frequency of a very strongly bowed open C-string of a cello by almost a semitone. However, under normal playing conditions, nonlinearity is rarely musically significant, at least in comparison with other more important perturbations of string vibrations, such as their interaction with the acoustically important structural resonances of an instrument, to be considered later.

Nonlinear Resonances

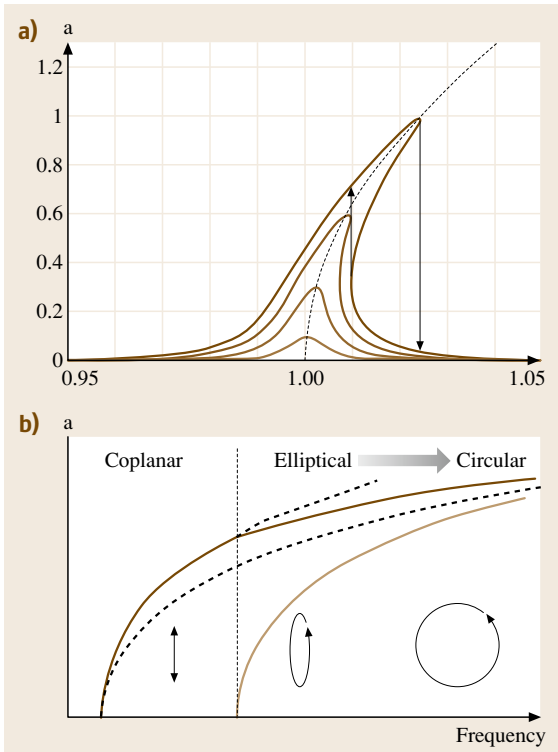
The nonlinear increase in frequency of modes with increasing amplitude leads to string resonances, which become increasingly skewed towards higher frequencies at large amplitudes, as illustrated in Fig. 15.29. For sufficiently large amplitudes and small damping, the resonance curves develop an overhang. On sweeping through resonance from the low-frequency side, the am-


Fig. 15.29 (a) The effect of nonlinearity on the resonance curves of a stretched string with a Q of 100, for increasing drive excitation plotted against normalised resonant frequency. The *dashed curve* represents the nonlinear amplitude of the frequency for free decay. Note the hysteretic transitions at large amplitude; **(b)** the transition at large amplitudes from linearly polarised vibrations coplanar with the driving force to elliptical and finally circular orbital motion of the string at very large amplitudes. The two *continuous curves* represent the induced amplitudes in the directions parallel and perpendicular to the driving force

plitude rises causing the resonance frequency to shift to higher frequencies, as indicated by the dashed line in Fig. 15.29a. Damping eventually leads to a sudden collapse, with the amplitude dropping to a much lower high-frequency value, illustrated by the downward arrow. On decreasing the frequency, the response initially remains on the low-amplitude curve before making a sudden hysteretic transition back to the large amplitude, strongly nonlinear, regime.

This behaviour is characteristic of any nonlinear oscillator with a restoring force that increases in strength on increasing amplitude. For a spring constant that softens with increases displacement, as we will discuss later

in relation to Chinese gongs, the resonance curves are skewed in the opposite direction.

Orbital Motion

Nonlinearity results in another surprising effect on the driven resonant response. At sufficiently large amplitudes of vibration, a sinusoidally driven string suddenly develops motion in a direction orthogonal to and in phase-quadrature with the driving force, illustrated schematically in Fig. 15.29b. The transverse displacements then execute elliptical orbits about the central axis approaching circular motion at very large amplitudes (*Miles* [15.50]). In this limit, the string is under constant increased tension, producing an amplitude-dependent inward force balancing the centrifugal force of the orbiting string, resulting in an amplitude-dependent orbital frequency $\omega_{1*}^2 = \omega_1^2(1 + 2\beta a^2)$. For circular motion, the extension of the string and hence the increase in tension and resonant frequency are determined by the orbital radius of the whirling string, so there is now no variation in tension with time. The sense of clockwise or anticlockwise rotation is determined by chance or in practice by slight geometrical or material anisotropies of the string or supporting structure.

Such transitions have been investigated by *Hanson* and coworkers [15.51, 52] using a brass harpsichord string stretched to playing tension. The transition from linear to elliptically polarised motion was observed in addition to chaotic behaviour at very large amplitude. However, their measurements were complicated by the very long time constants predicted to reach equilibrium behaviour close to the transitional region and to rather strong and not well-understood splitting of the degeneracy of the transverse modes, even at low amplitudes when nonlinearity is unimportant.

A related effect occurs when a string is plucked so that it is given some orbital motion, as is invariably the case when plucking a string on a stringed instrument such as the guitar. Nonlinearity introduces coupling between motions in orthogonal transverse directions, causing the orbits to precess (*Elliot* [15.53], *Gough* [15.54], *Villagier* [15.48]), as illustrated by computational simulations and measurements in Fig. 15.30. The precessional frequency Ω is given by $\frac{\Omega}{\omega} = \frac{ab}{L\Delta L}$, where a and b are the major and minor semi-axes of the orbital motion and ΔL is the amount by which the string is stretched to bring it to tension [15.54].

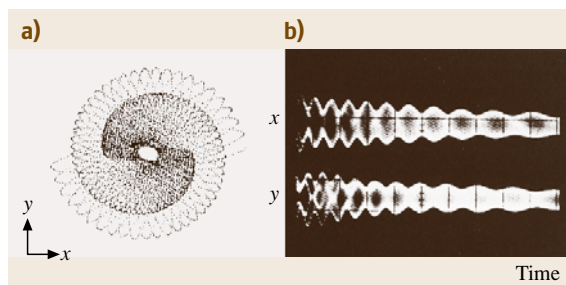
Such precession can lead to the rattling of the string against the fingerboard on a strongly plucked instrument, as the major axis of the orbiting string precesses


Fig. 15.30 (a) The computed precession of the damped elliptical orbits of a strongly plucked string, and **(b)** measurements of the orthogonal transverse components of such motion for a string plucked close to its mid-point (after [15.54])

towards the fingerboard. The nonlinear origin of such effects can easily by distinguished from other linear effects causing degeneracy of the string modes and hence beats in the measured waveform, by the very strong dependence of the precession rate on amplitude, as illustrated in Fig. 15.30b.

15.2.3 The Bowed String

Realistic Models

Although the main features of the bowed string can be described by a simple Helmholtz wave, it is important to consider how such waves are excited and maintained by the frictional forces between the bow and string. The simple Helmholtz solution is clearly incomplete for a number of reasons including:

1. The unphysical nature of infinitely sharp kinks.
2. The insensitivity of the Helmholtz bowed waveform to the position and pressure of the bow on the string. In particular, the simple Helmholtz waveform involves partials with amplitudes proportional to $1/n$, whereas such partials must be absent if the string is bowed at any integer multiple of the fraction $1/n$ along its length, since energy cannot be transferred from the bow to the string at a nodal position of a partial.
3. The neglect of frictional forces in the slipping regime.
4. The neglect of losses and reaction from mechanical coupling to structural modes at the supporting bridge.
5. The excitation of the string via its surface, which must involve the excitation of additional torsional modes.

Understanding the detailed mechanics of the strongly nonlinear coupling between the bow and string has been a very active area of research over the last few decades, with major advances in our understanding made possible by the advent of the computer and the ability to simulate the problem using fast computational methods. *Cremer* [15.30, Sects. 3–8], provides a detailed account of many of the important ideas and techniques used to investigate the dynamics of the bowed string. In addition, *Hutchins* and *Benade* [15.28, Vol. 1], includes a useful introduction to both historical and recent research prefacing 20 reprinted research papers on the bowed string. *Woodhouse* and *Galluzzo* [15.55] have recently reviewed present understanding of the bowed string.

Pressure, Speed and Position Dependence

In the early part of the 20th century, *Raman* [15.36], later to be awarded the Nobel prize for his research on opto-acoustic spectroscopy, confirmed and extended many of Helmholtz's earlier measurements and theoretical models of the bowed string. Raman used an automated bowing machine to investigate systematically the effect of bow speed, position and pressure on bowed string waveforms. He also considered the attenuation of waves on the string and dissipation at the bridge. From both measurements and theoretical models, he showed that a minimum downward force was required to maintain the Helmholtz bowed waveforms on the string, which was proportional to bow speed and the square of bow distance from the bridge. He also measured and was able to explain the wolf-note phenomenon, which occurs when the pitch of a bowed note coincides with an over-strongly coupled mechanical resonance of the supporting structure. At such a coincidence, it is almost impossible for the player to maintain a steady bowed note, which tends to *stutter* and jump in a quasi-periodic way to the note an octave above, illustrated previously for a cello with a bad wolf note, audio ⏵ **EXTRAS** .

Saunders [15.56], well known for his work in atomic spectroscopy (Russel–Saunders spin-orbit coupling) was a keen violinist and a cofounder of the Catgut Acoustical Society. He showed that, for any given distance of the bow from the bridge, there was both a minimum and a maximum bow pressure required for the Helmholtz kink to trigger a clean transition from the sticking to slipping regimes and vice versa. Subsequently, *Schelling* [15.57] derived explicit formulae for these pressures in terms of the downward bow force F as a function of bow speed v_B, assuming a simple model for friction between bow hair and string in the slipping

region of $\mu_d F$ and a maximum sticking force of $\mu_s F$,

$$F_{min} = \frac{R_0^2 v_B}{2R\beta^2 (\mu_s - \mu_d)} \quad \text{and}$$

$$F_{max} = \frac{2R_0 v_B}{\beta (\mu_s - \mu_d)} = 4\beta \frac{R}{R_0} F_{min} , \qquad (15.51)$$

where R_0 is the characteristic impedance of the string terminated by a purely resistive load R at the bridge, and β is the fractional bowing point along the string. If the downwards force is larger than F_{max} the string remains stuck to the string instead of springing free into the slipping regime, while for downward forces less than F_{min} an additional slip occurs leading to a double-slipping motion.

Figure 15.31 is taken from the article by *Schelling* on the bowed string in the Scientific American special issue on the *Physics of Musical Instruments* [15.58]. It shows how the sound produced by a bowed cello string changes with bow position and downward bow pressure for a typical bow speed of 20 cm/s. Note the logarithmic scales on both axes. In practice, a string can be bowed over a quite a large range of distances from the bridge, bow speeds and pressures with relatively little change in the frequency dependence of the spectrum and quality of the sound of an instrument, apart from regions very close and very distant from the bridge. Nevertheless, the ability to adjust the bow pressure, speed and distance from the bridge, to produce a good-quality steady tone, is one of the major factors that distinguish an experienced performer from the beginner.
Fig. 15.31 The playing range for a bowed string as a function of bow force and distance from bridge, with the bottom and right-hand axis giving values for a cello open A-string with a constant bow velocity of $20 \, \text{cms}^{-1}$ (after *Schelling* [15.57])

Slip–Stick Friction

An important advance was the use of a more realistic frictional force, dependent on the relative velocity between bow and string, shown schematically for three downward bow pressures in Fig. 15.32. Such a dependence was subsequently observed by *Schumacher* [15.59] in measurements of steady-state sliding friction between a string and a uniformly moving bow. The frictional force is proportional to the downward bow pressure.

Friedlander [15.60] showed that a simple graphical construction could be used to compute the instantaneous velocity v at the bowing point from the velocity $v_p(t)$ at the bowing point induced by the previous action of the bow. The new velocity is given by the intersection of a straight line with slope $2R_0$ drawn through v_p with the friction curve, where R_0 is the characteristic string impedance. This follows because the localised force between the bow and string generate secondary waves with velocity $F/2Z_0$ at the bowing point as previously described (15.34). In the slipping region well away from capture, there will be just a single point of intersection, so the problem is well defined. However, close to capture, as illustrated by the intersections marked by the black dots with the upper frictional curve, the straight line can intersect in three points (two in the slipping regime and one in the sticking regime) as first noted by Friedlander.
Fig. 15.32 Schematic representation of the dependence of the frictional force between bow and string on their relative velocity and downward pressure of the bow on the string. The *straight line* with slope $2R_0$ passes through the velocity v_p of the string determined by its past history and the intersection with the friction curves determines its current velocity. The *open circle* represents the single intersection in the slipping regime at low bow pressures, while the *closed circles* illustrate three intersections at higher pressures

Computational Models

This model has been used in a number of detailed computational investigations of both the transient and steady-state dynamics of the bowed string, notably by the Cambridge group lead by *McIntyre* and *Woodhouse* [15.61–63], their close collaborator *Schumacher* [15.59, 64] from Carnegie-Mellon, and *Guettler* [15.65], who is also a leading international double-bass virtuoso. Readers are directed to the original publications for details of the various computational schemes used, which are also discussed in some detail by *Cremer* [15.30, Sect. 8.2].

Whenever a string is bowed at an integer interval along its length, the secondary waves excited by the frictional forces between bow and string can give rise to coherent reflections between the bow and bridge, giving rise to pronounced *Schelling ripples* on the Helmholtz waveform and hence significant changes in the spectrum of the radiated sound. However, because the bowing force tends to be distributed across the ≈ 1 cm width of the bow hairs, such effects tend to be smeared out and are not generally of significant musical importance. *McIntyre* et al. [15.63] have also shown that uncertainties in the sticking point from the finite-width strand of bow hairs leads to a certain amount of jitter or aperiodicity in the pitch of the bowed string amounting of a few cents, which is again of little musical significance, though the noise generated may be significant in contributing to the characteristic sound of bowed string instruments.

It is instructive to consider the kind of computational methods developed by Woodhouse and his collaborators to investigate both the initial transient and the steady-state dynamics of the bowed string. This is illustrated schematically in Fig. 15.33, where u and u' represent the velocity under the bow from waves travelling
Fig. 15.33 Schematic representation of the model used by *McIntyre* and *Woodhouse* to compute bowed string dynamics. The velocities u and v represent incoming and outgoing waves from the two ends, with reflections of impulse functions from the bridge and end-stop represented in their digitised form

towards the bow from the bridge and from the stopped end of the string respectively, and v and v' are the velocities at the bowing point of the waves travelling away from the bow. In the absence of any bowing force $v = u'$ and $v' = u$. However, in the presence of a frictional force between the bow and string, the outgoing waves will acquire an additional velocity $f/2R_0$, where the frictional force is determined by the velocity from the incoming waves $u + u'$ excited by previous events. The outgoing wave travelling towards the stopped end or nut of the string will simply be reflected, while the outgoing wave reaching the bridge will not only be reflected, but will also excite continuing vibrations at the bridge from the excitation of the coupled structural modes.

Such problems can be solved using a Green's function approach *Cremer* [15.30, Sect. 8.4], in which the outgoing waves can be considered in terms of the response to forces represented as a succession of short impulses. The problem is then reduced to understanding the response of the system for the reflection of a sequence of short impulses or δ functions. At the end-stop, an impulse will simply be reflected with reversed sign, but reduced amplitude in the case of a soft finger stopping the string. The incoming wave u' generated by the reflected impulse will therefore be an impulse function delayed in time by the transit time from the bow to the end-stop and back. Similarly, the impulse returning from the bridge will be an impulse delayed by the transit time between bow and bridge and back followed by a wave generated by the induced motions of the bridge on reflection. The time-delayed impulse responses from reflections at the bridge and end-stop can described by the functions $K(t)$ and $K'(t)$. The incoming waves $(u(t), u'(t))$ can then be described by the convolution of $K(t)$ and $K'(t)$ with the outgoing waves $(v(t), v'(t))$ considered as a succession of impulse functions at all previous times t', such that

$$u(t) = \int^t v(t')K(t - t')\,\mathrm{d}t' \quad \text{and}$$

$$u'(t) = \int^t v'(t')K'(t - t')\,\mathrm{d}t \ . \tag{15.52}$$

To compute the resulting dynamics of string motion digitally, one simply computes the above velocities at a succession of short time intervals, with the outgoing waves determined from the incoming waves plus the secondary waves induced by the resulting frictional force, such that

$$v'_{n+1} = u_n + f_n/2R_0 \quad \text{and}$$

$$v_{n+1} = u'_n + f_n/2R_0 \tag{15.53}$$

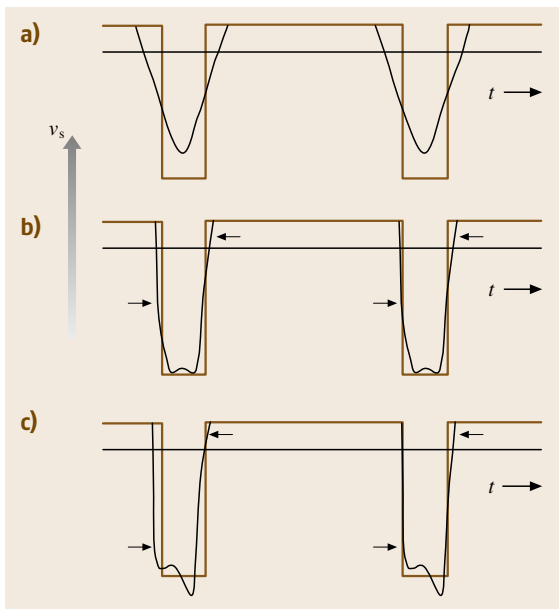
and

$$u_{n+1} = \sum_{}^{n} v_{\mathrm{m}} K_{n-m} \quad \text{and}$$

$$u'_{n+1} = \sum_{}^{n} v'_{\mathrm{m}} K'_{n-m} \,, \tag{15.54}$$

where K_j and K'_j are now the digital equivalents of the time-delayed impulse responses, illustrated schematically in Fig. 15.33. The frictional force f_n entering (15.53) is evaluated from the pressure- and velocity-dependent frictional force using the Friedlander construction with the computed string velocity under the bow given by $u_n + u'_n$.

Pressure Broadening and Flattening

As an example, Fig. 15.34 illustrates the computed velocity of the string under the bow as a function of increasing bow pressure (*McIntyre* et al. [15.61]). In contrast to the rectangular waveform predicted by the simple Raman model, the waveform is considerably rounded, especially at low bow pressures. This results in a less strident, less intense sound, with the higher partials strongly attenuated. At higher pressures, but at the same position and with the same bow velocity, the rounding is less pronounced, so that higher partials become increasingly important. The increased intensity of the higher partials leads to an increased perceived intensity with bow pressure, in contrast to the Raman model, in which the waveform and hence intensity remains independent of bow pressure. This is referred to as the *pressure effect*. At even higher pressures, the ambiguity in intersections noted by Friedlander leads to a pronounced increase in the capture period and hence the pitch of the bowed note, known as the *flattening effect*. These features are discussed in considerable detail along with his own important research and that of his collaborators on such effects by *Cremer* [15.30, Chaps. 7 and 8].


Initial Transients

Computational models can also describe the initial transients of the bowed string before the steady-state Helmholtz wave is established. Figure 15.35 compares the computed and measured initial transients of the string velocity under the bow for a string played with a sharp attack (a martelé stroke) (*McIntyre* and *Woodhouse* [15.61]). These computations also include the additional excitation of torsional waves, which are excited because the bowing force acts on the outer diameter of the wire, exerting a couple in addition to a transverse force. The excitation and loss of energy to the torsional waves appears to encourage the rapid stabilisation of the bowed Helmholtz waveform.

For low-pitched stringed instruments such as the double bass, it is very important that the Raman bowed waveform is established very quickly, otherwise there will be a significant delay in establishing the required pitch. Remarkably, *Guettler* [15.65] has shown that, by

Fig. 15.34a–c Computed velocity of string at bowing point for increasing bow pressures in the ratios $0.4 : 3 : 5$ (after *McIntyre* and *Woodhouse* [15.61]) illustrating both the broadened waveform and pitch dependence on bow pressure compared with the idealised rectangular Helmholtz bowed waveform
Fig. 15.35 (a) Computed transient string velocity at the bowing point for a strongly bowed string including coupling to both transverse and torsional modes and **(b)** the measured string velocity for a strongly played martelé bow stroke (after *McIntyre* and *Woodhouse* [15.61])

simultaneously controlling both bow speed and downward pressure, the player can establish a regular Raman waveform in a single period. The speed with which a steady-state bowed note can be established can be represented on a *Guettler diagram*, where the number of slips before a steady-state Helmholtz motion is established can be illustrated as a two-dimensional histogram as a function of bowing force and acceleration of the bow speed from zero.

To investigate such effects experimentally, *Galluzzo* and *Woodhouse* [15.55, 67] have recently developed a dynamically controlled bowing machine with active feedback, providing programmable control of both downward bow pressure and bow speed. This enables reliable and reproducible results to be made over a very wide range of possible playing parameters, extending Guettler's original measurements.

Viscoelastic Friction

Recent measurements have shown that the frictional model assumed in these investigations is oversimplistic. The force between the bow hairs and the string is maintained by a thin layer of rosin which coats them both. Rosin is a rather soft, sticky substance, with a glass-to-liquid transition not far above room temperature, resulting in viscoelastic properties, which are very sensitive to temperature (*Smith, Woodhouse* [15.66]). As the bow slides past the bow hair, the frictional forces will heat the rosin and hence reduce its viscoelasticity frictional properties. During the sticking regime, with no work being done at the bow–string interface,
the rosin will cool down and the friction will increase. The frictional forces are therefore hysteretic and will be strongly dependent on past history within a given period of string vibration. *Woodhouse* et al. [15.68] and *Smith* [15.69] have investigated this hysteretic behaviour in some detail using rosin-coated glass rods. The hysteretic properties shown in Fig. 15.36 were deduced from measurements at the two supported ends of the string. *Woodhouse* [15.70] subsequently extended his computational models to incorporate the hysteretic frictional properties. Somewhat surprisingly, this more realistic model made little qualitative difference to the predicted behaviour. Such measurements contribute to our understanding of the physical processes underlying viscoelastic properties of various coatings and lubricants and have become an important tool in the field of tribology (studies of friction).

15.2.4 Bridge and Soundpost

We now consider the role of the bridge and soundpost in providing the coupling between the vibrating strings and the vibrational modes of the body of instruments of the violin family. We also consider the influence of such coupling on the modes of string vibration, which involves a discussion of the very important influence of damping on the normal modes of any coupled system.

Bridges

Many plucked and struck stringed instruments, such as the piano or guitar, use a rather low solid bridge to support the strings and transfer energy directly from the transverse string vibrations perpendicular to the supporting soundboard or front-plate of the instrument. The bridge needs only to be sufficiently high to prevent the strings from vibrating against the fingerboard or shell of the instrument. This is also true for the Chinese two-string violin, the *erhu*, which is held and played so that the bow excites string vibrations perpendicular rather than parallel to the stretched snake-skin membrane supporting the bridge and strings. The strings of a harp are attached to an angled sounding board, so that transverse string vibrations in the plane of the strings couple directly to the perpendicular vibrations of the supporting soundbox *Fletcher* and *Rossing* [15.5, Sect. 11.2].

For such instruments, the bridge and other string terminations play a relatively insignificant acoustic role, apart from adding a small inertial mass and additional stiffness to the soundboard or top plate, which only slightly perturbs the frequencies of the structural modes of vibration.

Fig. 15.36 Measured hysteretic frictional force between string and a glass bow coated with rosin, with the *dashed line* indicating previously assumed velocity dependence (after *Smith* and *Woodhouse* [15.66])
Fig. 15.37 The lowest in-plane resonant modes and frequencies of violin and cello bridges (after *Reinicke* [15.71]). The *arrows* represent the vibrational directions of the bowed outer and middle strings

In contrast, the rather high bridges on instruments of the violin and viol families have a profound influence on the acoustical properties, particularly at frequencies comparable with and above any mechanical resonances of such structures. Figure 15.37 illustrates the shape of modern violin (and viola) and cello bridges and indicates their principal vibrational modes, as measured by *Reinicke* and *Cremer* [15.71,72] using laser interference holography. Bridges are cut from maple and taper in thickness from the two feet to the top surface supporting the four strings, which are set in small v-shaped locating grooves.

Reinicke [15.71, 72] showed that the lowest violin bridge resonance at typically around 3 kHz involves a rotational motion of the top half of the bridge about its waist. The rotational motion induced by the vibrating strings supported on the top of the bridge results in a couple acting on the top plate via the two feet. The next most important in-plane resonance is at ≈ 6 kHz and involves the top of the bridge bouncing up and down on its feet, resulting in forces via the legs perpendicular to the supporting surface. The cello bridge has rather longer legs, resulting in two low-frequency twisting modes with resonances at around 1 and 2 kHz, both of which exert a couple on the top plate. Longitudinal forces from the vibrating strings can also induce bridge motion perpendicular to its plane (at double the frequency of the vibrating strings), but such motion is generally rather small and will be ignored for the purposes of this chapter.

Any transverse string force at the top of the bridge, from bowing, plucking or striking the string, will be transferred to the supporting body via the two feet. This will induce a linear motion of the centre of mass of the instrument, rotation about its centre of mass and the excitation of both flexural and longitudinal waves in the plates of the instrument. Because bowing involves a static force which reverses with bow direction,

a bowed instrument has to be held fairly firmly by the player, which introduces an extra channel for energy loss through the supporting chin and fingers. The induced linear and rotational motions of an instrument are relatively unimportant at audio frequencies as they involve the whole mass M of the instrument with admittances varying $\approx 1/\mathrm{i}M\omega$.

If a tall bridge is placed centrally on a symmetric shell structure, like the body of an early renaissance viol, the plucked or bowed motion of the strings parallel to the supporting top plate would excite only asymmetrical modes of the supporting structure, whereas perpendicular string vibrations would excite only symmetrical modes. For instruments of the violin family, an offset soundpost is wedged between the front and back plates, which destroys the symmetry. The coupled modes will then involve a linear combination of symmetrical and asymmetric body modes, as discussed later (Sect. 15.2.6).

The arching of the top of the bridge allows each of the supported four strings to be bowed separately or together (double stopping), with the bow direction making an angle of around $\pm 15-20°$ relative to the top plate for the outer two strings and almost parallel for the middle two strings. Bowing on the outer two strings therefore involves significant perpendicular in addition to parallel forces, but only slightly different sounds from a single type of string when supported in different positions on the bridge. Audio 🔊 EXTRAS compares the sound of a bowed covered-gut D-string mounted in the normal position and in the G-, A- and E-string positions on the same violin. On a guitar almost all the sound is produced by the vertical motion of the plucked string rather than by parallel vibrations, which primarily excite nonradiating longitudinal modes of the top plate.

Simplified Bridge Model
Cremer [15.30, Chap. 9] gives a detailed historical and scientific introduction to research on violin and cello bridges and their coupling to the body of the instrument. Relatively complicated mechanical models are described composed of several masses and springs to account for the various possible vibrational modes of the bridge. However, the principal resonances of the violin bridge shown in Fig. 15.37 can be modelled very simply by a two-degree-of-freedom mechanical model, with effective masses representing the linear and rotational energy of the top of the bridge coupled to the supporting surface through the two supporting feet via a rotational or vertical spring, illustrated schematically in Fig. 15.38. The relatively light mass and added rigid-
Fig. 15.38a,b Simplified mechanical models for the lowest (a) rotational and (b) bouncing motions of the bridge supported by its two feet on a rigid surface

Fig. 15.39 The admittance at the top of the bridge on a single violin, plotted on the same but arbitrary dB scale, for a number of violin bridges having the same height and resonant frequency ($\approx 2\,\text{kHz}$) but different masses. The *upper curve* corresponds to the lightest bridge that could be fabricated from a standard bridge blank and the *lowest curve* by the heaviest. Subtracting 45 dB from the results would give the approximate admittance in units of $\text{ms}^{-1}\text{N}^{-1}$ (data kindly provided by *Woodhouse* [15.73])

ity of the lower half of the bridge will only slightly perturb the resonant frequencies of the more massive supporting plates and can therefore be ignored as a first approximation. The effective masses and strength of the coupling springs can be chosen to reproduce the vibrational characteristics of the first two vibrational modes of the violin (or cello) bridge, which dominate the acoustical properties of the instrument.

At low frequencies, well below any resonant frequency, the bridge will vibrate as a rigid body, adding a small amount of additional mass, moment of inertia and rigidity to the top plate, which will again only slightly perturb the vibrational frequencies of the supporting shell structure. The additional relative height of the cello bridge compared with that of the violin bridge enables a rather larger couple to be exerted by the bowed string on the more massive top plate. There is a delicate balance between increasing the coupling to enhance the intensity at low frequencies without making it so strong that troublesome wolf-note problems arise, as referred to earlier.

Bridge–Hill (BH) Feature
Reinicke [15.71,72] and *Cremer* [15.30] highlighted the importance of the bridge resonance on both the sound of the violin and on admittance measurements, which are traditionally made by exciting the violin at the top of the bridge using an external force parallel to the top supporting plate. In recent year, this problem has attracted renewed interest, in an attempt to describe the rather broad peak and associated phase changes superimposed on the multi-resonant response of the instrument, which Jansson refers to as the *Bridge-Hill* (BH) feature [15.74, 75].

Figure 15.39 shows recent measurements by *Woodhouse* [15.73] of the modulus of the admittance at the bridge for a particular instrument using a series of bridges with different masses but the same resonant frequency at $\approx 2\,\text{kHz}$. A strong but rather wide overall BH peak is observed in the vicinity of the bridge resonance.

Note the marked decrease in admittance with increasing bridge mass above the bridge resonance. There is also an associated overall 90° change in the phase of the admittance on passing through the peak.

Evidence for the BH feature can also be seen in *Dünnwald*'s [15.76] superimposed measurements of the sound output of a large number of high-quality Italian, modern master and factory violins as a function of sinusoidal input force at top of the bridge, shown in Fig. 15.40. A surprising aspect of these measurements is the apparent lack of any such feature for modern master violins, possibly because of a wider variation in bridge resonances and effective masses of bridge and plate resonances in the chosen instruments. From measurements of the radiated sound of over 700 violins, Dünnwald proposed that the presence of a number of strong acoustic resonances in the broad frequency band from 1.5 to 4 kHz was one of the distinguishing features of a really fine instrument. The influence of the bridge in accounting for such a peak and the reduced response at higher frequencies is clearly important.

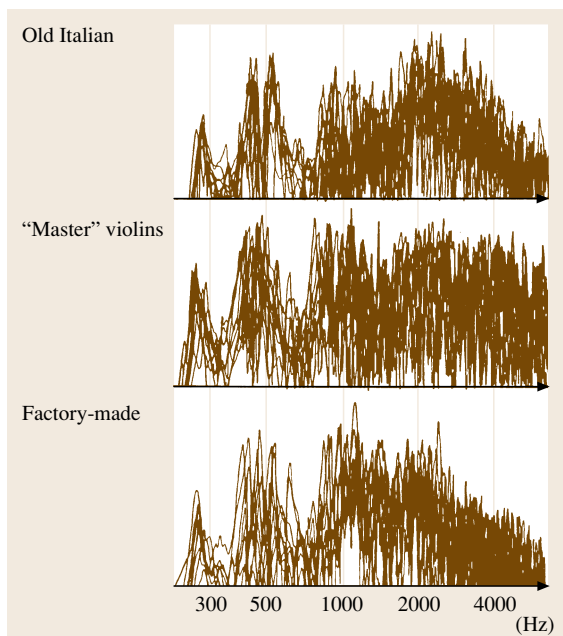
Woodhouse [15.77] has recently revisited the problem of the coupling between bridge and body of the instrument and the origin of the BH peak. A simple theoretical model shows that the peak depends on


Fig. 15.40 Overlays of the sound output of 10 typical old Italian, modern master instruments, and 10 factory instruments for a constant sinusoidal force at the top of the bridge (after *Dünnwald* [15.76])

many factors, such as the effective masses, Q-values and resonant frequencies of the major vibrational modes of the bridge and the multi-resonant properties of the instrument. To demonstrate the overall effect of the bridge without having to consider the detailed vibrational response of a particular instrument, Woodhouse first considered coupling to a simplified model for the vibrational modes of the coupled instrument. This assumed a set of coupled vibrational modes each having the same effective mass M and Q-value, with a constant spacing of resonances $\omega_0 = 2\pi \Delta f$. Different values for these parameters would need to be used to model the independent rotational or bouncing modes, though Woodhouse concentrates on the influence of the lowest frequency *rocking* bridge mode. The merit of such a model is that the multi-resonant response of such a system varies monotonically with frequency. The features introduced by the resonant properties of the bridge can then be easily identified and the input admittance expressed relative to the admittance A_V for a completely rigid bridge of the same mass, where

$$A_V(\omega) = \frac{1}{M} \sum_n \frac{i\omega}{(n\omega_0)^2 - \omega^2 + i\omega n\omega_0/Q} . \quad (15.55)$$

The corresponding input admittance for the one-degree-of-freedom model bridge is then given by

$$A_{BB}(\omega) = \frac{A_V + i\omega/m\omega_B^2}{1 - (\omega/\omega_B)^2 + i\omega m A_V} , \quad (15.56)$$

where m is the effective mass of the bridge and ω_B its resonant frequency and internal damping of the bridge has been neglected.

We can also define a nonlocal admittance or mobility A_{VB} to describe the induced body motion per unit force at the foot of the bridge given by

$$A_{VB}(\omega) = \frac{A_V}{1 - (\omega/\omega_B)^2 + i\omega m A_V} . \quad (15.57)$$

The simulations in Fig. 15.41 illustrate the major effect of the bridge resonance on both the input response and induced body motion and hence radiated sound at, around and above the resonant frequency of the bridge (3 kHz in the above example). For a real instrument, the spacing and Q-values of the individual modes will be very irregular and highly instrument dependent; nevertheless, the effect of the bridge resonance on the overall response will be very similar. In particular, the bridge resonance gives a broad peak in input admittance followed by a 6 dB/octave decrease in the admittance above resonance, where the response is largely dominated by the bridge dynamics rather than that of the instrument itself, with $A_{BB} \approx 1/im\omega$. Note that the height and width of the peak is largely determined by energy lost to the coupled structural vibrations (including, in practice, additional energy lost to all the supported strings) rather than from internal bridge losses, which have been neglected in this example.

The bridge resonance introduces a somewhat smaller peak in the induced body mobility and hence radiated sound. Well above the bridge resonance, the induced body velocity is given by $A_{VB}(\omega_B/\omega)^2$, with an intensity decreasing by 12 dB/octave. Unlike the input bridge admittance, the induced body motion and output sound retains the characteristic resonances of the instrument, though attenuated.

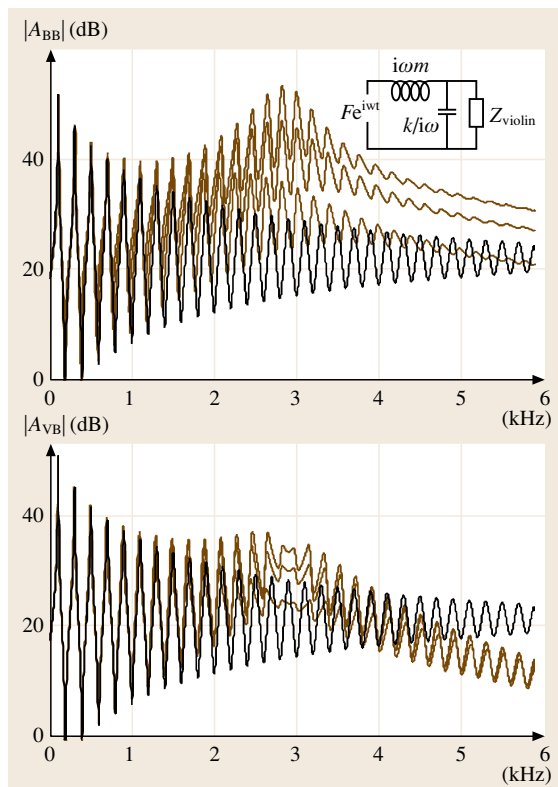
The predicted difference in admittance at the top of the bridge A_{BB} and top of the instrument A_V is illustrated in Fig. 15.42, in measurements by *Moral* and *Jansson* [15.78] reproduced by *Cremer* ([15.30], Fig. 15.9). Whereas the average admittance of the violin varies relatively little with frequency, the admittance at the bridge shows a pronounced BH peak with a relatively featureless and approximately $1/f$ (the added solid line) variation above the peak, as anticipated from the above model.


Fig. 15.41a,b Response curves for a one-degree-of-freedom bridge coupled to an artificial set of regularly spaced (200 Hz), constant effective mass (100 g) and constant Q (50) structural resonances. Panel **(a)** illustrates the effect of bridge mass on the admittance A_{BB} measured at the point of excitation at the top of the bridge, while **(b)** illustrates the corresponding induced body mobility A_{VB}. The *coloured response curves* are for lossless bridges with effective masses 1, 1.5 and 3 g (highest to lowest response), having the same resonant frequency at 3 kH (after *Woodhouse* [15.77]) The *black curves* show the violin body response A_V that would be measured using a massless rigid bridge

Woodhouse [15.77] has extended this idealised model to describe the coupling of the bridge to a more realistic, but still simplified, model for the vibrational modes of the violin with a soundpost. This changes the detailed response, but not the overall qualitative features. Because the response of a violin depends rather randomly at higher frequencies on the positions and Q-values of the structural modes, Woodhouse uses a logarithmic scale to average the peaks and troughs at the maxima and minima of the admittance (approx-
Fig. 15.42 Admittances of a violin measured at the top of the bridge (*top trace*) and at the left foot of the bridge (*lower trace*) illustrating a strong BH peak when measured at the top of the bridge but a relatively monotonic dependence of the body of the instrument (after *Cremer* [15.30, Fig. 12.9]). The added *solid line* represents the $1/f$ reduction in the predicted BH response above the bridge resonance

imately proportional to Q and $1/Q$), to give a *skeleton curve* describing the global variation of the violin's complex admittance (more details are given in the later Sect. 15.2.3 on shell modes). This enables Woodhouse to illustrate the influence of various bridge parameters on the acoustical properties of the instrument, suggesting ways in which violin makers could vary bridge properties to optimise the sound quality of an instrument, though that will always be a matter of personal taste rather than being scientifically defined.

The important role of the bridge in controlling the sound of the violin or cello has often been overlooked, even by many skilled violin makers. Indeed one of the reasons why Cremonese violins generally produce such highly valued sounds is the experience and skill involved in adjusting the mass, size and fitting of the bridge (and the position of the soundpost) to optimize the sound quality, investigated experimentally by *Hacklinger* [15.79].

Added Mass and Muting

A familiar demonstration of the importance of the mass of the bridge on the sound of an instrument is to place a light mass or mute on the top of the bridge. This dramatically softens the tone of the instrument by decreasing the resonant frequency of the bridge and hence amplitude of the higher-frequency components in the spectrum of sound. The added mass Δm lowers the resonant frequency ω_B by a factor $[m/(m+\Delta m)]^{1/2}$. Figure 15.43 illustrates changes in resonant frequency measured by Reinicke for a bridge mounted on a rigid support for an additional mass of 1.5 g and when wedges are inserted between the *wings* of the bridge to inhibit the rotational motion of the top of the bridge and hence the resonant frequency. Audio [?] EXTRAS illustrates the changes in sound of a violin before and after first placing a commonly used 1.8 g mute and then a much heavier practice mute on top of the bridge, and after wedges were inserted in the bridge to inhibit the rocking motion.

Soundpost and Bass Bar

In instruments of the violin family, a soundpost is wedged asymmetrically between the top and back plates, as illustrated schematically in Fig. 15.44. Additionally, a bass bar runs longitudinally along much of the length of the bass-side of the front plate. The soundpost and bass bar give added mechanical strength to the instrument, helping it to withstand the rather large downward force from the angled stretched strings passing over the bridge, which is typically ≈ 10 kg weight for the violin.

Fig. 15.44 Schematic cross section of the violin illustrating the position of the soundpost, bass-bar and f-hole openings

Fig. 15.43 Measurements of bridge resonances from measurements of the ratio of the force exerted by one bridge foot on a rigid surface to the applied force, for an added mass of 1.5 g and for wedges introduced between the *wings* of the bridge to increase its rotational stiffness (after *Reinicke* data reproduced in *Fletcher* and *Rossing* [15.5, Fig. 10.19])

The influence of the soundpost on the quality of sound is so strong that the French refer to it as the *âme* (soul) of the instrument. Its acoustic function is to provide a rather direct coupling of the induced bridge vibrations to both the back and the front plates of the instrument and to provide an additional mechanical constraint, so that the bowed string vibrations excite normal modes, which are linear combinations of the asymmetric and symmetric modes of vibration of the front and back plates of the instrument.

Of modern stringed instruments, only the violin family makes use of a soundpost. However, soundposts were probably used in the medieval fiddle and other early instruments including the viol. The ancient Celtic *crwyth* effectively combined the functions of the bridge and soundpost by using a bridge with feet of unequal length, the first resting on the top plate and the second passing through a hole in the front face to rest on the back plate – a bridge design still used today in the folk-style Greek *rebec* (see *Gill* [15.80]).

15.2.5 String–Bridge–Body Coupling

We now consider the interaction of the strings with the vibrational modes of the body of the instrument via the bridge. Because we are dealing with the coupling of the vibrational modes of the strings, bridge and body of the instrument, the problem has to be considered in terms

of the normal modes of the coupled system. An important aspect of this problem that is often not widely recognised, but is always important in dealing with musical instruments, is the profound influence of damping on the nature of the coupled modes. This is a generic phenomenon for any system of coupled oscillators. As we will see, the strength of the damping relative to the strength of the coupling determines whether a system can be considered as weakly or strongly coupled.

String–Body Mode Coupling

For simplicity, we only consider the perturbation of string resonances from the induced motion of the bridge and ignore any damping introduced by, for example, a finger stopping the string at its opposite end. In general, as we have already seen, the admittance at the point of string support on the bridge will be a complicated, multi-resonant, function of frequency reflecting the normal modes of vibration of the coupled structure. The normal modes will include the combined motions of all parts of the violin body, including the body, bridge, neck, tailpiece, etc.

Each coupled normal mode will contribute a characteristic admittance, which will be spring-like below its resonant frequency, resistive at resonance and mass-like above resonance. The effect of such terminations on the vibrating string is therefore to shift its effective nodal position, as illustrated in Fig. 15.45a–c, for a spring-like string termination with spring constant K, an effective mass M and a lossy support with resistance R.

For a spring-like termination with spring constant K, the bridge will move in phase with the force acting on it. This will increase the effective length of the vibrating string between nodes by a distance $\Delta_{\mathrm{B}} = T/K$, lowering the frequency of a string mode by a fraction T/KL. For a mass-like termination M, the end-support will move in anti-phase with the forces acting on it, so that the effective string length is shortened. The string frequencies are then increased by the fraction $T/M\omega_n^2 = (1/n\pi)^2 m/M$, where m is the mass of the string. It is less easy to visualise the effect of a resistive support because the induced displacement is in phase-quadrature with the driving force. Mathematically, however, a resistive termination can be considered as an imaginary mass $m^* = R/\mathrm{i}\omega$ leading to an imaginary fractional increase in frequency $\mathrm{i}\omega_n 1/(n\pi)^2 m/R$. This imaginary frequency is equivalent to an exponential decay $\mathrm{e}^{-t/\tau}$ for all modes with $\tau = \pi^2 R/m\omega_1^2$, where ω_1 is the frequency of the fundamental string mode. This result can also be derived using somewhat more physical arguments, by equating the loss of stored
Fig. 15.45a–c Coupling of vibrating string to a weakly coupled normal mode via the bridge for the string resonance (**a**) below the resonant frequency of the coupled mode, (**b**) above the resonant frequency, and (**c**) at resonance

vibrational energy to the energy dissipated at the end-support.

The terminating admittance at the bridge for a single coupled vibrational mode can be written in the form

$$A_n(\omega) = \frac{1}{M_n} \frac{\mathrm{i}\omega}{\omega_n^2 - \omega^2 + \mathrm{i}\omega\omega_n/Q_n} \, , \tag{15.58}$$

with the real part of this function determining the decay time of the coupled string resonances and the imaginary part the perturbation in their resonant frequencies. The perturbations are proportional to the ratio of mass of the vibrating string to the effective mass of the coupled resonance at the point of string support on the bridge and vary with frequency with the familiar dispersion and dissipation curves of a simple harmonic oscillator. For a multi-resonant system like the body of any stringed instrument, the string perturbations from each of the coupled structural resonances are additive.

Normal Modes and Damping

Strictly speaking, whenever one considers the coupling between any two or more vibrating systems, one should always consider the normal modes or coupled vibrations rather than treat the systems separately, as we have done above. However, the inclusion of damping has a profound influence on the normal modes of any system of coupled oscillators (*Gough* [15.81]) and justifies the above *weak-coupling approximation*, provided that the coupling at the bridge is not over-strong. Although we

consider the effect of damping in the specific context of a lightly damped string coupled to a more strongly damped structural resonance, the following discussion is completely general and is applicable to the normal modes of any coupled system of damped resonators.

Consider a string vibrating in its fundamental mode coupled via the bridge to a single damped structural resonance. The string has mass m, an unperturbed resonant frequency of ω_s a Q-value of Q_s and a displacement at its mid-point of v. The coupled structural resonance has an effective mass M at the point of string support, an unperturbed resonant frequency of ω_M a Q-value of Q_M and displacement of u.

The vibrating string exerts a force on the coupled body mode, such that

$$M \left(\frac{\partial^2 v}{\partial t^2} + \frac{\omega}{Q_m} \frac{\partial v}{\partial t} + \omega_M^2 v \right) = T \left(\frac{\pi}{L} \right) u \ . \quad (15.59)$$

Multiplying this expression through by $\partial v / \partial t$, one recovers the required result that the rate of increase in stored kinetic and potential energy of the coupled mode is simply the work done on it by the vibrating string less the energy lost from damping. Similar energy balance arguments enable us to write down an equivalent expression for the influence of the coupling on the string vibrations,

$$\frac{m}{2} \left(\frac{\partial^2 u}{\partial t^2} + \frac{\omega}{Q_m} \frac{\partial u}{\partial t} + \omega_M^2 u \right) = T \left(\frac{\pi}{L} \right) v \ , \quad (15.60)$$

where the effective mass of the vibrating string is $m/2$ (i. e. its energy is $1/4 \, m\omega^2 u^2$). To determine the normal-mode frequencies, we look for solutions varying as $\mathrm{e}^{\mathrm{i}\omega t}$. Solving the resultant simultaneous equations we obtain

$$\left(\omega_M^2 - \omega^2 (1 - \mathrm{i}/Q_M) \right) \left(\omega_m^2 - \omega^2 (1 - \mathrm{i}/Q_m) \right)$$
$$= \left(T \frac{\pi}{l} \right)^2 \frac{2}{mM} = \alpha^4 \ , \quad (15.61)$$

where α is a measure of the coupling strength.

Solving to first order in $1/Q$-values and α^2 we obtain the frequencies of the normal modes $\Omega_\pm$ of the coupled system,

$$\Omega_\pm^2 = \omega_+^2 \pm \left(\omega_-^4 + \alpha^4 \right)^{1/2} \ , \quad (15.62)$$

where

$$\omega_\pm^2 = \frac{1}{2} \left[\omega_M^2 \pm \omega_m^2 + \mathrm{i} \left(\frac{\omega_M^2}{Q_M} \pm \frac{\omega_m^2}{Q_m} \right) \right] . \quad (15.63)$$

If the damping terms are ignored, we recover the standard perturbation result with a splitting in the

frequencies of the normal modes at the crossover frequency (when the uncoupled resonant frequencies of the two systems coincide) such that $\Omega_\pm^2 = \omega_M^2 \pm \alpha^2$.

In the absence of damping, the two normal modes at the crossover frequency are linear combinations of the coupled modes vibrating either in or out of phase with each other, with equal energy in each, so that $v/u = \pm\sqrt{m/2M}$. Well away from the crossover region, the mutual coupling only slightly perturbs the individual coupled modes, which therefore retain their separate identities. However, close to the crossover region, when $|\omega_M - \omega_m| \leqslant 2\alpha^2 / (\omega_M + \omega_m)$, the coupled modes lose their separate identities, with the normal modes involving a significant admixture of both.

The inclusion of damping significantly changes the above result. If we focus on the crossover region, coupling between the modes will be significant when

$$\alpha^2 \approx \omega_M^2 - \omega_m^2 \ . \quad (15.64)$$

At the crossing point, when the uncoupled resonances coincide, the frequencies of the coupled normal are given by

$$\Omega_\pm^2 = \omega_M^2 \left(1 + \mathrm{i}/2Q_+ \right) \pm \left(\alpha^4 - \left(\frac{\omega_M^2}{2Q_-} \right)^2 \right)^{1/2} \ , \quad (15.65)$$

where

$$\frac{1}{Q_\pm} = \frac{1}{Q_M} \pm \frac{1}{Q_m} \ . \quad (15.66)$$

The sign of the terms under the square root clearly depends on the relative strengths of the coupling and damping terms. When the damping is large and the coupling is weak, such that $(\omega_M^2/2Q_-)^2 > \alpha^4$, one is in the *weak-coupling* regime, with no splitting in frequency of the modes in the crossover region. In contrast, when the coupling is strong and the damping is weak, such that $(\omega_M^2/2Q_-)^2 < \alpha^4$, the normal modes are split, but by a somewhat smaller amount than had there been no damping.

Figure 15.46 illustrates the very different character of the normal modes in the crossover region in the weak- and strong-coupling regimes. The examples shown are for an undamped string interacting with a structural resonance with a Q of 25, evaluated for coupling factors,

$$K = \frac{2Q_M}{\omega_M^2} \alpha = \frac{2Q_M}{n\pi} \sqrt{\frac{2m}{M}} \ , \quad (15.67)$$
Fig. 15.46 Normal modes of coupled oscillators illustrating the profound effect of damping on the behaviour in the cross-over region illustrated for K-values of 0.75 and $\sqrt{5}$ for an undamped string resonance coupled to a body resonance with a typical $Q = 25$. The *solid line* shows the shifted frequencies of the normal modes as the string frequency is scanned through the body resonance, while the *dashed lines* show the 3 dB points on their damped resonant response (*Gough* [15.81])

of 0.75 and $\sqrt{5}$, in the weak- and strong-coupling regimes, respectively.

In the weak-coupling limit, the frequency of the vibrating string exhibits the characteristic perturbation described in the previous section, with a shift in frequency proportional to the imaginary component of the terminating admittance and an increased damping pro-

portional to the real part. Note that the coupling also weakly perturbs the frequency and damping of the coupled structural resonance. However, there is no splitting of modes at the crossover point and the normal modes retain their predominantly string-like or body-like character throughout the transition region.

In the strong-coupling limit, $K > 1$, the normal modes are split at the crossover point. The losses are also shared equally between the split modes. As the string frequency is varied across the body resonance, one mode changes smoothly from a normal mode with a predominantly string-like character, to a mixed mode at cross over, and to a body-like mode at higher frequencies, and vice versa for the other normal mode.

Our earlier discussion of the perturbation of string resonances by the terminating admittance is therefore justified in the weak-coupling regime ($K \ll 1$), which is the usual situation for most string resonances on musical instruments. However, if the fundamental mode of a string is over-strongly coupled at the bridge to a rather light, weakly damped body resonance, such that $K > 1$, the normal-mode resonant frequency of the vibrating string, when coincident in frequency with the coupled body mode, will be significantly shifted away from its position as the fundamental member of the harmonic set of partials. It is then impossible to maintain a steady Helmholtz bowed waveform on the string at the pitch of the now perturbed fundamental, which is the origin of the wolf-note problem frequently encountered on otherwise often very fine-stringed instruments, and cellos in particular.

To overcome such problems, it is sometimes possible to reduce K by using a lighter string, but more commonly the effective Q-value is reduced by extracting energy from the coupled system by fitting a resonating mass on one of the strings between the bridge and tailpiece. A lossy material can be placed between the added mass and the string to extract energy from the system, which might otherwise simply move the wolf note to a nearby frequency.

String Resonances

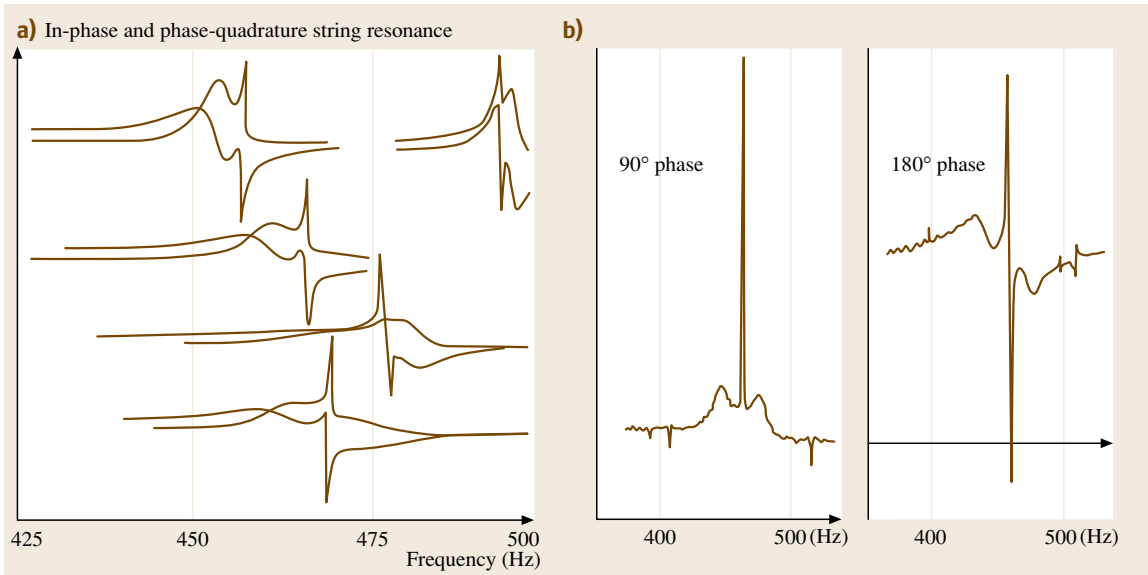
Figure 15.47 illustrates: (a) the frequency dependence of the in-phase and phase-quadrature resonant response of an A-string as its tension increased, so that its frequency passes through a relatively strongly coupled body resonance at ≈ 460 Hz; (b) the splitting in frequency of the normal modes of the second partial of the heavier G-string frequency tuned to coincide with the frequency of the coupled body resonance. Superimposed on these relatively broad resonances is


Fig. 15.47a,b Measurements of the in-phase and in-quadrature resonant response of violin strings coupled via the bridge to a strong body resonance (*Gough* [15.34]). The shift of the broader resonances relative to the unperturbed narrow resonance indicates the extent of the perturbative coupling. **(a)** tuning the A-string resonance through a coupled resonance at $\approx 460\,\mathrm{Hz}$; **(b)** the splitting of the string–body normal modes for the more strongly coupled, second partial, of the heavier G-string

a very sharp resonance arising from transverse string vibrations perpendicular to the strong coupling direction, to be explained in the next section. This very weakly perturbed string resonance provides a marker, which enables us to quantify the shifts and additional damping of string vibrations in the strong coupling direction.

When the frequency of the lighter A-string is tuned below that of the strongly coupled body resonance, the coupling lowers the frequency of the coupled string mode, as anticipated from our earlier discussion. In contrast, when tuned above the coupled resonance the frequency of the coupled string mode is increased, while at coincidence there is a slight indication of split modes somewhat smaller than the widths. The splitting of modes is clearly seen for the second partial of the much heavier G-string (Fig. 15.47b), with symmetrically split broad string/body modes above and below the narrow *uncoupled mode*. Not surprisingly, this violin suffered from a pronounced wolf note when played at 460 Hz in a high position on the G-string, but not on the lighter D- or A-string. Such effects tend to be even more pronounced on cellos due to the very high bridge providing strong coupling between the vibrating strings and body of the instrument.

On plucked string instruments the inharmonicity of the partials of a plucked note induced by coupling at the bridge to prominent structural resonances causes beats in the sound of plucked string, which contribute to the characteristic sound of individual instruments. *Woodhouse* [15.82,83] has recently made a detailed theoretical, computational and experimental study of such effects for plucked notes on a guitar taking account of the effect of damping on the coupled string–corpus normal modes. This is sometimes not taken into proper account in finite-element software, in which the normal modes of an interacting system are first calculated ignoring damping, with the damping of the modes then added. As is clear from Fig. 15.46, such an approach will always break down whenever the width of resonances associated with damping becomes comparable with the splitting of the normal modes in the absence of damping, as is frequently the case in mechanical and acoustical systems.

Polarisation

We have already commented on the response of a bridge mounted centrally on a symmetrically constructed instrument, with string vibrations perpendicular to the front plate exciting only symmetric modes of the body

of the instrument, while string vibrations parallel to the front plate induce a couple on the front plate exciting only asymmetric modes. The terminating admittance at the bridge end of the string will therefore be a strongly frequency dependent function of the polarisation direction of the transverse string modes. The angular dependence of the terminating admittance lifts the degeneracy of the string modes resulting in two independent orthogonal modes of transverse string vibration, with different perturbed frequencies and damping, polarised along the frequency-dependent principal directions of the admittance tensor. If a string is excited at an arbitrary angle, both modes will be excited, so that in free decay the directional polarisation will precess at the difference frequency. The resultant radiated sound from the excited body resonances will also exhibit beats, which unlike the nonlinear effects considered earlier will not vary with amplitude of string vibration.

In instruments of the violin family, the soundpost removes the symmetry of the instrument, with normal modes involving a mixture of symmetric and asymmetric modes. Measurements like those shown in Fig. 15.47 demonstrate that below ≈ 700 Hz, the effect of the soundpost is to cause the bridge to rock backwards and forwards about the treble foot closest to the soundpost, which acts as a rather rigid fulcrum. This accounts for the very narrow string resonances shown in Fig. 15.47, which correspond to string vibrations polarised parallel to the line between the point of string support and the rigidly constrained right-hand foot, as indicated in Fig. 15.44. In contrast, string vibrations polarised in the orthogonal direction result in a twisting couple acting on the bridge, with the left-hand foot strongly exciting the vibrational modes of the front plate giving the frequency-shifted and broadened string resonances of the strongly coupled string modes.

By varying the polarisation direction of an electromagnetically excited string, one can isolate the two modes and determine their polarisations (*Baker* et al. [15.84]). When such a string is bowed, it will in general be coupled to both orthogonal string modes. The unperturbed string mode may well help stabilise the repetitive Helmholtz bowed waveform.

String–String Coupling

A vibrating string on any multi-stringed instrument is coupled to all the other strings supported on a common supporting bridge. This is particularly important on the piano, where pairs and triplets of strings tuned to the same pitch are used to increase the intensity of the notes in the upper half of the keyboard. Such coupling is also important on instruments like the harp, where the strings and their partials are coupled via the soundboard. On many ancient bowed and plucked stringed instruments, a set of coupled sympathetic string were used to enhance the sonority and long-term decay of plucked and bowed notes. Even on modern instruments like the violin and cello, the coupling of the partials of a bowed or plucked string with those of the other freely vibrating open (unstopped) strings enhances the decaying aftersound of a bowed or plucked note. This may be one of the reasons why string players have a preference for playing in the bright key signatures of G, D and A major associated with the open strings, where both direct and sympathetic vibrations can easily be excited.

The musical importance of such coupling on the piano is easily demonstrated by first playing a single note and holding the key down so that the note remains undamped and then holding the sustaining pedal down, so that many other strings can also vibrate in sympathy and especially those with partials coincident with those of the played note. Composers, such as Debussy, exploit the additional sonorities produced by such coupling, as in La Cathédrale Engloutie |?⟩ **EXTRAS** .

The influence of coupling at the bridge of the normal modes of string vibration on the piano has been discussed by *Weinreich* [15.85] and for sympathetic string in general by the present author [15.81]. Consider first two identically tuned string terminated by a common bridge with string vibrations perpendicular to the soundboard and relative phases represented by arrows. The normal modes can therefore be described by the combination ↑↑ and ↓↑ with the strings vibrating in phase or in anti-phase. When the strings vibrate in anti-phase ↓↑, they exert no net force on the bridge, which therefore remains a perfect node inducing no perturbation in frequency or additional damping or transfer of energy to the soundboard. In contrast, when the strings vibrate in the same phase ↑↑, the force on the bridge and resultant amplitude of sound produced will be doubled, as will the perturbation in frequency and damping of the normal modes, and the amplitude of the resultant sound, relative to that of a single string.

Reactive terms in the common bridge admittance tend to split the frequencies of the normal modes in the vicinity of the crossover frequency region, while resistive coupling at the bridge tends to draw the modal frequencies together over an appreciable frequency range. This is illustrated by Weinreich's predictions for two strings coupled at the bridge by a complex admittance shown in Fig. 15.48, which shows the veer-
Fig. 15.48 Normal modes of a string doublet coupled at the bridge by a complex impedance. The *dashed* and *dotted curves* illustrate the effect of increasing the reactive component (after *Weinreich* [15.85])

Fig. 15.49 Decay in string vibration of a struck C4 (262 Hz) piano string, first with other members of the string triplet damped and then with one other similarly tuned string allowed to vibrate also (after *Weinreich* [15.85])

ing together of the normal modes induced by resistive coupling and the increase in splitting as the reactive component of the coupling is increased.

If the two strings are only slightly mistuned, the amplitudes of the string vibrations involved in the normal modes can still be represented as ↑↑ and ↓↑, but the amplitudes of the two string vibrations will no longer be identical. Hence, when the two strings of a doublet are struck with equal amplitude by a hammer, the mode can be represented by a combination of vibrations ↑↑ with equal amplitude with a small component with opposite amplitudes the ↓↑ dependent on the mistuning. This leads to a double decay in the sound intensity, with the strongly excited ↑↑ mode decaying relatively quickly, leaving the smaller amplitude but weakly damped ↓↑ mode persisting at longer times. Figure 15.49, from *Weinreich* [15.85], shows the rapid decay of a single C4 string, when all other members of the parent string triplet are damped, followed by the much longer long-term decay of the normal mode excited when one other member of the triplet is also allowed to vibrate freely. More-complicated decay patterns with superimposed slow beats are observed for various degrees of mistuning, from interference with small-amplitude

orthogonally polarised string modes excited when the strong-coupling direction is not exactly perpendicular to the soundboard. Weinreich suggests that skilled piano tuners deliberately mistune the individual strings of string doublets and triplets to maximise their long-term ringing sound. Any weakly decaying component of a decaying sound is acoustically important because of the logarithmic response of the ear to sound intensity.

15.2.6 Body Modes

Stringed instruments come in a great variety of shapes and sizes, from strings mounted on simple boxes or on skins stretched over hollow gourds to the more complex renaissance shapes of the viols, guitars and members of the violin family. The vibrational modes of all such instruments, which are ultimately responsible for the radiated sound, involve the collective modes of vibration of all their many component parts. For example, when a violin or guitar is played, all parts of the instrument vibrate – the individual strings, the bridge, the front and back plates and ribs that make up the body of the instrument, the air inside its hollow cavity, the neck, the fingerboard, the tailpiece and, for members of the violin family, the internal soundpost also.

Because of the complexity of the dynamical structures, it would be well nigh impossible to work out the modal shapes and frequencies of even the simplest stringed instruments from first principles. However, as we will show later in this section, with the advent of powerful computers and finite-element analysis software, it is possible to compute the modal vibrations and frequencies of typically the first 20 or more nor-

mal modes for the violin and guitar below around 1 kHz. Such calculations do indeed show a remarkable variety of vibrational modes, with every part of the instrument involved in the vibrations to some extent. Such modes can be observed by direct experiment using Chladni plate vibrations, laser holography and modal analysis techniques, as briefly described in this section.

The frequencies of the vibrational modes can be obtained even more simply from the admittance measured at the position of string support or other selected position on the body of an instrument, when the instrument is excited at the bridge by a sinusoidal electromagnetic force or a simple tap. However, unless a large number of measurements over the whole body of the instrument (normal-mode analysis) are made, such measurements provide very little direct information about the nature of the normal modes and the parts of the violin which contribute most strongly to the excited vibrations.

Although a particular structural mode can be very strongly excited, it may contribute very little to the radiated sound and hence the quality of sound of an instrument. Examples of such resonances on the violin or guitar include the strong resonances of the neck and fingerboard. However, even if such resonances produce very little sound, their coupling to the strings via the body and bridge of the instrument can lead to considerable inharmonicity and damping of the string resonances, as discussed in the previous section. Such effects can have a significant effect on the sound of the plucked string of a guitar and the ease with which a repetitive waveform can be established on the bowed string.

To produce an appreciable volume of sound, the normal modes of instruments like the violin and guitar have to involve a net change in volume of the shell structure forming the main body of the instrument. This then acts as a monopole source radiating sound uniformly in all directions. However, when the acoustic wavelength becomes comparable with the size of the instrument, dipole and higher-order contributions also become important.

For the guitar and instruments of the violin family, there are several low-frequency modes of vibration which involve the flexing, twisting and bending of the whole body of the instrument, contributing very little sound to the lowest notes of the instruments. To boost the sound at low frequencies, use is often made of a Helmholtz resonance involving the resonant vibrations of the air inside the body cavity passing in and out of f-holes or rose-hole cut into the front plate of the instrument. This is similar to the way in which the low-frequency sound of a loudspeaker can be boosted by

mounting it in a bass-reflex cabinet. The use of a resonant air cavity to boost the low-frequency response has been a common feature of almost every stringed instrument from ancient times.

Although finite-element analysis and modal analysis measurement techniques provide a great wealth of detailed information about the vibrational states of an instrument, considerable physical insight and a degree of simplification is necessary to interpret such measurements. This was recognised by *Savart* [15.86] in the early part of the 19th century, when he embarked on a number of ingenious experiments on the physics of the violin in collaboration with the great French violin maker Vuillaume. To understand the essential physics involved in the production of sound by a violin, he replaced the beautiful, ergonomically designed, renaissance shape of the violin body by a simple trapezoidal shell structure fabricated from flat plates with two central straight slits replacing the elegant f-holes cut into the front. As Savart appears to have recognised, the detailed shape is relatively unimportant in defining the essential acoustics involved in the production of sound by a stringed instrument.

We will adopt a similar philosophy in this section and will consider a stringed instrument made up of its many vibrating components – the strings and bridge, which we have already considered, the supporting shell structure, the vibrations of the individual plates of such a structure, the soundpost which couples the front and back plates, the fingerboard, neck and tailpiece, which vibrate like bars, and the air inside the cavity. Although we have already emphasised that it is never possible to consider the vibrations of any individual component of an instrument in isolation, as we have already shown for the string coupled to a structural resonance at the bridge, it is only when the resonant frequencies of the coupled resonators are close together that their mutual interactions are so important that they change the character of the vibrational modes. Otherwise, the mutual interactions between the various subsystems simply provide a first-order correction to modal frequencies without any very significant change in their modal shapes.

Flexural Thin–Plate Modes

To radiate an appreciable intensity of sound, energy has to be transferred via the bridge from the vibrating strings to the much larger surfaces of a soundboard or body of an instrument. The soundboards of the harp and keyboard instruments and the shell structures of stringed instruments like the violin and guitar can formally be considered as thin plates. Transverse or

flexural waves on their surface satisfy the fourth-order thin-plate equation (*Morse* and *Ingard* [15.43, Sect. 5.3]), which for an isotropic material can be written as

$$\frac{\partial^2 z}{\partial t^2} + \frac{Eh^2}{12\rho(1-v^2)}\left(\frac{\partial^4 z}{\partial x^4} + 2\frac{\partial^2 z}{\partial x^2}\frac{\partial^2 z}{\partial y^2} + \frac{\partial^4 z}{\partial y^4}\right) = 0\,, \tag{15.68}$$

where z is the displacement perpendicular to the xy-plane, h is the plate thickness, E is the Young's modulus, v is the Poisson ratio, and ρ the density.

It is instructive first to consider solutions for a narrow quasi-one-dimensional thin plate, like a wooden ruler or the fingerboard on a violin. One-dimensional solutions can be written in the general form

$$z = (a\cos kx + b\sin kx + c\cosh kx + d\sinh kx)\mathrm{e}^{\mathrm{i}\omega t}\,, \tag{15.69}$$

where

$$\omega = \left(\frac{E}{12\rho(1-v^2)}\right)^{1/2} hk^2\,. \tag{15.70}$$

The hyperbolic functions correspond to displacements that decay exponentially away from the ends of the bar as $\exp(\pm kx)$. Well away from the ends, the solutions are therefore very similar to transverse waves on a string, except that the frequency now depends on k^2 rather than k with a phase velocity $c = \omega/k$ proportional to $k \approx \omega^{1/2}$. Flexural waves on thin plates are therefore dispersive and unlike waves travelling on strings any disturbance will be attenuated and broadened in shape as it propagates across the surface.

The k values are determined by the boundary conditions at the two ends of the bar, which can involve the displacement, couple $M = -ES\kappa^2\partial^2 z/\partial x^2$ and shearing force $F = \partial M/\partial x = -ES\kappa^2\partial^3 z/\partial x^3$ at the ends of the bar, where k is the radius of gyration of the cross section (*Morse* and *Ingard* [15.43, Sect. 5.1]).

For a flexible bar there are three important boundary conditions:

1. Freely hinged, where the free hinge cannot exert a couple on the bar, so that

$$z = 0 \quad \text{and} \quad \frac{\partial^2 z}{\partial x^2} = 0\,, \tag{15.71}$$

2. Clamped, where the geometrical constraints require

$$z = 0 \quad \text{and} \quad \frac{\partial z}{\partial x} = 0\,, \tag{15.72}$$

3. Free, where both the couple and the shearing force at the ends are zero, so that

$$\frac{\partial^3 z}{\partial x^3} = \frac{\partial^2 z}{\partial x^2} = 0\,. \tag{15.73}$$

A bar of length L, freely hinged at both ends, supports simple sinusoidal spatial solutions with m half-wavelengths between the ends and modal frequencies

$$\omega_m = h\sqrt{\frac{E}{12\rho(1-v^2)}}\left(\frac{m\pi}{L}\right)^2\,. \tag{15.74}$$

For long bars with clamped or free ends, the nodes of the sinusoidal component are moved inwards by a quarter of a wavelength and an additional exponentially decaying solution has to be added to satisfy the boundary conditions, so that at the $x = 0$ end of the bar

$$z \approx A\left[\sin(k_\mathrm{m}x - \pi/4) \pm \frac{1}{\sqrt{2}}\mathrm{e}^{-k_m x}\right]\,, \tag{15.75}$$

where the plus sign corresponds to a clamped end and the minus to a free end, and $k_m = (m+1/2)\pi/L$. The modal frequencies are given by

$$\omega_m = h\sqrt{\frac{E}{12\rho(1-v^2)}}\left(\frac{(m+1/2)\,\pi}{L}\right)^2 \tag{15.76}$$

which, for the same m value, are raised slightly above those of a bar with hinged ends. Corrections to these formulae from the leakage of the exponentially decaying function from the other end of the bar are only significant for the $m = 1$ mode and are then still less than 1%.

The solutions close to the end of a bar for hinged, clamped and free boundary conditions are illustrated in Fig. 15.50, with the phase-shifted sinusoidal component for the latter two indicated by the dotted line. The exponential contribution is only significant out to distances $\approx \lambda/2$.

The above formulae can be applied to the bending waves of quasi-one-dimensional bars of any cross section, by replacing the radius of gyration $\kappa = h/\sqrt{12}$ of the thin rectangular bar with $a/2$ for a bar of circular cross section and radius a, and $\sqrt{a^2+b^2}/2$ for a hollow cylinder with inner and outer radii a and b (*Fletcher* and *Rossing* [15.5, Fig. 2.19]).

Another case of practical importance in musical acoustics is a bar clamped at one end and free at the other. This would, for example, describe the bars of a tuning fork or could be used to model the vibrations of the neck or finger board on a stringed instrument. In this
Fig. 15.50 Boundary conditions for flexural waves at the end of a one-dimensional bar. The *dashed line* represents the phase-shifted sinusoidal component, to which the exponentially decaying component has to be added to satisfy the boundary conditions

Fig. 15.51 Schematic illustration of the lowest-frequency twisting (1,1) and bending (2,0) modes of a thin bar with free ends

case, there is an addition $m = 0$ vibrational mode, with exponential decay length comparable with the length of the bar. The modal frequencies are then given (*Fletcher* and *Rossing* [15.5, (2.64)]) by

$$\omega_m = \frac{h}{4}\left(\frac{\pi}{L}\right)^2 \sqrt{\frac{E}{12\rho(1-v^2)}}$$
$$\times \left[1.194^2, 2.988^2, 5^2, \ldots, (2m+1)^2\right].$$
(15.77)

In the above discussion, we have described the modes in terms of the number m of half-wavelengths of the sinusoidal component of the wave solutions within the length of the bar. A different nomenclature is frequently used in the musical acoustics literature, with the mode number classified by the number of nodal lines (or points in one dimension) m in a given direction *not including the boundaries* rather than the number of half-wavelengths m between the boundaries, as in Fig. 15.51.

Twisting or Torsional Modes

In addition to flexural or bending modes, bars can also support twisting (torsional) modes, as illustrated in Fig. 15.51 for the $z = xy$ (1,1) mode.

The frequencies of the twisting modes are determined by the cross section and shear modulus G, equal to $E/2(1+v)$ for most materials (*Fletcher* and *Rossing* [15.5, Sect. 2.20]). The wave velocity of torsional waves is dispersionless (independent of frequency) with $\omega_n = nc_T k$, where

$$c_T = \frac{\omega}{k} = \sqrt{\frac{GK_T}{\rho I}} = \alpha \sqrt{\frac{E}{2\rho(1+v)}},$$
(15.78)

where GK_T is the torsional stiffness given by the couple, $C = GK_T \partial\theta/\partial x$, required to maintain a twist of the bar through an angle θ and $I = \int \rho r^2 \, dS$ is the moment of inertia per unit length along the bar. For a bar of circular cross section $\alpha = 1$, for square cross section $\alpha = 0.92$, and for a thin plate with width $w > 6h$, $\alpha = (2h/w)$. For a bar that is fixed at both ends, $f_n = nc_T/2L$, while for a bar that is fixed at one end and free at the other, $f_n = (2n+1)c_T/4L$, where n is an integer including zero.

Thin bars also support longitudinal vibrational modes, but since they do not involve any motion perpendicular to the surface they are generally of little acoustic importance, other than possibly for the lowest-frequency soundpost modes for the larger instruments of the violin family.

Two-Dimensional Bending Modes

Solutions of the thin-plate bending wave solutions in two dimensions are generally less straightforward, largely because of the more-complicated boundary conditions, which couple the bending in the x- and y-directions. For a free edge parallel to the y-axis, the boundary conditions are (*Rayleigh* [15.3, Vol. 1, Sect. 216])

$$\frac{\partial^2 z}{\partial x^2} + v \frac{\partial^2 z}{\partial y^2} = 0$$

and

$$\frac{\partial}{\partial x}\left[\frac{\partial^2 z}{\partial x^2} + (2-v)\frac{\partial^2 z}{\partial y^2}\right] = 0.$$
(15.79)

Thus, when a rectangular plate is bent downwards along its length, it automatically bends upwards along its width and vice versa. This arises because downward bending causes the top surface of the plate to stretch and

the bottom surface to contract along its length. But by Poisson coupling, this causes the top surface to contract and lower surface to stretch in the orthogonal direction, causing the plate to bend in the opposite direction across its width. This is referred to as anticlastic bending. The Poisson ratio ν can be determined from the ratio of the curvatures along the bending and perpendicular directions.

In addition, for orthotropic materials like wood, from which soundboards and the front plates of most stringed instruments are traditionally made, the elastic constants are very different parallel and perpendicular to the grain structure associated with the growth rings. *McIntyre* and *Woodhouse* [15.88] have published a detailed account of the theory and derivation of elastic constants from measurement of plate vibrations in both uniform and orthotropic thin plates, including the influence of damping.

For an isotropic rectangular thin plate, hinged along on all its edges, a simple two-dimensional (2-D) sinewave solution satisfies both the wave equation (15.68) and the boundary conditions, with m and n halfwavelengths along the x- and y-directions, respectively, giving modal frequencies

$$\omega_{mn} = h\sqrt{\frac{E}{12\rho(1-\nu^2)}\left[\left(\frac{m\pi}{L_x}\right)^2 + \left(\frac{n\pi}{L_y}\right)^2\right]}.$$
(15.80)

By analogy with our discussion of flexural waves in one-dimensional bars, we would expect the modal frequencies of plates with clamped or free edges to be raised, with the nodes of the sinusoidal components of the wave solution moved inwards from the edges by approximately quarter of a wavelength. For the higherorder modes, the modal frequencies would therefore be given to a good approximation by

$$\omega_{mn} = h\sqrt{\frac{E}{12\rho(1-\nu^2)}}$$
$$\times\left[\left(\frac{(m+1/2)\pi}{L_x}\right)^2 + \left(\frac{(n+1/2)\pi}{L_y}\right)^2\right].$$
(15.81)

As recognised by *Rayleigh* [15.3, Vol. 1, Sect. 223], it is difficult to evaluate the modal shapes and modal frequencies of plates with free edges. The method used by Rayleigh was to make an intelligent guess of the wavefunctions which satisfied the boundary conditions and to determine the frequencies by equating the resulting potential and kinetic energies. *Leissa* [15.89] has reviewed various refinements of the original calculations. For a plate with free edges, the nodal lines are also no longer necessarily straight, as they were for plates with freely hinged edges.

Chladni Patterns

The modal shapes of vibrating plates can readily be visualised using Chladni patterns. These are obtained by supporting the plate at a node of a chosen mode excited electromagnetically, acoustically or with a rosined bow drawn across an edge. A light powder is sprinkled onto the surface. The plate vibrations cause the powder to bounce up and down and move towards the nodes of the excited mode, allowing the nodal line patterns to be visualised. Figure 15.52 illustrates Chladni patterns measured by *Waller* [15.87] for a rectangular plate with dimensions $L_x/L_y = 1.5$, with the number of nodal lines between the boundary edges determining the nomenclature of the modes. Note the curvature of the nodal lines resulting from the boundary conditions at the free edges.

Figure 15.53 illustrates the nodal line shapes and relative frequencies of the first 10 modes of a square plate with free edges, where $f_{11} = hc_L/L^2\sqrt{1-\nu/2}$ (after *Fletcher* and *Rossing* [15.5, Fig. 3.13]).

Another important consequence of the anticlastic bending is the splitting in frequencies of combination modes that would otherwise be degenerate. This is illustrated in Fig. 15.54 by the combination $(2,0) \pm (0,2)$ normal modes of a square plate with free edges. The $(2,0) \pm (0,2)$ modes are referred to as the X- and ringmodes from their characteristic nodal line shapes. The $(2,0)-(0,2)$ X-mode exhibits anticlastic bending in the same sense as that induced naturally by the Poisson coupling. It therefore has a lower elastic energy and hence
Fig. 15.52 Chladni pattern with *white lines* indicating the nodal lines of the first few modes of a rectangular plate (after *Waller* [15.87])
Fig. 15.53 Schematic representation of the lowest 10 vibrational modes of a square plate with free edge
Fig. 15.54 Formation of the ring- and *X*-modes by the superposition of the (2, 0) and (0, 2) bending modes

lower vibrational frequency than the (0, 2)+(2, 0) ring-mode, with curvatures in the same sense in both the *x*- and *y*-directions. The ring- and *X*-modes will therefore be split in frequency above and below the otherwise degenerate mode, as illustrated in *Fletcher* and *Rossing* [15.5, Fig. 13.11].

Plate Tuning

The modal shapes and frequencies of the lowest-order (1,1) twisting mode and the *X*-and ring-modes are widely used for the *scientific tuning* of the front and back plates of violins following plate-tuning guidelines developed by *Hutchins* [15.90, 91]. These are referred to as violin plate modes 1, 2 and 5, as illustrated in Fig. 15.55 by Chladni patterns for a *well-tuned* back plate. The violin maker aims to adjust the thinning of the plates across the area of the plate to achieve these symmetrical nodal line shapes at specified modal frequencies.

The use of such methods undoubtedly results in a high degree of quality control and reproducibility of
Fig. 15.55 Chladni patterns for the first twisting-(#1), X-(#2) and ring-(#5) modes of a viola back plate (after *Hutchins* [15.90])

the acoustic properties of the individual plates before assembly and, presumably, of the assembled instrument also, especially for the lower-frequency structural resonances. Unfortunately, they do not necessarily result in instruments comparable with the finest Italian instruments, which were made without recourse to such sophisticated scientific methods. Traditional violin makers instinctively assess the elastic properties of the plates by their feel as they are twisted and bent, and also by listening to the sound of the plates as they are tapped or even rubbed around their edges, rather like a bowed plate. From our earlier discussion, it is clear that the mass of the plates is also important in governing the acoustical properties.

Geometrical Shape Dependence

The above examples demonstrate that the lower-frequency vibrational modes of quite complicated shaped plates can often be readily identified with those of simple rectangular plates, though the frequencies of such modes will clearly depend on the exact geometry involved. This is further illustrated in Fig. 15.56 by the modal shapes of a guitar front plate obtained from time-averaged holography measurements by *Richardson* and *Roberts* [15.92], where the contours indicate lines of constant displacement perpendicular to the surface. For the guitar, the edges of the top plate are rather good nodes, because of the rather heavy supporting ribs and general construction of the instrument. The boundary conditions along the edges of the plate are probably intermediate between hinged and clamped. The modes can be denoted by the number of half-wavelengths along the length and width of the instrument. Note that circular rose-hole opening in the front face, which plays an important role in determining the frequency of the Helmholtz air resonance boosting the low-frequency response of the instrument, tends to concentrate most of

the vibrational activity to the lower half of the front plate.

Mode Spacing

Although the frequencies of the modes of complicated shapes such as the violin, guitar and piano soundboard are rather irregularly spaced, at sufficiently high frequencies, one can use a statistical approach to estimate the spacing of the modal frequencies (*Cremer* [15.30, Sect. 11.2]). For large m and n values, the modal frequencies of an isotropic rectangular plate are given by

$$\omega_{mn} \approx h \sqrt{\frac{E}{12\rho(1-\nu^2)}} \left(k_m^{~2} + k_n^2\right) , \qquad (15.82)$$

where $k_m = m\pi/L_x$ and $k_n = n\pi/L_y$. The modes can be represented as points (m, n) on a rectangular grid in k-space, with a grid spacing of π/L_x and π/L_y along the k_x and k_y directions. Each mode therefore occupies an area in k-space of π^2/L_xL_y. For large m and n, the number of modes ΔN between k and $k + \Delta k$ is therefore on average just the number of modes in the k-space area between k and $k + \Delta k$, so that

$$\Delta N = \frac{\pi}{2}k\Delta k \frac{L_xL_y}{\pi^2} = \frac{\pi}{2}\frac{\Delta\omega}{2\beta}\frac{L_xL_y}{\pi^2} , \qquad (15.83)$$

where we have made use of the dispersion relationship $\omega = \beta k^2$.

The density of modes per unit frequency is then constant and independent of frequency,

$$\frac{\mathrm{d}N}{\mathrm{d}f} = \frac{1}{2\beta}L_xL_y = \frac{\sqrt{3(1-\nu^2)}}{c_\mathrm{L}h}S \approx 1.5\frac{S}{c_\mathrm{L}h} , \qquad (15.84)$$

where S is the area of the plate. The spacing of modes Δf will therefore on average be $\approx c_\mathrm{L}h/1.5S$, proportional to the plate thickness and inversely proportional to plate area. For large k values, this result becomes independent of the shape of the plate. For an orthotropic plate like the front plate of the violin or guitar, the spacing is determined by the geometric mean $(c_xc_y)^{1/2}$ of the longitudinal velocities parallel and along the grain. For the violin, *Cremer* [15.30, p. 292] estimates an asymptotic average mode spacing of 73 Hz for the top plate and 108 Hz for the back plate. Above around 1.5 kHz the width of the resonances on violin and guitar plates becomes comparable with their spacing, so that experimentally it becomes increasingly difficult to excite or distinguish individual modes.

On many musical instruments such as the violin and guitar, the presence of the f- and rose-hole open-
Fig. 15.56 Typical modal shapes for a number of low-frequency modes of a guitar top plate from time-averaged holographic measurements by *Richardson* and *Roberts* [15.92]

ings introduce additional free-edge internal boundary conditions, which largely confine the lower-frequency modes to the remaining larger areas of the plate. The effective area determining the density of lower-frequency modes for both instruments will therefore be significantly less that that of the whole plate. Any reduction in plate dimensions, such as the island region on the front plate of the violin between the f-holes, will limit the spatial variation of flexural waves in that direction. Such a region will therefore not contribute significantly to the normal modes of vibration of the plate until $\lambda(\omega)/2$ is less than the limiting dimension.

Anisotropy of Wood

Wood is a highly anisotropic material with different elastic properties perpendicular and parallel to the grain. Furthermore, the wood used for soundboards and plates of stringed instruments are cut from nonuniform circular logs (slab or quarter cut), so that their properties can vary significantly across their area.

McIntyre and *Woodhouse* [15.88] have described how the anisotropic properties affect the vibrational modes of rectangular thin plates and have shown how the most important elastic constants including their loss factors can be determined from the vibrational frequencies and damping of selected vibrational modes. For a rectangular plate with hinged edges

$$\omega_{mn}^2 = \frac{h^2}{\rho}\left[D_1k_m^4 + D_3k_n^4 + (D_2+D_4)\,k_m^2k_n^2\right] , \qquad (15.85)$$

where $D_1–D_4$ are the four elastic constants required to describe the potential energy of a thin plate with orthotropic symmetry. These are related to the more familiar elastic constants by the following relationships

$$D_1 = E_x/12\mu \, , \ D_3 = E_y/12\mu \, , \ D_4 = G_{xy}/3 \, ,$$
$$D_2 = \nu_{xy}E_y/6\mu = \nu_{yx}E_x/6\mu \, , \qquad (15.86)$$

where $\mu = 1 - \nu_{xy}\nu_{yx}$. G_{xy} gives the in-plane shear energy when a rectangular area on the surface is distorted into a parallelogram. This is the only energy term involved in a pure twisting mode (i.e. $z = xy$). For an isotropic plate, $D_4 = E/6(1+\nu)$.

For many materials, $(D_2 + D_4) \approx 2\sqrt{D_1 D_2}$, so that (15.82) can be rewritten as

$$\omega_{mn}^2 = \frac{h^2}{\rho}\sqrt{D_1 D_3}$$
$$\times \left[\sqrt[4]{\frac{D_1}{D_3}}\left(\frac{m\pi}{L_x}\right)^2 + \sqrt[4]{\frac{D_3}{D_1}}\left(\frac{n\pi}{L_y}\right)^2 \right]^2 .$$
$$(15.87)$$

The vibrational frequencies are therefore equivalent to those of a shape of the same area with averaged elastic constant $\sqrt{D_1 D_3}$ and length scales L_x multiplied by the factor $\sqrt[8]{D_1/D_3}$ and L_y by its inverse. The relative change in scaled dimensions is therefore $\sqrt[4]{D_1/D_3}$. These scaling factors account for the elongation of the equal contour shapes along the stiffer bending direction in the holographic measurements of mode shapes for the front plate of the guitar (Fig. 15.56), where the higher elastic modulus along the grains is further increased by strengthening bars glued to the underside of the top plate at a shallow angle to the length of the top plate.

Typical values for the elastic constants of spruce and maple traditionally used for modelling the violin are listed in Table 15.5 from *Woodhouse* [15.77]. The anisotropy of the elastic constants along and perpendic-

Table 15.5 Typical densities and elastic properties of wood used for stringed instrument modelling (after *Woodhouse* [15.77]). (The values with asterisks are intelligent guesses in the absence of experimental data)

Property	Symbol	Units	Spruce	Maple
Density	ρ	kg/m³	420	650
	D_1	MPa	1100	860
	D_2	MPa	67	140*

Relative scaling factors	$\sqrt[4]{D_1/D_3}$		1.9	1.4

ular to the grain of a spruce plate cut with the growth rings running perpendicular to the surface would give a relative scaling factor for a violin front plate of almost double the relative width, if one wanted to consider the flexural vibrations in terms of an equivalent isotropic thin plate. The anisotropy is therefore very important in determining the vibrational modes of such instruments.

Plate Arching

The front and back plates of instruments of the violin family have arched profiles, which give the instrument a greatly enhanced structural rigidity to support the downward component of the string tension ($\approx 10\,\text{kg}$ weight). The arching also significantly increases the frequencies of the lowest flexural plate modes. In the case of lutes, guitars and keyboard instruments with a flat sounding board or front plate, the additional rigidity is achieved by additional cross-struts glued to the back of the sounding board. The bass bar in members of the violin family serves a similar purpose in providing addition strengthening to that of the arching.

The influence of arching on flexural vibration frequencies is easily understood by considering the transverse vibrations of a thin circular disc. For a flat disc, the modal frequencies are determined by the flexural energy associated with the transverse vibrations. The longitudinal strains associated with the transverse vibrations are only second order in displacement and can therefore be neglected. However, if the disc is *belled out* to raise the centre to a height H, the transverse vibrations now involve additional first-order longitudinal strains stretching the disc away from its edges. The energy involved in such stretching, which is resisted by the rigidity of the circumferential regions of the disc, introduces an additional potential energy proportional to H^2. By equating the kinetic to the increased potential energy, is follows that the frequency of the lowest-order symmetrical mode will be increased by a factor $[1 + \alpha(H/h)^2]^{1/2}$, where $\alpha \approx 1$ has to be determined by detailed calculation. *Reissner* [15.93] showed that, when the arching is larger than the plate thickness, $H \gg h$, the frequency of the fundamental mode is raised by a factor $\omega/\omega_0 = 0.68H/h$ for a circular disc with clamped edges, and $0.84H/h$ with free edges. For a shallow shell with $H/a < 0.25$, where a is the radius of the disc, the asymptotic frequency can conveniently be expressed as $\omega_n \approx 2(E/\rho)^{1/2}H/a^2$. The arching dependence of the modal frequencies is greatest for the lowest-frequency modes. At high frequencies, the radius of curvature is large compared to the wavelength, so arching is much less important.

The combined effect of the arching and the f- and rose-holes cut into the front face of many stringed instruments is to raise the frequency of the acoustically important lower-frequency modes to well above the asymptotic spacing of modal frequencies predicted by (15.82). For example, the lowest-frequency plate modes of the violin front and back plates are typically in the range 400–500 Hz compared with Cremer's predictions for an asymptotic spacing of modes ≈73 Hz for the top plate and 108 Hz for the back plate [15.30, p. 292].

The more highly arched the plates the stiffer they will be and, for a given mass, the higher will be their associated vibrational frequencies. High arching may well contribute to the relatively soft and sweet sounds of the more highly arched early Amati and Stainer violins and the more powerful and brilliant sounds of the flatter later Stradivari and Guarneri models.

Shell Structures

Although it is interesting to investigate the free plates of violins and other instruments before they are assembled into the instrument as a whole, once assembled their vibrational properties will generally be very different, as they are subject to completely different boundary conditions at their supporting edges and by the soundpost constraint for instruments of the violin family. The supporting ribs tie the outer edges of the back and front plates together. The curvature of the outer edge shape gives the 1–2 mm-thick ribs of a violin considerable structural strength and rigidity, in much the same way as the bending of a serpentine brick wall. In many instruments there are extra strips and blocks attached to the ribs and plate edges to strengthen the joint, which still allow a certain amount of angular flexing, as indicated by the schematic normal-mode vibrations illustrated in Fig. 15.57. The supporting ribs add mass loading at the edges of the plates and impose a boundary condition for the flexing plates intermediate between freely hinged and clamped.

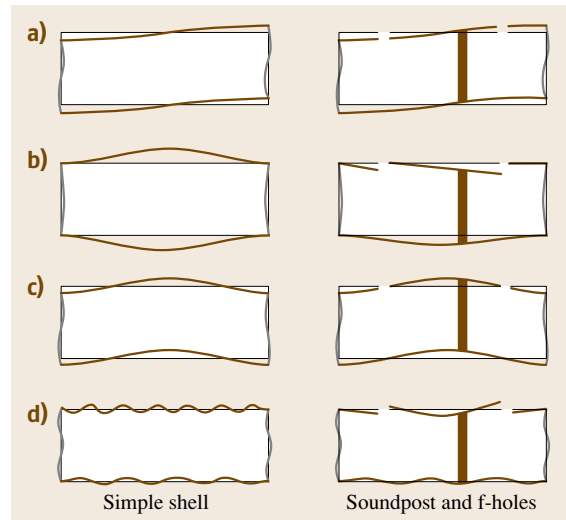
For a simple shell structure, Fig. 15.57a represents a low-frequency twisting mode in which the two ends of the instrument twist in opposite directions, just like the simple $(z = xy)$ twisting mode of a rectangular plate. Figure 15.57b–d schematically represent normal modes involving flexural modes of the front and back plates. Mode (b) is the important *breathing mode*, which produces a strong monopole source of acoustic radiation at relatively low frequencies. In mode (c), the two plates vibrate in the same direction, resulting in a much weaker dipole radiation source along the vertical axis. The above examples assumed identical top and back


Fig. 15.57a–d Schematic cross-sectional representation of typical shell modes for a simple box and a *violin-type* structure with f-holes and a soundpost

plates, whereas in general they will have different thicknesses arching, and will be constructed from different types of wood with different anisotropic elastic properties: spruce for the front and maple for the back plate of the violin. Hence, for typical high-frequency normal modes (e.g. shown schematically in Fig. 15.57d), the wavelengths of flexural vibrations will be different in the top and back plates.

Note that, at low frequencies, several of the normal modes involve significant motion of the outer edges of the front and back plate, since the centre of mass of the freely supported structure cannot move. Hence, when an instrument is supported by the player, additional mode damping can occur by energy transfer to the chin, shoulder or fingers supporting the instrument at its edges, as indeed observed in modal analysis investigations on hand-held violins by *Marshall* [15.94] and *Bissinger* [15.95].

Skeleton Curves

In this idealised model, the normal modes of the structure at high frequencies will be similar to those of the individual plates. Such modes will only be significantly perturbed when the resonances of the separate plates are close together, apart from a general background interaction from the average weak but cumulative interaction with all other distant modes. *Woodhouse* [15.77] has recently shown that the averaged amplitude and phase of the admittance can be described by *skeleton*
Fig. 15.58 The rotational admittance across the two feet of a bridge on an idealised rectangular violin structure with a soundpost under the treble foot but with no f-holes (after Woodhouse [15.77])

curves, indicated by the dashed lines in Fig. 15.58, on which peaks and troughs of height Q and $1/Q$ and phase changes from individual resonances are superimposed. These curves were evaluated analytically for the rotational admittance across the two feet of a bridge mounted on the front plate of an idealised rectangular box-like violin without f-holes but with a soundpost close to the treble foot of the bridge.

At low frequencies the averaged input impedance across the two feet of the bridge is largely reactive, with a value close to the static *springiness*, which can be identified with the low-frequency limit of the normal-mode admittance $\sum_n i\omega/m_n\omega_n^2$, where the effective mass of each mode will depend on where and how the instrument is excited. However, at high frequencies the admittance becomes largely resistive resulting from internal damping and energy loss to the closely overlapping modes. The use of skeleton curves enables Woodhouse to illustrate the effect of various different bridge designs on the overall frequency response of a violin, without having to consider the exact positions, spacing or damping of the individual resonances of the shell structure. Although the idealised model is clearly over-simplistic, the general trends predicted by such a model will clearly be relevant to any multi-resonant shell model.

Soundpost and f–Holes

The soundpost and f-holes cut into the front plate of the violin and related instruments have a profound ef-

fect on the frequencies and waveforms of the normal modes, illustrated schematically by the right-hand set of examples in Fig. 15.57. The f-holes create an island area on which the bridge sits, which separates the top and lower areas of the front plate. Like the rose-hole on a guitar illustrated in Fig. 15.56, the additional internal free edges introduced by the f-holes tend to localise the vibrations of the front plate to the regions above and below the *island area*. In addition, the soundpost acts as a rather rigid spring locking the vibrations of the top and back plates together at it its ends. At low frequencies, the soundpost introduces an approximate node of vibration on both the top and back plates, unless the frequencies of the uncoupled front and back plates modes are close together.

For some low-frequency modes, the soundpost and f-hole have a relatively small effect on the modes of the shell structure, such as the twisting mode (a) and mode (c), when the plates vibrate in the same direction. However, the breathing mode (c) will be strongly affected by the soundpost forcing the front and back plates to move together across its ends.

As indicated earlier, any string motion parallel to the plates will exert a couple on the top of the bridge. In the absence of the soundpost, only asymmetric modes of the top plate could then be excited. However, to satisfy the boundary conditions at the soundpost position, the rocking action now induces a combination of symmetric and antisymmetric plate modes (illustrated schematically in Fig. 15.57b), approximately doubling the number of modes that can contribute to the sound of an instrument including the very important lower-frequency symmetric *breathing modes*. Because of the f-holes, the central island can vibrate in the opposite direction to the wings on the outer edges of the instrument. The mixing of symmetric and antisymmetric modes is strongly dependent on the position of the soundpost relative to the nodes of the coupled waveforms. As a result, the sound of a violin instrument is very sensitive to the exact placing of the soundpost. The difference in the sound of a violin with the soundpost first in place and then removed is illustrated in ⟨ EXTRAS ⟩.

To a good approximation, in the audible frequency range, the violin soundpost can be considered as a rigid body, as its first longitudinal resonance is $\approx 100\,\mathrm{kHz}$, though lower-frequency bending modes can also be excited, particularly if the upper and lower faces of the soundpost fail to make a flat contact with the top and back plates (*Fang* and *Rogers* [15.96]). At high frequencies, there is relatively little induced motion of the outer edges of top and back plates, so that the

impedance $Z(\omega)$ (force/induced velocity) measured at the soundpost position is simply given by the sum of the impedances at the soundpost position, $Z(\omega)_{\text{top}} + Z(\omega)_{\text{back}}$, of the individual plates with fixed outer edges. If one knows the waveforms of the individual coupled modes, it is relatively straightforward to evaluate the admittance at any other point on the two surfaces, and hence to evaluate the rotational admittance across the two feet of the bridge (*Woodhouse* [15.77]).

We have already described the important role of the bridge dynamics in the coupling between the strings and the vibrational modes of the instrument. For instruments of the violin family, the island region between the f-holes probably plays a rather similar role to the bridge, as it is via the vibrations of this central region that the larger-area radiating surfaces of the front plate are excited. At low frequencies this will be mainly by the lowest-order twisting and flexing modes of the central island region. It therefore seems likely that the dynamics of the central island region also contributes significantly to the BH hill feature and the resulting acoustical properties of the violin in the perceptually important frequency range of $\approx 2-4$ kHz, as recognised by Cremer and his colleagues [15.11].

Historically, the role of the soundpost and the coupling of plates through enclosed air resonances were first considered analytically using relatively simple mass–spring models with a limited number of degrees of freedom to mimic the first few resonances of the violin, as described in some detail by *Cremer* [15.30, Chap. 10]. Now that we can obtain detailed information about not only the frequencies, but also the shapes of the important structural modes of an instrument from finite-element calculations, holography and modal analysis, there is greater emphasis on analytic methods based on the observed set of coupled modes.

The Complete Instrument

Bowing, plucking or striking a string can excite every conceivable vibration of the supporting structure including, where appropriate, the neck, fingerboard, tailpiece and the partials of all strings both in front of and behind the bridge. Many of the whole-body lower-frequency modes can be visualised by considering all the possible ways in which a piece of soft foam, cut into the shape of the instrument with an attached foam neck and fingerboard, can be flexed and bent about its centre of mass.

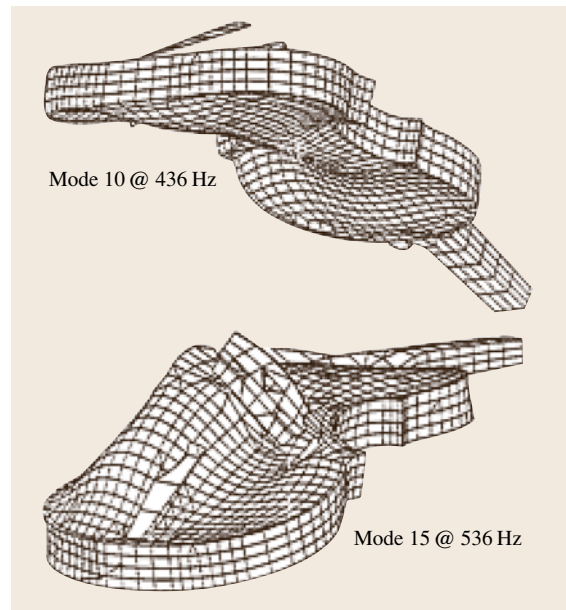
Figure 15.59 illustrates the flexing, twisting and changes in volume of the shell of a freely supported violin for two prominent structural resonances com-


Fig. 15.59 Representative finite element simulations of the structural vibrations of a violin, with greatly exaggerated vibrational amplitudes (after *Knott* [15.97])

puted by *Knott* [15.97] using finite-element analysis. However, not all modes involve a significant change in net volume of the shell, so that many of the lower-frequency modes are relatively inefficient acoustic radiators. Nevertheless, since almost all such modes involve significant bridge motion, they will be strongly excited by the player and will produce prominent resonant features in the input admittance at the point of string support on the bridge. They can therefore significantly perturb the vibrations of the string destroying the harmonicity of the string resonances and resulting playability of particular notes on the instrument, especially for bowed stringed instrument.

Helmholtz Resonance

Almost all hand-held stringed instruments and many larger ones such as the concert harp make use of a Helmholtz air resonance to boost the sound of their lowest notes, which are often well below the frequencies of the lowest strongly excited, acoustically efficient, structural resonances. For example, the lowest acoustically efficient body resonance on the violin is generally around 450 Hz, well above the bottom note G3 of the instrument at ≈ 196 Hz. Similarly, the first strong structural resonance on the classical acoustic guitar is ≈ 200 Hz, well above the lowest note of ≈ 82 Hz.

To boost the sound in the lower octave, a relatively large circular rose-hole is cut into the front plate of the guitar and two symmetrically facing f-holes are cut into the front plate of instruments of the violin family. The air inside the enclosed volume of the shell of such instruments vibrates in and out through these openings to form a Helmholtz resonator.

The frequency of an ideal Helmholtz cavity resonator of volume V, with a hole of area S in one of its rigid walls is given by

$$\omega_H = \sqrt{\frac{\gamma P}{\rho} \frac{S}{L'V}} = c_0 \sqrt{\frac{S}{L'V}} \,, \tag{15.88}$$

where L' is the effective length of the open hole. For a circular hole of radius a, *Rayleigh* [15.3, Vol. 2, Sect. 306] showed that $L' = \frac{\pi}{2}a$, while for an ellipse $L' \approx \frac{\pi}{2}(ab)^{1/2}$, provided the eccentricity is not too large. Noting that the effective length depends largely on area, *Cremer* [15.30, Fig. 10.6] modelled the f-hole as an ellipse having the same width and area as the f-hole. The two f-holes act in parallel to give an air resonance for the violin at $\approx 270\,\text{Hz}$, at an interval of just over a fifth above the lowest open string. For the acoustic guitar, the circular rose-hole produces an air resonance around $100\,\text{Hz}$, which, like for the violin, is close to the frequency of the second-lowest open string on the instrument.

Any induced motion of the top and bottom plates that involves a net change in volume results in coupling to the Helmholtz mode. Such coupling will perturb the Helmholtz and body-mode frequencies, in just the same way that string resonances are perturbed by coupling to the body resonances (see *Cremer* [15.30, Sect. 10.3] for a detailed discussion of such coupling). Since the acoustically important coupled modes are at considerably higher frequencies than the Helmholtz resonance, the mutual perturbation is not very large. Because of such coupling, purists often object to describing this resonance as a Helmholtz resonance. Similar objections could apply equally well to string resonances, since they too are perturbed by their coupling to body modes. But, as already discussed, in many situations the normal modes largely retain the character of the individually coupled modes other then when their frequencies are close together and, even then, when the damping of either of the coupled modes is large compared to the splitting in frequencies induced by the coupling in the absence of damping (Fig. 15.46).

Well below the Helmholtz resonance, any change in volume of the shell of the violin or guitar induced

by the vibrating strings will be matched by an identical volume of air flowing out through the rose- or f-holes, with no net volume flow from the instrument as a whole. Since at low frequencies almost all the radiated sound is monopole radiation associated with the net flow of air across the whole surface of an instrument, little sound will be radiated. However, above the air resonance, the response of the air resonance will lag in phase by 180°, so that the flow from body and cavity will now be in phase, resulting in a net volume flow and strong acoustic radiation. The Helmholtz resonance serves the same purpose as mounting a loudspeaker in a bass-reflex cabinet, with the air cavity resonance boosting the intensity close to and above its resonant frequency.

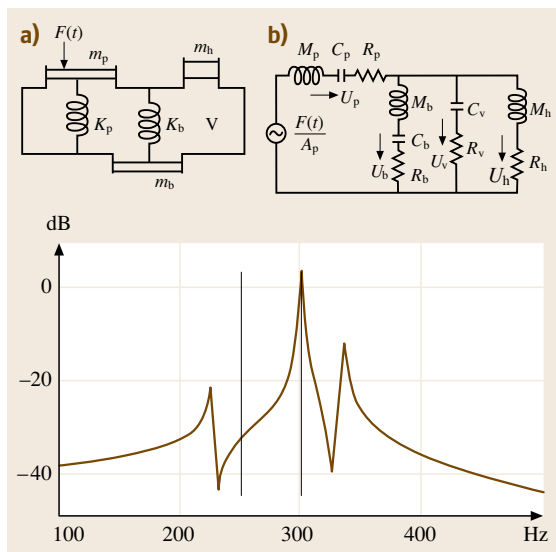
A number of authors have considered the influence of the enclosed air on the lowest acoustically important modes of the violin (*Beldie* [15.98]) and guitar (*Meyer* [15.99], *Christensen* [15.100] and *Rossing* et al. [15.101]) using simple mechanical modes of interacting springs and masses with damping and their equivalent electric circuits. Figure 15.60 shows the me-


Fig. 15.60a,b The mechanical (**a**) and equivalent electrical (**b**) circuit for a three-mass model describing the vibrations of the front and back plates of a stringed instruments coupled via a Helmholtz resonance (after *Fletcher* and *Rossing* [15.5]). The modulus of the admittance at the top plate has been evaluated for identical front and back plates with uncoupled frequencies of $300\,\text{Hz}$, coupled via a Helmholtz air resonator at $250\,\text{Hz}$ in the absence of coupling. The frequencies of the uncoupled air and body resonances are indicated by the *vertical lines*

chanical and equivalent electrical circuits and resulting admittance curve for the top plate for the illustrative three-mass model used by Rossing et al., which accounts for the qualitative features of the first three most important resonances of a guitar body. To emphasise a number of important points, we have calculated the admittance for a cavity with identical front and back plates with uncoupled resonances at 300 Hz, coupled via a cavity Helmholtz resonance at 250 Hz. The closeness in frequencies of the coupled resonators has been chosen to emphasise the influence of the coupling on the modal frequencies.

Without concerning oneself with mathematical detail, one can immediately recognise an unshifted normal mode associated with the uncoupled body resonances at 300 Hz, corresponding to the two plates vibrating in the same phase, with no volume change and hence no coupling to the air resonance. However, the coupling via the Helmholtz resonance splits the degenerate plate modes, to give a normal mode at a raised frequency, with the plates vibrating in opposite directions in a breathing mode. The coupling also decreases the frequency of the Helmholtz cavity resonance. The unperturbed mode may dominate the measured admittance and affect the playability of the instrument via its perturbation of string resonances. But, because there is no associated volume change, it will be an inefficient acoustic radiator. One should note that, because of the changes in phase of the air resonance on passing through resonance, it appears as a dispersive curve superimposed on the low-frequency wings of the stronger higher-frequency body resonances. The frequency of the excited normal mode is not the peak in the admittance curve (i.e. its modulus), as often assumed but is more nearly mid-way between the maximum and minimum, where its phase lags 90° relative to the phase of the higher frequency normal modes. Similarly, the upper body mode results in a dispersive feature in the opposite sense, as its phase changes from almost 180° to 0° relative to the unshifted normal mode. Very similar, but narrower, dispersive features are also observed in admittance-curve measurements from string resonances, unless they are purposely damped.

Cavity Modes

In addition to the Helmholtz air resonance, there will be many other cavity resonances of the air enclosed within the shell of stringed instruments, all of which can in principle radiate sound through the f- or rose-holes. Alternatively, the internal air resonances can radiate sound via the vibrations they induce in the shell of the instru-

ment, as discussed in some detail by *Cremer* [15.30, Sect. 11.4]. Because of the relatively small height of the violin ribs, below around 4 kHz the cavity air modes are effectively two dimensional in character. Simple statistical arguments based on the overall volume of the violin cavity show that there are typically ≈ 28 resonances below this frequency, as observed in measurements by *Jansson* [15.102]. Whether or not such modes play a significant role in determining the tonal quality of an instrument remains a somewhat contentious issue. However, at a given frequency, the wavelengths of the flexural modes of the individual plates and the internal sound modes will not, in general, coincide. The mutual coupling and consequent perturbation of modes will therefore tend to be rather weak. Even if such coupling were to be significant, it is likely to be far smaller than the major changes in modal frequencies and shapes introduced by the f-holes and soundpost.

Finite–Element Analysis

To progress further in our understanding of the complex vibrations of instruments like the violin and guitar, it is necessary to include the coupled motions of every single part of the instrument and to consider the higher-order front and back plate modes, which will be strongly modified by their mutual coupling via the connecting ribs and, for the violin, the soundpost as well.

Such a task can be performed by numerical simulations of the vibrations of the complete structure using finite-element analysis (FEA). This involves modelling any plate or shell structure in terms of a large number of interconnected smaller elements of known shape and elastic properties. This division into smaller segments is known as tessellation. Provided the scale of the tessellation is much smaller than the acoustic wavelengths at the frequencies being considered, the motion of the structure as a whole can be described by the three-dimensional translations and rotations of the tessellated elements. The motion of each element can be related to the forces and couples acting on the adjoining faces of each three-dimensional (3-D) element. The problem is then reduced to the solution of N simultaneous equations proportional to the number of tessellated elements. Deriving the frequencies and mode shapes of the resulting normal modes of the system involves the inversion of a $N \times N$ matrix. Such calculations can be performed very efficiently on modern computer systems, though the computation time, proportional to N^2, can still be considerable for complex structures, particularly if a fine tessellation is used to evaluate the higher-frequency, shorter-wavelength, modes.

Figure 15.59 has already illustrated the potential complexity of the vibrational modes of a violin. The displacements have been greatly exaggerated for graphical illustration. In practice, the displacements of the plates are typically only a few microns, but can easily be sensed by placing the pad of a finger lightly on the vibrating surfaces. The first example shows a typical low-frequency mode involving the flexing and bending of every part of the violin, but with little change in its volume, so that it will radiate very little sound. The second example illustrates a mode involving a very strong asymmetrical vibration of the front plate, excited by the rocking action of the bridge with the soundpost inhibiting motion on the treble side of the instrument. Such a mode involves an appreciable change in volume of the shell-like structure, which will therefore radiate sound quite strongly.

One of the virtues of FEA is that the effects of changes in design of an instrument, or of the materials used in its construction, can be investigated systematically, without having to physically build a new instrument each time a change is made. For example, *Roberts* [15.104] has used FEA to investigate the changes in normal-mode frequencies of freely supported violin as a function of thickness and arching, the effects of cutting the f-holes and adding the bass bar, and the affect of the soundpost and mass of the ribs on the normal modes of the assembled body of the instrument, but without the neck and fingerboard. This enables a systematic correlation to be made between the modes and frequencies of the assembled instrument with the modes of the individual plates before assembly. Without the soundpost, the modes of the assembled violin were highly symmetric, with the bass-bar having only a marginal effect on the symmetry and frequency of modes. As expected, adding the soundpost removed the symmetry and changed the frequencies of almost all the modes, demonstrating the critical role of the soundpost and its exact position in determining the acoustic response of the violin.

Similar FEA investigations have been made of several other stringed instruments including the guitar (*Richardson* and *Roberts* [15.105]). Of special interest is the recent FEA simulation from first principles of the sound of a plucked guitar string by *Derveaux* et al. [15.103]. Their model includes interactions of the guitar plates, the plucked strings, the internal cavity air modes and the radiated sound. A DVD illustrating the methodology involved in such calculations [15.106] recently won an international prize, as an outstanding example of science com-munication. The effects of changing plate thickness, internal air resonances and radiation of sound on both admittance curves and the decay times and sound waveforms of plucked strings were investigated. Figure 15.61 compares the admittance curves at the guitar bridge computed for damped strings for a front-plate thickness of 2.9 mm first in vacuo and then in air. Note the addition of the low-frequency Helmholtz and higher-order cavity resonances in air and the perturbations of the structural resonances by coupling to the air modes.

15.2.7 Measurements

In this section we briefly consider the various methods used to measure the acoustical properties of stringed instruments, a number of which have already been referred to illustrate specific topics in the preceding section.
Fig. 15.61a,b FEA computations of admittance at bridge for a guitar with a 2.9 mm-thick front plate (**a**) in vacuo and (**b**) coupled to the air-cavity resonances (after *Derveaux* et al. [15.103])

Admittance

The most common and easiest method used to investigate and characterise the acoustical properties of any stringed instrument is to measure the admittance $A(\omega)$ (velocity/force) at the point of string support on the bridge. *Fletcher* and *Rossing* [15.5] give examples of typical admittance curves for many stringed (and percussion) instruments including the violin, guitar, lute, clavichord and piano soundboard.

As described earlier, the admittance is in reality a complex tensor quantity, with the induced velocity dependent on and not necessarily parallel to the direction of the exciting force. In practice, most published admittance curves for the high-bridge instruments of the violin family show the amplitude and phase of the component of induced bridge velocity in the direction of an applied force parallel to the top plate. In contrast, for low-bridge instruments like the guitar, piano or harpsichord, the induced motion perpendicular to the top plate or soundboard is of primary interest.

The admittance at the bridge can be expressed in terms of the additive response of all the damped normal modes, which includes the mutual interactions of the plates of the instrument and all the component parts including, where appropriate, the neck, tailpiece, fingerboard, and all the strings. The admittance can then be written as

$$A(\omega) = \sum_n \frac{1}{m_n} \frac{\mathrm{i}\omega}{\omega_n^2 - \omega^2 + \mathrm{i}\omega\omega_n/Q_n} , \qquad (15.89)$$

where ω_n and Q_n are the frequency and Q-value of the nth normal mode and m_n is the associated effective mass at the point of measurement. The value of m_n depends on how well the normal mode is excited by a force at the point of measurement on the bridge. If, for example, the bridge on a guitar is at a position close to the nodes of particular normal modes, then the coupling will be weak and the corresponding effective mass will be rather large. Conversely, the low-frequency rocking action of the bridge on a bowed stringed instrument couples strongly into the breathing mode of the violin shell, so that the effective mass will be relatively low. The strength of this coupling plays an important role in determining the sound output from a particular instrument and also affects the playability of the bowed string and the sound of a plucked string.

In practice, by measuring the frequency response of the admittance, including both amplitude and phase, it is possible to decompose the admittance into the sum of the individual modal contributions and hence determine the effective mass, frequency and damping of the contributing normal modes. For the violin there are ≈ 100 identifiable modes below $\approx 4\,\mathrm{kHz}$ (*Bissinger* [15.107]), though not all of these are efficient acoustic radiators.

To avoid complications from the numerous sympathetic string resonances that can be excited, which includes all their higher-frequency partials, measurements are often made with all the strings damped by a piece of soft foam or a piece of card threaded between the strings. However, it should always be remembered that the damped strings still contribute significantly to the measured admittance. At low frequencies the strings still exert the same lateral restoring force on the bridge whether damped or not, while at high frequencies the damped strings present a resistive loading with their characteristic string impedances μc in parallel. When undamped, the strings present an additional impedance and transient response, which reflects the resonances of all the partials of the supported strings. This can make a significant difference to the sound of an instrument, notably when the sustaining pedal is depressed on a piano and in the ringing sound of any multi-stringed instrument, when a note is plucked or bowed and especially instruments like the theorbo and viola d'amore with freely vibrating sympathetic strings.

Figure 15.62 illustrates admittance measurements for six different violins by *Beldie* [15.98] reproduced from *Cremer* [15.30, Fig. 10.1]. The arrows indicate the position of the dispersive-shaped Helmholtz air resonance, which is the only predictable feature in such measurements, though its relative amplitude varies significantly from one instrument to the next. Such measurements provide a fingerprint for an individual instrument, highlighting the very large number of almost randomly positioned resonances that can be excited, which must ultimately be responsible for the distinctive sound of an instrument. As described earlier, above $\approx 1500\,\mathrm{Hz}$ the admittance often exhibits an underlying BH peak at $\approx 2\,\mathrm{kHz}$ followed by a characteristic decrease at higher frequencies, which can be attributed to a resonance of the bridge/central island region [15.75, 77].

Although most instruments have very different acoustic fingerprints, Woodhouse (private communication), in a collaboration with the English violin maker David Rubio, demonstrated that it is possible to construct instruments with almost identical admittance characteristics, provided one uses closely matching wood from the same log, with a nearly perfect match of plate thickness and arching. The German violin maker *Martin Schleske* [15.108] also claims considerable success in producing *tonal copies* with almost

Fig. 15.62 Admittance measurements at bridge for six violins (after *Beldie* [15.98]). The *arrows* indicate the position of the Helmholtz air resonance. The *horizontal lines* are 20 dB markers

ated by a small magnet waxed to the bridge and driven by a sinusoidally varying magnetic field. The admittance can equally well be determined from the transient response $f(t)$ following a very short impulse to the bridge, since it is simply the Fourier transform,

$$A(\omega) = \int_0^\infty f(t)\,\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}t\ . \tag{15.90}$$

If signal-to-noise ratio from a single measurement is insufficient, one can use a sequence of impulses or a noise source, which is equivalent to a random succession of short pulses. In addition to many professional systems, relatively inexpensive PC-based versions using sound cards have been developed for researchers and instrument makers, such as the WinMLS system by *Morset* [15.109].

Laser Holography

Admittance measurements at the bridge provide detailed information on the frequencies, damping and effective masses of the normal modes of vibration of an instrument, but provide no information on the nature of the modes excited. Laser holography, which is essentially the modern-day equivalent of Chladni plate measurements, enables one to visualise the vibrational modes of stringed and percussion instruments. In such measurements, photographs or real-time closed-circuit television images of the interference patterns of laser light reflected from a stationary mirror and from the vibrating object are recorded. Using photographic or electronic/software reconstruction of the original image from the recorded holograms, a 3-D image of the vibrating surface is formed with superimposed contours indicating lines of equal vibrational amplitude, as already illustrated for a number of prominent guitar modes in Fig. 15.56.

Recent developments in laser and electronic data-acquisition technology allow one to record such interferograms electronically and to display them in real time on a video monitor (for example, *Saldner* et al. [15.110]). To record the shapes of individual vibrational modes of an instrument excited by a sinusoidal force, care has to be taken to avoid contamination from neighbouring resonances, by judicious placing of the force transducer (e.g. placing it at a node of an unwanted mode). *Cremer* [15.30, Chap. 12] reproduces an interesting set of holograms by *Jansson* et al. [15.111] for the front plate of a violin at various stages of its construction, before and after the f-holes are cut, before and after the bass-bar is added and with a soundpost sup-

identical acoustical properties to those of distinguished Cremonese instruments by grading the thickness and arching of the plates to reproduce both the input admittance and radiated sound.

In contrast, slavishly copying the dimensions of a master violin rarely produces an instrument with anything like the same tonal quality. This is easily understood in terms of the differing elastic and damping properties of the wood used to carve the plates, which remains a problem of great interest, but beyond the scope of this article.

Traditionally, the admittance is usually measured using a swept sinusoidal frequency source, often gener-

ported on a rigid back plate. These highlight the major effect of the f-holes and soundpost on the modal shapes and frequencies, but the relatively small influence of the bass-bar, consistent with the FEA computations by *Roberts* [15.104] referred to earlier. However, the bass bar strengthens the coupling between the island area between the f-holes and the larger radiating surfaces of the top plate and therefore has a strong influence on the intensity of radiated energy.

With modern intense pulsed laser sources, one can also investigate the transient response of instruments using single pulses. For example, *Fletcher* and *Rossing* [15.5, Fig.10.15] reproduce interferograms of the front and back plate of a violin by *Molin* et al. [15.112, 113], which illustrate flexural waves propagating out from the feet of the bridge on the front face and from the end of the soundpost on the back plate at intervals from $100-450\,\mu s$ after the application of a sharp impulse at the bridge. Holograms can even be recorded while the instrument is being bowed [15.112, 113].

Modal Analysis

Modal analysis measurements have been extensively used to investigate the vibrational modes of the violin, guitar, the piano soundboards and many other stringed and percussion instruments (Chap. 28). Briefly, the method involves applying a known impulse at one point and measuring the response at a large number of other points on the surface of an instrument, which allows one to determine both the modal frequencies and the vibrations at all points on the surface. The Fourier transform of the impulse response is directly related to the nonlocal admittance, which in terms of the normal modes excited can be written as

$$A(r_1, r_2, \omega) = \mathrm{i}\omega \sum_n \frac{1}{m_n} \frac{\psi_n(r_1)\psi_n(r_2)}{\omega_n^2 - \omega^2 + \mathrm{i}\omega\omega_n/Q_n} ,$$

(15.91)

where $\psi_n(r_1)\psi_n(r_2)$ is the product of the wavefunctions describing the displacements at the measurment and excitation points normalised to the product at the point of maximum displacement, and m_n is now the effective mass of the normal mode at its point of maximum amplitude of vibration (i.e. $KE_{\max} = 1/2m_n\omega^2\psi_n^2|_{\max}$). An FFT of the recorded transient response will give peaks in the frequency response, which can be decomposed into contributions from all the excited normal modes. By keeping the point of excitation fixed and moving the measurement point, one can record the amplitude and phase of the induced motion for a specific mode and, using the spatial dependence in (15.91), can

map out the nodal waveform. Alternatively, one can keep the measurement point fixed and apply the impulse over the surface of the structure to derive similar information.

One of the first detailed modal analysis investigations of the violin was made by *Marshall* [15.94], who used a fixed measurement point on the top plate of the violin near the bass-side foot of the bridge with a force hammer providing calibrated impulses at a large number of points over the surface of the violin. From the FFT of the resultant transient responses, the amplitudes and phases of the excited normal modes of the violin involving all its component parts including the body shell, neck, fingerboard and tailpiece could be determined. Marshall identified and characterised around 30 normal modes below $\approx 1\,$kHz. Many of the modes involved the relatively low-frequency flexing and twisting of the instrument as a whole. However, because such modes involved little appreciable change in overall volume of the shell of the instrument structure, they resulted in little radiated sound. Nevertheless, it was suggested that such modes might well play an important role for the performer in determining the feel of the instrument and its playability.

In any physical measurement, the instrument has to be supported in some way. Rigid supports introduce additional boundary conditions, which can significantly perturb the normal modes of the instrument. Many measurements are made with the instrument supported by rubber bands, which provide static stability without significant perturbation of the higher-frequency structural modes. However, *Marshall* [15.94] showed that, when an instrument is held and supported by the player under the chin, the damping of many of the normal modes was significantly increased, which will clearly affect the sound of the instrument when played. This observation has also been confirmed in more recent modal analysis measurements by *Bissinger* [15.95] and by direct measurements of the decaying transient sound of a freely and conventionally supported violin by the present author [15.18].

Bissinger [15.107] has made extensive admittance, modal analysis and sound radiation measurements on a large number of instruments. Measurements were made using impulsive excitation at the bridge and a laser Doppler interferometer to record the induced velocities at over 550 points on the surface of the violin. Simultaneous measurements of the overall radiation and directivity were made using 266 microphone positions over a complete sphere. Figure 15.63 shows cross sections illustrating the displacements associated with four
Fig. 15.63 Modal analysis measurements illustrating the displacements associated with four representative low-frequency modes of a violin (data provided by George Bissinger)

low frequency modes. The 159 Hz mode |👁 EXTRAS| involves major vibrations of the neck, fingerboard, tailpiece and body of the instrument. The second example at 281 Hz |👁 EXTRAS| illustrates the body displacements associated with the Helmholtz air resonance. The mode at 425 Hz |👁 EXTRAS| illustrates a mode with asymmetric in-phase vibrations of the front and back plates, with little net volume change and hence little radiated sound, while the mode at 480 Hz |👁 EXTRAS| is a strong breathing mode.

By combining the modal analysis and radiativity measurements, Bissinger has shown that the radiation efficiency of the plate modes (i. e. the fraction of sound energy radiated by the violin relative to a baffled piston of the same surface area having the same root mean square surface velocity displacement) rises to nearly 100% at a *critical frequency* of ≈2–4 kHz, when the wavelength of the flexural vibrations of the plates matches that of sound waves in air. Little apparent correlation was observed between the perceived quality of the measured violins and the frequencies and strengths of prominent structural resonances below ≈1 kHz or with the internal damping of the front and back plates. This runs contrary to the general view of violin makers that the front and back plates of a fine violin should be made of wood with a very long ringing time when tapped. Interestingly, the American violin maker Joseph Curtin has also observed that individual plates of old Italian violins often appear to be more heavily damped than their modern counterparts [15.114]. This is clearly an area that merits further research.

15.2.8 Radiation and Sound Quality

As already emphasised, at low frequencies, when the acoustic wavelength is smaller than the size of an instrument, the radiated sound is dominated by isotropic monopole radiation. As the frequency is increased, higher-order dipole and then quadrupole radiation become progressively important, while above the critical frequency, when the acoustic wavelength is shorter than the that of the flexural waves on the shell of an instrument, the radiation patterns become increasingly directional, so that it is no longer appropriate to consider the radiation in terms of a multipole expansions.

Fletcher and *Rossing* [15.5, Fig. 10.30] reproduce measurements on both the violin and cello by *Meyer* [15.115], which highlight the increasing directionality of the sound produced with increasing frequency and the rather strong masking effect of the player at high frequencies. More recently, *Weinreich* and *Arnold* [15.116, 117] have made detailed theoretical and experimental studies of multipole radiation from the freely suspended violin at low frequencies (typically below 1 kHz). Interestingly, they made use of the principle of acoustic reciprocity, based on the fact that the amplitude of vibration at the top of the bridge produced by incoming sound waves is directly related to the sound radiated by a force applied to the violin at the same point. The violin was radiated by an array of loudspeakers to simulate incoming spherical or dipole sound fields and the induced velocity at the bridge recorded by a very light gramophone pick-up stylus.

Hill et al. [15.118] have used direct measurements to investigate the angular dependence of the sound radiated by a number of high-quality modern acoustic guitars with different cross-strutting, when excited by a sinusoidal force at the bridge. From such measurements, they were able to derive the fraction of sound radiated as the dominant monopole and dipole (with components in three directions) radiation, in addition to effective masses and Q-values, for a number of prominent modes up to ≈ 600 Hz. Significant differences were observed for the three different strutting schemes investigated.

Bissinger [15.119] has made an extensive investigation of radiation from both freely supported and hand-held violins, including measurements above 1 kHz, where the multimodal radiation expansion is no longer appropriate. Bissinger correlates the sound radiated over a large number of points on a sphere surrounding the violin with measurements of the input admittance at the bridge and the induced surface velocities over the whole violin structure. Figure 15.64 shows a typical set of simultaneous measurements up to 1 kHz. Although the low-frequency Helmholtz resonance contributes strongly to the radiated sound, it results in a relatively small feature on the mobility curves for the body of the instrument (or on the measured admit-
Fig. 15.64 Plots of the root-mean-square (rms) mobility $\langle Y \rangle$ (m/sN) averaged over the surface of the front and back plate (*solid shaded region*) and ribs (*white curve*) of the instrument, the radiativity $\langle R \rangle$ (Pa/N) averaged over a sphere, and directivity $\langle D \rangle$, the ratio of forward to backward radiation averaged over hemispheres. The *top arrows* represent the positions of the open-string resonances and their partials. A0 is the position of the Helmholtz air resonance and A1 the first internal cavity air resonance, CBR is a strong corpus bending mode and B1 and B2 are the two strong structural normal mode resonances of the coupled front and back plates (data kindly supplied by George Bissinger)

tance at the bridge, not shown). Bissinger was unable to find any significant correlation between the frequencies and Q-values of the prominent *signature* modes excited (see, for example, *Jansson* [15.120]) below ≈ 1 kHz and the perceived quality of the instruments investigated. Above ≈ 1 kHz the modes strongly overlap, so that it becomes more appropriate to compare the frequency averaged global features. The measurements show that the fraction of mode energy radiated increases monotonically from close to zero at low frequencies up to around almost 100% efficient at 4 kHz and above, where almost all the energy is lost by radiation rather than internal damping. The ultimate aim of these detailed modal analysis studies is to correlate the measured acoustical properties with the results obtained from finite-element analysis and to produce sufficient information about the acoustical properties that might allow a more realistic comparison between physical properties and the properties of an instrument judged from their perceived sound quality and playability.
Fig. 15.65 Ratio of sound intensities along neck and perpendicular to front plate for four violins of widely different qualities (after *Weinreich* [15.121])

Directional Tone Colour

Although the acoustic power radiated averaged over a given frequency range is clearly an important signature of the sound of a particular instrument, the intensity at a particular frequency in the important auditory range above 1 kHz can vary wildly from note to note. This is illustrated in Fig. 15.65 by *Weinreich* [15.121], which compares the intensities of radiated sound in an anechoic chamber along the direction of the neck and perpendicular to the front plate for four violins of widely differing quality, with 0 dB representing an isotropic response. Above around 1 kHz, the wavelengths of flexural waves on the plates of the instrument become comparable with the wavelength of the radiated sound. This leads to strong diffraction effects in the radiated sound, which fluctuate wildly with direction as different modes are preferentially excited. At a particular point in the listening space, the spectral

content of the bowed violin therefore varies markedly from note to note, as will the sound within a single note played with vibrato resulting in frequency modulation. The spectral content will also vary from position to position around the violin, especially if the player moves whilst playing. Weinreich has emphasised the importance of such effects in producing a greater sense of *presence* and *vibrancy* in the perceived sound from a violin than would be produced by a localised isotropic sound source, such as a small loudspeaker. Weinreich has coined the term *directional tone colour* to describe such effects. He has also designed a loudspeaker system based on the same principles, which gives a greater sense of realism to the sound of the recorded violin than a simple loudspeaker.

In addition to the intrinsic directionality of the violin, the time-delayed echoes from the surrounding walls of a performing space also have a major influence on the complexity of the sound waveforms produced by a violin (or any other instrument) played with vibrato, as first noted by *Meyer* [15.122]. This arises from the interference between the different frequencies associated with the prompt sound reaching the listener (or microphone) and the sound generated at earlier times reflected from the surrounding surfaces. As discussed by the present author (*Gough* [15.18]), the additional complexity is largely a dynamic effect associated with the time-delayed interference between signals of different frequencies rather than caused by the amplitude modulation of individual partials associated with the multi-resonant response of the violin, first highlighted by *Fletcher* and *Sanders* [15.123] and *Matthews* and *Kohut* [15.124].

Perceived Quality

No problem in musical acoustics has attracted more attention or interest than the attempts made over the last 150 or so years to explain the apparent superiority of old Cremonese violins, such as those made by Stradivarius and Guarnerius, over their later counterparts, which have often been near exact copies. Many explanations have been proposed – a magic recipe for the varnish, chemical treatment of the wood and finish of the plates prior to varnishing [15.125], the special quality of wood resulting from micro-climate changes [15.126], etc. However, despite the committed advocacy for particular explanations by individuals, there is, as yet, little agreement between researchers, players or dealers on the acoustical attributes that distinguish a fine Italian violin worth $1M or more from that of a $100 student instrument.

From a physicist's point of view, given wood of the same quality as that used by the old Italian makers, there is no rational reason why a modern violin should not be just as good from an acoustic point of view as the very best Italian instrument. We have already commented on Martin Schleske's attempts to replicate the sounds of fine Italian instruments, by making *tonal copies* having as near as possible the same acoustical properties [15.108]. In addition, we have also highlighted Dünnewald's attempt to correlate the physical properties of well over 200 violins with their acoustical properties [15.76], including the comparison of selected student, modern and master violins reproduced in Fig. 15.62. Such studies appear to show a correlation between the amount of sound radiation in the acoustically important range around 3–4 kHz. As we have emphasized, this is just the region where the resonant properties of the bridge have a major influence on the spectrum.

It must also be remembered that the changed design of the bridge, the increase in string tension, higher pitch, increased size of the bass-bar, neck and soundpost, and the use of metal-covered rather than gut strings have resulted in a modern instrument sounding very different from the instruments heard by the 17th and early 18th century maker and performer. Even amongst the violins of the most famous Cremonese luthiers, individual instruments have very different distinctive tones and degrees of playability, particular as judged by the player. The gold standard itself is therefore very elusive. What is currently and may always be lacking is reliable measurements on the individual plates and shells of a large number of really fine instruments. We still largely rely on a small number of measurements performed by Savart in the nineteenth century and a few measurements by Saunders in the 1950s on which to base scientific guidelines for modern violin makers.

Performance Acoustic

It should also be recognised that, when a violin (or any other instrument) is played, the performer excites not only the vibrational modes of the instrument but also the multi-resonant normal modes of the performance space. Whereas the sound heard by a violinist is dominated by the sound of the violin, for the listener the acoustics of the performance space can dominate the timbre and quality of the perceived sound. To distinguish between the intrinsic sound qualities of violins, comparisons should presumably best be made in a rather dry acoustic, even though such an acoustic is generally disliked

by the performer (and listener), who appreciates the improvement in sound quality provided by a resonant room acoustic.

One cannot review progress towards our understanding of what makes a good violin without recognising the inspiration and enthusiastic leadership of Carleen Hutchins, the doyenne and founder of the Catgut Society and scientific school of violin making, which has attracted many followers world-wide. By matching the frequencies and shapes of the first few modes of free plates before they are assembled into the completed instrument (Fig. 15.55), the scientific school of violin makers clearly achieve a high degree of quality control, which goes some way towards compensating for the inherent inhomogeneities and variable elastic properties of the wood used to carve the plates. However, in practice, there is probably just as much variability in the sound of such instruments as there is in instruments made by more traditional methods, where makers tap, flex and bend the plates until they feel and sound about right, this being part of the traditional skills handed down from master to apprentice even today. That is certainly the way that the Italian masters must have worked, without the aid of any scientific measurements beyond the feel and the sound of the individual plates as they are flexed and tapped.

Scientific Scaling

The other interesting development inspired by Carleen Hutchins and her scientific coworkers Schelling and Saunders has been the development of the modern violin octet [15.127], a set of eight instruments designed according to physical scaling laws based on the premise that the violin is the most successful of all the bowed stringed instruments. The aim is to produce a consort of instruments all having what are considered to be the optimised acoustical properties of the violin. Each member of the family is therefore designed to have the frequencies of the main body and Helmholtz resonances in the same relationship to the open strings as that on the violin, where the Helmholtz air resonance strongly supports the fundamental of notes around the open D-string, while the main structural resonances support notes around the open A-string and the second and generally strongest partial of the lowest notes played on the G-string. Several sets of such instruments have been constructed and admired in performance, though not all musicians would wish to sacrifice the diversity and richness of sounds produced by the different traditional violin, viola, cello and double bass in a string quartet or orchestra. Nevertheless, the scaling methods have led to rather successful intermediate and small-sized instruments.

15.3 Wind Instruments

In this section we consider the acoustics of wind instruments. These are traditionally divided into the woodwind, played with a vibrating reed or by blowing air across an open hole or against a wedge, and brass instruments, usually made of thin-walled brass tubing and played by buzzing the lips inside a metal mouthpiece attached to the input end of the instrument.

In general, the playing pitch of woodwind instruments is based on the first two modes of the resonating air column, with the pitch changed by varying the effective length by opening and closing holes along its length. In contrast, brass players pitch notes based on a wide range of modes up to and some times beyond the 10th. The effective length of brass instruments can be changed by sliding interpenetrating cylindrical sections of tubing (e.g. the trombone) or by a series of valves, which connect in additional length of tubing (e.g. trumpet and French horn). The pitch of many other instruments, such as the organ, piano-accordion and harmonium, is determined by the resonances of a set of separate pipes or reeds to excite the full chromatic range of notes, rather like the individual strings on a piano.

A detailed discussion of the physics and acoustical properties underlying the production of sound in all types of wind instruments is given by *Fletcher* and *Rossing* [15.5], which includes a comprehensive list of references to the most important research literature prior to 1998. As in many fields of acoustics, *Helmholtz* [15.128] and *Rayleigh* [15.3] laid the foundations of our present-day understanding of the acoustics of wind instruments. In the early part of the 20th century, *Bouasse* [15.129] significantly advanced our understanding of the generation of sound by the vibrating reed. More recently, *Campbell* and *Greated* [15.130] have written an authoritative textbook on musical acoustics with a particular emphasis on musical aspects, including extensive information on wind and brass instruments. Recent reviews by *Nederveen* [15.131] and *Hirschberg* et al. [15.132] provide valuable introductions to recent research on both wind

and brass instruments. Earlier texts by *Backus* [15.133] and *Benade* [15.134], both leading pioneers in research on wind-instrument acoustics, provide illuminating insights into the physics involved and provide many practical details about the instruments themselves. A recent issue of *Acta Acustica* [15.135] includes a number of useful review articles, especially on problems related to the generation of sound by vibrating reeds and air jets and on modern methods used to visualise the associated air motions. For a mathematical treatment of the physics underlying the acoustics of wind instruments, *Morse* and *Ingard* [15.136] remains the authoritative modern text. Other important review papers will be cited in the appropriate sections, and selected publications will be used to illustrate the text, without attempting to provide a comprehensive list of references.

We first summarise the essential physics of sound propagation in air and simple acoustic structures before considering the more complicated column shapes used for woodwind and brass instruments. An introduction is then given to the excitation of sound by vibrating lips and reeds, and by air jets blown over a sharp edge. The physical and acoustical properties of a number of woodwind and brass instruments will be included to illustrate the above topics.

A brief introduction to freely propagating sound in air was given in Sect. 15.1.3. In this section, we will be primarily concerned with the propagation of sound in the bores of wind and brass instruments, the excitation of standing-wave modes in such bores, the mechanics involved in the excitation of such modes and the resultant radiation of sound.

15.3.1 Resonances in Cylindrical Tubes

Standing waves in cylindrical tubes with closed or open ends provide the simplest introduction to the acoustics of wind instruments. For example, the flute can be considered as a first approximation as a cylindrical tube open at both ends, while the clarinet and trombone are closed at one end by the reed or the player's lips. For a cylindrical pipe open at both ends, wave solutions are of the general form

$$p_n(x, t) = A \sin(k_x x) \sin(\omega_n t) , \qquad (15.92)$$

with the acoustic pressure zero at both ends. Neglecting end-corrections, open ends are therefore displacement antinodes and pressure nodes. These *boundary conditions* result in eigenmodes with $k_n = n\pi/L$ and $\omega_n = nc_0\pi/L$, where L is the length of the pipe and n is an integer.

Such modes are closely analogous to the transverse standing-wave solutions on a stretched string having n half-wavelengths along the length L and a *harmonic* set of frequencies $f_n = nc_0/L$, which are integral multiples of the *fundamental* (lowest) frequency $f_1 = c_0/2L$. When a cylindrical pipe open at both ends, such as a flute, is blown softly, the pitch is determined by the fundamental mode, but when it is *overblown* the frequency doubles, with the pitch stabilising on the second mode an octave above (audio |?⟩ EXTRAS).

A cylindrical pipe played by a reed or vibrating lips has a pressure antinode and displacement node at the playing end. This results in standing-wave solutions with an odd number of 1/4-wavelengths between the two ends, such that $k_n = n\pi/4L$, where n is now limited to odd integer values. The corresponding modal frequencies, $\omega_n = n\pi/4L$, are therefore in the ratios $1 : 3 : 5 : 7 :$ etc. The lowest note on the cylindrical bore clarinet, closed at one end by the mouthpiece, is therefore an octave below the lowest note on a flute of the same length. Furthermore, when overblown, the clarinet sounds a note three times higher than the fundamental, musical interval of an octave plus a perfect fifth (audio |?⟩ EXTRAS). The weak intensity of the even-n-value modes in the spectrum accounts for the clarinet's characteristic hollow sound, particularly for the lowest notes on the instrument.

Real Instruments

For real wind and brass instruments, the idealised model of cylindrical tube resonators is strongly perturbed by a number of important factors. These include:

1. The shape of the internal bore of an instrument, which is often noncylindrical including conical and often flared tubes with a flared bell on the radiating end
2. The finite terminating impedance of the reed or mouthpiece used to excite the resonances, no longer providing a perfect displacement node
3. Radiation of sound from the end of the instrument, which is therefore no longer a perfect displacement antinode
4. Viscous and thermal losses to the walls of the instrument
5. Open and shut tone holes in the sides of wind instruments used to vary the pitch of the sounded note
6. Bends and valves along the length of brass instruments, connecting additional lengths of tubing, which allow the player to play all the notes of

a chromatic scale within the playing range of the instrument.

The skill of wind-instrument makers lies in their largely intuitive understanding of the way that changes in bore shape and similar factors affect the resonant modes of an instrument. This allows the design of instruments that retain, as closely as possible, a full set of harmonic resonances across the whole playing range of the instrument. This facilitates the stable production of continuous notes by the player, as the resulting harmonic set of Fourier components or partials coincide with the natural resonances of the instrument. For brass instruments with a flaring end this can often be achieved for all but the lowest natural resonance of the air column.

In discussing the acoustics of wind instruments with variable cross-sectional area S, the flow rate $U = Sv$ is a more useful parameter than the longitudinal particle velocity v. For example, the force acting on an element of air of length Δx along the bore length of an air column is then given by

$$-S\frac{\partial p}{\partial x}\Delta x = \rho S\frac{\partial v}{\partial t}\Delta x = \rho\frac{\partial U}{\partial t}\Delta x \,. \tag{15.93}$$

For travelling waves, $e^{i(\omega t \pm kx)}$, this results in a ratio between the pressure and flow rate, defined as the tube impedance

$$Z = \frac{p}{U} = \pm\frac{\rho c_0}{S} \,, \tag{15.94}$$

where the plus and minus signs refer to waves travelling in the positive and negative x-directions, respectively. There is a very close analogy with an electrical transmission line, with pressure and flow rate the analogue of voltage and current, as discussed later. Because the impedance is inversely proportional to area, it can be appreciably higher at the input end of a brass or wind instrument than at its flared output end. The flared bore of a brass instrument or the horn on an old wind-up gramophone can therefore be considered as an acoustic transformer, which improves the match between the high impedance of the vibrating source of sound to the much lower impedance presented by air at the end of the instrument. There is clearly an optimum matching, which enhances the radialed sound without serious degredation of the excited resonant modes.

Acoustic Radiation

In elementary textbook treatments, the pressure at the end of an open pipe is assumed to be zero and the flow rate a maximum, so that $Z_{\text{closed}} = p/U = 0$. However,
Fig. 15.66 Real and imaginary components of f, the impedance at the unbaffled open end of a cylindrical tube of radius a, in units of $\rho c_0/\pi a^2$, as a function of ka (after *Beranek* [15.137])

in practice, the oscillatory motion of the air extends somewhat beyond the open end, providing a pulsating source that radiates sound, as described by *Rayleigh* [15.3, Vol. 1, Sect. 313]. Such effects can be described by a complex terminating load impedance, $Z_L = R + jx$. Figure 15.66 shows the real (*radiation resistance*) R and imaginary (inertial *end-correction*) x components of Z_L as a function of ka, where a is the radius of the open-ended pipe. The impedance is normalised to the tube impedance $pc_0/\pi a^2$.

When $ka \ll 1$, the reactive component is proportional to ka and corresponds to an effective increase in
Fig. 15.67 Polar plots of the intensity radiation from the end of a cylindrical pipe of radius a for representative ka values, calculated by *Levine* and *Schwinger* [15.138]. The radial gradations are in units of 10 dB. The intensities in the forward direction ($\theta = 0$) relative to those of an isotropic source are 1.1, 4.8 and 11.8 dB (*Beranek* [15.137])

the tube length or end-correction of $0.61a$. At low frequencies, the real part of the impedance represents the radiation resistance $R_{rad} = \rho c/4S(ka)^2$. In this regime, the sound will be radiated isotropically as a monopole source of strength $U e^{i\omega t}$, illustrated in Fig. 15.67 by the polar plots of sound intensity as a function of angle and frequency.

When ka is of the order of and greater than unity, the real part of the impedance approaches that of a plane wave acting across the same area as that of the tube. Almost all the energy incident on the end of the tube is then radiated and little is reflected. For $ka \gg 1$, sound would be radiated from the end of the pipe as a beam of sound waves. The transition from isotropic to highly directional sound radiation is illustrated for a sequence of ka values in Fig. 15.67. The ripples in the impedance in Fig. 15.66 arise from diffraction effects, when the wavelength becomes comparable with the tube diameter.

For all woodwind and brass instruments, there is therefore a crossover frequency $f_c \approx c_0/2\pi a$, below which incident sound waves are reflected at the open end to form standing waves. Above f_c waves generated by the reed or vibrating lips will be radiated from the ends of the instrument strongly with very little reflection. Narrow-bore instruments can have a large number of resonant modes below the cut-off, while instruments with a large output bell, like many brass instruments, have far fewer.

For a narrow-bore cylindrical bore wind instrument with end radius $a \approx 1$ cm, the cut-off frequency ($ka \approx 1$) is ≈ 5.5 kHz. Below this frequency the instrument will support a number of relatively weakly damped resonant modes, which will radiate isotropically from the ends of the instrument or from open holes cut in its sides. In contrast, for brass instruments the detailed shape and size ot the flared end-bell determines the cut-off frequency. The large size of the bell leads to an increase in intensity of the higher partials and hence brilliance of tone-color, especially when the bell is pointed directly towards the listener. For French horns, much of the higher-frequency sound is therefore projected backwards relative to the player, unless there is a strongly reflecting surface behind.

For $ka \ll 1$, the open end of a musical instrument acts as an isotropic monopole source with radiated power P given by

$$P = U_{rms}^2 R_{rad} = \omega^2 \frac{\rho}{8\pi c} (S\omega\xi)^2 .\qquad (15.95)$$

For a given vibrational displacement, the radiated power therefore increases with the fourth power of both frequency and radius. This very strong dependence on size explains why brass instruments tend to have rather large bells and why high-fidelity (HI-FI) *woofer* speakers and the horns of public address loudspeakers tend to be rather large. Conversely, it explains why the sound of small loudspeakers, such as those used in PC notebooks, fall off very rapidly below a few hundred Hz.

Acoustic radiation will lower the height and increase the width of resonances in a cylindrical tube. The resulting Q-values can be determined from

$$Q = \omega \frac{\text{stored energy}}{\text{radiated energy}}$$
$$= \omega \frac{\frac{1}{4}\rho SL\omega^2\xi^2}{\omega^4 (\rho/8\pi c) S^2\xi^2} = 2\pi cL/\omega S .\qquad (15.96)$$
Fig. 15.68 Input impedance of a length of 1 cm diameter trumpet tubing with and without a bell attached to the output end (after *Benade* [15.134])

Narrow-bore instruments will therefore have larger Q-values and narrower resonances than wide-bore instruments such as brass instruments, where the flared end-sections enhance the radiated energy at the expense of increasing the net losses.

The increased damping introduced by radiation from the end of an instrument is illustrated in Fig. 15.68, which compares the resonances of a length of 1 cm-diameter trumpet tubing, first with a normal open end and then with a bell attached (*Benade* [15.133, Fig. 20.4]). Attaching a bell to such a tube dramatically increases the radiated sound from the higher partials and perceived intensity, but at the expense of a cut-off frequency at around ≈ 1.5 kHz and a significant broadening of the resonances at lower frequencies. Audio [?> EXTRAS] demonstrates the sound of a mouthpiece-blown length of hose pipe with and without a conical chemical filter funnel attached to its end.

Viscous and Thermal Losses

In addition to radiation losses, there can be significant losses from viscous damping and heat transfer to the walls, as discussed in detail in *Fletcher* and *Rossing* [15.5, Sect. 8.2]. Although simple models for waves propagating along tubes assume a constant particle displacement across the whole cross-section, in reality the air on the surface of the walls remains at rest. The particle velocity only attains the assumed plane-wave constant value over a boundary-layer distance of δ_η from the walls. This is determined by the viscosity η, where $\delta_\eta = (\eta/\omega\rho)^{1/2}$, which can be expressed as $\approx 1.6/f^{1/2}$ mm for air at room temperature. At 100 Hz, $\delta_\eta \approx 0.16$ mm. which is relatively small in comparison with typical wind-instrument pipe diameters. Nevertheless, it introduces a significant amount of additional damping of the lower-frequency resonances of wind and brass instruments.

The viscous losses lead to an attenuation of sound waves, which can be described by adding an imaginary component to the k value such that $k' = k - \mathrm{i}\alpha$. Waves therefore propagate as $\mathrm{e}^{-\alpha x}\,\mathrm{e}^{\mathrm{i}(\omega t - kx)}$, with an attenuation coefficient

$$\alpha = \frac{1}{ac_0}\sqrt{\frac{\eta\omega}{2\rho}} = \frac{k\delta_\eta}{a}\,. \tag{15.97}$$

In addition, heat can flow from the sinusoidally varying adiabatic temperature fluctuations of the vibrating column of air into the walls of the cylinder. At acoustic frequencies, this takes place over the thermal diffusion boundary length $\delta_\theta = (\kappa/\omega\rho C_\mathrm{p})^{1/2}$, where κ is the thermal conductivity and C_p is the heat capacity of the gas

at constant pressure. In practice, $\delta_\theta \approx \delta_\eta$, as anticipated from simple kinetic theory (for air, the values differ by only 20%). Viscous and heating losses are therefore comparable in size giving an effective damping factor for air at room temperature, $\alpha = 2.210^4 k^{1/2}/a$ m^{-1} (*Fletcher* and *Rossing* [15.5, Sect. 8.2]). The ratio of the real to imaginary components of k determines the damping and effective Q-value of the acoustic resonances from wall losses alone, with $Q_\mathrm{walls} = k/2\alpha$.

The combination of radiation and wall losses leads to an effective Q_total of the resonant modes given by

$$\frac{1}{Q_\mathrm{total}} = \frac{1}{Q_\mathrm{radiation}} + \frac{1}{Q_\mathrm{wall\text{-}damping}}\,. \tag{15.98}$$

Because of the different frequency dependencies, wall damping tends to be the strongest cause of damping of the lowest-frequency resonances of an instrument. It can also be significant in the narrow-bore tubes and *crooks* used to attach reeds to wind instruments.

Input Impedance

The method used to characterize the acoustical properties of a wind or brass instrument is to measure the input impedance $Z_\mathrm{in} = p_\mathrm{in}/U_\mathrm{in}$ at the mouthpiece or reed end of the instrument. Such measurements are frequently made using the capillary tube method. This involves connecting an oscillating source of pressure fluctuations to the input of the instrument through a narrow-bore tube. This maintains a constant oscillating flow of air into the instrument, which is largely independent of the frequency-dependent induced pressure fluctuations at the input of the instrument. Several examples of such measurements, similar to those for the length of trumpet tubing (Fig. 15.68), for woodwind and brass instruments are shown and discussed by *Backus* [15.133] and *Benade* [15.134], who pioneered such measurements, and in *Fletcher* and *Rossing* [15.5, Chap. 15]. Alternatively, a piezoelectric driver coupled to the end of the instrument can provide a known source of acoustic volume flow.

The input impedance of a cylindrical tube is a function of both the tube impedance $Z_0 = \rho c_0/S$ and the terminating impedance Z_L at its end. It can be calculated using standard transmission-line theory, which takes into account the amplitude and phases of the reflected waves from the terminating load. The reflection and transmission coefficients R and T for a sound wave impinging on a terminating load Z_L are given by

$$R = \frac{Z_\mathrm{L} - Z_0}{Z_\mathrm{L} + Z_0} \quad \text{and} \quad T = \frac{2Z_\mathrm{L}}{Z_\mathrm{L} + Z_0}\,. \tag{15.99}$$
Fig. 15.69a,b Real and imaginary components of the input impedance in units of Z_0 as a function of $2kL/\pi$ for **(a)** an ideally open-ended, $Z_L = 0$, cylindrical tube with wall losses varying as $k^{1/2}$, and **(b)** the same components shifted downwards for a pipe with radiation resistance proportional to k^2 also included

For a cylindrical tube of length L, the input impedance is given by

$$Z_{in} = Z_0 \frac{Z_L \cos kl + iZ_0 \sin kl}{iZ_L \sin kl + Z_0 \cos kl} , \qquad (15.100)$$

with complex k values $k - i\alpha$, if wall losses need to be included.

In Fig. 15.69 we have plotted the kL dependence of the real and imaginary components of the input impedance of an open-ended cylindrical pipe. The upper plot includes wall losses alone proportional to $k^{1/2}$ while the lower plot includes losses from the end of the instrument with radiation resistance $\mathrm{Re}(Z_L)$ varying as k^2. The input impedance is high when $k_n = nc_0/4L$, where n is an odd integer. The input impedance is a minimum when n is even.

It is instructive to consider the magnitude of the input impedances on a logarithmic scale, as shown in Fig. 15.70. When plotted in this way, the resonances and anti-resonances are symmetrically placed about the tube impedance Z_0. The magnitude of the impedance of the nth resonance is $Q_n Z_0$, where Q_n is the quality factor of the excited mode. In contrast the anti-resonances have values of Z_0/Q. The widths $\Delta\omega/\omega$ of the modes at half or double intensity are given by $1/Q_n$.

For efficient transfer of sound, the input impedance of a wind instrument has to match the impedance of the
Fig. 15.70 The modulus of the input impedance plotted on a logarithmic scale of cylindrical pipe with wall damping alone and with additional radiative damping as a function of k in units of $\pi/2$

sound generator. For instruments like the flute, recorder and pan pipes, sound is excited by imposed fluctuations in air pressure across an open hole, so that the generator impedance is small. The resonances of such instruments are therefore located at the minima of the anti-resonance impedance dips, corresponding to the evenly spaced resonances, $f_n = nc_0/2L$, of a cylindrical tube with both ends open. In contrast, for all the brass instruments and woodwind instruments played by a reed, the playing end of the tube is closed by a relatively massive generator (the lips or reed). Resonances then occur at the peaks of the input impedance with frequencies $f_n = nc_0/4L$, where n is now an odd integer, corresponding to the resonances of a tube closed at one end. If we had plotted the magnitude of the input admittance, $A(\omega) = 1/Z(\omega)$, instead of the impedance, the positions of the resonances and anti-resonances would have been reversed. The resonant modes of a double-open-ended wind instrument therefore occur at the peaks of the input admittance, whereas the resonant modes of wind or brass instruments played with a reed or mouthpiece are at the peaks of the input impedance. This is a general property of wind instruments, whatever the size or shape of their internal bores.

15.3.2 Non-Cylindrical Tubes

Although there are simple wind instruments with cylindrical bores along their whole length, the vast majority of modern instruments and many ancient and ethno-

logically important instruments have internal bores that flare out towards their ends. One of the principle reasons for such flares is that they act as acoustic transformers, which help to match the high impedance at the mouthpiece to the much lower radiation impedance of the larger-area radiating output end. However, increasing the fraction of sound radiated decreases the amplitude of the reflected waves and hence the height and sharpness of the natural resonances of the air resonances. In addition, the shape of the bore can strongly influence the frequencies of the resonating air column, which destroys the harmonicity of the modes. This makes it more difficult for the player to produce a continuous note that is rich in partials, since any repetitive waveform requires the excitation of a harmonic set of frequencies.

Conical Tube

We first consider sound propagation in a conical tube, approximating to the internal bore of the oboe, saxophone, cornet, renaissance cornett and bugle. If side-wall interactions are neglected, the solutions for wave propagation in a conical tube are identical to those of spherical wave propagating from a central point. Such waves satisfy the wave equation, which may be written in spherical coordinates as

$$\nabla^2(rp) = \frac{1}{c_0^2}\frac{\partial^2(rp)}{\partial t^2} \ . \tag{15.101}$$

We therefore have standing-wave solutions for rp that are very similar to those of a cylindrical tube, with

$$p = C\frac{\sin kr}{r}\,\mathrm{e}^{\mathrm{i}\omega t} \ . \tag{15.102}$$

Note that the pressure remains finite at the apex of the cone, $r = 0$, where $\sin(kr)/r \to k$. For a conical tube with a pressure node $p = 0$ at the open end, we therefore have standing wave modes with $k_n L = n\pi$ and $f_n = nc_0/2L$, where n is any integer. The frequencies of the excited modes are therefore identical to the modes of a cylindrical tube of the same length that is open at both ends. The lowest note at $f_1 = c_0/2L$ for a conical tube instrument with a reed at one end (e.g. the oboe and saxophone) is therefore an octave above a reed instrument of the same length with a cylindrical bore (e.g. the clarinet) with a fundamental frequency of $c_0/4L$.

The flow velocity U is determined by the acceleration of the air resulting from the spatial variation of the pressure, so that

$$\rho\frac{\partial U}{\partial t} = \frac{\partial(r^2 p)}{\partial r} = C(\sin kr + kr\cos kr)\,\mathrm{e}^{\mathrm{i}\omega t} \ . \tag{15.103}$$
Fig. 15.71 Pressure and flow velocity of the $n = 5$ mode along the length of a conical tube

Figure 15.71 illustrates the pressure and flow velocity for the $n = 5$ mode of a conical tube. Unlike the modes of cylindrical tube, the nodes of U no longer coincide with the peaks in p, which is especially apparent for the first few cycles along the tube. Furthermore, the amplitude fluctuations increase with distance r from the apex ($\approx r$), whilst the fluctuations in pressure decrease $\approx 1/r$. A conical section therefore acts as an acoustic transformer helping to match the high impedance at the input mouthpiece end to the low impedance at the output radiating end.

Attaching a mouthpiece or reed to the end of a conical tube requires truncation of the cone, which will clearly perturb the frequencies of the harmonic modes. However, using a mouthpiece or reed unit having the same internal volume as the volume of the truncated section removed will leave the frequencies of the lowest modes unchanged. Only when the acoustic wavelength becomes comparable with the length of truncated section will the perturbation be large.

Fletcher and *Rossing* [15.5, Sect. 8.7] consider the physics of the truncated conical tube and give the input impedance derived by *Olson* [15.139]

$$Z_\mathrm{in} = \frac{\rho c_0}{S_1}\,\frac{\mathrm{i}Z_\mathrm{L}\left(\frac{\sin(kL-\theta_2)}{\sin\theta_2}\right) + \left(\frac{\rho c_0}{S_2}\right)\sin kL}{Z_\mathrm{L}\frac{\sin(kL+\theta_1-\theta_2)}{\sin\theta_1\sin\theta_2} + j\left(\frac{\rho c_0}{S_2}\right)\frac{\sin(kl+\theta_1)}{\sin\theta_1}} \ , \tag{15.104}$$

where x_1 and x_2 are the distances of the two ends from the apex of the truncated conical section. The length $L = x_2 - x_1$, the end areas are S_1 and S_2, with $\theta_1 = \tan^{-1} kx_1$ and $\theta_2 = tan^{-1} kx_2$.
Fig. 15.72a,b The first four resonant frequencies of truncated cones with (**a**) both ends open, and (**b**) the input end closed, as a function of the ratio of their input to output diameters (after *Ayers* et al. [15.140])

For a cone with $Z_L = 0$ at the open end, (15.104) reduces to

$$Z_{in} = -j \frac{\rho c_0}{S_1} \frac{\sin kL \sin \theta_1}{\sin(kL + \theta_1)}, \qquad (15.105)$$

which is zero for $kL = n\pi$. The resonant frequencies of truncated cones with both ends open are therefore independent of cone angle and are the same as the equally spaced harmonic modes of a cylinder of the same length with both ends open, as shown in Fig. 15.72a. In contrast, the resonant frequencies of a truncated cone with one end closed (e.g. by the reed of an oboe or saxophone or mouthpiece of a bugle) are strongly dependent on the cone angle or ratio of input to output diameter, as shown in Fig. 15.72b, adapted from *Ayers* et al. [15.140]. As the ratio of input to output diameters of a truncated cone increases, the modes change from the evenly spaced harmonics of an open-ended cylinder of the same length, to the odd harmonics of a cylinder closed at one end. In the transitional regime, the frequencies of the modes are no longer harmonically re-

lated. This has a significant effect on the playability of the instrument, as the upper harmonics are no longer co-incident with the Fourier components of a continuously sounded note. However, for an instrument such as the oboe, with a rather small truncated cone length, the perturbation of the upper modes is relatively small, as can be seen from Fig. 15.71b.

Cylindrical and nontruncated conical tubes are the only tubes that can produce a harmonically related set of resonant modes, independent of their length. Hence, when a hole is opened in the side walls of such a tube, to reduce the effective length and hence pitch of the note played, to first order, the harmonicity of the modes is retained. This assumes a node at the open hole, which will not be strictly correct, as discussed later in Sect. 15.3.3.

In reality, the bores of wind instruments are rarely exactly cylindrical or conical along their whole length. Moreover, many wind instruments have a small flare at the end to enhance the radiated sound, while others, like the cor anglais and oboe d'amore, have an egg-shaped cavity resonator towards their ends, which contributes to their characteristic timbre or tone colour. Table 15.6 lists representative wind instruments that are at least approximately based on cylindrical and conical bore shapes. The modern organ makes use of almost every conceivable combination of closed- and open-ended cylindrical and conical pipes.

Hybrid Tubes

Although many brass instruments include considerable lengths of cylindrical section, they generally have a fairly long, gently flared, end-section terminated by a very strongly flared output bell to enhance the radiated sound. The shape of such flares can be optimized to preserve the near harmonicity of the resonant modes, as described in the following section.

One can use (15.104) to model the input impedance of a flared tube of any shape, by approximating the shape by a number of short truncated conical sections

Table 15.6 Instruments approximately based on cylindrical and conical air columns

$f_n = nc_0/2L$ n even and odd	$f_n = nc_0/4L$ n odd	$f_n = nc_0/2L$ n even and odd
Flute	Clarinet	Oboe
Recorders	Crumhorn	Bassoon
Shakuhachi	Pan pipes	Saxophone
Organ flue pipes (e.g. diapason)	Organ flue pipes (e.g. bourdon)	Cornett
	Organ reed pipes (e.g. clarinet)	Serpent
		Organ reed pipes (e.g. trumpet)

joined together. Starting from the radiating end, one evaluates the input impedance of each cone in turn and uses it to provide the terminating impedance for the next, until one reached the mouthpiece end.

A weakness of all such models is the assumed plane wavefront across the air column, whereas it must always be perpendicular to the walls and belled outwards in any rapidly flaring region. We will return to this problem later.

Typical brass instruments, like the trumpet and trombone, have bores that are approximately cylindrical for around half their length followed by a gently flared section and end bell, while others have initial conical sections, like the bugle and horn. The affect on the resonant frequencies of the first six modes of adding a truncated conical section to a length of cylindrical tubing is shown as a function their relative lengths in Fig. 15.73, from *Fletcher* and *Rossing* [15.5, Fig. 8.9]. Note the major deviations from harmonicity of the resonant modes, apart from when the two sections are of nearly equal lengths. These results highlight the complexity involved, when adding flaring sections to brass instruments to increase the radiated sound.

Horn Equation
Physical insight into the influence of bore shape on the modes of typical brass instruments is given by the *horn equation* introduced by *Webster* [15.141], though similar models date back to the time of *Bernoulli* (*Rossing*
Fig. 15.73 The frequencies of the first six modes of a compound horn formed from different fractional lengths of cylindrical and conical section (after *Fletcher* and *Rossing* [15.5])

and *Fletcher* [15.5, Sect. 8.6]). In its simplest form, the horn equation can be written as

$$\frac{1}{S}\frac{\partial}{\partial x}\left(S\frac{\partial p}{\partial x}\right) = \frac{1}{c_0^2}\frac{\partial^2 p}{\partial t^2} , \qquad (15.106)$$

where $S(x)$ is the cross-sectional area of the horn at a distance x along its length. Provided the flare is not too large, the above plane-wave approximation gives a good approximation to the exact solutions and preserves the essential physics involved.

If we make the substitution $p = \psi S^{1/2}$ and look for solutions varying as $\psi(x)e^{i\omega t}$, the horn equation can be expressed as

$$\frac{\partial^2 \psi}{\partial x^2} + \left[\left(\frac{\omega}{c_0}\right)^2 - \frac{1}{a}\frac{\partial^2 a}{\partial x^2}\right]\psi = 0 , \qquad (15.107)$$

where the radius $a(x)$ is now a function of position along the length. The above equation is closely related to the Schrödinger wave equation in quantum mechanics, with $1/a\,\partial^2 a/\partial x^2$ the analogue of potential energy and $-\partial^2 \psi/\partial x^2$ the analogue of kinetic energy $-h^2/2m\,\partial^2 \psi/\partial x^2$, where m is the mass of the particle and h is Planck's constant. One can look for solutions of the form $e^{i(\omega t \pm kx)}$. At any point along the horn at radius x the radius of curvature of the horn walls, $R = (\partial^2 a/\partial x^2)^{-1}$, so that

$$k^2 = \left(\frac{\omega}{c_0}\right)^2 - \frac{1}{aR} . \qquad (15.108)$$

If $\omega > \omega_c = c_0/(aR)^{1/2}$, k is real, so that unattenuated travelling and standing-wave solutions exist. However, when $\omega < \omega_c$, k is imaginary and waves no longer propagate, but are exponentially damped as $e^{-x/\delta}e^{i\omega t}$ with a decay length of $c_0/(\omega_c^2 - \omega^2)^{1/2}$.

The propagation of sound waves in a horn is therefore directly analogous to the propagation of particle waves in a spatially varying potential. If the curvature is sufficiently large sound waves will be reflected before they reach the end of the instrument. However, just like particle waves in a potential well, sound waves can still tunnel through the potential barrier and radiate into free space at the end of the flared section. For a horn with a rapidly increasing flare, the reflection point occurs when the wavelength $\lambda^2 \approx (2\pi)Ra$. The effective length of an instrument with a flared horn on its end is therefore shorter for low-frequency modes than for the higher-frequency modes. This is illustrated schematically in Fig. 15.77 for resonant modes of a flared Bessel horn, which will be considered in more detail in the next section.

Exponential Horn

We now consider solutions of the horn equation, for a number of special shapes that closely describe sections of the internal bore of typical brass instrument. Cylindrical and conical section horns are special solutions with $(1/a)\partial^2 a/\partial x^2 = 0$, so that ψ satisfies the simple dispersionless wave equation. Figure 15.74 illustrates a number of other horn shapes described by analytic functions.

The radii of exponential and cosh function horns vary exponentially as $A\,e^{mx}$ and $A\cosh(mx)$, respectively, so that $(1/a)\partial^2 a/\partial x^2 = m^2$. The $\cosh mx$ function provides a smooth connection to a cylindrical tube at the input end. For both shapes, the horn equation can then be written as

$$\frac{\partial^2 \psi}{\partial x^2} + \left[\left(\frac{\omega}{c_0}\right)^2 - m^2\right]\psi = 0, \qquad (15.109)$$

which has travelling solutions for the sound pressure $p = \psi/S^{1/2}$, where

$$p(x) = e^{-mx}\,e^{i(\omega t - \sqrt{k^2 - m^2 x^2})}, \qquad (15.110)$$

and $k = \omega/c_0$. Above a critical cut-off frequency, $f_c = c_0 m/2$, waves can propagate freely along the air column with a dispersive phase velocity of $c_0/\sqrt{1 - (\omega_c/\omega)^2}$, while below the cut-off frequency the waves are exponentially damped. The cut-off frequency occurs when the free-space wavelength is approximately six times the length for the radius to increase by the exponential factor e.

Figure 15.75 compares the input resistance and reactance of an infinite exponential horn with that of a baffled piston having the same input area (*Kinsler* et al. [15.142, Fig. 14.19]). The plots are for an exponential horn with $m = 3.7\,\mathrm{m}^{-1}$, which corresponds to a cut-off frequency of $\approx 100\,\mathrm{Hz}$, and a baffled piston having the same radius of $2\,\mathrm{cm}$ as the throat of the
Fig. 15.75 Comparison of input impedance at the input throat of an infinitely long exponential horn and a piston of the same area set into an infinite baffle (after *Kinsler* et al. [15.142])

exponential horn. Above $\approx 400\,\mathrm{Hz}$, there is very little difference between the impedance of an infinitely long horn and a horn with a finite length of $\approx 1.5\,\mathrm{m}$ or longer, though below this frequency reflections cause additional fluctuations around the plotted values. Below the cut-off frequency, no acoustic energy can be radiated. Above the cut off the input resistance rises rather rapidly towards its limiting 100% radiating value. The exponential horn with a piston source at its throat is therefore a much more efficient radiator of sound than a baffled piston at all frequencies above the cut-off frequency.

The exponential horn illustrates how the flared cross section of brass instruments enhances the radiation of sound, though brass instruments are never based on exponential horns, otherwise no resonant modes could be set up. However, exponential horns were widely used in the early days of the gramophone. In the absence of any electronic amplification, they amplified the sound produced by the input diaphragm excited by the pick-up stylus on the recording cylinder or disc. They are still widely used in powerful public address systems. Such horns can also be used in reverse, as very efficient detectors of sound, with a microphone placed at the apex of the horn.

Bessel Horn

We now consider more realistic horns with a rapidly flaring end bell, which can often be modelled by what are known as Bessel horn shapes, with the radius varying as $1/x^m$ from their open end. Typical flared horn shapes are shown in Fig. 15.76 for various values of m, where the horn functions $A/(x + x_0)^m$ have been nor-

Fig. 15.74 Analytic horn shapes
Fig. 15.76 Bessel horns representing the rapid outward flare of the bell on the end of a brass instrument, for a sequence of m values giving a ratio of input to output diameters of 10

Fig. 15.77 Fundamental and fourth mode of an $m = 1/2$ Bessel horn, illustrating the increase in wavelength and resulting shift inwards of the effective nodal position. The *dashed lines* illustrate the extrapolated sine-wave solutions from well inside the bore. The plot is of $p(x)/x$

malised by suitable choice of A and x_0, to model horns with input and output values 1 and 10. Increasing the value of m increases the rapidity with which the flare opens out at the end.

Again assuming the plane-wave approximation, the horn equation can be written as

$$\frac{\partial^2 \psi}{\partial x^2} + \left[\left(\frac{\omega}{c_0} \right)^2 - \frac{m(m+1)}{x^2} \right] \psi = 0 , \qquad (15.111)$$

with solutions

$$\psi(kx) = x^{1/2} J_{m+1/2}(kx) \qquad (15.112)$$

and pressure varying from the end as

$$p(kx) = \frac{1}{x^{1/2}} J_{m+1/2}(kx) , \qquad (15.113)$$

where $J_{m+1/2}(kx)$ is a Bessel function of order $m + 1/2$, giving the name to such horns.

In the plane-wave approximation, the sharpness and height of the barrier to wave propagation arising from the curvature could result in total reflection of the incident waves, so that no sound would be emitted from the end of the instrument. In reality, the curvature of the waveform will smear out any singularity in the horn function over a distance somewhat smaller than the output bell radius. Nevertheless, despite its limitations, the plane-wave model provides an instructive description of the influence of a rapidly flaring bell on a brass instrument. This is illustrated in Fig. 15.77 for

the fundamental and fourth modes of a Bessel horn with $m = 1/2$, with the pressure $p(x)$ varying from the output end as $x J_1(kx)$.

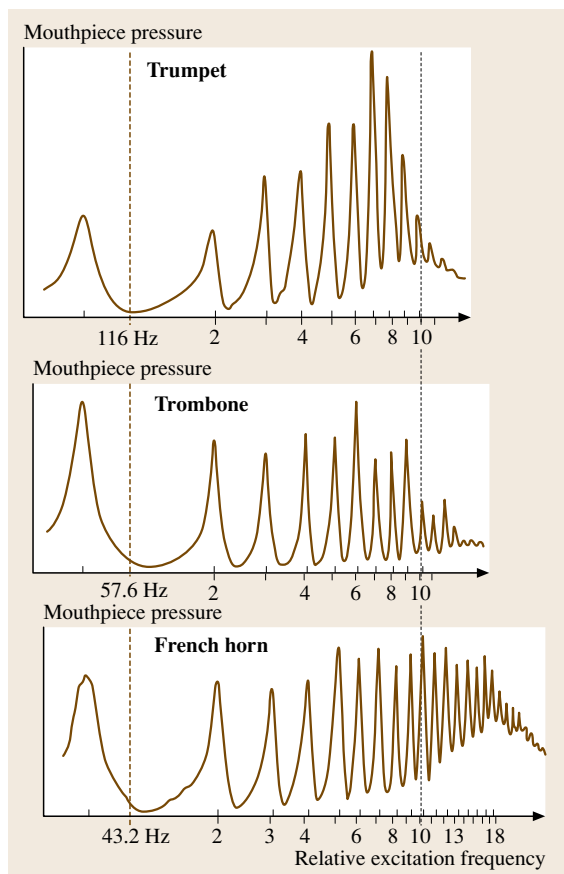
The most important point to note is the way that the flare pushes the effective node of the incident sine-wave solutions (extended into the flared section as dashed curves) away from the end of the instrument. The effective length is therefore shortened and resonant frequencies increased, the effect being largest for the lower frequency modes. The flare and general outward curvature of the horn cross section therefore destroys the harmonicity of the modal frequencies. This is a completely general result for any horn with a flared end. In practice, the nodal positions will also be affected by the curvature of the wavefront, which will further perturb the modal frequencies, but without changing the above qualitative behaviour.

Benade [15.134, Sect. 20.5] notes that, from the early 17th century, trumpets and trombones have been designed with strongly flaring bell corresponding to m values of 0.5–0.65, while French horns have bells with a less sudden flare with m values of 0.7–0.9.

From Fig. 15.77, it is easy to see how the player can significantly affect the pitch of a note on the French horn, by moving the supporting hand up into the bell of the instrument, which is referred to as hand-stopping. The pitch can be lowered by around a semitone, by placing the downwardly cupped hand and wrist against the top of the flared bell, effectively reducing the flare and increasing the effective length of the instrument. Alternatively, the pitch can be raised by a similar amount when the hand almost completely closes the inner bore. This leads to a major perturbation of the boundary conditions, effectively shortening the air column and reducing the output sound. The increase in frequency can

be explained by the player using an almost unchanged embouchure to excite a higher frequency mode of the shortened tube. Because of the increased reflection of sound by the presence of the hand, the resultant sound although quieter is also much richer in higher partials (Fig. 15.113). Both effects are illustrated in Audio example |?〉 **EXTRAS**.

Flared Horns

Use is made of the dependence of modal frequencies on the curvature of horn shapes to design brass instruments with a set of resonances, which closely approximate to a harmonic series with frequencies $f_n = n f_1$. This should be contrasted with the modes of a cylindrical tube closed at one end by the mouthpiece, which would


only involve the odd-n integer modes with frequencies of $f_n = c/2L$.

Historically, this has been achieved by empirical methods, with makers adjusting the shapes of brass instrument to give as near perfect a set of harmonic resonances as possible, as illustrated in Fig. 15.78 from *Backus* [15.133, Chap. 12]. A harmonic set of modes enhances the playability of the instrument, as the partials of any continuously blown note then coincide with the natural resonances of the instrument. However, the fundamental mode is always significantly flatter than required and is therefore not normally used in musical performance. Nevertheless, the brass player can still sound a *pedal note* corresponding to the *virtual fundamental* of the higher harmonics by exciting a repetitive waveform involving the higher harmonics, but with only a weak Fourier component at the pitch of the sounded note.

The way that this is achieved is shown schematically in Fig. 15.79 starting from the odd-n resonances of a cylindrical tube closed at one end by the mouthpiece to an appropriately flared horn of the same length. In practice, one can achieve a nearly perfect set of harmonic resonances, midway between the odd-integer modes of a cylindrical tube closed at one end, for all but the fundamental mode, which cannot be shifted upwards by a sufficient amount to form a harmonic fundamental, stopping and of the new set of modes.

Benade [15.134, Sect. 20.5] has given an empirical expression for the frequencies of the partials of Bessel horns closed at the mouthpiece end, which closely de-

Fig. 15.78 Input impedances of the trumpet, trombone and French horn with the positions of the resonant peaks marked above the axis to show their position relative to a harmonic series based on the second harmonic of the instrument (after *Backus* [15.133])

scribes these perturbations,

$$\frac{f'_n}{f_n} \approx \left(1 + 0.637 \frac{\sqrt{m(m+1)}}{2n-1}\right), \tag{15.114}$$

where the $(2n-1)$ in the denominator emphasising the preferential raising in frequency of the lower-frequency modes. This gives frequencies for the first six modes of a Bessel function horn with $m = 0.7$ are in the ratios 0.94, 2.00, 3.06, 4.12, 5.18 and 6.24, normalised to the $n = 2$ mode. These should be compared with the ideal 1, 2, 3, 4, 5, 6 ratios. Apart from the lowest note, which is a semitone flat, the higher modes are less than a semitone sharp compared with their ideal values.

Perturbation Models

Perturbation theory can be used to describe how changes in bore shape perturb the resonant modes of brass and woodwind instruments. *Fletcher* and *Rossing* [15.5, Sect. 8.10] show that the change of frequency of a resonant mode $\Delta\omega$ resulting from small distributed changes $\Delta S(x)$ in bore area $S(x)$ is given by

$$\frac{\Delta\omega_n}{\omega_n} = -\frac{1}{2}\left(\frac{c_0}{\omega_n}\right)\int_0^L \left[\frac{\partial}{\partial x}\left(\frac{\Delta S(x)}{S(x)}\right) p_n \frac{\partial p_n}{\partial x} \, dx\right] \Big/$$

$$\times \int_0^L \left[S(x) p_n^2 \, dx\right]. \tag{15.115}$$

An alternative equivalent derivation uses Rayleigh's harmonic balance argument and equates the peak kinetic energy to the peak potential energy. To first order, the perturbation is assumed to leave the shape of the modal wavefunction unchanged. The kinetic and potential energy stored in a particular resonant mode can be expressed in terms of the local kinetic $\frac{1}{2}\rho\omega_n^2\xi_n^2$ and strain $\frac{1}{2}\gamma P_0(\partial\xi_n/\partial x)^2$ energy densities. For simplicity, we consider the perturbation of the nth resonant mode of a cylindrical air column open at one end, with particle displacement $\xi_n \approx \sin(n\pi x/L)\cos(\omega_n t)$, where n is an odd integer. Equating the peak kinetic and potential energy over the perturbed bore of the cylinder, we can then write

$$\omega_n'^2 \int_0^L \rho \left[S + \Delta S(x)\right] \sin^2(kx) \, dx$$

$$= \gamma P_0 k_n^2 \int_0^L \left[S + \Delta S(x)\right] \cos^2(kx) \, dx, \tag{15.116}$$

where ω'_n is the perturbed frequency. This can be rewritten as

$$\frac{\omega_n'^2}{\omega_n^2} = \int_0^L \left[S + \Delta S(x)\right] \cos^2(kx) \, dx \Big/$$

$$\times \int_0^L \left[S + \Delta S(x)\right] \sin^2(kx) \, dx. \tag{15.117}$$

Because the perturbations are assumed to be small, we can rearrange (15.117) to give the fractional change in frequency

$$\frac{\Delta\omega_n}{\omega_n} = \frac{1}{L}\int_0^L \frac{\Delta S(x)}{S}(\cos^2 kx - \sin^2 kx) \, dx. \tag{15.118}$$

Hence, if the tube is increased in area close to a displacement antinode, where the particle flow is large (low pressure), the modal frequency will increase, whereas the frequency will decrease, if constricted close to a nodal position (large pressure) (*Benade* [15.134, Sect. 22.3]). This result can be generalised to a tube of any shape. Hence, by changing the radius over an extended region close to a node or antinode, the frequencies of a particular mode can be either raised or lowered, but at the expense of similar perturbations to other modes. Considerable art and experience is therefore needed to correct for the inharmonicity of several modes simultaneously.

Electric Circuit Analogues

It is often instructive to consider acoustical systems in terms of equivalent electric circuit analogues, where voltage V and electrical current I can represent the acoustic pressure p and flow along a pipe U. For example, a volume of air with flow velocity U in a pipe of area S and length l has a pressure drop $(\rho l/S)\partial U/\partial t$ across its length, which is equivalent to the voltage $L\partial I/\partial t$ across an inductor in an electrical circuit. Likewise, the rate of pressure rise, $\partial p/\partial t = \gamma P_0 U/V$, as gas flows into a volume V, is equivalent to the rate of voltage rise, $\partial V/\partial t = I/C$ across a capacitance $C \equiv V/\gamma P_0$.

As a simple example, we re-derive the Helmholtz resonance frequency, previously considered in relation to the principal air resonance of the air inside a violin or guitar body (Sect. 15.2.4), but equally important, as we will show later, in describing the resonance of air within the mouthpiece of brass instruments.

In its simplest form, the Helmholtz resonator consists of a closed volume V with an attached cylindrical

pipe of length l and area S attached, through which the air vibrates in and out of the volume. All dimensions are assumed small compared to the acoustic wavelength, so that the pressure p in the volume and the flow in the pipe U can be assumed to be spatially uniform. The volume acts as an acoustic capacitance $C = V/\gamma P_0$, which resonates with the acoustic inductance $L = \rho l/S$ of the air in the neck. The resonant frequency is therefore given by

$$\omega_{\text{Helmholtz}} = \frac{1}{\sqrt{LC}} = \sqrt{\frac{S}{\rho l}\frac{\gamma P_0}{V}} = c_0\sqrt{\frac{S}{lV}} \, ,$$

(15.119)

as derived earlier.

Any enclosed air volume with holes in its containing walls acts as a Helmholtz resonator, with an effective *kinetic inductance* of the hole region equivalent to a tube of the same diameter with an effective length of wall thickness plus ≈ 0.61 hole radius (*Kinsler* et al. [15.142, Sect. 9.2]). This is the familiar end-correction for an open-ended pipe (*Kinsler* et al. [15.142, Sect. 9.2]). Open holes of different diameters will therefore give resonances corresponding to different musical tones. The ocarina is a very simple musical instrument based on such resonances, in which typically four or five holes with different areas can be opened and closed in combination, to give a full range of notes on a chosen musical scale (audio ⏴❓ **EXTRAS**). Because the sound is based on the single resonance of a Helmholtz resonator, there are no simply related higher-frequency modes that can be excited. Ocarinas appear in many ancient and ethnic cultures around the world and are often sold as ceramic toys.

Acoustic Transmission Line

There is also a close equivalence between acoustic waves in wind instruments and electrical waves on transmission lines, with an acoustic pipe having an equivalent inductance $L_0 = \rho/S$ and capacitance $C_0 = S/\gamma P_0$ per unit length. For a transmission line the wave velocity is therefore $c_0 = \sqrt{1/L_0 C_0} = \sqrt{\gamma P_0/\rho}$ and characteristic impedance $Z_0 = \sqrt{L_0/C_0} = \rho c_0/S$, as expected. The input impedance of a transmission line as a function of its characteristic impedance and terminating load is given by (15.100).

Valves and Bends

To enable brass instruments to play all the notes of the chromatic scale, short lengths of coiled-up tubing are connected in series with the main bore by a series of piston- or lever-operated air valves. The constriction of air flow through the air channels within the valve structures and the bends in the tubing, used to reduce the size of the instruments to a convenient size for the player to support, will clearly present discontinuities in the acoustic impedance of the air bore and will lead to reflections. Such reflections will influence the feel of the instrument for the player exciting the instrument via the mouthpiece and will also perturb the frequencies of the resonant modes of the instrument.

If the discontinuities are short in size relative to the acoustic wavelengths involved, the discontinuity can be considered as a discrete (localised) lumped circuit element. Using our electromechanical equivalent, a short, constricted channel through a valve can be represented as an inductance $\rho L_{\text{valve}}/S_{\text{valve}}$ in series with the acoustic transmission line, or an equivalent additional extra length of bore tubing $L_{\text{valve}} S_{\text{tube}}/S_{\text{valve}}$ of cross section S_{tube}. For all frequencies such that $kL_{\text{valve}} \ll 1$, the valve simply increases the length of the acoustic air column slightly and the frequencies of all the lower modes by the same fractional amount. Only at very high frequencies, outside the normal playing range, will the constricted air channel significantly change the modal frequencies.

When a straight length of cylindrical tube of radius a is connected to the same size tubing but bent into a circle of radius R, there will a small change in the acoustic impedance and velocity of sound waves, which arises because the forces acting on each element induces rotational in additional to linear motion. The presence of bends will lead to reflections and slight perturbations of resonant frequencies, though these effects will again be relatively small. *Nederveen* [15.143] showed that fractional increase in phase velocity and decrease in wave impedance of a rectangular duct is given by the factor $F^{1/2}$, where

$$F = \frac{B^2}{2} \Big/ \left[1 - \left(1 - B^2\right)^{1/2}\right]$$
$$= 1 - B^2/4 \quad \text{for} \quad B \ll 1 \, ,$$

(15.120)

$B = a/R$, a is the half-width of the duct and R its radius. *Keefe* and *Benade* [15.144] subsequently generalised this result to a bent circular tube, with its radius r replacing a.

Finger Holes

In many woodwind instruments, tone holes can be opened or closed to change the effective resonating length of an air column and hence pitch of the sounded

note. The holes can be closed by the pad of the finger or a hinged felt-covered pad operated with levers. To a first approximation, opening a side hole creates a pressure node at that position, shortening the effective length of the instrument and raising the modal frequencies. However, as described in *Fletcher* and *Rossing* [15.5, Sect. 15.2] and in detail by *Benade* [15.134, Chaps. 21 and 22], the influence of the side holes is in practice strongly dependent on the hole size, position and frequency, as summarised below.

At low frequencies, when the acoustic wavelength is considerably longer than the size and spacing of the tone holes, one can account for the effect of the tone holes by considering their equivalent capacitance when closed and their inductance when open, as illustrated schematically in Fig. 15.80.

Because the walls of wind instruments and particularly woodwind instruments have a significant thickness, the tone holes when shut introduce additional small volumes distributed along the length of the vibrating air column. Each closed hole will introduce an additional volume and equivalent capacitance $C_{\text{c-hole}} = \pi b^2 / \gamma P_0$, which will perturb the frequencies of the individual partials upwards or downwards by a small amount that will depend on its position relative to the pressure and displacement nodes and the closed volume of the hole. In severe cases, the perturbations can be as large as a few per cent (one semitone is 6%), which requires compensating changes in bore diameter along the length of the instrument, to retain the harmonicity of the partials. However, this is essentially a problem that depends on geometrical factors involving the air column alone. Once solved, like all acoustic problems involving the shape and detailed design, instruments can be mass-produced with almost identical
acoustic properties, quite unlike the problems that arise for stringed instruments.

The more interesting situation is when the holes are opened, introducing a pressure node at the exit of the tone hole and shortening the effective acoustical length of the instrument. An open hole can be considered as an inductance, $L \approx \rho(t + 0.6b)/\pi b^2$, where the effective length of the hole is increased by the unflanged hole end-correction. Neglecting radiation losses from the hole (*Fletcher* and *Rossing* [15.5, (15.21, 22)]), the effective impedance Z^* of an open-ended cylindrical pipe of length l and radius a shunted by the inductive impedance of a circular hole of radius b set into the wall of thickness t is given by

$$\frac{1}{Z^*} \approx \frac{\pi b^2}{i\omega\rho(t + 0.6b)} + \frac{\pi a^2}{i\rho c_0 \tan kl}$$
$$= \frac{\pi a^2}{i\rho c_0 \tan kl'} . \tag{15.121}$$

Thus can be expressed in terms of an impedance of an effectively reduced length l'.

$$\text{For } kl \ll 1 , \quad \frac{l'}{l} = \left[1 + \frac{t + 0.6b}{l}\left(\frac{a}{b}\right)^2\right]^{-1} . \tag{15.122}$$

The change in effective length introduced by the open hole depends strongly on its area relative to that of the cylinder, the thickness of the wall and its length from the end. This gives the instrument designer a large amount of flexibility in the positioning of individual holes on an instrument. Figure 15.81 illustrates the dependence of the effective pipe length on the ratio of hole to cylinder radii for two lengths of pipe between the hole and end of the instrument.

Not surprisingly, a very small hole with $b/a \ll 1$ has a relatively small effect on the effective length of an instrument. In contrast, a hole with the same diameter as that of the cylinder shortens the effective added length to about one hole diameter.

In practice, there will often be several holes open beyond the first open tone hole, all of which can affect the pitch of the higher partials.

Consider a regular array of open tone holes spaced a distance d apart. The shunting kinetic inductance of each open hole is in parallel with the capacitance associated with the volume of pipe between the holes. At low frequencies, such that $\omega \ll 1/\sqrt{L_{\text{hole}} C_0 d}$, the impedance is dominated by the hole inductance, so that each hole attenuates any incident wave by approxi-

Fig. 15.80 Equivalent circuits for a short length d of cylindrical pipe containing a closed and an open tone hole, shunting the acoustic transmission line with a capacitance and inductance, respectively
Fig. 15.81 Low-frequency ($kl \ll 1$) fractional reduction of effective length of a cylindrical end-pipe as a function of hole to cylinder radius, for additional lengths of 10 (*lower curve*) and 20 (*upper curve*) times the tube radius in length. The side wall thickness is 0.4 times the tube radius

mately the ratio

$$\approx L_{\text{hole}}/\left(L_{\text{hole}} + L_0 d\right) = \left[1 + \frac{d}{t + 1.5b}\left(\frac{a}{b}\right)^2\right]^{-1},$$
(15.123)

where L_0 is the inductance of the pipe per unit length. Incident waves are therefore attenuated with an effective node just beyond the actual hole as discussed above.

However, for frequencies such that $\omega \gg 1/\sqrt{L_{\text{hole}}C_0 d}$, the impedance of the shunting hole inductance is much larger than that of the capacitance of the air column, so that the propagating properties of the incident waves is little affected be the presence of the open hole. There is therefore a *crossover* or *cut-off* frequency

$$\omega \approx 1/\sqrt{L_{\text{hole}}C_0 d} = c_0 \frac{a}{b}\left(\frac{1}{t_{\text{eff}}d}\right)^{1/2},$$
(15.124)

below which the incident waves are reflected to give a pressure node just beyond the first hole of the array and above which waves propagate increasingly freely through the array to the open end of the instrument.

Figure 15.82 (*Benade* [15.134, Fig. 21.1]) illustrates the effect of an array of open holes on the first few partials of a typical woodwind instrument, highlighting the increase in acoustic length of the instrument (indicated
Fig. 15.82 Schematic representation of the influence of open holes on the first four partials of a woodwind instrument, with the effective length indicated by the intercept n_{eff} on the axis of the extrapolated incident wave (after *Benade* [15.134])

by the intercept of the extrapolated incident waveform) with increasing frequency. The dependence of the effective length of the acoustic air column on frequency is therefore rather similar to the influence of the flare on the partials of a brass instrument.

A consequence of the greater penetration at high frequencies of the acoustic wave through the array of open tone holes is the greater attenuation of such waves by radiation and the consequent reduction in the amplitude of the higher resonant modes in measurements of the input impedance. This is illustrated in Fig. 15.83 for a length of clarinet tubing first without and then with an added section containing an array of equally spaced tone holes (*Benade* [15.134, Fig. 21.3]).

Benade [15.134, Sect. 21.1] states that

specifying the cut-off frequency for a woodwind instrument is tantamount to describing almost the whole of its musical personality

– assuming the proper tuning and correct alignment of resonances for good oscillation. His measured values of the cut-off frequency for the upper partials of classical and baroque instruments are 1200–2400 Hz for
Fig. 15.83 Illustration of the cut-off-frequency effect, when adding an addition length of tubing with an array of open tone holes (after *Benade* [15.134])

Fig. 15.84 Soprano recorder fingering for the first seven notes of a whole-tone scale (after *Fletcher* and *Rossing* [15.5])

oboes, 400–500 Hz for bassoons, and 1500–1800 Hz for clarinets.

Cross–Fingering

The notes of an ascending scale can be played by successively opening tone holes starting from the far end of the instrument. In addition, by overblowing, the player can excite notes in the *second register* based on the second mode. As remarked earlier, instruments like the flute and oboe overblow at the octave, whereas the clarinet overblows at the twelfth (an octave plus a perfect fifth). To sound all the semitones of the western classical scale on the flute or oboe would therefore require 12 tone holes and the clarinet 20 – rather more than the fingers on the two hands! In practice, the player generally uses only three fingers on the left hand and four on the right to open and close the finger holes. The thumb on the left hand is frequently used to open a small *register* hole near the mouthpiece, which aids the excitation of the overblown notes in the higher register.

In practice, *cross-* or *fork-fingering* enables all the notes of the chromatic scale to be played using the seven available fingers and combinations of open and closed tone holes. This is illustrated in Fig. 15.84 for the baroque recorder (*Fletcher* and *Rossing* [15.5, Fig. 16.21]). The bottom two notes can be sharpened by a semitone by half-covering the lower two holes and the overblown notes an octave above are played with

the thumb hole either fully open or half closed. Cross-fingering makes use of the fact that the standing waves set up in a pipe extend an appreciable distance into an array of open tone holes (Fig. 15.82), so that opening and closing holes beyond the first open hole can have an appreciable influence on the effective length of the resonating air column.

Modern woodwind instruments use a series of interconnected levers operated by individual keys, which facilitates the ease with which the various hole-opening combinations can be made.

Radiated Sound

Although the reactive loading of an open hole determines the effective length of the resonant air column, particularly at low frequencies, it does not follow that all the sound is radiated from the open tone holes. Indeed, since the intensity of the radiated sound depends on $(ka)^2$, very little sound will be radiated by a small hole relative to the much wider opening at the end of an instrument. The loss in intensity of sound passing an open side hole may therefore, in large part, be compensated by the much larger radiating area at end of the instrument. This also explains why the characteristic hollow sound quality of a cor anglais, derived in part from the egg-shaped resonating cavity near its end, is retained, even when the tone holes are opened on the mouthpiece side of the cavity.

In practice, the sound from the end and open tone holes of a woodwind instrument act as independent monopole sources. When the acoustic wavelength becomes comparable with the hole spacing, interesting interference effects in the output sound can occur contributing to strongly directional radiation patterns, as discussed by *Benade* [15.134, Sect. 21.4]. Similarly, reciprocity allows one to make use of such interference effects to produce a highly directional microphone by placing a microphone at the end of a cylindrical tube with an array of open side holes.

Brass Mouthpiece

Brass instruments are played using a mouthpiece insert, against which the lips are pressed and forced to vibrate by the passage of air between them. The mouthpiece not only enables the player to vibrate their lips over a wide range of frequency, but also provides a very important acoustic function in significantly boosting the amplitude of the higher partials, helping to give brass instruments their bright and powerful sounds.

Typical mouthpiece shapes are shown in Fig. 15.85. Mouthpieces can be characterized by the mouthpiece volume and the *popping* frequency characterizing the Helmholtz resonator comprising the mouthpiece volume and backbore. The popping frequency can easily be estimated from the sound produced when the mouthpiece is slapped against the open palm of the hand (audio |?⟩ EXTRAS).

By adjusting the tension in the lips, the shape of the lips within the mouthpiece (the embouchure), and the flow of air between the lips via the pressure in the mouth, the skilled brass player forces the lip to vibrate at the required frequency of the note to be played. This can easily be demonstrated by making a pitched buzzing sound with the lips compressed against the rim of the mouthpiece cup. The circular rim constrains the lateral motion of the lips making it far easier to produce stable high notes. A brass player can sound all the notes on an instrument by simply blowing into the mouthpiece alone, but the mouthpiece alone produces relatively little volume. The instrument both stabilises the playing

Fig. 15.86 Input impedance of a length of cylindrical trumpet pipe with and without a mouthpiece attached (after *Benade* [15.134])

frequencies and increases the coupling between the vibrating lips and radiated sound.

Figure 15.86 illustrates the enhancement in the input impedance around the popping frequency, when a mouthpiece is attached to the input of a cylindrical pipe, as measured by *Benade* [15.134]. Benade showed that the influence of the mouthpiece on the acoustical characteristics of a brass instrument is, to a first approximation, independent of the internal bore shape and can be characterized by just two parameters, the internal volume of the mouthpiece and the popping frequency.

Benade also measured the perturbation of the resonant frequencies of an instrument by the addition of a mouthpiece, as illustrated in Fig. 15.87. At low frequencies, the mouthpiece simply extends the effective input end of a terminated tube by an equivalent length of tubing having the same internal volume as the mouthpiece. In the measurements shown, Benade removed lengths of the attached tube to keep the resonant frequencies unchanged on adding the mouthpiece. However, since the fractional changes in frequency are small, the measurements are almost identical to the effective increase in length from the addition of the mouthpiece.

At the mouthpiece *popping* frequency (typically in the range 500 Hz to 1 kHz depending on the mouthpiece and instrument considered), the effective increase in length is $\lambda/4$. This can result in decreases in resonant frequencies by as much as a tone, which could have

Fig. 15.85a,b Cross sections of (a) trumpet mouthpiece and (b) horn mouthpiece (after *Backus* [15.133])
Fig. 15.87 The amount by which a trumpet tube of length 137 cm would have to be lengthened to compensate for the lowering in frequency of the instrument's resonant frequencies when a mouthpiece is attached to the input (after *Benade* [15.134]). The changes in length to give a semitone and a whole-tone change in frequency are indicated by the *horizontal lines*

a significant influence on the harmonicity, and hence the playability, of an instrument. The effective length continues to increase above the popping frequency before decreasing at higher frequencies. In many brass instruments, such as the trumpet, there is also a longer transitional conical section (*the lead pipe*) between the narrow bore of the mouthpiece and the larger-diameter main tubing. This reduces the influence of the mouthpiece on the tuning of individual resonances and the overall formant structure of resonances.

It is straightforward to write down the input impedance inside the cup of a mouthpiece attached to an instrument using an equivalent electrical circuit. The volume within the cup is represented by a capacitance C in parallel with the inductance L and resistance R of air flowing through the backbore, which is in series with the input impedance of the instrument itself, so that

$$Z_{in} = \frac{1}{i\omega C} \frac{i\omega L + R + Z_{horn}}{(1/i\omega C) + i\omega L + R + Z_{horn}} . \quad (15.125)$$

Figure 15.88 shows the calculated input impedance of an 800 Hz Helmholtz mouthpiece resonator, of volume 5 cm^3 with a narrow-backbore neck section resulting in a Q-value of 10, before and after attachment to a cylindrical pipe of length 1.5 m and radius 1 cm,
Fig. 15.88 The calculated impedance of an 800 Hz Helmholtz mouthpiece (*dark brown*), an attached pipe (*black*) and the combination of mouthpiece and pipe (*light brown*)

radiating into free space at its open end. The input impedance of the pipe alone is also shown. Note the marked increase in heights and strong frequency shifts of the partials in the neighbourhood of the mouthpiece resonance. As anticipated from our previous treatment of coupled resonators in the section on stringed instruments, the addition of the mouthpiece introduces an additional normal mode resonance in the vicinity of the Helmholtz resonance. In addition, it lowers the frequency of all the resonant modes below the popping frequency and increases the frequency of all the modes above.

Above the mouthpiece resonance, the input impedance is dominated by the inertial input impedance of the mouthpiece. The resonances of the air column are superimposed on this response and exhibit the familiar dispersive features already noted for narrow violin string resonances superimposed on the much broader body resonances. The calculated behaviour is very similar to the measured input admittance of typical brass instrument (Fig. 15.78) as extended to instruments with realistic bore shapes by *Caussé*, *Kergomard* and *Lurton* [15.145].

15.3.3 Reed Excitation

In the next sections, we consider the excitation of sound by: (a) the single and double reeds used for many woodwind instruments and selected organ pipes, (b) the vibrating lips in the mouthpiece of brass instrument, and (c) air jets used for the flute, certain organ stops and many ethnic instruments such as pan pipes.
Fig. 15.89a–d Examples of wind and brass instrument reeds: (**a**) a single reed (clarinet), (**b**) a double reed (oboe), (**c**) a cantilever reed (harmonium) and (**d**) the mouthpiece lip-reed (horn) (after *Fletcher* and *Rossing* [15.5])

Reed Types

Figure 15.89 shows a number of reed types used in woodwind and brass instruments (*Fletcher* and *Rossing* [15.5, Figs. 13.1, 7]).

Helmholtz [15.128] classified two main types of reed: *inward-striking reeds*, which are forced shut by an overpressure within the mouth, and *outward-striking reeds*, forced open by an overpressure. Modern authors often prefer to call such reeds inward-closing and outward-opening or swinging-door reeds. In addition there are reeds that are pulled shut by the decreased Bernoulli pressure created by the flow of air between them. Such reeds are often referred to as sideways-striking or sliding-door reeds.

A more formal classification (*Fletcher* and *Rossing* [15.5, Sect. 13.3]) characterises such reeds by a doublet symbol (σ_1, σ_2), where the values of $\sigma_{1,2} = \pm 1$ describe the action of over- and under-pressures at the input and output ends of the reed. When the valve is forced open by an overpressure at either end, $\sigma_{1,2} = +1$; if forced open by an under-pressure, $\sigma_{1,2} = -1$. The force tending to open the valve can then be written as $(\sigma_1 p_1 S_1 + \sigma_2 p_2 S_2)$, where $S_{1,2}$ and $p_{1,2}$ are the areas and pressures at the reed input and output. The operation of reeds can therefore be classified as $(+, -)$, $(-, +), (-, -)$ or $(+, +)$. Single and double woodwind reeds are inward-striking $(-, +)$ valves, while the vibrating lips in a mouthpiece and the vocal cords involve both outward-swinging $(+, -)$ and sideways-striking $(+, +)$ actions.

Figure 15.90 summarises the steady-state and dynamic flow characteristics of the above reeds for typical operating pressures across the valve, $\Delta p = p_{\mathrm{m}} - p_{\mathrm{ins}}$, where p_{m} and p_{ins} are the input and output pressures in the mouth and instrument input, respectively. For the
Fig. 15.90 Main classifications of vibrating reeds summarising reed operation, nomenclature and the associated static and *ac* conductance, with the negative resistance frequency regimes indicated by *solid shading*

inward-swinging $(-, +)$ reed, the flow rate initially increases for a small pressure difference across the valve, but then decreases as the difference in pressures tends to close the valve, leading to complete closure above a certain pressure difference p_{max}. Before closure, there is an extended range of pressures where the flow rate decreases for increasing pressure difference across the reed. This is equivalent to an input with a negative resistance to flow. This results in positive feedback exciting resonances of any attached air column, provided the feedback is sufficient to overcome viscous, thermal and radiation losses.

It is less obvious why the outward-swinging $(-, +)$ reed can give positive feedback, because the steady-state flow velocity always increases with increasing pressure across the valve. However, this is only true at low frequencies below the mechanical resonance of the reed. Above its resonant frequency, the reed will move in anti-phase with any sinusoidally varying fluctuations in pressure. This will result in a regime of negative resistance and the resonant excitation of any attached air column, as discussed by *Fletcher* et al. [15.146].

Sideways-striking $(+, +)$ or $(-, -)$ reeds behave rather like inward-striking reeds, with an extended re-

gion of negative conductance. However, such reeds will never cut off the flow completely, so that for large pressure differences the dynamic conductance again becomes positive, as indicated in Fig. 15.90.

Bernoulli Pressures

Figure 15.91 schematically illustrates the variation of flow velocity and pressure as air flows from the mouth into the reed and attached air column. To solve the detailed dynamic response from first principles for a specific reed geometry would require massive computer modelling facilities. Fortunately, the physics involved is reasonably well understood, so that relatively simple models can be used to reproduce reed characteristics rather well, as illustrated for the clarinet reed in the next section.

The operation of all reed generators is controlled by the spatial variations in Bernoulli pressure exerted by the air flowing across the reed surfaces. Such variations in P arise because, within any region of streamlined flow with velocity v, $P + \frac{1}{2}\rho v^2$ remains constant. Hence the pressure will be lowered on any surface over which the air is flowing. The flow of air is determined by the specific reed assembly geometry and the nonlinear Navier–Stokes equation, which also includes the effects of viscous damping.

After passing through the narrow reed constriction, the air emerges as a jet, which breaks down into turbulent motion on the downstream side of the reed. The turbulence leads to a rapid lateral mixing of the air, so that the flow is no longer streamlined. As a result, the pressure on the downstream end of the reed opening remains low and fails to recover to the initial pressure inside the mouth. The double reeds used for playing the oboe, bassoon and bagpipe chanter are mounted on a relatively long, narrow tube connected to the wider bore of the instrument. Turbulent flow in this region could contribute significantly to the flow characteristics, though recent measurements by *Almeida* et al. [15.147] have shown that such effects are less important than initially envisaged, as discussed later.
Single Reed

We first consider the clarinet reed, which is one of the simplest and most extensively studied of all woodwind reeds (*Benade* [15.134, Sect. 21.2], *Fletcher* and *Rossing* [15.5, Chap. 13], and recent investigations by *Dalmont* and collaborators [15.148, 149]). Figure 15.92 shows a cross section of a clarinet mouthpiece, defining the physical parameters of a highly simplified but surprisingly realistic model.

The lungs are assumed to supply a steady flow of air U, which maintains a steady pressure P_{mouth} within the mouth. Air flows towards the narrow entrance or lip of the reed through which it passes with velocity v. Because the air flowing into the reed is streamlined, the pressure drops by $\frac{1}{2}\rho v^2$ on entering the reed, while the much slower-moving air on the outer surfaces of the reed leaves the pressure on the outer reed surfaces largely unchanged. The air is then assumed to stream through the narrow gap of the reed to form an outward-going jet, which breaks up into vortices and turbulent flow on the far side of the input constriction, with no further change in overall pressure p in the relatively wide channel on the downstream side of the reed entrance.

The resulting pressure difference $\frac{1}{2}\rho v^2$ across the reed forces the reed back towards its closing position on the curved *lay* of the mouthpiece, indicated by the dashed line in Fig. 15.92. The pressure difference Δp is

Fig. 15.91 Schematic representation of vocal tract, mouth cavity, reed and instrument, illustrating the variation of local velocity and pressure for air flowing into and along the reed and attached instrument
Fig. 15.92 Cross section of air flow through a clarinet mouthpiece and reed assembly, illustrating the streamlined flow into the gap with jet formation and turbulence on exiting the reed entrance

assumed to reduce the area of reed opening from S_0 to $S_0(1 - \Delta p/p_{max})$, where p_{max} is the pressure difference required to close the reed. The net flow of air through the reed is therefore given by

$$U(\Delta p) = \alpha(\Delta p)^{1/2}(1 - \Delta p/p_{max}) \,. \qquad (15.126)$$

The player can control these characteristic by varying the position and pressure of the lips on the reed, which is referred to as the *embouchure*. A lower pressure is required to close the reed, if the reed is already partially closed by pressing the lips against the reed to constrict the entrance gap.

The flow rate U as a function of static pressure across a clarinet reed is illustrated by the measurements of *Backus* and *Nederween* [15.150] redrawn in Fig. 15.93. Apart from a small region near closure, where the exact details of the closing geometry and viscous losses may also be important, the shape of these curves and later measurements by *Dalmont* et al. [15.149, 151], which exhibit a small amount of hysteresis from viscoelastic effects on increasing and decreasing pressure, are in excellent agreement with the above model. The measurements also illustrate how the player is able to control the flow characteristics by changing the pressure of the lips on the reed.

The *reed equation* can be written in the universal form

$$\frac{U\left(\frac{\Delta p}{p_{max}}\right)}{U_{max}} = \frac{3^{3/2}}{2}\left(\frac{\Delta p}{p_{max}}\right)^{1/2}\left(1 - \frac{\Delta p}{p_{max}}\right),$$
$$\qquad (15.127)$$

with just two adjustable parameters: U_{max} the maximum flow rate and p_{max}, the static pressure required to force the reed completely shut. The maximum flow occurs when $\Delta p/p_{max} = 1/3$.

Double Reeds

Instruments like the oboe, bassoon and bagpipe chanters use double reeds, which close against each other with a relatively long and narrow constricted air channel on the downstream side before entering the instrument. The turbulent air motion in the constricted air passage would result in an additional turbulent resistance proportional to the flow velocity squared, which would add to the pressure difference across the reed. This could result in strongly hysteretic re-entrant static velocity flow characteristics as a function of the total pressure across the reed and lead pipe (see, for example, *Wijnands* and *Hirschberg* [15.152]).

A recent comparison of the flow-pressure characteristics of oboe and bassoon double reeds and a clarinet single reed, Fig. 15.94, by *Almeida* [15.147]) shows no evidence for re-entrant double-reed features. Nevertheless, the measurements are strongly hysteretic, because of changes in the properties of the reeds (elasticity and mass), as they absorb and desorb moisture from the damp air passing through them. In the measurements the static pressure was slowly increased from zero to its maximum value and then back again. Under normal

Fig. 15.93 Quasistatic flow through a clarinet single reed as a function of pressure across it illustrating the influence of the player's embouchure on the shape (after *Benade* [15.134])
Fig. 15.94 A comparison of the normalised, hysteric static pressure/flow characteristics of single (clarinet) and double (oboe and bassoon) reeds measured on first increasing and then decreasing the flow rate of moist air through the reeds (after [15.147])

playing conditions, one might expect to play on a non-hysteretic operating characteristic somewhere between the two extremes of the hysteretic static measurements. Thus, although the shape of the flow-pressure curves for the double reeds differs significantly from those of the clarinet single reed, the general form is qualitatively similar, with a region of dynamic negative resistance above the peak flow. The strongly moisture dependent properties of reeds are very familiar to the player, who has to moisten and *play-in* a reed before it is ready for performance.

There therefore appears to be no fundamental difference between the way single and double reeds operate. Indeed, the sound of an oboe is apparently scarcely changed, when played with a miniature clarinet reed mouthpiece instead of a conventional double reed (Campbell and Gilbert, private communication).

Dynamic Characteristics

Fletcher [15.153] extended the quasistatic model by assuming the reed could be described as a simple mass–spring resonator resulting in a dynamic conductance of

$$Y(\omega) = Y(0) \frac{1}{1 - (\omega/\omega_0)^2 + i\omega/\omega_0 Q} \qquad (15.128)$$

where $Y(0) = \partial U/\partial(\Delta p)|_{\omega=0}$ is the quasistatic flow conductance and the denominator describes the dynamic resonant response of the reed. The Q-value is determined by viscous and mechanical losses in the reed.

The resistive and reactive components of $Y(\omega)_{\mathrm{reed}}$ given by (15.128) are plotted in Fig. 15.95a,b for an inward-closing reed $(-, +)$, in the negative flow conductance regime above the velocity flow maximum,
Fig. 15.95a,b Real (*dark brown*) and imaginary (*light brown*) components of the reed admittance $Y(\omega)$ for **(a)** an inward-closing reed in the negative dynamic conductance regime and for **(b)** an outward-opening reed, as a function of frequency normalised to the resonant frequency of the reed for reeds having Q-values of 5

and for the outward-closing $(+, -)$ reed. As discussed qualitatively above, the negative input dynamic conductance of the inward-striking reed remains negative at all frequencies below its resonant frequency, whereas the conductance of the outward-opening reed only becomes negative above its resonant frequency.

For the oscillations of any attached air column to grow, feedback theory requires that

$$\mathrm{Im}(Y_r + Y_p) = 0$$
$$\mathrm{Re}(Y_r + Y_p) < 0\,, \qquad (15.129)$$

where Y_p and Y_r are the admittances of the pipe and reed, respectively. The negative dynamic conductance of the reed must therefore be sufficiently small to overcome the losses in the instrument. Furthermore, the reactive components of the reed conductance will perturb the frequencies of the attached air column.

Fletcher and *Rossing* [15.5, Chap. 13] give an extended discussion of the dynamics of reed generators including polar plots of admittance curves for typical outward and inward-striking reed generators as a function of blowing pressure.

For the inward-striking reeds of the clarinet, oboe and bassoon, the real part of the reed admittance is negative below the resonant frequency of the reed. For the oboe this is typically around 3 kHz, above the pitch of the reed attached to its staple (joining section) alone (⎮? EXTRAS). However, when attached to an instrument, the negative conductance will excite the lower-frequency natural resonances of the attached tube (⎮? EXTRAS). In this regime, the reactive load presented by the reed is relatively small and positive and equivalent to a capacitive or spring loading at the input end of the attached pipe. This results in a slight increase in the effective length of the pipe and a slight lowering of the frequencies of the resonating air column.

Free reeds, like the vibrating brass cantilevers used in the mouth organ, harmonium and certain organ reed pipes (Fig. 15.89c), are rather weakly damped inward-closing $(-, +)$ reeds (*Fletcher* and *Rossing* [15.5, Sect. 13.4]). The reed is initially open. High pressure on one side or suction on the other (as in the harmonium or American organ) forces the reed back into the aperture, controlling the air flow. Like the clarinet reed, above a certain applied pressure the reed will close and restrict the flow resulting in a negative conductance regime. If the reed is forced right through the aperture, it becomes an outward-opening $(+, -)$ reed with a positive conductance. Because of its low damping, the blown-closed reed tends to vibrate at a frequency rather close to its

resonant frequency. In practice, as soon as a threshold pressure is reached that is significantly below the maximum in the static characteristics, a harmonium reed starts to vibrate with a rather large sinusoidal amplitude (typically $\approx 4\,\mathrm{mm}$) resulting in highly non-sinusoidal flow of air through the aperture (*Koopman* et al. [15.154]). For such high-Q-value mechanical resonators, the vibrational frequency is strongly controlled by the resonant frequency of the reed itself, so that a separate reed is needed for each note, as in the piano accordion, harmonium, mouth organ and reed organ pipes. The reeds in a mouth organ are arranged in pairs in line with the flow of air. They are individually excited by overpressure and suction.

In contrast, the dynamic conductance of an outward-opening reed $(+, -)$ is only negative above its resonant frequency. The conductance then decreases rather rapidly with increasing frequency, so that there may only be a relatively narrow range of frequencies above resonance over which oscillations can occur. The vibrating lips provide a possible example of such a reed, with an increase in steady-state pressure always increasing the static flow through them. Above their resonant frequency, the dynamic conductance becomes negative and could excite oscillations in an attached pipe. In such a regime, the reactive component of the reed admittance is negative. This corresponds to an inductive or inertial load, which will shorten the effective length of the air column and increase its resonant frequencies. The influence of the reed on the resonant frequencies of an attached instrument therefore provides a valuable clue to the way in which a valve is operating, as we will discuss later in relation to the vibrations of the lips in a brass-instrument mouthpiece.

Small–Amplitude Oscillations

We now consider the stability of the oscillations excited by the negative dynamic conductance of the reed. In particular, it is interesting to consider whether the oscillations, once initiated, are stabilised or grow quickly in amplitude into a highly nonlinear regime. Surprisingly, this depends on the bore shape of the attached air column, as discussed by *Dalmont* et al. [15.155]. Several authors have investigated such problems, including *Backus* [15.156] using simple theoretical models and measurements, *Fletcher* [15.157] using analytic models, *Schumacher* [15.158,159] in the time rather than the frequency domain, and *Gilbert* et al. [15.155, 160] using a harmonic balance approach, which we will briefly outline in the following section. Recent overviews of the nonlinear dynamics of both wind and brass instruments have been published by *Campbell* [15.161] and by *Dalmont* et al. [15.155].

We first consider the excitation of small-amplitude oscillations based on the reed equation, which is replotted in Fig. 15.96 as a universal curve together with the negative dynamic admittance or conductance, $-\partial U/\partial p$ above the flow-rate maximum.

The onset of self-oscillations occurs when the sum of the real and the imaginary parts of the admittance of the reed and attached instrument are both zero (15.129). If losses in the reed and the attached instrument were negligible, resonances of the air column would be excited as soon as the mouthpiece pressure exceeded $\frac{1}{3}p_{\max}$. However, when losses are included, the negative conductance of the reed has to be sufficiently large to overcome the losses in the instrument. The onset then occurs at a higher pressure, as illustrated schematically in Fig. 15.96.

The onset of oscillations depends not only on the mouthpiece pressure but also on the properties of the reed, such as the initial air gap and its flexibility, which will depend on its thickness and elastic properties. The elastic properties also change on the take up of moisture during playing. It is not surprising that wind players take great care in selecting their reeds. Furthermore, notes are generally tongued. This involves pressing the
Fig. 15.96 Plot of normalised flow rate and differential negative conductance of an inward-striking reed valve as a function of pressure across the reed normalised to the pressure required for closure. The intersection of the negative conductance curve with the real part of the input admittance $Y_{\mathrm{inst}}(\omega)$ of the instrument determines the pressure in the mouthpiece for the onset of oscillations, illustrated schematically for $Y_{\mathrm{inst}}(\omega) \approx 0.78 Y_{\max}$

tongue against the lip of the reed to stop air passing through it, so that the pressure builds up to a level well above that required to just excite the note. When the tongue is removed, the note sounds almost immediately giving a much more precise definition to the start of a note.

The transition to the oscillatory state can be considered using the method of small variations and harmonic balance (*Gilbert* et al. [15.160]). For a given mouth pressure defining the overall flow rate, oscillations of the flow rate u can be written as a Taylor expansion of the accompanying small pressure fluctuations p at the output of the reed, such that

$$u = Ap + Bp^2 + Cp^3 + \ldots . \tag{15.130}$$

From the reed equation plotted in Fig. 15.96, the coefficient A is positive for mouthpiece pressures above $p_{max}/3$, while B and C are positive and negative respectively. We look for a periodic solution with Fourier components that are integer multiples of the fundamental frequency ω, so that

$$p(t) = \sum p_n e^{in\omega t} , \tag{15.131}$$

with a corresponding oscillatory flow $u(t)$ superimposed on the static flow U,

$$u(t) = \sum u_n e^{in\omega t} . \tag{15.132}$$

At the input to the instrument, the oscillatory flow can be expressed in terms of the Fourier components of the input pressure and admittance, so that

$$u(t) = \sum p_n Y(n\omega) e^{in\omega t} . \tag{15.133}$$

Using the method of harmonic balance, we equate the coefficients of the Fourier components in (15.130) with those in (15.133) having substituted (15.131) for the pressure. The first three Fourier components are then given by

$$p_1 = \pm \left(\frac{Y_1 - A}{2B^2/(Y_2 - A) + 3C} \right) ,$$
$$p_2 = \left(\frac{B}{Y_2 - A} \right) p_1^2 ,$$
$$p_3 = \left(\frac{C}{Y_3 - A} \right)^{1/2} p_1^3 . \tag{15.134}$$

For a cylindrical-bore instrument like the clarinet at low frequencies, only the odd-n partials will be strongly excited, so that Y_2 is very large. The amplitude of the fundamental component is then given by $\pm[(Y_1 - A)/C]^{1/2}$, with a vanishingly small second harmonic p_2. The amplitude p_1 of small oscillations is then

stabilised by the cubic coefficient C. Stable, small-amplitude oscillations can therefore be excited as soon as the negative conductance of the reed exceeds the combined admittance of the instrument and any additional losses in the reed itself.

Because the transition is continuous, p_1 rises smoothly from zero, taking either positive or negative values (simply solutions with opposite phases). The transition is therefore referred to as a *direct bifurcation*. The player can vary the pressure in the mouthpiece and the pressure of the lips on the reed to vary the coefficients A and C and hence can control the amplitude of the excited sound continuously from a very quiet to a loud sound, as often exploited by the skilled clarinet player.

In contrast, for a conical-bore instrument, the amplitude of the fundamental,

$$p_1 = \pm \left(\frac{(Y_1 - A)(Y_2 - A)}{2B^2 + 3C(Y_2 - A)} \right)^{1/2} , \tag{15.135}$$

involves the admittance of both the fundamental and second partial. On smoothly increasing A by increasing the pressure on the reed, *Grand* et al. [15.162] showed that there can again be a direct smooth bifurcation to small-amplitude oscillations, if $2B^2 > -3C(Y_2 - Y_1)$. However, if this condition is not met, there will be an indirect transition, with a sudden jump to a finite-amplitude oscillating state. This gives rise to the hysteresis in the amplitude as the mouth pressure is first increased and then decreased. This means that the player may have to exert a larger pressure to sound the note initially, but can then relax the pressure to produce a rather quieter sound. It may also explain why it is more difficult to initiate a very quiet note on the saxophone with a conical bore than it is on the clarinet with a cylindrical bore.

For a direct bifurcation transition, the small nonlinearities in the dynamic conductance will result in a spectrum of partials with amplitudes varying as p_1^n, where p_1 is the amplitude of the fundamental component excited. The spectral content or *timbre* of wind and brass instruments, as discussed later, therefore changes with increasing amplitude. This is illustrated by measurements of the amplitude dependence of the partials of a trumpet, clarinet and oboe by *Benade* [15.134, Fig. 21.6c], which are reproduced for the trumpet in Fig. 15.104. For the largely cylindrical-bore trumpet and clarinet, nonlinearity results in partials varying as p_1^n over quite a large range of amplitudes. However, for the oboe, with its conical bore, the relative increase in strength of the partials is rather more complicated

(*Benade* [15.134, Sect. 21.3]). Eventually, the small-amplitude approximation will always break down, with a transition to a strongly nonlinear regime. Benade associates this transition with a change in timbre and responsiveness of the instrument for the player.

Large–Amplitude Oscillations

For a *lossless* cylindrical-bore instrument with only odd integer partials, the large-amplitude solutions are particularly simple. The flow of air from the lungs and pressure in the mouth is assumed to remain constant resulting in an average flow rate through the instrument. The pressure at the exit of the reed then switches periodically from a high-pressure to a low-pressure state, with equal amplitudes above and below the mean mouth pressure, spending equal times in each. The net acoustic energy fed into the resonating air column per cycle is therefore zero, $U \int p(t)\,dt = 0$, as required for a lossless system.

Such a solution can easily be understood in terms of the excess-pressure wave propagating to the open end of the instrument, where it is reflected with change of sign. On return to the reed it reverses the pressure difference across the reed, which switches to the reduced pressure state. The subsequent reflection of the reduced pressure wave then switches the reed back to its original high-pressure state and the process repeats indefinitely, with a periodic time of $4L/c_0$, as expected.

The dependence of the square-wave pressure fluctuations on the applied pressure can be obtained by the simple graphical construction illustrated in Fig. 15.97. The locus of the static pressure required to excite square-wave pressure fluctuations above and below the mouth pressure is shown by the solid line drawn from $p_{\mathrm{mouth}} = 1/3$ to $1/2 p_{\mathrm{max}}$, which bisects the high and low pressures for a given flow rate. If losses are taken into account, the horizontal lines are replaced by load lines with a downward slope given by the real part of the instrument's input admittance (*Fletcher* and *Rossing* [15.5], Fig. 15.9). At large amplitudes, the solutions can then involve periods during which the reed is completely closed. The transition from small-amplitude to large-amplitude solutions is clearly of musical importance, as it changes the sound of an instrument, and remains an active area of research [15.155].

Analogy with Bowed String

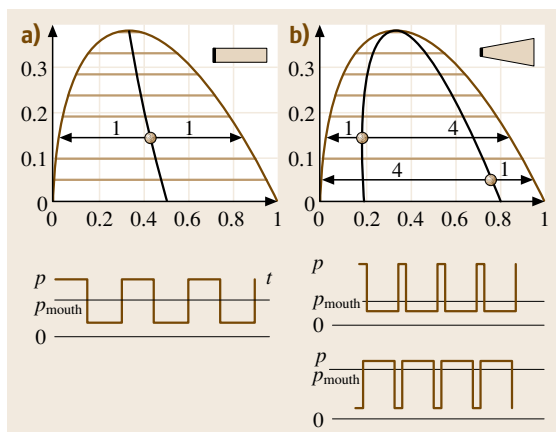
In recent years, an interesting analogy has been noted between the large-amplitude pressure fluctuations of a vibrating air column in a cylindrical or truncated conical tube and simple Helmholtz waves excited on


Fig. 15.97a,b Large-amplitude Helmholtz pressure fluctuation of (**a**) a cylinder and (**b**) a truncated cone with length to apex of 1/4 of its length, illustrating the dependence of fluctuation amplitudes as a function of mouthpiece pressure. For the cylinder, the mouthpiece pressure is single valued for a given flow rate, but for the truncated cone there are two possible solutions referred to as the standard and inverted Helmholtz solutions

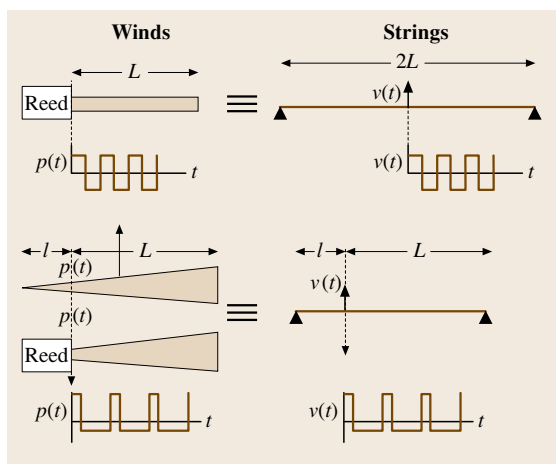
a bowed string (*Dalmont* and *Kergomard* [15.163]). For example, the square-wave pressure fluctuations at the output of the reed attached to a cylindrical tube are analogous to the velocity of the bowed Helmholtz transverse waves of a string bowed at its centre, illustrated schematically in Fig. 15.98. Helmholtz waves


Fig. 15.98 Analogy between large-amplitude pressure waves in the bores of wind instruments and the transverse velocity of Helmholtz waves on a bowed stretched string, where the reed position is equivalent to the bowing position

could equally well be excited on a bowed string by a transducer with a square-wave velocity output placed halfway along the length of the string, in just the same way that the reed with a square-wave pressure output excites Helmholtz sound pressure waves into a cylinder, which acts like half the string length.

The analogy is particularly useful in discussing the large-amplitude pressure fluctuations in conical-bore instruments such as the oboe or saxophone. As described earlier, the conical tube has the same set of resonances as a cylindrical tube that is open at both ends. Therefore, in addition to having the same set of standing-wave sinusoidal solutions for the transverse oscillations of a stretched string, a conical tube can also support Helmholtz wave solutions. For the bowed string, the closer one gets to either end of the string the larger becomes the mark-to-space ratio between the regions of high to low transverse velocity. The same is also true for the switched fluctuations in pressure in a lossless conical tube, shown schematically in Fig. 15.97. Hence, if one truncates a conical tube with a vibrating reed system, the resonant modes of the remaining air column will be unchanged, provided the vibrating reed produces the same pressure fluctuations that would otherwise have been produced by the reflected Helmholtz waves returning from the removed apex end of the cone. Hence a conical tube, truncated by a vibrating reed at a distance l from the apex, can support Helmholtz wave solutions in the remaining length L. To produce such a wave the reed has to generate a rectangular pressure wave with a mark-to-space ratio and pressure fluctuations about the mean in the ratio $L : l$, as illustrated in Fig. 15.98, for a truncated cone with $L/l = 4$.

The period of the Helmholtz wave solutions of a conical bore instrument modelled as a truncated cone will therefore be $2(L+l)/c_0$, with a spectrum including all the harmonics $f_n = nc_0/2(L+l)$, other than those with integer values of $n = (L+l)$. To determine the amplitude of the rectangular pressure wave as a function of mouthpiece pressure, a graphical construction can be used similar to that used for the cylindrical tube, except that the pressures have now to be in the ratio L/l, as indicated in Fig. 15.97b. For the lossless large-amplitude modes of a truncated cone, there are two possible solutions involving high and low mouth pressures, which are known as the standard and inverted Helmholtz solutions, respectively.

Any complete model of a reed driven instrument must include losses and departures from harmonicity of an instrument's partials. This leads to a rounding of the rectangular edges of the Helmholtz waveforms and
Fig. 15.99 Measured pressure waveform at input to a saxophone compared with the Helmholtz waveform expected for a truncated cone (after *Dalmont* et al. [15.163])

additional structure, in much the same way that bowed string waveforms are perturbed by frictional forces and nonideal reflections at the end-supports (Fig. 15.34). Figure 15.99 shows a typical pressure waveform input for the conical-bore saxophone, which is compared with the Helmholtz waveform predicted for an ideal lossless system (*Dalmont* et al. [15.163]).

A completely realistic model for the excitation of sound in wind instruments must also include coupling to the vocal tracts (*Backus* [15.164] and *Scavone* [15.165]), since the assumption of a constant flow rate and constant mouth pressure is clearly oversimplistic.

Register Key

This analysis implicitly assumes that the reed excites the fundamental mode of the attached instrument. In practice, the reed will generally excite the partial with the lowest admittance corresponding to the highest peak in impedance measurements. For most instruments this is usually the fundamental resonance. However, the amplitude of the fundamental can be reduced relative to the higher resonances by opening a small hole, the register hole, positioned between the reed and first hole used in normal fingering of the instrument. Because of the difference in wavelengths and position of nodes, opening the register hole preferentially reduces the Q-value and shifts the frequency and amplitude of the fundamental relative to the higher partials. This allows the player to excite the upper register of notes based on the second mode, which in the case of the conical-bore saxophone, oboe and bassoon is an octave above the fundamental but is an octave and a perfect fifth above the fundamental for the cylindrical-bore clarinet. The lower and upper registers of the clarinet are sometimes referred to as the chalumeau and chanter registers, after the earlier instruments from which the clarinet was derived.
Fig. 15.100 Resonance curves for the note E3 on a clarinet, showing the shift of the lowest partial on opening the register hole (after *Backus* [15.133])

Figure 15.100 illustrates the lowering in amplitude and shift in resonant frequency of the fundamental mode on opening the register hole for the note E3 on a clarinet, which leaves the upper partials relatively unchanged (*Backus* [15.133]). The measurements also show the significant departures from the 1, 3, 5, 7 harmonicity of the resonant modes of the instrument, which act as a warning not to take ideal models for the harmonicity of modes in real wind instruments too literally. Fletcher has developed a mode-locking model to account for the excitation of periodic waveforms on instruments with inharmonic partials [15.166].

15.3.4 Brass–Mouthpiece Excitation

The excitation of sound by the vibrating lips in the mouthpiece of a brass instrument cannot be described by any of the above simple models alone, which consider the reed as a simple mass–spring resonator. As we will show, the vibrations of the lips are three-dimensional and much more complicated. As a result, in some regimes the lips behave rather like outward-swinging-door valves, as first proposed by Helmholtz, and Bernoulli pressure operated sliding-door reeds in others. In addition the air flow is also affected by three-dimensional wave-like vibrations on the surface of the lips.

When playing brass instruments, the lips are firmly pressed against the rim of the mouthpiece with the lips pouted inwards. Pitched notes are produced by blowing air through the tightly clenched lips to produce a buzzing sound. The excitation mechanism can easily be demonstrated by buzzing the lips alone, though it is difficult to produce a very wide range of pitched sounds However, if the lips are buzzed when pressed

against the rim of a mouthpiece, the input rim provides an additional constraint on the motion of the lips, which makes it much easier to produce pitched notes over a wide range of frequencies (⏸️ **EXTRAS**). The audio demonstrates the *popping* sounds of trumpet and horn mouthpieces followed by the sound of the player buzzing the mouthpiece alone up to a pitch close to the popping frequency and back again. Attaching the mouthpiece to an instrument locks the oscillations to the various possible resonances of the instrument (⏸️ **EXTRAS**).

Figure 15.101 shows a series of time-sequence plots of spectra of the sound produced by a player *buzzing* into a trumpet mouthpiece (*Ayers* [15.167]), which acts rather like a simple Helmholtz resonator. In the lower sequence, the player excites well-defined pitched notes from low frequencies up to slightly above the mouthpiece *popping frequency* (see Sect. 15.3.3). The middle set of traces shows the spectrum as the player starts
Fig. 15.101 Time sequence (*from bottom to top*) of spectra of the sound produced by a player *buzzing* into a trumpet mouthpiece, first for an upward slide in frequency, then for a downward slide and finally for a steady low note at high intensity showing the excitation of a note with many Fourier components. The *dashed line* is the spectrum of the *popping* note excited by slapping the open end of the mouthpiece against the palm of the hand (after *Ayers* [15.167])

at a high frequency and lowers the pitch. The upper traces shows the spectrum of a loudly sounded, low-frequency, note, illustrating the rich spectrum of harmonics produced by the strongly nonlinear sound-generation processes involved (see, for example, *Elliot* and *Bowsher* [15.168]).

These measurements on the mouthpiece alone strongly suggest that the lips can generate periodic fluctuations at frequencies up to, but not significantly beyond, the resonant frequency of any coupled acoustic resonator. This was confirmed in an investigation of lip-reed excitation using a simple single-resonant-frequency Helmholtz resonator by *Chen* and *Weinreich* [15.170], who used a microphone and loudspeaker in a feedback loop to vary the Q-value of the Helmholtz resonator played using a normal mouthpiece. They concluded that a player could adjust the way they vibrated their lips in the mouthpiece to produce notes that were slightly higher or lower than the Helmholtz frequency, though the most natural playing parameters generated frequencies in the range $20-350$ Hz below the resonator frequency.

Attached Mouthpiece

Ayers [15.167] also compared the frequencies produced in the mouthpiece before and immediately after attachment of the instrument. In these measurements the player first excited a pitched note in the mouthpiece with the instrument effectively decoupled by opening a large hole in its bore close to the mouthpiece. The hole was then closed and the immediate change in frequency measured before the player had time to make any adjustments to the embouchure. The results of such measurements are shown in Fig. 15.102, where the diagonal line represents the pitched notes before the instrument was connected and the discontinuous solid line through the triangular points are the modified frequencies for the same embouchure with the instrument connected.

At the higher frequencies, the jumps between successive branches are from just above the resonant frequency of one partial to just below the resonant frequency of the next, with a monotonic increase in frequency on tightening the embouchure in between. However, for the first two branches, the instrument resonances initially have a relatively small effect on the frequencies excited by the mouthpiece alone until such frequencies approach a particular partial frequency. The frequency then approaches the resonant frequency of the instrument before jumping to a frequency well below the next partial and the sequence repeats. The dif-
Fig. 15.102 Frequencies produced by a trumpet mouthpiece without (*diagonal line*) and with (*broken line*) the instrument strongly coupled using an unchanged embouchure under the same playing conditions. The *solid horizontal lines* are the resonant frequencies of the assembled trumpet. The *squares* and *circles* are predictions for the Helmholtz outwardly opening-door and sliding-door models computed by *Adachi* and *Sato* [15.169] for a trumpet with slightly lower-frequency resonant modes indicated by the *dashed horizontal lines* (after *Ayers* [15.167])

ference in behaviour of the lower and higher branches suggests that more than one type of lip-reed action is involved.

Comparison with computational models by *Adachi* and *Sato* [15.169] appear to rule out the outward-swinging-door model first proposed by Helmholtz, indicated by the squares in Fig. 15.101, as the predicted frequencies are always well above those of the instrument's partials. The computed predictions for the Bernoulli sliding door model, indicated by the circles, are in better agreement with measurements, but with predicted frequencies rather lower than those observed and never rising above the resonant frequencies of the instrument, in contrast to the observed behaviour for the higher modes excited.

Any model for the lip-reed sound generator has to explain all such measurements. Such measurements also highlight the way that a brass player can adjust the embouchure and pressure acting on the lips in the mouthpiece to change the frequency of the excited mode. On tightening the embouchure and pressure the player can progressively excite successive modes and

can *lip* the pitch of the note up and down by surprisingly large amounts, used with great expressive effect by jazz trumpeters.

Vibrating Lips

In practice, the production of sound by the vibrating lips inside a mouthpiece is a highly complex three-dimensional problem closely analogous to the production of sound by the vocal folds – see, for example, *Titze* [15.171]. A complete model would involve solving the coupled solutions of the Navier–Stokes equations describing the flow of air from the mouth, through the lips and into the mouthpiece, and the three-dimensional motions of the soft tissues of the lips induced by the Bernoulli pressures acting on their surfaces.

Stroboscopic and ultra-fast photography of the brass players lips while playing reveal highly complex three-dimensional motions (*Coppley* and *Strong* [15.172], *Yoshikawa* and *Muto* [15.173]) suggest that the upper lip is primarily involved in the generation of sound. Figure 15.103 and the video clip |👁 **EXTRAS** | provided by Murray Campbell show high-speed photography clips of such motion. The lips inside the mouthpiece open and shut rather like the gasping opening and shutting of the mouth of a goldfish, but speeded up several hundred times. Points on the surface of the upper lip exhibit cyclic orbital motions involving the in-quadrature motions of the upper lip parallel and perpendicular to the flow. To model such motion clearly requires at least two independent mass–spring systems to account for the induced motions of the lips along and perpendicular to the flow (*Adachi* and *Sato* [15.169]). In addition, there is a pulsating wave-like motion along the surface of the lips in the direction of air flow, with the rear portion of lips moving in anti-phase with the front. *Yoshikawa* and *Muto* [15.173] identify such motion as strongly damped Rayleigh surface waves travelling through the mucous tissue of the upper lip.

The simplest possible model to describe such motion therefore requires at least three interacting mass–spring elements; one to describe the lip motion along the direction of flow, and two to describe the motions of the front and back surfaces of the lips. But even then, the model will still only be an approximation to the three-dimensional bulk tissue motions involved. Not surprisingly, research into the lip-reed sound-excitation mechanism remains a problem of considerable interest.

Artificial Lips

To achieve a better understanding of lip dynamics and its effect on the sound produced by brass instrument, several groups have developed artificial lips to excite brass instrument (e.g. *Gilbert* et al. [15.174] and *Cullen* et al. [15.175]). These can be used to investigate instruments under well-controlled and reproducible experimental conditions. Typically, the lips are simulated by two slightly separated thin-walled (0.3 mm thickness) latex tubes filled with water under a controlled pressure. The tubes are rigidly supported from behind so that the internal pressure forces the lips together. The tubes are placed across an opening in an otherwise hermetically sealed unit that represents the mouth and throat cavities. Air is fed into the mouth cavity at a constant flow rate. A fixed mouthpiece is then pushed against the artificial lips with a measured force. By varying this force, the applied pressure and the pressure within the artificial lips, the experimenter can simulate the various ways in which a player can control the dynamics of the lips (the *embouchure*) to produce different sounding notes. Despite the considerable simplification in comparison with the dynamics of real lips, the sound of brass instruments played by artificial lips is extremely close to that produced by a real player. Such systems enable acoustical studies to be made on brass instruments with a much greater degree of flexibility, reproducibility and stability than can be achieved by a player. Using a fixed mouthpiece, the playing characteristics of different attached instruments can easily be compared.

Fig. 15.103 High-speed photograph clips showing one cycle of lip vibration in a trombone mouthpiece

Nonlinear Sound Excitation

When played very quietly, brass instruments can produce sounds that are quasi-sinusoidal with relatively weak higher harmonics. However, as previously noted for vibrating reeds, any nonlinearity will lead to the generation of harmonics of the fundamental frequency

ω at frequencies 2ω, 3ω, etc., with initially amplitudes increasing as $|p_0(\omega)|^n$, where $p_0(\omega)$ is the amplitude of the fundamental. However, in the strongly nonlinear region at high amplitudes, all partials become important and increase in much the same way with increasing driving force (*Fletcher* [15.176] and *Fletcher* and *Rossing* [15.5, Sects. 14.6 and 14.7]). Such effects are illustrated in Fig. 15.104 for measurements on a B-flat trumpet by *Benade* and *Worman* [15.134, Sect. 21.3]. The spectral content and resulting brilliance of the sound or timbre of a trumpet, or any other brass instrument, therefore depends on the intensity with which the instrument is played. Benade noted a change in the sound and feel of an instrument by the player in the transition region between the power-law dependence of the Fourier component and the high-amplitude regime, where the harmonic ratios remain almost constant. Similar characteristics were observed for the clarinet though rather different characteristics for the oboe.

Examples of the strongly nonsinusoidal periodic fluctuations of the pressure and flow velocity within the mouthpiece for two loudly played notes on a trombone are shown in Fig. 15.105 (*Elliot* and *Bowsher* [15.168]).

Fletcher and *Rossing* [15.5, Sect. 14.7] discuss such waveforms in terms of the lips operating slightly above the resonant frequency of their outward-swinging-door resonant frequencies.

The nonlinearity of the lip-reed excitation mechanism enables the player to vibrate the lips at the frequency of the missing fundamental of the quasi-harmonic series of modes of brass instruments, illustrated in Fig. 15.38. This is referred to as the *pedal note* and is an octave below the lowest mode normally excited on the instrument. The lips vibrate at the pedal-note frequency but only excite the quasi-harmonic $n = 2, 3, 4, \ldots$ modes.

The pressure fluctuations in Fig. 15.104 of ≈ 3 kPa correspond to a sound intensity of nearly 160 dB. As the static pressure in the mouthpiece is only a few percent above atmospheric pressure (10^5 Pa), such pressure excursions are a significant fraction of the excess static pressure. Even larger-amplitude pressure fluctuations can be excited on the trumpet and trombone when played really loudly, to produce a brassy sound. *Long* [15.177] has recorded pressure levels in a trumpet mouthpiece as high as 175 dB, corresponding to pressure fluctuations of ≈ 20 kPa.

At such high amplitudes, one can no longer neglect the change in density of a gas when considering its acceleration under the influence of the pressure gradi-

Fig. 15.104 Intensity of the first four partials of the note C4 on a trumpet as a function of the intensity of the first partial, measured from the minimum to the maximum playing intensity (after *Benade* [15.134, Fig. 21.8]). On this logarithmic scale, the dashed lines through the measurements for the second, third and fourth Fourier components have slopes 2, 3 and 4, respectively
Fig. 15.105 Non-sinusoidal pressure fluctuations within the mouthpiece for two notes played at large amplitudes on the trombone (after *Elliot* and *Bowsher* [15.168])

ent. To a first approximation, the wave equation then becomes

$$\frac{\partial^2 \xi}{\partial x^2} = \left(1 + \frac{\partial \xi}{\partial x}\right) \frac{1}{c_0^2} \frac{\partial^2 \xi}{\partial t^2} \ . \tag{15.136}$$

The speed of sound will now depend on both frequency and wave shape, with the velocity varying as

$$c' = c_0 \left\langle \left(1 + \frac{\partial \xi}{\partial x}\right)^{-1/2}\right\rangle_{x,t} \approx c_0 \left[1 + \alpha \, (k\xi)^2 \right], \tag{15.137}$$

where the averaging is taken over both time and wavelength giving a value for $\alpha \approx 1/8$. In practice, for waves propagating down a tube, other terms involving momentum transport, viscosity and heat transfer also have to be included in any exact solution. However, the essential physics remains unchanged. The net effect of the nonlinearity is to progressively increase the slope of the leading edge of any wave propagating along the tube. A propagating sine wave is then transformed into a sawtooth waveform, or shockwave, with an infinitely steep leading edge, at sufficiently large distances along the tube.

Such waves have indeed been observed in trumpet and trombone bores, which are long and relatively narrow. The effect is illustrated in Fig. 15.106 by the measurements of *Hirschberg* et al. [15.178], for waves propagating along a trombone tube. The sound intensity of ≈ 175 dB is considerably higher than the intensities illustrated in Fig. 15.99. As predicted, the sharpness of the leading edge of the waveform progressively increased on propagating along the bore. The discontinuity in waveform of the fully developed shockwave dramatically increases the intensities of the higher harmonics of a continuously played note and gives the trumpet and trombone (and trompette organ pipes) their characteristic brassy sound at very high intensities (? **EXTRAS**). The high-frequency components of all such sounds will make them highly directional. *Campbell* [15.161] reviews nonlinear effects in woodwind and brass instruments, with many references to recent research.

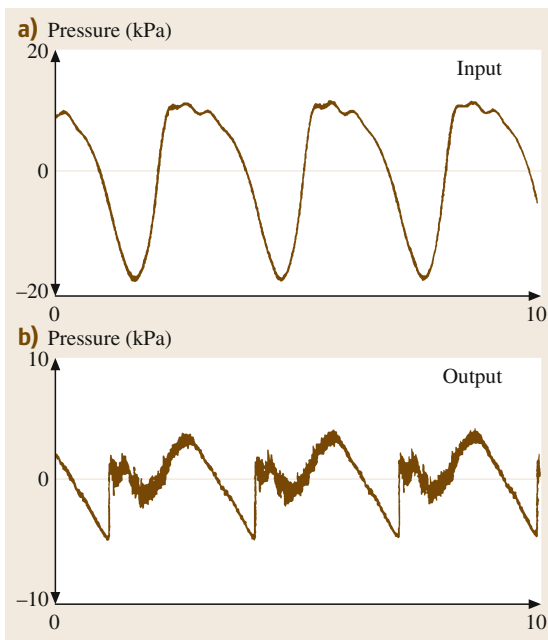
To achieve such brassy sounds, the instrument must have a sufficiently long length of relatively narrow pipe, like the trumpet and trombone, in which the pressure fluctuations remain high and have time to build up into a shock wave. Shockwaves are far more difficult to set up in instruments like the horn and cornet, with flaring conical bores, because the pressure drops rather rapidly with increasing diameter along the bore.


Fig. 15.106a,b Internal acoustic pressure in a trombone played at a dynamic level fortissimo (ff). **(a)** Pressure at the input to the air column in the mouthpiece; **(b)** pressure at the output of the slide section, showing the characteristic profile of a shock wave (after *Hirschberg* et al. [15.178])

Time–Domain Analysis

When nonlinearity is important or when the initial transient response is of interest, it is more appropriate to consider the dynamics in the time- rather than frequency-domain, just as it was for analysing the transient dynamics of the bowed string. Time-domain analysis in wind and brass instruments was pioneered by *Schumacher* [15.159], *McIntyre* et al. [15.179] and *Ayers* [15.180], and is discussed in *Fletcher* and *Rossing* [15.5, Sect. 8.14]. Time-delayed reflectometry measurements are made by producing short pressure pulses inside the mouthpiece generated by a spark or by a sudden piezoelectric displacement of the mouthpiece end-wall. The pressure in the mouthpiece is then recorded as a function of time after the event.

In the linear response regime, measurement in the time domain gives exactly the same information about an instrument as measurements in the frequency domain, assuming both the magnitude and phase of the frequency response is recorded. This follows because the frequency response $Z(\omega)$ measured in the mouthpiece is simply the Fourier transform of the transient

pressure response $p(t)$ for a δ- or impulse-function flow (Av) induced by the spark or wall motion. Knowing $p(t)$ or $Z(\omega)$ one can obtain the other by applying the appropriate Fourier transform

$$Z(\omega) = \int_0^\infty p(t)\,e^{-i\omega t}\,dt \quad \text{or}$$

$$p(t) = \frac{1}{2\pi} \int_{-\infty}^\infty Z(\omega)\,e^{i\omega t}\,d\omega . \quad (15.138)$$

Measurements of the impulse response are particularly useful in identifying large discontinuities in the acoustic impedance along the bore of instruments produced by tone holes, valves and bends, which can significantly perturb particular partials. The position of any such discontinuity can be determined by the time it takes for the reflected impulse to return to the mouthpiece.

Time-domain analysis is essential, if one wishes to investigate starting transients, where reflections from the end of the instrument are required to stabilise the pitch of a note. This problem is particularly pronounced for horn players pitching, for example, notes as high as the 12th resonant mode of the instrument. The player must buzz the lips a dozen or so cycles into the mouthpiece before the first reflection from the end of the instrument returns to stabilise the pitch. If the player gets the initial buzzing frequency slightly wrong, the instrument may lock on to the 11th or 13th harmonic rather than the intended 12th, leading to the familiar *cracked note* of the beginner and sometimes even professional horn players. Furthermore, *false* reflections from discontinuities along the length of the tube, may well confuse the initial feedback, making it more difficult to pitch particular notes. This leads to small pitch-dependent changes in the playing characteristics of instruments made to different designs adopted by different manufacturers.

15.3.5 Air–Jet Excitation

Many ancient and modern musical instruments are excited by blowing a jet of air across a hole in a hollow tube or some other acoustic resonator. Familiar examples include the flute, pan pipes, the ocarina and simple whistle in addition to many organ pipes. Sound excitation in flutes and organ pipes was first considered by *Helmholtz* [15.128] in terms of an interaction between the air jet produced by the lips or a flue channel in the mouthpiece of an instrument and the coupled air column resonator.

In practice, the dynamics of sound production is a very complex aerodynamic flow problem requiring the solution of the Navier–Stokes equations governing fluid flow in often complex geometries. Various simplified solutions have been considered by many authors since the time of *Helmholtz* and *Rayleigh* [15.3]. *Fletcher* and *Rossing* [15.5, Sect. 16.1] provide references to both historic and more-recent research. *Fabre* and *Hirschberg* [15.181] have also written a recent review of simple models for what are sometimes referred to as flue instruments.

Rayleigh showed that the interface separating two fluids moving with different velocities was intrinsically unstable, resulting in an oscillating sinuous lateral disturbance of the interface that grows exponentially with time Fig. 15.107. This arises because, in the frame of reference in which the two fluids move with the same speed in opposite directions, any disturbance of the interface towards one of the fluids will increase the local surface velocity on that side. This will result in a decrease in Bernoulli pressure on that side of the interface and increase it on the other, creating a net force in the same sense as the disturbance, which will therefore grow exponentially with time. For a layer of air moving at velocity V without friction over a stationary layer, a sinusoidally perturbed deflection of the jet in the laboratory frame of reference at rest increases exponentially with distance as it travel along the interface with velocity $V/2$.

Similar arguments were used by Rayleigh to describe the instability of an air jet of finite width b and velocity V produced by blowing through an arrow constriction between the pouted lips when playing the flute, or by blowing air through an air channel towards the sharp lip of the recorder or an organ pipe. *Fletcher* [15.182] showed that the lateral displacement $h(x)$ of the jet induced by an acoustic velocity field $v\,e^{i\omega t}$ between the jet orifice and the lip varies with position
Fig. 15.107 Propagating sinuous instability of an air jet emerging from a flow channel with two possible positions of the angled labium or lip to excite resonances of an attached air column for a given jet velocity V

and time as

$$h(x) = -j\left(\frac{v}{\omega}\right)\left[1 - \cosh\mu x \exp(-i\omega x/u)\right]e^{i\omega t},$$

(15.139)

illustrated schematically in Fig. 15.107. The first term simply corresponds to the jet moving with the impressed acoustic field, while the second describes the induced travelling-wave instability moving along the jet with velocity $u \approx V/2$, which dominates the jet displacement at the lip of the instrument. For long-wavelength instabilities on a narrow jet, such that the characteristic wavevector $k \ll 1/b$, Rayleigh showed that the phase velocity $u = \omega/k \approx kbV/2 = (\omega bV/2)^{1/2}$, while the exponential growth factor $\mu = (k/b)^{1/2}$.

In practice, the velocity profile of the jet is never exactly rectangular but in general will be bell-shaped. This results in a slightly different frequency, width b and velocity dependence of the phase velocity, with

$$u = 0.55(\omega b)^{1/3}V^{2/3}$$

(15.140)

and corresponding changes in the exponential growth factor (*Savic* [15.184]). Typical propagation velocities of disturbances on the jet of flute and organ pipes measured by *Coltman* [15.183] range from 6.7 m/s to 3.7 m/s with velocity ratios u/V from 0.35 to 0.5 for blowing pressures from 1 to 0.15 inches of water.

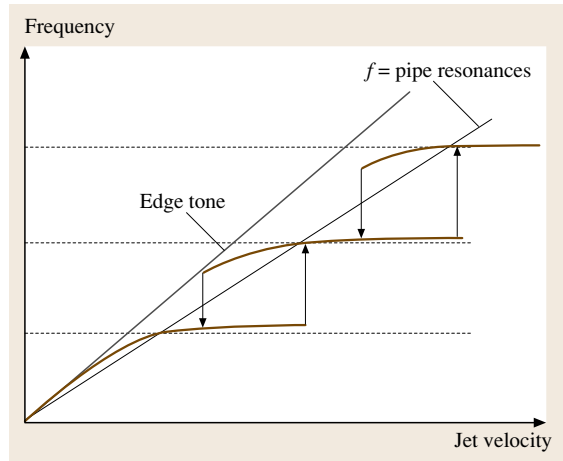
Resonances of the attached resonator can be excited when the air-jet instability is in phase with oscillations within the resonator, as shown for the two positions indicated in Fig. 15.107. This corresponds to an odd number of half-wavelengths of the propagating instability, so that $\omega l/u = n\pi$, which is equivalent to $f \approx nV/4$, where n is an odd integer and we have assumed $u \approx V/2$. For a given length between jet orifice and lip, different frequencies can be excited by varying the jet velocity $V = \sqrt{2P_{\text{mouth}}/\rho}$, where P_{mouth} is the pressure in the mouth creating the jet. When coupled to an acoustic resonator with a number of possible resonances, such as an organ pipe or the pipe of a flute or recorder, the interaction between the jet and oscillating resonator causes the frequency to lock on to a particular resonance, with hysteretic jumps between the resonance excited as the blowing pressure is increased and decreased, as illustrated schematically in Fig. 15.108 (*Coltman* [15.183]). This explains why the pitch of an instrument like the recorder or flute doubles when it is blown more strongly. The line marked *edge tones* indicates the frequency of the excited jet mode instability for the same orifice–lip geometry without an attached pipe and the line marked $f = pipe\ resonance$


Fig. 15.108 Schematic representation of the frequency of a jet-edge oscillator before and after coupling to a multi-resonant acoustic resonator. The *line* marked f = pipe resonator indicates the pressures when the frequencies are the same as the modes of the uncoupled acoustic resonator (after *Coltman* [15.183])

indicates when the frequency of the coupled jet coincides with the free vibrations of the attached air column. In practice the instrument is played in close vicinity to the pipe resonances.

The above model is strictly only applicable to small perturbations in jet shape ($\ll b$) and to a nonviscous medium. In practice, measurements of jet displacement by Schlieren photography, hot-wire anemometry (*Nolle* [15.185]), smoke trails *Cremer* and *Ising* [15.186] and *Coltman* [15.187] and particle image velocimetry (PIV) (*Raffel* et al. [15.188]) show that within an acoustic cycle the jet moves to either side of the lip of the instrument with large displacement amplitudes comparable with the physical dimensions of the distance between the orifice and lip. In addition, viscous forces lead to a change in profile of the jet as it moves through the liquid from rectangular to bell-shaped (*Ségoufin* et al. [15.189]). Furthermore, the associated shear forces eventually induce vorticity downstream, with individual vortices shearing away from the central axis of the jet on alternate sides, as observed by *Thwaites* and *Fletcher* [15.190, 191].

In recent years, major advances have also been made in studying such problems by computation of solutions of the Navier–Stokes equations describing the nonlinear aerodynamic flow. An example is illustrated by the simulated jet deflections by *Adachi* [15.192] shown in Fig. 15.109. Adachi's computational results are in
Fig. 15.109 A computed snapshot showing the breakup of a jet and generation of vortices (*Adachi* [15.192])

reasonably good agreement with Nolle's flow measurements [15.185] made with a hot-wire anemometer. A sequence of such computations by Macherey for the jet in a mouthpiece with flute-like geometry is included in a recent review paper on the acoustics of woodwind instruments by *Fabre* and *Hirschberg* [15.193]. The computations show a relatively simple jet structure switching from one side of the lip of a flute to the other during each period of the oscillation.

Air–Jet Resonator Interaction

Despite the obvious limitations of any small-amplitude linear approach to the jet–lip interaction and the excitation of resonator modes, it is instructive to consider the analytic model introduced by *Fletcher* [15.182], which is discussed in some detail in *Fletcher* and *Rossing* [15.5, Sect. 16.3], as it includes much of the essential physics in a way that is not always apparent from purely computational models. The assumed geometry is illustrated schematically in Fig. 15.110 and
Fig. 15.110 Model to illustrate interaction between air jet and pipe modes (after *Fletcher* [15.194])

can easily be generalised to model sound excitation in air-jet-driven instruments with different mouthpiece geometries such as the recorder, organ pipe or flute. A uniform jet with a rectangular top-hat velocity profile of width b and velocity V is assumed to impinge on the lip or labium of the instrument, with the jet passing through a fraction A of the attached pipe area S_p. The oscillating travelling-wave jet instability will result in a periodic variation of the fractional area varying as $\alpha e^{i\omega t}$. On entering the pipe channel, the jet will couple to all possible modes of the attached pipe, which in addition to the principle acoustic modes excited, will include many other modes involving radial and azimuthal variations [15.194] that are very strongly attenuated. Much of the energy of the incident jet will therefore be lost by such coupling with typically only a few percent transferred to the important acoustic resonances of the instrument.

To evaluate the transfer of energy to the principle acoustic mode, we consider the pipe impedance across the plane M. In the absence of the jet, the impedances of the attached pipe and mouthpiece section are Z_p and Z_m, where the mouthpiece section has a certain volume and hole area, with the volume in the case of a flute involving an adjustable length of pipe used for fine-tuning. Fletcher simplified an earlier model introduced by *Elder* [15.195], in assuming the principle of linear superposition, with a jet flow superimposed on that of the instrument. The oscillating incident jet then has two principal effects: the oscillating fraction of area α of the jet entering the pipe introduces a flow into the attached pipe

$$U_1 = \alpha S_p Z_m / \left(Z_m + Z_p \right), \qquad (15.141)$$

while the effective pressure acting on the plane M derived from momentum-balance arguments results in a pipe flow of

$$U_2 = \alpha \rho V^2 / \left(Z_m + Z_p \right). \qquad (15.142)$$

There is also an additional nonlinear term U_3 mathematically arising from the nonlinear effect of the fractional insertion area of the jet insertion at large amplitudes, which is negligible in comparison with the many other nonlinearities in any realistic model. This model integrates and simplifies earlier models introduced by *Cremer* and *Ising* [15.186], *Coltman* [15.187] and *Elder* [15.195].

It immediately follows from the above arguments that, provided the phase of the jet instabilities are appropriate, instabilities on the jet will excite strong resonances of the instrument when the series impedance

$(Z_\mathrm{m} + Z_\mathrm{p})$ is a minimum, which is just the impedance of the pipe loaded by the impedance of the mouthpiece assembly. Provided the lengths involved are much less than an acoustic wavelength, $Z_\mathrm{m} = \mathrm{i}\rho\Delta L/S_\mathrm{p}$ where ΔL is the end correction introduced by the mouthpiece assembly. The net flow is then given by

$$U_p = \frac{(V + \mathrm{i}\omega\Delta L)\,\rho V\alpha}{S_\mathrm{p}\,(Z_\mathrm{m} + Z_\mathrm{p})}\;. \tag{15.143}$$

The resonances are therefore those of a pipe that is open at both ends, but with a small end-correction for the effective volume of the mouthpiece and any additional closed tuning tube and flow in and out of the mouthpiece.

Because the mouthpiece impedance is reactive, the induced vibrations in flow from direct jet flow (U_1) and that induced by the jet pressure (U_2) are in phase quadrature. In addition, the two terms have a different dependence on jet velocity and frequency. In practice, $\omega\Delta L$ is often larger than V, so that the second term usually dominates, though this will not necessarily be true in more realistic models.

For small sinusoidally varying jet perturbations and a top-hat velocity profile, the driving force would only include single frequency components. However, in practice, viscous damping results in a spreading out of the velocity profile in the lateral direction with a bell-shaped profile that increases in width with distance along the jet. If such a profile is offset from the lip, any sinusoidal disturbance of the jet will introduced additional harmonics at frequencies, 2ω, 3ω, etc., with increasing amplitudes for increasing jet oscillations. In practice, the amplitudes of jet oscillation are so large that the jet undergoes a near switching action, alternating its position from one side to the other of the lip. The driving force is therefore strongly nonsinusoidal and provides a rich spectrum of harmonics to excite the upper partials of any sounded note. A flute player, for example, has considerable control over the quality of the sound produced, by variation of mouth pressure and jet velocity, its velocity profile on leaving the lips, and its direction in relation to the labium or lip of the instrument.

For most musical instruments excited by an air jet, the sinuous instability is the most important, though *Chanaud* [15.196] and *Wilson* et al. [15.197] have highlighted the importance of varicose instabilities (periodic variations in area of the jet), which were also investigated by Rayleigh, as in whistles and whistling, where the air passes through an aperture rather than striking an edge.

Regenerative Feedback

We now consider the effective acoustic impedance of the exciting air column as we did for the vibrating reed. Our emphasis here is to highlight the essential physics rather than provide a rigorous treatment. More details and references are given in *Fletcher* and *Rossing* [15.5, Sect. 16.4] and *Fletcher* [15.194].

The flow U_m into the mouth of the resonator can be expressed as

$$U_\mathrm{m} = v_\mathrm{m}S_\mathrm{m} = p_\mathrm{m}Y_\mathrm{m} \approx \frac{p_\mathrm{m}S_\mathrm{p}}{\mathrm{i}\omega\rho\Delta L}\;. \tag{15.144}$$

From (15.139), the lateral displacement of the jet at the lip a distance l from the exit channel of the jet is then given by

$$hl \approx \mathrm{i}\left(\frac{v_\mathrm{m}}{\omega}\right)\cosh\mu l\exp\left(-\omega l/u\right), \tag{15.145}$$

where u is the phase velocity for disturbances travelling along the jet and the implicit time variation has been omitted. From the ratio of the net flow into the mouthpiece-end and attached resonator to the pressure acting on the air jet, Fletcher and Rossing derive the effective admittance of the air-jet generator,

$$Y_\mathrm{i} \approx \frac{VW}{\rho\omega^2\Delta L}\left(\frac{S_\mathrm{p}}{S_\mathrm{m}}\right)\cosh\mu l\exp\left[-\mathrm{i}\left(\frac{\omega l}{u}\right)\right]. \tag{15.146}$$

Apart from a small phase factor ($\phi \approx V/\omega L$), which we have omitted, the admittance is entirely real and *negative* when $\omega l/u = \pi$, which corresponds to the first half-wavelength of the instability just bridging the distance from channel exit to lip, as shown in Fig. 15.106. This is also true for $\omega l/u = n\pi$, where n is any odd integer, corresponding to any odd number of half-wavelengths of the growing instability between the jet exit and lip of the instrument.

These are just the conditions for positive feedback and the growth of acoustic resonances in the pipe resonances will be excited when $\mathrm{Im}(Y_\mathrm{p} + Y_\mathrm{m}) = 0$, which is equivalent to the condition that Z_s should be a minimum, as expected from (15.129). As *Coltman* [15.183] pointed out, the locus of $\mathrm{Im}(Y_\mathrm{j})$ plotted as a function or $\mathrm{Re}(Y_\mathrm{j})$ as a function of increasing frequency is a spiral about the origin in a clockwise direction (*Fletcher* and *Rossing* [15.5, Fig. 16.10]). The jet admittance therefore has a negative real component at all frequencies when the locus point is in the negative half-plane. Resonances can therefore be set up over frequency ranges from $\approx (1/2$ to $3/2)\omega^*$, $(5/2$ to $7/2)\omega^*$, etc. where ω^*, $3\omega^*$, $5\omega^*$ are the frequencies when the admittance is

purely conductive and negative. By varying the blowing pressure and associated phase velocity of the jet instability, the player can therefore excite instabilities of the jet with the appropriate frequencies to lock on to the resonances of the attached air column, as illustrated schematically in Fig. 15.108.

Measurements by *Thwaites* and *Fletcher* [15.190] are in moderately good agreement with the above model at low blowing pressures and reasonably high frequencies, but deviate somewhat at low frequencies and high blowing pressures. This is scarcely surprising in view of the approximations made in deriving the above result.

Edge Tones and Vortices

Edge tones are set up when jet of air impinges on a lip or thin wire without any coupling to an acoustic resonator. The high flow rates in the vicinity of the lip or wire can generate vortices on the downstream side, which spin off on alternating sides, setting up an alternating force on the lip or wire. If the object is itself part of a mechanical resonating structure, such as a stretched telegraph wire or the strings of an Aeolian harp, wind-blown resonances can be set up, with different resonant modes excited dependent on the strength of the wind. In extreme cases, the excitation of vortices can result in catastrophic build up of mechanical resonances, as in the Tacoma bridge disaster.

Before 1970, many treatments of wind instruments discussed air-jet sound generation in such terms. *Holger* [15.198], for example, proposed a nonlinear theory for edge-tone excitation of sound in wind instruments based on the formation of a vortex sheet, with a succession of vortices already created on alternate sides of the mid-plane of the emerging jet before it hit the lip or labium of the instrument. Indeed, measurements of the flow instabilities and phase velocity of instabilities in a recorder-like instrument by *Ségoufin* et al. [15.189], as a function of Strouhal number $\omega b/u$, fit the Holger theory rather better than models based on the Rayleigh instability and refined by later authors for both short and long jets, but the experimental errors are rather large. However, the vortex-sheet model does not include the growth of disturbances in the sound field with distance (as measured by *Yoshikawa* [15.199]), which is a crucial parameter for the prediction of the oscillation threshold observed for instruments such as the recorder.

It is also clear that vortex production is important in many wind instruments, especially where the acoustic amplitude is large, as in the vicinity of sharp edges or corners of both open and closed tone holes, as observed in direct measurements of the flow field. For example,

Fabre et al. [15.200] have recently shown that vortex generation is a significant source of energy dissipation for the fundamental component of a flute note.

In view of the complexity of the fluid dynamics involves, it seems likely that future progress in our understanding of jet-driven wind instruments will largely come from computational simulations, though physical models still provide valuable insight into the basic physics involved.

15.3.6 Woodwind and Brass Instruments

In this last section on wind instruments, we briefly describe a number of woodwind and brass instruments of the modern classical orchestra. All such instruments were developed from much earlier instruments, many of which still exist in folk and ethnic cultures from all around the World. Illustrated guides to a very large number of such instruments are to be found in *Musical Instruments* by *Baines* [15.201] and the encyclopaedia *Musical Instruments of the World* [15.31]. The two text by *Backus* [15.133] and Benade [15.134], both leading researchers in the acoustics of wind instruments, provide many more technical details concerning the construction and acoustics of specific woodwind and brass instruments than space allows here, as does *Fletcher* and *Rossing* [15.5, Chaps. 13–17] and *Campbell*, *Myers* and *Greated* [15.7].

Woodwind Instruments

The simplest instruments are those based on cylindrical pipes, such as bamboo pan pipes excited by a jet of air blown over one end, or hollow resonators, such as primitive ocarinas, which act as simple Helmholtz resonators with the pitch determined by the openings of the mouthpiece and fingered open holes. Woodwind instruments use approximately cylindrical or conical tubes excited by a reed or a jet of air blown over a hole in the wall of the tube. As we have seen, simple cylindrical and conical tubes retain a harmonic set of resonances independent of their length, which in principle allows a full set of harmonic partials to be sounded when the instrument is artificially shortened by opening the tone holes. In practice, as discussed in the previous section, the harmonicity of the modes is strongly perturbed by a large number of factors including the strongly frequency-dependent end-corrections from tone holes and significant departures from simple cylindrical and conical structures. Such perturbations can, to some extent, be controlled by the skilled instrument maker to preserve the harmonicity of the lowest modes responsi-

ble for establishing the playing pitch of an instrument. We will describe the various methods of exciting vibrations by single and double reeds and by air flow in the next section.

Figure 15.111 shows four typical modern orchestral woodwind instruments. All such instruments have distinctive tone qualities and come in various sizes, which cover a wide range of pitches and different tone-colours.

The flute, bass flute and piccolo are based on the resonances of a cylindrical tube, with the open end and mouthpiece hole giving pressure nodes at both ends. Like the recorder, all the chromatic notes of the musical scale can be played by selectively opening and shutting a number of tone holes in the walls of the instrument using the player's fingers (on ancient and baroque flutes) or felted hinged pads operated by a system of keys and levers (on modern instruments). Primitive flutes appear in most ancient cultures.

The clarinet is based on a cylindrical tube excited by a single reed at one end. The reed and mouthpiece close one end of the tube, so that the odd-integer partials are more strongly excited than the even partials, particularly for the lowest notes, when most sideholes are closed. In addition, when overblown, the clarinet sounds a note three times higher (an octave and a fifth). Like all real instruments, perturbations from the tone holes,

Fig. 15.111 The modern flute, oboe, clarinet and bassoon (not to scale)

variations in tube diameter and the nonlinear processes involved in the production of sound vibrations by the reed strongly influence the strength of the excited partials, all of which contribute to the characteristic sound of the instrument.

The single-reed clarinet is a relatively modern instrument developed around 1700 by the German instrument maker Denner. It evolved from the chalumeau, an earlier simple single-reed instrument with a recorder-like body, which still gives its name to the lower register of the clarinet's playing range. In the 1840s, the modern system of keys was introduced based on the Boehm system previously developed for the flute [15.201].

The oboe is based on a conical tube truncated and closed at the playing end by a double reed. As described earlier, a conical tube supports all the integer harmonic partials giving a full and penetrating sound quality that is very rich in upper partials. This is why an oboe note is used to define the playing pitch (usually A4 = 440 Hz) of the modern symphony orchestra. Like all modern instruments, today's oboe developed from much earlier instruments, in this case from the double-reed shawn and bagpipe chanters, which still exist in many ethnic cultures in Europe, Asia and parts of Africa. In addition to the bass oboe, the oboe d'amore and cor anglais, with their bulbous end cavity just before the output bell, have been used for their distinctive plaintive sounds by Bach and many later composers. Like the flute and clarinet, early oboes used mostly open-side holes closed by the fingers, with only one or two holes operated by a key, but developed an increasingly sophisticated key system over time to facilitate the playing of the instrument.

The bassoon is a much larger instrument, producing lower notes of the musical scale. Because of the length of the air column, the spacing of the tone holes would be far too wide to operate by the player's fingers alone. To circumvent this problem, the instrument is folded along its length and relatively long finger holes are cut diagonally through the large wall thickness, so that normally fingered holes can connect to the much wider separation of holes in the resonant air column. The bore of the instrument is based on a largely conical cross section, with the mouthpiece end terminated by a narrow bent tube or *crook* to which a large double reed is attached. Early bassoons included a single key to operate the most distant tone hole on the instrument. Modern instruments have an extended key system to facilitate playing all the notes of the chromatic scale. The contrabassoon includes an additional folded length of tube. Like the oboe, the sound of the bassoon is very rich in upper partials and has a very rich, mellow sound.

Related to the bassoon is the renaissance racket played with a crook and double reed. The instrument looks like a simple cylinder with a set of playing holes cut into its surface. However, in reality, it is a highly convoluted pipe with twelve parallel pipes arranged round the inner diameter of the cylinder and interconnected with short bends at their ends to produce a very long acoustic resonator with easily accessible tone holes. This provides a beautiful example of the centuries-old ingenuity of instrument makers in solving the many acoustic and ergonomic problems involved in the design of musically successful wind instruments.

Brass Instruments

Figure 15.112 illustrates the trumpet, trombone and horn, which like all brass instruments are based on lengths of cylindrical, conical and flared resonant air columns. They are excited by a mouthpiece at one end and a bell at the open end, as described in the previous section. The player selects the note to be sounded by buzzing the lips, usually at a frequency corresponding to one of the natural resonances of the coupled air column. The essential nonlinearity of this excitation process also excites multiples in frequency of the playing pitch. Ideally, for ease of playing, these harmonics should coincide with the higher modes of the excited air column. As already described, brass instruments are therefore designed to have a full harmonic set of modes. However, because of their shape and outward flare, it is impossible to achieve this for the fundamental mode (Fig. 15.77).

By adjusting the pressure and the tightness of the lips in the mouthpiece, the player can pitch notes based on the $n = 2, 3, 4 \ldots$ modes – the $n = 2$ mode, a fifth above, an octave above, an octave and a fourth above,

Fig. 15.112 The trombone, French horn and trumpet

etc. Trumpet players typically sound notes up to the 8–10 th mode, while skilled horn players can pitch notes up to and sometimes above the 15*th*. In the higher registers, the instruments can therefore play nearly all the notes of a major diatonic scale. A few of the notes can be rather badly out of tune, but a skilled player can usually correct for this by adjusting the lip pressure and flow of air through the mouthpiece. The low notes are based on simple intervals: the perfect fifth, octave, perfect fourth, etc. Trumpets and horns were therefore often used in early classical music to add a sense of military excitement and to emphasise the harmony of the key in which the music is written. However, in later classical music and music of the romantic period, all the notes of the chromatic scale were required. To achieve this, brass instruments such as the trumpet and horn were developed with a set of air valves, which enabled the player to switch in and out various combinations of different lengths of tube, to change the effective resonating length of the vibrating air column and hence playing pitch. Uniquely, the pitch of the trombone is changed by the use of interpenetrating cylindrical sliding tubes, which change the effective length. Modern instruments generally use a folded or coiled tube structure to keep the size of the instrument to manageable proportions.

The trombone can sound all the semitones of the chromatic scale, by the player sliding lengths of closely fitting cylindrical tubing inside each other. In the *first position*, with the shortest length tube (Fig. 15.112), the B-flat tenor trombone sounds the note B-flat at ≈ 115 Hz, corresponding to the $n = 2$ mode, an octave below the lowest note on the B-flat trumpet. To play notes at successive semitones lower, the total length has to be extended sequentially by fractional increases of 1.059. From the shortest to longest lengths there are seven such increasingly spaced *positions*. When fully extended, the trombone then plays a note six semitones lower (E) than the initial note sounded. One can then switch to the $n = 3$ mode to increase the pitch by a perfect fifth, to the note B a semitone higher than the initial note sounded. Using the closer positions enables the next six higher semitones to be played. Higher notes can be excited by suitable combinations of both position and mode excited. The trombone is one of the few musical instruments that can slide continuously over a large range of frequencies, simply by smoothly changing its length. This is widely used in jazz, where it also enables the player to use a very wide, frequency-modulated, vibrato effect and bending of the pitch of a note for expressive effect.
The fully extended length of the vibrating air column in the first position is ≈ 2.5 m. Two-thirds of the length is made up of 1.3 cm-diameter cylindrical tubing with the remaining gently flared end-section opening out to a bell diameter of 16–20 cm.

The trumpet achieves the full chromatic range by the use of three piston valves, which enable additional lengths of tubing to be switched in and out of the resonating air column. In the inactive *up* position, the sound travels directly through a hole passing directly through the valve. When the piston is depressed, the valve enables the tube on either side of the valve to be connected to an additional length of tubing, which includes a small, preset, sliding section for fine tuning. The pitch is decreased by a tone on depressing the first piston and a semitone by the second. Pressing them down together therefore lowers the pitch by three semitones (a minor third). Depressing the third valve also lowers the pitch by three semitones, so that when all three valves are depressed the pitch is lowered by six semitones. However, the tuning is not exact, because whenever any single valve is depressed the effective tube length is lengthened. Therefore, when a second (or third) valve is depressed, the fractional increase in effective length is less when the second valve alone is used. This is related to the need to *increase* the spacing of the semitone positions on the trombone as it is extended. Similar mistuning problems arise for all combinations of valves used.

To circumvent these difficulties, compromises have to be made, if the instrument is to play in tune (*Backus* [15.133, pp. 270–271]). The added length of tubing to produce the semitone and tone intervals are therefore purposely made slightly too long, giving semitone and tone intervals that are slightly flat, but which in combination produce a three-semitone interval which is slightly sharp. Similarly, the third valve is tuned to give a pitch change of slightly more than three semitones. This allows the full of range of semitones to be played with only slight fluctuations above and below the correct tuning. The error is greatest when all three pistons are depressed. In the modern trumpet, the mistuning can be compensated by a small length of tubing operated by an additional small valve operated by the little finger of the playing hand. To regulate the overall tuning of the instrument, the playing length of the instrument can be varied by a sliding U-tube section at the first bend away from the mouthpiece. As we will show later, the skilled player can adjust the muscles controlling the dynamics of the lip-reed excitation to correct for any slight mistuning inherent in the design of the instrument.

The bends and valves incorporated into the structure of brass instruments will clearly result in sudden changes in acoustic impedance of the resonating air column, which will produce reflections and perturbations in the frequency of the frequency of the excited modes. Surprising, as shown earlier, such effects are acoustically relatively unimportant, though for the player they may affect the feel of the instrument and ease with which it can be played. In particular, when a brass player is pitching one of the higher modes of an instrument such as the horn several oscillations have to be produced before any feedback returns from the end of the instrument to stabilise the playing frequency. For example, when pitching the 12th mode on a horn, the player has to buzz the lips for about 12 cycles before the first reflection returns from the end of the instrument, which demonstrated the difficulty of exact pitching of notes in the higher registers. Note that, because of the dispersion of sound waves in a flared tube, the group velocity determining the transit time will not be the same as the phase velocity determining modal frequencies. Any strong reflections from sharp bends and discontinuities in acoustic impedance introduced by the valve structures can potentially confuse the pitching of notes and the playability of an instrument. Such transients can be investigated directly by time-domain acoustic reflectometry (see, for example, *Ayers* [15.180]). Different manufacturers choose different methods to deal with the various tuning and other acoustic problems involved in the design of brass instruments and players develop strong preferences for a particular type of instrument based on both the sound they produce and their ease of playing.

The trumpet bore is ≈ 137 cm long with largely cylindrical tubing with a diameter of ≈ 1.1, which tapers down to ≈ 0.9 cm at the mouthpiece end over a distance of ≈ 12–24 cm. It opens up over about the last third of its length with an end bell of diameter ≈ 11 cm. To reduce the overall length, its length is coiled with a single complete turn, as illustrated in Fig. 15.112.

The cornet is closely related to the trumpet but has a largely conical rather than cylindrical bore and is further shortened by having two coiled sections. This results in a somewhat lower cut-off frequency giving a slightly warmer but less brilliant sound quality. The bugle is an even simpler double-coiled valveless instrument of fixed length, so that it can only sound the notes of the natural harmonics. It was widely used by the military to send simple messages to armies and is still used today in sounding the *last post*, accompanying the burial of the military dead.

The modern French horn developed from long straight pipes with flared ends played with a mouthpiece. Technology then enabled horns to be made with coiled tubes, like hunting horns, greatly reducing their size. In early classical music, horns were only expected to play a few simple intervals in the key in which the music was written. For music written in different keys, the player had to add an additional section of coiled tube called a *crook*, to extend the length of the instrument accordingly.

To extend the range of notes that a horn could play, the player can place his hand into the end of the instrument. Depending how the hand is inserted, the pitch of individual harmonics can be lowered or raised by around a semitone, producing what is referred to as a *hand-stopped* note. If the hand is partially inserted into the bell, it dramatically increases the cut-off frequency giving the player access to a much larger number of higher modes, as illustrated in measurements by *Benade* [15.134, Fig. 20.17] reproduced in Fig. 15.113. Although the associated changes in pitch may be relatively small, inserting the hand into the end of a horn significantly changes the spectrum of the radiated sound, which allows the horn player some additional freedom in the quality of the sound produced.

The modern orchestral horn produces all the notes of the chromatic scale using rotary valves to switch in combinations of different length tube, rather like the trumpet. The modern instrument is a combination of a horn in F and a horn in B-flat, which can be interchanged by a rotary valve operated by the thumb of the left hand, while the first three fingers operate the three main valves, which are common to both horns.

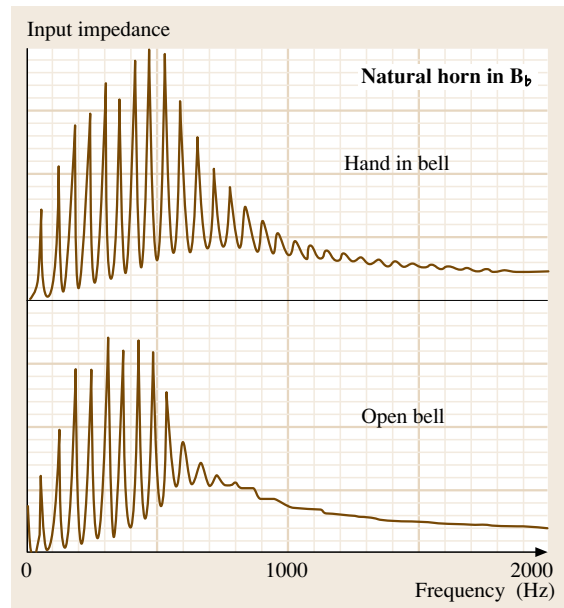
The total length of the F horn is about 375 cm, a third longer than the B-flat trombone, enabling it to play down to the note F2. The F-horn is used for the lowest notes on the instrument, while the B-flat horn is used to give the player a much higher degree of security in pitching the higher notes. Like the primitive hunting horn, the modern horn is coiled to accommodate its great length and has a bore that opens up gently over its whole length from a diameter of ≈ 0.9 mm at


Fig. 15.113 Input impedance measurements of a natural horn, with and without a hand in the bell (after *Benade* [15.134])

the mouthpiece end to a rapidly flared output bell with a diameter of ≈ 30 cm.

There are many other instruments played with a mouthpiece in both ancient and ethnic cultures around the world. Many primitive instruments are simply hollowed-out tubes of wood, bamboo or animal bones. The notes that such instruments can produce are limited to the principal, quasi-harmonic, resonances of the instrument. There are also many hybrid instruments played with a mouthpiece, which use finger-stopped holes along their length, just like woodwind instruments. Important examples are the renaissance *cornett* and the now almost obsolete *serpent*, a spectacularly large, multiple bend, s-shaped, instrument. Many modern players of baroque-period *natural* trumpets have also added finger holes to the sides of their instruments, to facilitate the pitching of the highest notes.

15.4 Percussion Instruments

Compared with the extensive literature on stringed, woodwind and brass instruments, the number of publications on percussion instruments is somewhat smaller. This is largely because the acoustics of percussion instruments is almost entirely dominated by the well-

understood, free vibrations of relatively simple structures, without complications from the highly nonlinear excitation processes involved in exciting string and wind instruments. However, as this section will highlight, the physics of percussion instruments involves

a number of fascinating and often unexpected features of considerable acoustic interest.

The two most important references on the acoustics of percussion instruments are *The Physics of Musical Instruments*, *Fletcher* and *Rossing* [15.5, Chaps. 18–21] and the *Science of Percussion Instruments* [15.202] by *Rossing*, the general editor of this Handbook, who has pioneered research on a very wide range of classical and ethnic percussion instruments. *James Blade*'s *Percussion Instruments and their History* [15.203] provides an authoritative survey of the development of percussion instruments from their primitive origins to their modern use.

Percussion instruments are amongst the oldest and most numerous of all musical instruments. Primitive instruments played by hitting sticks against each other or against hollowed-out tree stumps or gourds are likely to have evolved very soon after man discovered tools to make weapons and other simple artefacts essential for survival. The rhythmic beating of drums by Japanese Kodo drummers, the marching bands of soldiers down the centuries, and the massed percussion section of a classical orchestra still instil the same primeval feelings of power and excitement used to frighten away the beasts of the forest and to raise the fighting spirits of early groups of hunters. The beating of drums would also have provided a simple way of communicating messages over large distances, the rhythmic patterns providing the foundation of the earliest musical language – the organisation of sound to convey information or emotion. Martial music, relying heavily on the beating of drums continues to be used, and as often misused, to instil a sense of belonging to a particular group or nation and to instil fear in the enemy.

In China, bells made of clay and copper were already in use well before 2000 BC. The discovery of bronze quickly led to the development of some of the most sophisticated and remarkable sets of cast bells ever made, reaching its peak in the western Zhou (1122–771 BC) and eastern Zhou (770–249 BC) dynasties (*Fletcher* and *Rossing* [15.5, Sect. 21.15]). Inscriptions on the set of 65 tuned chime bells in the tomb of Zeng Hou Yi (433 BC), show that the Chinese had already established a 12-note scale, closely related to our present, but much later, western scale. The ceremonial use of bells and gongs is widespread in religious cultures all over the world and in western countries has the traditional use of summoning worshippers to church and accompanying the dead to their graves.

In the 18th century classical symphony orchestra of Haydn and Mozart's time, the timpani helped emphasise the beat and pitch of the music being played, particularly in loud sections, with the occasional use of cymbals and triangle to emphasise exotic and often Turkish influences. The percussion section of today's symphony orchestra may well be required to play up to 100 different instruments for a single piece, as in *Notations I–IV* by *Boulez* [15.204]. This typical modern score includes timpani, gongs, bells, metals and glass chimes, claves, wooden blocks, cowbells, tom-toms, marimbas, glockenspiels, xylophones, vibraphones, sizzle and suspended cymbals, tablas, timbales, metal blocks, log drums, boobams, bell plates in C and B flat, side drums, Chinese cymbals, triangles, maracas, a bell tree, etc. Modern composers can include almost anything that makes a noise – everything from typewriters to vacuum cleaners. The percussion section of the orchestra is required to play them all – often simultaneously.

We will necessarily have to be selective in the instruments that we choose to consider and will concentrate largely on the more familiar instruments of the modern classical symphony orchestra. We will also constrict our attention to instruments that are struck and will ignore instruments like whistles, rattles, scrapers, whips and other similar instruments that percussion players are also often required to play.

15.4.1 Membranes

Circular Membrane

A uniform membrane with areal density σ, stretched with uniform tension T over a rigid circular supporting frame, supports acoustically important transverse displacements z perpendicular to the surface described by the wave equation

$$T\left(\frac{\partial^2 z}{\partial r^2} + \frac{1}{r}\frac{\partial z}{\partial r} + \frac{1}{r^2}\frac{\partial^2 z}{\partial \phi^2}\right) = \sigma\frac{\partial^2 z}{\partial t^2} , \qquad (15.147)$$

which has solutions of the form

$$z(r, \phi, t) = J_m(k_{mn}r)\left\{ \begin{array}{c} A\cos m\phi \\ +B\sin m\phi \end{array} \right\} e^{i\omega t} . \qquad (15.148)$$

$J_m(k_{mn}r)$ are Bessel functions of order m, where n denotes the number of radial nodes and m the number of nodal diameters. The eigenfrequencies $\omega_{mn} = k_{mn}\sqrt{T/\sigma}$ are determined by the requirement that $J_m(k_{mn}a) = 0$ on the boundary at $r = a$. The frequency of the fundamental (01) mode is $(2.405/2\pi a)\sqrt{T/\sigma}$, where $J_0(k_{01}a) = 0$. The relative frequencies of the first

01   11   21   02   31   12

41   22   03   51   32   61

3.16   3.50   3.60   3.65   4.06   4.15
Fig. 15.114 The first 12 modes of a circular membrane illustrating the mode nomenclature, nodal lines and frequencies relative to the fundamental 01 mode

12 modes and associated nodal lines and circles are shown in Fig. 15.114.

For ideal circular symmetry, the independent azimuthal cosine and sine solutions result in degenerate modes having the same resonant frequencies. The degeneracy of such modes can be lifted by a nonuniform tension, variations in thickness when calfskin is used, and a lack of ideal circularity of the supporting rim. Any resulting splitting of the frequencies of such modes can result in beats between the sound of given partials, which the player can eliminate by selectively adjusting the tension around the perimeter of the membrane or by hitting the membrane at a nodal position of one of the contributing modes.

Unlike transverse waves on a stretched string, the modes of a circular membrane are inharmonic. As a consequence, the waveforms formed by the combination of such partials excited when the drumhead is struck are nonrepetitive. Audio [?] EXTRAS illustrates the frequencies of the first 12 modes played in sequence. [?] EXTRAS illustrates their sound when played together as a damped chord, which already produces the realistic sound of a typical drum, having a reasonably well-defined sense of pitch, despite the inharmonicity of the modes.

Although percussion instruments may often lack a particularly well-defined sense of pitch, one can nevertheless describe the overall pitch as being high or low. For example, a side drum has a higher overall pitch than a bass drum and a triangle higher than a large gong. From an acoustical point of view, we will be particularly interested in the lower-frequency quasi-harmonic modes. However, one must never forget the importance of the higher-frequency inharmonic modes in defining the initial transient, which is very important in characterising the sound of an instrument.

Nonlinear effects arise in drums in much the same way as in strings (Sect. 15.2.2). The increase in tension, proportional to the square of the vibrational amplitude, leads to an increase in modal frequencies. In addition, nonlinearity can result in mode conversion (Sect. 15.2.2) and the transfer of energy from initially excited lower-frequency modes with large amplitudes to higher partials. Although the pitch of a drum is raised when strongly hit, this may to some extent be compensated by the psychoacoustic effect of a low-frequency note sounding flatter as its intensity increased. Changes in perceived pitch of a drum with time can often be emphasised by the use of digital processing, to increase the frequency of the recorded playback without changing the overall envelope in time (audio [?] EXTRAS).

Air Loading and Radiation

The above description of the vibrational states of a membrane neglects the induced motion of the air on either side of the drum skin. At low frequencies, this adds a mass $\approx \frac{8}{3}\rho a^3$ to the membrane (*Fletcher* and *Rossing* [15.5, Sect. 18.1.2]), approximating to a cylinder of air with the same thickness as the radius a of the drum head. The added mass lowers the vibrational frequencies relative to those of an ideal membrane vibrating in vacuum. The effect is largest at low frequencies, when the wavelength in air is larger than or comparable with the size of the drumhead. For higher-frequency modes, with a number of wavelengths λ across the width of the drumhead, the induced air motion only extends a distance $\approx \lambda 2\pi (\ll a)$ from the membrane. Air loading therefore leaves the higher-frequency modes relatively unperturbed.

Drums can have a single drum skin stretched over a hollow body, such as the kettle drum of the timpani, or two drum heads on either side of a supporting cylinder or hollowed out block of wood, like the side drum and southern Indian mrdanga (*Fletcher* and *Rossing* [15.5, Sect. 18.5]). By stretching the drum head over a hollow body, the sound radiated from the back surface is eliminated, just like mounting a loudspeaker cone in an enclosure. At low frequencies, the drum then acts as a monopole source with isotropic and significantly enhanced radiation efficiency. This is illustrated by the much reduced 60 dB decay time of the (11) dipole mode of a stretched timpani skin, when the drum skin was attached to the kettle – from 2.5 s to 0.5 s (*Fletcher* and *Rossing* [15.5, Table 18.4]).

In addition, any net change in the volume of the enclosed air resulting from vibrations of the drum skin will increase the restoring forces acting on it and hence raise

Table 15.7 Ideal and measured frequencies of the modal frequencies of a timpani drum head normalised to the acoustically important (11) mode before and after mounting on the kettle, and the internal air resonances of the kettle. The *arrows* indicate the sense of the most significant perturbations of drum head frequencies and the *asterisks* indicate the resulting quasi-harmonic set of acoustically important modes (adapted from Fletcher and Rossing)

Mode	Ideal membrane	Drumhead in air		Coupled internal air resonances		Drumhead on kettle

the modal frequencies, see Table 15.7. In this example, the coupling raises the frequency of the (01) drumhead mode from 82 to 127 Hz, the (02) mode from 241 to 252 Hz, and the (03) mode from 407 to 418 Hz. In contrast, the asymmetric, volume-conserving, (11) mode is lowered in frequency from 160 to 150 Hz, which probably results from coupling to the higher frequency 337 Hz internal air mode having the same aerial symmetry.

As in any coupled system in the absence of significant damping, the separation in frequency of the normal modes resulting from coupling will tend to be greater than the separation of the uncoupled resonators (Fig. 15.46b). In addition, any enclosed air will provide a coupling between the opposing heads of a double-sided drum. For example, the 227 and 299 Hz (01) uncoupled (01) modes of the opposing heads of a snare drum become the 182 and 330 Hz normal modes of the double-sided drum (*Fletcher* and *Rossing* [15.5, Fig. 18.7]).

Excitation by Player

The quality of the sound produced by any percussion instrument depends as much on the player's skills as on the inherent qualities of the instrument itself. Drums are not simply hit. A player uses considerable manual dexterity in controlling the way the drumstick strikes and is allowed to bounce away from the stretched drum skin,

xylophone bar or tubular bell. It is important that contact of the stick with the instrument is kept to a minimum; otherwise the stick will strongly inhibit the vibrational modes that the player intends to excite. The *lift off* is just as important as *the strike*, and it takes years of practice to perfect, for example, a continuous side drum or triangle roll.

It is also important to strike an instrument in the right place using the right kind of stick or beater to produce the required tone, resonance or loudness required for a specific musical performance. As discussed earlier in relation to the excitation of modes on a stretched string and modal analysis measurements, one can selectively emphasise or eliminate particular partials by striking an instrument at antinodes or nodes of particular modes. A skilled timpani player can therefore produce a large number of different sounds by hitting the drumhead at different positions from the rim. Striking timpani close to their outer rim preferentially excites the higher-frequency modes, while striking close to the centre results in a rather dull *thud*. This is due to the preferential excitation of the inefficient (00) mode and elimination of the acoustically important (0n) modes. The most sonorous sounding notes are generally struck about a quarter of the way in from the edge of the drum.

The sound is also strongly affected by the dynamics of the beater–drumhead interaction, which is rather soft and *soggy* near the centre and much harder and

springy near the outer rim. The sound is also strongly affected by the type of drumstick used. Light, hard wooden sticks will make a more immediate impact with a bar or drum skin than heavily felted beaters. Such difference are similar to the effect of using heavy or light force hammers to preferentially excite lower- or higher-frequency modes in modal analysis investigations. A professional timpanist or percussion player will use completely different sticks for different styles of music and obtain effects on the same instrument ranging from the muffled drum beats of the *Death March* from Handel's *Saul* to the sound of cannons firing in Tchaikovsky's 1812 overture.

There has been much less research on the mechanics of the drumstick–skin interaction than on the excitation of piano strings by the piano hammer (Sect. 15.2.2), though much of the physics involved is very similar. In particular, the shortest time that the drumstick can remain in contact with the skin will be determined by the time taken for the first reflected wave to return from the rim of the drum to bounce it off. This is illustrated schematically in Fig. 15.115, which illustrates qualitatively the force applied to the drumhead as a function of time for a hard and a soft drumstick struck near the centre (*solid line*) and then played nearer the edge (*dashed*). The overall spectrum of sound of the drum will be controlled by the frequency content of such impulses. Short contact times will emphasise the higher partials and give rise to a more percussive and brighter sound. Higher partials will also be emphasised by the use of metal beaters or drumsticks with hard-wooden striking heads rather than leather or soft felt-covered stick heads. This is illustrated by the second pulse, which would produce a softer, mellower sound, without such a strong initial attack. Clearly, the loudness of the drum note will be proportional to the mass m of the striking drumstick
Fig. 15.115 Schematic impulses from a striking drumstick, illustrating the effect of exciting the drum head at different positions, with different strengths, and with a hard and soft drumstick

head and its impact velocity v, delivering an impulse of $\approx mv$.

Audio |?⟩ **EXTRAS** illustrates the change in sound of a timpani note, as the player progressively strikes the drum with a hard felt stick, starting from the outside edge and moving towards the centre, in equal intervals of $\approx$ one eighth of the radius. Audio |?⟩ **EXTRAS** illustrates the sound of a timpani when struck at one quarter of the radius from the edge, using a succession of drumsticks of increasing hardness, from a large softly felted beater to a wooden beater.

In modern performances of baroque and early classical music, the timpanist will use relatively light sticks, with leather-coated striking heads, while for music of the romantic period larger and softer felt-covered drumsticks will often be used.

Many drums of ethnic origin are played with the hands, hitting the drum head with fingers, clenched fists or open palms to create quite different kinds of sounds. In some cases, the player can also press down on the drum head to increase the tension and hence change pitch of the note. For a double-headed drum, the coupling of the air between the drum heads can even enable the player to change the pitch and sound of a given note by applying pressure to the drum head not being struck.

We now consider a number of well-known percussion instruments based on stretched membranes, which illustrate the above principles. These will include drums with a well defined pitch, such as kettle drums (timpani) and the Indian tabla and mrdanga, and drums with no defined pitch, such as the side and bass drum.

Kettle Drums (Timpani)

The kettle drum or timpani traditionally used a specially prepared calfskin stretched over a hollow, approximately hemispherical, copper kettle generally beaten out of copper sheet. Nowadays, thin (0.19 mm) mylar sheet is often used in preference to calfskin for the drum skin, because of its uniformity and reduced susceptibility to changes in tension from variations in temperature and humidity. The drum skin is stretched over a supporting ring attached to the kettle, with the tension of the skin typically adjusted using 6–8 tuning screws equally spaced around the circumference. The player adjusts these screws to tune the instrument and to optimise the quality of tone produced. In modern instruments, a mechanical pedal arrangement can be used to quickly change the tension and thereby the tuning, by pushing the supporting ring up against the drumhead. Typically, such an arrangement can increase the tension by up to a factor of two, raising the pitch by a perfect fifth. In
Fig. 15.116 Decaying waveform of a timpani note and FFT spectra at the start of a note (*upper trace*) and after 1 s (*lower trace*)

the modern classical symphony orchestra, the timpanist will use two or three timpani of different sizes to cover the range of pitched notes required.

Figure 15.116 shows the waveform and spectrum of the immediate and delayed sound of a timpani note (the first drum note in audio ⏵ EXTRAS). The initial sound includes contributions from all the modes excited. This includes not only the vibrational modes of the drum head, but also the air inside the kettle, the kettle itself and even the supporting legs and vibrations induced in the floor. Many of these vibrations die away rather quickly, leaving a number of prominent, slowly decaying, drum-skin modes. Note in particular, the strongly damped (01) mode at ≈ 140 Hz and the less strongly damped modes (02) and (03) modes at 210 Hz and 284 Hz, tuned approximately to a perfect fifth and an octave above the fundamental. As noted by Rayleigh in relation to church bells [15.3, Vol. 1, Sect. 394], the pitch of a note is often determined by the higher quasi-harmonically related partials rather than the lowest partial present. This is demonstrated by the second drum beat in ⏵ EXTRAS , which has all frequency components below 250 Hz removed. The perceived pitch at

long times is unchanged, though there is a considerable loss in *depth* or *body* of the resulting sound.

Modal frequencies for a typical kettle drum have already been listed in Table 15.7, which includes a set of nearly harmonic modes indicated by asterisks achieved, in part, by empirical design of the coupled membrane and kettle air vibrations. To a first approximation, the modal frequencies are determined by the volume of the kettle rather than its shape. The smaller the enclosed volume, the larger its effect on the lowest-order drumhead modes. Nevertheless, there are distinct differences in the sounds of timpani used by orchestras in Vienna and those used elsewhere in Europe (*Bertsch* [15.205]). Such differences can be attributed to the Viennese preference for calfskin rather than mylar drum heads, a small shape dependence affecting the coupling to the internal air resonances, and a different tuning mechanism. The modal frequencies of the Viennese timpani measured by Bertsch were similar to those listed in Table 15.7, with the (11), (21), (31) and (41) modes again forming a quasi-harmonic set of partials, in the approximate ratios 1:1.5:2.0:2.4:2.9. Rather surprisingly, the relative frequencies of the lower two modes could be interchanged with tuning.

Indian Tabla and Mrdanga

Another way of achieving a near harmonic set of resonances of a vibrating drumhead is to add mass to the drum head and hence change the frequencies of its normal modes of vibration. For the single- and double-headed Indian tabla and mrdanga drums, this is achieved by selectively loading the drum skin with several coatings of a paste of starch, gum, iron oxide and other materials – see *Fletcher* and *Rossing* [15.5, Sect. 18.5]. The acoustics of the tabla was first investigated by *Raman* [15.206], who obtained Chladni patterns for many of the lower-frequency modes of the drum head. *Rossing* and *Sykes* [15.207] measured the incremental changes in frequency of the loaded membrane as each additional layer was added. A 100 layers lowered the fundamental mode by about an octave. The resulting five lowest modes were harmonically related and including several degenerate modes derived from the smoothly transformed modes of the original unloaded membrane. The results were very similar to those obtained earlier by Raman. Investigations by *Ramakrishna* and *Sondhi* [15.208] and by *De* [15.209] showed that, to achieve a quasi-harmonic set of low-frequency modes, the areal density at the centre of such drums should be approximately 10 times that of the unloaded sections.

Figure 15.117 illustrates the decaying waveform and spectra of a well-tuned tabla drum (audio ⏯ EXTRAS) from 200 ms FFTs of the initial sound and after 0.5 s. The spectra show three prominent partials at 549, 826 and 1107 Hz, in the near-harmonic ratios 1:1.51:2.02, which results in a well-defined sense of pitch. In contrast to the timpani, these partials dominate the sound and determine the pitch from the very beginning of the note. Note too the very wide spectrum of the rapidly decaying initial transient.

Side and Snare Drum

The side or snare drum is the classical two-headed drum of the modern symphony orchestra. It is usually played with either very short percussive beats or as a roll, with rapidly alternating notes from two alternating drumsticks. This results in a quasi-continuous *noise source*, which can be played over a very wide range of intensities, from very soft to very loud, to support, for example, a Rossini crescendo. Because the side drum is designed to produce short percussive sounds or a wideband source of noise, little effort is made to tune the partial frequencies of the two drum heads.

Like the timpani and Indian drums, the vibrational modes of the drumheads can be strongly perturbed in frequency by the air coupling. When used as a snare drum, the induced vibrations of the nonstriking head can be sufficient for it to rattle against a number of metal cables tightly stretched a few mm above the surface of the nonstriking head. The resulting interruption of the vibrations, on impact with the snares, leads to the generation of additional high-frequency noise and the *sizzle* effect of the sound excited. A not dissimilar effect is used on the Indian tambura, an Indian stringed instrument investigated by *Raman* [15.210], which has a bridge purposely designed to cause the strings to rattle *Fletcher* and *Rossing* [15.5, Fig. 9.30].

Figure 15.118 shows the waveform and time-averaged FFT of a side-drum roll (audio ⏯ EXTRAS). The spectrum is lacking in spectral features other than a modest peak in noise at around 100−200 Hz, associated with the vibration of the lower head against the snares.

Although the exact placing of the vibrational modes of the strike and snare heads are of little acoustic importance, their coupling via the enclosed air illustrates the general properties of double-headed drums of all types. The first four coupled normal modes are shown in Fig. 15.119, which is based on data from *Rossing* [15.211, Sect. 4.4]. For a freely supported drum, momentum has to be conserved, so that normal modes
Fig. 15.117 Decaying waveform of a tabla drum with initial FFT spectrum (*upper trace*) and after 0.5 s (*lower*) illustrating the weakly damped, near-harmonic, resonances of the loaded drumhead
Fig. 15.118 Time-averaged FFT spectrum and waveform of the sound of a snared side-drum roll of increasing intensity

with the two heads vibrating in the same phase will also involve motion of the supporting shell of the drum, as indicated by the arrows in Fig. 15.119.

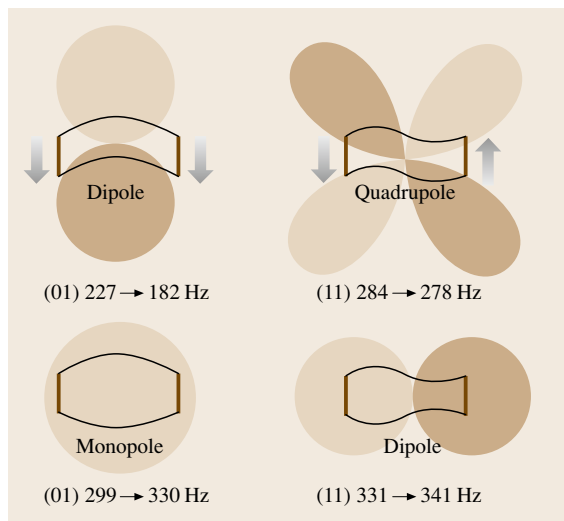
As anticipated, the air coupling increases the separation of the (01) modes from 227 and 299 Hz to 182 and


Fig. 15.119 Coupled motions of the two drumheads of a side drum, indicating the change in frequency of the drumhead modes from air coupling within the drum and the associated polar radiation patterns (after *Zhao* et al. [15.212])

330 Hz, and the (11) modes from 284 and 331 Hz to 278 and 341 Hz. The perturbations in modal frequencies will always be largest when the coupled modes have similar frequencies. Such perturbations becomes progressively weaker at higher frequencies, partly because the coupling from the enclosed air modes becomes weaker and partly because the frequencies of the two drum-head modes having the same symmetry become more widely separated. The higher modal frequencies are therefore little different from those of the individual drum heads in isolation.

Figure 15.119 also illustrates the anticipated polar radiation patterns for the normal modes measured by *Zhao* [15.212] and reproduced in *Rossing* [15.202, Figs. 4.7 and 4.8]. The coupled (10) normal modes act as a monopole radiation source, when the heads move in opposite directions, and a dipole source, when vibrating in anti-phase. In contrast, the (11) modes with heads vibrating in phase act as a quadrupole source, and a dipole source, when vibrating in anti-phase.

Although any induced motion of the relatively heavy supporting structure will not significantly affect the frequencies of the normal modes, it can result in appreciable additional damping. As a consequence, the sound of a side drum can sound very different depending on how it is supported – freely suspended on rubber bands or rigidly supported by a heavy stand (*Ross-*

Table 15.8 Modal frequencies in Hz of the batter head of a 82 cm bass drum (after *Fletcher* and *Rossing* [15.5])

Mode	Batter head with carry head at lower tension	Batter head with heads at same tension (Hz)
(01)	39	44, 104 split normal modes
(11)	80	76, 82 split normal modes
(21)	121	120
(31)	162	160
(41)	204	198
(51)	248	240

ing [15.202, Sect. 4.4]). Rossing has also made detailed vibrational and holographic studies of the free drum shell [15.202, Fig. 4.5]. As the induced motions are only a fraction of a percent of those of the drumhead, such vibrations will not radiate a very large amount of sound. Nevertheless, they may play an important role in defining the initial sound.

Bass Drum

The bass drum is large with a typical diameter of 80–100 cm. It can produce a peak sound output of 20 W, the largest of any orchestral instrument. Single-headed drums are used when a well-defined sense of pitch is required, but double-headed drums sound louder because they act as monopole rather than dipole sources. Modern bass-drum heads generally use 0.25 mm-thick mylar, though calfskin is also used.

The *batter* or beating drum head is normally tuned to about a fourth above the *carry* or resonating head (*Fletcher* and *Rossing* [15.5, Sect. 18.2]). The change in modal frequencies induced by the enclosed air is illustrated in Table 15.8 (*Fletcher* and *Rossing* [15.5, Table 18.5]). Note the strong splitting of the lowest frequency (01) and (11) normal modes, when the two heads are tuned to the same tension. In this example, the frequencies of the first five modes are almost harmonic, giving a sense of pitch to the sound (audio ⟨?⟩ **EXTRAS** illustrates the rather realistic synthesised sound of the first six modes of the batter head tuned to the carry head with equal amplitude and decay times). Drums with heads tuned to the same pitch have a distinctive timbre.

15.4.2 Bars

This section is devoted to percussion instruments based on the vibration of wooden and metallic bars, both in isolation and in combination with resonating air

columns. Such instruments are referred to as idiophones – bars, plates and other structures that vibrate and produce sound without having to be tensioned, unlike the skins of a drum (membranophones). Representative instruments considered in this section include the glockenspiel, celeste, xylophone, marimbas, vibraphone and triangle.

The vibrations of thick and thin plates have already been considered in the context of the vibrational modes of the wooden plates of stringed instruments (Sect. 15.2.6). The most important acoustic modes of a rectangular plate are the torsional (twisting) and flexural (bending) modes, both of which involve acoustically radiating displacements perpendicular the surface of the plate.

The torsional vibrations of a bar are discussed by *Fletcher* and *Rossing* [15.5, Sect. 2.20]. For a bar of length L, the frequency of the twisting modes is given by $f_n = n c_\theta / 2L$, where c_θ is the dispersionless velocity of torsional waves. For a rectangular bar with width w significantly larger than its thickness h, by $c_\theta \approx 2t/w \sqrt{E/2\rho(1+\nu)}$, where E is the Young's modulus and ν the Poisson ratio. For a bar with circular, cross-section, like the sides of a triangle, $c_\theta = \sqrt{E/2\rho(1+\nu)}$.

Musically, the most important modes of a thin bar are the flexural modes involving a displacement z perpendicular to their length, which for a rectangular bar satisfies the fourth-order wave equation

$$\frac{E}{12(1-\nu^2)}h^2 \frac{\partial^4 z}{\partial x^4} + \rho \frac{\partial^2 z}{\partial t^2} = 0 \,, \tag{15.149}$$

with standing-wave solutions of the general form

$$\begin{aligned} z(x,t) = (&A \sin kx + B \cos kx \\ &+ C \sinh kx + D \cosh kx) \, e^{i\omega t} \,, \end{aligned} \tag{15.150}$$

where

$$\omega = \sqrt{\frac{E}{12\rho(1-\nu^2)}} h k^2 \,. \tag{15.151}$$

As discussed in the earlier section on the vibrational modes of soundboards and the plates of a violin or guitar, the sinh and cosh functions decay away from the ends of the bar or from any perturbation in the geometry, such as local thinning or added mass, over a distance

$$k^{-1} \approx \left(\frac{E}{12\rho \left(1-\nu^2\right)} \right)^{1/4} \sqrt{\frac{h}{\omega}} \,.$$

Well away from the ends of a bar, the standing-wave solutions at high frequencies are therefore dominated by the sinusoidal wave components.
Fig. 15.120 Ratio of the frequencies of the first three partials of a simple rectangular bar for three selectively thinned xylophone bars and a typical marimba bar (after *Fletcher* and *Rossing* [15.5])

The lowest flexural modes of a freely supported thin rectangular bar are inharmonic, with frequencies in the ratios $1 : 2.76 : 5.40 : 8.93$. However, by selectively thinning the central section, the frequency of the lowest mode can be lowered, to bring the first four harmonics more closely into a harmonic ratio, as illustrated schematically for a number of longitudinal cross-sections in Fig. 15.120, which also includes the measured frequencies of a more-complex-shaped marimba bar (*Fletcher* and *Rossing* [15.5, Figs. 19.2 and 19.7]).

Pitch Perception

The audio |?⟩ **EXTRAS** contrasts the synthesised sounds of the first four modes of a simple rectangular bar, followed by a note having the same fundamental but with partials in the ratio $1 : 3 : 6$, while the final note has the inharmonic $(1 : 8.96)$ fourth partial of the rectangular bar added. Despite the inharmonicity of the partials, the synthesised sound of a rectangular bar has a surprisingly well-defined sense of pitch. The main effect of replacing the second and third partials with partials in the ratio 1:3:6 is to raise the perceived pitch by around a tone, even though the first partial is unchanged at $400 \, \text{Hz}$. This again emphasises that the perceived pitch is determined by a weighted average of the partials present and not by the fundamental tone alone. Adding the fourth inharmonic partial gives an increased edge or *metallic* characteristic to the perceived sound, without changing the perceived pitch.

The metal or wooden bars of tuned percussion instruments are usually suspended on light threads or rest on soft pads at the nodal positions of their fundamental mode, which reduces the damping to a minimum.

The resulting 60 dB decay time for an aluminium vibraphone bar can be as long as 40 s (*Rossing* [15.202, Sect. 7.3]) compared with a few seconds for the lower-frequency notes on the wooden bars of a marimba (*Rossing* [15.202, Sect. 6.4]). The damping of vibrating bars is therefore highly material dependent and is largely determined by internal damping losses rather than radiation. This accounts for the very different sounds of wooden and metal bars on instruments like the glockenspiel and xylophone.

Glockenspiel and Celeste

The simplest of all idiophones are those instruments based on the vibrations of freely supported thin rectangular plates. Such instruments include the glockenspiel played with a variety of hard and soft round-headed hammers and the celeste played with strikers operated from a keyboard, with a sustaining pedal to control the damping. The playing range of the glockenspiel is typically two and a half octaves from G5 to C8, while the celeste has a range of 4–5 octaves, with a separate box-resonator used for each note.

Both instruments produce a bright, high-pitched, bell-like, sparkling sound, as in the *Dance of the Sugar Plum Fairy* in Tchaikovsky's *Nutcracker Suite*. No attempt is made to adjust the thickness of the plates to achieve a more nearly harmonic set of modes.
Fig. 15.121 Measured flexural and torsional modes of a glockenspiel bar (after *Fletcher* and *Rossing* [15.5])

Figure 15.121 illustrates the lowest order flexural and torsional modes and measured ratios of frequencies for a C6 glockenspiel bar (*Fletcher* and *Rossing* [15.5, Fig. 19.1]). A typical wave-envelope and spectrum of a glockenspiel note is shown in Fig. 15.122. FFT spectra are shown for 200 ms sections from the initial transient and after 200 ms. There are two strongly contributing weakly damped partials at 1045 Hz and 2840 Hz (in the ratio 1:2.72), which can be identified as the first two flexural modes of the bar. The lower of the two long sounding partials gives the sense of pitch, while the strong inharmonic upper partial gives the note its *glockenspiel* character. Audio |?⟩ EXTRAS compares the recorded glockenspiel note with synthesised tones at 1045 and 2840 Hz, first played separately then together. In this case, the inharmonicity of the strongly sounded partials plays a distinctive role in defining the character of the sound. The spectrum is typical of all the notes on a glockenspiel, which demonstrates that only a few of
Fig. 15.122 The waveform envelope and FFT spectra of the prompt sound (*upper*) and the sound after ≈ 0.2 s (*lower*) of a typical glockenspiel note illustrating the long-time dominance of a few slowly decaying, inharmonic partials

the modes shown in Fig. 15.121 contribute significantly to the perceived sound.

Xylophone, Marimba and Vibraphone

We now consider a number of acoustically related idiophones, with bars that are selectively thinned to produce a more nearly harmonic set of resonances and well-defined sense of pitch.

The modern xylophone has a playing range of typically 3 to 4 octaves and uses wooden bars, which are undercut on their back surface to improve the harmonicity of the lower frequency modes (Fig. 15.120). Each bar has an acoustic resonator immediately below it, consisting of a cylindrical tube, which is closed at the far end. Any of the flexural and torsional modes can contribute to the initial sound, when the bar is struck by a hammer; however, most modes die away rather

Fig. 15.123 The initial 60 ms of a xylophone waveform showing the rapid decay of high-frequency components and FFT spectra at the start of the note (*upper trace*) and after 0.2 s (*lower trace*), highlighting the persistence of the strong low-frequency air resonances excited

quickly so that at longer times the sound is dominated by the resonances of the coupled pipe resonator.

Figure 15.123 shows the initial part of the waveform and spectrum of a typical xylophone note (EXTRAS), illustrating the initial large amplitudes and rapid decay of the higher frequency bar modes excited and the strongly excited but slowly decaying resonances of the first two modes of the air resonator. All modes contribute to the initial sound but the sound at longer times is dominated by the lowest-frequency bar modes and resonantly tuned air resonators.

The marimba is closely related to the xylophone, but differs largely in its playing range of typically two to four and a half octaves from A2 (110 Hz) to C7 (2093), though some instruments play down to C2 (65 Hz). In contrast to xylophone bars, which are undercut near their centre to raise the frequency of their second partial from 2.71 to 3.0 above the fundamental, marimba bars are often thinned still further to raise the frequency of the second partial to four times the fundamental frequency (Fig. 15.119).

Marimbas produce a rather mellow sound and are usually played with much softer sticks than traditionally used for the xylophone. Although the marimba is nowadays used mostly as a solo percussion instrument, in the 1930s ensembles with as many as 100 marimbas were played together. In many ways, such ensembles were the forerunners of today's Caribbean steelbands, to be described later in this section.

The vibraphone is similar to the marimba, but uses longer-sounding aluminium rather than wooden bars and typically plays over a range of three octaves from F3 to F6. Like the marimba, the bar thickness is varied to give a second partial two octaves above the fundamental. They are usually played with soft yarn-covered mallets, which produce a soft, mellow tone. In addition, the vibraphone incorporates electrically driven rotating discs at the top of each tuned air resonator, which periodically changes the coupling. This results in a strong amplitude-modulated vibrato effect. The wave envelope of audio EXTRAS is shown in Fig. 15.124 for a succession of notes played on the vibraphone with vibrato, which are then allowed to decay freely. The vibrato rate can be adjusted by changing the speed of the electric motor. Note the very long decay of the sound, which can be controlled by a pedal-operated damper.
Triangle

The triangle is a very ancient musical instrument formed from a cylindrical metal bar bent into the shape of a triangle, with typical straight arm lengths
Fig. 15.124 Envelope of a succession of notes on the vibraphone, which freely decay with modulated coupling to tuned air resonators to produce an amplitude modulated vibrato effect

of $15-25$ cm. They are usually struck with a similar-diameter metal rod. Although the instrument is small and therefore a very inefficient acoustic radiator, it produces a characteristic high-frequency *ping* or repetitive high-pitched rattle, which is easily heard over the sound of a large symphony orchestra (audio $\boxed{?\rangle\ \textbf{EXTRAS}}$). The quality of the sound can be varied by beating at different positions along the straight arms. The triangle is usually supported be a thread around the top bend of the hanging instrument.

The flexural modes of a freely suspended bar of circular cross section are $f_n \approx (a/2)\sqrt{E/\rho}(2n+1)^2\pi/8L^2$, with frequencies in the ratios $3^2{:}5^2{:}7^2{:}9^2{:}11^2{:}13^2$ (see Sect. 15.2.4). Transverse flexural vibrations can be excited perpendicular or parallel to the plane of the instrument. For vibrations perpendicular to the plane, the bends are only small perturbations. Transverse modes in this polarisation are therefore almost identical to those of the straight bar from which the triangle are bent (*Rossing* [15.213, Sect. 7.6]). However, for flexural vibrations in the plane, there is a major discontinuity in impedance at each bend, because the transverse vibrations within one arm couple strongly to longitudinal vibrations in the adjacent arms. Hence each arm will support its own vibrational modes, which will be coupled to form sets of normal-mode triplets, since each arm is of similar length.

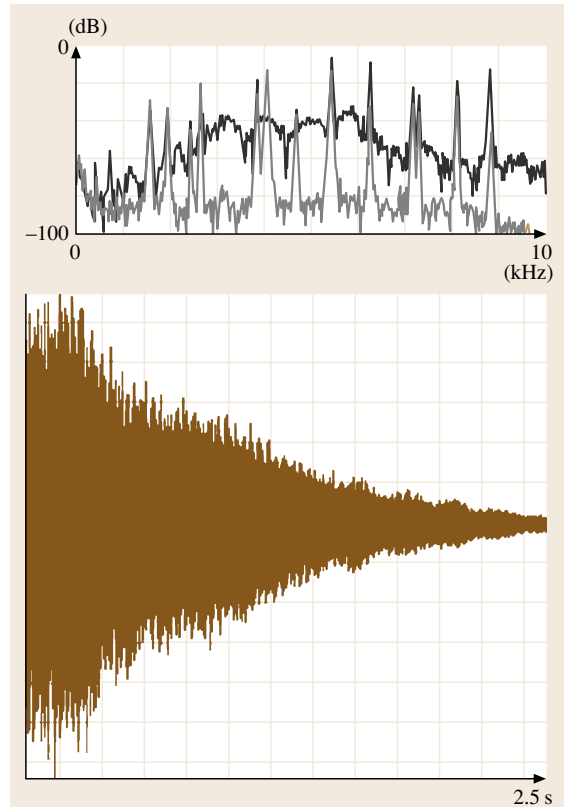
Figure 15.125 illustrates the envelope and 50 ms FFTs of the initial waveform and after 1 s, illustrating the very well-defined and only weakly attenuated high-


Fig. 15.125 The decaying waveform and FFT spectra at the start (*upper trace*) and after 1 s (*lower trace*) of a struck triangle note

frequency modes of the triangle. Note the wide-band spectrum at the start of the note from the initial impact with the metal beater.

Chimes and Tubular Bells

We include orchestral chimes and bells in this section because their acoustically important vibrations are flexural modes, just like those of a xylophone or triangle. The radius of gyration of a thin-walled cylindrical tube of radius a is $\approx a/\sqrt{2}$. The frequency of the lowest flexural modes is then be given by $f_n \approx a\sqrt{E/2\rho}(2n+1)^2\pi/8L^2$.

Orchestral chimes are generally fabricated from lengths of $32-38$ mm-diameter thin-walled tubing, with the striking end often plugged by a solid mass of brass with an overhanging lip, which provides a convenient striking point.

Fletcher and *Rossing* [15.5, Sect. 19.8] note that the perceived pitch of tubular bells is determined by the

frequencies of the higher modes, excited with frequencies proportional to 9^2, 11^2, and 13^2, in the approximate ratios $2:3:4$. The pitch should therefore sound an octave below the lowest of these. Readers can make there own judgement from audio |?⟩ EXTRAS , which compares the rather realistic sound of a tubular bell synthesised from the first six equal amplitude modes of an ideal bar sounded together, followed by the 9^2, 11^2, and 13^2 modes in combination, and then by a pure tone an octave below the 9^2 partial. Such comparisons highlight the problem of subjective pitch perception in any sound involving a combination of inharmonic partials.

15.4.3 Plates

Flexural Vibrations

This section describes the acoustics of plates, cymbals and gongs, which involve the two-dimensional flexural vibrations of thin plates described by the two-dimensional version of (15.149). Unlike stringed instruments, we can usually assume that the plates of percussion instruments are isotropic. Well away from any edges or other perturbing effects such as slots or added masses, the standing-wave solutions at high frequencies will be simple sinusoids. However, close to the free edges, and across the whole plate at low frequencies, contributions from the exponentially decaying solutions will be equally important over a distance $\approx (E/12\rho(1-v^2))^{1/4}(h/\omega)^{1/2}$. The nodes of the sinusoidal wave contributions will be displaced a distance $\approx 1/4\lambda$ from the edges. Hence, the higher frequency modes of a freely supported rectangular plate of length a, width b and thickness h will be given, to a first approximation, by

$$\omega_{mn} \approx h \left(\frac{E}{12\rho\left(1-v^2\right)} \right)^{1/4} \pi^2$$
$$\times \left[\left(\frac{m+1/2}{a} \right)^2 + \left(\frac{n+1/2}{b} \right)^2 \right].$$
(15.152)

A musical instrument based on the free vibrations of a thin rectangular metal plate is the thunder plate, which when shaken excites a very wide range of closely spaced modes, which can mimic the sharp clap followed by the rolling sound of thunder in the clouds.

Before the age of digital sound processing, such plates were often used in radio and recording companies to add artificial reverberation to the recorded sound. The plate was suspended in a chamber along with a loudspeaker and pick-up microphone. The sound to which reverberation was to be added was played through the loudspeaker, which excited the weakly damped vibrational modes of the plate, which were then re-recorded using the microphone to give the added reverberant sound. As described earlier (Sect. 15.2.4), the density of vibrational modes of a flat plate of area A and thickness h is given by $1.75A/c_L h$. This can be very high for a large-area thin metal sheet, giving a reverberant response with a fairly uniform frequency response.

Most percussion instruments which involve the flexural vibrations of thin sheets are axially symmetric, such as cymbals, gongs of many forms, and the vibrating plate regions of steeldrums or pans used in Caribbean steelbands. Such instruments have many interesting acoustical properties, many derived from highly nonlinear effects when the instrument is instrument is struck strongly.

The displacements of the flexural modes of an axially symmetric thin plate in polar coordinates are given by

$$z(r, \phi, t) = [A J_m (k_{mn}r) + B I_m (k_{mn}r)]$$
$$\times [C \cos (m\phi) + D \sin(m\phi)] \, e^{i\omega_{mn}t} ,$$
(15.153)

where $J_m(kr)$ and $I_m(kr)$ are ordinary and hyperbolic Bessel functions, the equivalent of the sinusoidally varying and exponentially damped sinh and cosh functions used to describe flexural waves in a rectangular geometry. The hyperbolic Bessel functions are important near the edges of a plate or at any perturbation, but decay over a length scale of $\approx k_{mn}^{-1}$. The values of k_{mn} are determined from the boundary conditions, in just the same way as considered earlier for rectangular plates.

The first six vibrational modes for circular plates with free, hinged and clamped outside edges are shown in Fig. 15.126, with frequencies expressed as a ratio relative to that of the fundamental mode (*Fletcher* and *Rossing* [15.5, Sect. 3.6]). In each case, for large values of m and n, the frequency is given by the empirical Chladni's Law (1802),

$$\omega_{mn} \approx \sqrt{\frac{E}{12\rho\left(1-\sigma^2\right)}} \frac{\pi^2 h}{4a^2}(m+2n)^2 , \qquad (15.154)$$

justified much later by *Rayleigh* [15.3, Vol. 1, Chap. 10]. For arched plates, *Rossing* [15.214] showed that the frequencies are more closely proportional to $(m+bn)^p$, where p is somewhat less than 2 and b is in the the range 2–4.

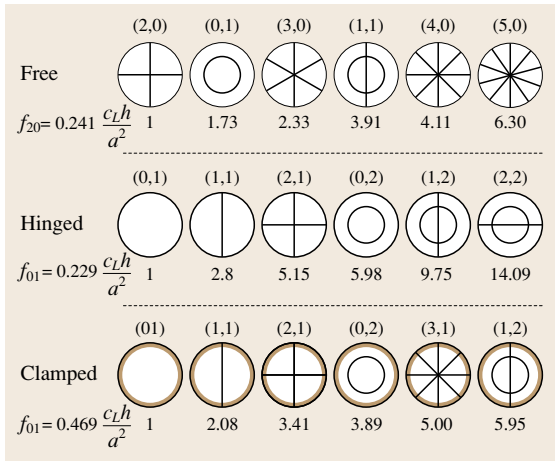
All the axially symmetric modes involving nodal diameters are doubly degenerate, with a complementary


Fig. 15.126 The vibrational modes of circular plates with free, hinged and clamped outer edges, with the lowest frequencies and ratio of frequencies of higher modes indicated

solution with nodal diameters bisecting those drawn in Fig. 15.126. Any perturbation of the structure from cylindrical symmetry will split the degeneracy of such modes. Modes with a nodal diameter passing through the point at which the plate is struck will not be excited.

Instruments like the cymbal are slightly curved over their major surfaces but with a sudden break to a more strongly arched central section, to which the leather holding straps or support stand are attached. The outer edges can therefore be treated as free surfaces with the transition to the central cupped region providing an additional internal boundary condition, which will be intermediate between clamped and hinged. In contrast, gongs tend to have a relatively flat surface but with their edges turned though a right angle to form a cylindrical outer rim. The rim will add mass to the modes involving a significant radial displacement at the edge, but will also increase the rigidity of any mode having an azimuthal dependence. Thus, although the modes of an ideal circular plate provide a guide to modal frequencies and waveforms, we would expect significant deviations in modal frequencies for real percussion instruments. Any sudden change in plate profile on a length scale smaller than an acoustic wavelength will involve a strong coupling between the transverse flexural and longitudinal waves resulting in reflections from the discontinuity in acoustic impedance. This is why, for example, the indented region on the surface of a steeldrum pan can support localised standing waves on the indented regions. Indented areas of different sizes

can then be used to produce a wide range of different notes on a single drum head with relatively little leakage in vibrations between them.

Nonlinear Effects

Figure 15.127 illustrates the cross section of some typical axially symmetric cymbals, gongs and a steelpan. Nonlinear effects in such instruments can be important when excited at large amplitudes. Such effects are particularly marked for gongs with relatively thin plates. For Chinese opera gongs, the nonlinearity can result in dramatic upward or downward changes in the pitch of the sound after striking. In addition, nonlinearity results in mode conversion, with the high-frequency content of cymbal and large gong sounds increasing with time, giving a characteristic *shimmer* to the sound quality.

The shape dependence of the nonlinearity arises from the arching of the plate. For the lowest mode of a flat plate, the potential energy initially increases quadratically with displacement, though the energy increases more rapidly at large-amplitude excursions from stretching, as indicated schematically in Fig. 15.128a. Although the energy of an arched plate initially also increases quadratically with distance about its displaced equilibrium position, the energy will first increase then decrease when the plate is pushed through the central plane, (Fig. 15.128b). If the plate were to be pushed downwards with increasing force, it would suddenly spring to a new equilibrium position displaced about the central plane by the same initial displacement, but in the opposite direction. In combination with a Helmholtz radiator, this is indeed how some insects such as cicadas generate such strong acoustic signals – as high as 1 mW at 3 kHz (see Chap. 19 by Neville Fletcher). The nonlinear bistable flexing of a belled-out plate can be
Fig. 15.127 Schematic cross sections of axially symmetric plate instruments and a steelpan, with *arrows* indicating the principal areas producing sound
Fig. 15.128a,b Potential energy and restoring force of (**a**) a clamped flat and (**b**) arched circular plate as a function of displacement from the central plane

Fig. 15.129 Vibration amplitude a dependence of frequency of lowest axisymmetric mode of a spherical cap of dome height H as a function of thickness h to H ratio

disastrous, turning a cheap pair of thin cymbals inside out, when crashed together too strongly.

The central peak in potential energy of an arched plate, like the gently domed Chinese gong illustrated in Fig. 15.127, therefore leads to a reduced restoring force for large-amplitude vibrations and a lower pitch. In contrast, the restoring force of a flat plate, like the central playing region of the upper of the two Chinese gongs, increases with vibration amplitude. This arises from the additional potential energy involved in stretching the plate, in just the same way as we considered earlier for the large-amplitude vibrations of a stretched string.

For a flat plate of thickness h, *Fletcher* [15.215] has shown that the increase in frequency of the lowest axisymmetric mode increases with the amplitude of vibration a approximately as

$$\omega \approx \omega_0 \left[1 + 0.16 \left(\frac{a}{h} \right)^2 \right] . \tag{15.155}$$

The nonlinearity also generates additional components at three times the frequency of any initial modes present and at multiples of any new modes excited. In addition it produces cross-modulation products when more than one mode is present. For example, for modes with frequencies f_i and f_2 initially present, the nonlinearity will generate inter-modulation products at $2f_1 \pm f_2$ and $2f_2 \pm f_1$.

Grossmann et al. [15.216] and *Fletcher* [15.215] have considered the vibrations of a spherical-cap shell

of height H and thickness h. Interestingly, the change in frequency of the asymmetric vibrations about the equilibrium point depends only on the ratio of the amplitude to the arching height, a/H, as illustrated in Fig. 15.129. When the height of the dome is much less than the thickness, the frequency increases approximately as a^2, as expected from the induced increase in tension with amplitude. However, when the arching becomes comparable with and greater than the thickness, the asymmetry of the potential energy dominates the dynamics and results in an initial decrease in frequency, which increases strongly with the ratio of arching height to thickness. At very large amplitude, $a \gg H$, the frequency is dominated by the increase in tension and therefore again increases with amplitude like a flat plate. At large amplitudes, *Legge* and *Fletcher* [15.217] have shown that changes in the curvature of the plate profile result in a large transfer of energy to the higher-frequency plate modes.

We now show how many of the above properties relate to the sounds of cymbals, gongs of various types and steelpans.

Cymbals

Many types of cymbals are used in the classical symphony orchestra, marching bands and jazz groups. They are normally made of bronze and have a diameter of 20–70 cm. The low-frequency modes of a cymbal are very similar to those of a flat circular plate and can be described using the same (*mn*) mode nomenclature (*Fletcher* and *Rossing* [15.5, Fig. 20.2]). However,

small changes in curvature across a cymbal will results in modes that are linear combinations of ideal circular-plate modes.

Cymbals are usually played by striking with a wooden stick or soft beater or a pair can be crashed together, each method producing a distinctive sound. They can even be played by bowing with a heavy rosined bow against the outer rim. Rossing and Shepherd showed that the characteristic 60 dB decay time of the excited modes of a large cymbal varies approximately inversely proportional with frequency, with a typical decay time for the lowest (20) mode as long as 300 s (*Fletcher* and *Rossing* [15.5, Fig. 20.5])

Figure 15.130 shows the waveform envelope and spectra of the initial sound of a cymbal crash and after 1 s. Audio |?⟩ EXTRAS illustrates a recorded cymbal crash followed by the same sound played first through a 0−1 kHz and then a 1−10 kHz band-pass filter, illustrating the decay of the low- and high-frequency wide-band noise.

When a cymbal is excited with a drumstick, waves travel out from the excitation point with a dispersive group velocity proportional to k, inversely proportional to the dimensions of the initial flexural indention of the surface made by the drumstick. The dispersive pulse strikes and is reflected from the edges of the cymbal and the transitional region to the central curved cup, so
that eventually the energy will be dispersed across the whole vibrating surface. This has been investigated using pulsed video holography by *Schedin* et al. [15.218]. On reflection there will also be considerable mixing of modes. In addition, because the plates are rather thin and are often hit extremely strongly, nonlinear effects are important. On large cylindrical plates this results in the continuous transfer of energy from strongly excited low-frequency modes to higher modes. Many of the nonlinear effects can be investigated in the laboratory using sinusoidal excitation. Measurements by *Legge* and *Fletcher* [15.217] have revealed a wide range of nonlinear effects including the generation of harmonic, bifurcations and even chaotic behaviours at large intensities.

When a plate is struck by a beater, the acoustic energy is distributed across a very wide spectrum of closely spaced resonances of the plate. To distinguish individual partials requires the sound to be sampled over a time of at least $\approx 1/\Delta f$, where Δf is the separation of the modes at the frequencies of interest. However, because the modes of a large cymbal are so closely spaced, the times involved can be rather long. Unlike the sound of pitched instruments such as the glockenspiel and xylophone, there are no particular resonances of the cymbal that dominate the sound, which is characterised instead by the *sizzle* produced by the very wide spectrum of very closely spaced resonances almost indistinguishable from wide-band high-frequency noise.

Large Gongs and Tam–Tams

Gongs are also very ancient instruments, which have a very characteristic sound when strongly struck by a soft beater, notably as a prelude to classic films by the Rank organisation. A typical tam-tam gong used in a symphony is a metre or even larger in diameter. It is made of bronze and, like cymbals, is sufficiently ductile not to shatter when strongly hit. The damping is very low, so the sound of large gongs can persist for very long times.

When initially struck strongly by a soft beater, the initial sound is largely associated with the lower-frequency partials that are strongly excited. However, on a time scale of a second or so, the sound can appear to grow in intensity, as nonlinear effects transfer energy from lower- to higher-frequency modes (audio |?⟩ EXTRAS). This is illustrated in Fig. 15.131 (*Fletcher* and *Rossing* [15.5, Fig 20.8]), which shows the build up and subsequent decay of acoustic energy in the higher-frequency bands at considerable times after the initial impact. The fluctuations in intensity within these bands were taken as evidence for chaotic behaviour. How-

Fig. 15.132 The wave envelope of sounds from three downward-sliding Chinese gongs followed by the spectrum of the third gong at the start, after 0.75 and 1.5 s illustrating the nonlinear frequency shifts

ever, even in a linear system, interference between the large number of very closely spaced inharmonic partials would also result in apparently random fluctuations in amplitude.

Chinese Opera Gongs

Chinese gongs provide the most dramatic illustration of nonlinearity in percussion instruments, with upwards or downwards pitch glides of several semitones over a sizeable fraction of a second after being strongly struck. The direction of the pitch *glide* depends on the profile of the vibrating surface as previously described.

Figure 15.132 shows the decaying waveforms of the sound of three Chinese gongs with a downward pitch glide (audio ⏵ **EXTRAS**) played in succession. The initial spectrum of the third note played is followed by spectra at 0.75 and 1.5 s after striking, illustrating the transfer of energy to lower-frequency modes. The much broader width of the initial spectrum reflects the decrease in lifetime of the initial modes struck resulting from the nonlinear loss of energy to higher-frequency modes. The two well-defined peaks between the two major peaks are from the long-ringing principal partials of the first two gongs.

Steelpans

Finally, in this section on percussion instruments based on vibrating plates, we consider steelpans originating from the Caribbean, which were initially fabricated by indenting the top of oil cans left on the beaches by the British navy after World War II. They have become a immensely popular instrument in that part of the world and are just as interesting from a musical acoustics viewpoint (see *Fletcher* and *Rossing* [15.5, Sect. 20.7] for further details).

Pitched notes on a given drum are produced by hammered indentations of different sizes on the top face of the drum. Different ranges of notes are produced by drums or pans of different sizes (e.g. lead tenor, double tenor, alto, cello and bass). Typical indented regions on a double-tenor steelpan are shown in Fig. 15.133, adapted from drawings for a full set of pans in *Fletcher* and *Rossing* [15.5, Fig. 20.17]. The various indented areas on the drum head can be considered as an array of relatively weakly coupled resonators. An individual indented area on an infinite sheet would have very similar acoustic modes as those of a hemispherical cap indented in an infinite
Fig. 15.133 Typical indentation areas in a tenor steelpan (after *Fletcher* and *Rossing* [15.5])

plate. The frequency of the modes would be determined by the size and arching of the indented areas. The effective cap size would be defined by the rate of change of the curvature of the plate and the associated change in the acoustic impedance at the edge of the indented region. However, all such regions on a steelpan will be coupled together by the relatively weak transfer of acoustic energy between them, to form a set of coupled modes. Hitting one particular region will therefore excite other regions, especially those that have closely matching partials. The coupling between
Fig. 15.134 Waveform and initial and time-delayed spectra of the note C#4 on a steeldrum

such regions has been investigated holographically by *Rossing* [15.202, Fig. 20.20].

Audio ⏸ **EXTRAS** illustrates a succession of notes played on a steeldrum. Figure 15.134 shows a typical decaying waveform with initial and time-delayed spectra of a single note. A relatively large number of well-defined modes can easily be identified. However, the subjective absolute pitch of the note is not particularly well defined and there is a strong sense of pitch circularity in the sound of an ascending scale (Sect. 15.1.3 and audio ⏸ **EXTRAS**), sometimes making it difficult to identify the octave to which a particular note should be attributed. Note the *increase* in the amplitude of the second partial with time, which could result from nonlinear effects in such thin-walled structures, or possibly from interference beats between degenerate modes split in frequency by the lack of axial symmetry of the hand-beaten indentations.

15.4.4 Shells

Blocks and Bells

Finally, we consider the acoustics of three-dimensional shell-like structures. This could include percussion instruments such as the wooden-block and hollow gourd instruments like the maracas. However, the physics of such instruments is essentially the same as that of the soundbox of stringed instruments and involves little of additional acoustic interest. In this section, we will therefore concentrate on the acoustics of bell-like structures, which are usually axially symmetric structures, closed at one end, and of variable thickness and radius along their length. We will also consider nonaxisymmetric bells with a quasi-elliptical cross section, which produce two different pitched notes, depending on where the bell is struck. All such structures have a rich spectrum of modes, which are generally tuned to give long-ringing notes with a well-defined sense of pitch. The bronze used in their construction is typically an alloy of 80% copper and 20% tin and has to be sufficiently ductile not to crack under the impact of the beater or clapper. Metallurgical treatment is required to produce a grain structure producing little damping at acoustic frequencies.

Some of the oldest bells are to be found in China. Such bells are supreme examples of the art of bronze casting dating to the fifth century BC. Bells in church towers have traditionally marked the passage of time, while peals of bells with internal swinging clappers continue to summon the faithful to worship. In more recent times, carillons with up to 77 tuned bells have been

developed to play keyboard music from the top of specially constructed bell towers, notably in the centres of Dutch and American towns and college campuses. Bells come in all sorts of shapes and sizes ranging from small hand bells to the giant church bells on display inside the Kremlin walls. However, the acoustics of all bells is essentially the same, so no attempt will be made to provide a comprehensive coverage of every type (for such information, see *Fletcher* and *Rossing* [15.5, Chap. 21] and *Rossing* [15.202]).

Bell modes can be related to the longitudinal, torsional and flexural modes of a cylindrical disc that is axially deformed into a bell-shaped domed structure. Although the modal frequencies will clearly be strongly perturbed by such a transformation, the modal shapes will remain unchanged, as illustrated in Fig. 15.135, where m represents the number of radial nodal lines and n the number of nodal circles between the (fixed) centre and free edge.

The first example in Fig. 15.135 illustrates the rim displacements of the $(0, n)$ extensional modes. Although such *breathing* modes would be efficient sound radiators the energy involved in stretching the surfaces of the bell leads to very high modal frequencies, so that such modes are not strongly excited. Likewise, the torsional $(0, n)$–modes involve no motion perpendicular to the bell surfaces, and therefore generate a negligible amount of sound. With the bell rigidly supported at its top, the $m = 1$ swinging modes again involve large elastic strains and cannot be strongly excited. The first modes to produce a significant amount of sound are therefore the $m = 2$ and above flexural modes, which involve the transverse motions of the outer edges with negligible extension in circumferential length for small amplitude vibrations. When the wavelength of the flexural waves is much smaller than the overall curvature, the vibrational modes will be closely related to the flex-ural waves of a circular disc, with frequencies satisfying Chladni's generalised empirical law, $f_{mn} \approx c(m + 2n)^p$, as confirmed by *Perrin* et al. [15.219].

The flexural modes involve radial displacements proportional to $\cos(m\phi)$. Continuity requires that there must also be a tangential displacement, such that $u + \partial v/\partial \phi = 0$, where u and v are the radial and tangential velocities respectively. Coupling to the tangential motion explains why it is possible to feed energy into a vibrating wine glass or the individual glass resonators of a glass harmonica (*Rossing* [15.202, Chap. 14]), by rubbing a wetted finger around the rim. The excitation is very similar to the slip–stick mechanism used to excite the bowed string (Sect. 15.2.4).

Figure 15.136 illustrates a set of holographic measurements by *Rossing* [15.202, Fig. 12.4], which is typical of most bell shapes. The $(m, 1)$ and $(m, 2)$ modes can immediatly be related to the (m, n) modes of a cupped disc. However, there is a distinct change in character for $n > 0$, with an additional node appearing close to the rim – referred to as a $(m, 1\#)$ mode. Some insight is provided by the finite element solutions for a typical large English church bell illustrated in Fig. 15.137 [15.220]. The three modes illustrated are very similar to the $(3, 0)$, $(3, 1)$ and $(3, 2)$ modes expected from the simple cupped disc model, except for the lowest frequency $(3, 0)$ mode, in which the top surfaces of the bell move in antiphase with the rim, to
Fig. 15.136 Holographic interferograms and nomenclature for vibrational modes of a hand bell (after *Rossing* [15.202])

Fig. 15.135 Nomenclature of the (m, n) modes of a bell illustrating displacements of rim for given m-values
Fig. 15.137 Finite-element solutions for the lowest-order $m = 3$ modes of an English church bell (after *Perrin* et al. [15.221]) illustrating the (3,1), (3,1#) and (3,2) modes

give a nodal line about half-way along the length. Similarly, the anticipated (4, 0), (5, 0) and (6, 0) modes of the handbell investigated by *Rossing* [15.202] acquire an additional nodal line close to the end rim denoted as (4, 1#), (5, 1#) and (6, #) modes. Such features can generally only be accounted for by detailed computational analysis.

Bell Tuning

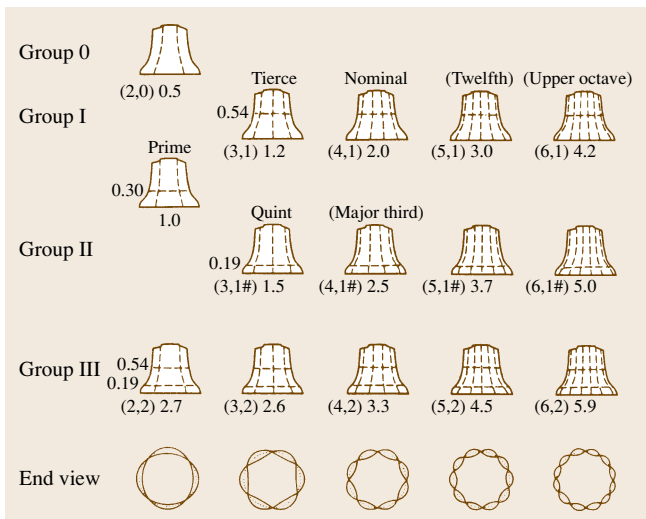
Figure 15.138 shows the frequencies and associated modes of a well-tuned traditional church bell (*Rossing* and *Perrin* [15.222]), ordered into groups based on mode shapes, which enable correlations to be made between bells of different shapes and sizes.


Fig. 15.138 Measured frequencies for a typical D5 church bell, indicating the relative frequencies of the observed mode, with the traditional names associated with such modes indicated (after *Rossing* and *Perrin* [15.222])

Fine-quality bells are carefully tuned by the bell maker, so that the lowest modes have harmonically related frequencies, thereby achieving a well-defined sense of pitch. This is achieved by selective thinning of the thickness of the bell on a very large lathe after its initial casting. In an ideally tuned bell, the principal modes are designated as the hum (2,0) mode, an octave below the prime or fundamental (2,1#) mode. A minor third above the prime (ratio 5:4) is the tierce (3,1) mode, a perfect fifth above that (ratio 3:2) is the quint or fifth (3,1#) mode, and an octave above is the nominal (4,1) mode. *Fletcher* and *Rossing* [15.5, Table 21.1] compare these and higher modes with measured values for a particular bell.

The art of tuning the partials of bells to achieve a well-sounding note was initially developed in the seventeenth century in the low countries (what is now Holland and the northern parts of Germany and France). Many fine bells from this period by François and Pieter Hemony are still in use in carillons today (*Rossing* [15.202]). However, the art of bell tuning then appears to have been lost until the end of the 19th century, when it was rediscovered by Canon Arthur Simpson in England, following Lord Rayleigh's pioneering research on the sound of bells [15.3, Vol. 1, Sect. 235].

Acoustic Radiation

The strongest-sounding partials of most bells are the group I $(m,1)$ modes, with a nodal circle approximately halfway up the bell (*Fletcher* and *Rossing* [15.5, Sect. 21.11]). Such modes have $2m$ antinodal areas providing spatially alternating sound sources in antiphase. The radiation efficiency of such modes increases rapidly with size of bell and frequency. If the acoustic wavelength is much larger than the separation of such antinodes, the sound from such sources will tend to cancel out. However, above a crossover frequency, such that the velocity of sound is equal to that of the flexural waves on the surface of the bell, $v_{\text{flex}} = \sqrt{1.8c_{\text{L}} h f}$, the spacing between the antinodes will exceed the wavelength in air and the modes will radiate more efficiently. For large church bells, this condition is satisfied for almost all but the very lowest partials, so almost all partials radiate sound rather efficiently. In contrast, hand bells with rather thin walls are significantly less efficient. There is also a small intensity of sound radiated axially at double the modal frequencies, from the induced fluctuations in the volume of air enclosed within the bell.

When a bell is struck, usually by a cast or wrought-iron, ball-shaped, clapper, the first sound heard, the

strike note, contains contributions from the very large range of largely inharmonic partials of the bell. Nevertheless the listener can usually identify a pitch to the initial note, determined by the prominent partials excited. However, it is not always easy to attribute the pitch of a note to a particular octave, which is a common feature of many struck percussion instruments (e.g. notes on a xylophone, steeldrum and even timpani). The pitch of the strike note appears to be determined principally by the excited partials with frequencies in the ratios 2:3:4. The ear attributes the pitch to be that of the missing fundamental an octave below the lowest of the partials principally excited, which does not necessarily correspond to the pitch of the lowest partial excited, unless the bell is well tuned.

The majority of the higher partials decay rather quickly, with the long-term sound dominated by the hum note. For a 70 cm church bell, *Perrin* et al. [15.219] measured T_{60} decay times of 52 s for the (2,0) hum mode, 16 s for the (2.1#) and (3,1) prime and minor third modes, 6 s for the (4,1) octave and 3 s for the (4,1#) upper major third, with progressively shorter decay times for the higher modes. Audio [?] EXTRAS illustrates the synthesised sound of the above harmonic modes excited with equal amplitudes. This is followed by a synthesised bell with a major rather than a minor third partial. Such a bell has recently been realised (1999) based on FEA studies at the Technical University in Eindhoven in collaboration with the Eijsbouts Bell foundry. It produces a less mournful sound when played in the major scale music in a carillon. In both cases the synthesised sound reproduces the gentle sound of a bell rather well, though it lacks the initial clang that results from the higher-frequency inharmonic modes of a real bell.

As an example of the waveform and spectrum of a large bell, in Fig. 15.139 and audio signal [?] EXTRAS, we illustrate the sound and rich spectrum of partials of one of the most famous large bells in the world, Big Ben, hung high above the Houses of Parliament in London. This bell is broadcast each day following the Westminster Chimes, marking the hours and end of broadcasting on the BBC each night for UK listeners.

Non–Axial Symmetry

Bell modes with $m > 1$ are doubly degenerate with orthogonal modes varying as $\cos m\phi$ and $\sin m\phi$ and nodal lines in the azimuthal directions that bisect each other. Any departures from axial symmetry will lift the degeneracy and give rise to a split pair of orthogonal modes. If both modes are excited together, the two fre-
Fig. 15.139 Decaying vibrations and spectrum of Big Ben, London

quencies will beat against each other, as already evident in the sound of Big Ben and in the sound ([?] EXTRAS) of a slightly asymmetrical glass beaker with a pouring spout, which lifts the degeneracy of the otherwise axially symmetric modes.

Bells with strongly distorted or elliptical cross sections can have two completely different pitches, which can be sounded independently by beating at the antinodal positions of one set of modes mode and nodes of the other. Drums with quasi-elliptical cross sections will therefore sound a single note when struck at the narrowest and widest cross-sectional radii, and a second note, when struck at appropriate positions in between.

A dramatic example of axially asymmetric bells is provided by the 65 ancient bells from the tomb of Zeng Hou Yi found at Sui Xiang from around 433 BC. These bells from the second millennium BC are masterpieces of Chinese art and bell casting. They have oval cross sections and range from small hand bells to well over 1.5 m in height. When struck at different positions along the flattened surfaces, two quite distinct tones can be excited, which were designed to be about a major or minor third apart. For further details of these and other Chinese and other eastern bells see *Rossing* [15.202, Chap. 13] and [15.223].

16. The Human Voice in Speech and Singing

Björn Lindblom, Johan Sundberg

This chapter describes various aspects of the human voice as a means of communication in speech and singing. From the point of view of function, vocal sounds can be regarded as the end result of a three stage process: (1) the compression of air in the respiratory system, which produces an exhalatory airstream, (2) the vibrating vocal folds' transformation of this air stream to an intermittent or pulsating air stream, which is a complex tone, referred to as the voice source, and (3) the filtering of this complex tone in the vocal tract resonator. The main function of the respiratory system is to generate an overpressure of air under the glottis, or a subglottal pressure. Section 16.1 describes different aspects of the respiratory system of significance to speech and singing, including lung volume ranges, subglottal pressures, and how this pressure is affected by the ever-varying recoil forces. The complex tone generated when the air stream from the lungs passes the vibrating vocal folds can be varied in at least three dimensions: fundamental frequency, amplitude and spectrum. Section 16.2 describes how these properties of the voice source are affected by the subglottal pressure, the length and stiffness of the vocal folds and how firmly the vocal folds are adducted. Section 16.3 gives an account of the vocal tract filter, how its form determines the frequencies of its resonances, and Sect. 16.4 gives an account for how these resonance frequencies

or formants shape the vocal sounds by imposing spectrum peaks separated by spectrum valleys, and how the frequencies of these peaks determine vowel and voice qualities. The remaining sections of the chapter describe various aspects of the acoustic signals used for vocal communication in speech and singing. The syllable structure is discussed in Sect. 16.5, the closely related aspects of rhythmicity and timing in speech and singing is described in Sect. 16.6, and pitch and rhythm aspects in Sect. 16.7. The impressive control of all these acoustic characteristics of vocal signals is discussed in Sect. 16.8, while Sect. 16.9 considers expressive aspects of vocal communication.

16.1 Breathing

The process of breathing depends both on mechanical and muscular forces (Fig. 16.1).

During *inspiration* the volume of the chest cavity is expanded and air rushes into the lungs. This happens mainly because of the contraction of the *external intercostals* and the *diaphragm*. The external intercostal muscles raise the ribs. The diaphragm which is the dome-shaped muscle located below the lungs, flattens on contraction and thus lowers the floor of the thoracic cavity.

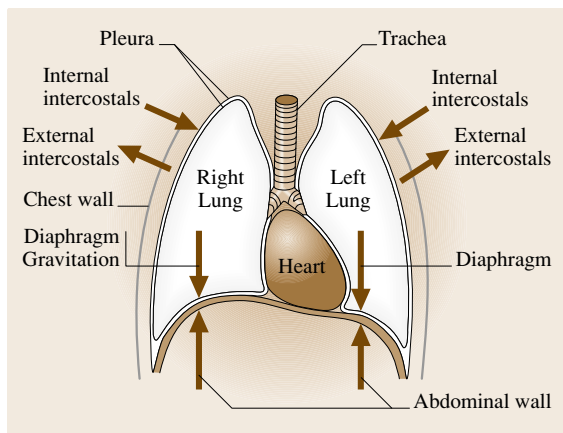
The respiratory structures form an elastic mechanical system that produces expiratory or inspiratory


Fig. 16.1 Directions of the muscular and elastic forces. The direction of the gravitation force is applicable to the upright position
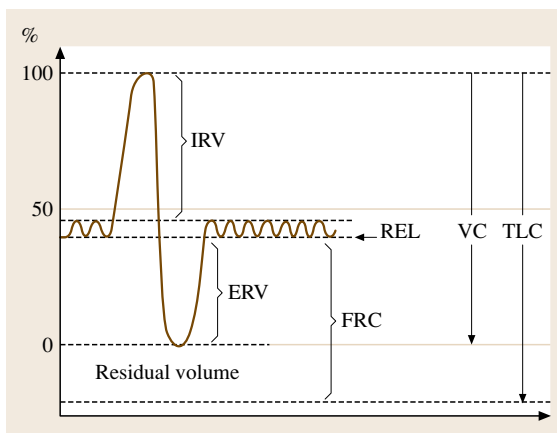
Fig. 16.2 Subglottal pressures produced at different lung volumes in a subject by the recoil forces of rib cage and lungs. The resting expiratory level (REL) is the lung volume at which the inhalatory and the exhalatory recoil forces are equal. The *thin* and *heavy chain-dashed lines* represent subglottal pressures typically needed for soft and very loud phonation


Fig. 16.3 Definition of the various terms for lung volumes. The graph illustrates the lung volume changes during quiet breathing interrupted by a maximal inhalation followed by a maximal exhalation. VC is the vital capacity, TLC is the total lung capacity, IRV and ERV are the inspiratory and expiratory reserve volume, REL is the resting expiratory level, FRC is the functional residual capacity

subglottal pressures, depending on the size of the lung volume, Fig. 16.2. Thus, exhalation and inhalation will always produce forces whose effect is to move the ribs and the lungs back to their resting state, often referred to as the resting expiratory level (REL). The deeper the breath, the greater this force of *elastic recoil*. This component plays a significant part in pushing air out of the lungs, both in speech and singing, and especially at large lung volumes. The elasticity forces originate both from the rib cage and the lungs. As illustrated in Fig. 16.2, the rib cage produces an exhalatory force at high lung volumes and an inhalatory force at low lung volumes, and the lungs always exert an exhalatory force. As a consequence, activation of inspiratory muscles is needed for producing a low subglottal pressure, e.g. for singing a soft (pianissimo) tone, at high lung volume. Conversely, activation of expiratory muscles is needed for producing a high subglottal pressure, e.g. for singing a loud (fortissimo) tone, at low lung volume.

In addition to mechanical factors, exhaling may involve the activity of the *internal intercostals* and the *abdominal muscles*. Contraction of the former has the effect of lowering the ribs and thus compressing the chest cavity. Activating the abdominal muscles generates upward forces that also contribute towards reducing the volume of the rib cage and the lungs. The function of these muscles is thus expiratory.
Fig. 16.4 Examples of speech breathing

Another significant factor is gravity whose role depends on body posture. In an upright position, the diaphragm and adjacent structures tend to be pulled down, increasing the volume of the thoracic cavity. In this situation, the effect of gravity is inspiratory. In contrast, in the supine position the diaphragm tends to get pushed up into the rib cage, and expiration is promoted [16.3].

The total air volume that is contained in a maximally expanded rib cage is called the *total lung capacity* (TLC in Fig. 16.3). After maximum exhalation a small air volume, the *residual volume*, is still left in the airways. The greatest air volume that can be exhaled after a maximum inhalation is called the *vital capacity* (VC) and thus equals the difference between the TLC and the residual volume. The lung volume at which the exhalatory and inhalatory recoil forces are equal, or REL, is reached after a relaxed sigh, see Figs. 16.2 and 16.3. During tidal breathing inhalation is initiated from REL, so that inhalation is active resulting from an activation of inspiratory muscles, and exhalation is passive, produced by the recoil forces. In tidal breathing only some 10% of VC is inhaled, such that a great portion of the VC, the *inspiratory reserve volume*, is left. The air volume between REL and the residual volume is called the *expiratory reserve volume*.

VC varies depending on age, body height and gender. At the age of about 20 years, an adult female
Fig. 16.5 Lung volume averages used in speech and operatic singing expressed as percentages of vital capacity relative to the resting expiratory level REL. The shaded band represents the mean lung volume range observed in untrained female voices' unscripted speech (after [16.1]). The filled and open symbols show the corresponding measures for professional opera singers of the indicated classifications when performing opera arias according to *Thomasson* [16.2]. The bars represent ± one SD

has a vital capacity of 3–3.6 l depending on body height, and for males the corresponding values are about 4–5.5 l.

Experimental data [16.4] show that, during tidal breathing, lung volume variations are characterized by a regular quasi-sinusoidal pattern with alternating segments of inspiration and expiration of roughly equal duration (Fig. 16.4). In speech and singing, the pattern is transformed. Inspirations become more rapid and expiration occurs at a slow and relatively steady rate. Increasing vocal loudness raises the amplitude of the lung volume records but leaves its shape relatively unchanged.

Figure 16.5 shows mean lung volumes used by professional singers when singing well-rehearsed songs. The darker band represents the mean lung volume range observed in spontaneous speech [16.1]. The lung volumes of conversational speech are similar to those in tidal breathing. Loud speech shows greater air consumption and thus higher volumes (Fig. 16.4). Breath groups in speech typically last for 3–5 seconds and are
Fig. 16.6 The records show lung volume (relative to the mid-respiratory level), subglottal (esophageal) pressure and stylized muscular activity for speaker counting from one to 32 at a conversational vocal effort (after *Draper* et al. [16.5]). To the *left of the vertical line* recoil forces are strongly expiratory, to the *right* they are inspiratory. *Arrows* have been added to the *x*-axis to summarize the original EMG measurements which indicate that the recoil forces are balanced by muscular activity (EMG = electromyography, measurement of the electrical activity of muscles). To the *left of the vertical line* (as indicating by *left-pointing arrow*) the net muscular force is inspiratory, to the *right* it is expiratory (*right-pointing arrow*). To keep loudness constant the talker maintains a stable subglottal pressure and recruits muscles according to the current value of the lung volume. This behavior exemplifies the phenomenon known as *motor equivalence*

terminated when lung volumes approach the relaxation expiratory level REL, as illustrated in Fig. 16.5. Thus, in phonation, lung volumes below REL are mostly avoided.

In singing, breath groups tend to be about twice as long or more, and air consumption is typically much greater than in conversational speech. Mostly they are terminated close to the relaxation expiratory level, as
Fig. 16.7 Example of oral and subglottal pressure variations for the phrase *phonetic aspects* (after *Netsell* [16.6]). As the glottis opens and closes for voiceless and voiced sounds and the vocal tract opens or closes for vowels and consonants, the expired air is opposed by varying degrees of glottal and supraglottal impedance. Both the oral and the subglottal pressure records reflect the combined effect of these resistance variations

in speech, but sometimes extend into the *expiratory reserve volume* as illustrated in Fig. 16.5. This implies that, in singing, breath groups typically start at much higher lung volumes than in speech. This use of high lung volumes implies that singers have to deal with much greater recoil forces than in speech.

Figure 16.6 replots, in stylized form, a diagram published by *Ladefoged* et al. [16.7]. It summarizes measurements of lung volume and subglottal pressure, henceforth referred to as Ps, recorded from a speaker asked to take a deep breath and then to start counting. The dashed line intersecting the Ps record represents the relaxation pressure. This line tells us that elastic recoil forces are strongly expiratory to the left of the vertical line. To the right they produce a pressure lower than the target pressure and eventually an inspiratory pressure. The Ps curve remains reasonably flat throughout the entire utterance.

The question arises: how can this relative constancy be achieved despite the continually changing contribution of the relaxation forces? In a recent replication of this classical work [16.8], various criticisms of the original study are addressed but basically the original answer to this question is restated: the motor system adapts to the external goal of keeping the Ps fairly

constant (Fig. 16.6). Initially, when recoil forces are strong, muscle activity is predominantly in the *inspiratory* muscles such as the *diaphragm* and the *external intercostals*. Gradually, as recoil forces decline, the *expiratory* muscles (the *internal intercostals*, the *rectus abdominis* among others) take over increasingly as the other group relaxes (cf. arrows, Fig. 16.6). According to our present understanding [16.8, 9], this adaptation of breathing for speech is achieved by constantly updating the balance between agonist and antagonist muscles in accordance with current conditions (lung volume, body posture, etc.) and in order to meet the goal of constant Ps. Muscle recruitment depends on lung volume.

Figure 16.7 presents a representative example of oral and Ps records. The phrase is *phonetic aspects* (after *Netsell* [16.6]). The top panel shows a record of oral air flow. Vertical lines indicate acoustic segment boundaries. The bottom diagram superimposes the curves for oral and subglottal pressure.

The Ps shows a falling pattern which becomes more pronounced towards the end of the phrase and which is reminiscent of the declination pattern of the fundamental frequency contour typical of declarative sentences [16.10, p. 127]. The highest values occur at the midpoints of [ɛ] and [æ], the stressed vowels of the utterance. For vowels, oral pressure is close to atmospheric pressure (near zero on the *y*-axis cm H_2O scale). The [k] of *phonetic* and the [p] of *aspects* show highly similar traces. As the tongue makes the closure for [k], the air flow is blocked and the trace is brought down to zero. This is paralleled by the oral pressure rising until it equals the Ps. As the [k] closure progresses, a slight increase builds up in both curves. The release of the [k] is signaled by a peak in the air flow and a rapid decrease in Ps. An almost identical pattern is seen for [p].

In analyzing Ps records, phoneticians aim at identifying variations based on an *active control* of the respiratory system and phenomena that can be attributed to the system's *passive response* to ongoing activity elsewhere, e.g., in the vocal tract and or at the level of the vocal folds [16.11].

To exemplify passive effects let us consider the events associated with [k] and [p] just discussed. As suggested by the data of Figs 16.4 and 16.6, speech breathing proceeds at a relatively steady lung volume decrement. However, the open or closed state of the glottis, or the presence of a vocal tract constriction/closure, is capable of creating varying degrees of impedance to the expired air. The oral pressure record reflects the combined effect of glottal and articulatory resistance variations. Ps is also affected by such chang-

ing conditions. As is evident from Fig. 16.7, the Ps traces during the [k] and [p] segments first increase during the stop closures. Then they decrease rapidly during the release and the aspiration phases. These effects are passive responses to the segment-based changes in supraglottal resistance and are unlikely to be actively programmed [16.12, 13].

Does respiration play an active role in the production of stressed syllables? In *phonetic aspects* main stress occurs on [ɛ] and [æ]. In terms of Ps, these vowels exhibit the highest values. Are they due to an active participation of the respiratory system in signaling stress, or are they fortuitous by-products of other factors?

An early contribution to research on breathing and speech is the work by *Stetson* [16.14]. On the basis of aerodynamic, electromyographic and chest movement measurements, Stetson proposed the notion of the *chest pulse*, a chunk of expiratory activity corresponding to the production of an individual syllable.

In the late fifties, *Ladefoged* and colleagues published an electromyographic study [16.7] which cast doubt on Stetson's interpretations. It reported increased activity in expiratory muscles (*internal intercostals*) for English syllables. However, it failed to support Stetson's chest pulse idea in that the increases were found only on stressed syllables. *Ladefoged* [16.8] reports findings from a replication of the 1958 study in which greater activity in the internal intercostals for stressed syllables was confirmed. Moreover, reduced activity in inspiratory muscles (*external intercostals*) was observed to occur immediately before each stressed syllable.

Ps measurements provide further evidence for a positive role for respiration in the implementation of stress. *Ladefoged* [16.15, p. 143] states: *Accompanying every stressed syllable there is always an increase in the Ps.* This claim is based on data on disyllabic English noun–verb pairs differing in the position of the main stress: *TORment* (noun)–*torMENT* (verb), *INsult* (noun)–*inSULT* (verb) etc. A clear distinction between the noun and verb forms was observed, the former having Ps peaks in the first syllable and the latter on the second syllable.

As for segment-related Ps variations (e.g., the stops in Fig. 16.7), there is wide agreement that such local perturbations are induced as automatic consequences of speech production aerodynamics. Explaining short-term ripple on Ps curves in terms of aerodynamics is consistent with the observation that the respiratory system is mechanically sluggish and therefore less suited to implement rapid Ps changes in individual phonetic segments. Basically, its primary task is to produce a Ps
Fig. 16.8 Changes in esophageal pressure, corresponding to subglottic pressure changes (*upper curve*) and phonation frequency (*middle*) in a professional baritone singer performing the coloratura passage shown at the bottom (after *Leanderson* et al. [16.16])

Fig. 16.9 The three *curves* show, from *top to bottom* F0 sound level and esophageal pressure in a professional baritone singer singing the music example shown in the *graph*, i. e. a descending scale with three tones on each scale tone. The singer marked the first beat in each bar by a pressure pulse (after *Sundberg* et al. [16.17])

contour stable enough to maintain vocal intensity at a fairly constant level (Fig. 16.6).

Singing provides experimental data on the behavior of the respiratory system that tend to reinforce the view that a time varying respiration activity can be an active participant in the sound generation process. Although there is ample justification for saying that the mechanical response of the respiratory structures is characterized by a long time constant, Ps in singing varies quickly and accurately. One example is presented in Fig. 16.8. It shows variations in pressure, captured as the pressure variations in the esophagus and thus mirroring the Ps variations [16.18], during a professional baritone singer's performance of the music example shown at the bottom. Each tone in the sequence of sixteenth notes is produced with a pressure pulse. Note also that in the fundamental frequency curve each note corresponds to a small rise and fall. The tempo of about six sixteenth notes per second implies that the duration of each rise–fall cycle is about 160 ms. It would take quite special skills to produce such carefully synchronized Ps and fundamental frequency patterns.

Synthesis experiments have demonstrated that this particular fundamental frequency pattern is what produces what is perceived as a sung legato coloratura [16.19, 20]. The voice organ seems incapable of producing a stepwise-changing F0 curve in legato, and such a performance therefore sounds as if it was produced by a music instrument rather than by a voice. In this sense this F0 variation pattern seems to be needed for eliciting the perception of a sung sequence of short legato tones.

The pressure variations are not likely to result from a modulation of glottal adduction. A weak glottal adduction should result in a voice source dominated by the fundamental and with very weak high spectrum partials, and mostly the amplitudes of the high overtones do not vary in coloratura sequences.

It is quite possible that the F0 variations are caused by the Ps variations. In the example shown in Fig. 16.8, the pressure variations amount to about 10 cm H_2O, which should cause a F0 modulation of about 30 Hz or so, corresponding to two semitones in the vicinity of 220 Hz. This means that the coloratura pattern may simply be the result of a ramp produced by the F0 regulating system which is modulated by the pressure pulses produced by the respiratory system.

As another example of the skilled use of Ps in singing, Fig. 16.9 shows the pressure variation in the esophagus in a professional baritone singer performing a descending scale pattern in 3/4 time, with three tones on each scale step as shown by the score fragment in the first three bars. The singer was instructed to mark the first tone in each bar. The pressure record demonstrates quite clearly that the first beat was produced with a marked pulse approximately doubling the pressure. Pulses of this magnitude must be produced by the respiratory apparatus. When the subject was instructed to avoid marking the first tone in each bar, no pressure pulses were observed [16.17].
Fig. 16.10 Mean subglottal pressure, captured as the oral pressure during /p/-occlusion, in five lyric and six dramatic professional sopranos (*heavy* and *thin curves*, respectively) who sang as loudly and as softly as possible at different F0. The *dashed curve* shows Titze's prediction of threshold pressure, i.e., the lowest pressure that produces vocal fold vibration. The *bars* represent one SD (after [16.21])

Fig. 16.11 Simultaneous recordings of sound level, subglottic pressure (captured as the oral pressure during /p/ occlusion) and F0 in a professional singer singing the note example shown at the bottom (after *Leanderson* et al. [16.16])

The effect of Ps on fundamental frequency has been investigated in numerous studies. A commonly used method is to ask the subject to produce a sustained vowel at a given steady pitch and then, at unpredictable moments, change the Ps by applying a push to the subject's abdomen or chest. The assumption underlying these studies is that there will be an initial interval during which possible reflex action of laryngeal muscles will not yet come into play. Hence the data from this time segment should give a valid picture of the relationship between fundamental frequency and Ps.

In a study using the push method, *Baer* [16.22] established this relationship for a single male subject. Data on steady phonations at 94, 110, 220 Hz and a falsetto condition (240 Hz) were collected. From electromyograms from the *vocalis* and the *interarytenoid* it was possible to tell that the first 30 ms after the push onset were uncontaminated by reflex muscle re-

sponses. Fundamental frequency was plotted against Ps for the four F0 conditions. These plots showed linear data clusters with slopes of 4, 4, 3 and 9 Hz/cm H_2O respectively. Other studies which assumed a longer reflex response latency (100 ms) report that F0's dependence on Ps occurs between 2 to 7 Hz/cm H_2O.

From such observations phoneticians have concluded that, in producing the F0 variations of natural speech, Ps plays only a secondary role. F0 control is primarily based on laryngeal muscle activity. Nonetheless, the falling F0 contours of phrases with statement intonation tend to have Ps contours that are also falling. Moreover, in questions with final F0 increases, the Ps records are higher towards the end of the phrase than in the corresponding statements [16.15].

There is clear evidence that the Ps needs to be carefully adapted to the target fundamental frequency in

Part E | 16.1

singing, especially in the high range ([16.23], [16.24, p. 36]). An example is presented in Fig. 16.10 which shows mean Ps for five dramatic and five lyric sopranos when they sang pp and ff tones throughout their range [16.21]. The bars represent one standard deviation. The dashed curve is the threshold pressure, i. e. the lowest pressure that produced vocal fold vibration, for a female voice according to *Titze* [16.25, 26].

The singers mostly used more than twice as high Ps values when they were singing their loudest as compared with their softest tones. The subjects reach up to 40 cm H_2O. This can be compared with values typical of normal adult conversational speech, which tend to occur in the range of 5–10 cm H_2O. However, loud speech and particularly stage speech may occasionally approach the higher values for singing.

Also interesting is the fact that lyric sopranos use significantly lower Ps values than dramatic sopranos both in soft and loud phonation. It seems likely that this difference reflects difference in the mechanical properties of the vocal folds.

Figure 16.11 presents another example of the close link between Ps and fundamental frequency. From top to bottom it plots the time functions for sound level (SPL in dB), pressure (cm H_2O), fundamental frequency (Hz) for a professional baritone singing an ascending triad followed by a descending dominant-

seventh triad (according to the score at the bottom). The pressure record was obtained by recording the oral pressure as the subject repeated the syllable [pæ] on each note. During the occlusion of the stop the peak oral pressure becomes equal to the Ps (as discussed in connection with Fig. 16.7). That means that the peak values shown in the middle diagram are good estimates of the actual Ps. It is important to note that, when the trace repeatedly returns to a value near zero, what we see is not the Ps, but the oral pressure reading for the [æ] vowel, which is approximately zero.

The exercise in Fig. 16.11 is often sung staccato, i. e. with short pauses rather than with a /p/ consonant between the tones. During these pauses the singer has to get ready for the next fundamental frequency value and must therefore avoid exhaling the pressurized air being built up in the lungs. Singers do this by opening the glottis between the tones and simultaneously reducing their Ps to zero, so that no air will be exhaled during the silent intervals between the tones. A remarkable fact demonstrated here is that, particularly when sung loudly – so that high Ps values are used – this exercise requires nothing less than a virtuoso mastering of both the timing and tuning of the breathing apparatus and the pitch control process. A failure to reach a target pressure is likely to result in a failure to reach the target F0.

16.2 The Glottal Sound Source

In speech and singing the general method to generate sound is to make a constriction and to let a strong flow of air pass through it. The respiratory component serves as the power source providing the energy necessary for sound production. At the glottis the steady flow of air generated by the respiratory component is transformed into a quasiperiodic series of glottal pulses. In the vocal tract, the glottally modified breath stream undergoes further modifications by the resonance characteristics of the oral, pharyngeal and nasal cavities.

Constrictions are formed at the glottis – by adjusting the separation of the vocal folds – and above the glottis – by positioning the articulators of the vocal tract. As the folds are brought close together, they respond to the air rushing through by initiating an open–close vibration and thereby imposing a quasiperiodic modulation of airflow. Thus, in a manner of speaking, the glottal structures operate as a device that imposes an AC modulation on a DC flow. This is basically the way that *voicing*, the sound source of voiced vowels and con-

sonants and the carrier of intonation and melody, gets made.

A second mechanism is found in the production of *noise*, the acoustic raw materials for voiceless sounds (e.g., [f], [s], [p], [k]). The term refers to irregular turbulent fluctuations in airflow which arise when air comes out from a constriction at a high speed. This process can occur at the glottis – e.g., in [h] sounds, whisper and breathy voice qualities – or at various places of articulation in the vocal tract.

The framework for describing both singing and speech is that of the *source-filter theory of speech production* [16.27, 28]. The goal of this section is to put speech and singing side by side within that framework and to describe how the speaker and the singer coordinate respiration, phonation and articulation to shape the final product: the acoustic wave to be perceived by the listener.

Figure 16.12 [16.29] is an attempt to capture a few key aspects of vocal fold vibrations. At the center a sin-
Fig. 16.12 Relationship between the flow glottogram, showing transglottal airflow versus time, and glottal configurations in a coronal plane (*upper series* of images) and from above, as through a laryngeal mirror (*lower series* of images). The airflow increases when the folds open the glottis and allow air to pass and decreases quickly when they close the glottis and arrest the airflow (after [16.29])

Fig. 16.13a,b Illustration of measures commonly used to characterize a flow glottogram (**a**) and its time derivative, the differentiated flow glottogram (**b**). (The *wiggles* in the latter are artifacts caused by an imperfect inverse filtering)

gle cycle of a glottal waveform is seen. It plots airflow through the glottis as a function of time. Alternatively, the graph can be used to picture the time variations of the glottal area which present a pattern very similar to that for airflow. The top row shows stylized cross sections of the vocal folds at selected time points during the glottal cycle. From left to right they refer to the opening of the folds, the point of maximum area and the point of closure. Below is a view of the vocal folds from above corresponding to the profiles at the top of the diagram.

There are a number of different methods for visualizing vocal fold vibrations. By placing an electrode on each side of the thyroid cartilage, a minute current can be transferred across the glottis. This current increases substantially when the folds make contact. The resulting *electroglottogram*, also called a *laryngogram*, thus shows how the contact area varies with time. It is quite efficient in measurement of F0 and closed phase. *Optical glottograms* are obtained by illuminating the trachea from outside by means of a strong light source and capturing the light traveling through the glottis by means of an optical sensor in the pharynx. The signal therefore reflects the glottal area, but only as long as the light suc-

cessfully finds it way to the sensor. A posterior tilting of the epiglottis may easily disturb or eliminate the signal.

Flow glottograms show transglottal airflow versus time and are derived by inverse filtering the audio signal, often picked up as a flow signal by means of a pneumotachograph mask [16.30]. Inverse filtering implies that the signal is passed through a filter with a transfer function equalling the inverted transfer function of the vocal tract. Therefore correct inverse filtering requires that the inverted resonance peaks of the inverse filter are tuned to the formant frequencies of the vowel being filtered.

As transglottal airflow is zero when the glottis is closed and nonzero when it is open, the flow glottogram is physiologically relevant. At the same time it is a representation of the sound of the voice source.

A typical example of a flow glottogram is given in the upper graph of Fig. 16.13. The classical parameters derived from flow glottograms are the durations of the period and of the closed phase, pulse peak-to-peak amplitude, and glottal leakage. The lower graph shows the differentiated glottogram. The negative peak amplitude is often referred to as the *maximum flow declination rate* (MFDR). As we shall see it has special status in the process of voice production.

In the study of both speech and singing, the acoustic parameter of main relevance is the time variations in sound pressure produced by the vocal system and re-

ceived by the listener's ears. Theoretically, this signal is roughly proportional to the derivative of the output airflow at the lips [16.28, 31] and it is related to the derivative of the glottal waveform via the transfer function of the vocal tract. Formally, the excitation signal for voiced sounds is defined in terms of this differentiated signal. Accordingly, in source-filter theory, it is the derivative of glottal flow that represents the source and is applied to the filter or resonance system of the vocal tract. The amplitude of the vocal tract excitation, generally referred to as the *excitation strength*, is quantified by the maximum velocity of flow decrease during vocal-fold closing movement (the MFDR, Fig. 16.13) which is a determinant of the level of the radiated sound. At the moment of glottal closure a drastic modification of the air flow takes place. This change is what generates voicing for both spoken and sung sounds and produces a sound with energy across a wide range of frequencies.

The Liljencrants–Fant (LF) model [16.32, 33] is an attempt to model glottal waveforms using parameters such as fundamental frequency, excitation strength, dynamic leakage, open quotient and glottal frequency (defined by the time period of glottal opening phase). Other proposals based on waveform parameters have been made by *Klatt* and *Klatt* [16.34], *Ljungqvist* and *Fujisaki* [16.35], *Rosenberg* [16.36] and *Rothenberg* et al. [16.37]. A second line of research starts out from assumptions about vocal fold mechanics and applies aerodynamics to simulate glottal vibrations [16.38, 39]. Insights from such work indicate the importance of parameters such as Ps, the adducted/abducted position of vocal folds and their stiffness [16.28].

During the early days of speech synthesis it became clear that the simplifying assumption of a constant voice source was not sufficient to produce high-quality natural-sounding copy synthesis. Experimental work on the voice source and on speech synthesis has shown that, in the course of an utterance, source parameters undergo a great deal of variation. The determinants of this dynamics are in part prosodic, in part segmental. Figure 16.14 [16.32] presents a plot of the time variations of the *excitation strength* parameter (i.e. MFDR) during the Swedish utterance: *Inte i DETta århundrade* [ɪntɪ ˣdɛtːaoːrhəndradɛ]. The upper-case letters indicate that the greatest prominence was on the first syllable of *detta*. Vertical lines represent acoustic segment boundaries.

Gobl collected flow data using the mask developed by *Rothenberg* [16.30] and applied inverse filtering to obtain records of glottal flow which, after differentiation, enabled him to make measurements of excitation strength and other LF parameters.

Figure 16.14 makes clear that excitation strength is in no way constant. It varies depending on both prosodic and segmental factors. The effect of the segments is seen near the consonant boundaries. As the vocal tract is constricted, e.g., in [d] and [tː], and as transglottal pressure therefore decreases (cf. the pressure records of Fig. 16.7), excitation strength is reduced. In part these variations also occur to accommodate the voicing and the voicelessness of the consonant [16.28]. This influence of consonants on the voice source has been documented in greater detail by *Ni Chasaide* and *Gobl* [16.40] for German, English, Swedish, French, and Italian. Particularly striking effects were observed in the context of voiceless consonants.

Prosodically, we note in Fig. 16.14 that excitation strength exhibits a peak on the contrastively stressed syllable in *detta* and that the overall pattern of the phrase

is similar to the falling declination contour earlier mentioned for declarative statements.

Examples of the fact that the Ps has a strong influence on the flow glottogram are given in the upper set of graphs of Fig. 16.15, which shows a set of flow glottograms for phonations produced at the same pitch but with varying degrees of *vocal loudness*. As we examine the series of patterns from loudest to softest we note that both the peak flow and the maximum steepness of the trailing end of the pulse, i. e., MFDR, increase significantly with increasing Ps. These shape changes are lawfully related to the variations in Ps and are directly reflected in sound pressure levels as indicated by the numbers in Table 16.1.

Holmberg and colleagues [16.41] made acoustic and airflow recordings of 25 male and 20 female speakers producing repetitions of [pæ] at soft, normal and loud vocal efforts [16.42, p. 136]. Estimates of Ps and glottal airflow were made from recordings of oral pressure and oral airflow. Ps was derived by interpolating between peak oral pressures for successive [p] segments and then averaging across repetitions. A measure of

Fig. 16.15a,b Typical flow glottogram changes associated with changes of loudness (**a**) or mode of phonation (**b**). As loudness of phonation is raised, the closing part of the curve becomes more steep. When phonation is pressed, the glottogram amplitude is low and the closed phase is long. As the adduction force is reduced, pulse amplitude grows and the closed phase becomes shorter (note that the flow scales are different for the (**a**) and (**b**) of glottograms). Flowy phonation is the least adducted, and yet not leaky phonation ◄

average flow was obtained by low-pass filtering the air-flow signal and averaging values sampled at the vowel midpoints. A copy of the airflow signal was low-pass filtered and inverse filtered to remove the effect of F1 and other formants. The output was then differentiated for the purpose of determining the MFDR (Fig. 16.13).

Figure 16.15 also illustrates how the voice source can be continuously varied between different *modes of phonation*. These modes range from hyperfunctional, or pressed, over neutral and flowy to hypofunctional, or breathy. The corresponding physiological control parameter can be postulated to be glottal adduction, i. e. the force by which the folds press against each other. It varies from minimum in hypofunctional to extreme in hyperfunctional. Flowy phonation is produced with the weakest degree of glottal adduction compatible with a full glottal closure. The physiologically relevant property that is affected is the vibration amplitude of the vocal folds, which is small in hyperfunctional/pressed phonation and wide in breathy phonation.

As illustrated in Fig. 16.15 the flow glottogram is strongly affected by these variations in phonation mode [16.43]. In pressed phonation, the pulse amplitude is small and the closed phase is long. It is larger in neutral and even more so in flowy. In breathy phonation, typically showing a waveform similar to a sine wave, airflow is considerable, mainly because of a large leakage, so there is no glottal closure.

Phonation mode affects the relation between Ps and the SPL of the sound produced. As shown in Table 16.1B pressed phonation is less economical from an acoustic point of view: a Ps of 11.4 cm H_2O produces an SPL at 0.3 m of only 83 dB, while in flowy phonation a lower Ps produces a higher SPL.

Pitch, loudness and phonation mode are voice qualities that we can vary continuously. By contrast, vocal registers, also controlled by glottal parameters, appear more like toggles, at least in untrained voices. The voice is operating either in one or another register. There are at least three vocal registers, *vocal fry*, *modal* and *falsetto*. When shifting between the modal and falsetto registers, F0 discontinuities are often observed [16.44].

The definition of vocal registers is quite vague, a set of tones along the F0 continuum that sound similar and are felt to be produced in a similar way. As registers depend on glottal function, they produce different flow glottogram characteristics. Figure 16.16 shows typical examples of flow glottograms for the falsetto and modal registers as produced by professional baritone, tenor and countertenor singers. The pulses are more rounded, the closed phase is shorter, and the glottal leakage is greater in the falsetto than in the modal register. However, the waveform of a given register often varies substantially between individuals. Classically trained sopranos, altos, and tenors learn to make continuous transitions between the modal and
Fig. 16.16a–c Typical flow glottograms for falsetto and modal register in (**a**) a baritone, (**b**) tenor and (**c**) countertenor singer, all professional. The flow scale is the same within subjects. The ripple during the closed phase in the lower middle glottogram is an artifact. In spite of the great inter-subject variability, it can be seen that the glottogram pulses are wider and more rounded in the falsetto register
Fig. 16.17 Long-term-average spectra curves obtained from an untrained male speaker reading the same text at 6 different degrees of vocal loudness. From *top to bottom* the corresponding L_{eq} values at 0.3 m were 93 dB, 88 dB, 85 dB, 84 dB, 80 dB, and 76 dB

Fig. 16.18a,b Graph (**a**) shows the relationship between the mean subglottal pressure and the mean MFDR for the indicated subject groups. Graph (**b**) shows the relationship between MFDR and the SPL at 0.3 m for a professional baritone singing the vowels /a/ and /æ/ at different F0s (after [16.45, p. 183] and [16.46, p. 184])

the falsetto registers, avoiding abrupt changes in voice timbre.

Variation of vocal loudness affects the spectrum slope as illustrated in Fig. 16.17, which shows long-term-average spectra (LTAS) from a male untrained voice. In the figure loudness is specified in terms of the so-called equivalent sound level L_{eq}. This is a commonly used time average of sound level, defined as

$$ L_{eq} = 10 \log \frac{1}{T} \int_0^T \frac{p^2}{p_0^2} \, dt \, , $$

where t is time and T the size of the time window. p and p_0 are the sound pressure and the reference pressure, respectively.

When vocal loudness is changed, the higher overtones change much more in sound level than the lower overtones. In the figure, a 14 dB change of the level near 600 Hz is associated with a 22 dB change near 3000 Hz, i.e., about 1.5 times the level change near 600 Hz. Similar relationships have been observed for professional singers [16.47]. In other words, the slope of the voice source spectrum decreases with increasing vocal loudness.

The physiological variable used for variation of vocal loudness is Ps. This is illustrated in the upper graph of Fig. 16.18, comparing averaged data observed in untrained female and male subjects and data obtained from professional operatic baritone singers [16.45, 46]. The relationship between the Ps and MFDR is approximately linear. It can be observed that the pressure range used by the singer is considerably wider than

that used by the untrained voices. The MFDR produced with a given Ps by the untrained female and male subjects is mostly higher than that produced by the baritones with the same pressure. This may depend on different mechanical characteristics of the vocal folds.

As we will see later, SPL depends on the strength of the excitation of the vocal tract, i.e. on MFDR. This

variable, in turn, depends on Ps and F0; the higher the pressure, the greater the MFDR value and the higher the F0, the greater the MFDR. The top graph of Fig. 16.18 shows how accurately MFDR could be predicted from Ps and F0 for previously published data for untrained male and female singers and for professional baritone singers [16.45, 46]. Both Ps and F0 are linearly related to MFDR. However, the singers showed a much greater variation with F0 than the untrained voices. This differ-

ence reflected the fact that unlike the untrained subjects the singers could sing a high F0 much more softly than the untrained voices. The ability to sing high notes also softly would belong to the essential expressive skills of a singer. Recalling that an increase of Ps increases F0 by a few Hz/cm H_2O, we realize that singing high tones softly requires more forceful contraction of the pitch-raising laryngeal muscles than singing such tones loudly.

16.3 The Vocal Tract Filter

The source-filter theory, schematically illustrated in Fig. 16.19, describes vocal sound production as a three-step process: (1) generation of a steady flow of air from the lungs (DC component); (2) conversion of this airflow into a pseudo-periodically pulsating trans-glottal airflow (DC-to-AC conversion), referred to as the voice source; and (3) response of the vocal tract to this excitation signal (modulation of AC signal) which is characterized by the frequency curve or transfer function of the vocal tract. So far the first two stages, respiration and phonation, have been considered.

In this section we will discuss the third step, viz. how the vocal tract filter, i. e. the resonance character-istics of the vocal tract, modifies, and to some extent interacts with, the glottal source and shapes the final sound output radiated from the talker's/singer's lips.

Resonance is a key feature of the filter response. The oral, pharyngeal and nasal cavities of the vocal tract form a system of resonators. During each glottal cycle the air enclosed by these cavities is set in motion by the glottal pulse, the main moment of excitation occurring during the closing of the vocal folds, more precisely at the time of the MFDR, the maximum flow declination rate (cf. the previous section on source).

The behavior of a vocal tract resonance, or *formant*, is specified both in the time and the frequency domains. For any transient excitation, the time response is an exponentially decaying cosine [16.27, p. 46]. The frequency response is a continuous amplitude-frequency spectrum with a single peak. The shape of either func-tion is uniquely determined by two numbers (in Hz): the formant frequency F and the bandwidth B. The bandwidth quantifies the degree of damping, i. e., how fast the formant oscillation decays. Expressed as sound pressure variations, the time response is

$$p(t) = A\,e^{-\pi Bt} \cos\left(2\pi Ft\right)\ . \tag{16.1}$$
Fig. 16.19 Schematic illustration of the generation of voice sounds. The vocal fold vibrations result in a sequence of voice pulses (*bottom*) corresponding to a series of harmonic overtones, the amplitudes of which decrease monotonically with frequency (*second from bottom*). This spectrum is filtered according to the sound transfer char-acteristics of the vocal tract with its peaks, the formants, and the valleys between them. In the spectrum radiated from the lip opening, the formants are depicted in terms of peaks, because the partials closest to a formant frequency reach higher amplitudes than neighboring partials ◄
Fig. 16.20 (a) Predictability of formant levels; **(b)** calculated spectral envelopes for a set of Swedish vowels. Graph **(a)** illustrates how varying only the frequency of F1 affects the amplitudes of other formants

For a single formant curve, the amplitude variations as a function of frequency f is given (in dB) by

$$L(f) = 20 \log \frac{\left[F^2 + \left(\frac{B}{2}\right)^2 \right]}{\sqrt{(f-F)^2 + \left(\frac{B}{2}\right)^2} \sqrt{(f+F)^2 + \left(\frac{B}{2}\right)^2}} .$$

(16.2)

In the frequency domain the bandwidth is defined as the width of the formant 3 dB down from the peak, that is, at the half-power points. A large bandwidth produces a flat peak whereas a small value (less damping, reduced acoustic losses) makes the peak higher and sharper.

Figure 16.20 shows spectral envelopes for a set of Swedish vowels. They were calculated from formant frequency data [16.48, 49] in accordance with source-filter theory which assumes that a vowel spectrum can be decomposed into formants (all specified with respect

to frequency and bandwidth), the spectrum of the voice source, the contribution of formants above F4 and radiation [16.27].

The individual panels are amplitude versus frequency plots. Vowels are portrayed in terms of their envelopes rather than as line spectra with harmonics. The panels are arranged in a *formant space*. From top to bottom the F2 in the panels decreases. From left to right F1 increases. The frequency scale is limited to showing the first three formant peaks.

We note that all envelopes have falling overall slopes and that the amplitudes of the formant peaks vary a great deal from vowel to vowel and depending on the relative configuration of formant frequency positions.

In acoustic phonetic specifications of vowels, it is customary to report no more than the frequencies of the first two or three formants ([16.50, p. 59], [16.51]). Experiments in speech synthesis [16.52] have indicated that this compact description is sufficient to capture the quality of steady-state vowels reasonably well. Its relative success is explained by the fact that most of the building blocks of a vowel spectrum are either predictable (bandwidths and formant amplitudes), or show only limited spectral variations (source, radiation, higher-formant correction) [16.27].

Formant bandwidths [16.28, 53] reflect acoustic losses. They depend on factors such as radiation, sound transmission through the vocal tract walls, viscosity, heat conduction, constriction size as well as the state of the glottis. For example, a more open glottis, as in a breathy voice, will markedly increase the bandwidth of the first formant.

Despite the complex interrelations among these factors, bandwidths pattern in regular ways as a function of formant frequency. Empirical formulas have been proposed [16.54] that summarize bandwidth measurements made using transient and sweep-tone excitation of the vocal tract for closed-glottis conditions [16.55, 56].

To better understand how formant levels vary let us consider the top diagram of Fig. 16.20. It compares envelopes for two vowel spectra differing only in terms of F1. It is evident that the lowering of F1 (from 750 to 250 Hz) reduces the amplitudes of F2 and F3 by about 15 dB. This effect is predicted by acoustic theory which derives the spectral envelope of an arbitrary vowel as a summation of individual formant curves on a dB scale [16.27]. Figure 16.20 makes clear that, as F1 is shifted, its contribution to the envelope is drastically changed. In this case the shift moves the entire F1 curve down in frequency and, as a result, its upper skirt (dashed line) provides less of a *lift* to the upper for-

mants. This interplay between formant frequency and formant levels is the major determinant of the various envelope shapes seen in Fig. 16.20.

One of the main lessons of Fig. 16.20 is accordingly that, under normal conditions of a stable voice source, formant amplitudes are predictable. Another important consequence of the source-filter theory is that, since knowing the formants will enable us to reconstruct the vowel's envelope, it should also make it possible to derive estimates about a vowel's overall intensity.

A vowel's intensity can be calculated from its power spectrum as

$$I = 10 \log \left[\sum (A_i)^2 \right], \qquad (16.3)$$

where A_i is the sound pressure of the i-th harmonic. This measure tends to be dominated by the strongest partial or partials. In very soft phonation the strongest partial is generally the fundamental while in neutral and louder phonation it is the partial that lies closest to the first formant. Thus, typically all partials which are more than a few dB weaker than the strongest partial in the spectrum do not contribute appreciably to the vowel's intensity.

As suggested by the envelopes in Fig. 16.20, the strongest harmonics in vowels tend to be found in the F1 region. This implies that a vowel's intensity is primarily determined by its F1. Accordingly, in the set shown in Fig. 16.20, we would expect [iːyːʉːuː] to be least intense and [æːaɑː] the most intense vowels. This is in good agreement with experimental observations [16.57].

The intrinsic intensity of vowels and other speech sounds has been a topic of interest to phoneticians studying the acoustic correlates of stress [16.58]. It is related to sonority, a perceptual attribute of speech sounds that tends to vary in a regular way in syllables [16.59]. We will return below to that topic in Sect. 16.5.

Let us continue to illustrate how formant levels depend on formant frequencies with an example from singing: the singer's formant. This striking spectral phenomenon is characteristic of classically trained male singers. It is illustrated in Fig. 16.21. The figure shows a spectrogram of a commercial recording of an operatic tenor voice (Jussi Björling) performing a *recitativo* from Verdi's opera Aida. Apart from the vibrato undulation of the partials, the high levels of partials in the frequency range 2200–3200 Hz are apparent. They represent the singer's formant.

The singer's formant is present in all voiced sounds as sung by operatic male singers. It was first discovered by *Bartholomew* [16.60]. It manifests itself as
Fig. 16.21 Spectrogram of operatic tenor Jussi Björling's performance of an excerpt from Verdi's opera *Aida*. The lyrics are given below the graph
Fig. 16.22 LTAS of the sound of a symphonic orchestra with and without a singer soloist (*dark* and *light curves*). The singer's formant constitutes a major difference between the orchestra with and without the singer soloist (after [16.61])
Fig. 16.23 Effect on the spectrum envelope of lowering formants F4 and F5 from 3500 Hz and 4500 Hz to 2700 Hz and 3500 Hz, respectively. The resulting gain in level at F3 is more than 10 dB

a high, marked peak in the long-term-average spectrum (LTAS).

A second example is presented in Fig. 16.22 showing an LTAS of the same tenor voice as in Fig. 16.21, accompanied by an orchestra of the traditional western opera type. The LTAS peak caused by the singer's formant is just a few dB lower than the main peak in the low-frequency range.

In the same figure an LTAS of a classical symphony orchestra is also shown. On the average, the partials in the low-frequency range are quite strong but those above 600 Hz decrease by about 10 dB/octave with rising frequency. Even though this decrease varies depending on how loudly the orchestra is playing, this implies that the level of the orchestral accompaniment is much lower at 3000 Hz than at about 600 Hz. In other words, the orchestral sound offers the singer a rather reasonable competition in the frequency range of the singer's formant. The fact of the matter is that a voice possessing a singer's formant is much easier to hear when the orchestral accompaniment is loud than a voice lacking a singer's formant. Thus, it helps the singer's voice to be heard when the orchestral accompaniment is loud.

The singer's formant can be explained as a resonance phenomenon [16.62]. It is a product of the same rules that we invoked above to account for the formant amplitudes of vowels and for intrinsic vowel intensities. The strategy of a classically trained male singer is to shape his vocal tract so as to make F3, F4, and F5 form a tight cluster in frequency. As the frequency separations among these formants are decreased, their individual levels increase, and hence a high spectral peak is obtained between 2500 and 3000 Hz.

Figure 16.23 shows the effects on the spectrum envelope resulting from lowering F5 and F4 from 3500 Hz and 4500 Hz to 2700 Hz and 3500 Hz, respectively. The resulting increase of the level of F3 amounts to 12 dB, approximately. This means that male operatic singers produce a sound that can be heard more easily through a loud orchestral accompaniment by tuning vocal tract resonances rather than by means of producing an excessive Ps.

The acoustical situation producing the clustering of F3, F4, and F5 is obtained by acoustically mismatching the aperture of the larynx tube, also referred to as the epilaryngeal tube, with the pharynx [16.62]. This can be achieved by narrowing this aperture. Then, the larynx tube acts as a resonator with a resonance that is not much affected by the rest of the vocal tract but rather by the shape of the larynx tube. Apart from the size of the aperture, the size of the laryngeal ventricle would be influential: the larger the ventricle, the lower the larynx tube resonance. Presumably singers tune the larynx tube resonance to a frequency close to F3. The articulatory means used to establish this cavity condition seems mainly to be a lowering of the larynx, since this tends to widen both the pharynx and the laryngeal ventricle. Many singing teachers recommend students to sing with a comfortably low larynx position.
Fig. 16.24 Mean LTAS derived from commercial recordings of four representatives of each of the indicated voice classifications. The *dashed curves* show LTAS of untrained female (red) and male (blue) voices' speech with an L_{eq} of 70 dB at 0.3 m. Note that the singer's formant produces a prominent peak with a level well above the level of the untrained voices' LTAS only for the male singers

The level of the singer's formant is influenced also by the slope of the source spectrum which, in turn, depends on vocal loudness, i. e. on Ps, as mentioned. Thus, the singer's formant tends to increase by about 15 dB for a 10 dB change of the overall SPL [16.47].

The center frequency of the singer's formant varies slightly between voice classifications, as illustrated in the mean LTAS in Fig. 16.24 which shows mean LTAS derived from commercial recordings of singers classified as soprano, alto, tenor, baritone and bass [16.64]. Each group has four singers. The center frequency of the singer's formant for basses, baritones and tenors are about 2.4, 2.6, and 2.8 kHz, respectively. These small differences are quite relevant to the typical voice timbres of these classifications [16.65]. Their origin is likely to be vocal tract length differences, basses tending to have longer vocal tracts than baritones who in turn have longer vocal tracts than tenors [16.66]. On the other hand, substantial variation in the center frequency of the singer's formant occurs also within classifications.

Also shown for comparison in Fig. 16.24 is a mean LTAS of untrained voices reading at an L_{eq} of 70 dB at 0.3 m distance. The singer's formant produces a marked peak some 15 dB above the LTAS of the untrained voices for the male singers. The female singers, on the other hand, do not show any comparable peak in this frequency range. This implies that female singers do not have a singer's formant [16.67–69].

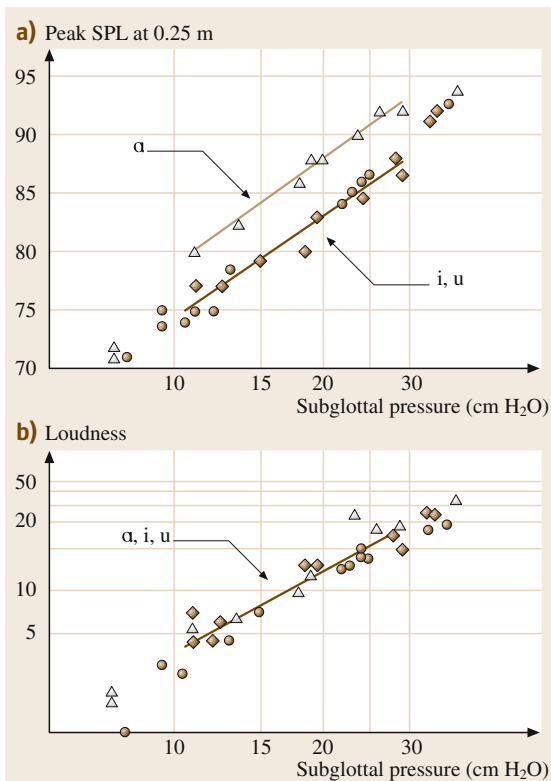
Female operatic singers' lack of a singer's formant is not surprising, given the fact that: (1) they sing at


Fig. 16.25a,b Perceived loudness of a vowel (**b**) correlates better with subglottal pressure Ps than does SPL (**a**) which depends on the intrinsic intensity of the vowel. This, in turn, is determined by its formant pattern (after [16.63])

high F0, i. e. have widely spaced spectrum partials, and (2) the F3, F4, F5 cluster that produces a singer's formant is rather narrow in frequency. The latter means that a narrow formant cluster will be hit by a partial only in some tones of a scale while in other scale tones there will be no partial in the formant cluster. This would lead to salient and quasi-random variation of voice timbre between scale tones.

The singer's formant is a characteristic of classically trained male singers. It is not found in nonclassical singing, e.g. in pop or musical theater singing, where audibility is the responsibility of the sound engineer rather than of the singer. Likewise, choir singers generally do not possess a singer's formant.

From the evidence in Fig. 16.18 we concluded that the logarithm of Ps does a good job of predicting the SPL over a large range of vocal intensities. This was shown for untrained male and female speakers as well as a professional baritone singer. In the next few para-

graphs we will look at how vowel identity affects that prediction and how listeners perceive loudness in the presence of vowel-dependent variations in SPL at constant Ps.

This topic was addressed by *Ladefoged* [16.63] who measured the peak SPL and the peak Ps in 12 repetitions of *bee*, *bay*, *bar*, *bore* and *boo* spoken by a British talker at varying degrees of loudness. SPL values were plotted against log(Ps) for all tokens. Straight lines could readily be fitted to the vowels individually. The vowels of *bay* and *bore* tended to have SPL values in between those of *bar* and *bee/boo*. The left half of Fig. 16.25 replots the original data for [ɑ] and [i]/[u] pooled. The [ɑ] line is higher by 5–6 dB as it should be in view of F1 being higher in [ɑ] than in [i] and [u] (cf. preceding discussion).

In a second experiment listeners were asked to judge the loudness of the test words. Each item was presented after a carrier phrase: *Compare the words: bar and ___.* The word bar served as reference. The subjects were instructed to compare the test syllable and the reference in terms of loudness, to give the value of 10 to the reference and another relative number to the test word. The analysis of the responses in terms of SPL indicated that, for a given SPL, it was consistently the case that *bee* and *boo* tended to be judged as louder than *bar*. On the other hand, there were instances of *bee* and *bar* with similar Ps that were judged to be equally loud.

This effect stood out clearly when loudness judgements were plotted against log(Ps) as in the bottom half of Fig. 16.25. Ladefoged concludes that …*in the case of speech sounds, loudness is directly related to the physiological effort* – in other words, Ps – rather than the SPL as for many other sounds.

Speech Sounds with Noise and Transient Excitation

A comprehensive quantitative treatment of the mechanisms of noise production in speech sounds is found in *Stevens* [16.28, pp. 100–121]. This work also provides detailed analyses of how the noise source and vocal tract filtering interact in shaping the bursts of stops and the spectral characteristics of voiced and voiceless fricatives. While the normal source mechanism for vowels always involves the glottis, noise generation may take place not only at the glottis but at a wide range of locations along the vocal tract. A useful rule of thumb for articulations excited by noise is that the output will spectrally be dominated by the cavity in front of the noise source. This also holds true for sounds with transient excitation such as stop releases and click sounds [16.28, Chaps. 7, 8].

While most of the preceding remarks were devoted to the acoustics of vowels, we should stress that the source-filter theory applies with equal force to the production of consonants.

16.4 Articulatory Processes, Vowels and Consonants

X-ray films of normal speech movements reveal a highly dynamic process. Articulatory activity comes across as a complex flow of rapid, parallel lip, tongue and other movements which shows few, if any, steady states. Although the speaker may be saying no more than a few simple syllables, one nonetheless has the impression of a virtuoso performance of a *polyphonic* motor score. As these events unfold, they are instantly reflected in the acoustic output. The articulatory movements modify the geometry of the vocal tract. Accordingly, the filter (transfer function) undergoes continual change and, as a result, so do the output formant frequencies.

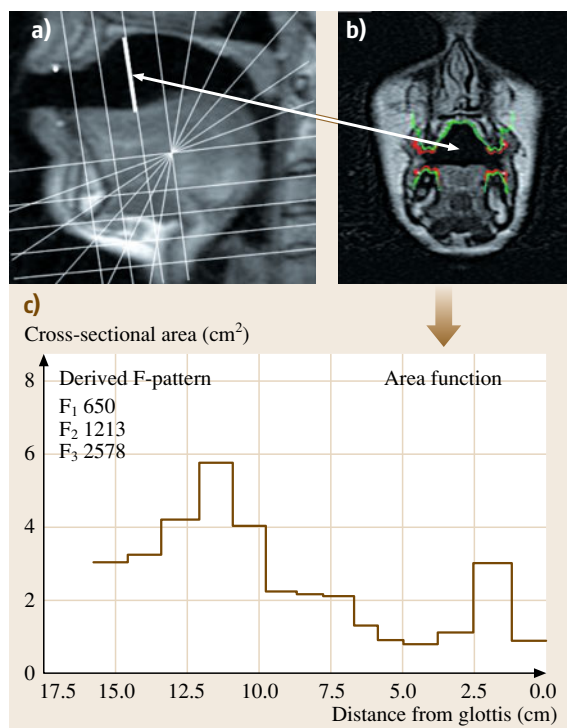
Quantitative modeling is a powerful tool for investigating the speech production process. It has been successfully applied to study the relations between formant and cavities. Significant insights into this mapping have been obtained by representing a given vocal tract configuration as an *area function* – i.e., a series
Fig. 16.26 Magnetic resonance images of the Swedish vowels of Fig. 16.20


Fig. 16.27a–c From articulatory profile to acoustic output. Deriving the formant patterns of a given vowel articulation involves (**a**) representing the vocal tract profile in terms of the cross-distances from the glottis to the lips; (**b**) converting this specification into a cross-sectional area function; and (**c**) calculating the formant pattern from this area function. To go from (**a**) to (**b**), profile data (*top left*) need to be supplemented by area measurements obtained from transversal (coronal and axial) images of the cross sections

of cylindrical cross sections of variable lengths and cross-sectional areas – and by simulating the effects of changes in the area function on the formant frequencies [16.27].

In the past, pursuing this approach, investigators have used lateral X-ray images – similar to the magnetic resonance imaging (MRI) pictures in Fig. 16.26 – to trace the outlines of the acoustically relevant articulatory structures. To make estimates of cross-sectional areas along the vocal tract such lateral profiles need to be supplemented with information on the transverse geometry of the cross sections, e.g., from casts of the vocal tract [16.70] and tomographic pictures [16.27, 71].

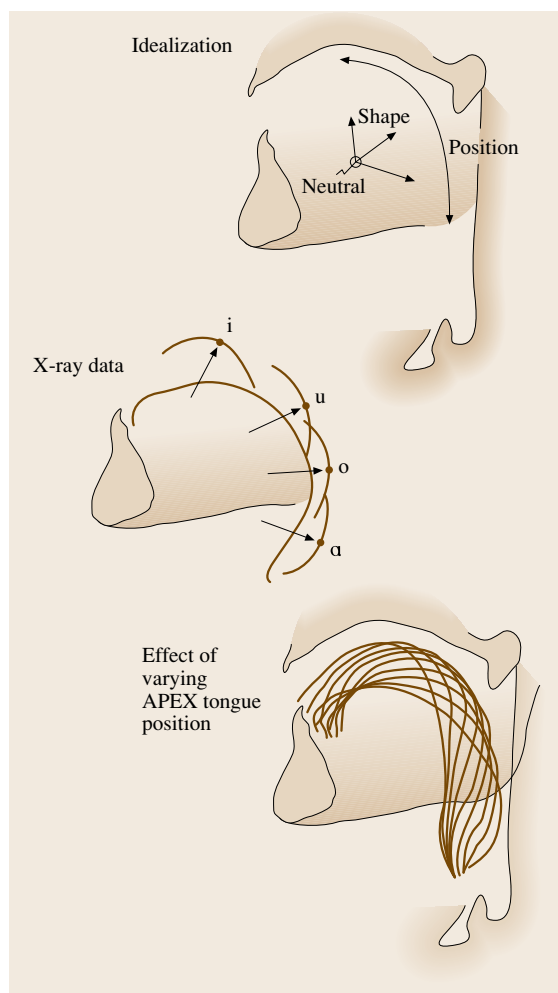
More currently, magnetic resonance imaging methods have become available, making it possible to obtain three-dimensional (3-D) data on sustained steady artic-


Fig. 16.28 The top drawing shows superimposed observed tongue shapes for [i], [u], [o] and [ɑ] differing in the place of the main constriction. Further analyses of similar data suggest that, for vowels, two main dimensions are used: The anterior–posterior location of the tongue body and its displacement from neutral which controls the degree of vocal tract constriction (*lower right*). These parameters are implemented numerically to produce vowels in the APEX articulatory model

ulations [16.72–76]. Figure 16.26 presents MRI images taken in the mid-sagittal plane of a male subject during steady-state productions of a set of Swedish vowels. These data were collected in connection with work on APEX, an articulatory model developed for studying the acoustic consequences of articulatory movements, e.g., the lips, the tongue and the jaw [16.77–81].

Fig. 16.29a,b Acoustic consequences of tongue body, jaw and lip movements as examined in APEX simulations. The tongue moves continuously between palatal, velar and pharyngeal locations while maintaining a minimum constriction area $A_{\min}$ of 0.25 cm, a 7 mm jaw opening and a fixed larynx height. **(a)** The *dashed* and *solid lines* refer to rounded and spread conditions. Diagram **(b)** illustrates the effect of varying the jaw. The *thin lines* show tongue movement at various degrees of jaw opening (6, 7, 8, 9, 12, 15, 19 and 23 mm). The *bold lines* pertain to fixed palatal, neutral or pharyngeal tongue contours ▶

Figure 16.27 highlights some of the steps involved in deriving the formant pattern from lateral articulatory profiles such those of Fig. 16.26. The top-left picture is the profile for the subject's [a]. The white lines indicate the coronal, coronal oblique and axial planes where additional MR images were taken to get information on the cross sections in the transverse dimension.

The location of the transverse cut is indicated by the bold white line segment in the lateral profile. In the coronal section to the right the airway of the vocal tract is the dark area at the center. Below it, the wavy surface of the tongue is evident. Since the teeth lack the density of hydrogen nuclei needed to show up on MR images, their intersection contours (green) were reconstructed from casts and added computationally to the image. The red lines indicate the outline of a dental plate custom-fitted to the subject's upper and lower teeth and designed to carry a contrast agent used to provide reference landmarks (tiny white dots) [16.82].

At any given point in the vocal tract, it would appear that changes in cross-sectional area depend primarily on the midsagittal distance from the tongue surface to the vocal tract wall. An empirically adequate approach to capturing distance-to-area relations is to use power functions of the form $A_x = \alpha d_x^{\beta}$, where d_x is the midsagittal cross distance at a location x in the vocal tract and α and β are constants whose values tend to be different in different regions and depend on the geometry of the vocal tract walls [16.24, 70, 72]. The cross-sectional area function can be obtained by applying a set of d-to-A rules of this type to cross distances measured along the vocal tract perpendicular to the midline. The final step consists in calculating the acoustic resonance frequencies of the derived area function.

In producing a vowel and the vocal tract shape appropriate for it, what are the main articulatory parameters that the speaker has to control? The APEX model [16.80] assumes that the significant informa-

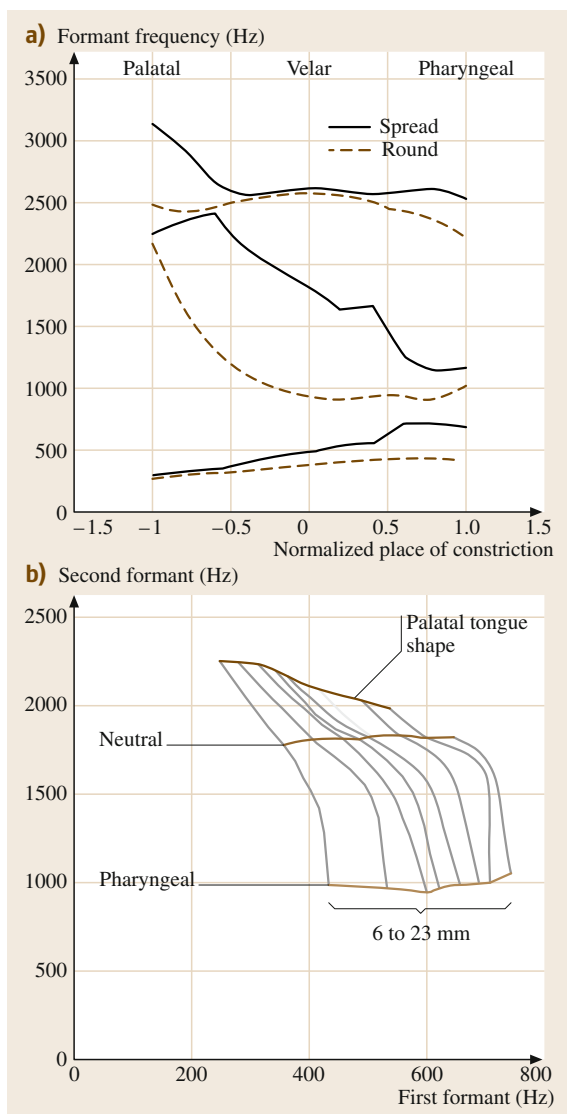
tion about the vowel articulations in Fig. 16.26 is the following. All the vowels exhibit tongue shapes with a single constriction. They differ with respect to how narrow this constriction is and where it is located. In other words, the vowels appear to be produced with control of two degrees of freedom: the palatal–pharyngeal dimension (*position*) and tongue height, or, in APEX terminology, *displacement* from neutral. This interpretation is presented in stylized form in Fig. 16.28 together with APEX tongue shapes sampled along the palatal–pharyngeal continuum. The choice of tongue parameters parallels the degree and place of


Fig. 16.30 Role of the tongue tip and blade in tuning F3. As the tongue is raised to produce the retroflex configuration required for the Swedish [r] sound an acoustically significant volume is created under the tongue blade. Simulations using APEX indicate that this cavity is responsible for the considerable lowering of the third formant associated with the [r]

constriction in the area-function models of *Stevens* and *House* [16.83] and *Fant* [16.27].

A useful application of articulatory models is that they can be set up to change a certain variable while keeping others constant [16.84]. Clearly, asking a human subject to follow such an instruction does not create an easily controlled task.

Figure 16.29 plots results from APEX simulation experiments. It demonstrates how F1, F2 and F3 vary in response to the tongue moving continuously between palatal, velar and pharyngeal locations and maintaining a minimum constriction area A_{min} of $0.25\,\text{cm}^2$, a 7 mm jaw opening and keeping the larynx height constant. The dashed and solid lines refer to rounded and spread conditions. The calculations included a correction for the impedance of the vocal tract walls ([16.54], [16.28, p. 158]).

It is seen that the tongue movement has strong effect on F2. As the constriction becomes more posterior F2 decreases and F1 rises. In general, rounding lowers formants by varying degrees that depends on the formant-cavity relations that apply to the articulation in question. However, for the most palatal position in Fig. 16.29 – an articulation similar to an [i] or an [y], it has little effect on F2 whereas F3 is affected strongly.

The F2 versus F1 plot of the lower diagram of Fig. 16.29 was drawn to illustrate the effect of varying the jaw. The thin lines show how, at various degrees of jaw opening (6, 7, 8, 9, 12, 15, 19 and 23 mm), the tongue moves between palatal and pharyngeal constric-

tions by way of the neutral tongue shape. The bold lines pertain to fixed palatal, neutral or pharyngeal tongue contours. We note that increasing the jaw opening while keeping the tongue configuration constant shifts F1 upward.

Figure 16.30 exemplifies the role of the tongue tip and blade in tuning F3. The data come from an X-ray study with synchronized sound [16.79, 85]. At the cen-
Fig. 16.31 The acoustic vowel space: *possible* vowel formant combinations according to the APEX model

ter a spectrogram of the syllable *par* [pʰɑːr]. Perhaps the most striking feature of the formant pattern is the extensive lowering of F3 and F4 into the [r].

The articulatory correlates are illustrated in the tracings. As we compare the profiles for [ɑː] and [r], we see that the major change is the raising of the tongue blade for [r] and the emergence of a significant cavity in front of, and below, the tongue blade. Simulations using APEX and other models [16.28, 86] indicate that this subapical cavity is responsible for the drastic lowering of F3.

The curves of Fig. 16.30 are qualitatively consistent with the nomograms published for three-parameter area-function models, e.g., *Fant* [16.27]. An advantage of more-realistic physiological models is that the relationships between articulatory parameters and formant patterns become more transparent. We can summarize observations about APEX and the articulation-to-formants mapping as:

- F1 is controlled by the jaw in a direct way;
- F2 is significantly changed by front–back movement of the tongue;
- F3 is influenced by the action of the tongue blade.

Another way of summarizing the acoustic properties of a speech production model is to translate all of its articulatory capabilities into a formant space. By definition that contains all the formant patterns that the model is capable of producing (and specifying articulatorily). Suppose that a model uses *n* independent parameters and each parameter is quantized into a certain number of steps. By forming all *legal* combinations of those parametric values and deriving their vocal tract shapes and formant patterns, we obtain the data needed to represent that space graphically.

The APEX vowel space is shown in 3-D in Fig. 16.31. The *x*-axis is F1. The depth dimension is F2 and the vertical axis is F3. Smooth lines were drawn to enclose individual data points (omitted for clarity).

A cloud-like structure emerges. Its projection on the F2/F1 floor plane takes the form of the familiar triangular pattern appears with [i], [a] and [u] at the corners. Adding F3 along the vertical axis offers additional room for vowel timber variations especially in the [i/y] region.

Figure 16.32 shows typical values for F1 and F2 for various vowels. At the top of the diagram, F1 is given also on the musical staff. The graph thus demonstrates that the fundamental frequency in singing is often higher than the normal value of F1. For example, the first formant of [iː] and [uː] is about 250 Hz (close to
Fig. 16.32 Schematic illustration of the variation ranges of F1 and F2 for various vowels as pronounced by female and male adults. Above the graph F1 is given in musical score notation together with typical F0 ranges for the indicated voice classifications

the pitch of C4), which certainly is a quite low note for a soprano.

Theory predicts that the vocal fold vibration will be greatly disturbed when F0 = F1 [16.87], and singers seem to avoid allowing F0 to pass F1 [16.88, 89]. Instead they raise F1 to a frequency slightly higher than F0. Some formant frequency values for a soprano singer are shown in Fig. 16.33. The results can be idealized in terms of lines, also shown in the figure, relating F1, F2, F3, and F4 to F0. Also shown are the subject's formant frequencies in speech. The main principle seems to be as follows. As long as fundamental frequency is lower than the normal value of the vowel's first formant frequency, this formant frequency is used. At higher pitches, the first formant is raised to a value somewhat
Fig. 16.33 Values of F1, F2, F3, and F4 for the indicated vowels in a professional soprano as function of F0. F1 and F3 are represented by open symbols and F2 and F4 by filled symbols. The values for F0 ≈ 180 Hz were obtained when the singer sustained the vowels in a speech mode (after *Sundberg* [16.88])

Fig. 16.34 Singers' jaw opening in the vowels [ɑː] and [e] plotted as functions of the distance in semitones between F0 and the individual singer's normal F1 value for these vowels. The singers belonged to different classifications: Sop = soprano, Mz = mezzosoprano, Alt = alto, Ten = tenor, Bar = baritone. Symbols refer to subjects (after *Sundberg* and *Skoog* [16.90])

higher than the fundamental frequency. In this way, the singer avoids having the fundamental frequency exceed the first formant frequency. With rising fundamental frequency, F2 of front vowels is lowered, while F2 of back vowels is raised to a frequency just above the second spectrum partial; F3 is lowered, and F4 is raised.

A commonly used articulatory trick for achieving the increase of F1 with F0 is a widening of the jaw opening [16.85]. The graphs of Fig. 16.34 show the jaw opening of professional singers as a function of the frequency separation in semitones between F0 and the F1 value that the singer used at low pitches. The graph referring to the vowel [ɑː] shows that most singers began to widen their jaw opening when the F0 was about four semitones below the normal F1 value. The lower graph of Fig. 16.34 shows the corresponding data for the vowel [e]. For this vowel, most subjects started to widen the jaw opening when the fundamental was about four semitones above the normal value of F1. It is likely

that below this pitch singers increase the first formant by other articulatory means than the jaw opening. A plausible candidate in front vowels is the degree of vocal tract constriction; a reduced constriction increases the first formant. Many singing teachers recommend their students to *release the jaw* or to *give space to the tone*; it seems likely that the acoustic target of these recommendations is to raise F1.

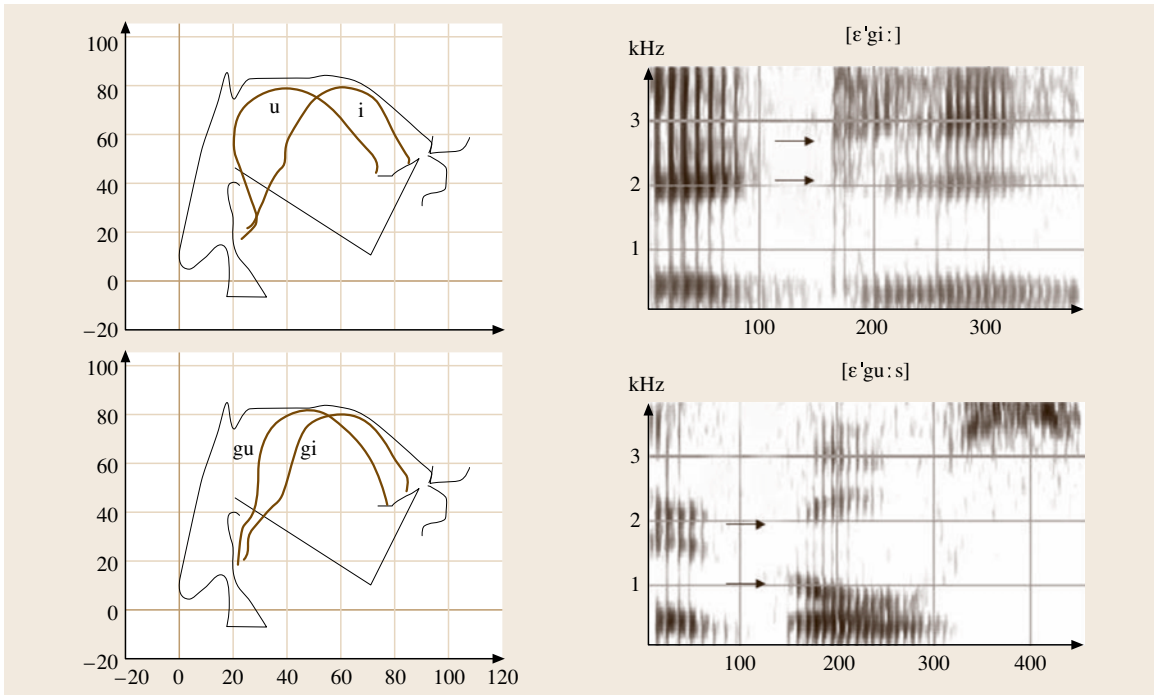
There are also other articulators that can be recruited for the purpose of raising F1. One is the lip opening. By


Fig. 16.35 The universal phenomenon of coarticulation illustrated with articulatory and acoustic data on Swedish [g]. The influence of the following vowel extends throughout the articulation of the stop closure. There is no point in time at which a *pure* (context-free) sample of the [g] could be obtained

retracting the mouth corners, the vocal tract is shortened; and hence the frequencies of the formants will increase. The vocal tract can also be shortened by raising the larynx, and some professional female singers take advantage of this tool when singing at high pitches.

This principle of tuning formant frequencies depending on F0 has been found in all singers who encounter the situation that the normal value of the first formant is lower than their highest pitches. In fact, all singers except basses encounter this situation at least for some vowels sung at high pitches. The benefit of these arrangements of the formant frequencies is an enormous increase of sound level, gained by sheer resonance.

Vowel quality is determined mainly by F1 and F2, as mentioned. Therefore, one would expect drastic consequences regarding vowel intelligibility in these cases. However, the vowel quality of sustained vowels seems to survive these pitch-dependent formant frequency changes surprisingly well, except when F0 exceeds the pitch of F5 (about 700 Hz). Above that frequency no formant frequency combination seems to help, and below it, the vowel quality would not be better if normal formant frequencies were chosen. The amount of text

intelligibility which occurs at very high pitches relies almost exclusively on the consonants surrounding the vowel. Thus, facing the choice between inaudible tones with normal formant frequencies or audible tones with strange vowel quality, singers probably make a wise choice.

One of the major challenges both for applied and theoretical speech research is the great variability of the speech signal. Consider a given utterance as pronounced by speakers of the same dialect. A few moments' reflection will convince us that this utterance is certain to come in a large variety of physical shapes. Some variations reflect the speaker's age, gender, vocal anatomy as well as emotional and physiological state. Others are stylistic and situational as exemplified by speaking clearly in noisy environments, speaking formally in public, addressing large audiences, chatting with a close friend or talking to oneself while trying to solve a problem. Style and situation make significant contributions to the variety of acoustic waveforms that instantiate what we linguistically judge as the *same utterance*.

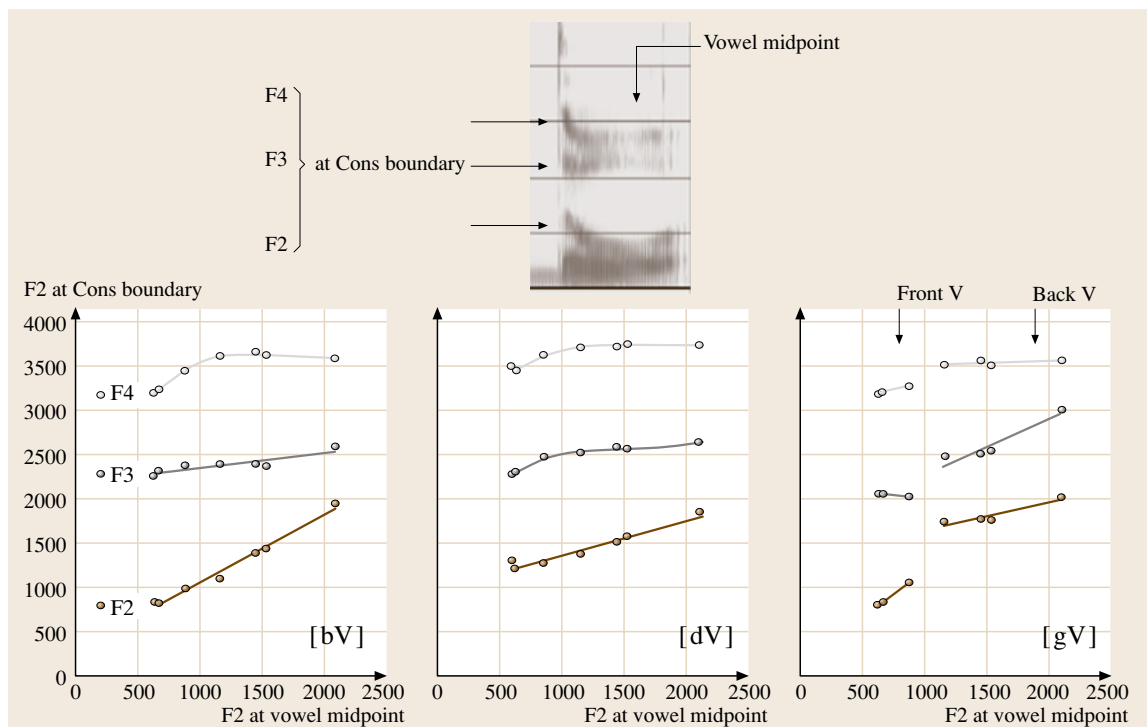
In phonetic experimentation investigators aim at keeping all of these stylistic and situational factors


Fig. 16.36 Coarticulation in [bV], [dV] and [gV] as reflected by measurements of F2, F3 and F4 onsets plotted against an acoustic correlate of front back tongue movement, viz., F2 at the vowel midpoint

constant. This goal tends to limit the scope of the research to a style labeled *laboratory speech*, which consists of test items that are chosen by the experimenter and are typically read from a list. Despite the marked focus on this type of material, laboratory speech nonetheless presents several variability puzzles. We will mention two: segmental interaction, or *coarticulation*, and prosodic modulation. Both exemplify the ubiquitous context dependence of phonetic segments. First a few remarks on coarticulation.

In Fig. 16.35 the phoneme [g] occurs in two words taken from an X-ray film [16.79, 85] of a Swedish speaker: [ɛˈgiː] and [ɛˈguːs]. In these words the first three phonemes correspond to the first three segments on the spectrogram: an initial [ɛ] segment, the [g] stop gap and then the final vowel. So far, so good. However, if we were to try to draw a vertical line on the spectrogram to mark the point in time where [ɛ] ends and [g] begins, or where [g] ends and the final vowel begins, we would soon realize that we have an impossible task. We would perhaps be able to detect formant movements in the [ɛ] segment indicating that articulatory activity towards the [g] had been initiated. However,

that point in time occurs during the acoustic [ɛ] segment. Similarly, we could identify the endpoint of the formant transitions following [g] but that event occurs when the next segment, the final vowel, is already under way.

What we arrive at here is the classical conclusion that strings of phonemes are not organized as *beads on a necklace* [16.91–93]. The acoustic correlates of phonemes, the acoustic segments, are produced according to a motor schema that requires parallel activity in several articulatory channels and weaves the sequence of phonemes into a smooth fabric of overlapping movements. We are talking about *coarticulation*, the overlap of articulatory gestures in space and time.

Not only does this universal of motor organization give rise to the segmentation problem, i.e., make it impossible to chop up the time scale of the speech wave into phoneme-sized chunks, it creates another dilemma known as the *invariance issue*. We can exemplify it by referring to Fig. 16.35 again and the arrows indicating the frequencies of F2 and F3 at the moment of [g] release. With [iː] following they are high in frequency. Next to [uː] they are lower. What acoustic attributes

define the [g] phoneme? How do we specify the [g] phoneme acoustically in a context-independent way?

The answer is that, because of coarticulation, we cannot provide an acoustic definition that is context independent. There is no such thing as an acoustic *pure sample* of a phoneme.

Articulatory observations confirm this account. There is no point in time where the shape of the tongue shows zero influence from the surrounding vowels. The tracings at the top left of Fig. 16.35 show the tongue contours for [iː] and [uː] sampled at the vowel midpoints. The bottom left profiles show the tongue shapes at the [g release. The effect of the following vowel is readily apparent.

So where do we look for the invariant phonetic correlates for [g]? Work on articulatory modeling [16.49, 94] indicates that, if there is such a thing as a single context-free target underlying the surface variants of [g], it is likely to occur at a deeper level of speech production located before the motor commands for [g] closure and for the surrounding vowels blend.

This picture of speech production raises a number of questions about speech perception that have been addressed by a large body of experimental work [16.95, 96] but which will not be reviewed here.

It should be remarked though that, the segmentation and invariance issues notwithstanding, the context sensitivity of phonetic segments is systematic. As an illustration of that point Fig. 16.36 is presented. It shows average data on formant transitions that come from the Swedish speaker of Fig. 16.36 and Figs. 16.26–

16.28. The measurements are from repetitions of CV test words in which the consonants were [b], [d] or [g] and were combined with [iː] [ɛː] [æː] [a] [ɑː] [oː] and [uː]. Formant transition onsets for F2, F3 and F4 are plotted against F2 midpoints for the vowels.

If the consonants are coarticulated with the vowels following, we would expect consonant onset patterns to co-vary with the vowel formant patterns. As shown by Fig. 16.36 that is also what we find. Recall that, in the section on articulatory modeling, we demonstrated that F2 correlates strongly with the front–back movement of the tongue. This implies that, in an indirect way, the *x*-axis labeled *F2 at vowel midpoint* can be said to range from back to front. The same reasoning applies to F2 onsets.

Figure 16.36 shows that the relationship between F2 onsets and F2 at vowel midpoint is linear for bV and dV. For gV, the data points break up into back (low F2) and front (high F2) groups. These straight lines – known as *locus equations* [16.97] – have received considerable attention since they provide a compact way of quantifying coarticulation. Data are available for several languages showing robustly that slopes and intercepts vary in systematic ways with places of articulation.

Furthermore, we see from Fig. 16.36 that lawful patterns are obtained also for F3 and F4 onsets. This makes sense if we assume that vocal tract cavities are not completely uncoupled and that hence, all formants – not only F2 – are to some extent influenced by where along the front–back dimension the vowel is articulated.

16.5 The Syllable

A central unit in both speech and singing is the syllable. It resembles the phoneme in that it is hard to define but it can be described in a number of ways.

Linguists characterize it in terms of how vowels and consonants pattern within it. The central portion, the nucleus, is normally a vowel. One or more consonants can precede and/or follow forming the onset and the coda respectively. The vowel/nucleus is always there; the onset and coda are optional.

Languages vary with respect to the way they combine consonants and vowels into syllables. Most of them favor a frame with only two slots: the CV syllable. Others allow more-elaborated syllable structures with up to three consonants initially and the mirror image in syllable final position. If there is also a length distinction in the vowel and/or consonant system, syllables frames

can become quite complex. A rich pattern with consonant clusters and phonological length usually implies that the language has a strong contrast between stressed and unstressed syllables.

In languages that allow consonant sequences, there is a universal tendency for the segments to be serially ordered on an articulatory continuum with the consonants compatible with the vowel's greater jaw opening occurring next to the vowel, e.g., [l] and [r], while those less compatible, e.g. [s], are recruited at the syllable margins [16.98, 99]. In keeping with this observation, English and other languages use [spr as an initial, but not final, cluster. The reverse sequence [rps] occurs in final, but not initial, position, cf. *sprawl* and *harps*. Traditionally and currently, this trend is explained in terms of an auditory attribute of speech sounds, sonor-

ity. The *sonority principle* [16.59] states that, as the most *sonorous* segments, vowels take the central nucleus position of the syllable and that the *sonority* of the surrounding consonants must decrease to the left and to the right starting from the vowel. Recalling that the degree of articulatory opening affects F1 which in turn affects sound intensity, we realize that these articulatory and auditory accounts are not incompatible. However, the reason for the syllabic variations in sonority is articulatory: the tendency for syllables to alternate close and open articulations in a cyclical manner.

The syllable is also illuminated by a developmental perspective. An important milestone of normal speech acquisition is *canonical babbling*. This type of vocalization makes its appearance sometime between 6–10 months. It consists of sequences of CV-like events, e.g., [dædæ], [baba] [16.100–104]. The phonetic output of deaf infants differs from canonical babbling both quantitatively and quantitatively [16.105–107], suggesting that auditory input from the ambient language is a prerequisite for canonical babbling [16.108–111]. What babbling shares with adult speech is its *syllabic* organization, that is, the alternation of open and close articulations in which jaw movement is a major component [16.112].

As mentioned, the regular repetition of open-close vocal tract states gives rise to an amplitude modulation of the speech waveform. Vowels tend to show the highest amplitudes contrasting with the surrounding consonants which have various degrees of constriction and hence more reduced amplitudes. At the acoustic boundary between a consonant and a vowel, there is often an abrupt rise in the amplitude envelope of the waveform.

When a Fourier analysis is performed on the waveform envelope, a spectrum with primarily low, sub-audio frequency components is obtained. This is to be expected given the fact that amplitude envelopes vary slowly as a function of time. This representation is known as the modulation spectrum [16.113]. It reflects recurring events such as the amplitude changes at consonant-vowel boundaries. It provides an approximate record of the rhythmic pulsating stream of stressed and unstressed syllables.

The time envelope may at first appear to be a rather crude attribute of the signal. However, its perceptual importance should not be underestimated. Room acoustics and noise distort speech by modifying and destroying its modulation spectrum. The modulation transfer function was proposed by Houtgast and Steeneken as a measure of the effect of the auditorium on the speech signal and as a basis for an index, the speech transmission index

(STI), used to predict speech intelligibility under different types of reverberation and noise. The success of this approach tells us that the modulation spectrum, and hence the waveform envelope, contains information that is crucial for robust speech perception [16.114]. Experimental manipulation of the temporal envelope has been performed by *Drullman* et al. [16.115, 116] whose work reinforces the conclusions reached by Houtgast and Steeneken.

There seems to be something special about the front ends of syllables. First, languages prefer CVs to VCs. Second, what children begin with is strings of CV-like pseudosyllables that emulate the syllable onsets of adult speech. Third there is perceptually significant information for the listener in the initial dynamics of the syllable. Let us add another phenomenon to this list: the *syllable beat*, or the syllable's P-center [16.117, 118].

In reading poetry, or in singing, we have a very strong sense that the syllables are spoken/sung in accordance with the rhythmic pattern of the meter. Native speakers agree more or less on how many syllables there are in a word or a phrase. In making such judgments, they seem to experience syllables as unitary events. Although it may take several hundred milliseconds to pronounce, subjectively a syllable appears to occur at a specific moment in time. It is this impression to which the phonetic term *syllable beat* refers and that has been studied experimentally in a sizable number of publications [16.119–125].

Rapp [16.126] asked three native speakers of Swedish to produce random sets of test words built from [aCˈɑːd] were the consonant C was selected from [s, t, d, l, n, st, str]. The instruction was to synchronize the stressed syllable with a metronome beat presented over earphones.

The results are summarized in Fig. 16.37. The *x*-axis represents distance in milliseconds from the point of reference, the metronome beat. The top diagram shows the total distribution of about 2000 time markers around the mean. The lower graph indicates the relative location of the major acoustic segment boundaries.

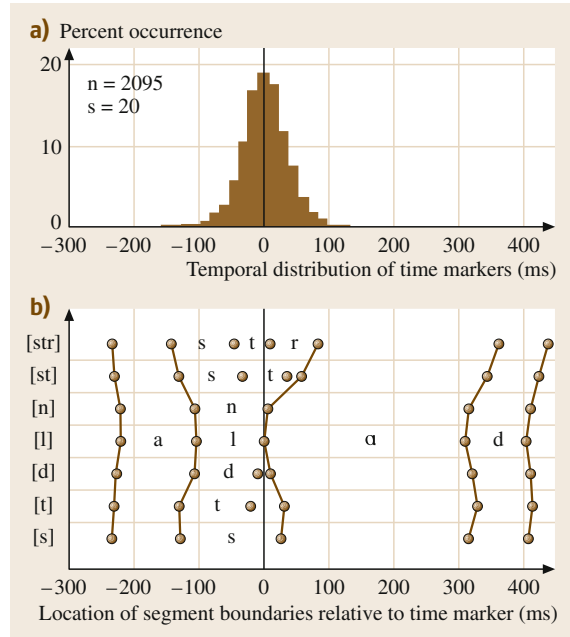
Several phonetic correlates have been proposed for the syllable beat: some acoustic/auditory, others articulatory. They all hover around the vowel onset, e.g., the amplitude envelope of a signal [16.127], rapid increase in energy in spectral bands [16.128, 129] or the onset of articulatory movement towards the vowel [16.130].

Rapp's data in Fig. 16.37 indicate that the mean beat time tends to fall close to the release or articulatory opening in [t, d, l, n] but that it significantly precedes the acoustic vowel onsets of [str-], [st-] and [s-]. However, when segment boundaries were arranged in relation to

Fig. 16.37a,b In *Rapp* [16.126] three male Swedish subjects were asked to produce test words based on an [a_ˈɑːd] frame with [s, t, d, l, n, st, str] as intervocalic segment(s). These items were pronounced in synchrony with metronome beats presented over headphones. The figure shows the temporal distribution of the metronome beats **(a)** in relation to the average time location of acoustic segment boundaries **(b)** ▶

a fixed landmark on the F0 contour and vowel onsets were measured relative to that landmark, the range of vowel onsets was reduced. It is possible that the syllable beat may have its origin, not at the acoustic surface, nor at some kinematic level, but in a deeper motor control process that coordinates and imposes coherence on respiratory, phonatory and articulatory activity needed to produce a syllable.

Whatever the definitive explanation for the syllable's psychological *moment of occurrence* will be, the syllable beat provides a useful point of entry for attempts to understand how the control of rhythm and pitch works in speech and singing. Figure 16.38 compares spectrograms of the first few bars of *Over the rainbow*, spoken (left) and sung (right).

Vertical lines have been drawn at vowel onsets and points where articulators begin to move towards a more


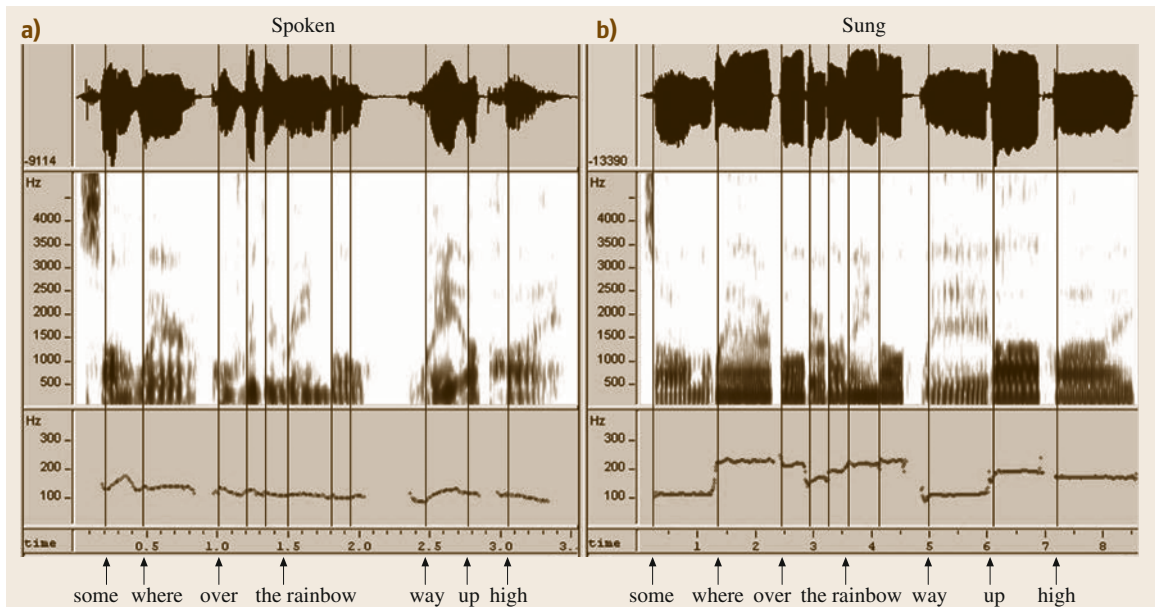
open configuration. The lines form an isochronous temporal pattern in the sung version which was performed at a regular rhythm. In the spoken example, they occur


Fig. 16.38a,b Waveforms and spectrograms of the first few bars of Over the rainbow, **(a)** spoken and **(b)** sung. *Below*: F0 traces in Hz. *Vertical lines* were drawn at time points corresponding to *vowel onsets* defined in terms of onset of voicing after a voiceless consonant, or the abrupt vocal tract opening following a consonant
Fig. 16.39 Spectrogram of Dietrich Fischer-Dieskau's recording of song number 4 from Robert Schumann's Dichterliebe, op. 48. The *vertical bars* mark the onset of the tones of the piano accompaniment. Note the almost perfect synchrony between vowel onset and the piano. Note also the simultaneous appearance of high and low partials after the consonants also after the unvoiced /t/ in Taube

at intervals that seem more determined by the syllable's degree of prominence.

The subject reaches F0 targets at points near the beats (the vertical lines). From there target frequencies are maintained at stationary values until shortly before it is time to go to the next pitch. Thus the F0 curve resembles a step function with some smoothing applied to the steps.

On the other hand, the F0 contour for speech shows no such steady states. It makes few dramatic moves as it gradually drifts downward in frequency (the declination effect).

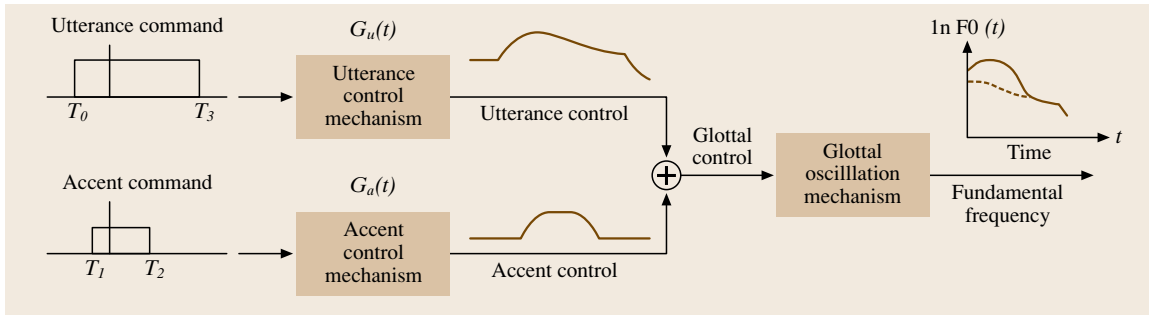
Figure 16.39 shows a typical example of classical singing, a spectrogram of a commercial recording of Dietrich Fischer-Dieskau's rendering of the song *Die Rose, die Lilie* from Robert Schumann's *Dichterliebe*, op. 48. The vertical dashed lines show the onsets of the piano accompaniment. The wavy patterns, often occurring somewhat after the vowel onset, reflect the vibrato. Apart from the vibrato undulation of the partials the gaps in the pattern of harmonics are quite apparent. At these points we see the effect of the more constricted articulations for the consonants. Note the rapid and crisply synchronous amplitude rise in all partials at the end


Fig. 16.40 A quantitative approach to synthesizing F0 contours by rule (after *Fujisaki* [16.131]). The framework shown here is an example of the so-called *superposition models* which generate F0 patterns by adding strongly damped responses to input step function target commands for phrase and accents

of the consonant segments, also after unvoiced consonants, e.g. the /t/ in *Taube*. These rises are synchronized with the onset of the piano accompaniment tones, thus demonstrating that in singing a beat is marked by the vowel. The simultaneous appearing of low and high partials seems to belong to the characteristics of classical singing as opposed to speech, where the higher partials often arrive with a slight delay after unvoiced consonants. As mentioned before, such consonants are produced with abduction of the vocal folds. To generate also high partials in this context, the vocal folds need to close the glottis at the very first vibratory cycle at the vowel onset. A potential benefit of this might be that this enhances the higher formants which are important to text intelligibility.

Several quantitative frameworks have been proposed for generating speech F0 contours by rule (for overview see *Frid* [16.132]). A subgroup of these has been called *superposition models* [16.131, 133]. A characteristic of such models is that they decompose the F0 curve into separate phrase and accent components. The accent commands are F0 step or impulse functions temporally linked to the syllables carrying stress. Accent pulses are superimposed on the phrase component. For a declarative sentence, the phrase component

is a falling F0 contour produced from rectangular step function *hat patterns* [16.134]. The phrase and accent commands are passed through critically damped filters to convert their sum into the smoothly varying output F0 contour. An example of this approach is shown in Fig. 16.40 [16.131].

The last few figures suggest that the F0 patterns of singing and speech may be rather different if compared in terms of the raw F0 curves. However, the superposition models suggest that speech F0 contours have characteristics in part attributable to the passive response characteristics of the neuro-mechanical system that produces them, and in part due to active control signals. These control commands take the form of stepwise changes, some of short, others of longer duration. This representation is not unlike the sequence of F0 targets of a melody.

The implication of this analysis is that F0 is controlled in similar ways in speech and singing in the sense that both are based on sequences of underlying steady-state targets. On the other hand, a significant difference is that in singing high accuracy in attainment of acoustic target frequencies is required whereas in speech such demands are relaxed and smoothing is stronger.

16.6 Rhythm and Timing

A striking characteristic of a foreign language is its rhythm. Phoneticians distinguish between stress-timed and syllable-timed languages. English, Russian, Arabic and Thai are placed in the first group [16.135]. French, Spanish, Greek, Italian, Yoruba and Telugu are examples of the second.

Stress timing means that stressed syllables recur at approximately equal intervals. For instance, it is possible to say *in ENGlish STRESses reCUR at EQual INtervals*, spacing the stressed syllables evenly in time and without sounding too unnatural. Stress increases syllable duration. In case several unstressed syllables

occur in between stresses they are expected to undergo compensatory shortening. Syllable, or *machine-gun*, timing [16.136] implies that syllables recur at approximately equal intervals. In the first case it is the stresses that are isochronous, in the second the syllables.

To what extent are speech rhythms explicitly controlled by the speaker? To what extent are they fortuitous by-products of other factors? Does acquiring a new language involve learning new rhythmic target patterns?

The answer depends on how speech is defined. In the reading of poetry and nursery rhymes it is clear that an external target, viz. the metric pattern, is a key determinant of how syllables are produced. Similarly, the groupings and the pausing in narrative prose, as read by a professional actor, can exhibit extrinsic rhythmic stylization compared with unscripted speech [16.137].

Dauer [16.138] points the way towards addressing such issues presenting statistics on the most frequently occurring syllable structures in English, Spanish and French. In Spanish and French, syllables were found to be predominantly open, i. e. ending with a vowel, whereas English showed a preference for closed syllables, i. e. ending with a consonant, especially in stressed syllables. Duration measurements made for English and Thai (stress-timed) and Greek, Spanish and Italian (syllable-timed) indicated that the duration of the interstress intervals grew at the same constant rate as a function of the number of syllables between the interstress intervals. In other words, no durational evidence was found to support the distinction between stress timing and syllable timing. How do we square that finding with the widely shared impression that some languages do indeed sound *stress-timed* and others *syllable-timed*?

Dauer [16.138, p. 55] concludes her study by stating that:

> *... the rhythmic differences we feel to exist between languages such as English and Spanish are more a result of phonological, phonetic, lexical and syntactic facts about that language than any attempt on the part of the speaker to equalize interstress or intersyllable intervals.*

It is clear that speakers are certainly capable of imposing a rhythmic template in the serial read-out of syllables. But do they put such templates in play also when they speak spontaneously? According to *Dauer* and others [16.139, 140] rhythm is not normally an explicitly controlled variable. It is better seen as an emergent product of interaction among the choices languages make (and do not make) in building their

syllables: e.g., from open versus closed syllable structures, heavy versus weak clusters, length distinctions and strong stressed/unstressed contrast. We thus learn that the distinction between syllable timing and stress timing may be a useful descriptive term but should primarily be applied to the phonetic output, more seldom to its input control.

Do speech rhythms carry over into music? In other words, would music composed by speakers of syllable-timed or stress-timed languages also be syllable timed or stress timed? The question has been addressed [16.141, 142] and some preliminary evidence has been reported.

There is more to speech timing than what happens inside the syllable. Processes at the word and phrase levels also influence the time intervals between syllables. Consider the English words *digest*, *insult* and *pervert*. As verbs their stress pattern can be described as a sequence of *weak–strong* syllables. As nouns the order is reversed: *strong–weak*. The syllables are the same but changing the word's stress contour (the lexical stress) affects their timing.

The *word length effect* has been reported for several languages [16.58, 143]. It refers to the tendency for the stressed vowel of the word to shorten as more syllables are appended, cf. English *speed*, *speedy*, *speedily*. In Lehiste's formulation:

> *It appears that in some languages the word as a whole has a certain duration that tends to remain relatively constant, and if the word contains a greater number of segmental sounds, the duration of the segmental sounds decreases as their number in the word increases.*

At the phrase level we find that rhythmic patterns can be used to signal differences in syntactic structure. Compare:

1. *The 2000-year-old skeletons*,
2. *The two 1000-year-old skeletons*.

The phrases contain syllables with identical phonetic content but are clearly timed differently. The difference is linked to that fact that in (1) *2000-year-old* forms a single unit, whereas in (2) *two 1000-year-old* consists of two constituents.

A further example is:

3. *Johan greeted the girl with the flowers*.

Hearing this utterance in a specific context a listener might not find it ambiguous. But it has two interpretations: (a) either Johan greeted the girl who was carrying

flowers, or (b) he used the flowers to greet her. If spoken clearly to disambiguate, the speaker is likely to provide temporal cues in the form of shortening the syllables within each syntactic group to signal the coherence of the constituent syllables (cf. the word length effect above) and to introduce a short pause between the two groups. There would be a lengthening of the last syllable before the pause and of the utterance-final syllable.

Version (a) can be represented as

4. [*Johan greeted*] # [*the girl with the flowers*].

In (b) the grouping is

5. [*Johan greeted the girl*] # [*with the flowers*].

The # symbol indicates the possibility of a short juncture or pause and a lengthening of the segments preceding the pause. This boundary cue is known as *pre-pausal lengthening*, or more generally as *final lengthening* [16.143, 144], a process that has been observed for a great many languages. It is not known whether this process is a language universal. It is fair to say that is typologically widespread.

Curiously it resembles a phenomenon found in poetry, folk melodies and nursery tunes, called *catalexis*. It consists in omitting the last syllable(s) in a line or other metrical unit of poetry. Instead of four mechanically repeated trochaic feet as in:

|− ⌣ |− ⌣ |− ⌣ |− ⌣ |
|− ⌣ |− ⌣ |− ⌣ |− ⌣ |

we typically find catalectic lines with durationally implied but deleted final syllables as in:

|− ⌣ |− ⌣ |− ⌣ |− |

Old McDonald had a farm

|− ⌣ |− ⌣ |− | |

ee-i ee-i oh

Final lengthening is an essential feature of speech prosody. Speech synthesized without it sounds both highly unnatural and is harder to perceive. In music performance frameworks, instrumental as well as sung, final lengthening serves the purpose of grouping and constituent marking [16.145, 146].

16.7 Prosody and Speech Dynamics

Degree of prominence is an important determinant of segment and syllable duration in English. Figure 16.41 shows spectrograms of the word *squeal* spoken with four degrees of stress in sentences read in response to a list of questions (source: [16.147]). The idea behind this method was to elicit tokens having emphatic, strong (as in focus position), neutral and weak (unfocused) stress on the test syllable. The lower row compares the strong and the emphatic pronunciations (left and right respectively). The top row presents syllables with weaker degrees of stress.

The representations demonstrate that the differences in stress have a marked effect on the word's spectrographic pattern. Greater prominence makes it longer. Formants, notably F2, show more extensive and more rapid transitions.

A similar experimental protocol was used in two studies of the dynamics of vowel production [16.147, 148]. Both report formant data on the English front vowels [i], [ɪ], [ɛ] and [eɪ] occurring in syllables selected to maximize and minimize contextual assimilation to the place of articulation of the surrounding consonants. To obtain a maximally assimilatory frame, words containing the sequence [w‿ɫ] were chosen, e.g., as in

wheel, *will*, *well* and *wail*. (The [w] is a labio-velar and English [ɫ] is velarized. Both are thus made with the tongue in a retracted position). The minimally assimilatory syllable was [h‿d].

Moon's primary concern was *speaking style* (clear versus casual speech). Brownlee investigated changes due to *stress variations*. In both studies measurements were made of vowel duration and extent of formant transitions. Vowel segment boundaries were defined in terms of fixed transition onset and endpoint values for [w] and [ɫ] respectively. The [h‿d] frame served as a *null context* reference. The [w‿ɫ] environment produced formant transitions large enough to provide a sensitive and robust index of articulatory movement (basically the front–back movement of the tongue).

Figure 16.42 presents measurements of F2 and vowel duration from tokens of [i] in the word *squeal* spoken by a male subject under four conditions of stress: emphatically stressed, focused, neutral stress and weak stress (out of focus). The subject was helped to produce the appropriate stress in the right place by reading a question before each test sentence.

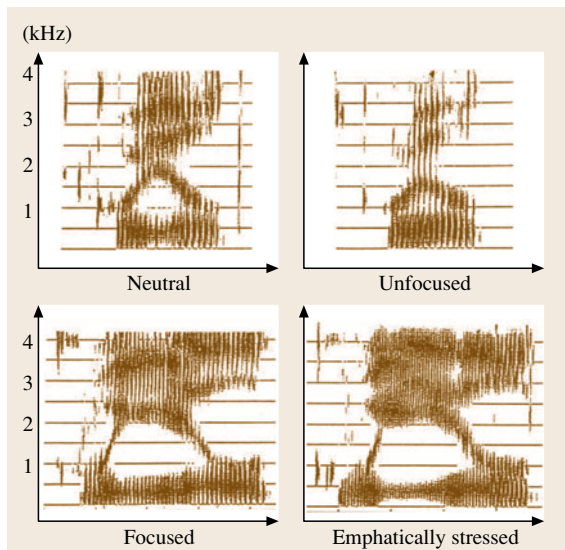
Filled circles pertain to individual measurements pooled for all stress conditions. The points form a co-


Fig. 16.41 Spectrograms of the word *squeal* spoken with four degrees of stress in sentences read in response to a list of questions (after *Brownlee* [16.147])

Fig. 16.42 Measurements of F2 as function of vowel duration from tokens of [i] in the word *squeal* spoken by a male subject under four conditions of stress: emphatically stressed, focused, neutral stress and weak stress (out of focus). *Filled circles* pertain to the individual measurements from all the four stress conditions. The *dashed horizontal line*, is the average F2 value of citation form productions of [h_d]. The averages for the four stress conditions are indicated by the *open squares*. As duration increases – which is approximately correlated with increasing stress – the *square symbols* are seen to move up along the smooth curve implying decreasing undershoot (after *Brownlee* [16.147])

herent cluster which is fairly well captured by an exponential curve. The asymptote is the dashed horizontal line, i. e., the average F2 value of the [h_d data for [i]. The averages for the stress conditions are indicated by the unfilled squares. They are seen to move up along the curve with increasing stress (equivalently, vowel duration).

To understand the articulatory processes underlying the dynamics of vowel production it is useful to adopt a biomechanical perspective. In the [w_ɫ test words the tongue body starts from a posterior position in [w] and moves towards a vowel target located in the front region of the vocal tract, e.g., [i], [ɪ], [ɛ] or [e]. Then it returns to a back configuration for the dark [ɫ]. At short vowel durations there is not enough time for the vowel gesture to be completed. As a result, the F2 movement misses the reference target by several hundred Hz. Note that in unstressed tokens the approach to target is off by almost an octave. As the syllable is spoken with more stress, and the vowel accordingly gets longer, the F2 transition falls short to a lesser degree. What is illustrated here is the phenomenon known as *formant undershoot* [16.149, 150].

Formant undershoot has received a fair amount of attention in the literature [16.151–155]. It is generally seen as an expression of the sluggish response characteristics of the speech production system. The term *sluggish* here describes both neural delays and me-

chanical time constants. The response to the neural commands for a given movement is not instantaneous. It takes time for neural impulses to be transformed into muscular contractions and it takes time for the tongue, the jaw and other articulatory structures to respond mechanically to the forces generated by those contractions. In other words, several stages of filtering take place between control signals and the unfolding of the movements. It is this filtering that makes the articulators sluggish. When commands for successive phonemes arrive faster than the articulatory systems are able to respond, the output is a set of incomplete movements. There is undershoot and failure to reach spatial, and thus also acoustic, targets.

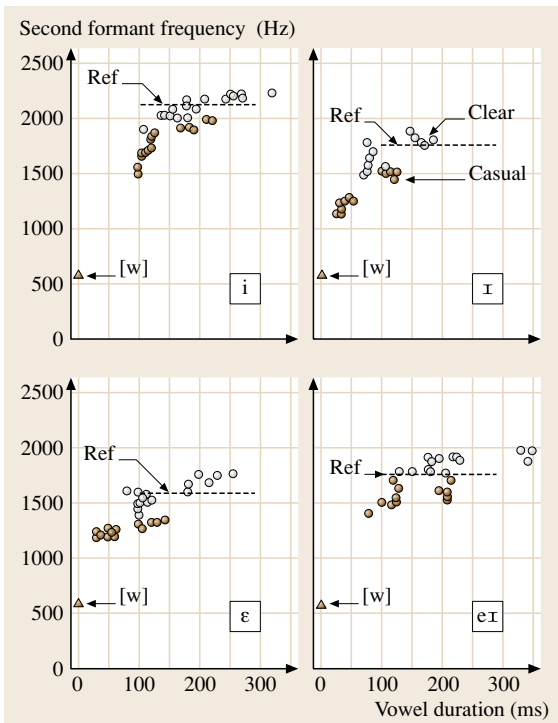
However, biomechanics tells us that, in principle, it should be possible to compensate for system char-


Fig. 16.43 Measurements F2 as function of vowel duration for five male subjects' casual citation-form style pronunciation of the words *wheel*, *wheeling*, *Wheelingham*, *will*, *willing*, *willingly* and for their pronunciation of the same words when asked to say them clearly in an overarticulated way. Casual style is represented by the *solid circles*, clear speech by *open circles*. The frequency of F2 in [w] is indicated by the *arrows* at 600 Hz. The mean F2 for the [h_d] data is entered as *dashed horizontal lines* (after [16.157, Fig. 4])

acteristics by applying greater force to the articulators thereby speeding up movements and improving target attainment [16.156]. Such considerations make us expect that, in speech movement dynamics, a given trajectory is shaped by:

1. The distance between successive articulatory goals (the extent of movement)
2. Articulatory effort (input force)
3. Duration (the time available to execute the movement).

The data of Brownlee are compatible with such a mechanism in that the stress-dependent undershoot observed is likely to be a joint consequence of:

1. The large distances between back and front targets
2. The stress differences corresponding to variations in articulatory effort
3. Durational limitations.

The three factors – movement extent, effort and duration – are clearly demonstrated in Moon's research on clear and casual speech. As mentioned, Moon's test syllables were the same as Brownlee's. He varied speaking style while keeping stress constant. This was achieved by taking advantage of the word-length effect. The segment strings [wɨɬ-], [wɪɬ-], [wɛɬ-] and [weɬ-] were used as the first main-stressed syllable in mono-, bi- and trisyllabic words to produce items such as *wheel*, *wheeling*, *Wheelingham*, *will*, *willing*, *willingly*, etc.

In the first part of his experiment, five male subjects were asked to produce these words in casual citation-form style. In the second section the instruction was to say them clearly in an *overarticulated* way. For the citation-form pronunciation the results replicated previously observed facts in that: (a) all subjects exhibited duration-dependent formant undershoot, and (b) the magnitude of this effect varied in proportion to the extent of the [w]–[vowel] transition. In the clear style, undershoot effects were reduced. The mechanism by which this was achieved varied somewhat from subject to subject. It involved combinations of increased vowel duration and more rapid and more extensive formant transitions. Figure 16.43 shows the response of one of the subjects to the two tasks [16.157].

Casual style is represented by the solid circles, clear speech by open circles. The frequency of F2 in [w] is indicated by the arrows at 600 Hz. The mean F2 for the [h_d data is entered as dashed horizontal lines.

The solid points show duration-dependent undershoot effects in relation to the reference values for the [h_d] environment. The open circles, on the other hand, overshoot those values suggesting that this talker used more extreme F2 targets for the clear condition. The center of gravity of the open circles is shifted to the right for all four vowels showing that clear forms were longer than citation forms. Accordingly, this is a subject who used all three methods to decrease undershoot: clear pronunciations exhibited consistently more extreme targets (F2 higher), longer durations and more rapid formant movements.

These results demonstrate that duration and context are not the only determinants of vowel reduction since, for any given duration, the talker is free to vary the degree of undershoot by choosing to articulate more forcefully (as in overarticulated *hyperspeech*)

or in a more relaxed manner (as in casual hypospeech). Taken together, the studies by Moon and Brownlee suggest that the dynamics of articulatory movement, and thus of formant transitions, are significantly constrained by three factors: extent of movement, articulatory effort and duration.

16.8 Control of Sound in Speech and Singing

When we perform an action – walk, run, or reach for and manipulate objects – our motor systems are faced with the fact that the contexts under which movements are made are never exactly the same. They change significantly from one situation to the next. Nonetheless, motor systems adapt effortlessly to the continually changing conditions presumably because, during evolution, they were shaped by the need to cope with unforeseen events and obstacles [16.158]. Their default mode of operation is compensatory [16.159].

Handwriting provides a good illustration of this ability. A familiar fact is that it does not matter if something is written on the blackboard or on a piece of paper. The characteristic features of someone's handwriting are nevertheless easily recognized. Different sets of muscles are recruited and the size of the letters is different but their shapes remain basically similar. What this observation tells us is that movements are not specified in terms of fixed set of muscles and constant contraction patterns. They are recruited in functionally defined groups, *coordinative structures* [16.160]. They are planned and executed in an external coordinate space, in other words in relation to the 3-D world in which they occur so as to attain goals defined outside the motor system itself. The literature on motor mechanisms teaches us that voluntary movements are prospectively organized or future-oriented.

Speech and singing provide numerous examples of this output-oriented mode of motor control [16.161–163]. Earlier in the chapter we pointed out that, in upright position, the diaphragm and adjacent structures are influenced by gravity and tend to be pulled down, thereby causing the volume of the thoracic cavity to increase. In this position, gravity contributes to the inspiratory forces. By contrast, in the supine position, the diaphragm tends to get pushed up into the rib cage, which promotes expiration [16.3, p. 40].

Sundberg et al. [16.164] investigated the effect of upright and supine positions in two baritone singers using synchronous records of esophageal and gastric pressure, EMG from inspiratory and expiratory muscles, lung volume and sound. Reorganization of respiratory activity was found and was interpreted as compensation for the different mechanical situations arising from the upright and supine conditions.

This finding is closely related to what we know about breathing during speech. As mentioned above (Fig. 16.6), the Ps tends to stay fairly constant for any given vocal effort. It is known that this result is achieved by tuning the balance between inspiratory and expiratory muscles. When the lungs are expanded so that the effect of elastic recoil creates a significant expiration force, inspiratory muscles predominate to put a brake on that force. For reduced lung volumes the situation is the opposite. The effect of elastic recoil is rather to increase lung volume. Accordingly, the muscle recruitment needed to maintain Ps is expected to be primarily expiratory. That is indeed what the data show [16.8, 63, 165].

The bite-block paradigm offers another speech example. In one set of experiments [16.166] subjects were instructed to pronounce syllables consisting only of a long vowel under two conditions: first normally, then with a bite block (BB) between the teeth. The subjects all non-phoneticians were told to try to sound as normal as possible despite the BB. No practice was allowed. The purpose of the BB was to create an abnormally large jaw opening for close vowels such as [i] and [u]. It was argued that, if no tongue compensation occurred, this large opening would drastically change the area function of the close vowels and disrupt their formant patterns. In other words, the question investigated was whether the subjects were able to sound normal despite the BB.

Acoustic recordings were made and formant pattern data were collected for comparisons between conditions, vowels and subjects. The analyses demonstrated clearly that subjects were indeed able to produce normal sounding vowels in spite of the BB. At the moment of the first glottal pulse formant patters were well within the normal ranges of variation.

In a follow-up X-ray investigation [16.167] it was found that compensatory productions of [i] and [u] were made with super-palatal and super-velar tongue shapes. In other words, tongue bodies were raised high above normal positions so as to approximate the normal cross-sectional area functions for the test vowels.

Speech and singing share a lot of features but significant differences are brought to light when we consider what the goals of the two behaviors are.

It is more than 50 years since the sound spectrograph became commercially available [16.91]. In this time we have learned from visible speech displays and other records that the relation between phonetic units and the acoustic signal is extremely complex [16.168]. The lesson taught is that invariant correlates of linguistic categories are not readily apparent in the speech wave [16.169]. In the preceding discussion we touched on some of the sources of this variability: coarticulation, reduction and elaboration, prosodic modulation, stylistic, situational and speaker-specific characteristics. From this vantage point it is astonishing to note that, even under noisy conditions, speech communication is a reliable and robust process. How is this remarkable fact to be accounted for?

In response to this problem a number of ideas and explanatory frameworks have been proposed. For instance, it has been suggested that acoustic invariants are relational rather than absolute (à la tone intervals defined as frequency ratios).

Speech is rather a set of movements made audible than a set of sounds produced by movements [16.14, p. 33].

In keeping with this classical statement, many investigators have argued that speech entities are to be found at some upstream speech production level and should be defined as *gestures* [16.170–173].

At the opposite end, we find researchers (e.g., *Perkell* [16.163]) who endorse Roman Jakobson's view which, in the search for units gives primacy to the perceptual representation of speech sounds. To Jakobson the stages of the speech chain form an [16.174]

... operational hierarchy of levels of decreasing pertinence: perceptual, aural, acoustical and articulatory (the latter carrying no direct information to the receiver).

These viewpoints appear to conflict and do indeed divide the field into those who see speech as a motoric code (the *gesturalist* camp) and those who maintain that it is primarily shaped by perceptual processes (the *listener-oriented* school).

There is a great deal of experimental evidence for both sides, suggesting that this dilemma is not an either–or issue but that both parties offer valuable complementary perspectives.

A different approach is taken by the H & H (Hyper and Hypo) theory [16.175, 176]. This account is developed from the following key observations about speaker–listener interaction:

1. Speech perception is always a product of signal information and listener knowledge;
2. Speech production is adaptively organized.

Here is an experiment that illustrates the first claim about perceptual processing. Two groups of subjects listen to a sequence of two phrases: a question followed by an answer. The subject groups hear different questions but a single physically identical reply. The subjects' task is to say how many words the reply contains.

The point made here is that Group 1 subjects hear [lɛsn̩ faɪv as *less than five*. Those in Group 2 interpret it as *lesson five*. The first group's response is *three words*, and the answer of the second is *two words*. This is *despite the fact* that physically the [lɛsn̩ faɪv stimulus is exactly the same. The syllabic [n̩] signals the word *than* in one case and the syllable *–on* in the other. Looking for the invariant correlates of the initial consonant *than* is doomed to failure because of the severe degree of reduction.

To proponents of H & H theory this is not an isolated case. This is the way that perception in general works. The speech percepts can never be raw records of the signal because listener knowledge will inevitably interact with the stimulus and will contribute to shaping the percept.

Furthermore, H & H theory highlights the fact that spoken messages show a non-uniform distribution of information in that predictability varies from situation to situation, from word to word and from syllable to syllable. Compare (a) and (b) below. What word is likely to be represented by the gap?

1. *The next word is __.*
2. *A bird in the hand is worth two in the __.*

Any word can be expected in (1) whereas in (2) the predictability of the word *bush* is high.

H & H theory assumes that, while learning and using their native language, speakers develop a sense of this informational dynamics. Introducing the abstraction of an *ideal speaker*, it proposes that the talker estimates the running contribution that signal-complementary information (listener knowledge) will make during the course of the utterance and then tunes his articulatory performance to the presumed short-term listener needs. Statistically, this type of behavior has the long-term consequence of distributing phonetic output forms along a continuum with clear and elaborated

forms (hyperspeech) at one end and casual and reduced pronunciations (hypospeech) at the other.

The implication for the invariance issue is that the task of the speaker is not to encode linguistic units as physical invariants, but to make sure that the signal attributes (of phonemes, syllables, words and phrases) carry discriminative power *sufficient* for successful lexical access. To make the same point in slightly different terms, the task of the signal is not to embody phonetic patterns of constancy but to provide *missing information*.

It is interesting to put this account of speech processes next to what we know about singing. Experimental observations indicate that singing in tune is not simply about invariant F0 targets. F0 is affected by the singer's expressive performance [16.177] and by the tonal context in which a given note is embedded [16.178]. Certain deviations from nominal target frequencies are not unlike the coarticulation and undershoot effects ubiquitously present in speech. Accordingly, with respect to frequency control, speaking and singing are qualitatively similar. However, quantitatively, they differ drastically. Recall that in describing the dynamics of vowel reduction we noted that formant frequencies can be displaced by as much as 50% from target values. Clearly, a musician or singer with a comparable under-/overshoot record would be rec-

ommended to embark on an alternative career, the margins of perceptual tolerance being much narrower for singing.

What accounts for this discrepancy in target attainment? Our short answer is that singing or playing *out of tune* is a bad thing. Where does this taboo come from? From consonance and harmony constraints. In simplified terms, an arbitrary sample of tonal music can be analyzed into a sequence of chords. Its melodic line is a rhythmic and tonal elaboration of this harmonic structure. Statistically, long prominent melody tones tend to attract chord notes. Notes of less prominence typically *interpolate* along scales in smaller intervals between the metrically heavier chord notes. The notion of *consonance* goes a long way towards explaining why singing or playing out of tune is tabooed in music: hitting the right pitch is required by the consonance and harmony constraints expected by the listener and historically presumably linked with a combination of the polyphony in our Western tradition of music composition and the fact that most of our music instruments produce tones with harmonic spectra. This implies that intervals departing too much from just intonation will generate beats between simultaneously sounding and only nearly coinciding partials, particularly if the fundamental frequencies are constant, lacking vibrato and flutter.

16.9 The Expressive Power of the Human Voice

The human voice is an extremely expressive instrument both when used for speech and for singing. By means of subtle variations of timing and pitch contour speakers and singers add a substantial amount of expressiveness to the linguistic or musical content and we are quite skilled in deciphering this information. Indeed a good deal of vocal artistry seems to lie in the artist's skill in making nothing but such changes of pitch, timbre, loudness and timing that a listener can perceive as carrying some meaning.

We perceive the extra-linguistic or expressive information in speech and singing in various shapes. For example, we can interpret certain combinations of acoustic characteristics in speech in terms of a smile or a particular forming of the lips on the face of the speaker [16.179]. For example *Fónagy* [16.180] found that listeners were able to replicate rather accurately the facial expression of speakers only by listening to their voices.

The emotive transforms in speech and singing seem partly similar and sometimes identical [16.181, 182]. Final lengthening, mentioned above, uses the same code for marking the end of a structural element, such as a sentence in speech or a phrase in sung and played music performance. Emphasis by delayed arrival is another example, i.e., delaying an emphasized stressed syllable or note by lengthening the unstressed syllable/note preceding it [16.183].

The expressive potential of the human voice is indeed enormous, and would transpire from the ubiquitous use of the voice for the purpose of communication. Correct interpretation of the extra-linguistic content of a spoken utterance is certainly important in our daily life, so we are skilled in deciphering vocal signals also along those dimensions. The importance of correct encoding of the extra-linguistic implies that speakers acquire a great skill in this respect. This skill would be the basic requirement for vocal art, in singing as well as in acting.

17. Computer Music

Computer Mu

Perry R. Cook

This chapter covers algorithms, technologies, computer languages, and systems for computer music. Computer music involves the application of computers and other digital/electronic technologies to music composition, performance, theory, history, and the study of perception. The field combines digital signal processing, computational algorithms, computer languages, hardware and software systems, acoustics, psychoacoustics (low-level perception of sounds from the raw acoustic signal), and music cognition (higher-level perception of musical style, form, emotion, etc.).

Although most people would think that analog synthesizers and electronic music substantially predate the use of computers in music, many experiments and complete computer music systems were being constructed and used as early as the 1950s.

Because of this rich legacy, and the large number of researchers working on digital audio (primarily in speech research laboratories), there are a large number of algorithms for synthesizing sound using computers. Thus, a significant emphasis in this chapter will be placed on digital sound synthesis and processing, first providing

Part E | 17

an overview of the representation of audio in digital systems, then covering most of the popular algorithms for digital analysis and synthesis of sound.

Pulse code modulation (PCM) is the means for sampling and retrieval of audio in computers, and PCM synthesis uses combinations of prerecorded waveforms to reconstruct speech, sound effects, and music instrument sounds. Additive synthesis uses fundamental waveforms (often sine waves), to construct more complicated waves. PCM and sinusoidal (Fourier) additive synthesis are often called *nonparametric* techniques. The word parametric in this context means that an algorithm with a few (but hopefully expressive) parameters can be used to generate a large variety of waveforms and spectral properties by varying the parameters.

Since PCM involves recording and playing back waveforms, no actual expressive parameters are available in PCM systems. Similarly, Fourier's theorem says that we can represent any waveform with a sum of sine waves, but in fact it might take a huge number of sine waves to represent a particular waveform accurately. So, without further work to *parameterize* PCM samples or large groups of additive sine waves, these techniques are nonparametric.

Modal synthesis recognizes the fact that many vibrating systems exhibit a relatively few strong sinusoidal modes (natural frequencies) of vibration. Rigid

bars and plates, plucked strings, and other structures are good candidates for modal synthesis, where after being excited (struck, plucked, etc.) the vibration/sound generation is restricted to a limited set of exponentially decaying sine waves. Modal synthesis is generally considered to be parametric, since the number of sine waves needed is often quite limited, and each one represents a physical mode of vibration.

Subtractive synthesis begins with spectrally complex waveforms (such as pulses or noise), and uses filters to shape the spectrum and waveform to the desired result. Subtractive synthesis works particularly well for certain classes of sounds, such as human speech, where a spectrally rich source (pulses of the vocal folds) is filtered by a time-varying filter (the acoustic tube of the vocal tract). Subtractive synthesis is parametric, because only a few descriptive numbers control such a model. For example, a subtractive speech model might be controlled by numbers expressing how pitched versus noisy the voice is, the voice pitch, the loudness, and 8–10 numbers describing the resonances of the vocal tract. Using only a dozen or so variable numbers (parameters), a rich variety of vowel and consonant sounds can be synthesized.

Frequency modulation (FM) synthesis exploits properties of nonlinearity to generate complex spectra and waveforms from much simpler ones. Modulating the frequency or phase of a sine wave (the carrier) by another sine wave (the modulator) causes multiple *sideband* sinusoids to appear at frequencies related to the ratio of the carrier and modulator frequencies. Thus an important parameter in FM is the carrier : modulator (C : M) ratio, and another is the amount (index) of modulation, which when increased causes the number of sidebands to increase.

Wavelets are waveforms that are usually compact in time and frequency. They are viewed by some as related to the fundamental unit of sound, by others as convenient building blocks for constructing sonic textures, and by others as related to important small events in nature and acoustics. *Formes d'onde formantiques* (FOFs, French for formant wave functions) are special wavelets that model the individual resonances of the vocal tract, and thus have been successfully used for modeling speech and singing.

Physical models solve the wave equation in space and time to generate waveforms in the same ways that physical acoustics does. Efficient techniques combining discrete simulation of physics with modern digital filtering techniques allow models of plucked strings, wind instruments, percussion, the vocal tract, and many other musical systems to be solved efficiently by computers.

After the presentation and examples of the main synthesis algorithms, some industry standards for representing and manipulating musical data in computerized systems will be discussed. The musical instrument digital interface (MIDI), downloadable sounds (DLS, and SoundFonts), open sound control (OSC), structured audio orchestra language (SAOL), and other score and control standards will be briefly covered.

Some languages and systems for computer music composition are discussed, including the historical MusicX languages, and many modern languages such as Cmusic and MAX/MSP, followed by a few real-time performance and interaction systems. Finally, some aspects of computer modeling of human listening and systems for machine-assisted and automatic composition are covered.

17.1 Computer Audio Basics

Typically, digital audio signals are formed by *sampling* analog (continuous in time and amplitude) signals at regular intervals in time, and then *quantizing* the amplitudes to discrete values. The process of sampling a waveform, holding the value, and quantizing the value to the nearest number that can be digitally represented (as a specific integer on a finite range of integers) is called analog-to-digital (A to D, or A/D) conversion [17.1]. A device that does A/D conversion is called an analog-to-digital converter (ADC). Coding and representing waveforms in sampled digital form is called pulse code modulation (PCM), and digital audio signals

are often called PCM audio. The process of converting a sampled signal back into an analog signal is called digital-to-analog conversion (D to A, or D/A), and the device is called a digital-to-analog converter (DAC). Low-pass filtering (smoothing the samples to remove unwanted high frequencies) is necessary to reconstruct the sampled signal back into a smooth continuous-time analog signal. This filtering is usually contained in the DAC hardware.

The time between successive samples is usually denoted by T (*the sampling period*). Sampling an analog signal first requires filtering it to remove unwanted high
Fig. 17.1 Linear sampling and quantization (SRATE = sampling rate)

frequencies (more on this shortly), holding the value steady for a period while a stable measurement can be made, then associating the analog value with a digital number (coding). Analog signals can have any of the infinity of real-numbered amplitude values. Since computers work with fixed word sizes (8 bit bytes, 16 bit words, etc.), digital signals can only have a finite number of amplitude values. In converting from analog to digital, rounding takes place and a given analog value must be quantized to the nearest digital value. The difference between quantization steps is called the quantum (not as in quantum physics or leaps, but the Latin word for a fixed-sized jump in value or magnitude). Sampling and quantization is shown in Fig. 17.1; note the errors introduced in some sample values due to the quantization process.

A fundamental law of digital signal processing states that, if an analog signal is bandlimited with bandwidth B Hz, (Hz = Hertz = cycles per second), the signal can be periodically sampled at a rate of $2B$ Hz or greater, and exactly reconstructed from the samples. Band-limited with bandwidth B means that no frequencies above B exist in the signal. The rate $2B$ is called the sampling rate, and B is called the Nyquist frequency. Intuitively, a sine wave at the highest frequency B present in a band-limited signal can be represented using two samples per period (one sample at each of the positive and negative peaks), corresponding to a sampling frequency of $2B$. All signal components at lower frequencies can be uniquely represented and distinguished from each other using this same sampling frequency of $2B$. If there are components present in a signal at frequencies greater than 1/2 the sampling rate, these components will not be represented properly, and will *alias* (i. e., show up as frequencies different from their original values).

To avoid aliasing, ADC hardware often includes filters that limit the bandwidth of the incoming signal
Fig. 17.2 Because of inadequate sampling rate, aliasing causes important features to be lost

before sampling takes place, automatically changing as a function of the selected sampling rate. Figure 17.2 shows aliasing in complex and simple (sinusoidal) waveforms. Note the loss of detail in the complex waveform. Also note that samples at less than two times the frequency of a sine wave could also have arisen from a sine wave of much lower frequency. This is the fundamental nature of aliasing, because frequencies higher than 1/2 sample rate *alias* as lower frequencies.

Humans can perceive frequencies from roughly 20 Hz to 20 kHz, thus requiring a minimum sampling rate of at least 40 kHz. Speech signals are often sampled at 8 kHz (*telephone quality*) or 11.025 kHz, while music is usually sampled at 22.05 kHz, 44.1 kHz (the sampling rate used on audio compact discs), or 48 kHz. Some new formats allow for sampling rates of 96 kHz, and even 192 kHz. This is because some engineers believe that we can actually hear things, or the effects of things, higher than 20 kHz. Dolphins, dogs, and some other animals can hear higher than us, so these new formats could be considered as catering to those potential markets.

In a digital system, a fixed number of binary digits (bits) are used to sample the analog waveform, by quantizing it to the closest number that can be represented. This quantization is accomplished either by rounding to the quantum value nearest the actual analog value, or by truncation to the nearest quantum value less than or equal to the actual analog value. With uniform sampling in time, a properly bandlimited signal
Fig. 17.3 Resampling by linear interpolation. Grey regions show the errors due to linear interpolation

can be exactly recovered provided that the sampling rate is twice the bandwidth or greater, but only if there is no quantization. When the signal values are rounded or truncated, the amplitude difference between the original signal and the quantized signal is lost forever. This can be viewed as an additive noise component upon reconstruction. Using the additive-noise assumption gives an approximate best-case signal-to-quantization-noise ratio (SNR) of approximately $6N$ dB, where N is the number of bits. Using this approximation implies that a 16 bit linear quantization system will exhibit an SNR of approximately 96 dB. 8 bit quantization exhibits a signal-to-quantization-noise ratio of approximately 48 dB. Each extra bit improves the signal-to-noise ratio by about 6 dB.

Most computer audio systems use two or three types of audio data words. 16 bit (per channel) data is quite common, and this is the data format used in compact disc systems. Many recent (high-definition) formats allow for 24 bit samples, and even larger word sizes and floating point representations. 8 bit data is common for speech data in personal computer (PC) and telephone systems, usually using methods of quantization that are nonlinear. In such systems the quantum is smaller for small amplitudes, and larger for large amplitudes.

Changing the playback sample rate on sampled sound results in a pitch shift. Many systems for recording, playback, processing, and synthesis of music, speech, or other sounds allow or require flexible control of pitch (sample rate). The most accurate pitch control is necessary for music synthesis. In sampling synthesis, this is accomplished by dynamic sample-rate conversion (interpolation). In order to convert a sampled data signal from one sampling rate to another, three steps are required: bandlimiting, interpolation, and resampling.

Bandlimiting: First, it must be assured that the original signal was properly bandlimited to less than half the new sampling rate. This is always true when *upsampling* (i. e., converting from a lower sampling rate to a higher one). When *downsampling*, however, the signal must be first low-pass filtered to exclude frequencies greater than half the new target rate.

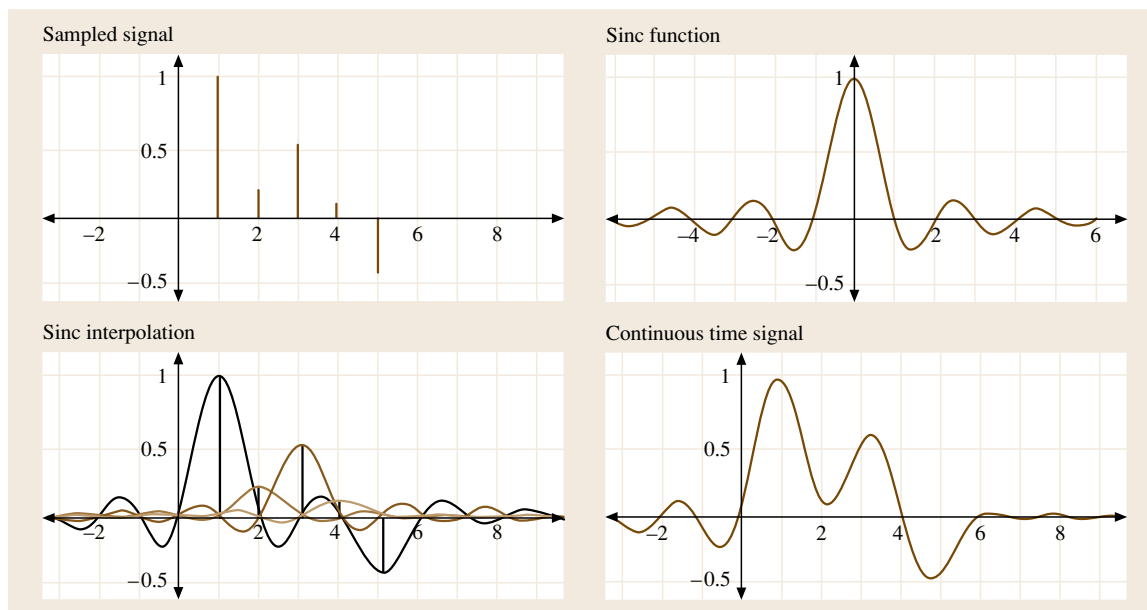
Interpolation: When resampling by any but simple integer factors such as 2, 4, 1/2, etc., the task


Fig. 17.4 Sinc interpolation for reconstruction and resampling

requires the computation of the values of the original bandlimited analog signal at the correct points between the existing sampled points. This is called interpolation. The most common form of interpolation used is linear interpolation, where the fractional time samples needed are computed as a linear combination of the two surrounding samples. Many assume that linear interpolation is the correct means, or at least an adequate means for accomplishing audio sample rate conversion. Figure 17.3 shows resampling by linear interpolation; note the errors shown by the shaded regions.

Some might notice that linear interpolation is not quite adequate, so they might assume that the correct solution must lie in more elaborate curve-fitting techniques using quadratics, cubics, or higher-order splines, and indeed these types of interpolation can be adequate for some applications. To arrive at the correct answer (provably correct from theory) the interpolation task should be viewed and accomplished as a filtering problem, with the filter designed to meet some appropriate error criterion. Linear time-invariant filtering is accomplished by convolution with a filter function. If the resampling filter is defined appropriately, we can exactly reconstruct the original analog waveform from the samples.

The correct (ideal in a provable digital signal processing sense) way to perform interpolation is convolution with the sinc function, defined as:

$$\text{sinc}\left(\frac{t}{T}\right) = \frac{\sin\left(\frac{\pi t}{T}\right)}{\frac{\pi t}{T}} ,$$

where

$$T = \frac{1}{\text{SRATE}} .$$

The sinc function is the ideal low-pass filter with a cutoff of SRATE/2, where SRATE is the sampling rate. Figure 17.4 shows reconstruction of a continuous waveform by convolution of a digital signal with the sinc function. Each sample is multiplied by a corresponding continuous sinc function, and those are added up to arrive at the continuous reconstructed signal [17.2].

Resampling: This is usually accomplished at the same time as interpolation, because it is not necessary to reconstruct the entire continuous waveform in order to acquire new discrete samples. The resampling ratio can be time varying, making the problem a little more difficult. However, viewing the problem as a filter-design and implementation issue allows for guaranteed tradeoffs of quality and computational complexity.

17.2 Pulse Code Modulation Synthesis

The majority of digital sound and music synthesis today is accomplished via the playback of stored pulse code modulation (PCM) waveforms. Single-shot playback of entire segments of stored sounds is common for sound effects, narrations, prompts, segments of music, etc. Most high-quality modern electronic music synthesizers, speech synthesis systems, and PC software systems for sound synthesis use pre-stored PCM as the basic data. This data is sometimes manipulated to yield the final output sound(s).

There are a number of different ways to look at sound for computer music, with PCM being only one. We can look at the physics that produce the sound and try to model those. We could also look at the spectrum of the sound and other characteristics having to do with the perception of those sounds. Indeed, much of the legacy of computer music has revolved around parametric (using mathematical algorithms, controlled by a few well-chosen/-designed control parameters) analysis and synthesis algorithms. We will discuss most of the commonly used algorithms later, but first we should look at PCM in more depth.

For speech, the most common synthesis technique is *concatenative* synthesis [17.3]. Concatenative phoneme synthesis relies on the concatenation of roughly 40 pre-stored phonemes (for English). Examples of vowel phonemes are /i/ as in beet, /I/ as in bit, /a/ as in father, etc. Examples of nasals are /m/ as in mom, /n/ as in none, /ng/ as in sing, etc. Examples of fricative consonant phonemes are /s/ as in sit, /sh/ as in ship, /f/ as in fifty, etc. Examples of voiced fricative consonants are /z/, /v/ (visualize), etc. Examples of plosive consonants are /t/ as in tat, /p/ as in pop, /k/ as in kick, etc. Examples of voiced plosives include /d/, /b/, /g/ (dude, bob, gag) etc. Vowels and nasals are essentially periodic pitched sounds, so the minimal required stored waveform is only one single period of each. Consonants require more storage because of their noisy (non-pitched, aperiodic) nature.

The quality of concatenative phoneme synthesis is generally considered quite low, due to the simplistic assumption that all of the pitched sounds (vowels, etc.) are purely periodic. Also, simply *gluing* /s/ /I/ and /ng/ together does not make for a high-quality realistic
Fig. 17.5 Wave-table synthesis of a trumpet tone

synthesis of the word *sing*. In actual speech, phonemes gradually blend into each other as the jaw, tongue, and other articulators move with time.

Accurately capturing the transitions between phonemes with PCM requires recording transitions from phoneme to phoneme, called *diphones*. A concatenative diphone synthesizer blends together stored diphones. Examples of diphones include see, she, thee, and most of the roughly 40×40 possible combinations of phonemes. Much more storage is necessary for a diphone synthesizer, but the resulting increase in quality is significant. PCM speech synthesis can be improved further by storing multiple samples, for different pitch ranges, genders, voice qualities, etc.

For musical sounds, it is common to store only a loop, or table, of the periodic component of a recorded sound waveform and play that loop back repeatedly. This is called *wave-table synthesis* [17.4]. For more realism, the attack or beginning portion of the recorded sound can be stored in addition to the periodic steady-state part. Figure 17.5 shows the synthesis of a trumpet tone starting with an attack segment, followed by repetition of a periodic loop, ending with an enveloped decay (or release). The *envelope* is a synthesizer/computer music term for a time-varying change applied to a waveform amplitude, or other parameter. Envelopes are often described by four components: the *attack time*, the *decay time* (decay here means the initial decay down to the steady state segment), the *sustain level*, and the *release time* (final decay). Hence, envelopes are sometimes called ADSRs.

Originally called *sampling synthesis* in the music industry, any synthesis using stored PCM waveforms has now become commonly known as *wave-table synthe-*

sis. Filters are usually added to high-quality wave-table synthesis, allowing control of spectral brightness as a function of intensity, and to get more variety (parameterization) of sounds from a given set of samples.

Pitch shifting of a PCM sample or wave table is accomplished via interpolation as discussed in the previous section. A given sample can be pitch-shifted only so far in either direction before it begins to sound unnatural. This can be dealt with by storing multiple recordings of the sound at different pitches, and switching or interpolating between these upon resynthesis. This is called *multi-sampling*. Multi-sampling might also include the storage of separate samples for loud and soft sounds. Linear or other interpolation is used to blend the loudness of multi-samples as a function of the desired synthesized volume. This adds realism, because loudness is not simply a matter of amplitude or power, and most sound sources exhibit spectral variations as a function of loudness. For example, there
Fig. 17.6 A synthesis *patch* showing interconnection of *unit generators*

is usually more high-frequency energy (*brightness*) in loud sounds than in soft sounds. Filters can also be used to add spectral variation.

A common tool used to describe the various components and steps of signal processing in performing digital music synthesis is the *synthesizer patch* (historically named from hooking various electrical components together using patch cords). In a patch, a set of fairly commonly agreed building blocks, called *unit generators* (also called modules, plug-ins, operators, op-codes, and other terms) are hooked together in a signal flow diagram. This historical [17.5] graphical method of describing signal generation and processing affords a visual representation that is easily printed in papers, textbooks, patents, etc. Further, graphical patching systems and languages have been important to the development and popularization of certain algorithms, and computer music in general. Figure 17.6 shows a PCM synthesizer patch with attack and loop wave tables whose amplitudes are controlled by an envelope generator, and a time-varying filter (also controlled by another envelope generator).

17.3 Additive (Fourier, Sinusoidal) Synthesis

Lots of sound-producing objects and systems exhibit sinusoidal modes. A plucked string might exhibit many modes, with the strength of each mode determined by the boundary conditions of the terminations, and the shape of the excitation pluck. Striking a metal plate with a hammer excites many of the vibrational modes of the plate, determined by the shape of the plate, and by where it is struck. A singing voice, struck drum head, bowed violin string, struck bell, or blown trumpet exhibit oscillations characterized by a sum of sinusoids. The recognition of the fundamental nature of the sinusoid gives rise to a powerful model of sound synthesis based on summing sinusoidal modes.

These modes have a very special relationship in the case of the plucked string, a singing voice, and some other limited systems, in that their frequencies are all integer multiples (at least approximately) of one basic sinusoid, called the *fundamental*. This special series of sinusoids is called a *harmonic series*, and lies at the basis of the Fourier-series representation of shapes, waveforms, oscillations, etc. The Fourier series [17.6] solves many types of problems, including physical problems with boundary constraints, but is also applicable to any shape or function. Any periodic waveform (repeating over and over again) f_{per} can be transformed into a Fourier series, written as

$$f_{per}(t) = a_0 + \Sigma_m [b_m \cos(2\pi f_0 m t)$$
$$+ c_m \sin(2\pi f_0 m t)] . \qquad (17.1)$$

The limits of the summation are technically infinite, but we know that we can cut off our frequencies at the Nyquist frequency for digital signals. The a_0 term is a constant offset, or the average of the waveform. The b_m and c_m coefficients are the weights of the mth harmonic cosine and sine terms. If the function $f_{per}(t)$ is purely even about $t = 0$ ([$f(-t) = f(t)$]),

only cosines are required to represent it, and only the b_m terms would be nonzero. Similarly, if the function $f_{per}(t)$ is odd ([$f(-t) = -f(t)$]), only the c_m terms would be required. An arbitrary function $f_{per}(t)$ will require sinusoidal harmonics of arbitrary (but specific) amplitudes and phases. The magnitude and phase of the m-th harmonic in the Fourier series can be found by:

$$A_m = \sqrt{b_m^2 + c_m^2} , \qquad (17.2a)$$

$$\theta_m = \arctan \frac{c_m}{b_m} . \qquad (17.2b)$$

Phase is defined relative to the cosine, so if c_m is zero, θ_m is zero. As a brief example, Fig. 17.7 shows the first few sinusoidal harmonics required to build up an approximation of a square wave. Note that due to symmetries (boundary conditions), only odd sine harmonics are required. Using more sines improves the approximation.

The process of solving for the sine and cosine components of a signal or waveform is called Fourier analysis, or the Fourier transform. If the frequency variable is sampled (as is the case in the Fourier series, represented by m), and the time variable t is sampled as well (as it is in PCM waveform data, represented by n),
Fig. 17.7 A sum of odd harmonics approximates a square wave

then the Fourier transform is called the *discrete Fourier transform* (DFT). The DFT is given by

$$F(m) = \sum_{n=0}^{N-1} f(n) \left[\cos\left(2\pi \frac{mn}{N}\right) \right.$$
$$\left. - i \sin\left(2\pi \frac{mn}{N}\right) \right] . \tag{17.3}$$

Where N is the length of the signal being analyzed. The inverse DFT (IDFT) is very similar to the Fourier series

$$f(n) = \frac{1}{N} \sum_{m=0}^{N-1} F(m) \left[\cos\left(2\pi \frac{mn}{N}\right) \right.$$
$$\left. + i \sin\left(2\pi \frac{mn}{N}\right) \right] . \tag{17.4}$$

The imaginary number $i (= \sqrt{-1})$ is used to place the cosine and sine components in a unique mathematical arrangement, where odd $[(x(-n) = -x(n))]$ terms of the waveform are represented as imaginary components, and even $([x(-n) = x(n)])$ terms are represented as real components. This gives us a means to talk about the magnitude and phase in terms of the magnitude and phase of $F(m)$ (a complex number).

There is a near-mystical expression of equality in mathematics known as Euler's identity, which links trigonometry, exponential functions, and complex numbers in a single equation

$$e^{i\theta} = \cos(\theta) + i \sin(\theta) .$$

We can use Euler's identity to write the DFT and IDFT in shorthand

$$F(m) = \sum_{n=0}^{N-1} f(n) e^{-i2\pi mn/N} , \tag{17.5}$$

$$f(n) = \frac{1}{N} \sum_{m=0}^{N-1} F(m) e^{i2\pi mn/N} . \tag{17.6}$$

Converting the cosine/sine form to the complex exponential form allows lots of manipulations that would be difficult otherwise. But we can also write the DFT in real-number terms as a form of the Fourier series

$$f(n) = \frac{1}{N} \sum_{m=0}^{N-1} F_b(n) \cos\left(2\pi \frac{mn}{N}\right)$$
$$+ F_c(n) \sin\left(2\pi \frac{mn}{N}\right) , \tag{17.7}$$

where

$$F_b(m) = \sum_{n=0}^{N-1} f(n) \cos\left(2\pi \frac{mn}{N}\right) , \tag{17.8}$$

$$F_c(m) = \sum_{n=0}^{N-1} -f(n) \sin\left(2\pi \frac{mn}{N}\right) . \tag{17.9}$$

The fast Fourier transform (FFT) is a cheap way of calculating the DFT. There are thousands of references on the FFT [17.6], and scores of implementations of it, so for our purposes we will just say that it is much more efficient than computing the DFT directly from the definition. A well-crafted FFT algorithm for real input data takes on the order of $N \log_2(N)$ multiply–adds to compute. Comparing this to the N^2 multiplies of the DFT, N does not have to be very big before the FFT is a winner. There are some down sides, such as the fact that FFTs can only be computed for signals whose lengths are exactly powers of 2, but the advantages of using it often outweigh the annoying power-of-two problems. Practically speaking, users of FFTs usually carve up signals into small chunks (powers of two), or *zero pad* a signal out to the next biggest power of two.

The short-time Fourier transform (STFT) breaks up the signal and applies the Fourier transform to each segment individually [17.7]. By selecting the window size (length of the segments), and hop size (how far the window is advanced along the signal) to be perceptually relevant, the STFT can be used as an approximate model of human audio perception. Figure 17.8 shows the waveform of the utterance of the word *synthesize*, and some STFT spectra corresponding to windows at particular points in time.

If we inspect the various spectra in Fig. 17.8, we can note that the vowels exhibit harmonic spectra (clear, evenly spaced peaks corresponding to the harmonics of the pitched voice), while the consonants exhibit noisy spectra (no clear sinusoidal peaks). Recognizing that some sounds are well approximated/modeled by additive sine waves [17.8], while other sounds are essentially noisy, spectral modeling [17.7] breaks the sound into deterministic (sines) and stochastic (noise) components. Figure 17.9 shows a general sines + noise additive synthesis model, allowing us to control the amplitudes and frequencies of a number of sinusoidal oscillators, and model the noisy component with a noise source and a spectral shaping filter.

The beauty of this type of model is that it recognizes the dominant sinusoidal nature of many sounds, while still recognizing the noisy components that might be
Fig. 17.8 Some STFT frames of the word *synthesize*
Fig. 17.9 Sinusoidal additive model with filtered noise added for spectral modeling synthesis

also present. More efficient and parametric representations, and many interesting modifications can be made to the signal on resynthesis. For example, removing the

harmonics from voiced speech, followed by resynthesizing with a scaled version of the noise residual, can result in the synthesis of whispered speech.

One further improvement to spectral modeling is the recognition [17.9] that there are often brief (impulsive) moments in sounds that are really too short in time to be adequately analyzed by spectrum analysis. Further, such moments in the signal usually corrupt the sinusoidal/noise analysis process. Such events, called transients, can be modeled in other ways (often by simply keeping the stored PCM for that segment).

Using the short-time Fourier transform, the *phase vocoder* (VoiceCoder) [17.10, 11] processes sound by calculating and maintaining both magnitude and phase. The frequency bins (basis sinusoids) of the DFT can be viewed as narrow-band filters, so the Fourier transform of an input signal can be viewed as passing it through a bank of narrow band-pass filters. This means that on the order of hundreds to thousands of sub-bands are used.

The phase vocoder has found extensive use in computer music composition. Many interesting practical and artistic transformations can be accomplished using

the phase vocoder, including nearly artifact-free and independent time and pitch shifting. A technique called *cross synthesis* assumes that one signal is the analysis signal. The time-varying magnitude spectrum of the analysis signal (usually smoothed in the frequency domain) is multiplied by the spectral frames of another input (or filtered) signal (sometimes brightened first by high-frequency emphasis pre-filtering), yielding a composite signal that has the attributes of both. Cross-synthesis has produced the sounds of talking cows, *morphs* between people and cats, trumpet/flute hybrids, etc.

17.4 Modal (Damped Sinusoidal) Synthesis

The simplest physical system that does something acoustically (and musically) interesting is the mass/spring/damper (Fig. 17.10) [17.12]. The differential equation describing that system has a solution that is a single exponentially decaying cosine wave. The Helmholtz resonator (large, contained air cavity with a small long-necked opening, like a pop bottle, Fig. 17.11 behaves like a mass/spring/damper system, with the same exponentially damped cosine behavior. The equations describing the behavior of these systems is

$$\frac{d^2y}{dt^2} + \left(\frac{r}{m}\right)\frac{dy}{dt} + \left(\frac{k}{m}\right) y = 0 \,, \tag{17.10}$$

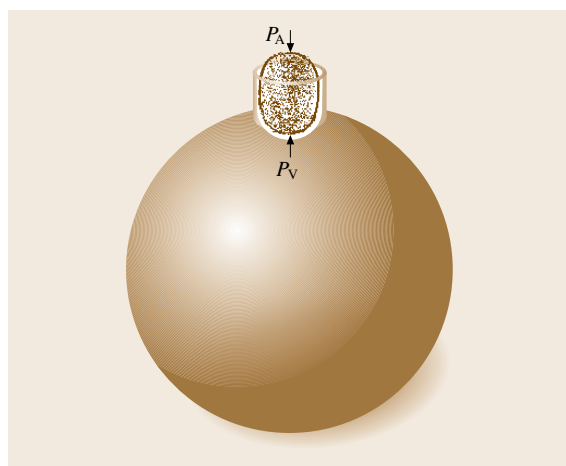
$$y(t) = y_0\, e^{(-rt/2m)} \cos\left(t\sqrt{\left[\frac{k}{m} - \left(\frac{r}{2m}\right)^2\right]} \right)\,. \tag{17.11}$$
Fig. 17.10 Mass/spring/damper system


Fig. 17.11 Helmholtz resonator
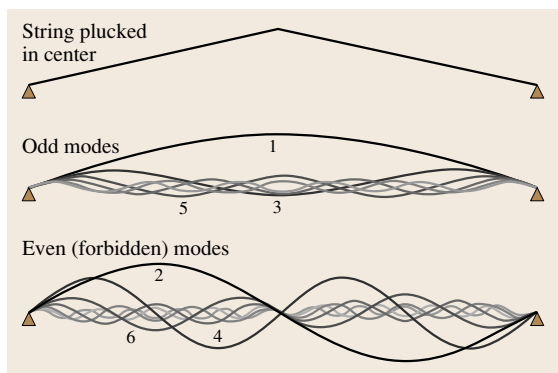

Fig. 17.12 Plucked string (*top*). The *center* shows sinusoidal *modes* of vibration of a center-plucked string. The *bottom* shows the even modes, which would not be excited by the center-plucked condition
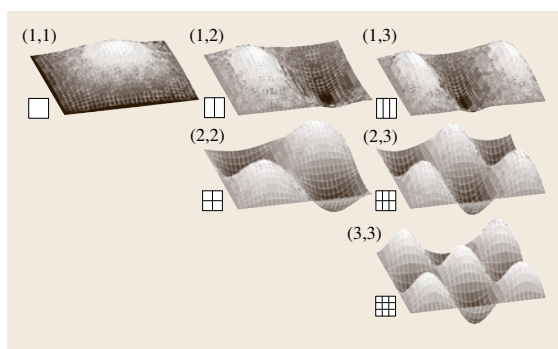

Fig. 17.13 Square-membrane modes
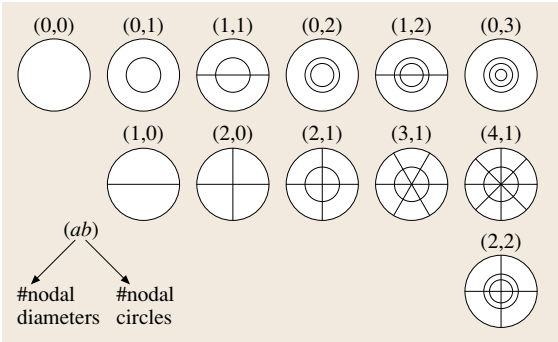

Fig. 17.14 Circular-membrane nodal lines

Fig. 17.16 Flexible parametric modal synthesis algorithm

Of course, most systems that produce sound are more complex than the ideal mass/spring/damper system, or a pop bottle. And of course most sounds are more complex than a simple damped exponential sinusoid. Mathematical expressions of the physical forces (thus the accelerations) can be written for nearly any system, but solving such equations is often difficult or impossible. Some systems have simple enough properties and geometries to allow an exact solution to be written out for their vibrational behavior. An ideal string under tension is one such system.

Here we will resort to some graphical arguments and our prior discussion of the Fourier transform to motivate further the notion of sinusoids in real physical systems. The top of Fig. 17.12 shows a string, lifted from a point in the center (halfway along its length). Below that is shown a set of sinusoidal modes that the center-plucked string vibration would have. These are spatial functions (sine as function of position along the string), but they also correspond to natural frequencies of vibration of the string. At the bottom of Fig. 17.12 is another set of modes that would not be possible with the center-plucked condition, because all of these even modes are restricted to have no vibration in the center of the string, and thus they could not contribute to the triangular shape of the string.

Fig. 17.15 Flexible parametric modal synthesis algorithm

These conditions of no displacement, corresponding to the zero crossings of the sine functions, are called *nodes*. Note that the end points are forced nodes of the plucked string system for all possible conditions of excitation.

Physical constraints on a system, such as the pinned ends of a string, and the center plucked initial shape, are known as *boundary conditions*. Spatial sinusoidal solutions like those shown in Fig. 17.12 are called *boundary solutions* (the legal sinusoidal modes of displacement and vibration) [17.13].

Just as one can use Fourier boundary methods to solve the one-dimensional (1-D) string, we can also extend boundary methods to two dimensions. Figures 17.13 and 17.14 show the first few vibration modes of uniform square and circular membranes. The small boxes at the lower left corners of each square modal-shape diagram depict the modes in a purely two-dimensional way, showing lines corresponding to the spatial sinusoidal nodes (regions of no displacement vibration). This is how the circular modes are presented. The natural modes must obey the two-dimensional boundary conditions at the edges, but unlike the string, the square membrane modes are not integer-related harmonic frequencies. In fact they obey the relationship

$$f_{mn} = f_{11}\sqrt{\left[\frac{m^2 + n^2}{2}\right]}, \qquad (17.12)$$

where m and n range from 1 to (potentially) infinity, and f_{11} is $c/2L$ (the speed of sound on the membrane divided by the square edge lengths). The circular modes are predictable from mathematics, but have a much more complex form than the square modes.

Unfortunately, circles, rectangles, and other simple geometries turn out to be the only ones for which the boundary conditions yield a closed-form solution in terms of spatial and temporal sinusoidal terms. However, we can measure and model the modes of any system by using the Fourier transform of the sound it produces, and looking for exponentially decaying sinusoidal components.

We can approximate the differential equation describing the mass/spring/damper system of (17.11) by replacing the derivatives (velocity as the derivative of position, and acceleration as the second derivative of position) with sampled time differences (normalized by the sampling interval T seconds). In doing so we would arrive at an equation that is a recursion in past values of $y(n)$, the position variable

$$\frac{y(n) - 2y(n-1) + y(n-2)}{T^2}$$
$$+ \left\{ \frac{\frac{r}{m}[y(n) - y(n-1)]}{T} \right\} + \frac{k}{m} y(n) = 0 . \quad (17.13)$$

Note that if the values of mass, damping, spring constant, and sampling rate are constant, then the coefficients $(2m + Tr)/(m + Tr + T^2k)$ for the single delay, and $m/(m + Tr + T^2k)$ for the twice-delayed signal applied to past y values are constant. Digital signal processing (DSP) engineers would note that a standard infinite impulse response (IIR) recursive filter as shown in Fig. 17.15 can be used to implement (17.13) (the z^{-1} represents a single sample of delay). In fact, the second order two-pole feedback filter can be used to generate an exponentially decaying sinusoid, called a *phasor* in DSP literature [17.14]. The connection between the second order digital filter and the physical notion of a mode of vibration forms the basis for modal sound synthesis [17.15]. Figure 17.16 shows a general model for modal synthesis of struck/plucked objects, in which an impulsive excitation function is used to excite a number of filters that model the modes. Rules for controlling the modes as a function of strike position, striking object, changes in damping, and other physical constraints can be included in the model.

17.5 Subtractive (Source–Filter) Synthesis

Subtractive synthesis uses a complex source wave, such as an impulse, a periodic train of impulses, or white noise, to excite spectral shaping filters. One of the earliest uses of electronic subtractive synthesis dates back to the 1920s and 1930s, with the invention of the *channel vocoder* (or VOiceCODER) [17.16]. In the this device, the spectrum is broken into sections called sub-bands, and the information in each sub-band is converted to a signal representing (generally slowly varying) power. The analyzed parameters are then stored or transmitted (potentially compressed) for reconstruction at another time or physical site. The parametric data representing the information in each sub-band can be manipulated in various ways, yielding transformations such as pitch or time shifting, spectral shaping, cross-synthesis, and other effects. Figure 17.17 shows a block diagram of a channel vocoder. The detected envelopes serve as control signals for a bank of bandpass synthesis filters (identical to the analysis filters used to extract the sub-band envelopes). The synthesis filters have gain inputs that are fed by the analysis control signals.

When used to encode and process speech, the channel vocoder explicitly makes an assumption that the signal being modeled is a single human voice. The *source analysis* block extracts parameters related to

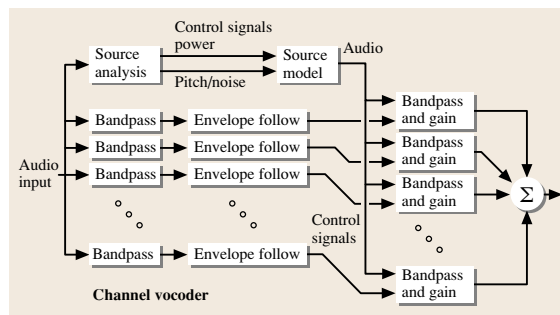
finer spectral details, such as whether the sound is pitched (vowel) or noisy (consonant or whispered). If the sound is pitched, the pitch is estimated. The overall energy in the signal is also estimated. These parameters become additional low-bandwidth control signals for the synthesizer. Intelligible speech can be synthesized using only a few hundred numbers per second. An example coding scheme might use eight channel gains + pitch + power, per frame, at 40 frames per second, yielding a total of only 400 numbers per second. The channel vocoder, as designed for speech coding, does not generalize to arbitrary sounds, and fails horribly


Fig. 17.17 Channel vocoder block diagram

when the source parameters deviate from expected harmonicity, reasonable pitch range, etc. But the ideas of sub-band decomposition, envelope detection, and driving a synthesis filter bank with control signals give rise to many other interesting applications and implementations of the vocoder concept.

A number of analog hardware devices were produced and sold as musical instrument processing devices in the 1970s and 1980s. These were called simply *vocoders*, but had a different purpose than speech coding. Figure 17.18 shows the block diagram of a cross-synthesizing vocoder. The main difference is that the parametric source has been replaced by an arbitrary audio signal. The cross-synthesizer can be used to make non-speech sounds talk or sing. A typical example would be feeding a voice into the analysis filter bank, and an electric guitar sound into the synthesis bank audio inputs to make a talking guitar. To be effective, the synthesis audio input should have suitably rich spectral content (for instance, distorted electric guitar works better than undistorted). Some vocoders allowed an additional direct *sibilance band* (like the highest band shown in Fig. 17.18) pass-through of the analyzed sound. This would allow consonants to pass through directly, creating a more intelligible speech-like effect.

Modal synthesis, as discussed before, is a form of subtractive synthesis, but the spectral characteristics of modes are sinusoidal and thus exhibit very narrow spectral peaks. For modeling the gross peaks in a spectrum, which could correspond to weaker resonances, we can exploit the same two-pole resonance filters. This type of source-filter synthesis has been very popular for voice synthesis.

Having its origins and applications in many different disciplines, time-series prediction is the task of estimating future sample values from prior samples. Linear prediction is the task of estimating a future sample (usually the next in the time series) by forming a linear combination of some number of prior samples. Linear predictive coding (LPC) is a technique that can automatically extract the gross spectral features and design filters to match those, and give us a source that we can use to drive the filters [17.17, 18]. Figure 17.19 shows linear prediction in block diagram form. The difference equation for a linear predictor is

$$y(n) = \hat{x}(n+1) = \sum_{i=0}^{m} a_i x(n-i) \, . \qquad (17.14)$$

The task of linear prediction is to select the vector of predictor coefficients

$$A = (a_0, a_1, a_2, a_2, \ldots, a_m)$$

such that $\hat{x}(n+1)$ (the estimate) is as close as possible to $x(n+1)$ (the real sample) over a set of samples (often called a frame) $x(0)$ to $x(N-1)$. Usually, *close as possible* is defined by minimizing the mean square error (MSE)

$$\text{MSE} = \frac{1}{N} \sum_{n=0}^{N-1} [\hat{x}(n+1) - x(n+1)]^2 \, . \qquad (17.15)$$

Many methods exist to arrive at the set of predictor coefficients a_i that yield a minimum MSE. The most common uses correlation or covariance data from each frame of samples to be predicted. The *autocorrelation* function, defined as

$$x \blacklozenge x(n) = \sum_{i=0}^{N-1} x(i)x(i+n) \, . \qquad (17.16)$$

Autocorrelation computes a time (lag) domain function that expresses the similarity of a signal to delayed versions of itself. It can also be viewed as the convolution of a signal with the time-reversed version of itself. Purely periodic signals exhibit periodic peaks in the autocorrelation function. Autocorrelations of white-noise sequences exhibit only one clear peak at the zero-lag position, and are small (zero for infinite-length sequences) for all other lags. Since the autocorrelation function contains useful information about a signal's similarity to itself at various delays, it can be used to compute

Fig. 17.18 Cross-synthesizing vocoder block diagram
Fig. 17.19 A linear prediction filter

the optimal set of predictor coefficients by forming the autocorrelation matrix

$$\mathbf{R} =$$

$$\begin{pmatrix} x{\blacklozenge}x(0) & x{\blacklozenge}x(1) & x{\blacklozenge}x(2) & ... & x{\blacklozenge}x(m) \\ x{\blacklozenge}x(1) & x{\blacklozenge}x(0) & x{\blacklozenge}x(1) & ... & x{\blacklozenge}x(m-1) \\ x{\blacklozenge}x(2) & x{\blacklozenge}x(1) & x{\blacklozenge}x(0) & ... & x{\blacklozenge}x(m-2) \\ x{\blacklozenge}x(3) & x{\blacklozenge}x(2) & x{\blacklozenge}x(1) & ... & x{\blacklozenge}x(m-3) \\ . & . & . & . \\ x{\blacklozenge}x(m) & x{\blacklozenge}x(m-1) & x{\blacklozenge}x(m-2) & ... & x{\blacklozenge}x(0) \end{pmatrix} \quad (17.17)$$

We can get the least-squares predictor coefficients by forming

$$A = (a_0 a_1 a_2 a_3 \ldots a_m) = \mathbf{P}R^{-1} , \qquad (17.18)$$

where P is the vector of prediction correlation coefficients

$$\boldsymbol{P} = (x{\blacklozenge}x(1) \quad x{\blacklozenge}x(2) \quad x{\blacklozenge}x(3) \quad \ldots \quad x{\blacklozenge}x(m+1)) . \qquad (17.19)$$

For low-order LPC (delay order of 6–20 or so), the filter fits itself to the coarse spectral features, and the residue contains the remaining part of the sound that cannot be linearly predicted. A common and popular use of LPC is for speech analysis, synthesis, and compression. The reason for this is that the voice can be viewed as a source-filter model, where a spectrally rich input (pulses from the vocal folds or noise from turbulence) excites a filter (the resonances of the vocal tract). LPC is another form of spectral vocoder (voice coder) as discussed previously, but since LPC filters are not fixed in frequency or shape, fewer bands are needed to model the changing speech spectral shape dynamically.

LPC speech analysis/coding involves processing the signal in blocks and computing a set of filter coefficients for each block. Based on the slowly varying nature of speech sounds (the speech articulators can only move so fast), the coefficients are relatively stable for milliseconds at a time (typically 5–20 ms is used in speech coders). If we store the coefficients and information about the residual signal for each block, we will have captured many of the essential aspects of the signal. Figure 17.20 shows an LPC fit to a speech spectrum. Note that the fit is better at the peak locations than at the valleys. This is due to the least-squares minimization criterion. Missing the mark on low-amplitude parts of the spectrum is not as important as missing it on high-amplitude parts. This is fortunate for audio signal modeling, in that the human auditory system is more sensitive to spectral peaks (formants, poles, resonances) than valleys (zeroes, anti-resonances).

Once we have performed LPC on speech, if we inspect the residual we might note that it is often a stream of pulses for voiced speech, or white noise for unvoiced speech. Thus, if we store parameters about the residual, such as whether it is periodic pulses or noise, the frequency of the pulses, and the energy in the residual, then we can get back a signal that is very close to the original. This is the basis of much of modern speech compression. If a signal is entirely predictable using a linear combination of prior samples, and if the predictor filter is doing its job perfectly, we should be able to hook the output back to the input and let the filter predict the rest of the signal automatically. This form of filter, with feedback from output to input, is called *recursive*. The recursive LPC reconstruction is sometimes called *all pole*, to reflect the high-gain poles corresponding to the primary resonances of the vocal tract. The poles do not capture all of the acoustic effects going on in speech, however, such as zeroes that are introduced in nasalization, aerodynamic effects, etc. However, as mentioned before, since our auditory systems are most sensitive to peaks (poles), the LPC representation does quite a good job of capturing the most important aspects of speech spectra.

In recursive resynthesis form, any deviation of the predicted signal from the actual original signal will show up in the error signal, so if we excite the recursive LPC reconstruction filter with the residual signal itself, we can get back the original signal exactly. This is a form of identity analysis/resynthesis, performing deconvolution to separate the source from the filter, and using the residue to excite the filter to arrive at the original signal, by convolution, or using the residue as the input to the filter.

For computer music composition, LPC can be used for cross-synthesis, by keeping the time-varying filter coefficients, and replacing the residual with some other sound source. Using the parametric source model also allows for flexible time and pitch shifting, without modifying the basic timbre. The voiced pulse period can be modified, or the frame rate update of the filter coef-
Fig. 17.20 Tenth order LPC filter fit to a voiced *ooo* spectrum
Fig. 17.21 Cascade factored formant subtractive synthesizer

Fig. 17.23 Ladder filter implementation of an all-pole LPC filter

ficients can be modified, independently. So it is easy to speed up a speech sound while making the pitch lower and still retaining the basic spectral shapes of all vowels and consonants.

In decomposing signals into a source and a filter, LPC can be a marvelous aid in analyzing and under-standing some sound-producing systems. The recursive LPC reconstruction filter can be implemented in a variety of ways. Three different filter forms are commonly used to perform subtractive voice synthesis [17.19]. The filter can be implemented in series (cascade) as shown in Fig. 17.21, factoring each resonance into a separate filter block with control over center frequency, width, and amplitude. The filter can also be implemented in parallel (separate sub-band sections of the spectrum added together), as shown in Fig. 17.22.

One additional implementation of the resonant filter is the ladder filter structure, which carries with it a notion of one-dimensional spatial propagation as well [17.20]. Figure 17.23 shows a ladder filter realization of a 10th-order IIR filter. We will refer to this type of filter later when we investigate some 1-D waveguide physical models.

17.6 Frequency Modulation (FM) Synthesis

Wave-shaping synthesis involves warping a simple (usually a sine or sawtooth wave) waveform with a non-linear function or lookup table. One popular form of wave-shaping synthesis, called frequency modulation (FM), uses sine waves for both input and warping waveforms [17.21–23]. Frequency modulation relies on modulating the frequency of a simple periodic waveform with another simple periodic waveform. When the frequency of a sine wave of average frequency f_c (called the carrier), is modulated by another sine wave of frequency f_m (called the modulator), sinusoidal sidebands are created at frequencies equal to the carrier frequency plus and minus integer multiples of the modulator frequency. Figure 17.24 shows a block diagram for simple FM synthesis (one sinusoidal carrier and one sinusoidal modulator). Mathematically, FM is expressed as

$$y(t) = \sin[2\pi t f_c + \Delta f_c \cos(2\pi t f_m)] . \qquad (17.20)$$

The index of modulation I is defined as $\Delta f_c / f_c$. The equation as shown is actually phase modulation, but FM and PM can be related by a differentiation/integration of the modulation, and thus do not differ for cosine modulation.

Carson's rule (a rule of thumb) states that the number of significant bands on each side of the carrier frequency (sidebands) is roughly equal to $I + 2$. For example, a carrier sinusoid of frequency 600 Hz, a modulator sinusoid of frequency 100 Hz, and a modulation index of 3 would produce sinusoidal components of fre-

Fig. 17.24 Simple FM (one carrier and one modulator sine wave) synthesis
Fig. 17.25 Simple FM with 600 Hz carrier, 100 Hz modulator, and index of modulation of 3
Fig. 17.26 Inharmonic simple FM with 500 Hz carrier and 273 Hz modulator. The index of modulation is ramped from zero to 5 then back to zero

Fig. 17.27 Frequency-modulation voice synthesis diagram
Fig. 17.28 Frequency-modulation voice spectrum

quencies 600, 700, 500, 800, 400, 900, 300, 1000, 200, 1100, and 100 Hz. Inspecting these components reveals that a harmonic spectrum with 11 significant harmonics, based on a fundamental frequency of 100 Hz can be produced by using only two sinusoidal generating functions. Figure 17.25 shows the spectrum of this synthesis.

Selecting carrier and modulator frequencies that are not related by simple integer ratios yields an inharmonic spectrum. For example, a carrier of 500 Hz, modulator of 273 Hz, and an index of 5 yields frequencies of 500 (carrier), 227, 46, 319, 592, 865, 1138, 1411 (negative sidebands), and 773, 1046, 1319, 1592, 1865, 2138, 2411 (positive sidebands). Figure 17.26 shows a spec-

trogram of this FM tone, as the index of modulation is ramped from zero to 5. The synthesized waveforms at $I = 0$ and $I = 5$ are shown as well.

By setting the modulation index high enough, huge numbers of sidebands are generated, and the aliasing and addition of these (in most cases) results in noise. By careful selection of the component frequencies and index of modulation, and combining multiple carrier/modulator pairs, many spectra can be approximated using FM. However, the amplitudes and phases (described by Bessel functions) of the individual components cannot be independently controlled, so FM is not a truly generic waveform or spectral synthesis method. Using multiple carriers and modulators, connection topologies (algorithms) have been designed for the synthesis of complex sounds such as human voices, violins, brass instruments, percussion, etc. Figures 17.27 and 17.28 show an FM connection topology for human voice synthesis, and a typical resulting spectrum [17.24]. Because of the extreme efficiency of FM, it became popular in the 1980s as a music synthesizer algorithm. Later FM found wide use in early PC sound cards.

17.7 FOFs, Wavelets, and Grains

In a source/filter vocal model such as LPC or parallel/cascade formant subtractive synthesis, periodic

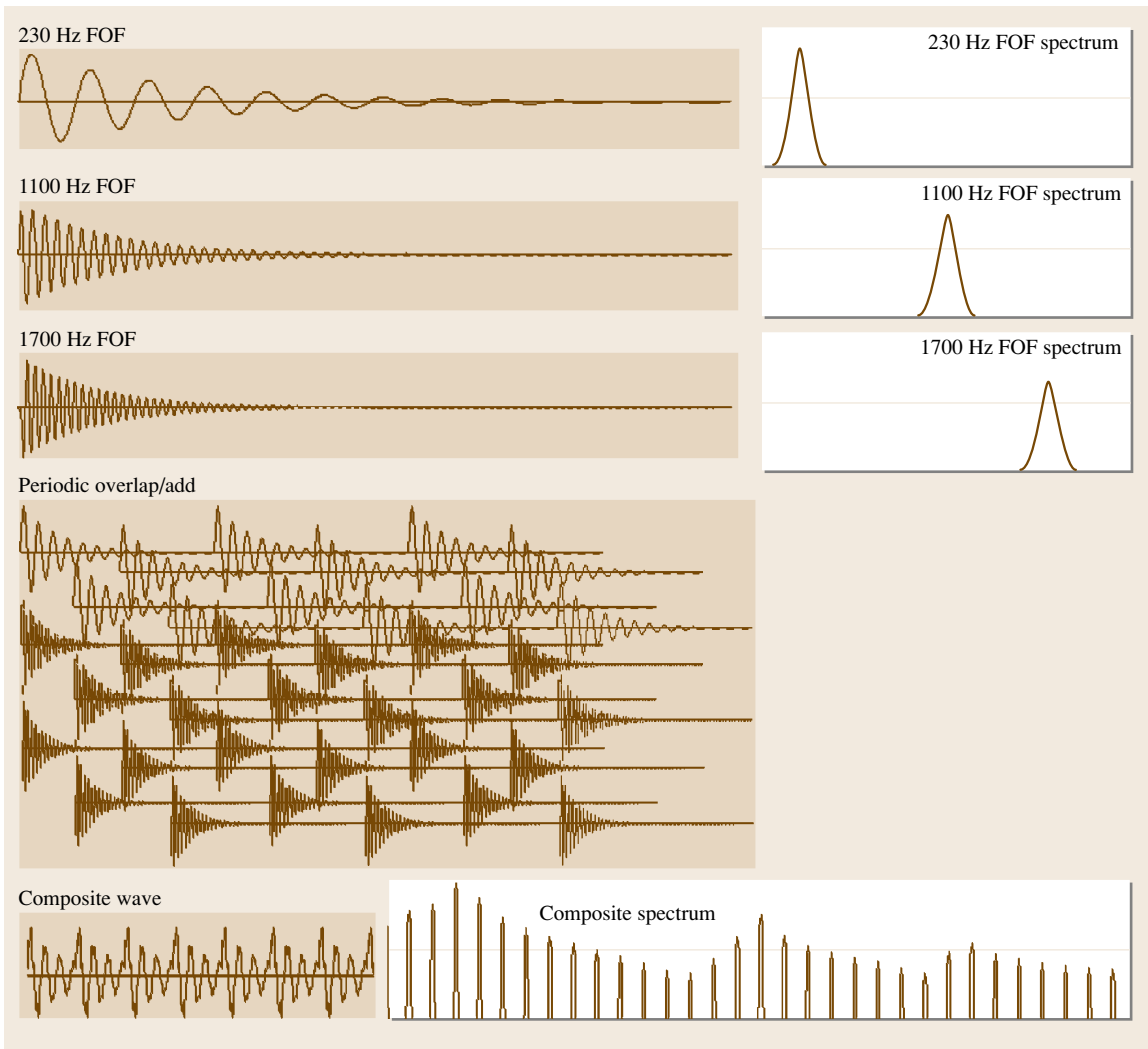
impulses are used to excite resonant filters to produce vowels. We could construct a simple alternative model


Fig. 17.29 FOF synthesis of a vowel

using three, four, or more tables storing the impulse responses of the individual vowel formants. Note that it is not necessary for the tables to contain pure exponentially decaying sinusoids. We could include any aspects of the voice source, etc., as long as those effects are periodic. Formes d'onde formantiques (FOFs, French for formant wave functions) were created for voice synthesis using such tables, overlapped and added at the repetition period of the voice source [17.25]. Figure 17.29 depicts FOF synthesis of a vowel. FOFs are composed of a sinusoid at the formant center frequency, with an amplitude that rises rapidly upon excitation, then decays exponentially. The control parameters define the center

frequency and bandwidth of the formant being modeled, and the rate at which the FOFs are generated and added determines the fundamental frequency of the voice.

Note that each individual FOF is a simple wavelet (local and compact wave both in frequency and time). A family of filter-based frequency transforms known as *wavelet transforms* have been used for the analysis and synthesis of sound. Instead of being based on steady sinusoids like the Fourier transform, wavelet transforms are based on the decomposition of signals into fairly arbitrary wavelets [17.26]. These wavelets can be thought of as mathematical sound grains. Some benefits of wavelet transforms over Fourier transforms

are that they can be implemented using fairly arbitrary filter criteria, on a logarithmic frequency scale rather than a linear scale as in the DFT, and that time resolution can be a function of the frequency range of interest. This latter point means that we can say accurate things about high frequencies as well as low. This contrasts to the Fourier transform, which requires the analysis window width to be the same for all frequencies. This means that we must either average out lots of the interesting high-frequency time information in favor of being able to resolve low-frequency information (large window), or opt for good time resolution (small window) at the expense of low-frequency resolution, or perform multiple transforms with different sized windows to catch both time and frequency details. There are a number of fast wavelet transform techniques that allow the sub-band decomposition to be accomplished in essentially $N \log_2(N)$ time just like the FFT.

Most of classical physics can be modeled as objects interacting with each other. Lots of small objects are usually called particles. Granular synthesis involves cutting sound into grains and reassembling them by mixing [17.27]. The grains usually range in length from 5 to 100 ms. The reassembly can be systematic, but often granular synthesis involves randomized grain sizes, locations, and amplitudes. The transformed result usually bears some characteristics of the original sound, just as a mildly blended mixture of fruits still bears some attributes of the original fruits, as well as taking on new attributes due to the mixture. Granular synthesis is mostly used as a compositional and musical-effect type of signal processing, but some also take a physically motivated look at sound grains. Other variants of granular synthesis include glisson synthesis, wherein the pitch of each grain is shifted over the length of the grain (glissando), and pulsar synthesis [17.28], where each grain is synthesized as a pulsar (sinusoidal snippit or impulse excited resonator).

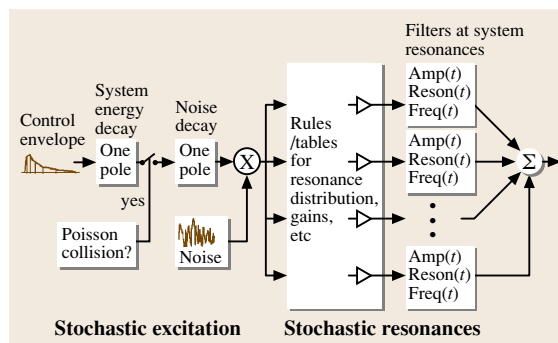
The physically informed stochastic event modeling (PhISEM) algorithm is based on pseudo-random overlapping and adding of parametrically synthesized sound grains [17.29]. At the heart of PhISEM algorithms are particle models, characterized by basic Newtonian equations governing the motion and collisions of point masses as can be found in any introductory physics textbook. By reducing the physical interactions of many particles to their statistical behavior, exhaustive calculation of the position, and velocity of each individual particle can be avoided. By factoring out the resonances of the system, the wavelets can be shortened to impulses


Fig. 17.30 Complete PhISEM model showing stochastic resonances

or short bursts of exponentially decaying noise. The main PhISEM assumption is that the sound-producing particle collisions follow a Poisson process. Another assumption is that the system energy decays exponentially (the decay of the sound of a maraca after being shaken once, for example). Figure 17.30 shows the PhISEM algorithm block diagram.

The PhISEM maraca synthesis algorithm requires only two random number calculations, two exponential decays, and one resonant filter calculation per sample. Other musical instruments that are quite similar to the maraca include the sekere and cabasa (afuche). Outside the realm of multicultural musical instruments, there are many real-world particle systems that exhibit one or two fixed resonances like the maraca. A bag or box of candy or gum, a salt shaker, a box of wooden matches, and gravel or leaves under walking feet all fit well within this modeling technique.

In contrast to the maraca and guiro-like gourd resonator instruments, which exhibit one or two weak resonances, instruments such as the tamborine (timbrel) and sleigh bells use metal cymbals, coins, or bells suspended on a frame or stick. The interactions of the metal objects produce much more pronounced resonances than the maraca-type instruments, but the Poisson event and exponential system energy statistics are similar enough to justify the use of the PhISEM algorithm for synthesis. To implement these in PhISEM, more filters are used to model the individual partials, and at each collision, the resonant frequencies of the filters are randomly set to frequencies around the main resonances. Other sounds that can be modeled using stochastic filter resonances include bamboo wind chimes (related to a musical instrument as well in the Javanese anklung) [17.30].

17.8 Physical Modeling (The Wave Equation)

One way to model a vibrating string physically would be to build it up as a chain of coupled masses and springs, as shown in Fig. 17.31. The masses slide on frictionless guide rods to restrict their motion to transverse (at right angles to the length), as is the case in the ideal string. In fact, some synthesis projects have used mass/spring/damper systems to represent arbitrary objects [17.31].

If we force the masses to move only up and down, and restrict them to small displacements, we do not actually have to solve the acceleration of each mass as a function of the spring forces pushing them up and down. There is a simple differential equation that completely describes the motions of the ideal string

$$\frac{d^2 y}{dx^2} = \frac{1}{c^2} \frac{d^2 y}{dt^2} \ . \tag{17.21}$$

This equation (called the wave equation) means that the acceleration (up and down) of any point on the string is equal to a constant times the curvature of the string at that point. The constant c is the speed of wave motion on the string, and is proportional to the square root of the string tension, and inversely proportional to the square root of the mass per unit length. This equation could be solved numerically, by sampling it in both time and space, and using the difference approximations

for acceleration and curvature (much like we did with the mass/spring/damper system earlier). With boundary conditions (like rigid terminations at each end), we could express the solution of this equation as a Fourier series, as we did earlier in graphical form (Fig. 17.12). However, there is one more wonderfully simple solution to (17.21), given by

$$y(x, t) = y_L \left(t + \frac{x}{c} \right) + y_R \left(t - \frac{x}{c} \right). \tag{17.22}$$

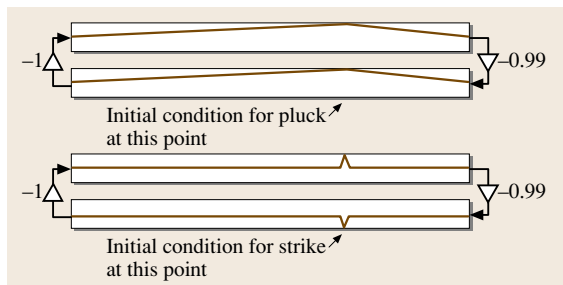
This equation says that any vibration of the string can be expressed as a combination of two separate traveling waves, one traveling left (y_L) and one traveling right (y_R). They move at the rate c, which is the speed of sound propagation on the string. For an ideal (no damping) string and ideally rigid boundaries at the ends, the wave reflects with an inversion at each end, and would travel back and forth indefinitely. This view of two traveling waves summing to make a displacement wave gives rise to the waveguide filter technique of modeling the vibrating string [17.32, 33]. Figure 17.32 shows a waveguide filter model of the ideal string. The two delay lines model the propagation of left- and right-going traveling waves. The conditions at the ends model the reflection of the traveling waves at the ends. The -1 in the left reflection models the reflection with inversion
Fig. 17.31 Mass/spring string network, with frictionless *guide rods* to restrict motion to one dimension
Fig. 17.32 Waveguide string modeled as two delay lines
Fig. 17.33 Filter view of a waveguide string
Fig. 17.34 Impulse response and spectrum of a comb (string) filter


Fig. 17.35 Waveguide pluck and strike initial conditions

Fig. 17.37 Commuted plucked string model

of a displacement wave when it hits an ideally rigid termination (like a fret on a guitar neck). The -0.99 on the right reflection models the slight loss that happens when the wave hits a termination that yields slightly (like the bridge of the guitar which couples the string motion to the body), and models all other losses the wave might experience (internal damping in the string, viscous losses as the string cuts the air, etc.) in making its round-trip path around the string.

Figure 17.33 shows the waveguide string as a digital filter block diagram. The $z^{-P/2}$ blocks represent a delay equal to the time required for a wave to travel down the string. Thus a wave completes a round trip each P samples (down and back), which is the fundamental period of oscillation of the string, expressed in samples. Initial conditions can be injected into the string via the input $x(n)$. The output $y(n)$ would yield the right-going traveling wave component. Of course, neither of these conditions is actually physical in terms of the way a real string is plucked and listened to, but feeding the correct signal into x is identical to loading the delay lines with a predetermined shape.

The impulse response and spectrum of the filter shown in Fig. 17.32 is shown in Fig. 17.34. As would be expected, the impulse response is an exponentially decaying train of pulses spaced $T = P/\text{SRATE}$ seconds apart, and the spectrum is a set of harmonics spaced $F_0 = 1/T$ Hz apart. This type of filter response and

spectrum is called a *comb filter*, so named because of the comb-like appearance of the time-domain impulse response, and of the frequency-domain harmonics.

The two delay lines taken together are called a *waveguide filter*. The sum of the contents of the two delay lines is the displacement of the string, and the difference of the contents of the two delay lines is the velocity of the string. If we wish to pluck the string, we simply need to load $1/2$ of the initial-shape magnitude into each of the upper and lower delay lines. If we wish to strike the string, we would load in an initial velocity by entering a positive pulse into one delay line and a negative pulse into the other (difference = initial velocity, sum = initial position = 0). These conditions are shown in Fig. 17.35.

Figure 17.36 shows a relatively complete model of a plucked string simulation system using digital filters. The inverse comb filters model the nodal effects of picking, and the output of an electrical pickup, emphasizing certain harmonics and forbidding others based on the pick (pickup) position [17.34]. Output channels for the pickup position and body radiation are provided separately. A solid-body electric guitar would have no direct radiation and only pickup output(s), while a purely acoustic guitar would have no pickup output, but possibly a family of directional filters to model body radiation in different directions [17.35].

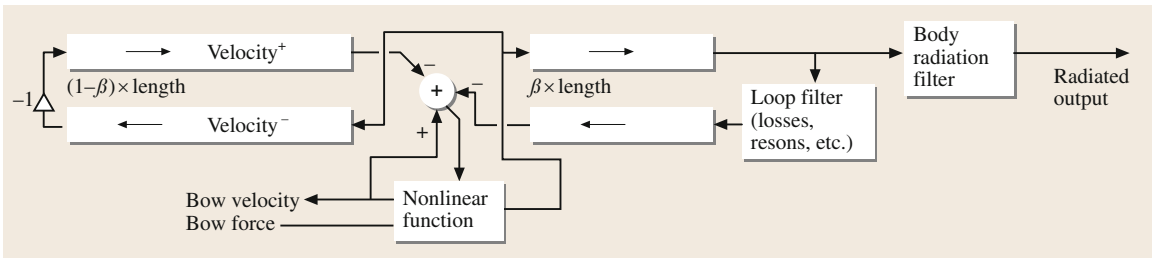
We should note that everything in the block diagram of Fig. 17.35 is linear and time invariant (LTI). Linearity means that for input x and output y, if $x_1(t) \rightarrow y_1(t)$
Fig. 17.36 Fairly complete digital filter simulation of the plucked string system


Fig. 17.38 Bowed string model

and $x_1(t) \to y_2(t)$, then $x_1(t) + x_2(t) \to y_1(t) + y_2(t)$, for any functions $x_{1,2}$ (signals add and scale linearly). Time invariant means that if $x(t) \to y(t)$, then $x(t - T) \to y(t - T)$ for any $x(t)$ and any T (the system doesn't change with time). Given that the LTI condition is satisfied, we can then happily (legally) commute (swap the order) of any of the blocks. For example, we could put the pick position filter at the end, or move the body radiation filter to the beginning. Since the body radiation filter is just the impulse response of the instrument body, we can actually record the impulse response with the strings damped, and use that as the input to the string model. This is called *commuted synthesis* [17.36]. Figure 17.37 shows a commuted synthesis plucked string model.

Adding a model of bowing friction allows the string model to be used for the violin and other bowed strings. This focused nonlinearity is what is responsible for turning the steady linear motion of a bow into an oscillation of the string [17.37,38]. The bow sticks to the string for a while, pulling it along, then the forces become too great and the string breaks away, flying back toward rest position. This process repeats, yielding a periodic oscillation. Figure 17.38 shows a simple bowed string model, in which string velocity is compared to bow velocity, then put through a nonlinear friction function controlled by bow force. The output of the nonlinear function is the velocity input back into the string.

In mathematically describing the air within a cylindrical acoustic tube (like a trombone slide, clarinet bore, or human vocal tract), the defining equation is

$$\frac{\mathrm{d}^2 P}{\mathrm{d} x^2} = \frac{1}{c^2} \frac{\mathrm{d}^2 P}{\mathrm{d} t^2} \qquad (17.23)$$

which we note has exactly the same form as (17.21), except that the displacement y is replaced by the pressure P. A very important paper in the history of physical modeling [17.37] noted that many musical instruments can be characterized as a linear resonator, modeled by filters such as all-pole resonators or waveguides, and

a single nonlinear oscillator like the reed of the clarinet, the lips of the brass player, the jet of the flute, or the bow–string friction of the violin. Since the wave equation says that we can model a simple tube as a pair of bidirectional delay lines (waveguides), then we can build models using this simple structure. If we would like to do something interesting with a tube, we could use it to build a flute or clarinet. Our simple clarinet model might look like the block diagram shown in Fig. 17.39.

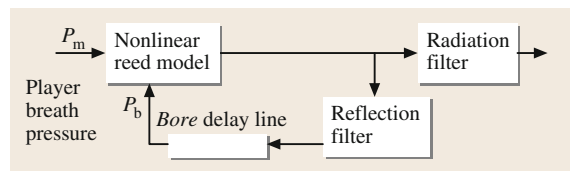
To model the reed, we assume that the mass of the reed is so small that the only thing that must be considered is the instantaneous force on the reed (spring). The pressure inside the bore P_b is the calculated pressure in our waveguide model, the mouth pressure P_m is an external control parameter representing the breath pressure inside the mouth of the player (Fig. 17.40). The net force acting on the reed/spring can be calculated as the difference between the internal and external pressures, multiplied by the area of the reed (pressure is force per unit area). This can be used to calculate a reed opening


Fig. 17.39 Simple clarinet model
Fig. 17.40 Reed model

position from the spring constant of the reed. From the reed opening, we can compute the amount of pressure that is allowed to leak into the bore from the player's mouth. If bore pressure is much greater than mouth pressure, the reed opens far. If the mouth pressure is much greater than the bore pressure, the reed slams shut. These two extreme conditions represent an asymmetric nonlinearity in the reed response. Even a grossly simplified model of this nonlinear spring action results in a pretty good model of a clarinet [17.38]. Figure 17.41 shows a plot of a simple reed reflection function (as seen from within the bore) as a function of differential pressure. Once this nonlinear signal-dependent reflection coefficient is calculated (or looked up in a table), the right-going pressure injected into the bore can be calculated as $P_b^+ = \alpha P_b^- + (1 - \alpha) P_m$.

The clarinet is open at the bell end, and essentially closed at the reed end. This results in a reflection with inversion at the bell and a reflection without inversion (plus any added pressure from the mouth through the reed opening) at the reed end. These odd boundary conditions cause odd harmonics to dominate in the clarinet spectrum.

We noted that the ideal string equation and the ideal acoustic tube equation are essentially identical. Just as there are many refinements possible to the plucked string model to make it more realistic, there are many possible improvements for the clarinet model. Replacing the simple reed model with a variable mass/spring/damper allows the modeling of a lip reed as is found in brass instruments. Replacing the reed model with an air-jet model allows the modeling of flute and recorder-like instruments. With all wind or friction (bowed) excited resonant systems, adding a little noise in the reed/jet/bow region adds greatly to the quality (and behavior) of the synthesized sound.
Fig. 17.41 Reed reflection table
Fig. 17.42 Stiffness-modified waveguide string filter

In an ideal string or membrane, the only restoring force is assumed to be the tension under which they are stretched. We can further refine solid systems such as strings and membranes to model more-rigid objects, such as bars and plates, by noting that the more-rigid objects exhibit internal restoring forces due to their stiffness. We know that if we bend a stiff string, it wants to return back to straightness even when there is no tension on the string. Cloth string or thread has almost no stiffness. Nylon and gut strings have some stiffness, but not as much as steel strings. Larger-diameter strings have more stiffness than thin ones. In the musical world, piano strings exhibit the most stiffness. Stiffness results in the restoring force being higher (thus the speed of sound propagation as well) for high frequencies than for low. So the traveling wave solution is still true in stiff systems, but a frequency-dependent propagation speed is needed

$$y(x, t) = y_L \left[t + \frac{x}{c}(f) \right] + y_R \left[t - \frac{x}{c}(f) \right]. \quad (17.24)$$

and the waveguide filter must be modified to simulate frequency-dependent delay, as shown in Fig. 17.42.

For basic stiff strings, a function that predicts the frequencies of the partials has this form

$$f_n = n \left[f_0 (1 + Bn^2) \right], \quad (17.25)$$

where B is a number slightly greater than 0, equal to zero for perfect harmonicity (no stiffness), and increasing for increasing stiffness. Typical values of B are 0.00001 for guitar strings, and 0.004 or so for piano strings. This means that $P(f)$ should modify P by the inverse of the $(1 + Bn^2)^{1/2}$ factor.

Unfortunately, implementing the $z^{-P(f)/2}$ frequency-dependent delay function is not simple, especially for arbitrary functions of frequency. One way to imple-
Fig. 17.43 First-order all-pass filter
Fig. 17.44 Banded decomposition of a struck-bar spectrum

Fig. 17.45 Banded waveguide model

ment the $P(f)$ function is by replacing each of the z^{-1} with a first-order all-pass (phase) filter, as shown in Fig. 17.43 [17.34]. The first-order all-pass filter has one pole and one zero, controlled by the same coefficient. The all-pass implements a frequency-dependent phase delay, but exhibits a gain of 1.0 for all frequencies. The coefficient α can take on values between -1.0 and 1.0. For $\alpha = 0$, the filter behaves as a standard unit delay. For $\alpha > 0.0$, the filter exhibits delays longer than one sample, increasingly long for higher frequencies. For $\alpha < 0.0$ the filter exhibits delays shorter than one sample, decreasingly so for high frequencies.

It is much less efficient to implement a chain of all-pass filters than a simple delay line. But for weak stiffness it is possible that only a few all-pass sections will provide a good frequency-dependent delay. Another option is to implement a higher-order all-pass filter, designed to give the correct stretching of the upper frequencies, added to simple delay lines to give the correct longest bulk delay required.

For very stiff systems such as rigid bars, a single waveguide with all-pass filters is not adequate to give enough delay, or far too inefficient to calculate. A technique called *banded waveguides* employs sampling in time, space, and frequency to model stiff one-dimensional systems [17.39]. This can be viewed as a hybrid of modal and waveguide synthesis, in that each waveguide models the speed of sound in the region around each significant mode of the system. As an example, Fig. 17.44 shows the spectrum of a struck marimba bar, with additional bandpass filters superimposed on the spectrum, centered at the three main modes. In the banded waveguide technique, each mode is modeled by a bandpass filter, plus a delay line to impose the correct round-trip delay, as shown in Fig. 17.45.

A variant of physical modelling known as Scanned Synthesis [17.40] employs the periodic scanning of a physically evolving system to generate PCM waveforms. The physically evolving system can be an actual object/system (the motions of the surface of a waterbed or other), or simulated, and the scanning trajectory can be fixed or varying. For example, the surface height of the waterbed can be scanned in a circular, oval, figure eight, back and forth, striped, or other pattern, while the waterbed is excited as desired. Similarly, a non-linear, inhomogeneous vibrating string or membrane can be simulated at an arbitrary computation rate, but scanned at an audio rate, again with arbitrary trajectory, to yield sound. This allows a flexible means to generate lively, time-varying sounds.

17.9 Music Description and Control

The musical instrument digital interface (MIDI) standard, adopted in 1984, revolutionized electronic music, and also profoundly affected the computer industry [17.41]. A simple two-wire serial electrical connection standard allows interconnection of musical devices and computers over cable distances of up to 15 m (longer over networks and extensions to the basic MIDI standard). The MIDI software protocol is best described as musical keyboard gestural, meaning that the mes-

sages carried over MIDI are the gestures that a pianist or organist uses to control a traditional keyboard instrument. There is no time information contained in the basic MIDI messages; they are intended to take effect as soon as they come over the wire. As such it is a real-time gestural protocol, and can be adapted for real-time non-musical sound synthesis applications. There are complaints about MIDI, however, mostly related to limited control bandwidth (approximately 1000–1500

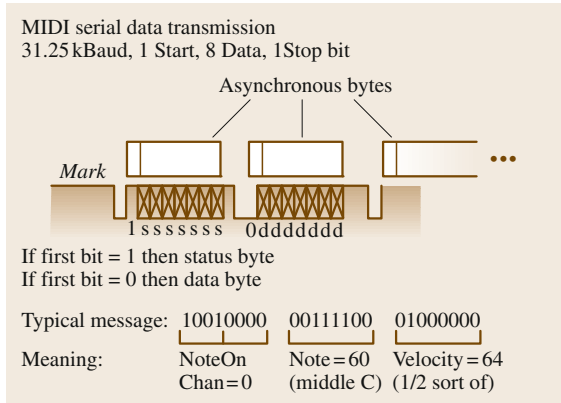

Fig. 17.46 MIDI software transmission protocol

continuous messages per second maximum), and the keyboard-centric bias of the messages.

Basic MIDI message types include NoteOn and NoteOff, sustain pedal up and down, amount of modulation (vibrato), pitch bend, key pressure (also called AfterTouch), breath pressure, volume, pan, balance, reverberation amount, and others. NoteOn and NoteOff messages carry a note number corresponding to a particular piano key, and a velocity corresponding to how hard that key is hit. Figure 17.46 shows the software serial format of MIDI, and gives an example of a NoteOn message.

Another MIDI message is program change, which is used to select the particular sound being controlled in the synthesizer. MIDI provides for 16 channels, and the channel number is encoded into each message. Each channel is capable of one type of sound, but possibly many simultaneous *voices* (a voice is an individual sound) of that same sound. Channels allow instruments and devices to all listen on the same network, and choose to respond to the messages sent on particular channels.

General MIDI (1991), and the standard MIDI file specifications serve to extend MIDI and made it even more popular [17.42]. General MIDI helps to assure the performance of MIDI on different synthesizers, by specifying that a particular program (the algorithm for producing the sound of an instrument) number must call up a program the approximates the same instrument sound on all general MIDI-compliant synthesizers. There are 128 such defined instrument sounds available on MIDI channels 1–9 and 11–16. For example, MIDI program 1 is grand piano, and 57 is trumpet. Some of the basic instrument sounds are sound effects. Program #125 is a telephone ring, #126 is helicopter,

#127 is applause, and #128 is a gunshot sound. On general MIDI channel 10, each note is mapped to a different percussion sound. For example, the bass drum is note number 35, and the cowbell is note number 56.

The MIDI file formats provide a means for the standardized exchange of musical/sonic information. A MIDI level 0 file carries the basic information that would be carried over a MIDI serial connection, which is the basic bytes in order, with added time stamps. Time stamps allow a very simple program to play back MIDI files. A MIDI level 1 file is more suited to manipulation by a notation program or MIDI sequencer (a form of multi-track recorder program that records and manipulates MIDI events). Data is arranged by *tracks*, (each track transmits on only one MIDI channel) which are the individual instruments in the virtual synthesized orchestra. Meta messages allow for information which is not actually required for a real-time MIDI playback, but might carry information related to score markings, lyrics, composer and copyright information, etc. An extension to the MIDI file format, the eXtensible Music File (XMF) format is a tree-based wrapper that allows for the specification and inclusing of scores, sounds, and other information (performance notes, etc.)

Recognizing the limitations of fixed PCM samples in music synthesizers, the downloadable sounds (DLS) specification was added to MIDI in 1999. This provides a means to load PCM into a synthesizer, then use MIDI commands to play it back. Essentially any instrument/percussion sound can be replaced with arbitrary PCM, making it possible to control large amounts of recorded sounds. The emergence of software synthesizers, on PC platforms made the use of DLS more feasible than in earlier days when the samples were contained in a static ROM within a hardware synthesizer. A variety of commercial formats, such as SoundFonts (Trademark and standard developed by Creative Labs) were developed to meet this need. Many hardware commercial sampling synthesizers, and essentially all software-based computer synthesis support some form of DLS.

The simplicity and ubiquity of MIDI, with thousands of supporting devices and software systems, leads many to use it for all sorts of projects and systems. While not being directly compatible with popular music synthesizers, using MIDI for the control of synthesis still allows the use of the large variety of MIDI control signal generators and processors, all of which emit standard and user-programmable MIDI messages. Examples include MIDI sequencers and other programs

for general-purpose computers, as well as breath controllers, drum controllers, and boxes with rows of sliders and buttons.

One thing still missing from MIDI is the ability to download or specify arbitrary synthesis algorithms. Beyond MIDI, a number of emerging standards for sound and multimedia control have been developed. As mentioned in the last section, one of the things MIDI lacks is high-bandwidth message capability for handling many streams of gestural/model control data. Another complaint about MIDI relates to the small word sizes, such as semitone quantized pitches (regular musical notes), and only 128 levels of velocity, volume, pan, and other controllers. MIDI does support some extended precision messages, allowing 14 bits rather than 7. Other specifications have proposed floating-point representations, or at least larger integer word sizes. A number of new specifications and systems have arisen recently.

One system for describing sounds themselves is called the sound description interchange format (SDIF 1999) [17.43], originally called the spectral description interchange file (SDIF) format. It is largely intended to encapsulate the parameters arising from spectral analysis, such as spectral modeling sinusoidal/noise tracks, or source/filter model parameters using LPC.

Related to SDIF, but on the control side, is open sound control (OSC, 2002) [17.43]. Open sound control allows for networked, extended-precision, object-oriented control of synthesis and processing algorithms over high-bandwidth transmission control protocol/internet protocol (TCP/IP), FireWire, and other high-bandwidth protocols. OSC has become extremely popular, supported by most all computer music languages (see next section), and also many commercial music software packages.

As part of the moving-picture experts group 4 (MPEG4) standard, the structured audio orchestra language (SAOL, 1999) allows for parametric descriptions of sound algorithms, controls, effects processing, mixing, and essentially all layers of the audio synthesis and processing chain [17.44]. One fundamental notion of structured audio is that the more understanding we have about how a sound is made, the more flexible we are in compressing, manipulating, and controlling it.

17.10 Language and Systems for Research and Composition

The history of computer languages for music dates back well into the 1950s. Beginning with Max Mathew's Music I, many features of these languages have remained constant, such as the notion of unit generators as discussed before, and the idea of instruments within an orchestra, controlled by a score. Early popular languages include Music V (a direct descendent of Music I) [17.5], Csound, CMix, and CMusic (written in C) [17.45]. More recent languages developed in the last two decades include SuperCollider [17.46], Jsyn (in Java) [17.47], STK in C^{++} [17.48], Aura [17.49], Nyquist [17.50], and ChucK [17.51].

One class of languages that has advanced education and participation in computer music are graphical systems such as MAX/MSP [17.52] and Pure Data (PD) [17.53]. These software systems allow novice (and expert) users to construct patches by dragging unit generator icons around on the desktop, connecting them with virtual patch cords (Fig. 17.47). Similarly, Fig. 17.48 shows computer code in the ChucK language, to accomplish the same thing, connecting the ADC to a delay line (using the ChucK operator ⇒, which resembles a directional patch cord), and the output of the delay line to the DAC output. The delay length is set to 0.5 s (time is a native data type in ChucK) using

the ChucK operator, which functions as the assignment operator in this case.

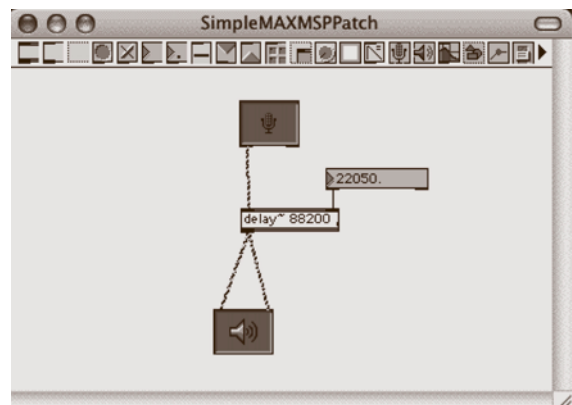
Nearly all music today is recorded, edited, mixed, processed, mastered, compressed, distributed, and played back in digital format. Popular programs for studio music production (often called Digital Audio Workstations, or DAWs [17.54]), include ProTools


Fig. 17.47 A simple MAX/MSP patch connects a microphone through a $1/2$ s ($22\,050$ samples at 44.1 kHz sampling rate) delay to the speaker output

(Avid Technology Inc., formerly DigiDesign), Logic Studio (Apple Computer), Digital Performer (Mark of the Unicorn), Cubase (Steinberg), Reaper (Cockos), Cakewalk Sonar, and others. All of these programs allow expansion via the loading of DSP *Plug-Ins* which can be bundled with software, but become instantly useable in other programs that support PlugIns, or bought outright, or downloaded for free.

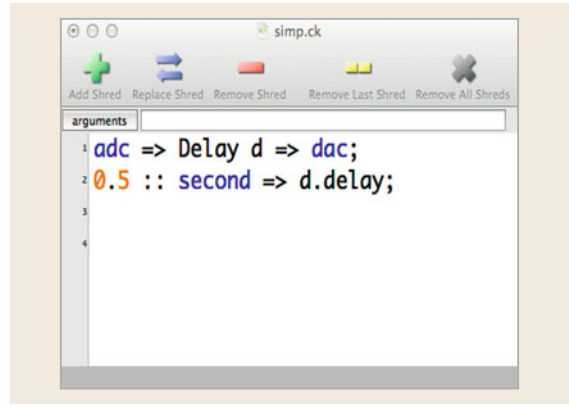
Popular programs for amateur music making include Apple's Garage Band, and Fruity Loops (from Image Line, now a more professional version known as FL Studio). Some DAW and other music software is optimized for live performance, allowing performers to sequence music in real-time, launch sections, change effects, etc. One popular program for live computer-music performance is Ableton's Live.


Fig. 17.48 A simple ChucK program to connect the ADC to the DAC output through a 1/2 s delay

17.11 Controllers and Performance Systems

Music performance is structured real-time control of sound, to achieve an aesthetic goal (hopefully for both the performers and audience). So one obvious application area for real-time computer sound synthesis and processing is in creating new forms of musical expression. Exciting developments in the last few years have emerged in the area of new controllers and systems for using parametric sound in real-time music performance, or in interactive installation art.

Figure 17.49 shows three recent real-time music performance systems, all using parametric digital sound synthesis and a variety of sensors mounted on the instruments and players. The author's DigitalDoo is a sensor/speaker enhanced/augmented didgeridoo. Dan Trueman's bowed sensor speaker array (BoSSA) resulted from work in modeling, refining, and redefining the violin player's interface [17.55]. Curtis Bahn's

"r!g" consists of a sensor enhanced upright (stick) bass, pedal boards, and other controllers. All three of these new instruments use spherical speakers to allow flexible control of the sound radiation into the performance space [17.56]. These instruments have been used with computers to control percussion sounds, animal noises, string models, flute models, and a large variety of other sample-based and parametric synthesis algorithms.

Various conducting systems, including Max Mathew's radio baton (Stanford's Center for Computer Research in Music and Acoustics) [17.57], and Theresa Marrin Nakra's conducting jacket (MIT Media Lab) [17.58] allow novices and experts to conduct music performed by the computer. Also, the growth and development of computer music has helped to advance greatly the technological capabilities of the fa-

miliar karaoke industry. Some modern karaoke systems now can deduce the song that is being sung and retrieve the appropriate accompaniment within just a few notes. Also, these systems can automatically correct the pitch and vocal qualities of a bad singer, making them sound more expert and professional. The next section will describe some of the algorithms being applied now in karaoke and other automatic accompaniment systems.

Some researchers and performers feel that there is significant potential in networked computer music performances and interactions. Projects range from MIT's Brain Opera [17.59], which allowed observers to participate and contribute content to the performance via the web, through the Auricle website, which is a kind of audio analysis/synthesis enhanced chat room [17.60]. Stanford's SoundWire Project [17.61] and Princeton's GigaPop Project [17.62] (Fig. 17.50) were aimed at synchronized multi-site live performance through high-bandwidth low-latency streaming of uncompressed audio and video.

Extending the idea of *Electronic Chamber Music*, the Princeton Laptop Orchestra (PLOrk) was founded in 2005 [17.63]. There had been ensembles of computer musicians performing live as far back as *The Hub* in the 1970's [17.64] but PLOrk was the first large-scale (15–45 players) ensemble where every player had

their own laptop, hemispherical speaker, and a variety of expressive controllers (Fig. 17.51). A large number of similar ensembles quickly followed, including the Stanford Laptop Orchestra (SLOrk), and Mobile Phone Orchestra (MoPho), BLOrk (Boulder, CO), OLO (Oslo, Norway), KLOrk (Kalamazoo, MI), L2Ork (The Linux Laptop Orchestra of Virginia Tech), LOL (Laptop Orchestra of Louisiana), LORkAS (Arizona State), and many others.

Others have begun to incorporate computer-mediated mechanical devices into the mix, with and without human performers, for real-time music making in permanent art installations and in live performance. These projects range from Trimpin's musical mechanical sound sculptures [17.65], to Eric Singer's League of Electronic Musical Urban Robots (LEMUR) [17.66], to Ajay Kapur's Karmetik Machine Orchestra [17.67].

Increasingly, mobile devices such as smart phones and tablets are capable of running sophisticated software for music. The same algorithms and programs that ran on desktop computers, then on laptops, often now can run on the phones and tablets many of us carry with us. This further democratizes the process of music consumption and making, increasing the potential market and space for creating new types of music software and experiences.

17.12 Music Understanding and Modeling by Computer

Over the years, new research and applications have arisen in the areas of content-based audio analysis, re-

trieval, and modeling. Also called music information retrieval (MIR), machine listening, and other terms, the

main tasks involve segmenting, separating, classifying, and predicting the textures and structures present in pieces of music or audio.

Audio segmentation is the process of breaking up an audio stream into sections that are perceptually different from adjacent sections. The audio texture within a given segment is relatively stable. Examples of segment boundaries could be the transition from background sound texture to a human beginning to speak over that background, or the change from verse to chorus in a popular song. Another segment boundary might occur when the scene changes, such as leaving an office building lobby and going outside onto a busy street. In movie production, the audio scene often changes just prior to the visual scene, allowing a noncausal mode of detecting a visual scene change.

Segmentation [17.68] can be accomplished in two primary ways: blind segmentation based on sudden changes in extracted audio features, and classification-based segmentation based on comparing audio features to a set of trained target feature values. The blind method works well and is preferred when the segment textures are varied and unpredictable, but requires the setting of thresholds to yield the best results. The classification-based method works well on a corpus of pre-labeled data, such as speech/music, musical genres, indoor/outdoor scenes, etc. databases. Both methods require the extraction of audio features.

Audio feature extraction is the process of computing a compact numerical representation of a sound segment. A variety of audio features exist, and have been used in systems for speech recognition, music/speech discrimination, musical genre (rock, pop, country, classical, jazz, etc.) labeling, and other audio classification tasks. Most features are extracted from short moving windows (5–100 ms in length, moving along at a rate of 5–20 windows per second) by using the short-time Fourier transform, wavelets, or compressed data coefficients (such as MP3). Each of the features described below can be computed at different time resolutions, and the value of each feature, along with the mean and variance of the features can be used as features themselves:

- One common feature for segmentation is the gross power in each window. If the audio stream suddenly gets louder or softer, then there is a high likelihood that something different is occurring. In speech recognition and some other tasks, however, we would like the classification to be loudness invariant (over some threshold used to determine if anyone is speaking).

- Another feature is the spectral centroid, which is closely related to the brightness of the sound, or the relative amounts of high- and low-frequency energy. The spectral roll-off is another important feature that captures more information about the brightness of an audio signal.

- Spectral flux is the amount of frame-to-frame variance in the spectral shape. A steady sound or texture will exhibit little spectral flux, while a modulating sound will exhibit more flux.

- One popular set of features used for speech and speaker recognition are mel-frequency cepstral coefficients, which are a compact (between 4 and 10 numbers) representation of spectral shape and structure.

- For multi-time-scale analysis systems, the low-energy feature is often used. This feature is defined as the percentage of small analysis windows that contain less power than the average over the larger window that includes the smaller windows. This is a coarser-time-scale version of flux, but computed only for energy.

- One other commonly used feature is zero-crossing rate, which is a simple measure of high-frequency energy.

- For music query/recognition, features such as the parametric pitch histogram, and beat/periodicity histogram can be calculated and used.

Selection of the correct feature set for a given task has proven to be an important part of building successful systems for machine audio understanding. For a fixed corpus, computing many features (40 dimensions or more), then using principal-components analysis (reduction of dimensionality through regression) has proven successful for reducing the dimensionality of the feature/search space. As an example, mapping the first three principal components onto color (red, green, blue) allows the automatic coloration of sound plots, as shown in Fig. 17.52. The three *timbregrams* on the left are speech, and the three on the right are classical music. The top two right timbregrams are orchestral recordings, while the lower right one is opera singing (hence the color similarity to speech).

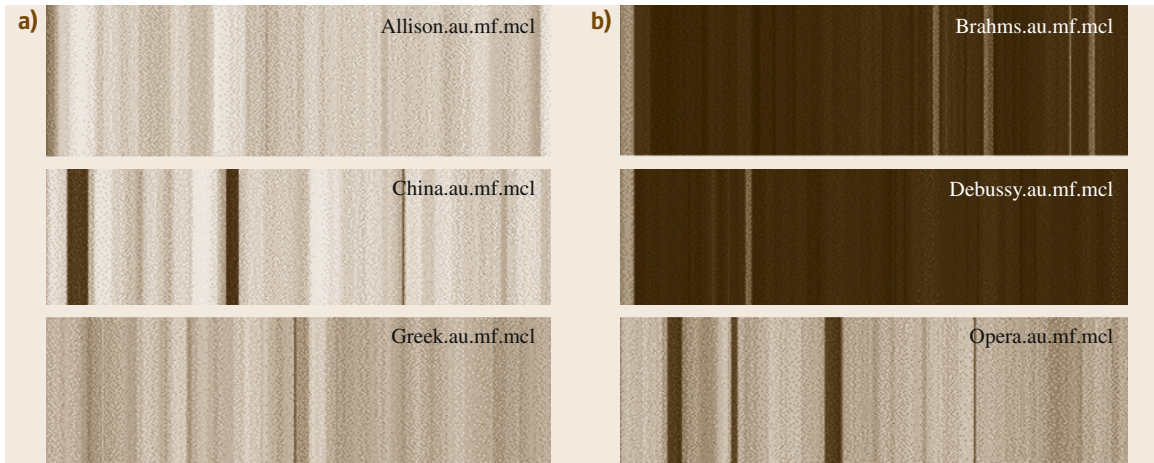
One holy grail in computer music research is automatic transcription, where in the ideal case a computer could generate a perfect musical score by analyzing only a recording of the music. This problem has been around for many decades, and has generated significant funding for computer music researchers. While research still continues on this difficult and unsolved problem,


Fig. 17.52a,b *Timbregrams* of speech (**a**) and music (**b**), where the two sounds at the *top* are orchestral music, while the one at the *bottom* is opera

the side effects of the research have given us a large number of developments in signal processing, analysis/synthesis algorithms, and human perception and cognition.

One other cognition-related research area in computer music is musical style modeling, also called automatic composition. One of the leading researchers in this area is David Cope, whose experiments in musical intelligence (EMI) projects have been developed over many years now. Through musical rules and data entered by Cope in the LISP computer language,

the simple analytic recombinant algorithm (SARA) program has generated imitative music in styles as varied as those of Palestrina, Bach, Brahms, Chopin, Mozart, Prokofiev, Stravinsky, Gershwin, and Scott Joplin [17.69].

The area of Music Information Retrieval continues to grow rapidly, with increasing commercial interest in crafting algorithms that can model and predict human responses to music (thus make recommendations about what types of music individual people would like, and thus possibly buy).

17.13 Conclusions, Communities, and the Future

With the advent of cheaper, more powerful, and more portable computers, especially laptops and mobile devices, the tools and techniques of computer music have been greatly democratized. Many free or inexpensive sound-editing tools now include features and algorithms that were the sole domain of academic researchers only a few years ago. Further, the World Wide Web has made computer tools and music available to more people. Computer-augmented performers and performance spaces have become more common, and more commonly accepted by the public.

The growth of computer music research, software, and hardware has also been accompanied by growth in the forums for presenting computer music research and artistic creations. The International Computer Music Conference (ICMC, computermusic.org) has convened yearly since the 1970's to present the

newest research and computer music. The IEEE Workshop on Applications of Signal Processing to Audio and Acoustics (WASPAA) meets every odd year at the Mohonk Mountain House (New Paltz NY). The yearly Digital Audio Effects (DAFX) conference first convened in 1998, and still meets yearly to cover a wide variety of topics in audio signal processing. To address the interest and issues related to crafting new controllers and systems for real-time computer music performance, the annual New Interfaces for Musical Expression (NIME, nime.org) conference began in 2001. The International Conference on Music Information Retrieval (ismir.net) meets yearly to cover topics related to machine *understanding* of music, and also holds a sub-conference/competition called MIREX (Music Information Retrieval Evaluation eXchange), where algorithms (and their human authors)

compete in various music classifying, modeling, and retrieving tasks. Other conferences focused on graphics, gaming, user interfaces, assistive technologies, and other topics have sub-sessions dedicated to digital sound and music. And the list grows, with more and more international and regional conferences to cover digital audio and computer music research, and festivals to present computer music performances and art installations.

It seems certain that the future of computer music is likely to include more developments in the areas of modeling and understanding of human perception and preference, and new tools and systems to expand creativity and expression.

18. Audio and Electroacoustics

Mark F. Davis

This chapter surveys devices and systems associated with audio and electroacoustics: The acquisition, transmission, storage, and reproduction of audio. The chapter provides an historical overview of the field since before the days of Edison and Bell to the present day, and analyzes performance of audio transducers, components and systems from basic psychoacoustic principles, to arrive at an assessment of the perceptual performance of such elements and an indication of possible directions for future progress.

The first, introductory section is an overall historical review of audio reproduction and spatial audio to establish the context of events. The next section surveys relevant psychoacoustic principles, including performance related to frequency response, amplitude, timing, and spatial acuity. Section 18.3 examines common audio specifications, with reference to the psychoacoustic limitations discussed in Sect. 18.2. The specifications include frequency and phase response, distortion, noise, dynamic range and speed accuracy. Section 18.4 examines some of the common audio components in light of the psychoacoustics and specifications established in the preceding sections. The components in question include microphones, loudspeakers, record players, amplifiers, magnetic recorders, radio, and optical media. Section 18.5 is concerned with digital audio, including the basics of sampling, digital signal processing, and audio coding. Section 18.6 is devoted to an examination of complete audio systems and their ability to reproduce an arbitrary acoustic environment. The specific systems include monaural, stereo, binaural, Ambisonics, and 5.1–channel surround sound. The final section provides an overall appraisal of the current state of audio and electroacoustics, and speculates on possible future directions for research and development.

Considering that human records extend back to cave drawings thousands of years old [18.1], it is notable that the technology to record, transmit, and reproduce sound has only existed for the last century or so. One can only wonder at the effect it might have had on the course of history, not to mention the effect it may yet have [18.2].

Sound is hardly the easiest quantity to work with. As a vibration in air, it is invisible, dynamic, and three-dimensional (3-D), not counting the dimensions of time and frequency. Human interaction with a sound field is often dynamic: Natural movements of the head and body alter the perceived sounds in a way that is difficult to predict or reproduce. Despite over a century of progress, the transducers available for recording and reproducing sound, microphones and loudspeakers, are still limited to being point-in-space devices, and are not necessarily well suited to interacting with a 3-D phys-

ical phenomenon. And yet, human beings make do with just two ears; so how hard can it be to capture and reproduce all the characteristics and nuances of what the ear perceives in nature?

The intent of this chapter is to review and evaluate the performance of audio systems based on the known performance of the human auditory system. Starting with a brief historical overview, the salient aspects of human auditory performance will be described. These in turn will be used to derive a set of general audio specifications that may be expected to apply to a broad range of audio systems. Then, some of the more common audio components will be examined in light of these specifications. Finally, the performance of complete systems will be considered, in the hope of gaining some overall perspective of progress to date and possibly fertile directions for further investigation.

18.1 Historical Review

The first golden age of audio research arguably started in the late 1800s with the inventions of the telephone by A. G. Bell and the phonograph by T. A. Edison [18.3], and ended in 1982 with the introduction of digital audio as a practical reality as embodied in the audio compact disc (CD). The inventions that inaugurated this age established that an audio channel could indeed be transmitted and recorded, as a continuous mechanical, magnetic, optical, or electrical analog of the sound vibrations. These inventions were accompanied by a raft of problems, including inadequate recording sensitivity and playback volume, noise, distortion, speed irregularities such as wow and flutter, nonlinear or limited frequency response, and media wear. Although steady incremental progress was made on these problems in the decades that followed, they were all largely resolved with digital audio. Efforts since then have focused on reduction of the required data rate (audio coding) and on extending the realm of audio from single isolated channels to full three-dimensional systems. Ongoing parallel efforts to fully understand the physiology and psychoacoustics of the human ear more fully have continued to extend the knowledge base, and in some cases have yet to be exploited by commercial audio systems.

Why wasn't sound recording invented sooner? It is hard to say. Bell's telephone may have required a steady electric current, which presumably was not available in ancient times, but Edison's phonograph was entirely mechanical. The key to the latter invention seems to have been the recognition that sound is a vibration and

that the vibration is mechanically transferable, but this notion that is readily demonstrable by putting your fingers to your lips or throat, and humming. The inventions seem to have been part of a general flourishing of physical sciences and mathematics, one that has continued to the present day. Prior to that, however, there is certainly evidence of some understanding of the acoustic processes involved, as seen in the creation of musical instruments and the design of concert halls.

Actually, both Edison and Bell were driven in part by a desire to improve telegraph systems. The telegraph was popularized by Samuel Morse, starting around 1837, although the notion of an electrical telegraph harks back at least to a demonstration of sending a simple signal over a long wire by William Watson in 1747 [18.4]. The cause was greatly helped by the invention of the electric battery by Alessandro Volta in 1799, and the storage battery in 1859 by Gaston Plante [18.5].

Many of the theoretical and mathematical foundations of early audio technologies were established in the 1800s, with work in the electrical sciences by Ohm, Faraday, Henry and others, together with research in acoustics and hearing physiology by Helmholtz, Lissajous and others. Although Edison is credited with the invention of the first device to reproduce sound, the first audio recording device is generally credited to Leon Scott, who on March 25, 1857, patented the phonautograph [18.6]. As shown in Fig. 18.1, this device combined a diaphragm and a stylus to inscribe a trace of a sound on a visual medium, such as a smoke-blackened

glass or cylinder, but it had no way to reproduce the recording audibly. John Tyndall seems to have followed Scott's work on visualizing sound vibrations, using a variety of different devices.

Alexander Graham Bell filed his patent for the telephone on February 14, 1876, just two hours before Elisha Gray filed for a similar device. Aside from its intrinsic value, the invention was significant for employing acoustical to electrical and electrical to acoustical transduction, principles that are still almost universally employed in telephony, broadcast, and audio recording.

Transduction between acoustical and electrical energy was initially less important to Edison's invention of the phonograph on December 8, 1877, since a physical medium to store the recording was necessary in any case, and there neither was nor is a ready way to directly store a dynamic electrical signal on such a physical medium. So it is perhaps not too surprising that the original invention employed purely mechanical transduction for both recording and playback.

With these two inventions, the foundations for analog audio were established, and the race was on to refine and commercialize the systems. In 1887, Emile Berliner patented a recording format that used lateral groove modulation on a flat disk [18.8], in contrast to Edison's use of vertical modulation on a cylinder. The underlying principles may have been much the same, but Berliner's arrangement qualified as a separate patent, and the practical aspects of mass-producing, playing, and storing disks instead of cylinders led to the grooved disk becoming the commercial recording medium of choice for over half a century.

Lacking the means to record an electrical signal directly, but seeking to avoid the wear accompanying the playback of grooved recordings with a stylus, other media were soon being explored, such as magnetic recording by Valdemar Poulson in 1898 and optical recording, by Leon Gaumont in 1901. Meanwhile, the eventual foundation of the broadcast industry was begun in 1894, with the invention of the wireless telegraph by Guglielmo Marconi.

These systems were initially handicapped by a lack of viable amplification means, and although there were some imaginative attempts at mechanical amplification, the key breakthrough occurred in 1906, with Lee de Forest's invention of the *audion* vacuum-tube triode amplifier. Vacuum tubes could and would be used to amplify all manner of electrical signals, but de Forest's choice of the name *audion* seems derived directly from the word audio. It is therefore a matter of some speculation as to whether the tube amplifier would have
Fig. 18.1 Leon Scott and the phonautograph (after [18.7])

come about when it did had it not been for the formative invention of sound recording just 29 years earlier.

Aside from resolving the problems of providing better recording sensitivity and adequate playback volume, the vacuum tube also enabled the wireless transmission of audio, giving rise to the radio receiver and broadcast industries.

So by 1910, the basic principles, physics, and devices of audio and electroacoustics were in place, resulting in widespread continuing efforts to develop, patent, and refine components and systems, establish standards where required, and commercialize a growing variety of formats and services. Amidst competitive struggles and numerous patent fights, the following years saw a dramatic series of audio innovations, including [18.9, 10]:

- 1913: An early *talking* movie by Edison, using a cylinder synchronized with the picture.
- 1916: A superheterodyne radio circuit patented by Edwin F. Armstrong.

- 1917: A condenser microphone developed by E. C. Wente at Bell Laboratories.
- 1921: The first commercial amplitude-modulated (AM) broadcast, KDKA, Pittsburgh, PA.
- 1925: An electrical record cutter developed at Bell Laboratories, followed by the commercial release of 78 revolutions per minute (RPM) records.
- 1926: Iron-oxide-coated paper tape for magnetic recording developed by O'Neill.
- 1927: *The Jazz Singer*, the first commercial sync-sound film, using audio on disk synchronized to the picture.
- 1929: The sampling theorem, the basis of digital signal processing, developed by Harry Nyquist.
- 1935: Plastic-based magnetic recording tape, from BASF.
- 1936: The first tape recording of a symphony concert, by Sir Thomas Beecham.
- 1936: A cardioid condenser microphone, by Von Braunmuhl and Weber.
- 1941: Commercial frequency-modulated (FM) broadcasting inaugurated in the US.
- 1947: The Williamson high-fidelity power amplifier developed.
- 1948: The 33 $\frac{1}{3}$-RPM long-play record, developed by CBS laboratories.
- 1951: The transistor developed at Bell Laboratories.
- 1954: The transistor radio, Sony.
- 1963: Tape cassette format developed by Philips.
- 1965: Dolby *A* noise-reduction system developed.
- 1969: Dr. Thomas Stockham experiments with digital recording.
- 1976: Stockham produces the first 16-bit digital recording, of the Santa Fe Opera.
- 1982: The digital compact disc is released commercially.

Much of the thrust of these and countless other developments in this period was to improve the quality of a given audio channel, by extending the frequency response, reducing noise, etc. As noted earlier, once digital recording came of age, these concerns were rendered somewhat moot, as adequate quality became a matter of using a sufficient number of bits per sample and adequately sampling rate to avoid audible degradation. Of course, certain parts of the audio chain, notably transducers such as microphones and loudspeakers, and associated interface electronics, have remained analog, as is likely to continue to be true at least until a direct link is established to the human nervous system, bypassing the ears altogether.

18.1.1 Spatial Audio History

Perhaps the one area of audio that was not immediately improved with the adoption of digital recording techniques was spatial reproduction. It is unlikely that the importance of the spatial aspect of audio was lost on early audio developers, nor the fact that most humans do in fact, possess two ears. It was probably just a case of priorities. Spatial audio systems would almost certainly require more channels and/or other information, which was hard to accommodate with early audio media, and the emphasis was, quite reasonably, on refining the quality of the single-channel monophonic format.

Still, there were some promising early experiments, notably a demonstration in 1881 by Clement Ader, who set up a series of microphones in front of the stage of the Paris Opera, and ran their outputs to earphones set up in a nearby room [18.9, 10]. Whether by accident or design, some of the listeners elected to use two headphones, one on each ear, and were rewarded with a crude but effective binaural spatial presentation.

Despite isolated experiments such as Ader's, there was little organized investigation of spatial audio until 1931, when Alan Blumlein single-handedly developed a range of devices and protocols to support stereo sound, including techniques to upgrade the entire audio broadcast and recording infrastructure of the time. Blumlein filed a far-ranging patent covering the bulk of his work; unfortunately, it seems to have been about a quarter century ahead of his time, as it would be the late 1950s before stereophonic sound became a commercial reality.

In the 1930s, Bell Laboratories also became interested in spatial audio, albeit with more of an emphasis on audience presentation. They concluded that stereo was ineffective for such uses, as the virtual imaging of just two channels would not work for listeners removed from the centerline. They further concluded that adding a center channel produced a far more satisfactory result, as demonstrated by Fletcher, Steinberg, and Snow in 1933.

With consumer media still limited to single-channel operation, it fell for a time to film studios to engage in occasional commercial forays into spatial audio. A notable experiment in the venue was the film *Fantasia* (1940), the road show productions of which used a synchronized three-channel soundtrack, plus control track, to feed as many as 10 loudspeakers [18.9, 10].

The use of multiple film channels accelerated somewhat in the 1950s, as film studios sought ways to differentiate their product from television. One popular approach was to use wider-than-standard 70 mm film

stock, instead of the normal 35 mm, which provided enough room along the edge for several audio channels on magnetic stripes. A common arrangement was three front channels plus a surround channel, the latter usually fed to an array of loudspeakers arranged around the sides and rear of the theater.

In the 1970s, the blockbuster movie genre was kicked off with the releases of *Star Wars* and *Close Encounters of the Third Kind*, along with the synergistic Dolby matrix surround system, which encodes control signals in the audio to pan two optical film channels to four output channels (again, three in front, plus surround).

In the 1990s, multichannel digital soundtracks came into use, first in movie theaters and then in home systems, generally supporting three front channels, a pair of surround channels, and a low-frequency channel, otherwise referred to as a 5.1-channel system. This trend has continued with increasingly elaborate channel configurations.

18.2 The Psychoacoustics of Audio and Electroacoustics

In order to evaluate the requirements and performance of audio systems, it is necessary to establish their relation to the capabilities and limitations of the human hearing. People perceive sound on the basis of frequency, amplitude, time and, somewhat indirectly, space. The perceptual resolution limits of these quantities are fairly well established, even if the underlying mechanisms are still being explored.

18.2.1 Frequency Response

1. Range: The commonly quoted frequency range of human hearing is 20–20 000 Hz, representing the range of frequencies that can be heard as sounds. In many cases, this is a somewhat optimistic specification, and in any case certainly varies with the individual. Only young people are likely to hear out to 20 kHz. With age generally comes a reduction in the upper limit (along with other reductions in hearing acuity, a process known as presbycusis [18.11]), with typical values of the upper limit of hearing in the range of 8–15 kHz common for middle-aged adults. There has been considerable debate about the ability to hear above 20 kHz, with some claiming some sort of perception out to frequencies of 40–50 kHz. Hearing limits above 20 kHz are known to exist in some small animals. At the low-frequency end of the spectrum, a frequency of perhaps 32 Hz is typically the minimum value at which a pitch can be discerned, below which the sensation becomes more of a series of discrete vibrations. Although it is difficult to construct loudspeakers with flat response below 20 Hz, humans can still perceive such vibrations if they are sufficiently large in amplitude.
2. Sensitivity: The ear is not uniformly sensitive to all frequencies, due in part to resonances and mechanical limitations of structures in the outer and middle ear, and in part to neural effects. The sensitivity also tends to be a function of absolute loudness (defined later). Contours of perceived equal loudness were first measured by Fletcher and Munson at Bell Laboratories in the 1930s [18.12]. Figure 18.2 shows typical equal loudness curves as a function of absolute level (dB sound pressure level (SPL)).
3. Resolution: As illustrated in Fig. 18.3, the ear exhibits a curious duality with respect to the degree it can differentiate frequencies. On the one hand, certain frequency-dependent processes, such as masking, appear to indicate a grouping of the frequency range into somewhat coarse sub-bands about $\frac{1}{4}$ to $\frac{1}{3}$ octave wide, called *critical bands*. On the other hand, frequency discrimination of individual sine waves on the basis of their perceived pitch has a typical resolution limit on the order of $\frac{1}{100th}$ of an octave, corresponding to a frequency change of about 0.7%. This is one of the cases where the un-
Fig. 18.2 Equal-loudness curves as a function of frequency and absolute level (after [18.9])
Fig. 18.3 Critical bandwidths (*upper curve*) and sine-wave pitch just noticeable difference (JND) as a function of frequency

derlying mechanisms are uncertain, and a mixture of temporal and spectral discrimination appears to be necessary to explain the various observed phenomena.

4. Pitch: In general terms, pitch is the perceptual response to differences in the frequency content of a source, but it is far more complex than a simple mapping of frequency to a perceptual scale, and can be affected by parameters such as the loudness of the signal, which ear it is played to, and the timing of the signal. The perception of pitch of spectrally complex signals is especially difficult to model, in part because a given signal may be perceived as having more than one pitch, and the signal itself may or may not actually contain spectral components corresponding to the perceived pitch [18.13].

18.2.2 Amplitude (Loudness)

Absolute Sensitivity

The total dynamic range of the human ear, that is, the range from loudest to softest sound one can perceive, is generally given to be about 120 dB, a pressure range

of about a million to one, or a power range of about a trillion to one. The term *sound pressure level* (SPL) is used to indicate where in this range a given sound falls, with 0 dB SPL taken as the approximate threshold of hearing at 1 kHz, corresponding to a level of about 20 μPa [18.14]. The mathematical relation between a sound pressure p and corresponding SPL value is

$$L_\mathrm{p} = \mathrm{SPL} = 20 \log \left(\frac{p}{p_0} \right) ,$$

where p_0 corresponds to the 0 dB SPL quoted above.

The upper limit of loudness perception is not well defined, but corresponds in principle to the onset of nonaudible phenomena such as tingling and outright pain. Depending on the listener, the upper limit is likely to be in the range of 115–140 dB SPL. (Note that exposure to such levels, especially for extended periods, can lead to hearing loss [18.11]).

As noted, sensitivity is a function of frequency and absolute level, with the greatest sensitivity observed in the range 3500–4000 Hz, mainly due to resonance of the ear canals, where the hearing threshold may actually be slightly lower in level than 0 dB SPL. The greatest variation as a function of frequency is at the lowest levels, where the threshold of hearing may rise to more than 20 dB SPL at high frequencies, and fully 60 dB SPL at low frequencies.

The variation of perceived loudness with actual sound pressure, while monotonic, is certainly nonlinear, as can be seen from the differences in spacing between the equal loudness curves at different frequencies. The actual perception of a difference in loudness will generally be less than the actual difference in SPL. According to the sone scale of loudness perception, a difference in SPL of 10 dB at 1 kHz is roughly equivalent to a doubling of perceived loudness $\mathrm{Sones} = 2^{[(\mathrm{Phons}-40)/10]}$ [18.15].

Because of the variation in perceived loudness with the actual SPL and frequency of a signal, it is a nontrivial matter to calculate the perceived loudness of an arbitrary, spectrally complex signal. Recent efforts using multiband analysis and power summation have improved the predictability to within close to a loudness just noticeable difference (JND) for most signals [18.16].

Resolution

The amplitude resolution of the ear is generally taken to be about 0.25 dB under best-case conditions, although for some situations it is considered to be slightly larger, on the order of 0.5–1.0 dB.

Masking

The audibility of a sine wave in isolation may be modified in the presence of other spectral components. In particular, the addition of spectral components is likely to render an existing component less audible, a process referred to as masking.

The basic notion of masking is that a louder sound will tend to render as less audible or inaudible a softer sound that would otherwise be audible in isolation. The degree of masking will tend to depend in part on the frequency spacing of the spectral components in question. This gives rise to the notion of a prototype masking curve, delineating the threshold of audibility in the presence of a sine wave of some frequency and amplitude, as a function of frequency, as shown in Fig. 18.4.

To at least first-order approximation, the masking effect of two or more sine waves can be calculated by summing their respective individual masking curves. Since, from Fourier theory, any signal can be decomposed into a sum of sinusoids, a composite masking curve from an arbitrary signal can be calculated as the sum of the masking curves of each spectral component. This constitutes a convolution (filtering operation) of a prototype masking curve with the signal spectrum. In practice, the prototype masking curve used for the convolution is likely to vary as a function of frequency, amplitude, or signal type (noise versus sine wave). Further, nonlinearities in the ear may result in significant deviations from the predicted curve at times.

Although the masking effect of a signal is, quite logically, maximized while the signal is present, some residual of the masking effect will extend beyond the termination of the signal, and even slightly before its onset. This process is referred to as temporal masking, and typical behavior is illustrated in Fig. 18.5) [18.17].
18.2.3 Timing

Because the transduction structure of the ear – the basilar membrane and associated hair cells – functionally resembles a filter bank, questions of timing must be considered as applying to the filtered output signals of that filter bank. The brain does not *see* the wide-band audio signal arriving at the ear, as it might appear on an oscilloscope, but instead processes the outputs of the basilar membrane filter bank, subject to effective half-wave rectification and loss of high-frequency synchrony by the neurons (Fig. 18.6). Output neural signals from each ear are ultimately processed by multiple areas of the brain. So it is not surprising that issues of timing are a little ill-defined, and that there are a number of time constants associated with different aspects of hearing.

For starters, there is the basic ability of the neurons in the auditory nerve to follow the individual cycles of audio impinging on the basilar membrane; i.e. to exhibit phase locking. Current research seems to put the upper frequency of this activity at about 5 kHz, although this seems somewhat at odds with lateralization of sine waves on the basic of interaural time difference, which only extends up to about 1500 Hz.

The ability to follow individual cycles of audio may aid in pitch perception, as the effective shapes of the basilar membrane filters appear too broad to account for the observed pitch resolution. However, the physiological mechanisms for how this might be accomplished are still the subject of some debate.

Fig. 18.4 Frequency Domain Masking: Curve A is hearing threshold with no signal present. Curve B is revised threshold in presence of 1 kHz tone C. Signal D, rising above curve A but below curve B, will be audible by itself but masked by signal C
Fig. 18.5 Temporal masking characteristic
Fig. 18.6 Neural phase locking at low frequencies and lack of phase locking at higher frequencies (after [18.18])

Other time constants appear to apply to the aggregate audio, regardless of the presence of a filter bank at the input. Already noted are the masking time constants, which substantially extend only 1–2 ms prior to the onset of a loud sound, but continue for several tens of milliseconds after its cessation.

Each of these may be related to a more fundamental time constant. The short time constant of about 1–2 ms may represent the shortest time one can perceive without relying on spectral cues, while the post-masking interval may be related to the fusion time. The fusion time in particular seems to represent a kind of acoustic

Table 18.1 Summary of approximate perceptual time/amplitude limits

Parameter	Range	JND
Amplitude	120 dB	0.25 dB
Premask	N/A	2 ms
Postmask	N/A	30–50 ms
Binaural timing	700 μs	10 μs

integration time, or the limit of primary acoustic memory, typically on the order of 30–50 ms, and appears to be associated with the lower frequency limit of the audio band (20–30 Hz). It also seems to explain why echoes are only heard as such in large cathedral-like rooms, as they are integrated with the direct arrivals in normal-size rooms.

On the other hand, binaural timing clearly exhibits higher resolution, as differences of interaural timing on the order of 10 μs may be audible. The range of audio timing phenomena is summarized in Table 18.1.

18.2.4 Spatial Acuity

Strictly speaking, the spatiality of a sound field is not perceived directly, but is instead derived from analysis of the physical attributes already described. However, given its importance to audio and electroacoustics, it is nonetheless useful to review the processes involved.

Specification of the position of a sound source relative to a listener in three-space requires three coordinates. From the mechanisms used by the human ear, the natural selection is to use a combination of azimuth, elevation, and distance. Of these, distance is generally considered to be an inferred metric, based on the amplitude, spectral balance, and reverberation content of a source relative to other sources, and is not especially accurate in any absolute sense.

This leaves directional estimation as the primary localization task. It appears that the ear uses separate processes to determine direction in a left/right sense and a front/top/back sense. Given the physical placement of the ears, it is not surprising that the left/right decision is the more direct and accurate, depending on the interaural amplitude difference (IAD) and interaural time difference (ITD) localization cues.

Although the ear is sensitive to IAD at all audible frequencies, as can be verified by headphone listening, the head provides little shadowing effect at low frequencies, since the wavelengths become much longer than the size of the head, so IAD is mostly useful at middle to high frequencies (Fig. 18.7).

The JND for IAD is about 1 dB, corresponding to about 1 degree of an arc for a front/centered high-frequency source. As a sound moves around to the side of the head, the absolute IAD will tend to increase, and the differential IAD per degree will decrease, causing the angular JND to decrease accordingly.

The ITD lateralization cue has a rather astonishing JND of just 10 μs, for a source on the centerline between

Interaural intensity difference (dB)
Fig. 18.7 Interaural amplitude difference as a function of direction (after [18.19])

the ears, corresponding to an angle of about 1 degree. For signals off to one side, the ITD will typically reach a maximum value of just $750\,\mu s - \frac{3}{4}$ of a millisecond. As with the IAD cue, the sensitivity of the ITD cue declines as a source moves around to the side of the head.

Also like IAD, this cue is usable at all frequencies, albeit with a key qualification. At frequencies below about 1500 Hz, the neural response from the basilar membrane remains phase locked to the bandpass-filtered audio waveform. At such frequencies, even a modest amount of interaural phase shift of a sine wave can result in a shift in the position of the audio image. Above 1500 Hz, neural phase synchrony is effectively lost, at least as far as ITD perception is concerned, so the interaural phase of a high-frequency sine wave has little or no perceptual effect on its apparent position. However, the brain can still make fairly accurate judgments of the ITD of the *envelopes* of the high-frequency bandpass-filtered signals, assuming there is sufficient variation in the filtered envelopes. This will tend to make spectrally dense high-frequency signals easier to localize than sparse signals, since the latter may exhibit constant-envelope sine waves only after the critical band filtering of the basilar membrane.

While localization in the horizontal direction is firmly mediated by two strong, well-behaved cues, localization in the vertical dimension is decidedly less well behaved. The goal of vertical localization is to differentiate the positions of sources on locus of constant IAD/ITD. For sources equidistant from the two ears, the locus is a plane passing though the center of the head, referred to as the median plane. For sources off to one side, the locus is a cone, sometimes referred to as the *cone of confusion*. The best-case resolution, for front-centered sources, is typically on the order of 5°, which is quite a bit less precise than the horizontal resolution of about 1° under the same conditions. As with horizon-

tal localization, vertical resolution appears to diminish for side sources, although since the cone of confusion becomes progressively narrower, the net spatial error resulting from a vertical localization error is likely to diminish. For sources at the side, the cone of confusion collapses to a line.

One demonstrated vertical localization cue [18.20] is generated by the interaction of the arriving sound and the folds of the pinnae. The pattern of reflections off the folds depends on the direction of arrival of a sound, although not in any simple, monotonic fashion. One consequence of these pinna reflections is the introduction of sharp peaks and dips in the frequency response, which the brain can apparently learn to associate with specific directions. Because of the size of the pinna, and resulting reflection delays, these direction-dependent response delays appear only at high frequencies, above about 7 kHz, and so are less effective for low-frequency or narrow-band signals. Vertical localization of signals below 7 kHz may be possible on the basis of pinna cues if the brain is performing some sort of autocorrelation of each ear's signal, and can detect the delays in the time domain, but so far there is little evidence to support this hypothesis.

A second vertical localization cue is dynamic in nature, namely the modulation of the horizontal localization cues – ITD and IAD – with movement of the head, which will vary with the vertical position of the source. Given a front source on the median plane, for example, a rightward movement of the head will result in a left ear arrival that is louder and sooner than the right ear arrival. For a rear source, the correspondence will be opposite, and for a top source, there will be essentially no change in the ITD/IAD values. By correlating head movement with these sonic changes, the brain can deduce the vertical position of the source.

Finally, the presence and pattern of room echoes, once learned, and in concert with the above cues, can reinforce the vertical position of a source, especially whether in front of or behind the listener.

Even so, the vertical localization cues tend to be somewhat individual, like fingerprints, and, for example, playing a recording made with microphones placed in the ear canals of one subject may not result in good vertical localization for another listener.

Common experience suggests that the perceived location of a sound may be strongly influenced by visual cues.

18.3 Audio Specifications

With the basic limits of auditory resolution now reviewed, consideration can be given to the requirements for high-quality audio systems in terms of those limits. While individual audio components can be expected to exhibit correspondingly individual performance requirements, as will overall systems, there are some specifications that can be expected to apply to all elements of the signal chain. Some of these are considered traditional audio specs that have been used as general metrics for many years. Happily, in at least some cases, modern audio systems are of such high quality as to render some specifications moot. In other cases, complete fulfillment of some of the requirements is something that may never be completely realized.

18.3.1 Bandwidth

It is reasonably evident that, given the nominal 20–20 kHz range of human hearing, it will be desirable for audio systems with aspirations to sonic accuracy to support at least that frequency range. Since an audio signal may pass through any number of processors on its way from acquisition to ultimate reproduction, it is generally advisable for each processor to have a wide-enough pass band to avoid progressive bandwidth limitation.

For most audio devices during the formative years of audio development, this requirement was daunting, and rarely achieved outside the laboratory, if then. There were too many mechanical vibrating structures in the chain, and it is very difficult to make them respond consistently over a 1000 : 1 frequency range. Grooved disc recordings were limited by large-diameter, low-compliance styli, and slow inner-groove velocities of constant-RPM discs. Optical media, like film, and magnetic media, were both limited by linear speed, and the size of the effective apertures used for recording and playback. The linear speed of such media was chosen as a compromise with playing time, and the smallness of the apertures was limited by high noise levels and diminishing signal level. Broadcast media were limited by bandwidth constraints and noise.

Not counting a straight piece of wire, amplifiers are the audio component that have probably had the easiest time achieving full audio bandwidth, particularly small-signal amplifiers, thanks in part to the relatively low mass of the electron. Power amplifiers have had a slightly harder time, partly because devices that handle high powers often come at the expense of compromises in other parameters, and partly because loudspeaker systems often exhibit ill-controlled, non-resistive loads. The response and linearity of amplifiers of all sorts were materially improved by the invention of negative feedback by Harold Black of Bell Laboratories, on August 2, 1927 [18.21].

An early recording system with fairly wide bandwidth was demonstrated on April 9–10, 1940, by Harvey Fletcher of Bell Laboratories, and conductor Leopold Stokowski. This employed three optical audio tracks on high-speed film, with a fourth track for a gain control signal, apparently implementing a wide-band compressor/expander for noise reduction, and possessing a frequency response of about 30–15 000 Hz.

It was probably not until the mid-1950s that such a bandwidth became commonplace in consumer media, with improvements such as the long-play record, commercial FM broadcasting, and refinements in magnetic tape, heads, and circuits.

As with a number of other basic audio specifications, the question of full-bandwidth frequency response was, to a great extent, rendered moot with the commercial introduction of digital audio in 1982. As discussed in a subsequent section, the bandwidth of a digitally sampled signal is largely dependent on the sampling rate chosen, which must be at least twice as high as the highest audio frequency of interest. Thus, conveying a bandwidth of 20 kHz requires a sampling frequency of at least 40 kHz. Current standard sampling frequencies in common use for full-bandwidth audio systems are 44 100 Hz and 48 000 Hz, depending upon the medium. Sometimes, a slight reduction in high-frequency response is tolerated, and a sampling frequency of 32 000 Hz is used to reduce the data rate slightly. Audio perfectionists, on the other hand, often prefer sampling rates of 96 000 Hz or more, to support an effective bandwidth in excess of 20 kHz and thereby provide additional safety margin to avoid alias distortion, preserve harmonics above 20 kHz, avoid possible intermodulation distortion, and mitigate possible filter distortion.

Once converted to digital representation, an audio signal tends to maintain its bandwidth unless explicitly limited by some digital signal processing (DSP) operation.

Despite the advances of digital audio, full-range audio systems are still the exception. The chief culprits for this situation are the transducers, especially loudspeakers. At low frequencies, naturally occurring com-

binations of mass and compliance lead to a fundamental resonance for most typical loudspeaker drivers that falls well inside the audio band, imparting a high-pass characteristic that usually rolls off at lower frequencies at a rate of at least 12 dB per octave. At high frequencies, a similar fundamental resonance leads to a similar roll-off, with a lowpass characteristic. Some of these roll-offs can be partially mitigated with electronic equalization, but the steepness of the characteristic makes it difficult to extend the response very far with equalization, without incurring unduly high-power requirements.

In general, most musical and speech energy is concentrated in a subset of the audio band, say from 100 Hz to 10 kHz, allowing the majority of audio signals to be satisfactorily reproduced with modestly compromised system bandwidth, to the benefit of size, cost, and bulk.

18.3.2 Amplitude Response Variation

From the basic amplitude acuity of the ear, it is logical to require that the pass-band deviation in frequency response be less than an amplitude JND, say within ±0.25 dB of flat. Of course, this is the desired net response of an entire signal chain, and if deviations are known to exist in one part of the chain, it may be possible to apply compensating equalization elsewhere in the chain.

As with the quest for full audio bandwidth, early audio systems for many years had trouble meeting this requirement, in part from mechanical limitations. Amplifiers again have traditionally had the easiest time meeting this specification, and modern-day DSP is limited only by the precision of the analog/digital converters, which is generally quite good in this regard, plus any deliberate signal-processing spectral modifications.

The worst offender is many cases is the listening room, where echoes and resonances are likely to make nearly any sine-wave frequency response plot a jumble of peaks and dips covering many dB. The three-dimensionality of the room and the fact that echoes arrive from diverse directions work to reduce the audibility of many of these measured deviations.

After rooms, loudspeakers have the hardest time meeting this flat-response requirement, being mechanical devices and having to handle a lot of power and move a lot of air. In order to cover the bulk of the audio band, loudspeaker designs typically employ multiple drivers, each optimized for a portion of the audio band, but this in turn introduces potential response deviations from required crossover networks.

In considering reasonable values for most audio specifications based on psychophysical performance, it is prudent to consider both monotic and dichotic performance; that is, each ear considered in isolation, and then the binaural performance of the two ears together. In the case of amplitude response variation, similar JNDs apply, so there is no compelling reason to differentiate the situations in this case.

18.3.3 Phase Response

In the course of passing through an audio component, an audio signal may encounter delays, which may be frequency dependent, and may therefore be categorized as either frequency-dependent time delays, group delays, or phase shifts. It is therefore prudent to establish preferred perceptual limits on the allowable deviations of these quantities.

Of course, a pure wide-band time delay will be manifested as a linear change in phase shift proportional to frequency, so to separate the effects of time delay and phase shift, so the latter (*frequency-differential single-channel phase shift*) may commonly be understood to represent the deviation from a linear-with-frequency phase characteristic.

It is a little difficult to be completely definitive about a phase-shift specification, in part because there are multiple neural timing mechanisms involved. For a sound channel considered in isolation, phase perception is rather weak. There does not seem to be an explicit means of comparing the fine-grain phase or timing of signals at significantly different frequencies (more than a critical bandwidth), at least for steady-state signals. This is sometimes used as the basis of a claim that the ear is virtually phase deaf, although that is probably an overstatement. Still, if one constructs a steady-state signal with widely space spectral components that are in slow precession, say a combination of 100 Hz and 501 Hz (360° per second relative phase precession), the resulting percept is almost entirely constant.

So under what conditions are phase shifts audible? There seem to be at least three such mechanisms: fusion time, transient fusion time, and critical band envelopes.

As noted earlier, fusion time refers to the audio event integration time of the ear, generally in the range of 20−50 ms. Separate audio events that occur farther apart than the fusion time will generally be heard as separate. If a spectrally complex signal is put through a system where some frequencies are phase- or time-shifted by more than the fusion time, the signal may temporally defuse, rendering the phase shift quite audible. (A 20 ms

phase delay at 30 Hz corresponds to 216 degrees of phase shift, not an unrealistically large value.) This can occur, for example, if a sharp pulse is passed through a third-order, 1/3-octave filter bank tuned for flat magnitude response. What starts out as a click will emerge as a *boing*, quite audibly distinct from the source.

Transient fusion time refers to the shortest interval the ear can differentiate temporally, as exemplified by the premasking interval of about 1–2 ms. If a sharp transient, shorter than the transient fusion time, is passed through an audio channel where the high-frequency phase shift exceeds the transient fusion time, the output signal may sound audibly time-smeared compared to the source. Although the effect can be subtle, it is often manifested as the difference, e.g., between a sharp strike with a hard mallet, and a wire-brush mallet hit.

Critical band envelopes come into play with regard to the audibility of phase shifts with steady-state spectrally dense signals, more specifically signals in which two or more significant signal components fall within a common critical band. Since the basilar membrane filter bank will be unable to segregate these signals into separate bands, they will beat with one another, and the pattern of beats may be quite audible, for example, a complex composed of equal parts 500 Hz and 501 Hz, which can be considered the 500th and 501st harmonic of a 1 Hz pulse train. These two spectral components are certainly within a critical band of one another, and the instantaneous phase relation between them will certainly be audible; indeed the signal will cancel altogether once per second. Compare that to the earlier example of 100 Hz and 501 Hz, the 100th and 501st harmonic of a 1 Hz pulse train, where the phase relation remained virtually inaudible because of the wider frequency spacing.

So it can be safely hypothesized that keeping frequency-differential single-channel phase shift under 1 ms is probably pretty inaudible, assuming small changes over the width of a critical band, and in practice, with most non-transient music, speech or other natural sounds, it can be expected that phase shifts corresponding to frequency-differential time shifts much under the fusion time of 20–50 ms (at least at low frequencies) will be fairly benign, if not almost totally inaudible under most conditions.

Once again, amplifiers have the easiest time meeting this requirement, with multi-driver loudspeaker systems being one of the more problematic components. Although sharp resonances, the bane of mechanical acoustic components, may exhibit audible amounts of phase shift, they will often be rendered insignificant compared to the amplitude deviations introduced by such resonances. And, again, with DSP systems, audible phase shift is not likely to be an issue as long as the signal remains in the digital domain, unless such phase shift is purposely introduced with signal processing.

As can be readily gleaned from binaural psychophysics, dichotic phase shift – the phase shift between a pair of channels – can be more audible at lower delay levels than monotic phase perception. A timing difference of even a single sample at 48 000 Hz sampling, about 20 μs, is twice the JND of this parameter. Of course, the perceptual metric for binaural phase difference is a change in apparent image position or width, rather than the spectral or amplitude change associated with monotic phase shift. It is possible for audio systems to have audible amounts of monotic phase shift and still meet the dichotic (interchannel) phase requirement, as long as all channels have the same amount of phase shift.

As usual, amplifiers and digital signals have the easiest time with this specification. In the past, some multichannel analog recording media, such as magnetic tape recorders or optical film recorders, tended to exhibit small amounts of interchannel timing error, owing to misalignment of the recording and playback apertures. Real-world rooms and loudspeakers have the hardest time, since differential timing of 10 μs corresponds to a path-length difference of only about one eighth of an inch, and few listeners are willing or able to hold their heads that still. This effect is somewhat mitigated because the plethora of echoes in a typical room leads the brain to discount timing information in favor of first-arrival amplitudes, which are somewhat better behaved. Still, it can be readily appreciated that the virtual imaging of stereo reproduction is likely to be fairly sweet-spot dependent, since listener positions near a loudspeaker will tend to receive sound both sooner and louder from the near loudspeaker, resulting in spatial distortion of the sound stage.

18.3.4 Harmonic Distortion

The presence of nonlinearities in the transfer function of an audio device or system is likely to have the effect of introducing new, spurious spectral components. For a single isolated sine wave, the nonlinearity will result in a new waveform with the same periodicity as the original signal, which can then be expressed via Fourier analysis as a sum of the original sine wave plus harmonics thereof [and perhaps a direct-current (DC) component]. For more spectrally complex signals, each
Fig. 18.8 Sine wave with crossover distortion (after [18.22])

discrete spectral component will be subject to such spurious harmonic generation. This process is referred to as harmonic distortion, and the power sum of the generated harmonics, divided by the power of the original signal, is referred to as total harmonic distortion (THD), usually expressed as a percentage.

The limit of acceptable quantities of THD is the point at which the generated harmonics become audible. In part, this may be signal dependent, since distortion products of a low-level signal may themselves fall below the threshold of hearing, rendering them inaudible. For higher-level signals, the distortion products will be inaudible if they are masked, rendering the effect of harmonic distortion decidedly signal dependent. (The amplitude dependency may by further emphasized by nonlinearities that are themselves amplitude dependent, such as clipping.) For example, a wide-band noise signal may mask all harmonic distortion components of a moderate level. Harmonic distortion may therefore be most audible with spectrally sparse signals, with minimal masking components, such as a single sine wave.

For a sine-wave signal, the maximum acceptable amount of harmonic distortion can be deduced from the masking curve of that sine wave. From the masking curve shown in Fig. 18.4, it may be deduced that, since the masking level for a 1 kHz tone is around -35 dB at 2 kHz, the tolerable amount of second-harmonic distortion is about 2%. By 3 kHz, the masking curve is down around 50 dB, or about 0.3% third-harmonic distortion. Higher-order harmonics would benefit from even less masking, making them even more likely to be audible, until their amplitude falls below the threshold of hearing. Thus, the audibility of harmonic distortion will depend on the order of the distortion, with low-order distortion generally being less audible than high-order distortion.

Low-order harmonic distortion is generally associated with smooth, gentle nonlinearities, such as the typical onset of clipping of a vacuum-tube amplifier or a loudspeaker driver. High-order harmonic distortion, in contrast, is likely to result from sudden, sharp nonlinearities, such as the crossover distortion of an improperly designed solid-state power amplifier (Fig. 18.8).

Among more traditional audio devices, playback of grooved media was probably fraught with the greatest amount of high-order THD, caused by sharp mistracking of the stylus. In the age of digital audio, low-level undithered digital signals will likely exhibit stair-step behavior which will also tend to be rich in high harmonic content, rendering them highly objectionable from the perspective of THD. Although this can lead to a desire for very high quantization accuracy (say 32-bits per sample), proper use of dither to spread the harmonic energy out as noise is generally the preferred solution.

18.3.5 Intermodulation Distortion

Intermodulation (IM) distortion results when two or more spectral components interact with a nonlinearity. The resulting distortion products will tend to be generated at sums and differences of the original spectral components. For even low-order IM distortion, these distortion products may be far in frequency from the source signal components, and may in fact be much lower in frequency. Since masking tends to be most effective when the signal to be masked is higher in frequency than the masker, having IM distortion products lower in frequency than the generating components renders them more likely to be audible, in turn making IM distortion potentially more bothersome than THD.

Serious IM distortion tends to be associated with sharp nonlinearities, and was a problem with analog grooved recordings when the stylus mistracked, as well as with poorly designed power amplifiers exhibiting crossover distortion. It can also show up with low-level signals and digital converters. Loudspeakers usually have less trouble with IM distortion, in part because any nonlinearities are usually more gentle (associated with maximum output limiting), and in part because IM distortion products located outside the range of a driver will tend not to be radiated.

Although the theoretical audible limit of IM distortion is a miniscule fraction of 1%, a value of 0.1% IM distortion or less is usually pretty safe.

18.3.6 Speed Accuracy

Considerations of speed accuracy encompass both absolute accuracy and dynamic variations, sometimes

subdivided into slow variations called *wow* and faster variations called *flutter*. Except in extreme cases, timing error is usually perceived as an error in pitch, rather than time. Unless it is drastically in error, absolute speed accuracy is likely to be of concern mostly to those with absolute pitch.

Speed variations such as wow and flutter are likely to be audible to anyone with normal pitch perception. Given a pitch JND of 0.7%, which would correspond to peak-to-peak just-noticeable speed variation, the corresponding root-mean-square (RMS) speed variation would be about 0.25%. Since speed variation may be cumulative, a preferred figure of 0.1% is likely to be specified [18.23]. There may also be cases in which cancellations from room echoes cause amplitude variations resulting from flutter that may require still lower limits of flutter to be rendered inaudible.

The analog mechanical and electromechanical recording devices of the past have all had to contend with speed accuracy. Turntables, tape drives of all stripe, and film projectors all fought off the effects of speed variation, usually with large flywheels and elaborate bearings. Getting a small lightweight tape drive like the Sony Walkman to have low flutter was a good engineering trick. Properly designed and maintained equipment was generally able to meet the required speed accuracy specification.

In the age of digital audio, speed errors of all sorts are mostly a dead issue. Sampling clocks controlled by quartz oscillators provide speed accuracy and steadiness far in excess of what the ear can hope to detect.

18.3.7 Noise

Noise is a first cousin to distortion in its characteristics and considerations. It is a random signal, hopefully low in level, that gets tacked onto an audio signal in the course of almost any processing, analog or digital, and it is generally cumulative in nature. It often sounds like a hiss. Noise will be inaudible if it is either below the threshold of hearing, or masked by the audio signal.

Sources of Noise
Noise sources include:

- *Acoustical*: Random fluctuations of air molecules against the eardrum or a microphone diaphragm
- *Electrical*: Tiny fluctuations of electrical charge in analog electronic circuits from discrete electrons
- *Mechanical*: Surface irregularities of grooved media

- *Magnetic*: Irregularities of magnetic strength from discrete magnetic particles in recording tape
- *Arithmetic*: Random errors from DSP quantization of numerical signals to discrete values.

There are other common spurious signals, such as hums and buzzes, that can corrupt an otherwise pristine audio signal, and although strictly speaking they may not be considered noise, they are generally at least as undesirable.

In any case, the level of noise can be considered as a function of frequency, giving rise to the notion of the spectrum or spectral density of the noise. If the value of an audio noise signal at any point in time is uncorrelated with the value of the noise at any other point in time, the signal is an example of what is called *white noise*. Spectrally, white noise is said to be flat in a linear frequency sense. That is, in essence, the output energy of a bandpass filter of bandwidth B Hz. supplied with white noise, will be the same regardless of the center frequency of the filter (provided, of course, that the pass-band of the filter is substantially within the audio band).

Because the filters on the basilar membrane are approximately logarithmic (not linear) in center frequency and bandwidth, and because they tend to integrate the signal energy within each pass-band, white noise will likely be perceived as having a rising high-frequency spectrum, even though it is flat on a linear frequency basis. In other words, as the center frequency of each effective basilar membrane bandpass filter increases, so too does its bandwidth, roughly in proportion, ergo the total filtered energy of a white-noise source will increase with frequency, leading to the bright, top-heavy perception. For each successive octave, or doubling of center frequency, the bandwidth will double, ergo so too will the bandpass white-noise signal energy, leading to a characteristic spectral rise of 3 dB per octave.

Note: dB $= 10 \log$ (ratio of power) $= 20 \log$ (ratio of amplitude).

If white noise is processed with a filter having a constant roll-off characteristic of -3 dB per octave, the output noise will have constant energy per octave, or fraction thereof, and will sound flatter to the ear. Such a signal is referred to as pink noise.

Although many forms of noise are independent of the presence of an actual signal, there are mechanisms whereby noise, or noise-like artifacts, are signal dependent. The most common such behavior is for the level of the noise to be roughly proportional to signal level. This type of artifact can be especially pernicious,

as the dynamic behavior tends to call attention to the noise.

Although there are numerous ways of dynamically suppressing noise if it is unavoidable, it is by far preferable to avoid it in the first place as much as possible via proper low-noise design, proper shielding and grounding, etc.

18.3.8 Dynamic Range

Dynamic range is the amplitude range from the largest to the smallest signal an audio device or channel can handle. In cases where there is no minimum signal, other than zero level, the minimum usable level may be taken as the noise level of the channel usable.

If the noise level of the channel is substantially independent of signal level, the dynamic range of the channel may alternately be referred to as the signal-to-noise ratio (SNR). If the noise is signal dependent, the audibility of the noise will depend on the instantaneous signal-to-noise ratio, which is likely to be quite different from the dynamic range.

Since both the noise level and the overload point of a channel are likely to be functions of frequency, so too will the dynamic range. A common characteristic of the noise of traditional analog recording systems has been rising noise levels at the ends of the audio band, cou-

pled with diminishing maximum signal levels, a double whammy that tends to limit the resulting dynamic range, in some cases rather severely.

Historically, unadorned analog channels have tended to have overall dynamic-range specifications on the order of 45–60 dB. This is true of such media as FM stereo, grooved records, optical film soundtracks, and magnetic tape. Perhaps the most limited hi-fi medium in this regard has been cassette tape, which manages about 55 dB at midband and on the order of 30 dB dynamic range at high frequencies.

Happily, DSP systems usually have flat overload characteristics and flat, or at least white, noise floors. The dynamic range of a DSP system is largely a question of the number of bits used to represent the signal. A rough rule of thumb is that each additional bit in the representation of sample values adds 6 dB to the dynamic range. The common 16-bit format used on digital compact discs yields a theoretical dynamic range of 96 dB. In practice, the combined effect of real-world imperfections and converter noise limits the practical attainable dynamic range with 16-bit audio to a little short of 96 dB, perhaps about 93 dB. A 24-bit converter can approach 144 dB dynamic range, which not only allows coverage of the full human auditory dynamic range, but allows margin for error in setting recording levels and subsequent mixing and processing operations.

18.4 Audio Components

With the common audio specifications now delineated, consideration can be given to some of the common audio components, their typical specifications, and specific characteristics and limitations.

18.4.1 Microphones

For any acoustical recording, the type, pickup pattern, position, and characteristics of the microphone are likely to have the greatest effect on the resulting quality of the recording. A microphone is, of course, an analog transducer, generally used to convert acoustic signals to proportional electrical signals. It is the functional analog of the eardrum in the human auditory system.

The term microphone was coined by Sir Charles Wheatstone in 1827, although at that point it referred to a purely acoustical device, such as a stethoscope. Its start as a transducer was pretty much coincident with Bell's invention of the telephone. Bell's initial *transmit-*

ter used a vibrating needle connected to a diaphragm and immersed in an acid bath to implement a variable resistance responsive to acoustic waves [18.24]. This was followed in short order by more practical, rugged designs by Bell, Edison, Berliner, Hughes, and others.

Common to virtually all microphones ever made is a diaphragm. Most microphones do not directly sense the instantaneous pressure deviations of an airborne acoustic wave. Instead, the sound waves impinging on a diaphragm cause movement of the diaphragm, and it is this movement that is sensed and converted to an electrical audio signal.

The methods used for the mechanical-to-electrical transduction are many and varied. Bell's telephone patent seems to describe an odd type of electromagnetic microphone, in which the diaphragm was mechanically coupled to an armature in a magnetic circuit. Acoustic vibrations caused vibration of the armature, in turn in-
Fig. 18.9 A dynamic microphone uses a coil of wire attached to a diaphragm, suspended in a magnetic field (after [18.25])

ducing changes in the reluctance of the magnetic circuit, which induced a dynamic current in a coil of wire.

Later dynamic microphones simply attached a fine coil of wire to the diaphragm (Fig. 18.9), and suspended it in a magnetic field. Movement of the diaphragm induces a voltage in the coil of wire, presumably proportional to the velocity of the diaphragm, and said voltage can then be amplified as necessary. Dynamic microphones do not require an external source of power. Their popularity was limited prior to World War II by a lack of powerful permanent magnets.

Many early telephone transmitters used carbon in one form or another, typically carbon granules coupled to the diaphragm such that vibration of the diaphragm would dynamically squeeze the granules, causing a variation in resistance that could be electrically sensed by an applied voltage (Fig. 18.10). This arrangement could be scaled up in size and voltage enough to produce a sizeable signal, of particular importance prior to the advent of electrical amplification.

Another type of self-generating microphone is the crystal microphone, based on the piezoelectric effect discovered by the Curies in 1880. Here, the diaphragm constricts a thin crystal made of Rochelle salt, ceramic, or similar material, directly producing a voltage (Fig. 18.11). The low compliance of the piezoelectric element typically limits the performance of such a microphone, especially the extent of its frequency response.

Indeed, the performance of most of the microphone types mentioned so far is somewhat limited by the need to attach some object or structure to the diaphragm to detect its motion, increasing the mass of the moving elements, which in turn tends to limit the high-frequency response.
Fig. 18.10 A carbon microphone (after [18.26])

Two types of microphones avoid any mechanical attachment to the diaphragm: the ribbon microphone and the condenser microphone.

A popular variant of the dynamic microphone, the ribbon microphone, uses a thin metal ribbon diaphragm suspended in a magnetic field. Movement of the diaphragm induces a current in the diaphragm, which can then be amplified. In effect, the diaphragm acts as a single-turn moving coil. The ribbon microphone was developed by Schottky and Gerlach in 1923, and considerably refined by Harry Olson of RCA in 1930 [18.28].
Fig. 18.11 Piezoelectric microphones (after [18.27])
Fig. 18.12 A condenser microphone consists of a very thin diaphragm suspended parallel to a backplate (after [18.25])

The condenser microphone (Fig. 18.12) is based on the notion of electrical capacitance. A metal, or other conducting, diaphragm is placed close to a second, fixed conducting plate, forming a capacitor, and a polarizing voltage is applied between the plates. Movement of the diaphragm causes alterations in the capacitance, in turn causing corresponding alteration of the charge on the plates, which is converted to a dynamic voltage by a resistor, and amplified as necessary. The invention of the condenser microphone is generally credited to E. C. Wente of Bell Laboratories, in 1917 [18.29]. A popular modern variant is the electret condenser microphone, perfected in 1962 by Sessler and West of Bell Laboratories [18.30]. An electret is an object possessing a permanent electrostatic charge, making it rather like the electrical analog of the permanent magnet. Use of an electret to polarize the capacitor in a condenser microphone eliminates the need to supply a polarizing voltage for the capacitor. Since electret condenser microphones are used almost universally in cell phones, as well as other applications, they are probably the most popular type in current use. The diaphragm of electret condenser microphones is usually made of a thin sheet of flexible plastic which has had a metal coating deposited on it, a notably lightweight arrangement that permits good sensitivity and frequency response. Such microphones also usually exhibit good sample-to-sample consistency, making them practical for multi-microphone arrays.

A more recent variant of the condenser microphone is the silicon microphone. This is a microscopic condenser microphone constructed using micro electromechanical system (MEMS) technology. The required electrostatic polarizing field is provided by a charge pump, and the diaphragm can be free floating, being held in place by electrostatic attraction.

In recent years, the motion of a diaphragm has been measured using optical means, including laser interferometry, which may in time become a practical alternative to the capacitor microphone.

Microphone Dynamic Range

The noise level of a microphone is limited by Brownian motion of air molecules impinging on the diaphragm. Of course, it can be further limited by electrical noise of the amplification which follows it, but even discounting those effects, the so-called self-noise of a microphone is likely to be 10–20 dB higher than the threshold of hearing [18.31]. Lower self-noise is possible with larger diaphragms, say on the order of one inch, but this comes at a price of making the microphone more directional at high frequencies.

The loud signal limit of a microphone is often set by the maximum signal capacity of the associated preamplifier. Using large rail voltages can be of some aid in this regard. Eventually the diaphragm will reach the limits of its travel, and experience soft clipping. There has been some work on using force feedback to linearize the characteristics of the diaphragm [18.32, 33]. With a little effort and care, it is possible to make microphones that can handle high-level signals about as well as the human ear can.

Finally it should be noted that there has been some work on creating a microphone that does not require a diaphragm. Blondell and Chambers did some work on a flame microphone in 1902 and 1910 [18.24]. More recent efforts have used lasers to detect index of refraction changes due to acoustic pressure waves [18.34].

Microphone Pickup Pattern

Interacting with a real, three-dimensional sound field, a microphone is an audio device inextricably tied to spatial considerations. Immersed in the sound field, the microphone responds to the sound at essentially just one point, so its output represents a spatial sample of the total sonic event. This is not to say that it necessarily responds equally to sounds arriving from all directions; on the contrary, most microphones exhibit some directional bias, whether or not intended, and it is probably not possible to specify a single universally preferred pickup pattern.

The simplest arrangement is to put a sealed chamber behind the diaphragm, allowing only a slow leak for stabilization of quiescent atmospheric pressure. With short-term pressure behind the diaphragm fixed, the microphone responds to the sound pressure at the front of the diaphragm. Since pressure is a spatial scalar, it
Fig. 18.13 *Omnidirectional* microphone pickup pattern. Note the slight attenuation of sounds arriving from the rear (after [18.36])

might be expected that a pressure microphone might respond equally to sound from all directions, and indeed this might be the case if the diaphragm had zero dimension. As it is, a finite-dimension diaphragm will spatially integrate the sound pressure across its surface. This will tend to increase output for normal-incident waves and waves with long wavelength, but will have less boosting effect for random incidence sounds, such
Fig. 18.14 Bidirectional microphone pickup pattern, typical of an open-back ribbon microphone (after [18.36])
Fig. 18.15 Cardioid microphone pickup pattern, obtained by combining omnidirectional and bidirectional pickup patterns (after [18.36])

as Brownian noise, and may reduce response to sounds with oblique incidence and wavelengths shorter than twice the diameter of the diaphragm. The resulting pickup pattern may therefore become directional at high frequencies, while remaining omnidirectional at lower frequencies. To remain omnidirectional up to 20 kHz, a diaphragm will have to have a maximum diameter of half the wavelength at the upper frequency limit, or about 8 mm. Whether by accident or design, this happens to be the approximate diameter of the human eardrum [18.35]. The fact that the eardrum is so small, and is coupled to the structures of the inner ear, and yet the ear still manages to exhibit a maximum sensitivity of 0 dB SPL or better has to be considered impressive performance, especially considering that quiet sounds just fade into perceived silence, rather than some inherent background perceptual noise.

More elaborate microphone pickup patterns (Figs. 18.13–18.15) can be achieved by increasing the number and complexity of acoustic paths to the diaphragm. For example, simply opening the back surface of the diaphragm to the atmosphere, the arrangement used in the classic open ribbon microphone, results in a microphone sensitive to the difference between front and back pressure, so sounds arriving from the side produce no response, and the pickup pattern usually resembles that of Fig. 18.8, albeit with the front arrival signal of opposite phase to the rear arrival signal.

If a pickup pattern as in Fig. 18.8 is summed appropriately with an omnidirectional pickup pattern, the rear arrival sound can be made to cancel, producing a cardioid front-directional pickup pattern.

With more elaborate channeling of the audio reading the diaphragm, more specialized or directional pickup patterns may be obtained.

Greater flexibility in the choice of pickup pattern can be obtained by using arrays of microphones, typically arranged in fixed physical orientations, where the effective pickup pattern of the array is dependent on how the individual microphone signals are electrically summed. By recording the individual signals, the array can be effectively focused and oriented after the fact by postprocessing the recorded signals. The large-volume low-cost manufacture of certain types of microphones has made this approach especially attractive.

18.4.2 Records and Phonograph Cartridges

Although by now semi-obsolete, the phonograph cartridge has historically played a key role in sound reproduction, and is fairly close to a microphone in many aspects of operation. As with a microphone, the intent is to act as a transducer for acoustical vibration, in this case the vibration originating from a stylus following the undulations of a groove, rather than a diaphragm responding to vibrations in air.

Although early phonographs employed direct mechanical-to-acoustical transduction, the advent of electronic amplification made the electromechanical phono cartridge the default device for record playing.

Most of the methods of transduction used for microphones have been tried for phono cartridges as well, with piezoelectric and magnetic being the two most popular. Whereas most magnetic microphones have been of the moving-coil type, the magnetic cartridge design has employed both moving magnet and moving coil designs. Perhaps the use of a cantilever design of the stylus to reduce the effective mass of the coil or magnet seen by the stylus tip, coupled with the lack of a diaphragm, led to the preference of magnetic transduction for phonograph cartridges, while the use of capacitive transduction in condenser microphones has tended to be preferred in that transducer.

Despite the popularity of the grooved phonograph record for well over half a century, it has always been a difficult medium with which to achieve full fidelity.

For one thing, the stylus assembly is fraught with high-frequency resonance problems, much like the microphone, which have tended to limit the high-frequency response. In many cases, the high-frequency resonance has been underdamped, resulting in a serious peak in the mid-high-frequency response. The material used to mount the stylus in a way to secure it but still allow it to vibrate, often little bits of rubber, can sometimes degrade with age, impairing the characteristics of the cartridge. Then there is the need for the cartridge to drag a tonearm across the record with it.

In theory, the tonearm should provide a rock-stable platform for the cartridge at audio frequencies, so that only the stylus vibrates. Below the audio band, the tonearm should move as freely as possible, to follow the slowly spiraling groove and miscellaneous movements induced by the rotating disc, including horizontal eccentricity and vertical warp. In practice, this behavior cannot be achieved perfectly (since a perfect *brick-wall* filter is impossible), but at least the cartridge and tonearm should be matched, and the low-frequency resonance peak resulting from the compliance of the stylus and the effective mass of the tonearm should be properly damped, to avoid a peak either in the low-frequency audio response, or in the subsonic region where a resonance could make the system overly sensitive to record warp. Even in the best arrangement of properly damped resonance centered an octave or so below the audio band, the system is only second order, so some low-frequency tonearm vibration and some subsonic stressing of the stylus from pulling the tonearm is inevitable [18.37], which can lead to distortion and uneven frequency response. To avoid the build up of acoustic traveling waves in the tonearm, it is desirable to have its construction and material chosen to damp out such vibrations; not all tonearms have done this well.

Another problem that has hampered record playback, although not strictly the province of the phono cartridge, is that the playback stylus usually does not exactly follow the same path and orientation as the cutting stylus. This is because discs are cut on a cutting lathe, in which the cutter slowly traverses a straight-line path from the outer grooves to the inner grooves. The playback cartridge, in turn, is usually mounted on a pivoted arm, so its path is an arc. (The longer the tonearm, the smaller the disparity between record and playback orientations.) In order to minimize the path mismatch, a right dogleg bend has often been incorporated into the shape of the tonearm. The cartridge has to be carefully mounted on the tonearm so that the stylus is a specified distance from the pivot if this feature is to be properly exploited. Unfortunately, the bent tonearm traversing an arc results in a steady-state force from friction between the moving record groove and stylus tip,

one which does not pull straight down the length of the tonearm, but instead generates a sideways force, called the skating force, which pulls the stylus tip against one or the other of the groove walls, which is another potential source of distortion. The skating force varies with groove speed and stylus tip size and shape, among other things, making it challenging to fully compensate.

At various times straight-line tracking tonearms have been produced, usually with the back of the tonearm mounted via bearings to a platform intended to move in a straight line to follow the front of the arm (and the stylus). Since the stylus cannot be expected to drag the rear platform along with it, some sort of servo is used to insure that the platform follows the slow movements of the stylus/cartridge combination. Although this should mitigate skating-force problems, assuming the cartridge is mounted precisely, it still leaves the other difficulties of disc playback.

Another issue with phono cartridges is the shape of the stylus tip. The cutting stylus is chisel-shaped, with sharp corners, so it is capable of inscribing very fine undulations. But the traditional stylus tip shape is round, so the points of contact with the groove walls vary with the curvature of the groove. A round stylus will therefore follow a slightly different path than the cutting stylus, another source of distortion. In the 1960s, elliptically shaped styli became popular to reduce the tracing error, by more closely approximating the shape of the cutting stylus. The smaller stylus tip radius of curvature at the point of contact, compared to a spherical stylus tip, should allow the stylus to more accurately track the motion of the cutting stylus, but results in higher localized pressure, which can increase groove wear unless low tracking pressure is employed. Even so, the precision with which a given playback stylus follows the motions of the cutting stylus is unlikely to be sufficient to avoid some alteration in sound quality.

Around the time elliptical styli were becoming popular, RCA attempted to improve tracing performance by pre-distorting the cutter signal, anticipating playback with a round stylus. The system was not universally welcomed [18.38], in part because it arguably impaired performance with elliptical styli, and was eventually dropped.

Ultimately it has to be accepted that there will be some, hopefully slight, difference between the motion of the cutting stylus and the motion of the playback stylus, and that there are some signals that the playback stylus cannot hope to track properly, such as a constant-amplitude-cut square wave. The best one can hope for is that the deviation will be small and gentle, and that

the resulting distortion will be mostly low-order THD. Even so, distortion figures for records were not uncommonly in excess of 10%, especially for the slower inner grooves. The technique of stereo recording on discs, pioneered by Blumlein in 1931 and introduced commercially in 1957, further complicated the task of the playback stylus, as it then had to track both horizontal and vertical undulations simultaneously.

Getting adequate dynamic range from records was a tricky process, fraught with compromises. For one thing, the maximum signal level used tended to be traded off against total playing time. Large-amplitude grooves took up more real estate than quiet grooves, which led to the use of variable-pitch, look-ahead record cutters that could dynamically adjust groove spacing in response to groove amplitude. Such cutters functioned by increasing the spacing one revolution before the arrival of a loud sound, and maintaining the spacing for the revolution that followed. Further complicating the amplitude/playing-time conundrum is the desire on the part of some recording engineers to minimize use of the inner groove area, to minimize inner groove distortion and bandwidth limitations.

Maximum amplitude was also limited by considerations of what the playback styli and cartridges of the consumers could accommodate, which could lead to lowest-common-denominator compromises in performance. To better match tracking ability and noise floor to the average statistics of music spectra, the Recording Industry Association of America (RIAA) standard equalization curve was adopted in 1954 that progressively reduced low frequencies and boosted high frequencies on recordings, applying inverse compensation during playback. This, along with the characteristics of the stylus, record surface and groove speed, made the overload characteristic of records strong functions of both frequency and playing time, so the precise specification of overload characteristic of records is problematical at best. To be sure, there are specified suggestions for maximum cutting amplitude and velocity, but given the commercial realities, at least with pop music, that louder all too often equates with better, the suggested limits have not always been observed.

The noise level of a record is dependent on the smoothness with which a groove can be cut, which in turn depends on the cutting technique and the material used. Although wax and shellac were used in the early years of record production, more modern practice has been to use lacquer deposited on an aluminum disc base. In conjunction with the hot-stylus cutting technique in-

troduced in 1951 [18.9], a lacquer master disc is capable of a dynamic range approaching 70 dB, although in practice a somewhat lower figure is sometimes encountered for the end product on a production basis. Most of the steady-state noise encountered with records is concentrated at mid to low frequencies. In pursuit of the goal of fitting a performance to the dynamic-range characteristics and limitations of grooved discs, it has traditionally been common practice to employ a combination of compression and limiting to the signal in the course of cutting a master disc. There have been some attempts to apply complementary compression and expansion to record audio to improve the system dynamic range, notably discs produced by dbx Inc. in the 1970s.

Successful record playback can also run afoul of a problem known as acoustic feedback, if sound from the loudspeakers causes the disc itself to vibrate as a diaphragm. Solutions include the use of an inert turntable mat, remote positioning of the turntable, and limiting the playback level.

Of course, dust, dirt, scratches and wear will tend not only to degrade the recorded signal but also to raise the noise level, including the possible introduction of clicks and pops.

Given the litany of compromises and limitations in disc recording and playback, the level of performance that has been achieved with this medium is laudable. Although largely eclipsed by digital audio, some refinement of grooved record playback continues, including efforts to achieve the holy grail of disc playback, contactless playback via light or laser beam, notably by Fadeyev and Haber at Lawrence Berkeley National Laboratory [18.39]. The availability of advanced DSP has allowed after-the-fact improvements in noise reduction and distortion reduction that would have been impossible in an earlier age. It is tantalizing to consider the performance that might have been possible with this medium if such processing had been available and incorporated into the basic architecture of the disc recording system.

18.4.3 Loudspeakers

Loudspeakers and headphones provide complementary transduction to microphones, namely converting electrical audio energy to acoustical energy. Many of the principles and notions regarding microphones can be applied to loudspeakers either directly or by, in a sense, turning the ideas upside down.

In a manner reminiscent of microphones, few loudspeakers convert directly between electrical and acoustical energy. Instead, the electrical energy is converted to mechanical energy, specifically the movement of a diaphragm, often cone-shaped or dome-shaped, which then radiates acoustical energy, sometimes aided by an acoustical coupling horn or lens.

Indeed, many of the same transduction methods that have been used in microphones have at least been tried for loudspeakers including magnetic (also known as *dynamic*), piezoelectric, and condenser.

The genesis of loudspeaker-like transducer actually predates Bell's invention of the telephone by a couple of years when, in 1874, Ernst W. Siemens described a dynamic moving-coil transducer, although he does not seem to have initially done much with it [18.40].

Bell's telephone, patented in 1876, also used a dynamic receiver. With a magnetic armature mechanically coupled to a diaphragm secured at its edges, it was probably closer in spirit to a headphone than a loudspeaker.

There followed a series of refinements that progressively brought the output transducer closer to the modern concept of a loudspeaker. In 1898, Oliver Lodge patented a spacer to maintain the air gaps in the magnetic circuit. Three years later, John Stroh came up with the notion of attaching the cone to the frame via a flexible, corrugated surround that improved the linear travel of the cone. Proper, flexible centering of the rear of the cone in the magnetic gap was provided by the *spider*, developed by Anton Pollak in 1909.

Many of these early loudspeakers used an acoustic horn of some sort to project the loudspeaker output into the room. The horn improves efficiency, partly by improving the acoustic coupling from the loudspeaker to the room, and partly by collimating the sound into a beam directed at the listener. Credit for the first true direct radiator loudspeaker design to include all the elements of what can be regarded as the modern-day loudspeaker is generally accorded to Rice and Kellogg in 1925 [18.41]. Their design took explicit account of the baffle on which the driver was mounted in the overall acoustic design.

There were of course, countless follow-on refinements to the basic electrodynamic driver, a process that continues to present day. Other methods of transduction were also explored. In 1929, E. W. Kellogg filed a patent for an electrostatic loudspeaker, consisting of panels not unlike large condenser microphones. The design has not been as widely accepted as the dynamic driver, in part due to some limitations in maximum output. There have also been piezoelectric drivers, but the limited travel of the piezoelectric element has limited their use to mid-range drivers, tweeters, and earphones.

So, as the Rice/Kellogg baffle indicated, with the basic dynamic loudspeaker configuration established, much of the attention focused on refining the loudspeaker/cabinet combination as a system.

The output ultimately obtained from a raw loudspeaker driver is profoundly affected by the surrounding baffle or cabinetry. In isolation, a loudspeaker driver produces two acoustical outputs: one from the front of the diaphragm or cone, and the second from the back. Unfortunately, the two outputs are out of phase. Were they generated at the same place and time, they would cancel; the loudspeaker would produce nothing but heat. So part of the goal in designing a complete loudspeaker system is to keep those two outputs from annihilating each other.

At frequencies above the point where the wavelength is comparable to the size of the speaker cone, the radiation will tend to be a directional beam, and the front and back waves will tend to naturally go their own separate ways. At lower frequencies, the front and back radiation will tend to be more omnidirectional, and will therefore tend to cancel. This can be avoided by requiring that the size of the loudspeaker be at least as large as the wavelength of the lowest frequency of interest. For a low-frequency limit of 20 Hz, this would correspond to a diameter of at least 15 m, which at the very least would make for rather unwieldy boom boxes.

Happily, it is not necessary to rely on the loudspeaker itself to avoid low-frequency cancellation. Instead, a smaller driver can be mounted on a baffle, and the baffle can be used to prevent interaction of the front and back radiation. Indeed, a common concept in loudspeaker system theory is that of the *infinite baffle*, which precludes cancellation at any frequency, at the cost of being physically impossible. Even assuming a willingness to forego response below 20 Hz, a baffle of at least 15 m would still be required, which is not much more practical than an unadorned 15 m woofer. This leads to the notion of putting the loudspeaker in a box, or loudspeaker cabinet. (A speaker mounted in a car door or trunk lid is operating in an approximate infinite baffle, although the car interior can be considered a semi-sealed cabinet.)

The simplest arrangement is to make the box completely sealed, so that the rear radiation is trapped within the box, and cannot emerge to cancel the front radiation. Of course, this requires making the box quite rigid, else the rear speaker radiation will simply be conducted through the walls of the box. One problem with sealed-box systems is that the springiness of the air in the cabinet will decrease the natural compliance of the loudspeaker, so that a driver with a respectably low free-air resonance may have a much higher resonance mounted in a sealed box, with correspondingly reduced low-frequency response.

This issue was addressed in 1954 by Edgar Villchur, in a manner which in hindsight seems remarkably straightforward, namely increasing the compliance of the speaker to obtain the desired performance when it was mounted in a sealed box. This approach, referred to as an acoustic suspension design, made the cabinet an inherent part of the design, and is still in use today.

The alternative to the sealed-box loudspeaker enclosure is, logically enough, the vented box, in which at least a portion of the back radiation of the driver is allowed to emerge from the cabinet, often delayed or phase-shifted to better align it with the front radiation. One of the early examples of this approach was the bass reflex design by Albert Thuras of Bell Laboratories, in 1930. Other vented designs have used elaborate internal tubing, internal ductwork (such as the Klipsch folded horns), and or provided mass loading of the exit port via a diaphragm (the *passive radiator*). The goal is to improve efficiency, partially by relieving some of the back pressure behind the driver, but mostly by adding some of the back radiation to the front radiation in a nondestructive fashion, to achieve some increase in output, typically on the order of 3 dB.

More recently, hybrid enclosures have been developed, sometimes called bandpass enclosures, in which a vented or sealed box is used behind the driver and a vented box is used in front of the driver, to provide improved low-frequency efficiency over a somewhat narrow range of frequencies [18.42]. This design is popular in some smaller low-frequency speakers.

Regardless of its other characteristics, a bare loudspeaker cabinet is likely to impart a variety of spurious resonances to the response from sound waves bouncing helter-skelter around the inside of the cabinet. For this reason, loudspeaker cabinets are often lined or stuffed with sound-absorbing material. This alters the overall response as well as damping the resonances, and must be accounted for in the overall design.

Much of the modern modeling of loudspeaker systems is based on the work of Thiele and Small in the 1970s, who established the basic parameters governing the performance of loudspeaker systems, and developed accurate mathematical models incorporating those parameters, allowing rapid and precise mathematical prototyping [18.43].

Still, the implications of achievable, cost-effective drivers and practical cabinet size is that there is precious

little that can be done to get usable bass response down to 20 Hz from a small loudspeaker system. It is possible to apply low-level equalization to the signal upstream of the loudspeaker, but this can increase the cost and the power requirements, and will not be effective unless the driver can handle increased signal level without serious distortion. The closed-box design is considered one of the better choices for the use of equalization, as its response roll-off below primary resonance is only 12 dB per octave, which is gentler than most vented systems.

Most of the issues relating to speaker cabinetry pertain to low frequencies. Midrange and high-frequency drivers may also have their backs sealed, but the wavelengths are shorter, and the required resonant frequencies are a lot easier to attain.

The notion of using multiple drivers in a loudspeaker system seems to have originated in 1931 with a two-way system designed by Frederick of Bell Laboratories [18.44]. A three-way system followed within two years. It is simply much easier to design a system to have flat frequency response with multiple drivers, optimized to handle a subset of the audio band, than to try to accomplish the task with a single driver.

Part of the motivation for using multiple drivers is that the loudspeaker, like the microphone, is an inherently spatial entity. Sound radiates from a loudspeaker in all directions, depending on angle and frequency. In an anechoic environment, with a listener situated on the main axis of the loudspeaker, the response on that axis is well defined, and the only one that really matters. In a real room, however, the multidirectional acoustical output of the loudspeaker will reflect off walls and other surfaces, generally producing a complicated multiplicity of arrivals at the listener's ears. There is no easy way to characterize this process, or of the resulting perception, although in the 1970s, Roy Allison made significant strides in characterizing the loudspeaker–room interaction at low frequencies [18.45]. However, it certainly establishes the importance of the loudspeaker spatial response at all angles, and suggests the desirability of a loudspeaker having a consistent radiated frequency response (radiation pattern) at any angle.

This is another area in which multiple drivers can be beneficial. Again, the output of a driver will begin to get directional at a frequency corresponding to a wavelength about twice the diameter of the driver. Assuming consistently wide dispersion is desired, a 30 cm woofer will be useful up to about 500 Hz, a 7.5 cm midrange continuing to 2 kHz and a 2.5 cm tweeter maintaining wide dispersion to at least 6 kHz. These figures may be conservative, in part because controlled decoupling of the speaker cone can result in a progressively smaller radiation area at successively higher frequencies, decreasing the effective diameter and broadening the resulting dispersion. Other approaches to maintaining a desired radiation pattern across frequency include the use of acoustic lenses and phased arrays of multiple drivers within a given frequency range. It is rare for a speaker to have truly constant directionality across its entire pass-band, in part from that fact that most are at least somewhat directional at mid and high frequencies, and, because of the long wavelengths involved, almost unavoidably omnidirectional at low frequencies. (Such long wavelengths may be difficult to localize, enabling the use of satellite systems with only one woofer to support two or more channels.)

The use of two or more frequency-selective drivers generally imposes the need for a crossover network to apportion the signal on the basis of frequency. Not only does this avoid wasting power, but it can be absolutely necessary to avoid overdriving or burning-out a driver. Some care is generally required in the transition frequency region to maintain flat response, and although there are well-regarded canonical topologies, such as the Linkwitz–Riley crossover developed in 1976 [18.46], real-world deviations from ideal driver behavior may engender the use of recursive approximation techniques to optimize system response fully.

The combination of crossover networks, drivers, and room loading will often result in a loudspeaker having an electrical input impedance characteristic that is strongly frequency dependent, and which poses a challenge for a power amplifier.

As is no doubt evident, a loudspeaker system and its associated radiation pattern is a fiendishly complicated device that does not readily lend itself to characterization by traditional audio metrics or specifications. In consideration of such specifications, it is difficult to make definitive statements that fully characterize the sound of a speaker.

The bandwidth of most speakers may approach the ear's 20–20 kHz bandwidth, but few speakers make it all the way, particularly at low frequencies, and bandwidths on the order of, say, 70–14 kHz are far more common, at least in consumer equipment.

The deviation of the frequency response is difficult to talk about meaningfully, but it seems desirable for speakers to be within 1 dB of flat response across their useful bandwidth, at least on axis, and better speakers can approach or achieve this, although at low frequencies the room exerts enough effect as to likely

require tuning or experimentation with speaker position to maintain a flat response. The response at other angles should probably be smooth and well controlled, but the exact optimal specification has not been established. Perhaps the ideal speaker would adjust its radiation pattern to match the instruments being reproduced. (But then what is the preferred radiation pattern of a purely electronic instrument, such as a synthesizer?) Although it is necessary to measure the response of a loudspeaker in a room in order to accurately gauge the low-frequency response, a direct narrow-band or sine-wave measurement of the system response in a room at middle and high frequencies is likely to yield a useless, mad scribble of a response, owing to the complex interactions of the echoes at the point of measurement. Fortunately, the perceived response should be a lot smoother than what is measured, in part because the ear differentiates sound arrivals on the basis of direction. Measurement techniques that attempt to address this include the use of directional microphones, anechoic and semi-anechoic measurement, and time-gated response measurement.

Timing precision is another specification that is difficult to pin down with loudspeakers, again partly due to the effects of room echoes. In one respect, most speakers do pretty well in first-arrival timing, since the ear's temporal pre-masking resolution is on the order of $1-2$ ms, corresponding to about $30-60$ cm of path length, and speaker systems with all drivers mounted on a common front panel will generally be well within this tolerance for inter-driver path-length differences. Still, audible time disparities may result from primary resonances, particularly at low frequencies, and high-order crossovers.

In the area of distortion, loudspeakers also do pretty well, all things considered. At normal listening levels, a properly designed loudspeaker exhibits fairly low nonlinearity, with a fairly gentle limiting characteristic, leading to low IM distortion and fairly low THD, mostly third order, which is likely to be masked by most signals. Most properly operating loudspeakers do not produce drastic amounts of distortion until they reach the limits of their travel. To be sure, some loudspeakers can sound audibly harsh, but this is not necessarily a byproduct of distortion, it may be more related to an uneven response or radiation pattern. One bugaboo of many drivers is cone breakup, wherein the cone no longer acts as a piston. Although this can look unsightly in slow motion, it will not necessarily produce distortion unless there is nonlinearity present, and most speaker cones, being passive structures of paper, plastic,

or metal in and of themselves, are not especially nonlinear. While such breakup is likely to affect the response and/or the radiation pattern of the speaker, it may not produce much distortion per se.

Although the basic dynamic loudspeaker has now been in use for over 70 years, and has been greatly refined in that time, it is still the subject of active research, in both design and evaluation. One of the holy grails yet to be achieved is, like the diaphragm-free microphone, the cone-less loudspeaker that more directly converts electrical energy to acoustical energy. Aside from eliminating some troubling mechanical elements and their associated resonances, this might improve the efficiency, which is currently typically around 1% for consumer loudspeakers.

Another long-sought goal is the projection loudspeaker, which can make a sound appear to emanate from a specified remote location. The have been some encouraging results in the use of ultrasonics [18.47] and large-scale speaker arrays [18.48] in this regard.

18.4.4 Amplifiers

Of all the common audio analog devices, electronic amplifiers of all types probably have the easiest time meeting the preferred specifications of a good-quality audio system. This in no small part derives from the fact that they generally contain no mechanical processing stages, and simply have to push a bunch of very lightweight electrons around. Properly designed, an amplifier should have little difficulty achieving a dynamic range approaching 120 dB, nor is it likely to deviate significantly from the preferred specifications for bandwidth, response deviation, phase/timing response, or distortion.

This is despite the fact that most amplification devices, mainly vacuum tubes, transistors, and field-effect transistors (FETs), are not themselves inherently very linear. In the years following de Forest's invention of the triode, considerable and rapid strides were made in not only the refinement of the devices themselves, but in circuit designs which optimized the linearity and response of the complete amplifiers. A major milestone was the invention in 1928 of the negative-feedback amplifier by *Black* of Bell Laboratories [18.9]. This arrangement compares the output signal with the input signal, and to the extent that they may tend to differ, generates an instantaneous correction signal. Successful application of negative feedback carries with it specific requirements on the performance of the raw amplifier, such as maximum phase shift, and some of these requirements were

still being uncovered years after the initial development of negative feedback.

Several standard types of amplifiers are commonly found in audio use, each with specific requirements and design challenges, including preamplifiers, line amplifiers, power amplifiers, and radio frequency (RF) and intermediate frequency (IF) amplifiers for use in radio. Preamplifiers, for example, are required to handle the generally very small signal from transducers such as microphones, phonograph cartridges, tape heads, and optical photocells. Linearity is usually not a major problem, because of the small signals involved, but low noise and impedance matching to the transducer are often significant design considerations. At the other end of the chain, power amplifiers usually have a fairly easy time with dynamic range, but high required power-handling capability and the need to drive sometimes ill-behaved loudspeaker loads make power amplifier design an art unto itself, with the 1948 Williamson amplifier being just one early example of a notable design [18.49].

The advent of the transistor, by Brattain, Bardeen, and Shockley of Bell Laboratories in 1947, sparked a revolution in active devices, and stands as one of the foremost inventions of the 20th century [18.50, 51]. Operational differences between tubes and transistors were sufficiently great that, to an extent, the discipline of amplifier design had to be reinvented from the ground up, and it was some time before solid-state amplifiers were accepted in some high-end audio systems.

In time, the development of analog integrated circuits gave rise to the multi-transistor operational amplifier, an amazingly versatile device that facilitated cost-effective analog processors of great sophistication and complexity. These days, entire analog audio subsystems can be implemented on monolithic chips with many transistors and associated components.

Special mention should be made of one particularly challenging amplifier variant, the voltage-controlled variable-gain amplifier (VCA). Such a device, basically an analog multiplier, is essential for exercising automatic control of signal level, a common building block in many audio signal processors. Where fixed-gain amplifiers depend on fixed, highly linear passive components such as resistors to maintain operating point and linearity, VCAs require linear active elements, like FETs. In the late 1960s, Barry Blesser designed a novel variable pulse width multiplier, and a few years later, David Blackmer of dbx, Inc. designed a wide-range variable-transconductance VCA, elements of which are still used in commercial VCAs [18.52]. The complexity and cost of VCAs limited their use somewhat, which is perhaps ironic in these days of digital audio, where DSP chips typically perform millions of multiplications per second.

18.4.5 Magnetic and Optical Media

Part of the motivation for the use of magnetic and optical recording on linear media (tape, film) undoubtedly came from the desire to avoid the wear inherent in the playback grooved records. Both media involve the use of narrow apertures to record and play audio striations perpendicular to the motion of a linear medium.

Magnetic recording got its start in 1898, with Valdemar Poulsen recording on steel wire, an especially notable accomplishment considering that the invention of the triode amplifier tube was still several years away. The use of magnetic tape originated with O'Neill's patent of paper tape coated with iron oxide, in 1926, followed by the introduction of plastic tape by BASF in 1935. A serious nonlinearity problem with magnetic tape was largely resolved in 1939 with the development of alternating-current (AC) recording bias. Considerable refinement was achieved during and following World War II, and consumer reel-to-reel tape recording became a reality in the 1950s. There followed a series of formats which expanded the performance envelope and consumer friendliness, most notably the compact cassette and the venerable eight-track cartridge.

Optical recording on film was first investigated around 1901 [18.9], five years before the vacuum tube, and started to receive significant research and development attention starting around 1915, with the work of Arnold and others at Bell Laboratories, followed by a number of efforts by RCA and other groups. Lee De Forest may have come up with the first viable optical sound system, *Phonofilm*, in 1922 [18.53]. By 1928, synchronized optical sound on film was used commercially on Disney's *Steamboat Willie* cartoon.

Both of these formats rely on some sort of device with a narrow aperture to record and playback, and therefore both face a tradeoff between high-frequency response, corresponding to the smallest resolvable feature, and media speed/playback time.

Although there may be no vibrating mechanical elements in either the magnetic system or optical playback, both media exhibit difficulty reaching the full audible bandwidth, or in maintaining ruler-flat response, although, properly designed and adjusted, they can come fairly close. Beyond that, both media bear some similarities to modern record-based reproduction, including the use of fixed equalization, modest, gentle distortion

at typical operating levels, a typical dynamic range on the order of 50–70 dB, and both absolute and dynamic speed error sensitivity.

The viability of these formats was significantly enhanced by the invention in 1965 of analog noise reduction by Ray Dolby. Noise-reduction (NR) systems usually consist of a compressor/encoder and an expander/decoder. The compressor boosts low-level signals to keep them above the noise floor of the channel, while the expander restores the signals to their proper level, reducing the noise in the process. The Dolby A-type noise-reduction system and follow-on systems exploited a range of solid-state circuit tools, including active filters, precision rectifiers, and linear FET-based VCAs, to implement a comprehensive solution to the problems faced by noise-reduction systems. The frequency-selective nature of masking by the human ear was addressed by splitting the signal processing into multiple bands, and the problem of potential overload associated with the sudden onset of loud signals was resolved by the use of a novel dual-path limiter. Other well-known NR systems used wide-range bandpass compressors (Telcom C-4), wideband compressors with preemphasis (dbx I and II), sliding shelf filters (Dolby B), cascaded sliding shelf filters (Dolby C), cascaded wideband and variable slope compressors (dbx/MTS TV compressor), and cascaded combined sliding shelf and bandpass compressors (Dolby SR and S). Similar principles would subsequently be adapted for use in digital low-bitrate coders.

18.4.6 Radio

While the medium of analog radio has its own share of unique attributes, it shares with other analog media many of the same sorts of characteristics and limitations, including somewhat limited frequency response and dynamic range, which is partly associated with bandwidth conservation.

Commercial amplitude modulated (AM) radio broadcast kicked off in 1921 when KDKA went on air in Pittsburgh [18.9]. The use of dual-sideband modulation made for simpler receivers at the cost of channel spacing being twice the highest transmitted audio frequency. Although in theory AM radio was capable of supporting wide audio bandwidth, a channel spacing of just 10 kHz was chosen to conserve spectrum space, limiting audio bandwidth to something less than 5 kHz in practice.

Wide-band frequency modulated (FM) radio was developed by Edwin Armstrong in 1933, motivated in part by a desire to reduce the static that was common to AM radio, with commercial broadcast originating in 1941 [18.9, 54]. The dual sidebands of standard FM extend quite a bit farther than the maximum audio frequency supported, with channel spacing of 200 kHz for a typical audio bandwidth of 15 kHz. Dynamic range in excess of 60 dB is possible with mono FM, although this was compromised somewhat by the choice (in the US at least) made by the Federal Communications Commission (FCC) of the stereo multiplex system in 1961 [18.9].

18.5 Digital Audio

The advent of digital audio, perhaps best signified by the introduction of the audio compact disc in 1982 by Sony and Philips, completely revolutionized the world of audio engineering, in effect completely rewriting the rule book on what was readily achievable in mainstream audio systems, not to mention how signals were processed.

The basic notion of digital audio is discreteness. Instead of specifying a signal as a continuous function of time and amplitude, it is expressed as a rapid series of sample values at discrete time intervals, often with integer or finite-precision values. The signal becomes, in effect, a completely specified list of numbers, and as long as no explicit errors are made, can be copied an arbitrary number of generations without any loss or alteration whatsoever. (Error-correction schemes com-

monly help guard against the occasional error slipping through.)

The mathematical foundations of discrete sampling of continuous functions go back surprisingly far, with at least one claim on behalf of Archimedes, around 250 BC [18.55, 56]. Additional support for sampling theory was provided by *Fourier* in 1822 [18.57, 58] and *Cauchy* in 1841 [18.59, 60]. Modern sampling theory is usually credited to the combined work of *Whittaker* (1915) [18.61], *Nyquist* (1928), *Kotelnikov* (1933), and *Shannon* (1949) [18.62, 63], who provided a rigorous proof [18.64].

The key point of the sampling theorem is that a continuous band-limited signal can be discretely sampled without loss of information, and the original continuous signal subsequently recovered from the sampled ver-

sion, as long as the sampling frequency is higher than twice the signal bandwidth.

In order to exploit the sampling theorem and digital audio practically, quite a few other pieces of the puzzle had to be supplied. George Boole contributed the binary number system in 1854, which would provide the numerical and logical basis of modern digital processors. Alec Reeves used Boole's binary numbers to represent audio samples, creating the pulse code modulation (PCM) format, in 1937. By the late 1960s, prototype digital audio recorders were operating at companies like Sony, NHK, and Philips [18.59, 60], leading to the 1982 debut of the audio CD.

Some appreciation of the performance of digital audio can be had by considering the traditional audio specifications that analog systems have for so long tried to fully embody.

18.5.1 Digital Audio Specifications

Bandwidth
Traditionally an uphill battle fighting mechanical resonances and slit-loss effects, successfully meeting a bandwidth specification in the digital domain is simply a question of selecting a high enough sampling rate. Similar principles apply to maintaining the precision of a frequency response specification, usually a flat response: without parasitic or extraneous influences, the response will be ruler practically-flat by default, although it can otherwise be explicitly and predictably altered by application of appropriately designed DSP filters and equalizers.

Distortion
With signal processing implemented as a series of digital additions and multiplications, which are presumably accurate to the least significant bit, nonlinearity and distortion in the digital domain is absent unless, like deviation from flat response, it is explicitly introduced into the processing, to which end it can usually be precisely applied and controlled.

Dynamic Range and Signal–to–Noise Ratio
The dynamic range is usually expressed as the logarithmic difference between the maximal signal level and the noise level. By default, the maximal signal capacity of a PCM DSP system as a function of frequency is flat. The noise level is once again a design choice, ergo so is the net dynamic range. In somewhat simplified terms, the noise level of a digital signal process drops by a factor of two (6 dB) for each additional digital bit of precision employed in the representation of the sample values. So, maintaining a desired dynamic range is fundamentally a design choice to employ a sufficient number of bits of precision.

Speed
Once a signal is in the digital domain, there is of course no error or variation in speed unless it is explicitly imposed with appropriate processing.

In short, the attainment of performance that in the analog domain might require considerable design skill, and even then might simply be impractical or impossible, becomes in the digital domain a matter of design choices.

Of course, since most audio signals begin and end as analog vibrations in air (and, so far, correspondingly analog electrical signals associated with input and output transducers), there must be means to convert between analog and digital domains. This is the province of analog-to-digital converters (ADCs) and digital-to-analog converters (DACs). With so much of the overall performance of a digital audio system riding on the performance of these devices, their design has been the subject of intense activity since early experimental digital audio systems. Those early systems were fortunate to muster a precision of just 10-bits per sample, but that has slowly evolved over time to the point that current converters can operate at 24-bits per sample or better in a practical, cost-effective manner. Similarly, the various sources of subtle distortions that might otherwise limit ultimate converter performance have progressively been identified and, on the whole, reduced to the point of insignificance. And, where once speed accuracy of an audio system depended on the skill with which one turned a crank, or perhaps the vagaries of a wind-up clock motor and mechanical speed regulator, the sampling rate of a digital/audio converter is usually controlled by a high-precision electronic timing circuit, such as a quartz oscillator, reducing speed anomalies of all sorts to a level far below that of human perception.

Lest the case for digital audio appear at this point a bit overly rosy, it must be allowed that there are limitations, restrictions and pitfalls; and that it is perfectly possible to produce miserable sound via digital means.

For one thing, there is the matter of the Nyquist frequency, defined as half the sampling frequency and otherwise the highest frequency that can be represented at a particular sampling frequency. In some respects, the Nyquist frequency of a digital audio system corresponds to infinite frequency of an analog system. This intro-

duces certain response-warping effects, such that it may be difficult or impossible to replicate a given analog system response in the digital domain. (Example: the phase shift at the Nyquist frequency can only be 0° or 180°.)

An attempt to represent a frequency greater than the Nyquist frequency in the digital domain will result in a different frequency being generated within the band, usually by reflecting the original frequency value back through the Nyquist frequency, a form of intermodulation distortion. Unless the goal is to produce weird spacey effects, this process is usually not highly desirable, and a low-pass filter is commonly placed ahead of an ADC to prevent that occurrence.

Then there is the issue of performance levels being matters of system architectural choices, rather than the result of possibly elaborate or laborious designs. Such design choices are not always free, in that they may be tradeoffs with either other system resources, or simply cost more monetarily, which may therefore still have the result of limiting overall performance to something less than idyllic near-perfection.

For example, the dynamic range of the human ear was cited earlier to be on the order of 120 dB or more. If the digital representation of an audio signal yields an approximate dynamic range of 6 dB for each bit used, it would follow that the logical word size to use for digital audio samples would be at least 120 dB/6 dB per bit = 20 bits. Yet the standard chosen for compact discs, as well as many other current generation digital devices, is just 16-bits per sample, corresponding to a best-case dynamic range of only 96 dB. This decision was predicated in part on the performance limitations of analog/digital converters at the time the CD specification was cast, and further from a desire to provide a playing time of 74 min on a 12.7 cm disc. Had a larger word size been chosen, either the disc would have had to be larger, or the playing time reduced.

Does this result in audible impairment of the sound? It can, but it will not necessarily be the case, so it will be evident some hopefully small percentage of the time. For example, there should be no audible alteration if the maximum playback level does not exceed 96 dB SPL. Nor should there be a problem if the playback level is higher, but the room noise is high enough to mask the digital noise. Since the ear is only maximally sensitive in the upper-middle part of the audio band, the elevated thresholds towards the band edges provide additional noise margin. And the presence of signal components will tend to mask digital noise that might otherwise have been heard. So, consistent with practical experience, 16 bit PCM digital audio is free of serious imperfections for most listeners and most source material, most of the time.

18.5.2 Digital Signal Processing

With the practice of representing audio signals in the digital domain as PCM samples comes the need to perform signal processing in the digital domain. To some extent, this required a reinvention of signal processing in terms of discrete numerical sample values, but since the foundations of signal processing were mathematical to begin with, in some respects there was a more direct connection between theory and practice.

The most common signal processing operations – amplification, filtering, and equalization – are mostly implemented with the basic four mathematical functions: addition, subtraction, multiplication, and, perhaps to a lesser extent, division.

More elaborate signal processing functions, such as rectification or level derivation, may involve geometric or transcendental functions such as square roots, cosine, or logarithms, virtually all of which are easier to implement, more direct, more wide-range, and more stable as digital entities than analog alternatives. Even some seemingly simple functions, such as a pure delay, can be challenging to implement well as analog devices, but become more-or-less trivial with DSP.

Clearly, the requirement of audio DSP to perform large numbers of numerical calculations and the ability to perform such calculations with modern digital hardware, including personal computers and specialized DSP chips, whether by accident or design, has been auspiciously symbiotic. Large, elaborate analog breadboards of spaghetti wiring have been replaced with even more elaborate programs of (sometimes) spaghetti C code.

The ability to create and combine a virtually limitless number of new processing functions by simply typing in the code for them, using a computer language with full mathematical support, is an understandably powerful tool to extend signal processing, a little like a bottomless Tinker Toy. The effect is amplified by the ability to nest functions to an almost arbitrary extent, allowing the creation of labyrinthine tree-structured processes. And whereas every block of an analog circuit must be physically implemented, DSP programs usually get by with just one physical copy of each routine, regardless of how many times the function may appear in the block diagram.

With all this processing power available, one may inquire as to what has been applied. Certainly, one func-

tion category that has *not* been strongly needed has been aids to correct deficiencies inherent in the recording system. If a clean recording is obtained to begin with, there is often little need to clean it up further. Digital signal processors have, however, been very effective in cleaning up and correcting the imperfections of older, analog recordings, and have been used for noise suppression, speed correction, and even distortion reduction.

The additional processing power afforded by DSP processors has enabled re-engineering of most traditional audio processors, such as equalizers, with greater complexity and precision. The availability of a simple, cheap delay mechanism with equalization has allowed extremely elaborate and faithful reverberators to be employed in both professional and consumer applications. This is one area for which there was arguably never a truly effective analog electronic solution. The best pre-digital reverberators were electromechanical, using transducers attached to a metal reverberation plate.

In general, the availability of a cheap, low-noise, high-precision multiplication operation has, along with other DSP elements, made it much easier to implement elaborate dynamic systems, once limited by the relative scarcity and high cost of analog VCAs. This has also made it much easier to include specific nonlinearities, where appropriate, usually in the signal analysis of a processor. And the ability to combine multiple processing algorithms into a single DSP program has facilitated multifunctional systems implemented on a single DSP chip.

One of the key building blocks to be brought to bear in a variety of digital signal processors has been a digital model of some or all of the human auditory system. If a processor can be made to hear the same way as humans do, it can make processing decisions that reflect the truly audible elements of a signal, resulting in far more effective processing. A key component of such an approach has been the digital filter bank, essentially a bank of bandpass filters that, in most cases, cover the entire audio band. This component provides a cost-effective analog of the filter-bank-like processing performed by the basilar membrane of the inner ear. A major element of such processing has been the so-called fast Fourier transform (FFT), first devised in 1805 by *Gauss* [18.65–67], then rediscovered in 1965 by *Cooley* and *Tukey* [18.68, 69]. This one algorithm allows full-range filter banks of great complexity, typically implementing hundreds or thousands of bandpass filters, with dramatically less processing power than would otherwise be needed by direct implementation of such filters. The use of this technique does, how-

ever, carry with it some compromise, as the bandpass filters of an FFT filter bank all have the same bandwidth, measured in hertz, and are linearly spaced in center frequency, whereas the filters of the basilar membrane are logarithmically arranged in both bandwidth and center frequency. This discrepancy is sometimes compensated by processing the FFT outputs in groups, or bands, whose width and center frequency are arranged in an approximately logarithmic manner.

The transform-based filter bank is used both as an analysis tool, to present signals in a perceptually relevant domain for subsequent processing, and as a component of the actual signal path. In the latter instance, signals are processed in the transform domain, usually in overlapping blocks of samples, and ultimately restored to time-domain PCM values by performing running inverse transforms. This has elevated transform-based processing to the level of a new category of digital signal processing. In some situations, a variant transform of some sort may be used to provide, for example, logarithmic frequency selectivity, but in many cases such transforms are still based on a core FFT.

A final note on numerical precision: virtually any digital processor will employ finite-word-length symbols for numerical values, be they integers or floating-point numbers. This gives rise to the generation of digital noise, resulting from the round-off error of each arithmetic operation. Since there may be many thousands of such performed in the course of a DSP algorithm, the numerical precision of the processor must be great enough that the accumulated noise remains insignificant. For a 120 dB dynamic range, corresponding to 20 bits of precision, one might prefer at least 24 bit processing (that is, either 24 bit integers or 24 bit mantissas of float values). The actual precision required will depend some on the actual operations performed, with subtraction (or addition of opposite-signed values) especially troublesome, since it can leave a very small residual, potentially exposing the digital noise. As it happens, this is an issue in performing the FFT. As an additional hedge against the buildup of digital noise, many DSP processors employ double-length registers, so accumulated quantities are only rounded back to standard precision when stored back to memory, usually after multiple multiply–accumulate operations.

18.5.3 Audio Coding

The commercial introduction of digital audio in the form of the compact disc brought with it the reincarnation of a tradeoff that had long been a source

of compromise in analog audio, namely that between quality and capacity, or equivalently playing time, or bandwidth. Mechanical audio recordings (i. e. records) had started with cylinders that played for a minute or two, and had progressed to long-play records with about 20 minutes per side. Magnetic tape had used media running at speeds like 76 cm per second, and had progressed to cassette tapes with typical playback times of 45 minutes per side, usually aided with noise reduction. Broadcast channels were less flexible, but techniques had at least progressed to the practice of piggy-backing low-energy subcarriers onto to the main signal, e.g. to advance to stereo operation, sometimes accompanied by noise reduction, at least in the case of US multichannel television sound (MTS) audio. If the use of digital audio for recording and broadcast was to be adopted for media beyond the CD, the need to reduce the number of bits required was apparent. This has given rise to one of the premier pursuits of digital development since that time: the use of audio coding to convey a signal faithfully using the smallest possible number of bits.

The data rate of an audio CD derives from the use of two channels, a sampling rate of 44 100 Hz, and 16 bit PCM samples, a total of 1.4 megabits per second. This is greater than can be accommodated on a standard 35 mm movie print, or a standard cassette tape, or an FM radio channel. (It is also more than will fit on a standard long-play record, but since that medium is not especially compatible with digital storage in the first place, it is a moot point.) Even the CD can only accommodate the two channels; a 5.1-channel PCM format would reduce the playing time to something under 25 min.

So the need to reduce the data rate without sacrificing quality was readily apparent, which motivated interest and activity in the development of low-bitrate audio coders, and made practical such applications as digital cinema soundtracks, portable music players, and satellite radio. It is perhaps not self-evident that the data rate can be reduced in the first place, but for starters, one could simply use smaller PCM words. This would, of course, raise the effective noise floor, which in turn could be addressed by adapting an analog noise-reduction system as an associated DSP algorithm. However, the resulting reduction in data rate would still be relatively modest, as the compression ratios of noise-reduction systems never exceeded a range of about 2–3 : 1, to avoid mistracking problems, and this is less data compression than is required by many coding applications.

Overall, two general classes of techniques have been exploited in digital audio coders, lossless and lossy, or perceptual, coding. They share in common the arrangement of an encoder and a decoder which, instead of just conveying PCM samples, employ a common vocabulary or protocol for describing and conveying the audio at an elevated level of abstraction. This protocol is sometimes referred to as a bit-stream syntax. Although the signal connecting encoder and decoder is indeed usually just a stream of bits, the meaning and significance of a given bit will depend on the context in which it appears. This represents an additional advantage of digital audio systems over analog systems: a bit stream can consist of interleaved sequences of diverse information packets. Some of these will generally be representations of some derived form of the audio, and the rest will be descriptive information about the signal, referred to as side-chain information.

Lossless Audio Coding

The goal of lossless coding is to convey digital information in a more compact form while reliably recovering the original data in the decoder with bit-for-bit accuracy. Obviously, no psychoacoustic or perceptual considerations need enter into the picture.

The key to the ability to losslessly compress digital data is redundancy. Any time there is a pattern or common element to a block of data, it may be possible to express it in a more compact form by conveying the essence of the pattern along with the deviations from the pattern, such that the original data may be reconstructed. Of course, in order for this to happen, the bit-stream syntax must support a compact means of specifying the necessary range of patterns to the decoder.

The number of potentially useful patterns is actually fairly large, and considerable ingenuity has gone into the development of lossless coding algorithms which can recognize and concisely encapsulate the details of redundant information patterns. Some of the more common data structures that can be losslessly compressed are listed below.

1. A repeating sample value: rather than send the same value multiple times, the sample can be sent just once, along with a replication factor. This technique is sometimes referred to as *run-length coding*.
2. Similar values: a variant of run-length coding, this type of pattern can be compressed by sending the average value, followed by concise representations of the difference between each sample value and the average. Alternatively, differential coding may be used, in which the difference between successive samples is coded.

3. Repeating sinusoids: for an ongoing sinusoidal signal, the PCM samples can be replaced with parameters indicating the amplitude, frequency, phase, and length of the sample sequence. In general form, this is sometimes referred to as *linear prediction*. If there are small deviations, they may be sent as concise difference values.

4. Small values: a sequence of samples, each with one or more leading zeros, may be sent with the zeros omitted, along with a factor indicating how many leading zeros were suppressed. (Note: negative values expressed in two's-complement form will have leading ones, but the same factor should otherwise apply.) This is known as *block floating point* representation.

5. Commonly used values: sample values which appear more often than the average – like the letters 'e' and 's' in English text – may be assigned special, short transmission symbols to reduce the average data rate. Representative techniques which employ this include arithmetic coding and Huffman coding.

6. Interchannel difference coding: if two or more channels are used and are sufficiently similar, data-rate savings may be attained by sending sum and difference information, or a variant thereof. The expectation is that the difference values will be small, and can be coded in fewer bits using technique (4), above. In the case of stereo content, this approach is sometimes referred to as mid/side (M/S) coding.

In addition to the techniques described above (and others), a lossless coder may either directly code time-domain PCM samples, or may instead use running transforms and operate in the frequency domain. In the latter case, a specialized bit-exact transform may be used to guarantee that the final output is an exact clone of the input.

A fully realized lossless coder is likely to use a combination of techniques like those described above, requiring a flexible and perhaps elaborate bit stream syntax. The process of selecting which coding options will be brought to bear on a given block of samples is often not readily apparent from inspection or simple calculation, so the encoder may be required to try an exhaustive search of all possibilities for each block in order to select the best option. Needless to say, this can make for a rather slow-running encoder, but usually does not affect the speed of the decoder.

As may be evident, the effectiveness of a lossless coder is very much signal dependent: some signals can be compressed considerably more than others, and some, such as full-level white noise, basically cannot be losslessly compressed at all. Typical compression ratios run in the range of 2 : 1 to 3 : 1. Because lossless compression is inherently a variable bitrate (VBR) coding technology, it is not well suited to real-time streaming applications, such as broadcast or fixed-speed digital tape.

One weakness of lossless coding, and indeed of lossy coding as well, is that an error of even a single bit (in, say, one of the control codes specifying which method to use to unpack a block of data) can cause the loss of significant audio data. Some care must be used in the design of the bitstream to ensure that re-synchronization of the decoder in the face of data errors is reliably possible within an acceptably short period. More generally, the complexity and low error tolerance of almost any data-reduction algorithm raises the regrettable possibility that digital records, audio and otherwise, may be lost to future generations unless care is taken to avoid data errors, and to ensure that decoding algorithms are carefully documented and preserved in full detail. This is especially critical in the case of proprietary algorithms owned and maintained by commercial entities, whose long-term future operation may not be assured.

Perceptual/Lossy Audio Coding

While one might wish that lossless coding be used exclusively for digital audio compression, its limited performance and variable bitrate render it inappropriate for a large number of coding applications. For more-aggressive compression and acceptable performance within the constraint of constant bit rate, one must resort to the use of perceptual audio coding.

The goal of perceptual audio coding is to preserve and convey all of the perceptual aspects of audio content, without regard to preserving the signal literally, usually employing the fewest bits possible. Recall that the data rate for a standard audio CD was about 1.4 Mbit/s. As this is written, the lowest data rate in commercial use for conveying high-quality stereo audio is no higher than 48 Kbits/s, used by satellite radio and for Internet streaming, a data-compression ratio on the order of 30 : 1 or better.

How is this accomplished? For starters, the use of lossless coding is not retained and incorporated in overall lossy algorithms. Every packet of information generated and reduced to its ultimate compactness by any part of a perceptual coder is a candidate for further reduction in size if one or more lossless techniques can be brought to bear effectively.

Beyond that, the keys to high-efficiency perceptual coding are to:

1. Suppress any audio components not contributing to the ultimate perception.
2. Ensure that all the audible components are conveyed with no alteration in perceived quality, while using the minimum possible number of bits.
3. Employ, as much as possible, high-level abstractions to describe audio signals in purely perceptual terms, while retaining enough precision and detail to allow the decoder to accurately reconstitute a signal indistinguishable from the original encoder input signal.

One fundamental building block that has almost always been part of the foundation of perceptual coders is a digital filter bank. This, of course, mirrors the functionality of the basilar membrane; and the frequency-domain output signals are most commonly used for both the analysis sections of the coder and the signal path. Indeed, the fundamental data conveyed by most perceptual coders is not PCM time-domain data, but quantized frequency-domain information from which the decoder eventually produces PCM output by way of a synthesis filter bank. The most commonly used digital filter bank is a variant of the FFT called the time-domain alias cancellation (TDAC) transform, developed by Princen and Bradley in 1986 [18.70, 71]. This transform has the highly desirable property of being critically sampled, meaning that it produces exactly the same number of output frequency-domain samples as there are input PCM samples. There is also a companion inverse TDAC transform for producing output PCM from a set of decoded frequency-domain input samples.

In operation, PCM samples input to the encoder are divided into regular blocks of some predetermined length, and each block is transformed to the frequency domain, conveyed to the decoder, reconstituted as a block of PCM samples, and the successive blocks strung together, often in an overlapping manner, to recover the final outputs. This process is sometimes described as block-oriented processing using running transforms. The practice of coding an entire block of samples as a single entity facilitates data rates of less than one bit per original audio sample. One downside of block processing is that events which occupy a small fraction of a block, like a sharp transient, may become smeared across a range of frequencies, consuming a large number of bits. A number of techniques have evolved to deal with this situation, most commonly the

use of block switching, wherein such short events are detected (by, for example, a transient detector routine), and the block size is temporarily shortened to more closely isolate the transient within the shortened block.

The filter-bank output is of direct use in pursuit of the first two perceptual coding techniques listed above, principally by deriving the magnitude of the frequency-domain signals as a function of frequency to obtain a discrete approximation to the power spectral density (PSD) of the signal block. This in turn is processed by a routine implementing a perceptual model of human hearing to derive a masking curve, which specifies the threshold of hearing as a function of frequency for that signal block. Any spectral component falling below the masking curve will be inaudible, so need not be coded, as per the first listed coding technique. The remaining spectral components must be preserved if audible alteration is to be avoided, but the quantization precision is only that which is required to render the level of the quantization noise below the masking curve. Instead of the 120 dB/20 bit range one might require for PCM audio, the instantaneous masking range is more often on the order of 20–30 dB, about 4–5 bits per sample, assuming 6 dB per bit SNR. Thus, between suppression of inaudible components and dynamic quantization of audible components, the data rate can be expected to be reduced to something less than 4 bits per sample. Of course, an effective bit-stream syntax protocol must be devised to signal these conditions efficiently to the decoder, and considerable ingenuity has been brought to bear on that issue to ensure the requirement is met.

Notable lossy audio coders based on these principles include AC-3, MP3, DTS, WMA, Ogg, and AAC. These have been instrumental enablers of such technologies as portable music players, DVD's, digital soundtracks on 35 mm film, and satellite radio.

It should be noted that perceptual coding is much more compatible with constant-bit-rate operation than is lossless coding, for as the complexity of a signal increases, which might otherwise increase the required data rate, the masking afforded by that signal also increases, reducing the average quantization accuracy required, thereby holding the required data rate to a more nearly constant rate. In effect, the human auditory system can only absorb so much information per unit time, so as long as the coder accurately models that behavior, the required data rate should be largely constant. Of course, very simple signals, like silence, are not likely to require the same data rate as more complex signals, in which case a constant-bitrate coder may simply use far more than the minimum required data

rate in order to maintain a constant transmission rate. Some coders can defer use of bits in the presence of simple signals, saving them in a *bit bucket* until needed by a more complex signal.

The third listed technique used in perceptual coding, the application of higher-level abstractions to describe the signal, is much more general and open-ended; and is still an area of active investigation. It can be something as simple as using a single PSD curve to approximate the actual PSD curves of several successive transform blocks, or using decoder-generated noise in place of actually transmitting noise-like signals. More abstract approaches may fall under the heading of *parametric coding*.

One notable example of parametric coding is *bandwidth extension*, in which the entire high-frequency end of the spectrum is suppressed by the encoder, and is reconstituted by the decoder from analysis of the harmonic content of rest of the signal spectrum. This technique alone can reduce the data rate by 30% or more.

Another widely pursued approach to parametric coding is to segregate signal components into categories, such as sinusoidal, noise-like, or transient, then convey numerical descriptions of each to a synthesizing decoder. Although this is arguably far closer to a true perceptually grounded coder than a simple transform-based coder, the complexity of the descriptors needed to accurately portray the full range of possible signals has so far made it difficult to reduce the data rate required by more conventional coders dramatically.

Spatial Audio Coding

Although strictly speaking it may be a subset of perceptual audio coding, spatial audio coding (SAC) is a sufficiently independent approach to justify separate examination. SAC can be used to improve the transmission efficiency of multichannel content, typically either stereo or 5.1-channel surround material.

The approach involves coding the ensemble of channels as a single entity to achieve data savings that would be unavailable if each channel were to be coded individually. An element common of many SAC algorithms is to combine the source channels additively to a smaller number of channels, perhaps as few as a single channel, from which the decoded output channels are eventually reconstructed. The data rate is thereby reduced by the ratio of the number of input channels to the number of down-mixed channels, minus any side-chain information needed by the decoder to reconstruct the output channels.

Probably the simplest approach to SAC is to down-mix the input channels to mono in the encoder and then simply distribute the common signal equally to the output channels. If this is done to the full-bandwidth signal, the result will simply be monaural sound reproduced from multiple speakers, which is not likely to be a very satisfactory multichannel experience, but if limited to a subset of the audio range, say just high frequencies, the ear will tend to associate the spread mono content of the reproduced channels with the direction of the lower frequency, discrete content, and the alteration will be less noticeable.

A slightly more elaborate approach is to send channel-by-channel scale factors, representing relative signal amplitude in each input channel, which are subsequently used by the decoder to distribute signal components to each output channel. Sometimes referred to as either intensity stereo or channel coupling, the technique can be surprisingly effective, especially at high frequencies when individual scale factors are sent on something like a critical band frequency basis.

More recent spatial coding systems have augmented the use of amplitude coupling with transient flags and information about interchannel phase and coherence, allowing extension to progressively lower frequencies, with commensurately greater amounts of data rate reduction.

Although in most cases the spatial information about individual channels is sent as side-chain information comprising part of the total transmitted bit stream, there has been some success in encoding the information in the signal characteristics of the actual transmitted audio, which can reduce the net data rate.

Spatial audio coding remains at this time an area of very active investigation.

18.6 Complete Audio Systems

So far, this discussion of audio and electroacoustics has focused on the task of capturing, transmitting, and reproducing one or more individual channels of audio as accurately as possible. However, the goal of sound reproduction is not strictly to convey some designated number of channels, but to faithfully reproduce a full

acoustic event, be it live, synthesized, or some combination thereof, to an audience that, at any given venue, may range in number from one to many hundreds or more.

The use of individual channels is mandated by the available technology. Microphones and loudspeakers are basically point-in-space devices, and most audio media and processors are designed to handle individual channels. But sound is, by nature, a three-dimensional entity, not counting time and frequency, and a few isolated channels can at best represent a sparse spatial sampling of a full acoustic sound field.

So the question is raised as to just how effective are complete audio systems, from recording to reproduction, at least in perceptual, psychoacoustic terms.

Any attempt to perform such an evaluation is immediately faced with the conundrum as to just what should be the ultimate goal of sound reproduction. Should we be trying to transport the listener to the performance site (*we are there*), or is the goal to transport the performers to the listener's living room (*they are here*). The answer perhaps depends on the nature of the source material, as well as listener preference. For situational acoustics, from walking down a busy street to riding in a submarine, it would seem logical to go with *we are there*. This is most commonly the case for, say, cinema soundtracks, making a good case for surround-sound systems in commercial and home theaters. A similar case can be made for symphonic music, since the concert hall is such an integral part of the experience. However, a small ensemble or a solo artist might be more compelling if holographically projected into the listening room. Given unlimited wishes, one might hope to have both, with the ability choose which option according to one's predilections. In actual practice, we might be well served if either one is possible. But in any case, it is perhaps worth keeping in mind in evaluating the effectiveness of complete audio systems.

18.6.1 Monaural

For the first half century of recorded sound, monaural was all there was. In that time, considerable expertise was developed in microphone techniques for capturing sound with a viable balance of direct and ambient content. In this era of multichannel audio, it is easy to dismiss mono for failing to support any formal spatial audio cues. Still, there are times when a single channel should, at least in theory, be adequate for the task, such as a solo performer or other single, localized source, in a dry (relatively echo-free) ambient environment,

or *here*. Even in that case, however, the reproducing loudspeaker is unlikely to have the same spatial radiation pattern as the original source, a problem common to many sound formats to one degree or another, so that even with good frequency response and low distortion, the sound may be recognizable as emanating from a loudspeaker, rather than being a clone of the original performance. To its credit, mono does not exhibit the double-arrival problem of phantom images common to stereo and other multichannel formats (below), arguably resulting in a purer, less time-smeared sound. It is also gratifyingly free of sweet-spot dependence: one can sit pretty much anywhere in a listening room without worrying about impairment of imaging. And historically at least, mono was a big improvement over nothing at all.

18.6.2 Stereo

Two-channel stereophonic sound has been a commercial reality for nearly half a century, and shows little sign of being rendered obsolete anytime soon. The intuitive attraction of stereo is self-evident: we have two ears, and stereo provides two channels. On the surface, this is an apparently compelling argument. The result should perfect sound reproduction, yes? Well, no, although stereo did pretty much render mono obsolete for most media within a few years of its commercial deployment.

Stereo provides the smallest possible increment in spatial fidelity over mono: a horizontal line spread before the listener. But this is likely the most important single improvement one could hope to make, as the human ear is most sensitive to front-center horizontal position. In addition, performing ensembles are most often arrayed in such a manner. The arrangement also allows rendering, where appropriate, of frontal ambiance in a manner more natural than can be achieved with a single audio channel.

An important element of stereo reproduction is the creation of virtual images. These are sonic images that appear suspended in space between the two speakers, and they undoubtedly add considerably to the viability of the format. Virtual images depend for their existence on the primary horizontal localization cues: interaural time differences and interaural amplitude differences. The former cue is especially critical to the creation of virtual images, as the total range of the cue is only about $\pm 700\,\mu s$, corresponding to a horizontal displacement of the listener of only about a foot. This rather undermines the viability of stereo virtual imaging somewhat, and renders the format decidedly sweet-spot dependent. The

situation is partially compensated by the flexibility of the human auditory system, and its apparent ability to use dynamically whatever cues appear to be providing reliable localization information. A listener a little off the center line may still experience some degree of virtual imaging by virtue of the interaural amplitude cue, which may not degrade as rapidly as the interaural time delay cue. Indeed, in the course of mixing a multichannel source to a stereo track, a recording engineer will typically position a virtual source between the speakers using simple amplitude panning, with zero interaural time delay, and yet the ear generally accepts this.

But sensitivity to listener position is not the only issue relating to virtual images. There is also that double-arrival problem. The direct sound from almost any real sound source will generally arrive at each ear once, and that is it. But a virtual image from a stereo speaker array will result in two direct arrivals at each ear, one from each speaker. Assuming a centered listener, the left ear will hear from the left speaker at about the same time that the right ear hears the first arrival from the right speaker. Then the sound from each speaker will cross the head, in opposite directions, and the left ear will hear the right speaker arrival, and vice versa, a process sometimes referred to as loudspeaker crosstalk. The time delay between arrivals is typically on the order of $250 \mu s$, resulting in a small, subtle, but audible notch in the resulting response around $2 kHz$. Some temporal smearing of sharp transients may also be evident.

A final difficulty with virtual imaging of stereo systems is the relative inability to position virtual images outside the range of the speakers. This is another consequence of loudspeaker crosstalk, limiting the maximum interaural time difference to that corresponding to the position of the speaker, which again is about $250 \mu s$, and similarly limiting the maximum interaural amplitude difference. One way around this would be to put the speakers in different rooms and sit between them, one ear in each room, with a custom-fitted baffle doorway to block any crosstalk, which is a little impractical. Another approach is to employ a crosstalk cancellation (virtual-speaker) system, to cancel the second arrival at each ear, but such systems are themselves very sweet-spot dependent, and even then usually limited to creating images on the horizontal plane. The most direct way to provide sound from additional directions is to position additional speakers around the listener, including above and possibly below, assuming additional source channels are available to feed them, but that is no longer a stereo sound system.

18.6.3 Binaural

Like stereophonic sound, binaural makes use of just two channels, but it uses headphones instead of loudspeakers to avoid the crosstalk problem. On paper, this system seems like it should be even more perfect than stereo. However, the effect is often to place the sound images within the head, with little or no front/back differentiation.

Part of the problem appears to be that the presentation does not get altered when the listener's head moves, so that the image follows the head movement, which is rather unnatural. There has been some work exploring the use of tracking headphones, which alter the signal in response to head motion, but these have not yet been completely successful, and require more than two channels to be available.

Another issue with binaural reproduction seems to be the lack of pinna cues, those alterations in timing and spectra that are imparted by the pinnae to an arriving sound as a function of direction. Efforts to impart pinna cues electronically have had some success, but they tend to be as individual as fingerprints, making it difficult to have a single binaural track which works for everyone. There has also been some success in producing a universal binaural track by imparting a direction-dependent room reverberation characteristic to the signals, although some purists object to the addition, and the effect is still somewhat listener dependent.

One experimental system that mitigates some of the shortcomings of two-channel binaural is four-channel binaural. This employs two dummy heads or equivalently arranged directional microphones, with one head/microphone-pair in front of the other, preferably with an isolating baffle separating them. The resulting four-channel recording is played over four speakers, preferably placed close to the listener in fixed positions around the listener's head, corresponding to the microphone positions, possibly with a left–right isolating panel or crosstalk-canceling circuits to minimize crosstalk. Because the front–back pair each preserve ITD and IAD, the left–right space is properly preserved, while front–back differentiation and externalization are provided by using separate front and back external drivers. Dynamic IAD and ITD cues with head motion are also at least crudely preserved by the use of front and back channels. The resulting presentation can exhibit good spatial fidelity.

Although it may never be suitable for general audience presentation, the binaural format has compelling

qualities for the single listener, and remains an area of active investigation.

18.6.4 Ambisonics

This system, devised by Michael Gerzon, approximates the sound field in the vicinity of a listener using an array of precisely positioned loudspeakers, It is sweet-spot dependent, so not amenable to audience presentation, but can provide compellingly good spatial reproduction.

18.6.5 5.1–Channel Surround

The 5.1-channel format is a well-thought-out response to the shortcomings of stereo. The format employs three front speakers, two surround speakers placed to the side and/or back of the listening room, and the 0.1 low-frequency channel that only occupies a small fraction of the total bandwidth.

The addition of the center-front speaker anchors the front left–right spread, significantly mitigating the problems stereo has with virtual images, even with audience presentation. The surround channels provide sound more to the side than can be achieved with the front speakers (or stereo), exercising the full range of the ITD/IAD sensitivity of the ear, and providing the option of a far more immersive experience than can be attained with stereo.

The 5.1 format with high-quality source material provides the most accurate overall audio reproduction of any widely used format to date, within either the *here* or *there* reproduction paradigms.

18.6.6 Beyond 5.1 Surround

In recent years, the channel count of commercial surround systems has slowly grown, leading to ongoing (as of 2014) efforts to develop configuration neutral systems that will support arbitrary numbers of channels.

18.7 Appraisal and Speculation

We have been witness, from the crude but noble origins of sound reproduction, to an astonishing march of progress that has, by degrees, rolled down the problems and imperfections of sound reproduction, reaching a notably high level of performance, when considered in basic perceptual terms.

A cynic might note that, over a half century ago, children played little yellow plastic 78 RPM 17.78 cm discs on phonographs that had 12.7 cm loudspeakers, and now, after decades of dramatic, hard-won progress, many people play little 12.7 cm plastic (compact) discs on boom boxes with 12.7 cm loudspeakers or tablets or even smaller speakers in smart phones. Yes, the fidelity is better, as is the playing time, but have we really come that far?

The apparent answer from all the above is that a high-quality system of modern vintage can now satisfy a major percentage of the electroacoustic and spatial requirements implied by the capabilities of the human auditory system.

This does not mean that audio engineers call all just pack up and go home just yet. Indeed, the quantities of audio research papers and patents published each year show no sign of abating, giving rise to the speculation that further meaningful improvements may yet be attained.

One can certainly wish for a few more channels, to fill in the remaining gaps and perhaps even provide explicit coverage above and below the listener. The issue in that regard at this point is more of practicality than of theory. There have been some experiments with the addition of height or ceiling (*voice of God*) channels, and the specifications for digital cinema systems allow for the use of over a dozen channels.

One can also hope for enhanced ability to project sound into a room, rather than having it just arrive from the walls. That is another area of active investigation. One approach, referred to as wave field synthesis [18.72] has been to approximate a complete sound field by reproducing the sound-pressure profile around a periphery, and relying on the Huygens principle [18.73] to recreate the complete interior sound field. This requires large number of loudspeakers (192 in one experimental setup) to avoid spatial aliasing effects.

The other well-known approach to generating interior sounds is to use an ultrasonic audio projector, which projects acoustic signals above the audio band which heterodyne to produce audible sound which appears to come from a remote location [18.74].

Another problem that has only partly been solved is that of sweet-spot sensitivity. This has long been an is-

sue with cinema surround-sound systems, but is no less challenging for automotive surround systems, where there are often no centrally located seats and speaker locations may be less than optimal. The issues go beyond balanced sound to trying to provide a coherent, immersive experience at all listening positions.

Indeed, each new venue for audio seems to come with its own idiosyncratic problems, leading to active investigation of how to make compelling presentations for portable music players, cell phones, and interactive media such as game consoles.

It is also expected that there will be continuing refinement of binaural techniques for personal listening.

Ultimately there may come a wholesale revolution in audio techniques, perhaps with laser transducers replacing loudspeakers and microphones, along with holographic recording of entire sound fields. For personal listening, your music player might interface directly to your brain, bypassing the ear altogether, allowing otherwise deaf people to hear, and getting rid of that troublesome 3 kHz peak in the ear canal once and for all.

It should make for some interesting vibes.

Part F

Biologica

Part F Biological and Medical Acoustics

19. Animal Bioacoustics

Neville H. Fletcher

Animals rely upon their acoustic and vibrational senses and abilities to detect the presence of both predators and prey and to communicate with members of the same species. This chapter surveys the physical bases of these abilities and their evolutionary optimization in insects, birds, and other land animals, and in a variety of aquatic animals other than cetaceans, which are treated in Chap. 20. While there are many individual variations, and some animals devote an immense fraction of their time and energy to acoustic communication, there are also many common features in their sound production and in the detection of sounds and vibrations. Excellent treatments of these matters from a biological viewpoint are given in several notable books [19.1, 2] and collections of papers [19.3–8], together with other more specialized books to be mentioned in the following sections, but treatments from an acoustical viewpoint [19.9] are rare. The main difference between these two approaches is that biological books tend to concentrate on anatomical and physiological

details and on behavioral outcomes, while acoustical books use simplified anatomical models and quantitative analysis to model whole–system behavior. This latter is the approach to be adopted here.

19.1 Optimized Communication

Since animals use their acoustic and vibrational senses both to monitor their environment and to communicate with other animals of the same species, we should expect that natural selection has optimized these sensing and sound production abilities. One particular obvious optimization is to maximize the range over which they can communicate with others of the same species. Simple observation shows that small animals generally use high frequencies for communication while large animals use low frequencies – what determines the best choice? The belief that there is likely to be some sort of universal scaling law involved goes back to the classic work of *D'Arcy Thompson* [19.10], while a modern overview of physical scaling laws (though not includ-

ing auditory communication) is given by *West* and *Brown* [19.11].

The simplest assumption is that the frequency is determined simply by the physical properties of the sound-producing mechanism. For a category of animals differing only in size, the vibration frequency of the sound-producing organ depends upon the linear dimensions of the vibrating structure, which are all proportional to the linear size L of the animal, and upon the density ρ and elastic modulus E of the material from which it is made. We can thus write that the song frequency $f = A\rho^x E^y L^z$, where A, x, y, and z are constants. Since the dimensions of each side of the equation must agree, we must have $x = -1$, $y = 1$
Fig. 19.1 The frequency ranges of the emphasized frequencies of vocalization in a large range of land-dwelling animals, plotted as a function of the mass of the animal. The *dashed line* shows the regression $f \propto M^{-0.33}$ while the *solid line* is the regression $f \propto M^{-0.4}$, as discussed in the text [19.12]

and $z = -1$, which leads to the conclusion that song frequency should be inversely proportional to the linear size of the animal or, equivalently, that $f \propto M^{-1/3}$, where M is the mass of the animal. This simple result agrees quite well with observation, as shown by the dashed line in Fig. 19.1, for a wide variety of animals, but a more detailed analysis is desirable.

Over reasonable distances in the air, sound spreads nearly hemispherically, so that its intensity decays like $1/R^2$, where R is the distance from the source. But sound is also attenuated by atmospheric absorption, with the attenuation coefficient varying as f^2. An optimally evolved animal should have maximized its communication distance under the influence of these two effects. An analysis [19.12] gives the result that $f \propto M^{-0.4}$ which, as shown in Fig. 19.1, fits the observations even better than the simpler result. There are, however, many outliers even among the animals considered, due to different anatomies and habitats. Insects, which must produce their sound in an entirely different way as is discussed later, are not shown on this graph, but there is a similar but not identical relative size relation for them too.

The total sound power produced by an animal is also a function of its size, typically scaling about as $M^{0.53}$ for air-breathing animals of a given category. When the variation of song frequency is included, this leads [19.12] to a conspecific communication distance

proportional about to $M^{0.6}$. Again, while this trend agrees with general observations, there are many very notable outliers and great differences between different types of animals. Thus, while mammals comparable in size with humans typically produce sound power in the range $0.1-10$ mW, and large birds may produce comparable power, some small insects such as cicadas of mass not much more than 1 g can also produce almost continuous calls with a power of 1 mW, as will be discussed in Sect. 19.4. At intermediate sizes, however, many animals, particularly reptiles, are almost mute.

Elephants represent an interesting extreme in the animal world because of their very large mass – as much as 10 t. Their calls, which have a fundamental in the range $14-35$ Hz, can have an acoustic power as large as 5 W, leading to a detection distance as large as 5 km, or even up to 10 km after sunset on a clear night [19.13] when very low frequency propagation is aided by atmospheric inversion layers (Chap. 4). Vegetation too, of course, can have a significant effect upon transmission distance. These elephant calls are often misleadingly referred to as *infrasonic* in the biological literature, despite the fact that only the fundamental and perhaps the second harmonic satisfy this criterion, and the calls have many harmonics well within the hearing range of humans. Indeed, even other elephants depend upon these upper harmonics to convey information, and usually cannot recognize the calls of members of the same family group above a distance of about 1.5 km because of the attenuation of harmonics above about 100 Hz through atmospheric absorption [19.14].

When it comes to sound detection, rather similar scaling principles operate. As will be discussed briefly in Sect. 19.2, the basic neuro-physiological mechanisms for the conversion of vibrations to neural impulses are remarkably similar in different animal classes, so that it is to be expected that auditory sensitivity should vary roughly as the area of the hearing receptor, and thus about as $M^{2/3}$, and this feature is built into the analysis referred to above. While a few animals have narrow-band hearing adapted to detecting particular predators – for example caterpillars detecting wing beats from wasps – or for conspecific communication, as in some insects, most higher animals require a wide frequency range so as to detect larger predators, which generally produce sounds of lower frequency, and smaller prey, which may produce higher frequencies. The auditory range for most higher animals therefore extends with reasonable sensitivity over a frequency range of about a factor 300, with the central frequency being higher for smaller animals. In the

case of mammals comparable in size to humans, the range for mature adults is typically about 50 Hz to 15 kHz. This wide range, however, means that irrelevant background noise can become a problem, so that conspecific call frequencies may be adapted, even over a short time, to optimize communication. Small echo-locating animals, such as bats, generally have a band of enhanced hearing sensitivity and resolution near their call frequency.

Aquatic animals, of course, operate in very different acoustic conditions to land animals, because the density of water nearly matches that of their body tissues. In addition, while the water medium may be considered to be essentially three-dimensional over small distances, it becomes effectively two-dimensional for the very long-distance communication of which some large aquatic animals are capable. Some of these matters will be discussed in Sect. 19.8.

19.2 Hearing and Sound Production

Despite the large differences in anatomy and the great separation in evolutionary time between different animals, there are many surprising similarities in their mechanisms of sound production and hearing. The basic mechanism by which sound or vibration is converted to neural sensation is usually one involving displacement of a set of tiny hairs (cilia) mounted on a cell in such a way that their displacement opens an ion channel and causes an electric potential change in the cell, ultimately leading to a nerve impulse. Such sensory hairs occur in the lateral line organs of some species of fish, supporting the otoliths in other aquatic species, and in the cochlea of land-dwelling mammals. Even the sensory cells of insects are only a little different. In the subsequent discussion there will not be space to consider these matters more fully, but they are treated in more detail in Chap. 12.

Somewhat surprisingly, the auditory sensitivities of animals differing widely in both size and anatomy vary less than one might expect. Human hearing, for example, has a threshold of about 20 μPa in its most sensitive frequency range between 500 Hz and 5 kHz, where most auditory information about conspecific communication and the cries of predators and prey is concentrated, and the sensitivity is within about 10 dB of this value over a frequency range from about 200 Hz to 7 kHz. Other mammals have very similar sensitivities with frequency ranges scaled to vary roughly as the inverse of their linear dimensions, as discussed in Sect. 19.1. Insects in general have narrower bandwidth hearing matched to song frequencies for conspecific communication. Of course, with all of these generalizations there are many outliers with very different hearing abilities.

Sound production mechanisms fall into two categories depending upon whether or not the animal is actively air-breathing. For air-breathing animals there is an internal air reservoir, the volume and pressure of which are under muscular control, so that air can be either inhaled or exhaled. When exhalation is done through some sort of valve with mechanically resonant flaps or membranes, it can set the valve into vibration, thus producing an oscillatory exhalation of air and so a sound source. In the case of aquatic mammals, which are also air-breathing, it would be wasteful to exhale the air, so that it is instead moved from one reservoir to another through the oscillating valve, the vibration of the thin walls of one of the reservoirs then radiating the sound, as is discussed in more detail in Chap. 20. Animals such as insects that do not breathe actively must generally make use of muscle-driven mechanical vibrations to produce their calls, though a few such as the cockroach *Blaberus* can actually make *hissing* noises through its respiratory system when alarmed.

The amount of muscular effort an animal is prepared to expend on vocalization varies very widely. Humans, apart from a few exceptions such as trained singers, can produce a maximum sound output of a few hundred milliwatts for a few seconds, and only about 10 mW for an extended time. In terms of body mass, this amounts to something around 0.1 mW kg^{-1}. At the other end of the scale, some species of cicada with body mass of about 1 g can produce about 1 mW of sound output at a frequency of about 3 kHz, or about 1000 mW kg^{-1} on a nearly continuous basis. An interesting comparative study of birdsongs by *Brackenbury* [19.15] showed sound powers ranging from 0.15 to 200 mW and relative powers ranging from 10 to 870 mW kg^{-1}. The clear winner on the relative power criterion was the small *Turdus philomelos* with a sound output of 60 mW and a body mass of only 69 g, equivalent to 870 mW kg^{-1}, while the loudest bird measured was the common rooster *Gallus domesticus* with a sound output during crowing of 200 mW. Its body mass of 3500 g meant, however, that its relative power was only 57 mW kg^{-1}.

Nearly all sound-production mechanisms, ranging from animals through musical instruments to electrically driven loudspeakers, are quite inefficient, with a ratio of radiated acoustic power to input power of not much more than 1%, and often a good deal less than this. In the case of air-breathing animals, the losses are largely due to viscosity-induced turbulence above the vocal valve, while in insects that rely upon vibrating body structures internal losses in body tissue are dominant. Wide-bandwidth systems such as the human vocal apparatus are generally much less efficient than narrow-band systems, the parameters of which can be optimized to give good results at a single song frequency. To all this must then be added the internal metabolic loss in muscles, which has not been considered in the 1% figure.

19.3 Vibrational Communication

Most animals are sensitive to vibrations in materials or structures with which they have physical contact. Even humans can sense vibrations over a reasonably large frequency range by simply pressing finger tips against the vibrating object, while vibrations of lower frequency can also be felt through the feet, without requiring any specialized vibration receptors. Many insects make use of this ability to track prey and also for conspecific communication, and some for which this mode of perception is very important have specialized receptors, called subgenual organs, just below a leg joint. A brief survey for the case of insects has been given by *Ewing* [19.16].

For water gliders and other insects that hunt insects that have become trapped by surface tension on the surface of relatively still ponds, the obvious vibratory signal is the surface waves spreading out circularly from the struggles of the trapped insect. The propagation of these surface waves on water that is deep compared with the wavelength has been the subject of analysis, and the calculated wave velocity c_s, which is influenced by both the surface tension T of water and the gravitational acceleration g, is found to depend upon the wavelength λ according to the relation

$$c_s = \left(\frac{2\pi T}{\rho_w \lambda} + \frac{g\lambda}{2\pi} \right)^{1/2}, \tag{19.1}$$

where ρ_w is the density of water. From the form of this relation it is clear that the wave speed has a minimum value when $\lambda = 2\pi(T/g\rho_w)^{1/2}$, and substituting numerical values then gives a wavelength of about 18 mm, a propagation speed of about 24 cm s^{-1}, and a frequency of about 1.3 Hz. Waves of about this wavelength will continue to move slowly across the surface after other waves have dissipated. The attenuation of all these surface waves is, however, very great.

From (19.1) it is clear that, at low frequencies and long wavelengths, the wave speed c_s is controlled by gravitational forces and $c_s \approx g/\omega$. These are called gravity waves. At high frequencies and short wavelengths, surface tension effects are dominant and $c_s \approx (T\omega/\rho_w)^{1/3}$. These are called capillary waves. The frequencies of biological interest are typically in the range 10 to 100 Hz, and so are in the in the lower part of the capillary-wave regime, a little above the crossover between these two influences, and the propagation speeds are typically in the range 30 to 50 cm s^{-1}.

For insects and other animals living aloft in trees and plants, the waves responsible for transmission of vibration are mostly bending waves in the leaves or branches. The wave speed is then proportional to the square root of the thickness of the structure and varies also as the square root of frequency. Transmission is very slow compared with the speed of sound in air, although generally much faster than the speed of surface waves on water. Once again, the attenuation with propagation distance is usually large.

Disturbances on heavy solid branches or on solid ground also generate surface waves that can be detected at a distance, but these waves propagate with nearly the speed of shear waves in the solid, and thus at speeds of order 2000 m s^{-1}. On the ground they are closely related to seismic waves, which generally have much larger amplitude, and animals can also detect these. Underground, of course, as when an animal is seeking prey in a shallow burrow, the vibration is propagated by bulk shear and compressional waves.

19.4 Insects

The variety of sound production and detection mechanisms across insect species is immense [19.3, 16–18], but their acoustic abilities and senses possess many features in common. Many, particularly immature forms

such as caterpillars but also many other insects, use external sensory hairs to detect air movement and these can sense both acoustic stimuli, particularly if tuned to resonance, or the larger near-field air flows produced by the wings of predators [19.19]. These hairs respond to the viscous drag created by acoustic air flow past them and, since this is directional, the insect may be able to gain some information about the location of the sound source.

Analysis of the behavior of sensory hairs is complex [19.19], but some general statements can be made. Since what is being sensed is an oscillatory flow of air across the surface of the insect, with the hair standing normal to this surface, it is important that the hair be long enough to protrude above the viscous boundary layer, the thickness of which varies inversely with the square root of frequency and is about 0.1 mm at 150 Hz. This means that the length of the hair should also be about inversely proportional to the frequency of the stimulus it is optimized to detect, and that it should typically be at least a few tenths of a millimeter in length. The thickness of the hair is not of immense importance, provided that it is less than about $10 \, \mu m$ for a typical hair, since much of the effective mass is contributed by co-moving fluid. At the mechanical resonance frequency of the hair, the sensitivity is a maximum, and the hair tip displacement is typically about twice the fluid displacement, provided the damping at the hair root is not large, but the response falls off above and below this frequency.

Mature insects of some species, however, have auditory systems that bear a superficial resemblance to those of modern humans in their overall structure. Thus for example, and referring to Fig. 19.2a, the cricket has thin sensory membranes (tympana or eardrums) on its forelegs, and these are connected by tubes (Eustachian tubes) that run to spiracles (nostrils) on its upper body, the left and right tubes interacting through a thin membrane (nasal septum) inside the body. Analysis of this system [19.9] shows that the tubes and membranes are configured so that each ear has almost cardioid response, directed ipsilaterally, at the song frequency of the insect, allowing the insect to detect the direction of sound arrival. Some simpler auditory systems showing similar directional response are discussed in Sect. 19.5.

Detailed analysis of the response of anatomically complex systems such as this is most easily carried out using electric network analogs, in which pressure is represented by electric potential and acoustic flow by electric current. Tubes are then represented as 2×2 matrices, diaphragms by L, R, C series resonant circuits,

and so on, as shown in Fig. 19.2b. Brief details of this approach are given in Sect. 19.10 and fuller treatments can be found in the published literature [19.9, 20].

When it comes to sound production, insects are very different from other animals because they do not have the equivalent of lungs and a muscle-driven respiratory systems. They must therefore generally rely upon muscle-driven vibration of diaphragms somewhere on the body in order to produce sound. One significant exception is the Death's Head Hawk Moth *Acherontia atropos*, which takes in and then expels pulses of air from a cavity closed by a small flap-valve that is set into oscillation by the expelled air to produce short sound pulses [19.16].

Some insects, such as cicadas, have a large abdominal air cavity with two areas of flexible ribbed cartilage that can be made to vibrate in a pulsatory manner under muscle action, progressive buckling of the membrane as the ribs flip between different shapes effectively multiplying the frequency of excitation by as much as a factor 50 compared with the frequency of muscle contraction.
Fig. 19.2 (a) Schematic drawing of the auditory anatomy of a cricket. (**b**) Simplified electric network analog for this system. The impedances of the tympana and the septum are each represented by a set of components L, R, C connected in series; the tube impedances are represented by 2×2 matrices. The acoustic pressures p_i acting on the system are generally all nearly equal in magnitude, but differ in phase depending upon the direction of incidence of the sound
Fig. 19.3 Configuration of a typical file and pic as used by crickets and other animals to excite resonant structures on their wing cases

Fig. 19.4a,b Structure of the sound emitted by a typical insect: (**a**) three strokes of the file, the individual oscillations being the pic impacts on the file teeth; (**b**) expanded view of four of the pulses in (**a**), showing resonant oscillations of the structure produced by successive pic impacts on the file

The coupling between these tymbal membranes and the air cavity determines the oscillation frequency, and radiation is efficient because of the monopole nature of the source. The sound frequency is typically in the range 3 to 5 kHz, depending upon insect size, and the radiated acoustic power can be as large as 1 mW [19.21] on an almost continuous basis, though the actual sound signal may consist of a series of regularly spaced bursts corresponding to tymbal collapses and rebounds. Again, there are occasional insects that have developed extreme versions of this sound producing mechanism, such as the bladder cicada *Cystosoma Saundersii (Westwood)*, in which the whole greatly extended abdomen is a resonant air sac and the song frequency is only 800 Hz.

Most other insects do not have significant bodily air cavities and must produce sound by causing parts of their body shell or wings to vibrate by drawing a ribbed file on their legs, or in some cases on their wings, across the hard rim of the membrane, as shown in Fig. 19.3. The anatomical features making up the file and vibrating structure vary very greatly across species, as has been discussed and illustrated in detail by *Dumortier* [19.22]. In some cases the file is located on the vibrating structure and the sharp pic on the part that is moving. The passage of the pic across each tooth or rib on the file generates a sharp impulse that excites a heavily damped transient oscillation of the vibrator, and each repetitive motion of the leg or other structure passes the pic over many teeth. A typical insect call can therefore be subdivided into (a) the leg motion frequency, (b) the pic impact frequency on the file, and (c) the oscilla-

tion frequency of the vibrating structure. Since the file may have 10 or more teeth, the frequency of the pic impacts will be more than 10 times the frequency of leg motion, and the structural oscillation may be 10 times this frequency. The structure of a typical call is thus of the form shown in Fig. 19.4. The dominant frequency is usually that of the structural vibration, and this varies widely from about 2–80 kHz depending upon species and size [19.23]. Because of the structure of the call, the frequency spectrum appears as a broad band centered on the structural vibration frequency.

Such a vibrating membrane is a dipole source and so is a much less efficient radiator than is a monopole source, except at very high frequencies where the wing dimensions become comparable with the sound wavelength excited. Small insects therefore generally have songs of higher frequency than those that are larger, in much the same way as discussed in Sect. 19.1 for other animals. Some crickets, however, have evolved the strategy of digging a horn-shaped burrow in the earth and positioning themselves at an appropriate place in the horn so as to couple their wing vibrations efficiently to the fundamental mode of the horn resonator, thus taking advantage of the dipole nature of their wing source and greatly enhancing the radiated sound power [19.24].

19.5 Land Vertebrates

The class of vertebrates that live on land is in many ways the most largely studied, since they bear the closest relation to humans, but these animals vary widely in

size and behavior. Detailed discussion of birds is deferred to Sect. 19.6, since their songs warrant special attention, while human auditory and vocal abilities are

not considered specifically since they are the subject of several other chapters. Reptiles, too, are largely omitted from detailed discussion, since most of them are not notably vocal, and bats are given special attention in Sect. 19.7.

The feature possessed by all the land-dwelling vertebrates is that they vocalize using air expelled from their inflated lungs through some sort of oscillating vocal valve. The available internal air pressure depends upon the emphasis put by the species on vocalization, but is typically in the range $100-2000$ Pa (or $1-20$ cm water gauge) almost independent of animal size, which is what is to be expected if the breathing muscles and lung cavity diameter scale about proportionally with the linear size of the animal. There are, however, very wide variations, as discussed in Sect. 19.2. The auditory abilities of most animals are also rather similar, the 20 dB bandwidth extending over a factor of about 100 in frequency and with a center-frequency roughly inversely proportional to linear size, though again there are outliers, as shown in Fig. 19.1. Although the auditory and vocalization frequencies of different animals both follow the same trend with size, the auditory systems generally have a much larger frequency range than the vocalizations for several reasons. The first is that hearing serves many purposes in addition to conspecific communication, particularly the detection of prey and predators. The second is that, particularly with the more sophisticated animals, there are many nuances of communication, such as the vowels and consonants in human speech, for which information is coded in the upper parts of the vocalization spectrum. For humans, for example, the primary vocalization frequency is typically in the range 100 to 300 Hz, but the frequency bands that are emphasized in vowel formants lie between 1 and 3 kHz. The same pattern is exhibited in the vocalizations of other air-breathing animals, as shown for the case of a raven in Fig. 19.5. The same formant structure is seen in the cries of elephants, with a fundamental in the range $25-30$ Hz and in high-pitched bird songs, which may have a fundamental above 4 kHz.

In most such animals, sound is produced by exhaling the air stored in the lungs through a valve consisting of two taut tissue flaps or membranes that can be made to almost close the base of the vocal tract, as shown in Fig. 19.6a. The lungs in mammals are a complicated quasi-fractal dendritic network of tubules with as many as 16 stages of subdivision, the final stage being terminated by alveolar sacs that provide most of storage volume. The interaction of exhaled air pressure and air flow with the flaps of this valve when they have been brought together (or adducted) causes them to vibrate at very nearly their natural frequency, as determined by mass and tension, and this in turn leads to an oscillating air flow through the valve. The classic treatment of the human vocal valve is that of *Ishizaka* and *Flanagan* [19.25], but there have been many more recent treatments exploring modifications and refinements of this model. Very similar vocal valves are found in other mammals, while the major difference in the case of birds is that the flaps of the vocal folds are replaced by opposed taut membranes inflated by air pressure in cavities behind them, and there may be two such valves, as shown in Fig. 19.6b and discussed later in Sect. 19.6.

In most cases, the vibration frequency of the valve is very much lower than the frequency of the first maximum in the upper vocal tract impedance. The valve therefore operates in a nearly autonomous manner at a frequency determined by its geometry, mass and tension and, to a less extent, by the air pressure in the animal's lungs. Because any such valve is necessarily nonlinear in its flow properties, particularly if it actually closes once in each oscillation cycle, this mechanism generates an air flow, and thus a sound wave in the vocal tract, containing all harmonics of the fundamental
Fig. 19.5a,b A typical time-resolved spectrum for (**a**) human female speech, and (**b**) the cry of a raven, the level of each frequency component being indicated by its darkness. The frequency range is $0-6$ kHz and the duration about 0.7 s in (**a**) and 0.5 s in (**b**). It can be seen that at any instant the spectrum consists of harmonics of the fundamental, with particular bands of frequencies being emphasized. These are the formant bands that distinguish one vowel from another in humans and enable similar distinctions to be made by other animals. Consonants in human speech consist of broadband noise, an example occurring at the beginning of the second syllable in (**a**), and other animals may have similar interpolations between the tonal sounds

oscillation. The radiated amplitudes of these harmonics can be modified by resonances in the air column of the vocal tract to produce variations in sound quality and peaks in the radiated spectrum known generally as vocal formants. Changing the tension of the valve flaps changes the fundamental frequency of the vocal sound, but the frequencies of the formants can be changed independently by moving the tongue, jaws, and lips or beak.

To be more quantitative, suppose that the pressure below the valve is p_0 and that above the valve p_1. If the width of the opening is W and its oscillating dimension is $x(t)$, then the volume flow U_1 through it is determined primarily by Bernoulli's equation and is approximately

$$U_1(t) = \left(\frac{2(p_0 - p_1)}{\rho} \right)^{1/2} Wx(t) , \qquad (19.2)$$

where ρ is the density of air. In order for the valve to be maintained in oscillation near its natural frequency f, the pressure difference $p_0 - p_1$ must vary with the flow and with a phase that is about 90° in advance of the valve opening $x(t)$. This can be achieved if the acoustic impedance of the lungs and bronchi is essentially compliant, and that of the upper vocal tract small, at the oscillation frequency. The fact that this pressure difference appears as a square root in (19.2) then introduces upper harmonic terms at frequencies $2f, 3f, \ldots$ into the flow $U(t)$. Allowance must then be made for the fact that the vocal valve normally closes for part of each oscillation cycle, so that $x(t)$ is no longer simply sinusoidal, and this introduces further upper-harmonic terms into the flow. This is, of course, a very condensed and simplified treatment of the vocal flow dynamics, and further details can be found in the literature for the case of mammalian, and specifically human, animals [19.25] and also for birds [19.26].

This is, however, only the beginning of the analysis, for it is the acoustic flow out of the mouth that determines the radiated sound, rather than the flow from the vocal valve into the upper vocal tract. Suppose that the acoustic behavior of the upper vocal tract is represented by a 2×2 matrix, as shown in Fig. 19.11 of Sect. 19.10, and that the mouth or beak is regarded as effectively open so that the acoustic pressure p_2 at this end of the tract is almost zero. Then the acoustic volume flow U_2 out of the mouth at a particular angular frequency ω is

$$U_2 = \frac{Z_{21}}{Z_{22}} U_1 , \qquad (19.3)$$

where U_1 is the flow through the larynx or syrinx at this frequency. For the case of a simple cylindrical tube of
Fig. 19.6 (a) Sketch of the vocal system of a typical land mammal. The lungs force air through the dual-flap vocal-fold valve, producing a pulsating flow of air that is rich in harmonics of the fundamental frequency. Resonances of the upper vocal tract, which can be modified by motion of the tongue and lips, produce formants in the sound spectrum which encode vocal information. (b) Sketch of the vocal system of a typical song-bird. There are two inflated-membrane valves in the syrinx just below the junction of the bronchi with the trachea, which may be operated either separately or together. Again a harmonic-rich airflow is produced that can either have formants imposed by resonances of the vocal tract and beak, or can be filtered to near pure-tone form by an inflated sac in the upper vocal tract

length L at angular frequency ω, this gives

$$U_2 = \frac{U_1}{\cos kL} , \qquad (19.4)$$

where $k = (\omega/c) - i\alpha$, c is the speed of sound in air, and α is the wall damping in the vocal tract. If the spectrum of the valve flow U_1 has a simple envelope, as is normally the case, then (19.4) shows that the radiated sound power, which is proportional to $\omega^2 U_2^2$, has maxima when $\omega L/c = (2n - 1)\pi/2$, and thus in a sequence $1, 3, 5, \ldots$ These are the formant bands, the precise frequency relationship of which can be varied by changing the geometry of the upper vocal tract, which in turn changes the forms of Z_{21} and Z_{22}.

Some other air-breathing animals (and even human sopranos singing in their highest register) however, adjust their vocal system so that the frequency of the vocal valve closely matches a major resonance of the upper vocal tract, usually that of lowest frequency but not necessarily so. Some species of frogs and birds achieve this by the incorporation of an inflatable sac in the upper vocal tract. In some cases the sac serves simply to provide a resonance of appropriate frequency, and the sound is still radiated through the open mouth, but in others the walls of the sac are very thin so that they vibrate under the acoustic pressure and provide the primary radiation source. This will be discussed again in Sect. 19.6 in relation to bird song, but the analysis for frog calls is essentially the same.

The overall efficiency of sound production in vertebrates is generally only 0.1–1%, which is about the same as for musical instruments. The acoustic output power output is typically in the milliwatt range even for quite large animals, but there is a very large variation between different species in the amount of effort that is expended in vocalization.

The hearing mechanism of land-dwelling vertebrates shows considerable similarity across very many species. Sound is detected through the vibrations it induces in a light taut membrane or tympanum, and these vibrations are then communicated to a transduction organ where they are converted to nerve impulses, generally through the agency of hair cells. The mechanism of neural transduction and frequency discrimination is complex, and its explanation goes back to the days of *Helmholtz* [19.27] in the 19th century, with the generally accepted current interpretation being that of *von Békésy* [19.28] in the mid-20th century. Although these studies related specifically to human hearing, the models are generally applicable to other land-dwelling vertebrates as well, as surveyed in the volume edited by *Lewis* et al. [19.29]. All common animals have two auditory transducers, or ears, located on opposite sides of the head, so that they are able to gain information about the direction from which the sound is coming.

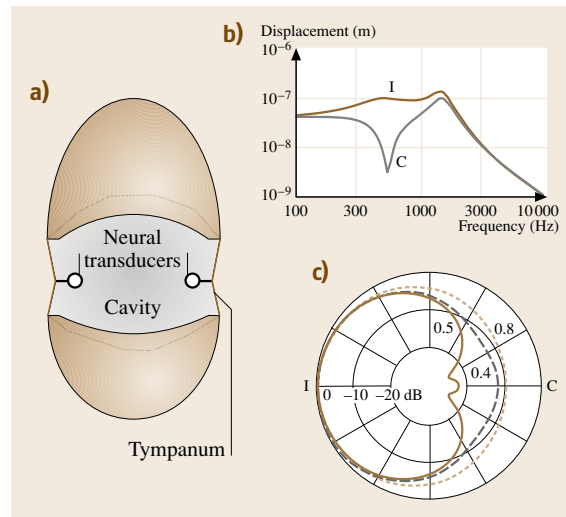
In the simplest such auditory system, found for example in frogs, the two ears open directly into the mouth cavity, as shown in Fig. 19.7a, one neural transducer being closely coupled to each of the two tympana. Such a system is very easily analyzed at low frequencies where the cavity presents just a simple compliance with no resonances of its own. Details of the approach are similar to those for the more complex system to be discussed next. For a typical case in which the ears are separated by 20 mm, the cavity volume is 1 cm^3, and the


Fig. 19.7 (a) A simple frog-ear model; **(b)** the calculated frequency response for ipsilateral (I) and contralateral (C) sound signals for a particular optimized set of parameter values; **(c)** the calculated directivity at different frequencies, shown in kHz as a parameter (after [19.9])

loaded tympanum resonance is at 500 Hz, the calculated response has the form shown in Fig. 19.7b. Directional discrimination is best at the tympanum resonance frequency and can be as much as 20 dB. In a more realistic model for the case of a frog, the nostrils must also be included, since they lead directly into the mouth and allow the entry of sound. The calculated results in this case show that the direction of maximum response for each ear is shifted towards the rear of the animal, typically by as much as 30° [19.9].

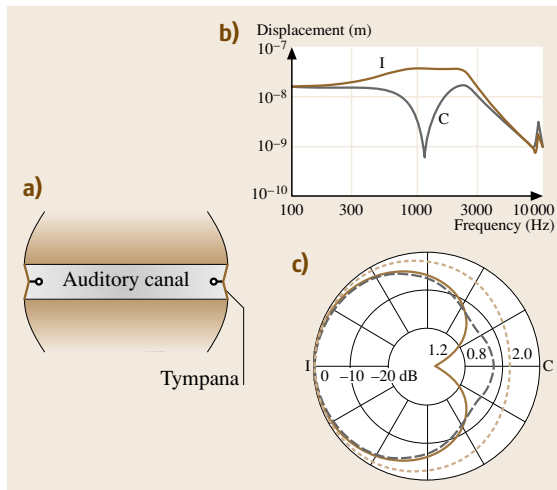
In another simple auditory system such as that of most reptiles, and surprisingly birds, the two tympana are located at the ends of a tube passing through the head and each is supplied with its own neural transducer, as shown in Fig. 19.8a. The tympana may be recessed at the end of short tubes to provide protection, these tubes only slightly modifying the frequency response. The behavior of such a system can be analyzed using the electric network analogs discussed in Sect. 19.10, with each tympanum involving a series L, R, C combination and the tube being represented by a 2×2 impedance matrix Z_{ij}. If the sound comes from straight in front, then it is the same in magnitude and phase at each ear, so that their responses are necessarily the same. When the sound comes from one side, however, there is a phase difference between the two ear pressures, along with a rather less significant amplitude


Fig. 19.8 **(a)** Idealized model of the auditory system of a lizard or bird. Each tympanum is connected to a neural transducer and the two are joined by a simple tube. **(b)** Response of a particular case of the system in **(a)** to ipsilateral (I) and contralateral (C) sound of amplitude 0.1 Pa (equivalent to 74 dB re 20 μPa). The tube diameter is assumed to be 5 mm and its length 20 mm, while the tympana have a thickness of 10 μm and are tensioned to a resonance frequency of 1000 Hz. **(c)** Directional response of this hearing system (after [19.9])

difference. The motion of each tympanum is determined by the difference between the internal and external pressures acting upon it, and the internal pressure depends upon the signal transferred from the opposite tympanum, modified by the phase delay or resonance of the coupling tube. The analysis is straightforward, but the resulting behavior, which depends upon the mass and tension of the tympana and the length and diameter of the connecting tube, can only be determined by explicit calculation [19.9]. When these parameters are appropriately chosen, each ear has a strongly directional response near the resonance frequency of the tympana, as shown in Fig. 19.8b, c. The balance between the depth and sharpness of the contralateral minimum is affected by the acoustic absorption in the walls of the connecting canal. In some animals, the bone lining of this canal is actually porous, which reduces the effective sound-wave velocity inside it and so increases the phase shift between internal and external signals, a feature that is of assistance when the physical separation of the ears is small.

In most mammals and other large animals, the auditory system is modified in several significant ways.

The first is that the auditory canal joining the two ears in birds and reptiles has generally degenerated in mammals to the extent that each ear functions nearly independently. The connecting canal in humans has become the pair of Eustachian tubes running from the middle ear cavity, which contains the bones linking the tympanum to the cochlea, down to the nasal cavities, and its main purpose is now simply to equalize internal and external static pressures and to drain excess fluids. The middle ear cavity itself is necessary in order that the enclosed air volume be large enough that it does not raise the resonance frequency of the tympanum by too much. The topology of the whole system is surprisingly similar to that of the cricket auditory system shown in Fig. 19.2a, but the functions of some of the elements are now rather different.

The other major change is that, instead of the tympana being located almost on the surface of the animal, they are buried below the surface at the end of short auditory canals (meati), which lead to external ears (pinnae) in the shape of obliquely truncated horns. As well as protecting the tympana from mechanical damage, the canals add a minor resonance of their own, generally in the upper part of the auditory range of the animal concerned. The pinnae both increase the level of the pressure signal, typically by about 10 dB and in some cases even more, and impart a directionality to the response [19.9, 30]. The convoluted form of some pinnae also imparts directionally-excited resonances that help distinguish direction from tonal cues, a feature that is necessary in order to distinguish up/down directions for sounds coming from immediately ahead or immediately behind. Some animals with particularly large pinnae, such as kangaroos, are able to rotate these independently to help locate a sound source. In all such cases, however, the neural system plays a large part in determining sound direction by comparing the phases and amplitudes, and sometimes the precise timing of transients, in the signals received by the two ears.

In a hearing system of any simple type it is clear that, if geometrical similarity is maintained and the system is simply scaled to the linear size of the animal concerned, then the frequency of maximum discrimination will vary as the inverse of the linear size of the animal, giving an approximate match to general trend of vocalization behavior. There is, however, one anomaly to be noted [19.31]. Vocalizations by some frogs have fundamental frequencies as high as 8 kHz and the vocal signal contains prominent formant bands in the case studied at 20 kHz and 80 kHz, so that they

might almost be classed as ultrasonic. Despite this, behavioral evidence indicates that these frogs cannot hear signals much above 10 kHz, so that perhaps the formant bands are simply an epiphenomenon of the sound production system. The same is true of the calls of some birds.

19.6 Birds

Because of their generally melodious songs, birds have excited a great deal of attention among researchers, as described in several classic books [19.32, 33]. Hearing does not require further discussion because the auditory system is of the simple tube-coupled type discussed in Sect. 19.5 and illustrated in Fig. 19.8. Research interest has focused instead on the wide range of song types that are produced by different species. These range from almost pure-tone single-frequency calls produced by doves, and whistle-like sounds sweeping over more than a 2 : 1 frequency range produced by many other species, through wide-band calls with prominent formants, to the loud and apparently chaotic calls of the Australian sulfur-crested cockatoo. Some birds can even produce two-toned calls by using both syringeal valves simultaneously but with different tuning.

As noted in Sect. 19.5 and illustrated in Fig. 19.6b, song birds have a syrinx consisting of dual inflated-membrane valves, one in each bronchus just below their junction with the trachea. These valves can be operated simultaneously and sometimes at different frequencies, but more usually separately, and produce a pulsating air-flow rich in harmonics. In birds such as ravens, the impedance maxima of the vocal tract, as measured at the syringeal valve, produce emphasized spectral bands or formants much as in human speech, as is shown in Fig. 19.5. The vocal tract of a bird is much less flexible in shape than is that of a mammal, but the formant frequencies can still be altered by changes in tongue position and beak opening. Studies with laboratory models [19.34] show that the beak has several acoustic functions. When the beak is nearly closed, it presents an end-correction to the trachea that is about half the beak length at high frequencies, but only about half this amount at low frequencies, so that the formant resonances are brought closer together in frequency. As the beak gape is widened, the end-correction reduces towards the normal value for a simple open tube at all frequencies. The beak also improves radiation efficiency, particularly at higher frequencies, by about 10 dB for the typical beak modeled. Finally, the beak enhances the directionality of the radiated sound, particularly at high frequencies and for wide gapes, this enhanced directionality being as much as 10 dB compared with an isotropic radiator.

The role of the tongue has received little attention as yet, partly because it is rather stiff in most species of birds. It does, however, tend to constrict the passage between the top of the trachea and the root of the beak, and this constriction can be altered simply by raising the tongue, thereby exaggerating the end-correction provided to the trachea by the beak. These models of beak behavior can be combined with models of the syrinx and upper vocal tract [19.26] to produce a fairly good understanding of vocalization in birds such as ravens. The fundamental frequency of the song can be changed by changing the muscle tension and thus the natural resonance frequency of the syringeal valve, while the formants, and thus the tone of the song, can be varied by changing the beak opening and tongue position. The role of particular anatomical features and muscular activities in controlling the fundamental pitch of the song has since been verified by careful measurement and modeling [19.35, 36].

Some birds have developed the ability to mimic others around them, a notable example being Australian Lyrebirds of the family *Menuridae* which, as well as imitating other birds, have even learned to mimic human-generated sounds such as axe blows, train whistles, and even the sound of film being wound in cameras. There has also been considerable interest in the vocalization of certain parrots and cockatoos, which can produce, as well as melodious songs, quite intelligible imitations of human speech. The important thing here is to produce a sound with large harmonic content and then to tune the vocal tract resonances, particularly those that have frequencies in the range 1–2.5 kHz, to match those of the second and third resonances of the human vocal tract, which are responsible for differentiating vowel sounds. Consonants, of course, are wide-band noise-like transients. Careful studies of various parrots [19.37, 38] show that they can achieve this by careful positioning of the tongue, much in the way that humans achieve the same thing but with quantitative differences because of different vocal tract size. The match to human vowels in the second and third

human formants can be quite good. The first formant, around 500 Hz in humans, is not reproduced but this is not important for vowel recognition.

These studies produce a good understanding of the vocalization of normal song-birds, the calls of which consist of a dominant fundamental accompanied by a range of upper harmonics. Less work has been done on understanding the nearly pure-tone cries of other birds. For many years there has been the supposition that the sound production mechanism in this case was quite different, perhaps involving some sort of aerodynamic whistle rather than a syringeal vibration. More recent experimental observations on actual singing birds, using modern technology [19.39], have established however that, at least in the cases studied, the syringeal valve is in fact normally active, though it does not close completely in any part of the cycle, thus avoiding the generation of large amplitudes of upper harmonics. Suppression of upper harmonics can also be aided by filtering in the upper vocal tract [19.40].

In the case of doves, which produce a brief pure-tone *coo* sound at a single frequency, the explanation appears to lie in the use of a thin-walled inflated esophageal sac and a closed beak, with fine tuning provided by an esophageal constriction [19.41]. The volume V of air enclosed in the sac provides an acoustic compliance $C = V/\rho c^2$ that is in parallel with an acoustic inertance $L = m/S^2$ provided by the mass m and surface area S of the sac walls. The resonance frequency f of this sac filter is given by

$$f = \frac{1}{2\pi}\left(\frac{\rho c^2 S^2}{m V}\right)^{1/2}, \tag{19.5}$$

where ρ is the density of air and c is the speed of sound in air. When excited at this frequency by an inflow of air from the trachea, the very thin expanded walls of the sac vibrate and radiate sound to the surrounding air. For a typical dove using this strategy, the wall-mass and dimensions of the inflated sac are about right to couple to the *coo* frequency of about 900 Hz. From (19.5), the resonance frequency varies only as the square root of the diameter of the sac, so that a moderate exhalation of breath can be accommodated without much disturbance to the resonance. The dove must, however, learn to adjust the glottal constriction to couple the tracheal resonance efficiently to that of the sac.

Some other birds, such as the Cardinal, that produce nearly pure-tone calls over a wide frequency range, appear to do so with the help of an inflated sac in the upper vocal tract that leads to the opened beak, with the tracheal length, sac volume, glottal constriction, tongue position, and beak opening all contributing to determine the variable resonance frequency of the filter. Because the sac is not exposed as in the dove, its walls are heavy and do not vibrate significantly. It thus acts as a Helmholtz resonator, excited by the input flow from the trachea and vented through the beak. The bird presumably learns to adjust the anatomical variables mentioned above to the syringeal vibration frequency, which is in turn controlled by syringeal membrane tension, and can then produce a nearly pure-tone song over quite a large frequency range. Despite this explanation of the mechanism of pure-tone generation in some cases, others have still to be understood, for the variety of birdsong is so great that variant anatomies and vocalization skills may well have evolved.

With most of the basic acoustic principles of birdsong understood, most of the interest in birdsong centers upon the individual differences between species. The variety found in nature is extremely great and, while sometimes correlated with large variations in bird anatomy, it also has many environmental influences. Some birds, surprisingly, have songs with prominent formant bands extending well into the ultrasonic region, despite the fact that behavioral studies and even auditory brainstem measurements show that they have no response above about 8 kHz [19.31, 42]. The formant bands in these cases are therefore presumably just an incidental product of the vocalization mechanism.

19.7 Bats

Since human hearing, even in young people, is limited to the range from about 20 Hz to about 20 kHz, frequencies lying outside this range are referred to as either infrasonic or ultrasonic. Very large animals such as elephants may produce sounds with appreciable infrasonic components, though the higher harmonics of these sounds are quite audible. Small animals such as bats, however, produce echo-location calls with dominant frequencies around 80 kHz that are inaudible to humans, though some associated components of lower frequency may be heard. In this section brief attention will be given to the sonar abilities of bats, though some other animals also make use of ultrasonic techniques [19.43].

Sound waves are scattered by any inhomogeneities in the medium through which they are propagating, the density of an animal body in air provides a large contrast in acoustic impedance and therefore a large scattered signal. The basic physics shows that, for a target in the form of a sphere of diameter d and a signal of wavelength $\lambda \gg d$, the echo strength is proportional to d^6/λ^4 times the incident intensity. This incident intensity is itself determined by the initial signal power and the angular width of the scanning signal, which varies about as λ/a, where a is the radius of the mouth of the probing animal. If R is the distance between the probing animal and the target, then the sound power incident on the target varies as $a^2/\lambda^2 R^2$ and the returned echo strength E thus varies as

$$E \propto \frac{d^6 a^2}{\lambda^6 R^4} \, , \qquad (19.6)$$

provided the wavelength λ is much greater than the diameter d of the scattering object and the radius a of the mouth. Another factor must, however, be added to this equation and that is the attenuation of the sound due to atmospheric absorption. This attenuation depends on relative humidity, but is about $0.1 \, \text{dB m}^{-1}$ at $10 \, \text{kHz}$, increasing to about $0.3 \, \text{dB m}^{-1}$ at $100 \, \text{kHz}$, and so is not a very significant factor at the short ranges involved.

Once the size of the target becomes comparable with the incident sound wavelength, the scattering tends towards becoming reflection and geometrical-optics techniques can be used. In this limit, the reflected intensity is proportional to the area of the target, but depends in a complicated way upon its shape and orientation. Finally, if a pure-tone sound is used, any Doppler shift in the frequency of the echo can give information about the relative motion of prey and predator. The reflected sound can therefore give information about the nature of the target and its motion, both of which are important to the pursuing bat.

The sonar-location cries of bats and other animals are, however, not pure-tone continuous signals but rather sound pulses with a typical frequency in the range $40–80 \, \text{kHz}$ and so a wavelength of about $4–8 \, \text{mm}$. This wavelength is comparable to the size of typical prey insects so that the echo can give information about size, shape and wing motion, while the echo delay reveals the distance. The bat's large ears are also quite directional at these frequencies, so that further information on location is obtained. Rather than using short bursts of pure tone, some predators use longer bursts in which the frequency is swept rapidly through a range of several kilohertz. This technique is known as *chirping*, and it allows the returned echo to be reconstructed as a single pulse by frequency-dependent time delay, although animal neural systems may not actually do this. The advantage of chirping is that the total energy contained in the probing pulse, and thus the echo, can be made much larger without requiring a large peak power.

Because of the high frequencies involved in such sonar detection, bats have a hearing system that is specialized to cover this high-frequency range and to provide extended frequency resolution near the signal frequency, perhaps to aid in the neural equivalent of *de-chirping* the signal and detecting Doppler frequency shifts. The auditory sensitivity curve of bats is similar in shape to that of humans (threshold about $20 \, \mu\text{Pa}$), but shifted up in frequency by a factor of about 20 to give high sensitivity in the range $10–100 \, \text{kHz}$ [19.1]. The threshold curve generally shows a particular sensitivity maximum near the frequency of the echo-location call, as might be expected. Bats also generally have forward-facing ears that are large in comparison with their body size. The functions of these in terms of increased directionality and larger receiving area are clear [19.30].

Sound production in bats is generally similar to that in other animals, but with the system dimensions tailored to the higher frequencies involved, and often with the sound emitted through the nose rather than the mouth. The complicated geometry of the nasal tract, which has several spaced enlargements along its length, appears to act as an acoustic filter which suppresses the fundamental and third harmonic of the emitted sound while reinforcing the second harmonic, at least in some species [19.44]. The physics of this arrangement is very similar to that of matching stubs applied to high-frequency transmission lines.

19.8 Aquatic Animals

The generation and propagation of sound under water, as discussed in Chap. 20, have many features that are different from those applying to sound in air. From a physical point of view, a major difference is the fact that water is often quite shallow compared with the range of sound, so that propagation tends to be two-dimensional at long distances. From the present biological viewpoint the major difference is that the

acoustic impedance of biological tissue is nearly equal to that of the surrounding water, while in air these differ by a factor of about 3500. This leads to some very significant differences in the auditory anatomy and behavior between aquatic and air-dwelling animals.

The variety of aquatic animal species is comparable to that of land-dwelling animals, and they can be divided into three main categories for the purposes of the present chapter. First come the crustaceans, such as shrimp, lobsters and crabs, which are analogous to insects, then the wide variety of fish with backbones, and finally the air-breathing aquatic mammals such as the cetaceans (whales, dolphins and porpoises, which are the subject of Chap. 20), though animals such as turtles also come into this category. There are, of course, many other categories of marine animal life, but they are not generally significant from an acoustic point of view. A good review has been given by *Hawkins* and *Myrberg* [19.45].

The crustaceans, like most insects, generally produce sound by rubbing a toothed leg-file against one of the plates covering their body, thus producing a pulse of rhythmic clicks. Some animals, such as shrimp, may produce a single loud click or pop by snapping their claws in much the same way that a human can do with fingers. Because this activity takes place under water, which has density ρ about 800 times greater and sound velocity c about 4.4 times greater than that of air, and thus a specific acoustic impedance ρc about 3500 times greater than air, the displacement amplitude of the vibration does not need to be large, and the vibrating structure is generally small and stiff. The peak radiated acoustic power in the *click* can, however, be very large – as much as several watts in the Pistol shrimp *Alpheidae* – probably from a mechanism involving acoustic cavitation. The click lasts for only a very short time, however, so that the total radiated energy is small.

Fish species that lack an air-filled *swim-bladder*, the main purpose of which is to provide buoyancy, must produce sound in a similar manner. For fish that do have a swim-bladder, however, the sound production process is much more like that of the cicada, with some sort of plate or membrane over the bladder, or even the bladder wall itself, being set into oscillation by muscular effort and its displacement being aided by the compressibility of the air contained in the bladder. The surrounding tissue and water provide a very substantial mass loading which also contributes to determining the primary resonance frequency of the bladder. This is a much more efficient sound production process than that of the crustaceans and leads to much louder sounds, again

generally consisting of a train of repetitive pulses at a frequency typically in the range 100–1000 Hz.

When it comes to sound detection, hair cells again come into play in a variety of ways. Because the density of the animal body is very similar to that of the surrounding water, a plane wave of sound tends to simply move the animal and the water in just the same way. The slight difference in density, however, does allow for some differential motion. The animal body is, however, relatively rigid, so that its response to diverging waves in the near field is rather different from that of the liquid. Any such relative motion between the body and the surrounding water can be detected by light structures such as hairs protruding from the body of the animal, and these can form the basis of hair-cell acoustic detectors. Even more than this, since such cells are generally sensitive to hair deflection in just one direction, arrays of hair cells can be structured so as to give information about the direction of origin of the sound. Although some such detector hairs may be mechanically strong and protrude from the body of the animal, others may be very small and delicate and may be protected from damage by being located in trench-like structures, these structures being called lateral-line organs. Their geometry also has an effect on sound localization sensitivity.

There is another type of hair detector that responds to acceleration rather than relative displacement and that therefore takes advantage of the fact that the body of the animal tends to follow the acoustic displacement of the surrounding water. This is the otolith, which consists of a small dense calcareous stone supported by one
Fig. 19.9a,b Two possible forms for a simple otolith detector: **(a)** a single-cell detector, **(b)** a multi-cell detector. As the mineral grain moves sideways relative to the substrate, the sensory hairs are deflected and open ion channels in the supporting transducer cells (after [19.9])

or more hair cells, as shown in Fig. 19.9. Since the motion of this stone tends to lag behind the motion of the liquid, and thus of its supports, the supporting hairs are deflected in synchrony with the acoustic stimulus, so that it can be detected by the cells to which they are attached. These sensors will normally have evolved so that combined mass of the otolith and stiffness of the hair give a resonance frequency in the range of interest to the animal, and detection sensitivity will be greatest at this frequency.

If the fish possesses an air-filled swim-bladder, then this can also be incorporated in the hearing system [19.46]. An air bubble in water is made to move in a sound wave by the differential pressure across it. Because its mass is small and the pressure gradient is the same as that on an equivalent volume of water, the bubble tends to move more than the surrounding liquid but, in order to do so, it must displace a significant amount of this liquid. The final result is that the amplitude of free bubble motion is about three times the amplitude of the motion of the surrounding liquid. Since the body of the fish tends to follow the liquid motion because its density is nearly the same, there is relative motion between the bladder and the rest of the fish, provided it is not rigidly enclosed. This relative motion can be detected by neural cells pressed against the bladder wall and provides an efficient sensor of underwater sound. The radial compressive resonances of the swim bladder can also be important in the detection of sound and, since these are also involved in sound production in these fish, there is a good match between call frequency and the frequency of maximum hearing sensitivity, which typically lies in the range 100 to 1000 Hz. Fish with swim bladders have thus evolved to use these primarily buoyancy-regulating structures for both the production and detection of sound.

19.9 Generalities

This brief survey has shown the strong resemblance between the basic sound-producing and auditory mechanisms in a wide variety of animals. Certainly there is a distinction in the matter of sound production between those animals that store air within their bodies and those that do not, and a rather similar distinction in the matter of sound detection, but the similarities are more striking than the differences. In particular, the universal importance of hair-cells in effecting the transduction from acoustic to neural information is most striking.

Also notable in its generality is the scaling of the dominant frequency of produced sound and the associated frequency of greatest hearing sensitivity approximately inversely with the linear dimensions of the animal involved. Certainly there are notable outliers in this scaling, but that in itself is a clue to the significantly different acoustic behavior of the animal species concerned.

Fortunately, quite straightforward acoustic analysis provides a good semi-quantitative description of the operation of most of these animal acoustic systems, and in some cases such analysis can reveal evolutionarily optimized solutions to modern acoustical design problems.

19.10 Quantitative System Analysis

Biological systems are almost always anatomically complex, and this is certainly true of vocal and auditory systems, which typically comprise sets of interconnecting tubes, horns, cavities and membranes driven over a wide frequency range by some sort of internal or external excitation. While a qualitative description of the way in which such a system works can be helpful, this must be largely based upon conjectures unless one is able to produce a quantitative model for its behavior. Fortunately a method has been developed for the construction of detailed analytical models for such systems from which their acoustic behavior can be quantitatively predicted, thus allowing detailed comparison with experiment. This section will outline how this can be done, more detail being given in [19.9] and [19.20].

In a simple mechanical system consisting of masses and springs, the quantities of interest are the force F_i applied at point i and the resulting velocity of motion v_j at point j, and we can define the mechanical impedance Z^{mech}_{jj} by the equation $Z^{\text{mech}}_{jj} = F_j/v_j$. Note that the subscripts on F and v are here both the same, so that Z^{mech}_{jj} is the ratio of these two quantities measured at

a single point j. It is also possible to define a quantity $Z_{ij}^{\text{mech}} = F_i/v_j$ which is called the transfer impedance between the two points i and j. There is an important theorem called the reciprocity theorem, which shows that $Z_{ji} = Z_{ij}$.

In such a simple mechanical system, as well as the masses and springs, there is normally some sort of loss mechanism, usually associated with internal viscous-type losses in the springs, and the situation of interest involves the application of an oscillating force of magnitude F and angular frequency ω. We denote this force in complex notation as $F e^{i\omega t}$ where $i = \sqrt{-1}$. (Note that, in the interest of consistency throughout this Handbook, this notation differs from the standard electrical engineering notation in which i is replaced by j.) For the motion of a simple mass m under the influence of a force F we know that $F = m \, dv/dt$ or $F = i\omega m v$, so that the impedance provided by the mass is $i\omega m$. Similarly, for a spring of compliance C, $F = \int v \, dt/C = -i/(\omega C)$, giving an impedance $-i/(\omega C)$. For a viscous loss within the spring there is an equivalent resistance R proportional to the speed of motion, so that $F = Rv$. Examination of these equations shows that they are closely similar to those for electric circuits if we assume that voltage is the electrical analog of force and current the analog of velocity. The analog of a mass is thus an inductance of magnitude m, the analog of a compliant spring is a capacitance C, and the analog of a viscous resistance is an electrical resistance R. A frictional resistance is much more complicated to model since its magnitude is constant once sliding occurs but changes direction with the direction of motion, so that its whole behavior is nonlinear.

These mechanical elements can then be combined into a simple circuit, two examples being shown in Fig. 19.10. In example (a) it can be seen that the motion of the mass, the top of the spring, and the viscous drag are all the same, so that in the electrical analog the same current must flow through each, implying a simple series circuit as in (b). The total input impedance is therefore the sum of the three component impedances, so that

$$Z^{\text{mech}} = R + i\omega m - \frac{i}{\omega C} = R + \frac{im}{\omega}\left(\omega^2 - \frac{1}{mC}\right),$$

(19.7)

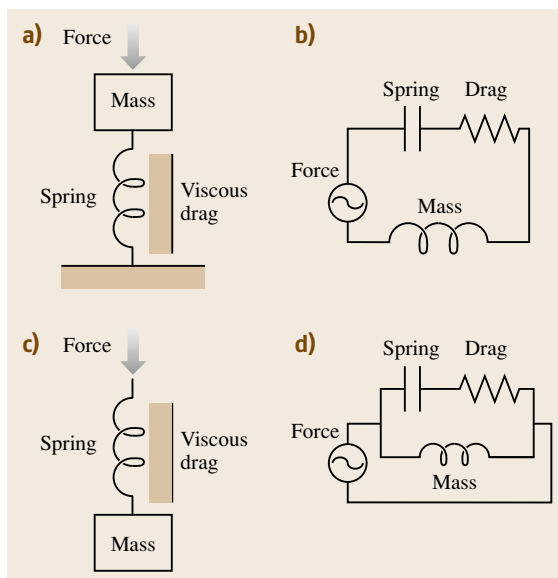
which has an impedance minimum, and thus maximum motion, at the resonance frequency $\omega^* = 1/(mC)^{1/2}$. In example (c), the displacement of the top of the spring is the sum of the compressive displacement of the spring and the motion of the suspended mass, and so the analog


Fig. 19.10 (a) A simple resonant assembly with an oscillating force applied to a mass that is resting on a rigidly supported spring, the spring having internal viscous losses. **(b)** Analog electric network for the system shown in **(a)**. **(c)** An alternative assembly with the mass being freely suspended from the spring and the oscillating force being applied to the free end of the spring. **(d)** Analog electric network for the system shown in **(c)**. (Note the potential source of confusion in that an electrical inductance symbol looks like a physical spring but actually represents a mass)

current is split between the spring on the one hand and the mass on the other, the viscous drag having the same motion as the spring, leading to the parallel resonant circuit shown in (d). There is an impedance maximum, and thus minimum motion of the top of the spring, at the resonance frequency, which is again $\omega^* = 1/(mC)^{1/2}$. In a simple variant of these models, the spring could be undamped and the mass immersed in a viscous fluid, in which case the resistance R would be in series with the inductance rather than the capacitance. These analogs can be extended to include things such as levers, which appear as electrical transformers with turns ratio equal to the length ratio of the lever arms.

While such combinations of mechanical elements are important in some aspects of animal acoustics, such as the motion of otolith detectors, most of the systems of interest involve the generation and detection of acoustic waves rather than of mechanical vibrations. The important physical variables are then the acoustic pressure p and the acoustic volume flow U, both being

functions of the frequency ω. By analogy with mechanical systems, the acoustic impedance is now defined as $Z^{acoust} = p/U$. For a system with a well-defined measurement aperture of area S, it is clear that $p = F/S$ and $U = vS$, so that $Z^{acoust} = Z^{mech}/S^2$, and once again we can define both the impedance at an aperture and the transfer impedance between two apertures. In what follows, the superscript *acoust* will be omitted for simplicity.

Consider first the case of a circular diaphragm under elastic tension and excited by an acoustic pressure $p e^{i\omega t}$ on one side. This problem can easily be solved using a simple differential equation [19.9], but here we seek a network analog. The pressure will deflect the diaphragm into a nearly spherical-cap shape, displacing an air volume as it does so. If the small mass of the deflected air is neglected, then deflection of the diaphragm will be opposed by its own mass inertia, by the tension force and by internal losses. The mass contributes an acoustic inertance (or inductance in the network analog) with magnitude about $2\rho_s d/S$, where ρ_s is the density of the membrane material, d is the membrane thickness, and S is its area, while the tension force T contributes an equivalent capacitance of magnitude about $2S^2/T$. This predicts a resonance frequency $\omega^* \approx 0.5(T/S\rho_s d)^{1/2}$, while the rigorously derived frequency for the first mode of the diaphragm replaces the 0.5 with 0.38. Because biological membranes are not uniform in thickness and are usually loaded by neural transducers, however, it is not appropriate to worry unduly about the exact values of numerical factors. For a membrane there are also higher modes with nodal diameters and nodal circles, but these are of almost negligible importance in biological systems.

The next thing to consider is the behavior of cavities, apertures, and short tubes. The air enclosed in a rigid container of volume V can be compressed by the addition of a further small volume dV of air and the pressure will then rise by an amount $p_0 \gamma \, dV/V$ where p_0 is atmospheric pressure and $\gamma = 1.4$ is the ratio of specific heats of air at constant pressure and constant volume. The electric analog for this case is a capacitance of value $\gamma p_0/V = \rho c^2/V$ where c is the speed of sound in air and ρ is the density of air.

In the case of a tube of length l and cross-section S, both very much less than the wavelength of the sound, the air within the tube behaves like a mass $\rho l S$ that is set into motion by the pressure difference p across it. The acoustic inertance, or analog inductance, is then $Z = \rho l/S$. For a very short tube, such as a simple aperture, the motion induced in the air just outside the two
Fig. 19.11 (a) A simple uniform tube showing the acoustic pressures p_i and acoustic volume flows U_i. **(b)** The electrical analog impedance element Z_{ij}. Note that in both cases the current flow has been assumed to be antisymmetric rather than symmetric

ends must be considered as well, and this adds an *end-correction* of 0.6–0.8 times the tube radius [19.47] or about $0.4S^{1/2}$ to each end of the tube, thus increasing its effective length by twice this amount.

These elements can be combined simply by considering the fact that acoustic flow must be continuous and conserved. Thus a Helmholtz resonator, which consists of a rigid enclosure with a simple aperture, is modeled as a capacitor and an inductor in series, with some resistance added due to the viscosity of the air moving through the aperture and to a less extent to radiation resistance. The analog circuit is thus just as in Fig. 19.10b and leads to a simple resonance.

If any of the components in the system under analysis is not negligibly small compared with the wavelength of the sound involved, then it is necessary to use a more complex analysis. For the case of a uniform tube of length l and cross section S, the pressure and flow at one end can be denoted by p_1 and U_1 respectively and those at the other end by p_2 and U_2. The analog impedance is then a four-terminal element, as shown in Fig. 19.11. The equations describing the behavior of this element are

$$p_1 = Z_{11}U_1 - Z_{12}U_2 ,$$
$$p_2 = Z_{21}U_1 - Z_{22}U_2 . \tag{19.8}$$

Note that the acoustic flow is taken to be inwards at the first aperture and outwards at the second, and this asymmetry gives rise to the minus signs in (19.8). Some texts take both currents to be inflowing, which removes the minus signs. For a simple uniform tube, symmetry

demands that $Z_{21} = Z_{12}$ and that $Z_{22} = Z_{11}$. The first of these relations, known as reciprocity, is universal and does not depend upon symmetry, while the second is not true for asymmetric tubes or horns.

For a uniform tube of length l and cross-section S, consideration of wave propagation between the two ends shows that

$$Z_{11} = Z_{22} = -iZ_0 \cot kl \ ,$$
$$Z_{21} = Z_{12} = -iZ_0 \csc kl \ , \qquad (19.9)$$

where $Z_0 = \rho c / S$ is the characteristic impedance of the tube. The propagation number k is given by

$$k = \frac{\omega}{c} - i\alpha \qquad (19.10)$$

where α represents the attenuation caused by viscous and thermal losses to the tube walls, and has the approximate value

$$\alpha \approx 10^{-5} \frac{\omega^{1/2}}{a} \qquad (19.11)$$

where a is the tube radius. Since auditory systems often involve quite narrow tubes, this term can become very important.

Similar but much more complicated relations apply for horns of various shapes, the simplest being conical, exponential or parabolic in profile [19.9]. As discussed elsewhere [19.47], horns act as acoustic transformers, basically because $Z_{22} \neq Z_{11}$, and can raise the acoustic pressure in the narrow throat by about the ratio of the mouth diameter to the throat diameter. This amplification is limited, however, to frequencies high enough that the horn diameter does not change greatly over an axial distance of about one wavelength.

With the aid of these electric circuit element analogs it is now possible to construct an analog network to represent the whole acoustic system, as shown by the example in Fig. 19.2. The major guiding principle in constructing such a network is the conservation of acoustic flow, or equivalently of electric current. In the case of an auditory system, there may be several openings connecting to the environment, and the acoustic pressures at these openings will generally differ in both phase and amplitude, depending upon the direction from which the sound is coming. Phase differences are generally more important for directional discrimination than are amplitude differences, particularly for small an-

imals, just as in directional microphones [19.47] and the combination of tubes, cavities and membranes in the system provides additional phase shifts. The sensory input is normally generated by the motion of tympanic membranes on the two sides of the animal, with the combination of external and internal pressure determining the motion of each membrane, as shown for example in Figs. 19.7 and 19.8.

When sound production is considered, it is usual to make the approximation of separating the basic sound-generation mechanism, such as the air flow through vibrating vocal folds, from the acoustics of the subsequent tubes and cavities, thus leading to a *source/filter model*. With this simplification, the source can be assumed to produce an oscillating acoustic flow at a particular frequency ω, generally accompanied by a set of harmonics at frequencies $n\omega$ generated by nonlinearity in the vibration of the flow valve. The sound production at each frequency is then determined by the final acoustic flow $U(n\omega)$ through an aperture into the surroundings. The square of this flow, multiplied the acoustic radiation resistance of the aperture, which depends upon its size, [19.47] then determines the radiated acoustic power at that frequency. In a much more complex model, the pressure generated by the acoustic input flow can be recognized to act back upon the acoustic source itself, thus modifying its behavior. Typically this results in a small shift in the source frequency to align it more closely with a neighboring strong resonance of the filter. Such interactions are well known in other systems such as musical wind instruments and probably assist in coupling the oscillations of the syrinx to the resonance of the vocal filter in *pure tone* birdsong.

Finally, it is worthwhile to emphasize that biological acoustic systems do not consist of straight tubes of uniform diameter with rigid walls, unloaded circular membranes, or other idealized elements. While it is possible in principle to include such refinements in a computational model, this will generally make that model so complex to analyze that it reveals little about the actual operation of the system. It is usually better, therefore, to construct the simplest possible model that includes all the relevant acoustic elements and to examine its predictions and the effect that changing the dimensions of some of those elements has on the overall behavior. In this way the behavior of the real biological system can be largely understood.

19.11 Information Transfer

The purpose of animal bioacoustics is essentially information transfer. Sometimes, as with sonar, the target information is overlaid on an initial signal sent from the animal, sometimes it involves collecting information about prey, but most often it involves information transfer between two or more individuals of the same species, and this is what is considered here. At the lowest level, a sound signal indicates existence and location, provided the receiver has an auditory system capable of directional discrimination. The frequency of a steady signal or the repetition frequency of a periodic signal may also convey information about animal status, territorial claim, or reproductive state. Of more interest, however, is the way in which variable information can be encoded in a vocal signal, ranging from birdsong to human speech, and this is what is considered briefly here. A more detailed account has been given elsewhere [19.48] and an excellent exposition is provided by *Bradbury* and *Vehrenkamp* [19.2]. For background information see Chap. 14.14.

Because of the way in which they are produced, most animal signals have a harmonic spectrum and information is encoded in time variations of the amplitude, the fundamental frequency, the spectral envelope of the harmonics (e.g. vowels in human speech produced by modifying the vocal tract shape with the tongue and lips) and by brief bursts of broadband noise (e.g. consonants produced by releasing a burst of air through a small constriction). The total possible information content of the signal depends upon the rate at which these components can be varied in a detectable manner but the received signal may be partly obscured by environmental noise and by the limitations of the auditory system.

While some auditory signals, such as those of insects, are very simple and repetitive, birds and mammals usually have much more complex vocalizations. Suppose the sound signal can be divided into small elements, such as syllables, and that there can be $n(T)$ meaningful combinations of these elements in a signal of length T, then by Shannon's formal definition [19.49] the information conveyed by this time-limited signal is $\log 2n(T)$ bits, where a *bit* is a binary digit 0 or 1. For non-repetitive human speech $n(T)$ increases exponentially with T so that the rate at which information is transmitted is constant and is typically about 30 bits per second. In the case of a repetitive signal, such as insect stridulation or many varieties of birdsong, the repetition conveys no extra information, so $n(T)$ is constant once T exceeds the repetition time and the rate of information transfer is then inversely proportional to the time considered. Repetition, however, can ensure the accurate reception of the information and can also transmit the signal to a wider community.

The study of information transfer by different varieties of animals is a very rich field that continues to excite the interest of a large number of biologists. Such studies can greatly enrich our knowledge of the animal world.

Further Reading

The number of books and papers published in this field is very large, so that the reference list below is a rather eclectic selection. Generally descriptive and behavioral references have not been included, and the list concentrates on those that apply physical and mathematical analysis to bioacoustic systems.

20. Cetacean Acoustics

Whitlow W. L. Au, Marc O. Lammers

The mammalian order cetacea consist of dolphins and whales, animals that are found in all the oceans and seas of the world. A few species even inhabit fresh water lakes and rivers. A list of 80 species of cetaceans in a convenient table is presented by *Ridgway* [20.1]. These mammals vary considerably in size, from the largest living mammal, the large blue whale (*balaenoptera musculus*), to the very small harbor porpoise (*phocoena phocoena*) and Commerson's dolphin (*cephalorhynchus commersonnii*), which are typically slightly over a meter in length.

Cetaceans are subdivided into two suborders, odontoceti and mysticeti. Odontocetes are the toothed whales and dolphins, the largest being the sperm whale (*physeter catodon*), followed by the Baird's beaked whale (*berardius bairdii*) and the killer whale (*orcinus orca*). Within the suborder odontoceti there are four superfamilies: *platanistoidea*, *delphinoidea*, *ziphioidea*, and *physeteridea*. Over half of all cetaceans belong to the superfamily *delphinoidea*, consisting of seven species of medium whales and 35 species of small whales

also known as dolphins and porpoises [20.1]. Dolphins generally have a sickle-shaped dorsal fin, conical teeth, and a long rostrum. Porpoises have a more triangular dorsal fin, more spade-shaped teeth, and a much shorter rostrum [20.1].

Mysticetes are toothless, and in the place of teeth they have rigid brush-like whalebone plate material called baleen hanging from their upper jaw. The baleen is used to strain shrimp, krill, micronekton, and zooplankton. All the great whales are mysticetes or baleen whales and all are quite large. The sperm and Baird's beaked whales are the only odontocetes that are larger than the smaller mysticetes such as Minke whales and pygmy right whales. Baleen whales are subdivided into four families, *balaenidae* (right and bowhead whales), *eschrichtiidae* (gray whales), *balaenopteridae* (Minke, sei, Bryde's, blue, fin, and humpback whales), and *neobalaenidae* (pygmy right whale).

Acoustics play a large role in the lives of cetaceans since sound travels underwater better than any other

form of energy. Vision underwater is limited to tens of meters under the best conditions and less than a fraction of a meter in turbid and murky waters. Visibility is also limited by the lack of light at great depths during the day and at almost any depth on a moonless night. Sounds are used by marine mammals for myriad reasons such as group cohesion, group coordination, communications, mate selection, navigation and locating food. Sound is also used over different spatial scales from tens of km for some species and tens of meters for other species, emphasizing the fact that different species utilize sound in different ways. All odontocetes seem to have the capability to echolocate, while mysticetes do not echolocate except in a very broad sense, such as listening to their sound bouncing off the bot-

tom, sea mounts, underwater canyon walls, and other large objects.

The general rule of thumb is that larger animals tend to emit lower-frequency sounds and the frequency range utilized by a specific species may be dictated more from anatomical constraints than any other factors. If resonance is involved with sound production, then anatomical dimensions become critical, that is, larger volumes resonate at lower frequencies than smaller volumes. The use of a particular frequency band will also have implications as to the distance other animals, including conspecifics, will be able to hear the sounds. Acoustic energy is lost in the propagation process by geometric spreading and absorption. Absorption losses are frequency dependent, increasing with frequency. Therefore, the sounds of baleen whales such as the blue whale that emit sounds with fundamental frequencies as low as 15 Hz can propagate to much longer distances than the whistles of dolphins that contain frequencies between 5 and 25 kHz.

20.1 Hearing in Cetaceans

One of the obvious adaptations for life in the sea is the absence of a pinna in cetaceans. The pinna probably disappeared through a natural selection process because it would obstruct the flow of water of a swimming animal and therefore be a source of noise. In the place of a pinna, there is a pin-hole on the surface of a dolphin's head which leads to a ligament inside the head, essentially rendering the pinna nonfunctional in conducting sounds to the middle ear. So, how does sounds enter into the heads of cetacean? Several electrophysiological experiments have been performed in which a hydrophone is held at different locations on an animal's head and the electrophysiological thresholds are determined as a function of the position of the hydrophone [20.2–4]. All three studies revealed greatest sensitivity on the dolphin's lower jaw.

The experimental configuration of *Møhl* et al. [20.2] is shown in Fig. 20.1a, which shows a *suction-cup hydrophone* and attached a bottlenose dolphin's lower jaw and the surface contact electrodes embedded in suction cups used to measure the auditory brainstem potential signals for different levels of sound intensity. The important differences in the experiment of *Møhl* et al. [20.2] are that the subject was trained and the measurements were done in air so that the sounds were limited to the immediate area where they were applied. The results of the experiment are shown in Fig. 20.1b. The location of maximum sensitivity to sound is slightly forward of the pan-bone area of the lower jaw, a location where *Norris* [20.5] hypothesized that sounds enter the head of a dolphin. Numerical simulation work by *Aroyan* [20.6] suggest that sounds enter the dolphin's
Fig. 20.1 (a) The experimental geometry used by *Møhl* et al. [20.2], (b) results of the auditory brainstem response (ABR) threshold measurements. The numerical values represent the amount of attenuation of the sound needed to obtain an ABR threshold. Therefore, the higher the number the more sensitive the location

head forward of the pan bone, but a good portion of the sound propagates below the skin to the pan bone and enters the head through the pan bone. The fact that sounds probably propagate through the lower jaw of dolphins and other odontocetes does not necessarily mean that the same or a similar propagation process is occurring with baleen whales.

20.1.1 Hearing Sensitivity of Odontocetes

Almost all our knowledge of hearing in cetaceans comes from studies performed with small odontocetes. The most studied species is the Atlantic bottlenose dolphin (*tursiops truncatus*). Despite the amount of research performed with the bottlenose dolphin, our understanding of auditory processes in these animals lags considerably behind that for humans and other terrestrial mammals. There are still many large gaps in our knowledge of various auditory processes occurring within the most studied odontocetes. The first audiogram for a cetacean was measured by *Johnson* [20.9] for a *tursiops truncatus*. Since then, audiograms have been determined for the harbor porpoise (*phocoena phocoena*) by *Andersen* [20.10] and *Kastelein* et al. [20.11], the killer whale (*orcinus orca*) by *Hall* and *Johnson* [20.12] and *Szymanski* et al. [20.13], the beluga whale (*delphinapterus leucas*) by *White* et al. [20.14], the Pacific bottlenose dolphin (*tursiops gilli*) by *Ljungblad* et al. [20.15], the false killer whale (*pseudorca crassidens*) by *Thomas* et al. [20.16], the Chinese river dolphin (*lipotes vexil-*

lifer) by *Wang* et al. [20.17], Risso's dolphins (*grampus griseus*) by *Nachtigall* et al. [20.18], the tucuxi (*sotalia fluviatilis*) by *Sauerland* and *Dehnhardt* [20.19], and the striped dolphin (*stenella coeruleoalba*) by *Kastelein* et al. [20.20]. The audiograms of these odontocetes are shown in Fig. 20.2. It is relatively striking to see how similar the audiograms are between species considering the vastly different habitats and areas of the world where some of these animals are found and the large differences in body size. All the audiograms suggest high-frequency hearing capabilities, with the smallest animal, *phocoena phocoena* having the highest hearing limit close to 180 kHz. However, the *orcinus orca*, which is over 95 times heavier and about six times longer can hear up to about 105 kHz. The actual threshold values shown in Fig. 20.2 should not be compared between species because the different methods of determining the threshold can lead to different results and because of the difficulties of obtaining good sound pressure level measurements in a reverberant environment. For example, *Kastelein* et al. [20.11] used a narrowband frequency-modulated (FM) signal to avoid multipath problems and the FM signals may provide additional cues not present in a pure-tone signal. Nevertheless, the audiograms shown in Fig. 20.2 suggest that all the animals had similar thresholds of 10–15 dB.

A summary of some important properties of the different audiograms depicted in Fig. 20.2 is given in Table 20.1. In the table, the frequency of best hearing is arbitrary defined as the frequency region in which
Fig. 20.2 Audiogram for different odontocetes species (after [20.7, 8])

Table 20.1 Some important properties of the audiograms plotted in Fig. 20.2

Species	Maximum sensitivity (dB re 1 : Pa)	Frequency of best hearing (kHZ)	Upper frequency limit (kHz)
phocoena phocoena	32	18–130	180
stenella coeruleoalba	42	30–125	160
tursiops truncatus	42	15–110	150
tursiops gilli	47	30–80	135
sotalia fluviatilis	50	35–50	135
delphinapterus leucas	40	11–105	120
pseudorca crassidens	39	17–74	115
orcinus orca	34	15–40	110
inia geoffrensis	51	12–64	100
lipotes vexillifer	55	15–60	100
grampus griseus	–	–	100

the auditory sensitivity is within 10 dB of the maximum sensitivity depicted in each audiogram of Fig. 20.2. With the exception of the *Orcinus* and the *Lipotes*, the maximum sensitivity of the rest of the species represented in Fig. 20.2 and Table 20.1 are very similar, and within experimental uncertainties, especially for audiograms obtained with the staircase procedure using relatively large step sizes of 5 dB or greater. At the frequency of best hearing, the threshold for *Orcinus* and *Phocoena* are much lower than for the other animals. It is not clear whether this keen sensitivity is a reflection of a real difference or a result of some experimental artifact. The data of Table 20.1 also indicate that *Phocoena phocoena*, *Stenella coeruleoalba* and *Tursiops truncatus* seem to have the widest auditory bandwidth.

20.1.2 Directional Hearing in Dolphins

Sound Localization
The ability to localize or determine the position of a sound source is important in order to navigate, detect prey and avoid predators and avoid hazards producing an acoustic signatures. The capability to localize sounds has been studied extensively in humans and in many vertebrates (see [20.21]). Lord Rayleigh in 1907 proposed that humans localized in the horizontal plane by using interaural time differences for low-frequency sounds and interaural intensity differences for high-frequency sounds. The sound localization acuity of a subject is normally defined in terms of a minimum audible angle (MAA), defined as the angle subtended at the subject by two sound sources, one being at a reference azimuth, at which the subject can just discriminate the sound sources as two discrete sources [20.22]. If the sound sources are separated symmetrically about a midline, the MAA is one half the threshold angu-

lar separation between the sound sources. If one of the sound sources is located at the midline, then the MAA is the same as the threshold angular separation between the two sources.

Renaud and *Popper* [20.23] examined the sound localization capabilities of a *tursiops truncatus* by measuring the MAA in both the horizontal and vertical planes. During a test trial the dolphin was required to station on a bite plate facing two transducers positioned at equal angles from an imaginary line running through the center of the bite plate. An acoustic signal was then transmitted from one of the transducers and the dolphin was required to swim and touch the paddle on the same side as the emitting transducer. The angle between the transducers was varied in a modified staircase fashion. If the dolphin was correct for two consecutive trials, the transducers were moved an incremental distance closer together, decreasing the angle between the transducer by 0.5°. After each incorrect trial, the transducers were moved an incremental distance apart, increasing the angle between the transducers by 0.5°. This modified staircase procedure allowed threshold determination at the 70% level. The threshold angle was determined by averaging a minimum of 16 reversals. A randomized schedule for sound presentation through the right or left transducer was used.

The localization threshold determined in the horizontal and vertical planes as a function of frequency for narrow-band pure-tone signals is shown in Fig. 20.3. The MAA had a U-shaped pattern, with a large value of 3.6° at 6 kHz, decreasing to a minimum of 2.1° at 20 kHz and then slowly increasing in an irregular fashion to 3.8° at 100 kHz. MAAs for humans vary between 1° and 3.7°, with the minimum at a frequency of approximately 700 Hz [20.24]. The region where the MAA decreased to a minimum in Figs. 20.19 and 20.20

a) MAA (deg)

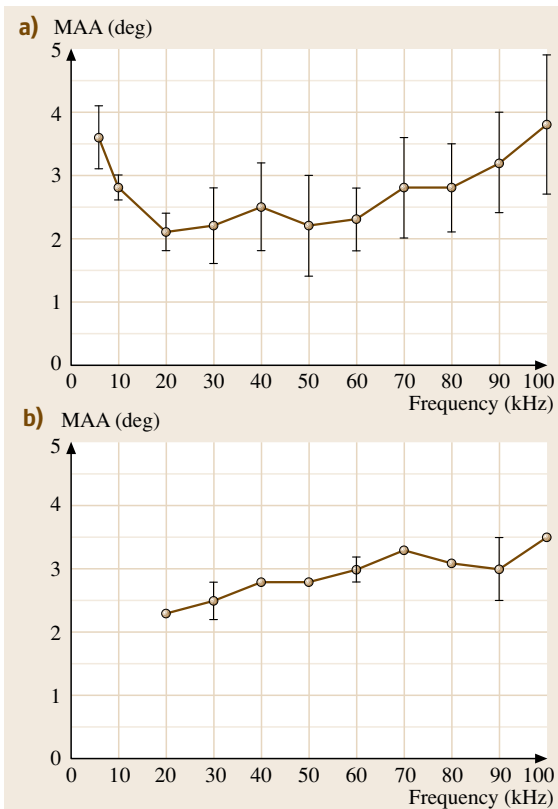
b) MAA (deg)


Fig. 20.3 (a) Localization threshold determined in the horizontal plane as a function of frequency. The mean ± one standard deviation is shown for seven determinations per frequency. The animal faced directly ahead at 0° azimuth. **(b)** Localization threshold determined in the vertical plane as a function of frequency. Standard deviation are indicated for 30, 60 and 90 kHz vertical data (seven sessions each). The dolphin's azimuth was 0° (after *Renauld* and *Popper*, [20.27]) Figs. 20.19 and 20.20

(about 20 kHz) may be close to the frequency at which the dolphin switches from using interaural time difference cues to interaural intensity difference cues. The MAAs for the bottlenose dolphin were smaller than the MAAs (in the horizontal plane) of 3.5° at 3.5 kHz and 6° at 6 kHz for a harbor porpoise measured by *Dudok van Heel* [20.25], and 3° at 2 kHz, measured by *Andersen* [20.26] also for a harbor porpoise.

In order to measure the MAA in the vertical plane, the dolphin was trained to turn to its side (rotate its body 90° along its longitudinal axis) and to bite on a sheet of plexiglass which was used as the stationing device. The MAA in the vertical plane varied between 2.3° at 20 kHz to 3.5° at 100 kHz. These results indicate that the animal could localize in the vertical plane nearly as well as in the horizontal plane. These results were not expected since binaural affects, whether interaural time or intensity, should not be present in the vertical plane. However, the dolphin's ability to localize sounds in the vertical plane may be explained in part by the asymmetry in the receive beam patterns in the vertical plane discussed in the next section.

Renaud and *Popper* [20.23] also determined the MAA for a broadband transient signal or click signal, having a peak frequency of 64 kHz and presented to the dolphin at a repetition rate of 333 Hz. The MAA in the horizontal plane was found to be approximately 0.9° and 0.7° in the vertical plane. It is not surprising that a broadband signal should result in a lower MAA than a pure-tone signal of the same frequency as the peak frequency of the click. The short onset time and the broad frequency spectrum of a click signal should provide additional cues for localization.

Receiving Beam Patterns

Having narrow transmission and reception beams allows the dolphin to localize objects in a three-dimensional volume, spatially separate objects within a multi-object field, resolve features of extended or elongated objects, and to minimize the amount of interference received. The amount of ambient noise from an isotropic noise field and the amount of reverberation interference received is directly proportional to the width of the receiving beam. The effects of discrete or partially extended interfering noise or reverberant sources can be minimized by simply directing the beams away from the sources.

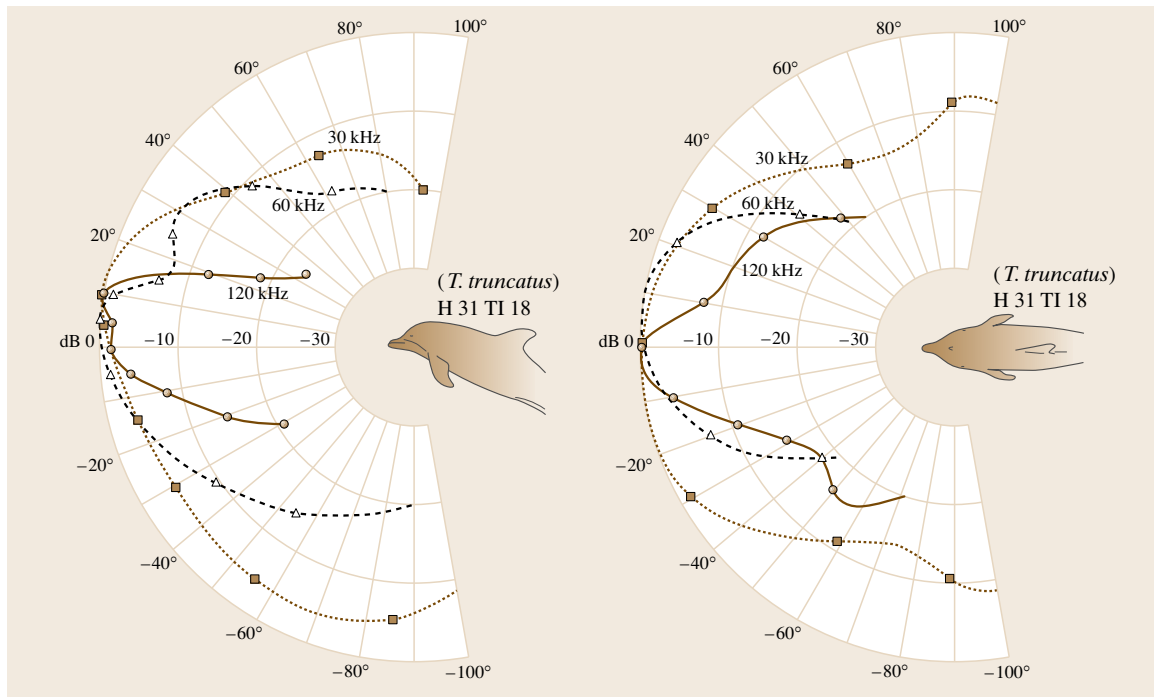
The receiving beam pattern of a dolphin was determined by measuring the masked hearing threshold as a function of the azimuth about the animal's head. The relative masked hearing threshold as a function of azimuth is equivalent to the received beam pattern since the receiving beam pattern is the spatial pattern of hearing sensitivity. *Au* and *Moore* [20.28] measured the dolphin's masked hearing threshold as the position of either the noise or signal sources varied in their angular position about the animal's head. The dolphin was required to voluntarily assume a stationary position on a bite plate constructed out of a polystyrene plastic material. The noise and signal transducers were positioned along an arc with the center of the arc located approximately at the pan bone of the animal's lower jaw. In order to measure the dolphin's receiving beam in the vertical plane, the animal was trained to turn


Fig. 20.4 Receive beam patterns in the vertical and horizontal planes for frequencies of 30, 60 and 120 kHz. The relative masked thresholds as a function of the elevation angle of the asking noise source are plotted for each signal frequency (after *Au* and *Moore*, [20.28])

onto its side before biting the specially designed vertical bite-plate stationing device. For the measurement in the vertical plane, the position of the signal transducer was fixed directly in line with the bite plate and its acoustic output was held constant. Masked thresholds were measured for different angular position of the noise transducer along the arc. The level of the noise was varied in order to obtain the masked threshold. A threshold estimate was considered complete when at least 20 reversals (10 per session) at a test angle had been obtained over at least two consecutive sessions, and if the average reversal values of the two sessions were within 3 dB. After a threshold estimate was achieved, the noise transducer was moved to a new azimuth over a set of randomly predesignated azimuths. As the azimuth about the dolphin's head increased, the hearing sensitivity of the dolphin tended to decrease, requiring higher levels of masking noise from a transducer located at that azimuth to mask the signal from a source located directly ahead of the animal.

The receiving beam patterns in both the vertical and horizontal plane are plotted for signal frequencies of 30, 60 and 120 kHz in Fig. 20.4. The radial axis of Fig. 20.4

represents the difference in dB between the noise level needed to mask the test signal at any azimuth and the minimum noise level needed to mask the test signal at the azimuth corresponding to the major axis of the vertical beam. The shape of the beams in Fig. 20.4 indicates that the patterns were dependent on frequency, becoming narrower, or more directional as the frequency increased. The beam of a planar hydrophone also becomes narrower as frequency increases. The 3 dB beam widths were approximately 30.4°, 22.7°, and 17.0° for frequencies of 30, 60, and 120 kHz, respectively. There was also an asymmetry between the portion of the beam above and below the dolphin's head. The shape of the beams dropped off more rapidly as the angle above the animal's head increased than for angles below the animal's head, indicating a more rapid decrease in the animal's hearing sensitivity for angles above the head than for angles below the head. If the dolphin receives sounds through the lower jaw, the more rapid reduction in hearing sensitivity for angles above the head may have been caused by shadowing of the received sound by the upper portion of the head structure including air in the nasal sacs [20.29]. There is a slight peculiarity in

the 60 kHz beam which shows almost the same masked threshold values for 15° and 25° elevation angles.

The radial line passing through the angle of maximum sensitivity is commonly referred to as the major axis of the beam. The major axis of the vertical beams is elevated between 5° and 10° above the reference axis. The 30 and 120 kHz results show the major axis at 10° while the 60 kHz results showed the major axis at 5°. It will be shown in a later section that the major axis of the received beam in the vertical plane is elevated at approximately the same angle as the major axis of the transmitted beam in the vertical plane.

In the horizontal beam pattern measurement, two noise sources were fixed at azimuth angles of ±20°. The level of the noise sources was also fixed. The position of the signal transducer was varied from session to session. Masked thresholds were determined as a function of the azimuth of the signal transducer, by varying the signal level of the signal transducer in a staircase fashion. A threshold estimate was considered completed when at least 20 reversals at a test angle had been obtained over at least two consecutive sessions, if the average reversal values were within 3 dB of each other. After a threshold estimate was determined, the signal transducer was moved to a new azimuth over a set of randomly predesignated azimuths. Two noise sources were used in order to discourage the dolphin from internally steering its beam in the horizontal plane. If the animal could steer its beam, it would receive more noise from one of the two hydrophones, and therefore not experience any improvement in the signal-to-noise ratio. The masking noise from the two sources was uncorrelated but equal in amplitude. The radial axis represents the difference in dB between the signal level at the masked threshold for the various azimuths and the signal level of the masked threshold for 0° azimuth (along the major axis of the horizontal beam). The horizontal receiving beams were directed forward with the major axis being parallel to the longitudinal axis of the dolphin. The beams were nearly symmetrical about the major axis. Any asymmetry was within the margin of experimental error involved in estimating the relative thresholds. The horizontal beam patterns exhibited a similar frequency dependence as the vertical beam patterns, becoming narrower or more directional as the frequency increased. The 3 dB beam widths were 59.1°, 32.0°, and 13.7° for frequencies of 30, 60, and 120 kHz, respectively.

Zaytseva et al. [20.30] measured the horizontal beam pattern of a dolphin by measuring the masked hearing threshold as a function of azimuth. Their beam width of 8.2° for a frequency of 80 kHz was much narrower than the 13.7° for a frequency of 120 kHz. The difference in beam width is even larger if the results of *Au* and *Moore* [20.28] are linearly interpolated to 80 kHz. We calculated an interpolated beam width of 25.9° at 80 kHz, which was considerably greater than the 8.2° obtained by *Zaytseva* et al. [20.30]. The difference in beam width measured by Zaytseva et al. and Au and Moore may be attributed to the use of only one noise source by Zaytseva et al. compared to the two noise sources used by Au and Moore. With a single masking noise source in the horizontal plane, there is the possibility of the animal performing a spatial filtering operation by internally steering the axis of its beam in order to maximize the signal-to-noise ratio. Another possibility is that Zaytseva et al. did not use a fixed stationing device. Rather, the dolphin approached the signal hydrophone from a start line, always oriented in the direction of the signal hydrophone. The animal responded to the presence or absence of a signal by either swimming or not swimming to the hydrophone. In such a procedure, it is impossible to control the orientation of the animal's head with respect to the noise masker so that the dolphin could move its head to minimize the effects of the noise.

Directivity Index

The directivity index is a measure of the sharpness of the beam or major lobe of either a receiving or transmitting beam pattern. For a spherical coordinate system, the directivity index of a transducer is given by the equation [20.31]

$$ \text{DI} = 10 \log \frac{4\pi}{\int\limits_{0}^{2\pi} \int\limits_{-\pi/2}^{\pi/2} \left(\frac{p(\theta,\phi)}{p_0} \right)^2 \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi} \,. \qquad (20.1) $$

Although the expression for directivity index is relatively simple, using it to obtain numerical values can be quite involved unless transducers of relatively simple shapes (cylinders, lines and circular apertures) with symmetry about one axis is involved. Otherwise, the beam pattern needs to be measured as a function of both θ, and ϕ. This can be done by choosing various discrete values of θ and measuring the beam pattern as a function of ϕ, a tedious process. Equation (20.1) can then be evaluated by numerically evaluating the double integral with a digital computer. The directivity indices associated with the dolphin's beam patterns in Fig. 20.4 were estimated by *Au* and *Moore* [20.28] using (20.1) and a two-dimensional Simpson's 1/3-rule algorithm [20.32]. The results of the numerical evaluation of
Fig. 20.5 Receiving directivity index as function of frequency for a *tursiops truncatus*

are plotted as a function of frequency in Fig. 20.5. DIs of 10.4, 15.3 and 20.6 dB were obtained for frequencies of 30, 60, and 120 kHz, respectively. A linear curve fitted to the computed DIs in a least-square-error manner is also shown in the Fig. 20.5. The equation of the line is

$$\text{DI(dB)} = 16.9 \log f(\text{kHz}) - 14.5 \,. \qquad (20.2)$$

The results of Fig. 20.5 indicate that the dolphin's receive directivity index increased with frequency in a manner similar to that of a linear transducer (Bobber, 1970). The expression in (20.2) is only valid for frequencies at which DI(dB) is greater or equal to 0.

Although the directivity index expressed by (20.1) is for a *tursiops*, it can also be used to estimate the directivity index of other dolphins by applying an appropriate correction factor, so that (20.2) can be rewritten as

$$\text{DI(dB)} = 16.9 \log f(\text{kHz}) - 14.5 + \text{CF(dB)} \,, \qquad (20.3)$$

where CF(dB) is a correction factor taking into account different head sizes. The directivity index of a planar circular plate is proportional to its diameter so if we let d_T be the diameter of the head of a *tursiops* at about the location of the blowhole and d_D be the diameter of the head of a different species of dolphin, then the correction factor can be expressed as

$$\text{CF(dB)} = 20 \log(d_D/d_T) \,. \qquad (20.4)$$

The correction factor will be positive for a dolphin with a larger head and negative for a dolphin with a smaller head than *tursiops*.

20.1.3 Hearing by Mysticetes

Our knowledge of the hearing characteristics of baleen whales is extremely limited. We do not know how they receive sounds, the frequency range of hearing, and the sensitivity of hearing at any frequency. Much of our understanding of hearing in baleen whales comes from anatomical studies of the ears of different species. Baleen whales have occluded external auditory canals that are filled with a homogeneous wax [20.33]. The lower jaws of mysticetes are designed for sieving or gulp feeding and have no evident connection to the temporal bones [20.33] making it very difficult to understand how sounds enter into the ears of these whales.

Various types of whales have been observed by many investigators to react strongly and drastically change their behavior in the presence of boats and low-flying aircraft, however, the sound pressure levels at the whales' locations are often difficult to define and measure. In some situations, the sound levels of the aversive sound could be estimated and a data point obtained. Bowhead whales were observed fleeing from a 13 m diesel-powered boat having a noise level at the location of the whales of about 84 dB re 1 µPa in the dominant 1/3-octave band, or about 6 dB above the ambient noise in that band [20.34]. Playback experiments with bowhead whales indicated that they took evasive action when the noise was about 110 dB re 1 µPa or 30 dB above the ambient noise in the same 1/3-octave band [20.35]. Playback experiments with migrating gray whales indicated that about 10% of the whales made avoidance behavior when the noise was about 110 dB in a 1/3 octave band, 50% at about 117 dB and 90% at about 122 dB or greater. These playback signals consisted of anthropogenic noise associated with the oil and gas industry.

Frankel [20.36] played back natural humpback whale sounds and a synthetic sound to humpback whales wintering in the waters of the Hawaiian islands. Twenty seven of the 1433 trials produced rapid approach response. Most of the responses were to the feeding call. Feeding call and social sounds produced changes in both separation and whale speed, indicating that these sounds can alter a whale's behavior. The humpback whales responded to sounds as low as 102–105 dB but the strongest responses occurred when the sounds were 111 to 114 dB re 1 µPa.

All of the playback experiments suggest that sounds must be between 85 and 120 dB before whales will react to them. These levels are very high compared to those that dolphins can hear and may suggest that it is very

difficult to relate reaction to hearing sensitivity. Whales may not be reacting strongly unless the sounds are much higher than their hearing threshold.

Determining the hearing sensitivity or audiogram of baleen whales represents an extremely difficult challenge and will probably require the use of some sort of electrophysiological technique as suggested by *Ridgway* et al. [20.37]. Perhaps a technique measuring auditory-evoked potentials with beached whales may provide a way to estimate hearing sensitivity. Even with evoked potential measurements, there are many issues that have to be considered. For example, if an airborne source is used, the results cannot be translated directly to the underwater situation. If a sound source is placed on a whale's head, relating that to a whale receiving a plane wave will also not be simple. Measurement of evoked potentials themselves may not be simple because of the amount of flesh, muscles and blubber that the brain waves would have to travel through in order to reach the measurement electrodes. *Ridgway* and *Carder* [20.38] reported on some attempts to use the evoked potential method with a young gray whale held at Sea World in California. They also showed that the pygmy whale auditory system was most sensitive to very high frequencies (120–130 kHz) in the same range as their narrow-band echolocation pulses. A young sperm whale was most sensitive in the 10–20 kHz region of the spectrum [20.38].

20.2 Echolocation Signals

Echolocation is the process in which an organism projects acoustic signals and obtains a sense of its surroundings from the echoes it receives. In a general sense, any animal with a capability to hear sounds can echolocate by emitting sounds and listening to the echoes. A person in an empty room can gain an idea of the size and shape of the room by emitting sounds and listening to the echoes from the different walls. However, in this chapter, echolocation is used in a more specific sense in which an animal has a very specialized capability to determine the presence of objects considerably smaller than itself, discriminate between various objects, recognize specific objects and localize objects in three-dimensional space (determine range and azimuth). Dolphins and bats have this specialized capability of echolocation.

The echolocation system of a dolphin can be broken down into three subsystems: the transmission, reception and signal processing/decision subsystems. The reception system has to do with hearing and localization. The transmission system consist of the sound production mechanism, acoustic propagation from within the head of the dolphin to into the water, and the characteristics of the signals traveling in the surrounding environment. The third subsystem has to do with processing of auditory information by the peripheral and central nervous system. The capability of a dolphin to detect objects in noise and in clutter, and to discriminate between various objects depends to a large extent on the information-carrying capabilities of the emitted signals.

Dolphins most likely produce sounds within their nasal system and the signals are projected out through the melon. Although there has been a long-standing controversy on whether sounds are produced in the lar-

ynx or in the nasal system of odontocetes, almost all experimental data with dolphins indicate that sounds are produced in the nasal system [20.39]. For example, *Ridgway* and *Carder* [20.40] used catheters accepted into the nasal cavity by trained belugas. The belugas preformed an echolocation task in open water, detecting targets and reported the presence of targets by whistling. Air pressure within the nasal cavity was shown to be essential for echolocation and for whistling [20.40].

The melon immediately in front of the nasal plug may play a role in channeling sounds into the water, a notion first introduced by *Wood* [20.41]. *Norris* and *Harvey* [20.42] found a low-velocity core extending from just below the anterior surface towards the right nasal plug, and a graded outer shell of high-velocity tissue. Such a velocity gradient could channel signals originating in the nasal region in both the vertical and horizontal planes. Using both a two-dimensional [20.43] and a three-dimensional model [20.6] to study sound propagation in a dolphin's head, Aroyan has shown that echolocation signals most likely are generated in the nasal system and are channeled into the water by the melon. *Cranford* [20.44] has also collected evidence from nasal endoscopy of trained echolocating dolphins that suggest that echolocation signals are most likely produced in the nasal system at the location of the monkey-lips, dorsal bursae complex just beneath the blow hole.

20.2.1 Echolocation Signals of Dolphins that also Whistle

Most dolphin species are able to produce whistle signals. Among some of the species in this category

in which echolocation signals have been measured include the bottlenose dolphin (*tursiops sp*), beluga whale (*delphinapterus leucas*), killer whale (*orcinus orca*), false killer whale (*pseudorca crassidens*), Pacific white-sided dolphin (*lagenorhynchus obliquidens*), Amazon river dolphin (*inia geoffrensis*), Risso's dolphin (*grampus griseus*), tucuxi (*sotalia fluviatilis*), Atlantic spotted dolphin (*stenella frontalis*), Pacific spotted dolphin (*Stenella attenuata*), spinner dolphin (*Stenella longirostris*), pilot whale (*globicephala sp*), rough-toothed dolphin (*steno bredanesis*), Chinese river dolphin (*lipotes vexillifer*) and sperm whales (*physeter catodon*). However, most of the available data have been obtained for three species: the bottlenose dolphin, the beluga whale and the false killer whale.

Prior to 1973, most echolocation signals of *tursiops* were measured in relatively small tanks and the results provided a completely different picture of what we currently understand. It was not until the study of *Au* et al. [20.45] that certain features of biosonar signals used by *tursiops* and other dolphins in open waters were discovered. We discovered that the signals had peak frequencies between 120 and 130 kHz, over an octave higher than previously reported peak frequencies between 30 and 60 kHz [20.46]. We also measured an average peak-to-peak click source level on the order of 220 dB re 1 μPa at 1 m, which represents a level 30 to 50 dB higher than previously measured for *tursiops*. Examples of typical echolocation signals emitted by *tursiops truncatus* are shown in Fig. 20.6 for two situations. The top signal is typical of signals used in the open waters of Kaneohe Bay, Oahu, Hawaii, and the second signal represents typical signals for a *tursiops* in a tank. Signals measured in Kaneohe Bay regularly have duration between 40 and 70 μs, 4 to 10 positive excursion, peak frequencies between 110 and 130 kHz and peak-to-peak source levels between 210 and 228 dB re 1 μPa. The signals in Fig. 20.6 are not drawn to scale; if they were, the tank signal would resemble a flat line.

Au et al. [20.47] postulated that high-frequency echolocation signals were a byproduct of the animals producing high-intensity clicks to overcome snapping shrimp noise. In other words, dolphins can only emit high-level clicks (greater than 210 dB) if they use high frequencies. The effects of a noisy environment on the echolocation signals used by a beluga or white whale (*Delphinapterus leucas*) was vividly demonstrated by *Au* et al. [20.47]. The echolocation signal of a beluga was measured in San Diego Bay, California before the whale was moved to Kaneohe Bay. The ambient noise
Fig. 20.6 Example of echolocation signals used by *tursiops truncatus* in Kaneohe Bay (after *Au* [20.45]), and in a tank

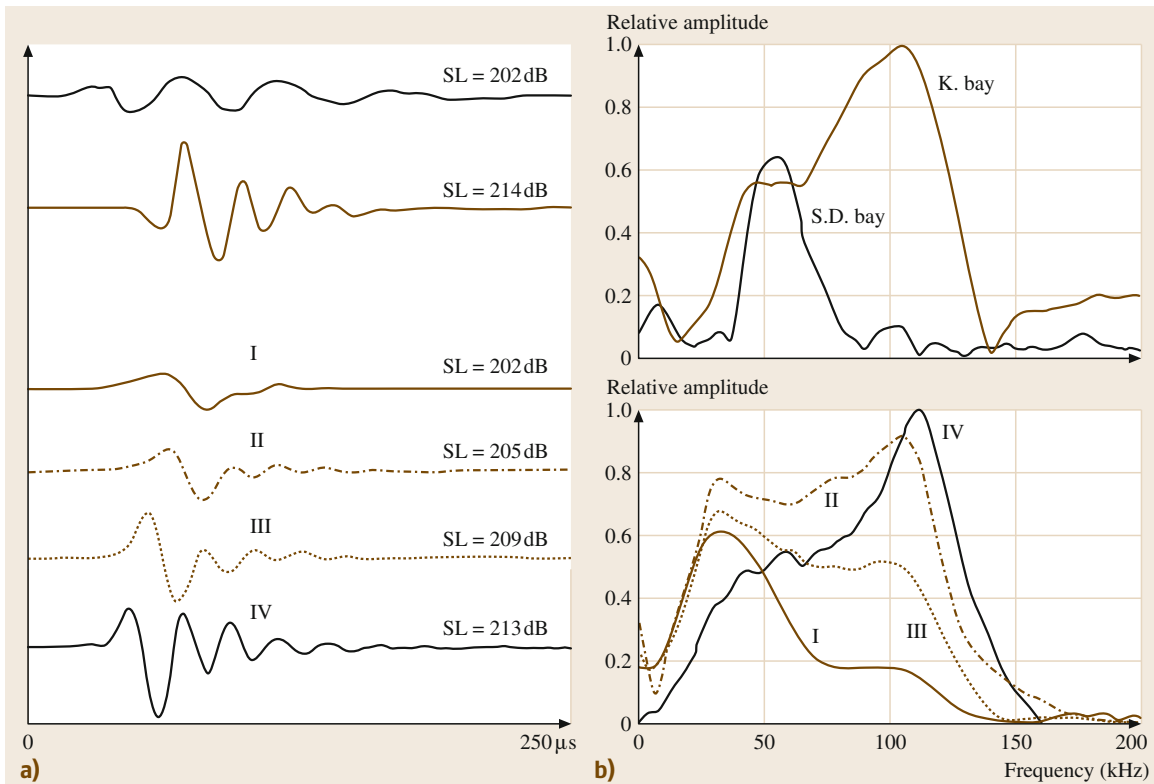
in Kaneohe Bay is between 15 to 20 dB greater than in San Diego Bay. The whale emitted echolocation signals with peak frequencies between 40 and 60 kHz and with a maximum averaged peak-to-peak source level of 202 dB re 1 μPa in San Diego Bay. In Kaneohe Bay, the whale shifted the peak frequency of its signals over an octave higher to 100 and 120 kHz. The source level also increased to over 210 dB re 1 μPa [20.47]. Examples of typical echolocation signals used by the whale in San Diego and in Kaneohe Bay are shown in Fig. 20.7a. Here, the signals are drawn to scale with respect to each other. Echolocation signals used by belugas in tanks also resemble the low-frequency signals shown in Fig. 20.2a [20.48, 49]. *Turl* et al. [20.50] measured the sonar signals of a beluga in a target-in-clutter detection task in San Diego Bay and found the animal used high-frequency (peak frequency above 100 kHz) and high-intensity (greater than 210 dB re 1 μPa) signals. Therefore low-amplitude clicks of the beluga had low peak frequencies and the high-amplitude clicks had high peak frequencies. The data of *Moore* and *Pawloski* [20.51] for *Tursiops* also seem to support the


Fig. 20.7 (a) Example of beluga echolocation signals measured in San Diego Bay and in Kaneohe Bay (after *Au* et al. [20.47]); **(b)** Examples of *pseudorca* echolocation signals, Sl is the averaged peak-to-peak source level (after *Au* et al. [20.52])

notion that the shape of the signal in the frequency domain is related to the intensity of the signal.

Recent results with a false killer whale showed a clear relationship between the frequency content of echolocation signals and source level [20.52]. The *Pseudorca* emitted four basic types of signals, which are shown in Fig. 20.7b. The four signal types have spectra that are bimodal (having two peaks); the spectra in Fig. 20.2 are also bimodal. The type I signals were defined as those with the low-frequency peak (< 70 kHz) being the primary peak and the high-frequency peak being the secondary peak with its amplitude at least 3 dB below that of the primary peak. Type II signals were defined as those with a low-frequency primary peak and a high-frequency secondary peak having an amplitude within 3 dB of the primary peak. Type III signals were those with a high-frequency primary peak (> 70 kHz), and a low-frequency secondary peak having an amplitude within 3 dB of the primary peak. Finally, type IV signals were those with a high-frequency primary peak

having an amplitude that was at least 3 dB higher than that of the secondary low-frequency peak.

The data of *Thomas* et al. [20.53, 54] also indicated a similar relationship between intensity and the spectrum of the signal. The echolocation signals of a *pseudorca* measured in a tank had peak frequencies between 20 and 60 kHz and source levels of approximately 180 dB re 1 µPa [20.53]. Most of the sonar signals used by another *pseudorca* performing a detection task in the open waters of Kaneohe Bay had peak frequencies between 100 and 110 kHz and source levels between 220 and 225 dB re 1 µPa [20.54].

A bimodal spectrum is best described by its center frequency, which is defined as the centroid of the spectrum, and is the frequency which divides the spectrum into two parts of equal energy. From Fig. 20.7, we can see that, as the source level of the signal increased, the frequency components at higher frequencies also increased in amplitude, suggesting a relationship between source level and center frequency. This relationship

can be examined by considering the scatter diagram of Fig. 20.8 showing center frequency plotted against source level. The solid line in the figure is a linear-regression curve fit of the data and has a correlation coefficient of 0.80.

The bimodal property of the echolocation signals of Fig. 20.7 seems to suggest that the response of the sound generator may be determined by the intensity of the driving force that eventually causes an echolocation signal to be produced. When the intensity of the driving force is low, only signals with low amplitudes and low-frequency peak are produced. Therefore, in small tanks, the signals resemble the tank signal of Fig. 20.1, and the bimodal feature is suppressed since the high-frequency portion of the source cannot be used for a low driving force. As the driving force increases to a moderate level, the low-frequency peak also increases in amplitude, and the high-frequency portion of the signal begins to come into use. As the driving force increases further the amplitude of the high-frequency peak becomes larger than that of the low-frequency peak, resulting in type III signals. As the driving force continues to increase to a high level, the amplitude of the high-frequency peak becomes much greater than the amplitude of the low-frequency peak and completely dominates the low-frequency peak causing the bimodal feature to be suppressed. Recent field measurements of free-ranging dolphins [20.55–57] suggest that the majority of echolocation clicks emitted by dolphins are bimodal.

The largest odontocete species is the sperm whale (*Physeter catodon*) and it too emits echolocation signals. Prior to the late 1990s the most prevalent understanding of sperm whale signals is that the clicks were broadband with peak frequencies between 4 and 8 kHz [20.58–61]. There were only two reports on source levels. *Dunn* [20.62] using sonobouys measured 148 sperm whale clicks from a solitary sperm whale and estimated an average peak-to-peak source level of 183 dB re 1 μPa. *Levenson* [20.59] estimated peak-to-peak source level of 180 dB re 1 μPa. The clicks were also thought to be essentially nondirectional and projected in codas [20.63]. Therefore, the notion of sperm whales echolocating was somewhat questionable. Part of the problem was the lack of measurements of sperm whale signaling in conjunction with foraging and the fact that click signals can have more than one function, such as communications and echolocation. In a review paper *Watkins* [20.63] spelled out his rational for not supporting the notion of a sonar function for sperm whale clicks, *Other features of their sounds however, do not so easily fit echolocation:* Watkin's rational included
Fig. 20.8 Center frequency of echolocation signals emitted by a *pseudorca* as a function of the peak-to-peak source level (after *Au* et al. [20.52])

his observations that clicks do not appear to be very directional, the inter-click interval does not varied as if a prey or obstacle is being approached, solitary sperm whales are silent for long periods, the level of their clicks appears to be generally greater than that required for echolocating prey or obstacles and the individual clicks are usually too long for good range resolution. It is important to state that most of Watkins measurements were conducted at low-temperate latitudes where females and calves are found.

Sperm whale echolocation began to be more fully understood with data obtained in ground-breaking work by Bertel Møhl and his students from the University of Aarhus, along with other Danish colleagues. They began to perform large-array aperture measurements of large bull sperm whales foraging along the slope of the continental shelf off Andenes, Norway beginning in the summer of 1977 [20.64]. Up to seven multi-platforms spaced on the order of 1 km apart were used in their study with hydrophones placed at depths varying from 5 to 327 m [20.65]. They also came up with a unique but logistically simple scheme of obtaining global positioning system (GPS) information to localize the position of each platform. Each platform continuously logged its position and time stamps on one track of a digital audio tape (DAT) recorder, the other track being used for measuring sperm whale clicks [20.64]. The GPS signals were converted to an analog signal by frequency-shift keying (FSK) modulation. In this way, each platform can be operated essentially autonomously and yet its location and time stamps could be related to all the other platforms.

An important finding of *Møhl* et al. [20.64] is the monopulsed nature of on-axis clicks emitted by the sperm whales that were similar in shape and spectrum to dolphin echolocation signals but with peak frequencies between 15 and 25 kHz (this peak frequency range is consistent with the auditory sensitivity observed from evoked potential responses by a young sperm whale to clicks presented by *Ridgway* and *Carder* [20.38]). *Møhl* et al. [20.64] also estimated very high source levels as high as 223 dB re 1 μPa per RMS (root mean square). The per RMS measure is the level of a continuous sine wave having the same peak-to-peak amplitude as the click. This measure is clearly an overestimate of the RMS value of a sperm whale click. Nevertheless, the 223 dB reported by *Møhl* et al. [20.64] can easily be given a peak-to-peak value of 232 dB (adding 9 dB to the per-RMS value). In a follow-on study, *Møhl* et al. [20.65] measured clicks with RMS source levels as high as 236 dB re 1 μPa using the expression

$$p_{\text{RMS}} = \sqrt{\frac{1}{T} \int_0^T p^2(t)\,\mathrm{d}t}\,. \tag{20.5}$$

For this measurement, they used a time interval corresponding to the 3 dB down points of the signal waveform. For this waveform, an RMS source level of 236 dB corresponds to a peak-to-peak source level of 243 dB re 1 μPa. Finally, they found that the clicks were very directional, as directional as dolphin clicks.

20.2.2 Echolocation Signals of Smaller Odontocetes that Do not Whistle

The second class of echolocation signals are produced by dolphins and porpoises that do not emit whistle signals. Not many odontocetes fall into this category and these non-whistling animals tend to be smaller than their whistling cousins. Included in this group of non-whistling odontocetes are the harbor porpoise (*phocoena phocoena*), finless porpoise (*neophocaena phocaenoides*), Dall's porpoise (*phocoenoides dalli*), Commerson's dolphin, *cephalorhynchus commersonii*), Hector's dolphin (*cephalorhynchus hectori*) and pygmy sperm whale (*kogia sp*).

Examples of harbor porpoise and Atlantic bottlenose dolphin echolocation signals presented in a manner for easy comparison are shown in Fig. 20.9. There are four fundamental differences in the two types

of echolocation signals. The non-whistling animal emit a signal with longer duration, narrower band, lower amplitude and single mode. The length of the *Phocoena phocoena* signal vary from about 125–150 μs compared to 50–70 μs for the *tursiops truncatus* signal. The bandwidth of the *Phocoena* signal is almost 0.2–0.3 that of the *tursiops* signal. Since the non-whistling dolphins are usually much smaller in length and weight than the whistling dolphins, the smaller animals might be amplitude limited in terms of their echolocation signals and compensate by emitting longer signals to increase the energy output. This issue can be exemplified by characterizing an echolocation click as [20.39]

$$p(t) = As(t)\,, \tag{20.6}$$

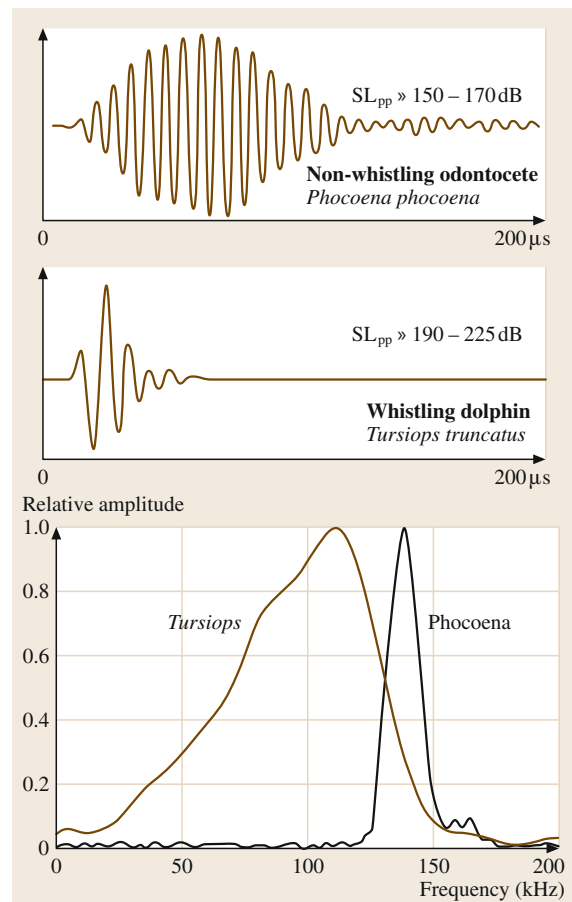
where $A = |p|_{\max}$ is the absolute value of the peak amplitude of the signal and $s(t)$ is the normalized wave-


Fig. 20.9 Examples of typical echolocation signals of *phocoena phocoena* and *tursiops truncatus* (after [20.8])
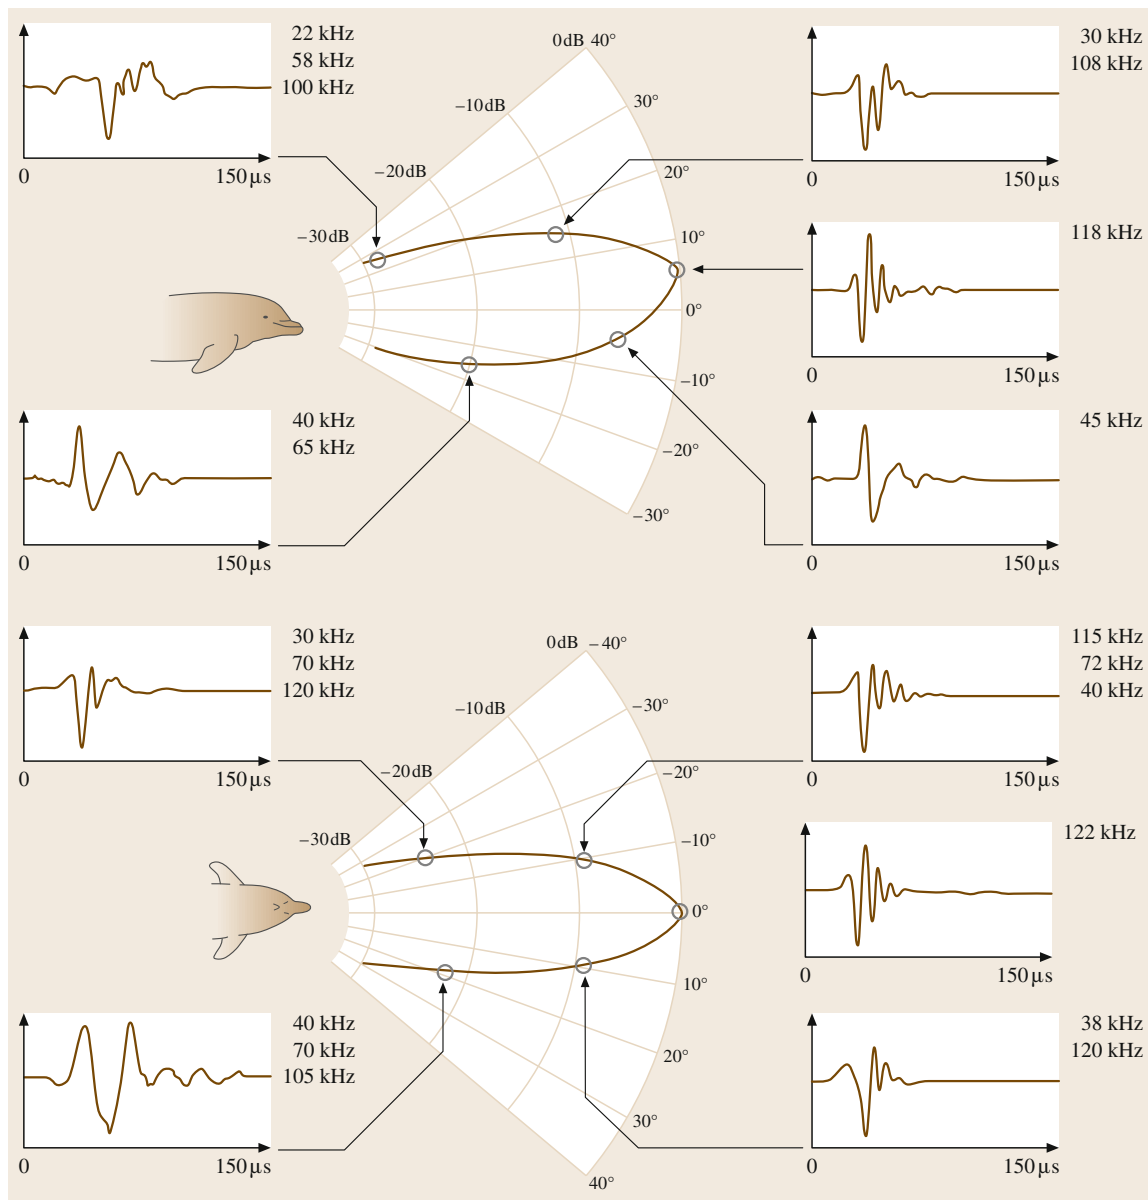

Fig. 20.10 The transmission beam pattern of a *tursiops truncatus* planes with the waveform of a click measured by 5−7 hydrophones (after *Au* [20.39]) in the vertical and horizontal planes

form having a maximum amplitude of unity. The source energy (SE)-flux density of the signal in dB can be expressed as

$$SE = 10 \log \left(\int_0^T p(t)^2 \, dt \right)$$

$$= 10 \log(A) + 10 \log \left(\int_0^T s(t)^2 \, dt \right), \qquad (20.7)$$

where T is the duration of the signal. Letting $2A \approx$ be the peak-to-peak sound pressure level, (20.4) can be

rewritten as

$$\mathrm{SE} = \mathrm{SL} - 6 + 10 \log \left[\int_0^T s(t)^2 \, \mathrm{d}t \right], \qquad (20.8)$$

where SL is the the peak-to-peak source level and is approximately equal to $10 \log(2A)$. From Fig. 20.9, the *Tursiops* can emit signals with peak-to-peak source levels in open water that are greater than 50 dB for *phocoena*. The portion of the source energy that can be attributed to the length of the signal is only about 2–4 dB greater for *phocoena* than *Tursiops* [20.39]. Therefore, one can conclude that the target detection range of *phocoena* is considerably shorter than for *Tursiops*. This has been demonstrated by *Kastelein* et al. [20.67] who measured a target detection threshold range of 26 m for a 7.62 cm water-filled sphere in a quiet environment. The target detection range in a noisy environment and a similar 7.62 cm water-filled sphere was 113 m [20.68].

The echolocation signals of other non-whistling odontocetes are very similar to the *Phocoena phocoena* signal shown in Fig. 20.9. Examples of the echolocation signals of other non-whistling odontocetes can be found in *Au* [20.7, 39, 69]. Unfortunately, reliable source-level data have been collected only for *Phocoena phocoena* [20.70] and *Kogia* [20.69].

20.2.3 Transmission Beam Pattern

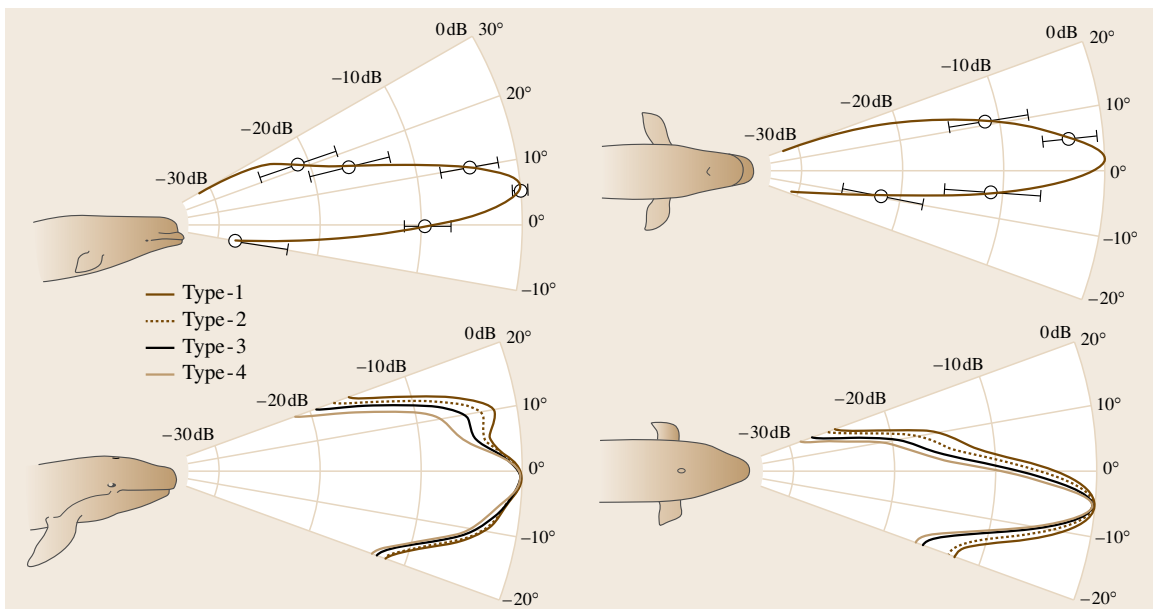
The outgoing echolocation signals of dolphins and other odontocetes are projected in a directional beam that have been measured in the vertical and horizontal planes for the bottlenose dolphin [20.39], beluga whale [20.66] and the false killer whale [20.52]. The composite beam pattern from the three measurements on *Tursiops* along with the averaged waveform from a single trial measured by 5 or the 7 hydrophones are shown in Fig. 20.10. The 3 dB beam width for the bottlenose dolphin was approximately 10.2° in the vertical plane and 9.7° in the horizontal plane. The waveforms detected by the various hydrophones in Fig. 20.10 indicate that signals measured away from the beam axis will be distorted with respect to the signals measured on the beam axis. The further away from the beam axis the more distorted the signals will be. This distortion come from the broadband nature of the click signals emitted by whistling dolphins. This characteristics also make it difficult to get good measurements of echolocation signals in the field even with an array of hydrophones since it is extremely difficult to obtain on-axis echolocation signals and also to know the orientation of the animal with respect to the measuring hydrophones. The frequencies shown with each waveform are the fre-


Fig. 20.11 The transmission beam pattern of a *delphinapterus leucas* (after *Au* et al. [20.66]) and a *pseudorca crassidens* (after *Au* et al. [20.52]) in the vertical and horizontal planes
Fig. 20.12 Beam patterns in the vertical and horizontal planes for *phocoena phocoena* (*Au* et al. [20.70])

Fig. 20.13 Transmission directivity index and 3 dB beam width for four odontocetes. The directivity index and beam width for *Tursiops truncatus* and *delphinapterus leucas* came from *Au* [20.39] and for *pseudorca crassidens* after *Au* et al. [20.52]. The wavelength λ corresponds to the average peak frequency of the animals' echolocation signals. The directivity index is fitted with a second-order polynomial curve the the beam width is fitted with a linear curve (after *Au* et al. [20.70])

quencies of local maxima in the spectrum. At some angles the averaged signal had multiple peaks in the spectrum and these peaks are listed in order of prominence.

The beam patterns for the beluga and false killer whale are shown in Fig. 20.11. The beam width for the beluga whale was approximately 6.5° in both planes. Four beam patterns corresponding to the four signal types described in Fig. 20.7 are shown for the false killer whale. For the highest frequency (type IV signal) the 3 dB beam width in the vertical plane was approximately 10°, and 7° in the horizontal plane. The beam axis in the vertical plane for the bottlenose dolphin and the beluga whale was +5° above the horizontal plane. For the false killer whale, 49% of the beam axis was at 0° and 32% at −5°. The four beam patterns for the false killer whale indicate that, like a linear transducer, the lower the frequency the wider the beam pattern. The type I signal has a peak frequency of about 30 kHz and has the widest beam. However, even though the peak frequency of the type IV signal is about 3.5 times higher than the type I signal, the beam does not seem to be substantially larger. This property can be used when discussing lower-frequency whistle signals to suggest that whistle signals are also emitted in a beam.

The only transmission beam pattern for a non-whistling odontocete, a *phocoena phocoena*, was measured by *Au* et al. [20.70]. Their results are shown in Fig. 20.12 in both the horizontal and vertical planes. One of the obvious difference between the beam patterns in Fig. 20.12 and those in Figs. 20.10 and 20.11 is the width of the beam. Although the harbor porpoise emitted the highest-frequency signals, its small head size caused the beam to be wider than for the other animals. The beam patterns of Figs. 20.10–20.12 were inserted into (20.1) and numerically evaluated to estimate the corresponding directivity index for *tursiops* and *delphinapterus* [20.39] and for *pseudorca* by *Au* et al. [20.52] and for *phocoena* [20.70], and the results are shown in Fig. 20.13 plotted as a function of the ratio of the head diameter (at the blow hole) of the subject and the average peak frequency of the animals echolocation signal. Also shown in Fig. 20.13 are the 3 dB beam width, where the 3 dB beam width in the vertical and horizontal planes were averaged.

The second-order polynomial fit of the directivity index is given by the equation

$$\mathrm{DI} = 28.89 - 1.04 \left(\frac{d}{\lambda}\right) + 0.04 \left(\frac{d}{\lambda}\right)^2 . \qquad (20.9)$$

The linear fit of the 3 dB beam width data is given by the equation

$$BW = 23.90 - 0.60 \left(\frac{d}{\lambda} \right). \tag{20.10}$$

The results of Fig. 20.13 provides a way of estimating the directivity index and 3 dB beam width of other odontocetes by knowing their head size and the peak frequency of their echolocation signals.

Another interesting characteristics of the beam pattern measurement on the *phocoena phocoena* is that the off-axis signals are not distorted in comparison to the on-axis signal. This is consistent with narrow-band signals whether for a linear technological transducer or a live animal. Therefore, measurements of echolocation signals of non-whistling odontocetes in the field can be performed much easier than for whistling odontocetes.

20.3 Odontocete Acoustic Communication

Members of the *Odontocete* suborder are an intriguing example of the adaptability of social mammalian life to the aquatic habitat. Most odontocetes, particularly marine dolphins, live in groups ranging from several to hundreds of animals in size, forage cooperatively, develop hierarchies, engage in alloparental care and form strong pair bonds and coalitions between both kin and non-kin alike (see [20.71–73] for a review of the literature on dolphin societies). These social traits are analogous to patterns found in many avian and terrestrial mammalian species. It is not surprising, therefore, that odontocetes mediate much social information via communication. Some river dolphins are usually found as solitary individuals or mother–calf pairs although they may occasionally congregate into larger groups.

Odontocetes communicate through a combination of sensory modalities that include the visual, tactile, acoustic and chemosensory channels [20.74]. Visual signals in the form of postural displays are thought to convey levels of aggression, changes in direction of movement, and affiliative states [20.72, 75]. Tactile interactions vary in purpose from sexual and affiliative signals to expressions of dominance and aggression [20.76, 77]. Although not well documented yet, it is thought that a derivative of chemosensory perception, termed *quasiolfaction* allows dolphins to relay chemical messages about stress and reproductive status [20.78, 79]. However, it is the acoustic communication channel in particular that is believed to be the main communication tool that enables odontocetes to function cohesively as groups in the vast, visually limited environment of the open sea [20.80]. Examining how odontocetes have adapted their use of sound is therefore an important step to understanding how social marine mammal life evolved in the sea and how it has found a way to thrive in a habitat so drastically different from our own.

When compared to all that has been learned about dolphin echolocation over the past several decades, surprisingly little is still known about how dolphins and other odontocetes use acoustic signals for communication. A major reason for this is that it is very difficult to observe the acoustic and behavioral interactions between the producer and the receiver(s) of social signals in the underwater environment. Sound propagation in the sea makes even a simple task like identifying the location of a sound source very challenging for air-adapted listeners. Therefore, matching signals with specific individuals and their behavior in the field is problematic without the use of sophisticated recording arrays [20.57, 76, 81, 82], or directional transducers. In addition, many questions remain unanswered about the nature of social signals themselves. Much still remains unknown about the functional design of dolphin social sounds. This is largely due to the fact that most species specialize in producing and hearing sounds with frequencies well beyond the limits of the human hearing range. Limitations in the technology available to study social signaling in the field have until recently restricted most analyses to the human auditory bandwidth (< 20 kHz). Yet, despite these significant challenges, a great deal of progress has been made in our understanding of odontocete acoustic communication. Rapidly advancing technologies are contributing greatly to our ability to study social signaling both in the field and in the laboratory. The emerging picture reveals that odontocetes have adapted their acoustic signaling to fit the aquatic world in a remarkably elegant way.

20.3.1 Social Acoustic Signals

Odontocetes have evolved in both marine and freshwater habitats for over 50 million years. Over such a long period of adaptive radiation one might expect that a variety of signaling strategies would have evolved among the approximately 65 species of small toothed whales and dolphins. Yet, remarkably, the vast majority of these

species have either conserved or converged on the production of two types of sounds: whistles and short pulse trains.

Whistles

Whistles are frequency- and amplitude-modulated tones that typically last anywhere from 50 ms to 3 s or more, as illustrated in Fig. 20.14. They are arguably the most variable signals produced by dolphins. Both within and across species they range widely in duration, bandwidth and degree of frequency modulation. How whistles are used in communication is an ongoing topic of debate among researchers, but most agree that they play an important role in maintaining contact between dispersed individuals and are important in social interactions [20.85].

Dolphin whistles exhibit both species and geographic specificity [20.86–90]. Differences are greatest between distantly related taxa and between species of different size. As a general rule, larger species tend to produce whistles with lower fundamental frequencies than smaller ones [20.88]. Geographic variations within a species are usually smaller than interspecific differences [20.87], but some species do develop regional dialects between populations [20.89, 90]. These dialects tend to become more pronounced with increasing geographic separation. In addition, pelagic species tend to have whistles in a higher-frequency range and with more modulation than coastal and riverine species [20.86, 88]. Such differences have been proposed as species-specific reproductive-isolating characteristics [20.86], as ecological adaptations to different environmental conditions and/or resulting from restrictions imposed by physiology [20.88]. On the other hand, it must also be noted that numerous whistle forms are also shared by both sympatric and allopatric species [20.91]. The communicative function of shared whistle forms is unknown, but it is intriguing as it suggests a further tendency towards a convergence in signal design.

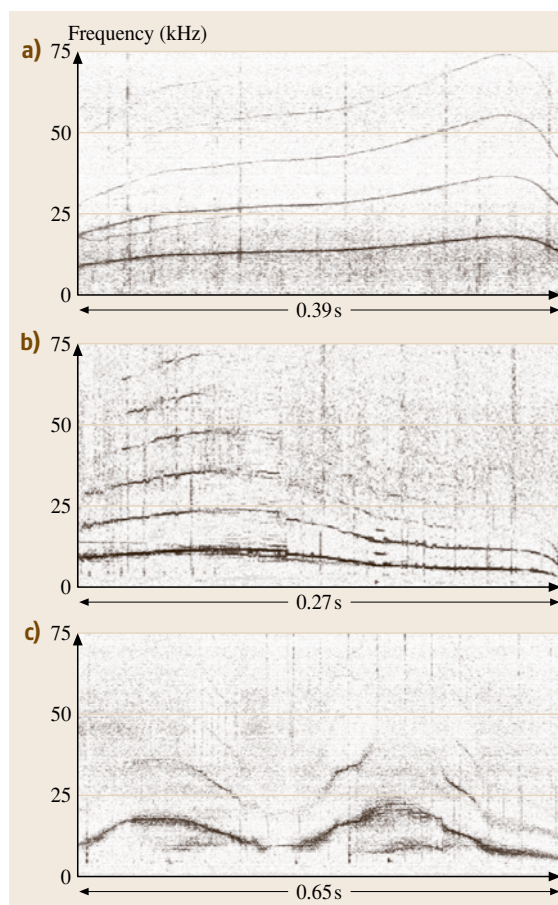
Dolphins produce whistles with fundamental frequencies usually in the human audible range (below 20 kHz). However, whistles typically also have harmonics (Fig. 20.14), which occur at integer multiples of the fundamental and extend well beyond the range of human hearing [20.84]. Harmonics are integral components of tonal signals produced by departures of the waveform from a sinusoidal pattern. Dolphin whistle harmonics have a *mixed directionality* property, which refers to the fact they become more directional with increasing frequency [20.83, 92]. It has been proposed that


Fig. 20.14a–c Variations in whistle forms produced by Hawaiian spinner dolphins (**a**) and Atlantic spotted dolphins (**b,c**) exhibiting multiple harmonics (after *Lammers* et al. [20.83, 84])

this signal feature functions as a cue, allowing listening animals to infer the orientation and direction of movement of a signaling dolphin [20.83, 92]. Harmonics may therefore be important in mediating group cohesion and coordination.

Burst Pulses

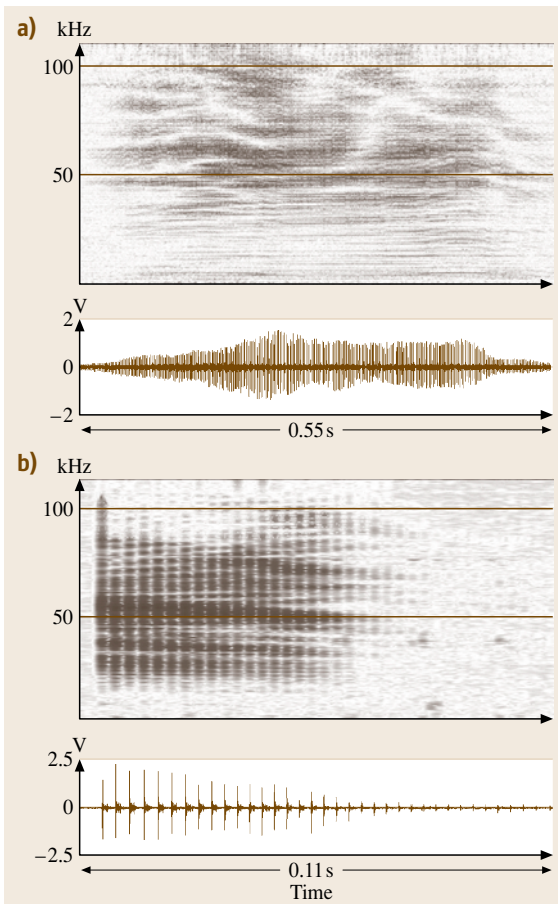
In addition to whistles, most odontocetes also produce pulsed social sounds known as *burst pulse* signals. Burst pulse signals are broadband click trains similar to those used in echolocation but with inter-click intervals of only 2–10 ms [20.93]. Because these intervals are considerably shorter than the processing period generally associated with echolocation and because they are often recorded during periods of high social activity, burst


Fig. 20.15a,b Examples of (a) high-quantity and (b) low-quantity burst pulses produced by Atlantic spotted dolphins (*stenella frontalis*). Click train *a* has 255 clicks with mean ICI (interclick interval) of 1.7 ms. Click train *b* has 35 clicks with a mean ICI of 2.9 ms (after *Lammers* et al. [20.83, 84])

pulse click trains are thought instead to play an important role in communication.

Burst pulses vary greatly in the inter-pulse interval and in the number of clicks that occur in a train, which can number anywhere from three to hundreds of pulses, as depicted in Fig. 20.15. This variation gives them distinctive aural qualities. Consequently, burst pulse sounds have been given many subjective labels, including *yelps* [20.94], *cracks* [20.95], *screams* [20.96] and *squawks* [20.97]. Their production has been reported in a variety of odontocete species including: the Atlantic bottlenose dolphin (*tursiops truncatus*) [20.95], the Hawaiian spinner dolphin

(*stenella longirostris*) [20.72], the Atlantic spotted dolphin (*stenella frontalis*) [20.98], the narwhal (*monodon monoceros*) [20.99], Hector's dolphin (*cephalorhynchus hectori*) [20.100], the pilot whale (*globicephala melaena*) [20.101], and the harbor porpoise (*phocoena phocoena*) [20.101]. To date, much remains unknown about how burst pulses function as communication signals. It is generally believed that they play an important role in agonistic encounters because they are commonly observed during confrontational head-to-head behaviors between individuals [20.95, 102–104]. However, some authors have suggested they may represent emotive signals in a broader sense [20.97, 105, 106], possibly functioning as graded signals [20.107].

Given that dolphins have temporal discrimination abilities well within the range required to resolve individual clicks in a burst pulse [20.39, 108], it is possible that the quantity of clicks and their temporal spacing could form an important basis for communication. However, as with whistles, no data presently exist on the classification and discrimination tendencies of dolphins with respect to different burst pulses.

20.3.2 Signal Design Characteristics

Although much remains unknown about how odontocetes use acoustic signals for communication, the communicative potential of their signals can, in part, be inferred by considering the design characteristics that have been uncovered thus far. Signal features such as their detectable range, the production duty cycle, the identification level, the modulation potential and the form–content linkage provide useful clues about how odontocetes might use whistles and burst pulses.

The Active Space of Social Signals
The effective range of signals used for communication is generally termed the *active space*. *Janik* [20.109] investigated the active space of whistles produced by bottlenose dolphins in the Moray Firth, Scotland, using a dispersed hydrophone array to infer geometrically the location of signaling animals and establish the source level of their whistles. The mean source level was calculated to be 158 dB ± 0.6 re 1 µPa, with a maximum recorded level of 169 dB. By factoring in transmission loss, ambient noise levels, the critical ratios and auditory sensitivity of the species involved the active space of an unmodulated whistle between 3.5 and 10 kHz in frequency was estimated to be between 20 and 25 km in a habitat 10 meters deep at sea state 0. At sea state 4 the estimated active space ranged from 14 to 22 km, while

for whistles at 12 kHz it dropped to between 1.5 and 4 km. These estimations were made for dolphins occurring in a relatively shallow, mostly mud-bottom, quiet environment. Presently, no data exist on the active space characteristics of delphinid whistles in pelagic waters and comparatively louder tropical near-shore environments. Similarly, no estimates have yet been made for the active space of burst pulses.

The Duty Cycle of Social Signals

Duty cycle refers to the proportion of time that any given signal or class of signals is *on* versus *off*. Signals can vary in the fine structure of their temporal patterning (e.g. duration), in their temporal spacing within a bout, and in their occurrence within a larger cyclical time frame, such as a 24 hour day. Each of these aspects of the temporal delivery of signals carries its own implication for communication. Fine-scale characteristics can define the nature of the signal itself and provide information about its relationship to other signals as well as constraints associated with its mechanism of production. The occurrence and timing of a signal within a bout can help convey information about the urgency of a situation, the level of arousal, the fitness of an individual and can assist the receiver in the task of localization. Finally, the periodicity of signals over hours or days can be an indicator of variables such as activity levels and reproductive state.

Murray et al. [20.110] investigated the fine-scale duty-cycle characteristics of delphinid social signals. Using a captive false killer whale (*pseudorca crassidens*) as their subject, they examined the temporal relationship between the units of a click train (individual clicks) and tonal signals. Their analysis revealed that false killer whales modulate the temporal occurrence of clicks to the point of grading them into a continuous wave (CW) signal such as a whistle. This finding was interpreted as evidence that *pseudorca* may employ graded signaling for communication (a topic discussed in more detail below), as well as to suggest that clicks and whistles are produced by the same anatomical mechanism.

The timing of signals within a bout has not been investigated with much success among delphinids. The primary obstacle towards this line of work has been the difficulty of identifying the signaler(s) involved for even short periods of time under field conditions. Early work by *Caldwell* and *Caldwell* [20.111] on a group or four naïve captive common dolphins (*delphinus delphis*) suggests that whistle exchanges do have temporal structure. In whistling bouts involving more than one sig-

naler, the onset of a whistle specific to an individual was followed within two seconds by that of another. Furthermore, initiation of a whistle by two animals within 0.3 s of one another always resulted in the inhibition of one of them, with some individuals deferring more than others. Initiations separated by 0.4–0.5 s caused inhibition less frequently while those longer than 0.6 s resulted in almost no inhibition. Repeated whistles produced without an intervening response by another animal were usually delayed by less than one second. Thus, the duty cycle of whistling bouts and chorusing behavior among common dolphins does appear to follow certain temporal rules, but their significance is not clear.

Periodicity in social signaling has been investigated in captive bottlenose dolphins and common dolphins [20.112–114], as well as free-ranging spinner dolphins (*stenella longirostris*) [20.72] and common dolphins [20.115]. In the captive studies, signaling activity was linked to feeding schedules, nearby human activities and responses to different forms of introduced stress [20.113]. For spinner and common dolphins in the wild, the occurrence of social acoustic signals was highest at night, when both species were foraging, and lowest in the middle of the day.

The Identification Level of Social Signals

The role of delphinid whistles as individual-specific signals has been the focus of more scientific attention than any other aspect of their social acoustic signaling. *Caldwell* and *Caldwell* [20.116] were the first to propose that individual dolphins each possess their own distinct *signature* whistle. The idea was borne out of the observation that recently captured dolphins each produce a unique whistle contour that makes up over 90% of the individual's whistle output. Since being proposed, the so-called *signature whistle hypothesis* has emerged as the most widely accepted explanation for whistling behavior among dolphins. The idea has received support from numerous studies involving captive and restrained animals [20.85, 117–121] as well as from field studies of free-ranging animals [20.97, 122, 123]. Some, however, have argued that a simple signature function for dolphin whistling cannot account for the diversity of signals observed in socially interactive dolphin groups [20.124, 125]. While not denying the presence of signature whistles per se, these authors have argued that the large percentage of stereotyped signature signals observed in other studies may be an artifact of the unusual circumstances under which they were obtained (isolation, temporary restraint, separation, captivity). The debate over the prevalence of signature whistles

among captive and free-ranging dolphins remains a contested topic in the literature and at scientific meetings. On the other hand, no evidence or formal discussions presently exist suggesting burst pulse signals carry any individual-specific information.

The Modulation Potential of Social Signals

The modulation potential describes the amount of variation present in any given signal as measured by its position along a scale from stereotyped to graded signaling [20.126]. Stereotyped signals are repeats of structurally identical forms and vary discretely between one another. They are used most often for communication when the prospect of signal distortion is high, such as in noisy or reverberant environments or for communicating over long ranges. Graded signals have more variants than stereotyped ones and are encoded by changing one or more signal dimensions. These can include intensity, repetition rate and/or frequency and amplitude modulation. Graded signals are usually employed when a continuous or relative condition must be communicated in a favorable propagation environment.

Many studies to date have made an a priori assumption that dolphin signaling is categorical in nature, with signals belonging to mutually exclusive classes on the basis of their shared similarities. Some evidence in support of this assumption comes from the signature-whistle hypothesis work, where restrained and isolated individuals are often observed producing highly stereotyped bouts of signaling. However, few data are presently available to suggest how dolphins perceive and distinguish social signals [20.127]. Therefore, it is unclear whether an assumption based on the occurrence of signature whistles is broadly applicable towards other forms of social acoustic signaling (i.e. non-signature whistles and burst pulses).

A few studies have explored the occurrence of graded signaling in the communication of delphinids and the larger whales. *Taruski* [20.128] created a graded model for the whistles produced by North Atlantic pilot whales (*globicephala melaena*). He concluded that these signals could be arranged as a *continuum or matrix (of signals) from simple to complex through a series of intermediates* (*Taruski* [20.128, p. 349]). *Murray* et al. [20.110], examining the signals of a captive false killer whale (*Pseudorca crassidens*), came to a similar conclusion and proposed that *Pseudorca* signals were also best represented along a continuum of signal characteristics, rather than categorically. Finally, *Clark* [20.129], examining the *call* signals of south-

ern right whales (a mysticete), made the observation that ... *the total repertoire of calls is best described as a sequence of intergraded types along a continuum* (*Taruski* [20.128, p. 1066]). Therefore, graded signaling may well play a role in odontocete communication. Controlled perceptual experiments and a better understanding of the acoustic environment dolphins inhabit are needed to test how odontocetes discriminate and classify social sounds.

The Form–Content Linkage of Social Signals

The degree to which the form of a signal is linked to its content depends on how information is coded and on proximate factors associated with the signal's production. The relationship between a signal's structural form and its message can range from being rather arbitrary to tightly linked to a specific condition [20.126]. Among odontocetes, a clear relationship between signal form and content has only been demonstrated for signature whistles (discussed above). Dolphins have been experimentally shown to be capable of labeling objects acoustically (also known as vocal learning), as well as mimicking model sounds following only a single exposure [20.130]. Additional evidence of vocal learning exists from culturally transmitted signals in the wild [20.131] and in captivity [20.132], as well as from the spontaneous production of acoustic labels in captivity [20.127]. Context-specific variations in signature whistle form have also been demonstrated [20.121]. However, to date, no semantic rules have been identified for naturally occurring social signals among odontocetes.

Geographic Difference and Dialect

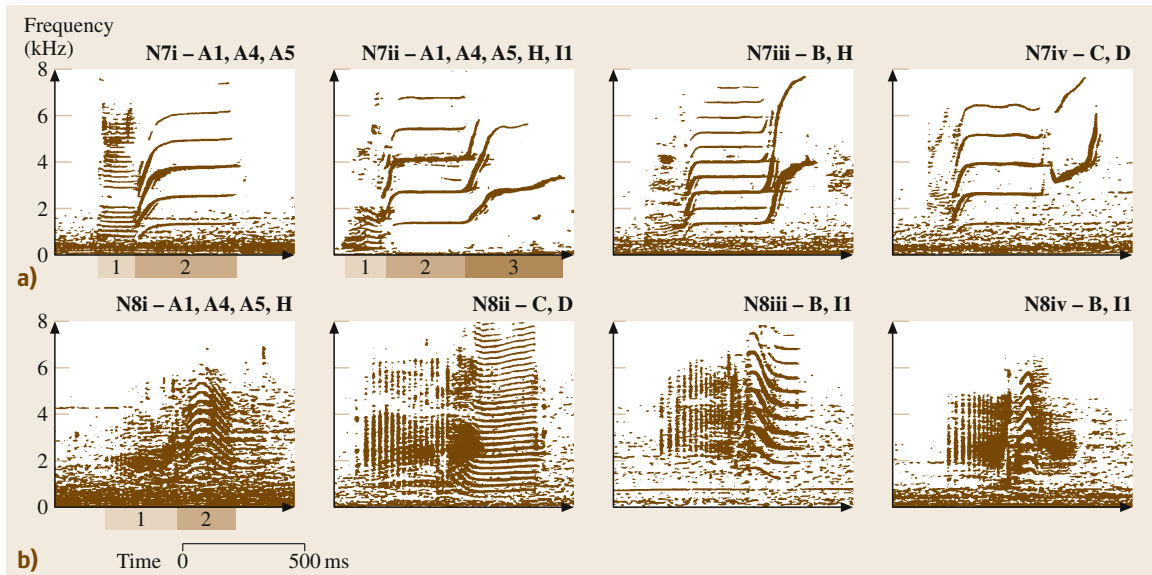
There is a distinct difference between geographical difference and dialect. Geographical differences are associated with widely separated populations that do not normally mix. Dialect is best reserved for sound emission differences on a local scale among neighboring populations which can potentially intermix [20.133]. Geographic variations are generally considered to result from acoustic adaptations to different environments, or a functionless byproduct of isolation and genetic divergence caused by isolation [20.134]. The functional significance of dialects is controversial, with some maintaining that dialects are epiphenomena of song learning and social adaptation, whereas others believe that they play a role in assorted mating and are of evolutionary significance [20.134]. Dialects are known to occur in many species of birds [20.135] but appear to be very rare in mammals.


Fig. 20.16a,b Spectrograms of call types **(a)** N7 and **(b)** N8 for clan A. Above each spectrogram is the subtype identification and the pods that produce the variant, and below certain spectrograms are division marks separating calls into their component parts (after *Ford* [20.134])

Killer Whale

Killer whales (*orcinus orca*) produce a specific type of burst pulse termed the *discrete call*. Discrete calls are thought to serve as contact calls between individuals, much like whistles in other odontocete species [20.136]. Discrete calls are population specific and even pod specific. The dialects of resident killer whales (*Orcinus orca*) in the coastal waters of British Columbia and Washington have been studied over a prolonged period by *Ford* and his colleagues [20.134, 137, 138]. They used photographic identification techniques, keying on unique natural markings on the whales to identify 16 pods or stable kin groups of 232 resident killer whales. Differences in acoustic behavior formed a system of related pod-specific dialects within the call tradition of each clan. *Ford* [20.134] has proposed that each clan is comprised of related pods that have descended from a common ancestral group and pod-specific repertoires probably serve to enhance the efficiency of acoustic communications within the group and act as behavioral indicators of pod affiliation.

Killer whale calls are typically made up of rapidly emitted pulses that to the human ear have a tonal quality [20.134]. Many calls have several abrupt shifts in pulse repetition rate allowing them to be divided into different segments or parts. Although all pods belonging to a clan share a number of calls, these calls were often rendered in consistently different form by different pods. Also, certain pods produced calls that were not used by the rest of the clan. Such variations produced a set of related group-specific dialects within the call tradition of each clan.

Spectrograms of call types N7 and N8 are shown in Fig. 20.16. In this example, we can see that different pods produce similar but different versions of call type N7 and N8. Pods A1, A4 and A5 produced two versions of call type N7 and pod B and I1 produced two versions of call type N8. All of the spectrograms have two parts except for call type N7ii, which had three parts.

Ford [20.134] contended that pod-specific repertories can be retained for periods in excess of 25 years. Discrete calls generally serve as signals for maintaining contact within the pod and that the use of repertoire of pod-specific calls enhances this function by conveying group identity and affiliation [20.134]. Killer whales, like most other small dolphins are able to learn and mimic a wide variety of sounds. Even from a young age, killer whale infants can selectively learn specific calls, especially the calls of their mothers. *Bowles* et al. [20.139] studied the development of calls of a captive-born killer whale calf and found that it learned and reproduced only the calls of its mother and ignored the calls of other killer whales in the same pool. *Ford* [20.134] also observed killer whales imi-

tating the call types of different pods, and even those from other clans. These instances were rare, but it does show a capacity for learning and mimicry of acoustic signals.

Sperm Whales

Sperm whales live in a matrilineal family unit where there exist cooperative behaviors including communal care of the young in ways similar to killer whales. The family units are very stable and females may live as long as 60–70 y [20.140]. One type of signals that sperm whales emit are denoted as codas, which are sequences of click signals that may be the primary means of acoustic communications for these animals [20.58]. *Weilgart* and *Whitehead* [20.141] recorded, for over a year, codas from a number of sperm whales around the South Pacific and in the Caribbean Sea. Photographic

identification also allowed them to assign recording sessions to particular groups. They found that the coda repertoire recorded from the same group on the same or different days were much more similar than those recorded from different groups in the same place. Groups recorded in the same place had more similar coda repertoire than those in the same broad area but different places. Groups from the same area were in turn marginally similar to those in the same ocean but different than those in different oceans. Coda class repertoires of groups in different oceans and in different areas within the same ocean were statistically significantly different. They concluded that strong group-specific dialects were apparently overlaid on weaker geographic variation. Sperm whales, killer whales and possibly bottlenose dolphins are the only cetaceans known to have dialects.

20.4 Acoustic Signals of Mysticetes

There are eleven species of mysticetes or baleen whales and sounds have been recorded from all but the pygmy right whale [20.142]. The vocalization of baleen whales can be divided into two general categories: (1) songs and (2) calls [20.142]. The calls can be further subdivided into three categories: (1) simple calls, (2) complex calls and (3) clicks, pulses, knocks and grunts [20.142]. Simple calls are often low-frequency, frequency-modulated signals with narrow instantaneous bandwidth that sound like moans if a recording is speeded up or slowed down, depending on the specific animal. Amplitude modulation and the presence of harmonics are usually part of a simple call, with most of the energy below 1 kHz. Complex calls are pulse-like broadband signals with a variable mixture of amplitude and/or frequency modulation. They sound like screams, roars, and growls, with most of the energy between 500–5000 Hz. Clicks, pulses, knocks and grunts are short-duration (< 0.1 s) signals with little or no frequency modulation. Clicks and pulses are very short (< 2 ms) signals with frequencies between 3–31 kHz, while grunts and knocks are longer (50–100 ms) signals in the 100–1000 Hz range [20.142].

20.4.1 Songs of Mysticete Whales

Songs are defined as *sequences of notes occurring in a regular sequence and patterned in time* [20.142]. Songs are easily discriminated from calls in most

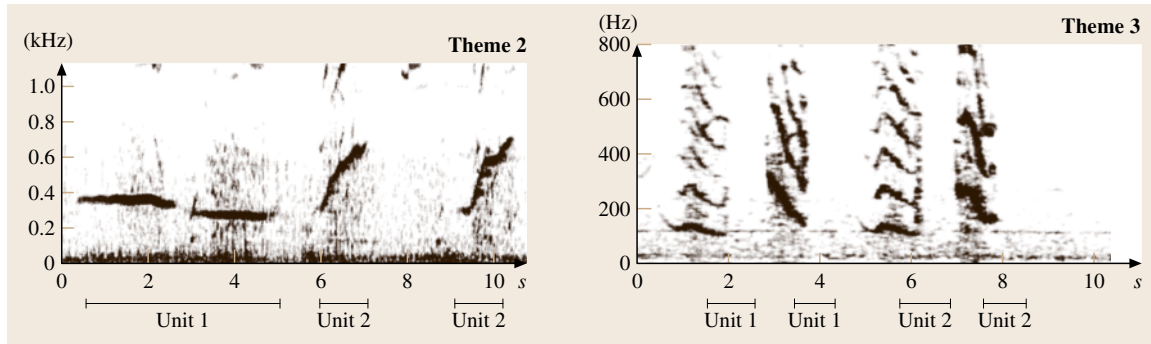
instances. Four mysticetes species have been reported to produce songs; the blue whale (*balaenoptera musculus*) [20.143], the fin whale (*balaenoptera physalus*) [20.144, 145], the bowhead whale (*balaena mysticetus*) [20.15], and the humpback whale [20.146]. Songs of humpback whales have without a doubt received the most attention from researchers. Part of the reason for this is the relative ease for investigators to travel and do research in the summer grounds of humpback whales, especially in Hawaii in the Pacific and Puerto Rico in the Atlantic.
Fig. 20.17 Examples of two themes from a humpback whale song (after *Frankel* [20.36])


Fig. 20.18 An example of a portion of a humpback whale song. The individual pulse sounds are defined as units and units are aurally categorized based on how they sound. In this example, there are five units. Phrases are formed by a combination of units and themes are formed by a combination of phrases. The whole song consist of a combination of themes that are continuously repeated for the length of the song

Humpback Whale Songs

The list of studies involving humpback whale songs is long and extends from 1971 to the present time, *Helweg* et al. [20.147]. Although some songs may sound almost continuous to human listeners the basic units in a song are pulsed sounds. Songs are sung only by males and consist of distinct units that are produced in some sequence to form a phrase and a repeated set of phrases form a theme and repeated themes form a song. A song can last from minutes to hours depending on the disposition of the singer. An example of a portion of song is shown in Fig. 20.17. Example of two themes of a song in spectrogram format are shown in Fig. 20.18. The variation in frequency as a function of time is clearly shown in the figure.

Some general properties of songs and the whales that are singing are:

1. Songs from the North Pacific, South Pacific and Atlantic populations are different.
2. Singing peaks during the winter months when humpback whales migrate to warmer waters at lower latitudes.
3. Whales within a population sing the same basic song in any one year, although the song may undergo slight changes during a breeding season.
4. Changes in songs are not due to forgetting during the summer months, which are non-singing months, since songs recorded early in the winter breeding season are nearly the same as songs recorded late in the previous breeding season.
5. Songs from consecutive years are very similar but songs across nonconsecutive years will have fewer similarities.

6. Singers are most probably only males, since no females have been observed singing.
7. Some singing also occurs during the summer and fall.
8. Singing whales are often alone, although they have been occasionally observed singing in the presence of other humpback whales.
9. Singers tend to remain stationary. However, they have also been observed singing while swimming.

Other Mysticetes

Bowhead whales emit a variety of different types of simple and complex sounds that sound like moans to the human ear. They also emit sequential sounds that contain repeatable phrases that can be classified as songs during their spring migration [20.15] but not during the summer or autumn [20.148]. The bowhead song had just one theme with basically only two sounds repeated over and over. *Ljungblad* et al. [20.15] reported that songs were very tonal with clear pitch even though they were produced by pulsive moans, whereas *Cummings* and *Holliday* [20.149] described songs as sounding like raucous elephant roars and trumpeting in discrete repetitions or phases that were put together to form longer sequences. Differences in the songs recorded by *Ljungblad* et al. [20.15] and by *Cummings* and *Holliday* [20.149] may be due to bowhead whales changing their songs from year to year.

The sounds from finback whales include single 20 Hz pulses, irregular series of 20 Hz pulses, and stereotyped 20 Hz signal bouts of repetitive sequences of 20 Hz pulses [20.145]. The 20 Hz signals are emitted in bouts that can last for hours. The pulse intervals in a bout were very regular. In general, signals are pro-

Table 20.2 Characteristics of mysticete whales vocalizations

duced in a relatively regular sequence of repetitions at intervals ranging from about 7–26 s, with bouts that can last as long as 32.5 h. During a bout, periodic rests averaged about 115 s at roughly 15 min intervals and sometimes longer irregular gaps between 20 and 120 min were observed. There was also some variability in the 20 Hz signals in that they were never exactly replicated.

The songs of the blue whales (*balaenoptera musculus*) have been observed by a number of researchers [20.143, 152, 167]. A typical two-part blue whale song time series and corresponding spectrogram is shown in Fig. 20.18. The spectrogram of the first part of the two part song had six spectral lines separated by about 1.5 Hz. This type of spectrogram is typically generated by pulses. *Cummings* and *Thompson* [20.150] previously reported on the pulsive nature of some blue whale moans. The second part of the song was tonal in nature with a slight FM down sweep varying from 19 Hz to 18 Hz in the first 3–4 s. The 18 Hz tone is then carried until the last 5 s when there is an abrupt step down

to 17 Hz. The amplitude modulation in the second part of the song was probably caused by multi-path propagation of the signal from the whale to the hydrophones. These two-part songs basically follow a pattern of a 19 s pulsive signal followed by a 24.5 s gap and a 19 s monotonic signal [20.152, 167].

Calls of Mysticete Whales

The calls of mysticete whales have been the subject of much research over the past three decades. As with dolphin sounds, there is also a lack of any standard nomenclature for describing emitted sounds. Similar calls are often given different names by different researchers. A summary of some of the acoustic properties of the different baleen whales is indicated in Table 20.2. Calls and songs are most likely used

for some sort of communication, however, at this time the specific meanings of these sounds are not known. It is extremely difficult to study the context and functions of baleen whale vocalization. The sounds of mysticete whales have also been summarized nicely by *Richardson* et al. [20.34]. Instead of discussing the characteristics of various sounds, the properties of calls are summarized in Table 20.2. The calls of mysticete whales are mainly in the low-frequency range, from an infrasonic frequency of about 12.5 Hz for the blue whale to about 3.5 kHz for the sei whale. There are a variety of different types of calls, from FM tones to moans, grunts and discrete pulses. How these sounds are used by whales is still an open question since it is often very difficult to observe behavior associated with different calls.

20.5 Discussion

Cetaceans use a wide variety of sounds from brief echolocation signals used by dolphins having durations less than 100 μs to very long duration songs that can last for hours by are emitted by humpback whales. The range of frequency is also very large, from low-frequency (infrasonic) sounds between 10–20 Hz used by blue and finback whales to high-frequency echolocation signals that extend to 130–140 kHz or perhaps higher (see earlier mention of 180 kHz). It is quite clear that acoustics is important in the natural history of cetaceans since all species regularly emit sounds throughout their daily routine. Yet, it is not at all clear how sounds are used by these animals. The difficulty in observing the behavior of these animals has made it difficult to attach any function to a particular or specific sound. It is nearly impossible to determine a one-to-one relationship between the reception or transmission of a specific sound to specific behavioral response. There are many possible functions of sounds, some of which may include providing contact information in a population of animals, signaling alarm or warning of approaching predators, attracting potential mates, echolocation for prey detection and discrimination while foraging, a way of establishing a hierarchy, providing individual identification, and a method for disciplining juveniles. Although researchers have not been successful in uncovering the role or function of specific sounds in any cetacean species, researchers should not be discouraged but should be innovative and imaginative in designing experiments that can be

conducted in the wild to delve deeper into this problem. Even with echolocation sounds, there are many unanswered question. It seems logical that echolocation sounds are used to detect and discriminate prey and to navigate, yet we still know very little about how often they are emitted during a daily routine for dolphins in the field.

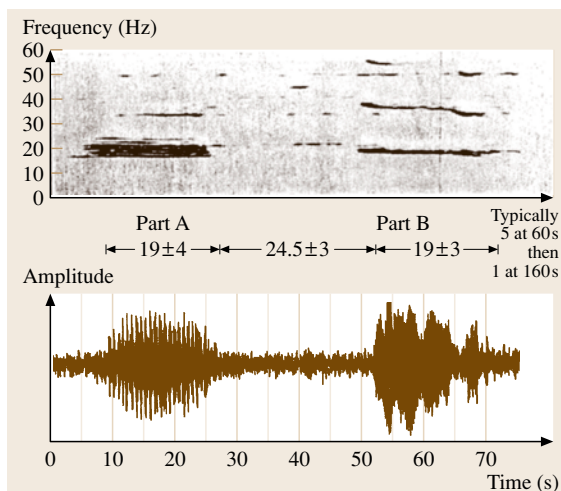
In this chapter, we have seen that the characteristics of the sounds emitted by cetaceans depends a lot on the size of the animals. Therefore the active space


Fig. 20.19 Time series and spectrogram of a typical blue whale song (after [20.152])

of different species is indirectly related to the size of the animals since the amount of sound absorption by sea water increases with frequency. Dolphins and small whales usually emit echolocation signals that can have peak frequencies up to 120–140 kHz and whistles between 10–20 kHz. These signals are not meant to travel large distances so that the active space is rather small, tens of meters for echolocations and burst pulse signals and several hundred meters for whistles. These signals will certainly propagate to much shorter distances than the low-frequency signals used by many of the baleen whales. The sound pressure level (SPL) of an emitted signal at any range from the animal is given by the equation

$$\text{SPL} = \text{SL} - \text{geometric spreading loss} - \alpha R,$$

(20.11)

where SL is the source level in dB, α is the sound absorption coefficient in dB/m and R is the distance the sound has traveled. The geometric spreading loss does not depend on frequency but is affected by the sound velocity profile, the depth of the source and the receiver. The most severe geometric spreading loss is associated with spherical spreading loss in which the amount of geometric spreading loss is equal to $20 \log R$. The least severe geometric spreading loss is associated with sound channels, such as the sound fixing and ranging (SOFAR) channel. In order to gain an appreciation of the effects of absorption losses for different types of cetacean signals, $-\alpha R$ in (20.9) was calculated as a function of range and the results are shown in Fig. 20.20. The results indicate that the low-frequency sounds used by baleen whales do not suffer as much absorption loss as the sounds of small odontocetes. Therefore, baleen whale signals can propagate long dis-
Fig. 20.20 Reduction to sound pressure level caused by sound absorption for different types of cetacean signals. The curve for the high-frequency echolocation signals was calculated at 120 kHz, and for the mid-frequency echolocation signals at 50 kHz. The curve for the dolphin whistle was calculated at 15 kHz. The baleen whale signal curve was determined at 1 kHz.

tances if some type of channel is present in the water column.

We have just scraped the top of the iceberg in regards to our understanding of cetacean acoustics. There is much to learn and understand about how these animals produce and receive sounds and how acoustics is used in their daily lives. The future looks extremely promising as new technology arrives on the scene that will allow researchers to delve into the many unanswered questions. As computer chips and satellite transmission tags get smaller and we apply state-of-the-art technologies to the study of cetaceans, our knowledge and understanding can but increase.

21. Medical Acoustics

Kirk W. Beach, Barbrina Dunmire

Medical acoustics can be subdivided into diagnostics and therapy. Diagnostics are further separated into auditory and ultrasonic methods, and both employ low amplitudes. Therapy (excluding medical advice) uses ultrasound for heating, cooking, permeablizing, activating and fracturing tissues and structures within the body, usually at much higher amplitudes than in diagnostics. Because ultrasound is a wave, linear wave physics are generally applicable, but recently nonlinear effects have become more important, even in low-intensity diagnostic applications.

This document is designed to provide the non-medical acoustic scientist or engineer with some insights into acoustic practices in medicine. Auscultation with a stethoscope is the most basic use of acoustics in medicine and is dependent on the fields of incompressible (circulation) and compressible (respiration) fluid mechanics and frictional mechanics. Detailed discussions of tribology, laminar and turbulent hemodynamics, subsonic and supersonic compressional flow, and surfactants and inflation dynamics are beyond the scope of this document. However, some of the basic concepts of auscultation are presented as a starting point for the study of natural body sounds. Ultrasonic engineers have dedicated over half a century of effort to the development of ultrasound beam patterns and beam scanning methods, stretching the current technical and economic limits of analog and digital electronics and signal processing at each stage. The depth of these efforts cannot be covered in these few pages. However, the basic progression of progress in the fields of transducers and signal processing will be covered. The study of the interaction of ultrasound with living tissues is complicated by complex anatomic structures, the high density of scatterers, and the constantly changing nature of the tissues with ongoing life processes including cardiac pulsations, the formation of edema and

intrinsic noise sources. A great deal of work remains to be done on the ultrasonic characterization of tissues. Finally, the effect of ultrasound on tissues, both inadvertent and therapeutic will be discussed.

Much of the medical acoustic literature published since 1987 is searchable online, so this document has included key words that will be helpful in performing a search. However, much of the important basic work was done before 1987. In an attempt to help the reader to access that literature, Denis White and associates have compiled a complete bibliography of the medical ultrasound literature prior to 1987. Under Further Reading in this chapter, the reader will find a link to a complete compilation of 99 citations from *Ultrasound in Medicine and Biology* which list the thousands of articles on medical acoustics written prior to 1987.

The academically based authors develop, use and commercialize diagnostic ultrasonic Doppler systems for the benefit of patients with cardiovascular diseases. To translate ultrasonic and acoustic innovation into widespread clinical application requires as much knowledge about the economics of medicine, the training and practices of medical personnel, and the pathology and prevalence of diseases as about the diffraction patterns of ultrasound beams and signal-to-noise ratio of an echo. Although a discussion of these factors is beyond the scope of this chapter, a few comments will help to provide perspective on the likely future contribution of medical acoustics to improved public health.

Standard Symbols

c sound propagation velocity [km/s = mm/μs]
p acoustic pressure fluctuation [d/cm^2; Pa = N/m^2]
t time [s]
Z tissue impedance [Rayles = ρc = kg/(m^{2}s) = 0.1 g/(cm^{2}s)]
λ acoustic wavelength [m]
ρ tissue density [g/cm^3]
σ surface tension [d/cm = mN/m]

κ tissue stiffness [d/cm^2]
θ angle of sound propagation from the normal at a refraction interface
Ψ distance to transition zone
θ_D Doppler angle of sound propagation to vessel axis or velocity vector axis
$\Delta\phi$ ultrasound echo phase shift
$\Delta\tau$ ultrasound echo time shift [ns]
PRF   pulse repetition frequency [Hz]
D thermal dose

Special Symbols

d diameter
f frequency [Hz]
f_D Doppler frequency [Hz]
f_us ultrasound center frequency [MHz]
fd vibration frequency [Hz]
P total instantaneous pressure [d/cm^2, kPa]
q acoustic molecular displacement [cm]
Q volume flow [cm^3/s]
R reflection coefficient
T transmission coefficient
v_f fluid velocity [cm/s]
v molecular velocity [cm/s]
w transducer element width [cm]
x distance in propagation direction [cm]

Subscripts

i   incident
r   reflected
s   shear wave
t   transmitted
1   incident material
2   second material

Dimensionless Numbers

St   Strouhal number St = $(fD)/V$
Re   Reynolds Number $(DV\rho)/\mu = (4Q\rho/\pi D)/\mu$

Units

Np   nepers
dB   decibels

21.1 Introduction to Medical Acoustics

Medical acoustics covers the use of sub-audio vibration, audible sound and ultrasound for medical diagnostics and treatment. Sound is a popular and powerful tool because of its low cost, noninvasive nature, and wide range of potential applications from passive listening to the application of high-energy pulses used for the destruction of kidney stones.

There are four frequency ranges of sound and three levels of intensity that will be presented in this chapter:

1. Infrasound, acoustic waves with frequencies below the level of human hearing. These vibrations, called *thrills*, are often caused by turbulent blood flow (which is abnormal). At the lowest extreme, the pulse can be considered infrasound with a frequency below 2 Hz. With fingertips, the physician can feel vibrations with amplitudes of 1 μm.
2. Audible sound, acoustic waves with frequencies in the range of human hearing. The audible frequency range for the average human is approximately 20 Hz–20 kHz, with a peak sensitivity around 3–4 kHz. At 1 kHz, the standard reference frequency, the ear is able to detect pressure variations on the order of one billionth of an atmosphere. This corresponds to intensities of about $0.1 \, \text{fW/cm}^2$ ($10^{-16} \, \text{W/cm}^2 = 10^{-12} \, \text{W/m}^2$). The oscillatory velocity of air molecules carrying such sound intensities is $v = 50 \, \text{nm/s}$ ($1 \, \text{nm} = 10^{-9} \, \text{m}$) and the maximum pressure fluctuation is $20 \, \mu\text{N/m}^2$ or 0.2 nanoatmospheres (nanobar). At 1 kHz, the air molecules oscillate back and forth about 0.05 nm. The intensity of conversation is $0.1 \, \text{nW/cm}^2$ ($1 \, \mu\text{W/m}^2$) causing molecules to oscillate with amplitudes of 50 nm, and oscillatory pressures of $20 \, \text{mN/m}^2$.
3. Low-frequency ultrasound, which is used for cleaning and tissue disruption.
4. Radio-frequency ultrasound, acoustic waves with frequencies near 1 MHz and wavelengths in the body near 1 mm.

A list of interesting frequencies in medicine is provided for reference Table 21.1.

Table 21.1 Medical frequencies

Title	Period	Frequency	Power/Intensity
Generation	25 years		
Ovulation	28 days		
Diurnal	1 day		
Respiration	6 s	0.15 Hz	
Heart Rate	1 s	1 Hz	
ECG surface bandwidth	10 ms	100 Hz	
ECG intramyocardial BW	250 μs	4 KHz	
Tremor	100 ms	3–18 Hz	
Electromyography surface	5 ms	200 Hz	
Electromyography intramuscle	100 μs	10 kHz	
Flicker fusion (visual)	60 ms	16 Hz	
Vibration sensation	10 ms	100 Hz	
Sound low	50 ms	20 Hz	
Telephone sound speech	3–0.3 ms	0.3–3 kHz	
Sound high	50 μs	20 kHz	
Electro-encephalography (EEG) surface waves			
Delta waves	300 ms	< 3.5 Hz	
Theta waves	200 ms	3.5–7.5 Hz	
Alpha waves	100 ms	7.5–13 Hz	
Beta waves	50 ms	13–30 Hz	
Intracerebral EEG	100 μs	10 kHz	

Table 21.1 (continued)

Title	Period	Frequency	Power/Intensity
Ultrasound cleaners		42 kHz	100 W, 1 W/cm^2
Ultrasound bacteriocidal		22.5 kHz	
Ultrasound therapeutic	0.5 μs	1 3 MHz	15 W, 3 W/cm^2
Ultrasound diagnostic			
Transcranial		1–3 MHz	100 mW/cm^2
Heart, abdomen		2–5 MHz	100 mW/cm^2
Vascular, skeletal		4–10 MHz	100 mW/cm^2
Skin, eye		10–40 MHz	8 mW/cm^2

21.2 Medical Diagnosis; Physical Examination

The most valuable application of acoustics in medicine is the communication from a patient to their physician. In the modern world of *efficient medicine*, however, physicians are encouraged to avoid wasting time listening to the patient so that objective tests can be ordered without delay. This approach avoids physician frustration from sorting out the complaints and symptoms of the patient, even though the patient initiated the appointment with the physician.

Having gathered background information, the physician can proceed to the physical examination, which includes optical methods, olfaction, palpation, testing the mechanical response of tissues and systems to manipulation, percussion, remote listening and aided auscultation, and acoustic transmission and reflection techniques. Only those techniques related to medical acoustics will be discussed further here. Of future importance in medical practice though, are those methods that can be performed remotely, via the internet.

21.2.1 Auscultation – Listening for Sounds

Sounds in the body are generated through the presence of disturbed flow, such as eddies and turbulence, by frictional rubs, and/or by other sources with high accelerations. There are both normal and abnormal sounds

within the body. Auscultation is the act of listening for sounds within the body for diagnostic purposes. This may be conducted on any part of the body from head to toe (Fig. 21.1). Anesthesiologists even use esophageal stethoscopes for convenient acquisition of chest sounds. Information gathered during auscultation includes the frequency, intensity, duration, timing, and quality of the sound.

Lung

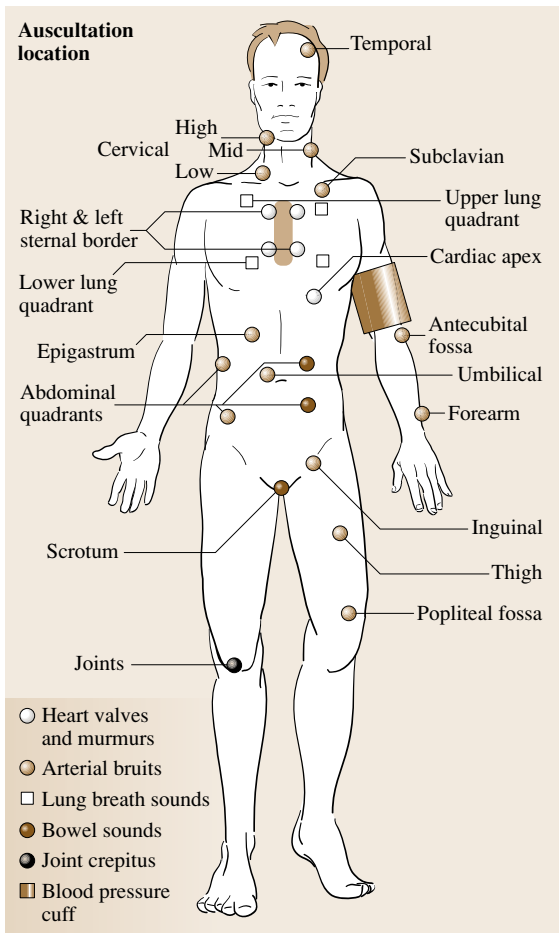
Both normal and abnormal sounds can be present in the lungs. The source of normal lung sounds is turbulent flow associated with air movement through orifices along the airways. These are large, low-frequency oscillations that cause the surrounding tissues to vibrate within the audible frequency range. The respiratory system is naturally optimized to minimize the work needed to exchange air, so little energy is converted into acoustic power, resulting in low-amplitude sounds. With constriction of the airways, in such conditions as asthma, the air velocity through the airways increases (conservation of mass). Through conservation of energy and momentum, an increase in flow velocity results in an increase in pressure loss, raising the power needed to drive the system. The energy is of course not lost, but converted, in part, into acoustic power. The increase


Fig. 21.1 Auscultation sites. Arterial bruits can be heard bilaterally indicating arterial stenoses. Heart valve sounds and heart murmurs are primarily heard in the peristernal intercostal spaces indicating cardiac timing, and valve stenosis and incompetence (insufficiency or regurgitation). Breath sounds in the lung indicate both airway sufficiency, lung inflation, alveolar inflation and pleural friction. Bowel sounds (after [21.1, 2]) indicate normal peristalsis; bowel in the scrotum indicate intestinal hernia. Crepitus on motion indicates air in the tissue, bone fracture or joint (after [21.3–6]) cartilage damage. Auscultation in the antecubital fossa during blood pressure cuff deflation yields Korotkoff sounds (after [21.7, 8]), 1 – a sharp sound each systolic peak when the cuff pressure equals the systolic pressure indicating the momentary separation of the artery walls and the onset of blood flow, 2 – a loud blowing sound due to blood turbulence, 3 – a soft thud when the artery under the cuff is exhibiting maximum change in arterial diameter, 4 – a soft sound indicating slight arterial deformation near diastolic pressure, 5 – silence when the cuff pressure is below the diastolic arterial pressure ◀

in flow velocity results in an increase in *turbulent diffusion*, or the transfer of energy from the flow to the surrounding tissues through a growing chain of turbulent eddies. When the passages are smaller, the eddies decrease in size, causing an increase in the frequency of the audible sound. The pressure drop caused by a small lumen is higher, causing an increase in eddy velocity and therefore an increase in acoustic power, and the flow rate is decreased, causing a longer duration of flow to fill and empty the lungs. Thus the breath sounds are louder, longer, higher-pitched sounds compared with normal lung sounds. In some medical conditions, the flow dynamics may be just right to produce coherent eddy structures, such as one would see in a smoke stack. These signals result in a narrow-band frequency tone.

Abnormal snapping or popping sounds may also be present in the lung. In the normal lung, the alveoli (terminal air sacks, $280\,\mu$m in diameter, 3×10^8 in lung) are filled with air. In pneumonia, regions of alveoli are filled with fluid, which prevents a rapid increase in size without the introduction of a gas phase. The rapid introduction of a gas phase when the lung is expanded during the inspiration phase of respiration causes a tiny snapping sound (broadband acoustic impulse) in each alveolus; many snaps together cause the sound of *rales*.

Because of the lubricant normally present in the pleura located between the lungs and the chest wall, there are normally no sounds generated through a friction rub due to the sliding of the lung along the chest wall. When the pleura are inflamed, coarse rubbing sounds can be heard during breathing.

Cardiac

The cardiovascular system also generates normal and abnormal sounds that can be heard in the chest with a stethoscope [21.9] (Table 21.2). Normal heart sounds [21.10–12] are caused by rapid blood decelerations resulting from the closure of the heart valves. Each of the four heart valves, the tricuspid, pulmonic, mitral and aortic (in order from the venous circulation to the arterial circulation), are flaccid sheets of tissue securely tethered in the closed position to form check (one-way) valves. Like a parachute opening, the valve leaflets move with the reversing blood flow until the tethers become taught, then the leaflets force a rapid deceleration of the blood which generates a sudden (broadband) *thump* with an acoustic power of several watts. No sim-

Table 21.2 Diagnosing valve disease from heart murmurs

	Time	**Side**	**Location**	**Position**
Tricuspid stenosis	Diastolic	Parasternal	3rd ICS	Supine
Tricuspid regurgitation	Systolic	Parasternal	3rd ICS	Supine
Pulmonic stenosis	Systolic	Right	Superior	Supine
Pulmonic regurgitation	Diastolic	Right	Superior	Seated
Mitral stenosis	Diastolic	Left	Apex	Supine
Mitral regurgitation	Systolic	Left	Apex-Axilla	Supine
Aortic stenosis	Systolic	Parasternal	Superior	Supine
Aortic regurgitation	Diastolic	Parasternal	Superior	Seated

Side parasternal: in the intercostal spaces on either side of the sternum
Location 3rd ICS: the space between the 3rd and 4th rib, Erb's point
Position seated: Seated, leaning forward, breath in expiration

ilar rapid acceleration is associated with valve opening. Because the sounds are primarily radiated along the axis of acceleration and conduct better through tissue than the air-filled lungs, the sound of each valve is most prominent at a particular location on the chest wall.

Though four valves are present, usually only two thumps are heard, and they occur at vary precise times in the cardiac cycle. 20 ms after the onset of ventricular contraction, the tricuspid and mitral valves close, causing the first heart sound. 50 ms after closure of the atrioventricular valves, the pulmonic and aortic valves open silently. 320 ms after the onset of ventricular contraction, when ventricular ejection is complete and the ventricular pressures drop below the pulmonary trunk and aortic pressures, the pulmonic and aortic valves snap shut, generating the second heart sound. These times do not vary with heart rate; each cardiac cycle acts like an independent impulse-response system. The systolic ejection volume does vary with the diastolic filling period from the prior cardiac cycle.

Thus, each of the two heart sounds is generated by two valve closures, one in the left heart and one in the right heart. These usually occur simultaneously, however, the sounds do split into two if the inflow valves (tricuspid and mitral) or outflow valves (pulmonic and aortic) close at different times. These *split heart sounds* [21.13] can be indicative of an abnormality. The closure of the tricuspid valve is dependent on contraction of the right ventricle, which in turn is dependent on the electrical conduction system from the pacemaker of the heart. As a result, a delay in conduction or a slow response of the right ventricular muscle (myocardium) will delay the tricuspid sound, causing splitting. Similarly, if there is a delay in the conduction system of the left heart, or the left ventricular myocardium contraction is slow, then the mitral sound is

delayed. The closure of the outflow valves is dependent on contraction strength, pressure in the outflow vessels, and ejection volume. A mismatch of any of those factors will cause the pulmonic and aortic valves to close at different times, splitting the second sound. Even the effects of respiration on the filling and emptying of the heart chambers cause some normal heart sound splitting.

Abnormal sounds that occur in the cardiovascular system are called *bruits* and *murmurs* [21.14–17]. A murmur is a sound lasting longer than 10 ms heard by a cardiologist from the heart; a bruit is a similar sound, but heard by an angiologist from an artery. Veins rarely make sounds; venous sounds are called *hums* because they are continuous. A *thrill* is a similar vibration felt by the hand. Because these represent power dissipation from the cardiovascular system, all are considered abnormal. The absence of normal bruits and murmurs results from a biological feedback that forms the shape of the cardiovascular system. The feedback mechanism is not well understood. In fluid mechanics, the transition from laminar flow to turbulent flow occurs near a Reynolds number of 2000. Turbulent flow is highly dissipative while laminar flow is minimally dissipative. Coincidentally, peak flow through the cardiovascular system maintains a condition of Reynolds number less than 2000. If a heart valve or an artery is required to carry higher flow rates, then the conduit will dilate until the Reynolds number (proportional to the flow divided by the diameter) becomes less than 2000. Distal to a stenosis, where turbulence occurs, the conduit dilates, causing post-stenotic dilation. Thus, it appears that sustained turbulence, which dissipates power, is the driving force for remodeling to avoid turbulence and make the hemodynamic system more energy efficient.

The vibrations indicate the presence of disturbed blood flow, caused by deceleration of the blood beyond

a narrow stenosis. The vibrations are associated with a pressure drop across the stenosis because of a transfer of hydraulic power to acoustic power through a cascade of eddies. In turbulent flow, the vibrations are broadband. When coherent eddies are present, the vibrations are narrow band, and the frequency of the eddies can be related to the flow velocity (v_f) and vessel diameter (d) through the Strouhal number ($St = fd/v_f$). In addition to the location and power of a bruit, the frequency of the bruit is also helpful in evaluating its clinical importance. The Strouhal number has been used for the prediction of the residual lumen diameters of carotid stenoses. If the frequency of a bruit is divided into the number 500 [mm Hz], the result is the minimum lumen diameter [21.18–25] in mm. In clinical testing, this method accurately predicted the stenosis in hundreds of cases. However, because cumbersome technology is involved, and because the method fails in tight stenoses, which are most clinically important, this clever method has been abandoned.

Heart murmurs are auscultated at a series of locations on the precordium (the front middle of the chest around the sternum). They are graded from grade 1 (barely audible) to grade 6 (no stethoscope needed). Murmurs may result from leaky (incompetent, regurgitant) valves, stenotic (narrow) valves, or other holes between heart chambers. The differential diagnosis of heart murmurs is based on the timing of the murmur and the locations on the chest wall [21.26, 27] where the murmur is best heard. A murmur can be early systolic, mid-systolic, late systolic, or early diastolic, or mid-diastolic. If a murmur is best heard in the left second intercostal space (the space between the second rib and the third rib along the left boarder of the sternum), it is most probably an aortic stenosis [21.28–30]. Each of the other valve pathologies has a corresponding location where the murmur is likely to be highest. Of course, there is a great deal of variability between patients, and the examiner must apply a full set of detective skills to sort out a proper diagnosis.

There are some common systolic heart murmurs. Athletes, with temporary increased blood flow due to exercise programs have physiologic systolic heart murmurs, as do pregnant women, who have a 30% increase in cardiac output to supply the placenta. Hemodialysis patients also often have systolic heart murmurs because of the increased cardiac output required to supply the dialysis access shunt [21.31] in addition to the supply to the body. In these cases, remodeling of the blood vessels to increase the flow diameter has not had time to occur.

Bruits are almost always associated with stenoses in arteries, which often require treatment. They are classified by their pitch and duration. The occurrence of bruits in the head, in the abdomen after eating and in the legs are all indications of arterial stenoses, or high-velocity blood entering vascular dilations. The presence of a bruit heard in the neck is usually indicative of a carotid stenosis. The carotid arteries are the major vessels located on the left and right side of the neck that supply blood to the brain. The development of an atherosclerotic plaque causes luminal narrowing and the corresponding onset of disturbed flow. This lesion is associated with a 20% risk of stroke in two years from material that can be released by the atherosclerotic plaque and travels to the brain to occlude a branch artery.

Carotid bruits are usually present when the residual lumen (stenotic) diameter is greater than 50% of the original lumen diameter (called a 50% diameter reduction), but less than 90% of the original lumen diameter (90% diameter reduction) In this range, the blood flow rate to the brain through the carotid artery is approximately $5 \, cm^3/s$. If the pressure [21.32] drop across the stenotic region is about 20 mmHg, then the power dissipation at the stenosis is 13 mW, which can appear as sound energy in a bruit. Unfortunately, as the stenosis becomes more severe, the flow rate along the artery decreases, reducing the acoustic power for the bruit, so the bruit is no longer detectable, even though this more severe stenosis carries a higher risk for stroke. The decreased blood flow will not cause symptoms in most people because 95% of the population have collateral connections (the circle of Willis) that can provide the required blood flow that is not delivered by the stenotic artery. In the remaining 5% of the population, a severe carotid stenosis causes impaired mental function.

One of the barriers to new methods in the classification of carotid stenosis is that the first description of the relationship between carotid artery stenosis and apoplexy (stroke) was provided by Egaz Moniz in 1938. Moniz used percent diameter reduction and everyone has followed suit, through a confusing and contentious evolution, even when more-rational and useful alternatives have been developed. Thus, a new method that predicts residual lumen diameter will not be easily adopted by the medical community because of the tradition of using percent diameter reduction.

Bruits may be generated in the abdomen by stenoses in the renal arteries, which supply the kidneys. A renal artery stenosis will cause renovascular hypertension because the kidney is a transducer for detecting low blood pressure. The pressure drop across a renal artery steno-

sis causes the kidney to measure a low pressure, and deliver the signals to raise blood pressure in the arterial system, causing hypertension in all arteries except those in the affected kidney. The transduction system is called the renin-angiotensin-aldosterone system.

Some cardiovascular sounds are so loud that they cannot be missed. A patient in renal failure, refusing dialysis, had a cardiac friction rub (friction in the pericardial sack from inflammation). The 1 kHz *squeak* occurring with each systole could be heard from the doorway of the patient's room.

A stethoscope can also be used to detect bowel sounds from the abdomen. These sounds are generated by the liquid and gaseous contents of the bowel being forced from one intestinal segment to another through an orifice created by peristaltic action. The same fluid eddies described above are responsible for these sounds. The presence of bowel sounds is an important indicator of a normally functioning gut. It is common, the day after abdominal surgery, to check to be sure that normal bowel sounds are present.

Palpation, though not an acoustic technique, is used to feel, rather than hear, the same vibrations. Hemodialysis patients have a *vascular access* shunt created by tying an artery directly to a vein. This shunt may have a flow rate of 3 liters per minute, half of the cardiac output. The pressure drop is equal to the systolic blood pressure 120 mmHg. So the hemodynamic power dissipated in the shunt is 800 mW of power. This energy is converted to a vibration (thrill) which can be felt with the fingers.

Acoustic Stethoscope

Auscultation may be performed directly, but is most commonly conducted with a stethoscope. The device was invented by Dr. Rene Theophile Hyacinthe Laennec in 1816. While examining a patient, Dr. Laennec rolled up a sheet of paper and placed one end over the patient's heart and the other end over his ear. Dr. Laennec later replaced the rolled paper with a wooden tube (similar in appearance to a candlestick), which was called a stethoscope from the Greek words *stethos* (chest) and *skopein* (to look at). Two modern versions of the stethoscope are notable: the binaural stethoscope and the fetal stethoscope. The common binaural stethoscope consists of a bell connected by flexible tubing to a pair of earpieces. Each earpiece is sealed into the corresponding external auditory meatus. The bell is sometimes covered with a diaphragm, which acts as a high-pass filter. For example, normal heart sounds have frequencies near 50 Hz while heart murmurs have frequencies exceed-

ing 100 Hz. Filtering out the normal heart sounds with the diaphragm of the stethoscope often allows pathologic murmurs to be detected. When using an open bell stethoscope, a diaphragm can be formed by pressing the bell tighter to the skin, stretching the skin and deeper tissue, which attenuates the lower frequencies [21.33–36].

The fetal stethoscope is designed for use in the auscultation of fetal heart sounds, which can be detected during the final half of a 40 week pregnancy. The fetal stethoscope uses a rod connecting the mother's abdominal wall to the examiner's forehead to transmit the sound by bone conduction in the examiner's head to the inner ear where it is converted into nerve impulses. This avoids the impedance changes between tissue and air at the skin surface and then again from air to tissue in the middle ear.

For the last 20 years, small ultrasonic Doppler ultrasound stethoscope systems have been available to detect the fetal heart beat [21.37, 38]. They operate like the ultrasound imaging *phono-angiograph* to easily detect solid tissue vibrations from deep in the body. These continuous-wave instruments allow the pregnant mother to perform easy self-examination. They are available on a rental basis without a medical prescription.

Electronic Stethoscope

Electronic stethoscopes [21.39–41] provide improved amplification and background noise cancelation over traditional stethoscopes. Some also have recording capabilities to provide quantitative, rather than just qualitative, assessment of the sounds heard. For example, by listening to the neck with a phono-angiograph (Fig. 21.2), the location and duration of the bruit can be documented. A phono-angiograph is just an electronic stethoscope with an attached oscilloscope. If applied to the heart, then it is called a phono-cardiograph. This bruit (Fig. 21.2), is a pan-systolic bruit (lasting all of systole) but not a pan-diastolic bruit (lasting all of systole and diastole). Since arterial blood velocities are higher during systole than diastole, all arterial bruits include systole. The exceptions, where arterial flow in a collateral pathway is reversed due to a *steal syndrome* are so rare that common names have not been adopted for this condition. To be sure that the bruit is systolic, the examiner can palpate the pulse at the wrist while listening, to associate the bruit timing with systolic arterial motion.

However, if such an image were gathered with a phono-cardiograph (Fig. 21.3) from the heart, it would be impossible to know whether the murmur was coming from aortic or pulmonic stenosis (during systole), aortic or pulmonic regurgitation (during diastole), from
Fig. 21.2a,b Carotid phono-angiography (CPA) (**a**) A microphone fitted with an acoustic coupling to the neck gathers sounds, which are displayed on an oscilloscope and captured with an instant camera. (**b**) The sounds displayed are classified by the location, amplitude, and duration of the bruit. A similar method, phono-cardiography, was used for the heart. A method, quantitative phono-angiography (QCPA) provided an analysis of the frequency content of the bruit

Fig. 21.3 Phono-cardiograph transducer. To avoid sounds and motions introduced by the examiner's hand on the chest, this phonocardiography transducer is fitted with a suction ring and elastic strap to secure the transducer element to the chest. Early echocardiographs had provision for amplifying and displaying the phono-cardiograph signals, which were filtered to display audible frequencies or infrasonic frequencies

tricuspid or mitral regurgitation (during systole), or tricuspid or mitral stenosis (during diastole), unless there were some indication of the timing of the cardiac cycle. A phono-cardiogram displays an associated electro-cardiograph (ECG) tracing to provide that timing information.

Unfortunately, electronic stethoscopes, phono-angiographs and phono-cardiographs are considered too complicated for use in everyday medical practice. Al-

though they do provide a graphical output for the patient chart (required documentation to receive payment for diagnostic procedures), a separate current procedural terminology (CPT) code is not available for phono-angiography, phonocardiography or for stethoscope examination. Like the stethoscope examination, these procedures, if performed, are considered part of a standard office visit. Physicians are reluctant to use technical examination methods if they cannot charge for the extra time involved. Although a few research facilities documented bruits and murmurs detected with these systems between 1965 and 1985, the systems have nearly disappeared from medical practice. Like the first half of the 20th century, physicians today are trained to use acoustic stethoscopes. Of course, as physicians become more experienced and more mature, their hearing deteriorates. Even the most respected cardiologist will fail to correctly diagnose cardiac valve disease in 50% of patients. Bruits with 35 μm, 300 Hz vibrations from the jugular vein (Fig. 21.4) documented by a new ultrasound imaging phono-angiograph were not detected by stethoscopic auscultation. So, in spite of the ubiquitous use of stethoscopes for bruit/murmur detection, their sensitivity may not be adequate for the task.

21.2.2 Phonation and Auscultation

In addition to listening for sounds with a stethoscope, an examiner may cause the generation of sounds to assess transmission or resonance. During auscultation of the lungs, an examiner may ask the patient to phonate (make voice sounds) at different frequencies "Say 'eeeeeee', now say 'aaaaaaaa'". During that period, the examiner will either palpate the chest wall for vibration or listen to the chest wall with a stethoscope. Poor sound transmission may indicate that the airways are obstructed, enhanced sound transmission (enhanced *fremitus*) indicates fluid has filled a space normally occupied by air.

21.2.3 Percussion

Percussion is another method of sound generation by striking the chest or abdomen to assess transmission or resonance. The skin may be struck with the hand or finger, or one hand may be placed on the skin and struck with the other hand. A higher-frequency shorter pulse can be generated by placing a coin on the skin and striking the coin with another coin. The resultant sound can be assessed by listening to the resonance through the air or by using a hand or stethoscope to assess trans-

Color Doppler

Vibrometry

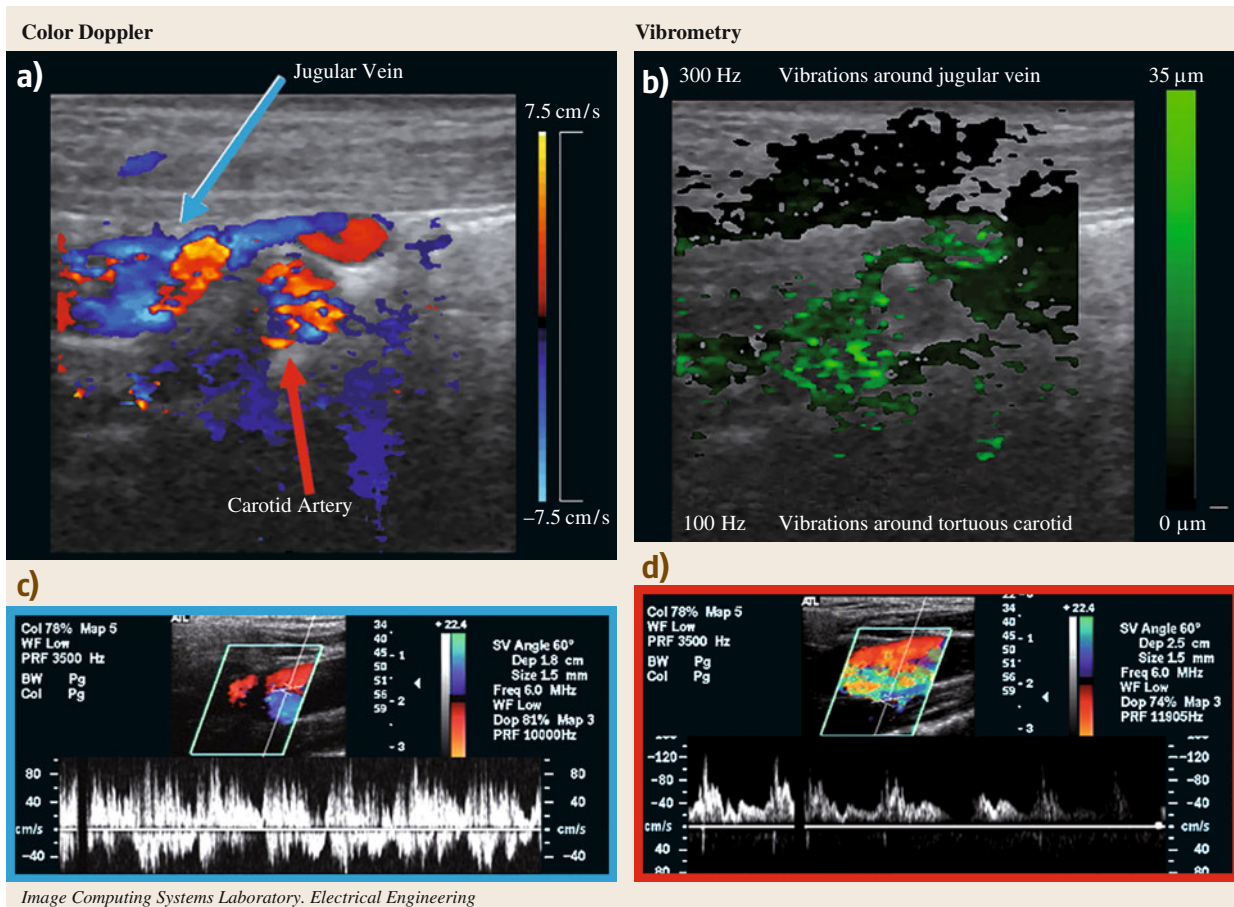
Image Computing Systems Laboratory. Electrical Engineering


Fig. 21.4a–d Imaging vibrometry of the neck. (**a**) Color Doppler image, (**b**) vibration image, (**c**) jugular vein Doppler and (**d**) carotid artery Doppler of a patient complaining of *vibrations in the head*. The 300 Hz vibrations with an amplitude of 35 μm could not be heard with a stethoscope by either of two experienced examiners (courtesy M. Paun, S. Sikdar)

mission of the impulse. Percussion that results in a dull sound indicates a fluid-filled space below the skin; a resonant sound indicates an air-filled space below the skin. These methods are often used to find the lower boarder of the lungs, to identify fluid-filled consolidation in the lungs, and to find the edge of the liver (fluid-filled) in the abdomen (air-filled intestines).

These acoustic examination techniques have been developed in medical practice over centuries, and al-

though efforts have been made to use electronic aids for diagnosis and for training, still, the common practice is to learn these methods from a mentor. In the last quarter of the 20th century, ultrasound has become adopted in specialty medical practice, but has not made inroads in general practice. It is likely that, if and when ultrasound diagnostic methods become widely used in general medical practice, it will be used with the same level of skill as stethoscope auscultation.

21.3 Basic Physics of Ultrasound Propagation in Tissue

The vibrations of molecules at any location (or time) in a sound wave can be characterized by four parameters: the pressure fluctuation from the mean static pressure

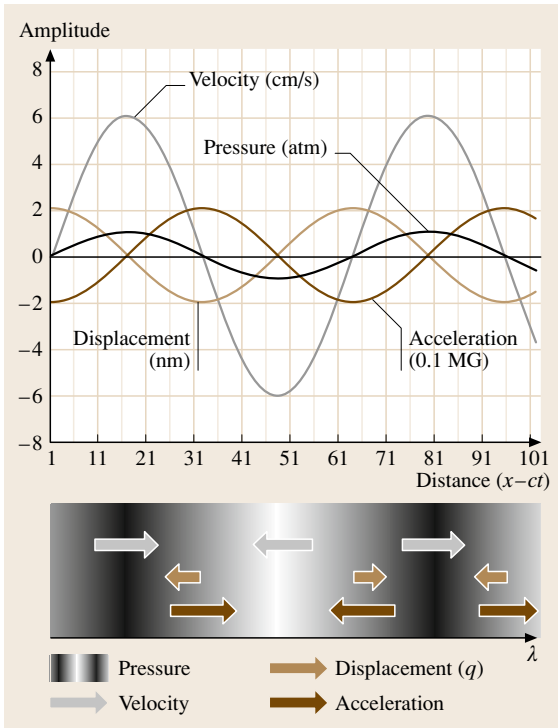
(p), the molecular velocity (v), the displacement of the molecules from the resting location (d), and the molecular acceleration (a). The two most basic parameters,


Fig. 21.5 Typical acoustic parameters of a $300\,\mathrm{mW/cm^2}$, $5\,\mathrm{MHz}$ ultrasonic wave in tissue impedance. Input parameters: Tissue impedance $= Z = 1.5\,\mathrm{MRayles} = 1.5\,\mathrm{MN\,s/m^3}$ $= 1.5 \times 10^6\,\mathrm{kg/(m^2 s)}$, pressure amplitude $= p = 1\,\mathrm{atm}$ (bar) $= 101\,\mathrm{kPa\,(kN/m^2)} = 760\,\mathrm{mmHg}$ (Torr), frequency $= 5\,\mathrm{MHz}$; resultant wave parameters: intensity $= 0.33\,\mathrm{W/cm^2}$ $= p^2/2Z$, peak molecular velocity $= 6\,\mathrm{cm/s} = p/Z$, molecular displacement $= 1.9\,\mathrm{nm}$, molecular acceleration of 0.19 million times the acceleration of gravity

pressure deviation and molecular velocity are dependent only on the intensity of the sound. Their ratio, p/v, is determined by the acoustic impedance ($Z = p/v$), a property of the tissue. At the sound level shown in Fig. 21.5, $300\,\mathrm{mW/cm^2}$ ($3\,\mathrm{kW/m^2}$), the maximum acoustic pressure fluctuation equals 1 atm. If the sound intensity is increased, then the negative peaks represent a pressure below zero. Most ultrasound examinations are performed at pulse peak intensities 25 times this high, and therefore, peak amplitudes five times atmospheric pressure, making the compressions 6 atm and the decompressions -4 atm.

The linear acoustic relationships can be easily derived using a simple linear elastic model of tissue (Fig. 21.5) and Newton's first law of motion on the molecules. The molecules in the tissue will accelerate

along the axis of the ultrasound propagation (x) and displace a distance (q) away from equilibrium because of a gradient in pressure ($\mathrm{d}p/\mathrm{d}x$), which is related to the tissue compression ($\mathrm{d}q/\mathrm{d}x$) and the tissue stiffness (κ).

$$p = -\frac{\kappa\,\mathrm{d}q}{\mathrm{d}x} = -\kappa q' \,, \tag{21.1}$$

$$\kappa\frac{\mathrm{d}^2 q}{\mathrm{d}x^2} = -\frac{\mathrm{d}p}{\mathrm{d}x} = \rho\frac{\mathrm{d}q^2}{\mathrm{d}t^2} \,. \tag{21.2}$$

Solving this equation with the variable $q(x - Ct)$ produces

$$\kappa q'' = \rho C^2 q'' \,, \tag{21.3}$$

so

$$C = \sqrt{\frac{\kappa}{\rho}} \,. \tag{21.4}$$

The molecular velocity ($v = \mathrm{d}q/\mathrm{d}t = -Cq'$) and the tissue pressure ($p = -\kappa q'$) form an important ratio

$$Z = \frac{p}{v} = \frac{\kappa}{c} = \sqrt{\kappa\rho} = \rho C \,. \tag{21.5}$$

Although the tissue density (ρ) and stiffness (κ) determine the acoustic impedance (Z) and acoustic wave
Fig. 21.6 Acoustic properties of materials of medical interest. Empirically, the acoustic properties of tissues fall on a line relating ultrasound speed (c) and tissue density (ρ); $c = 2\rho$. Using the equation for impedance $Z = \rho c$, then $Z = c^2/2 = 2\rho^2$. Polyvinylidene fluoride (PVDF) transducer material has acoustic properties near soft tissue, lead zirconate titanate (PZT) transducer material has much higher density and acoustic impedance

Wave velocity and density of tissue
Fig. 21.7 Acoustic properties of soft tissues

speed (C), it is more convenient to measure the density and wave speed of a material and compute the impedance.

A good deal of effort has been devoted to measuring the properties of tissues (Figs. 21.6–21.8). Measurement differences between laboratories and differences

Wave velocity and density of tissue
Fig. 21.8 Detailed acoustic properties of soft tissues

in tissue preparation contribute to the variability of tissue property values. While living mammalian body tissues are held to a temperature near $37\,°\mathrm{C}$, and have blood flow that swells the tissue and changes the average composition with the heart rate and respiratory rate, it is convenient to measure properties of dead tissue at bench-top temperatures ($25\,°\mathrm{C}$). Fortunately, the exact acoustic properties of tissues have not proven very useful in clinical diagnostic applications. Ultrasound imaging methods have not been able to differentiate tissue types in spite of a half century of efforts. The identification of disease with ultrasound imaging uses the shapes of large structures as the primary diagnostic tool.

21.3.1 Reflection of Normal–Angle–Incident Ultrasound

When ultrasound intersects an interface between two materials with differing acoustic impedances (Z_1 and Z_2), perpendicular to the interface, then the amplitude of the reflection of ultrasound at the interface can be computed from the requirement that the pressure change and molecular velocity of the incident wave (p_i, v_i) must equal sum of the pressure changes and molecular velocities of the transmitted and reflected waves (p_t, p_r, v_t, v_r). The impedances of the materials relate the pressures and molecular velocities ($Z_1 = p_i/v_i = -p_r/v_r$, $Z_2 = p_t/v_t$). The pressure reflection and transmission coefficients are

$$\frac{p_r}{p_i} = R = \frac{Z_2 - Z_1}{Z_2 + Z_1} , \tag{21.6}$$

$$\frac{p_t}{p_i} = T = 2\frac{Z_2}{Z_2 + Z_1} . \tag{21.7}$$

Note that if the acoustic impedance of the second material is lower than the acoustic impedance of the first material, then the reflected wave is inverted. The sum of the transmitted and reflected power equals the incident power.

21.3.2 Acute–Angle Reflection of Ultrasound

If the ultrasound is incident on the interface at an acute angle, the ultrasound that passes into the second tissue is tilted to a new direction according to Snell's law (Fig. 21.9).

$$\frac{C_1}{\sin\theta_1} = \frac{C_2}{\sin\theta_2} . \tag{21.8}$$
Fig. 21.9 Refraction of ultrasound as it passes from one material to another. *Dark brown*: incident compressional wavefronts and wave vector incident at angle θ_1. *Light brown*: reflected compressional wavefronts and wave vector reflecting at angle θ_1. *Gray*: transmitted compressional wave. The interfacial shear wave increases in intensity as the ultrasound beam cross section coherently contributes to the wave; attenuation of the shear wave causes a rapid decrease in amplitude outside the beam

Because the component of molecular velocity normal to the surface must be preserved:

$$\frac{p_r}{p_i} = R = \frac{\frac{Z_2}{\cos\theta_2} - \frac{Z_1}{\cos\theta_1}}{\frac{Z_2}{\cos\theta_2} + \frac{Z_1}{\cos\theta_1}} \ . \tag{21.9}$$

In this case, not all of the ultrasound power is found in the sum of the reflected wave and the transmitted wave. The remaining portion of the power appears as a surface *capillary* wave propagating along the surface of the interface. This capillary wave is subject to high attenuation. Because tissue has an interface on every cell boundary and every tissue boundary, this mechanism is responsible for some of the conversion of incident ultrasound power into heat as ultrasound propagates into tissue. It is important to notice that the propagation speed of the capillary wave is not the same as that of the component of the compressional wave directed along the interface, so the capillary wave is out of phase with the ultrasound wave, contributing to the transfer of energy into the capillary wave. Outside the ultrasound beam, the capillary wave takes on its conventional wavelength (c_s/f), where f is the ultrasound frequency. The propagation speed of the capillary wave (c_s) is proportional to the interfacial tension.

21.3.3 Diagnostic Ultrasound Propagation in Tissue

Diagnostic ultrasound uses ultrasound frequencies of 1–30 MHz. (MHz = cycles per μs). The speed of ultrasound in most tissues is near 1.5 mm/μs (1500 m/s). There are some notable exceptions. In bone the speed is between 3.5 mm/μs and 4 mm/μs, and in air the speed is 0.3 mm/μs. In cartilage the speed is 1.75 mm/μs which of course varies with composition. In fat the speed is 1.45 mm/μs (Table 21.3). In muscle, the speed of ultrasound varies by about 1.5%, depending on the angle of propagation to fiber orientation.

Although most authors focus attention on ultrasound frequency, ultrasound wavelength may be more convenient for understanding the important issues. There are three issues of importance:

- Ultrasound cannot resolve structures smaller than the wavelength.
- Scattering and attenuation [21.42] both depend on ultrasound wavelength and its relationship to the size of the scatterers.
- The focusing properties of ultrasound beam patterns and the formation of side-lobes depend on the ratio between the wavelength and the width of the transducer.

21.3.4 Amplitude of Ultrasound Echoes

Red blood cells (erythrocytes) are 0.007 mm in diameter and about 0.001 mm thick. The largest cells in the body, nerve axons, may be 1 m long, but their diameter is about 0.001 mm. A liver cell is about 0.04 mm in diameter. The smallest structures imaged by ultrasound in clinical practice are layers less than 1 mm thick, such as the media lining major arteries (the intima-media thickness, IMT) [21.43], corneal layers (with 30 MHz ultrasound) and skin surfaces. However, these structures can only be observed in the range (depth) direction because resolution is best in that direction. Lateral resolution is dependent on the numeric aperture of the ultrasound beam pattern and the relationship between the object of interest and the focus as well as the ultrasound wavelength. Only the ultrasound wavelength affects depth resolution. The result is that ultrasound images are anisotropic, with much better resolution in the depth direction than in the lateral direction. The image is delivered to the examiner as a pictorial map in two dimensions. In our optical experience, resolution is equal in the two dimensions. Therefore, we expect

Table 21.3 Ultrasound wavelength versus tissue thickness. To resolve the thickness of these structures, the ultrasound frequency must be much higher than listed in this table. Much lower-frequency ultrasound passes through with little interaction. For particles or cells, lower-frequency ultrasound is subject to Rayleigh scattering

Tissue	Property	Dimension (mm)	Ultrasound Speed (mm/μs)	Frequency (MHz)
Trachea	Lumen diameter	25	0.32	0.013
Aorta	Lumen diameter	30	1.57	0.063
Fat layer	Subcutaneous	20	1.45	0.080
Myocardium	Thickness	10	1.6	0.16
Skull	Thickness	10	4	0.4
Brain	Cortex	3	1.5	0.5
Artery	Wall	0.8	1.6	2
Trachea	Wall	0.6	1.75	2.9
Bone	Cortex	1	4	4
Eye	Cornea	0.6	1.64	2.73
Skin	Dermis	0.3	1.73	5.76
Fat	Cell	0.1	1.45	14.5
Brain	Cell, large	0.1	1.5	15
Skin	Epidermis	0.05	1.73	35
Erythrocyte	Cell	0.007	1.57	225
Bacteria	Cell, large	0.005	1.5	300
Brain	Cell, small	0.004	1.5	375

Notes:
1. Trachea lumen: for phonation below 13 kHz, the trachea diameter is smaller than the wavelength so that the trachea acts like a waveguide, bounded by cartilage with acoustic velocity and impedance higher than the luminal air.
2. Bone cortex and thin skull have thicknesses near the wavelength of transcranial ultrasound and a much higher ultrasound impedance, so the skull can act as an interference filter reflecting some wavelengths and passing others.
3. As the upper limit of most medical ultrasound systems is 15 MHz, small animal research instruments image at frequencies as high as 70 MHz, high enough to resolve the epidermis and large brain cells, but not high enough to image most cells.

that, if we can see detail in one dimension, we can also see the detail in the other, even when we cannot. This gives the impression that ultrasound has higher resolving power in the lateral direction than it in fact does. This is particularly important in measurements such as the IMT and measuring the thickness of the atheroscle-

rotic cap. Such structures can only be visualized when the ultrasound beam is oriented perpendicular to the structure.

To identify tissues and organs, the lateral dimensions must by at least 10 wavelengths wide. This number varies depending on the numeric aperture of the imaging system and on the acoustic contrast with the surrounding material. Small round structures such
Fig. 21.10 Near-field versus far-field difference in ultrasound image. This is an image taken with a diagnostic scanner using a 5 MHz ultrasound transducer (wavelength = 0.3 mm) with a concavity radius of 16 mm and a transducer diameter of 6.4 mm. The computed *transition zone* is $d^2/4\lambda = 34$ mm. The *focus* must be less than the 34 mm distance to the transition zone to be effective. With a fixed-focus fixed-aperture ultrasound transducer, the transition from the near field to the far field is marked by lateral spreading of the speckle in the far field. There is no effect on the range (depth) speckle dimension ◄

as tendons can be imaged using tricks, such as watching for motion, but most objects successfully imaged by ultrasound are larger. It is important to remember that it is possible to see an object that you cannot resolve. For instance, you are able see stars or lights at night, even though you cannot resolve closely spaced pairs of stars. When the signal from a target is strong, the target can be detected and located, even though a pair of targets cannot be resolved as two. If Doppler demodulation is used, rather than amplitude demodulation (used for B-mode), small vessels with blood flow can be resolved if the signals are strong enough.

Ultrasound imaging is a coherent process that generates speckle in the image. This is often called *tissue texture*, but the spacing of the speckle is about equal to the burst length of the ultrasound pulse, which is up to several wavelengths, and this is much greater than the fine cellular structure of the tissues under observation. Our visual processing is so good that we integrate prior knowledge, and outline shape seamlessly into our recognition process, while believing that we are recognizing texture.

Ultrasound imaging and aeronautical radar imaging are electronically identical. However, in aeronautics, the space between aircraft is very large compared to the size of the aircraft and to the wavelength of the radar wave. In medical ultrasound imaging, the cells are tight packed together, and the cell size ($10\,\mu m$) is smaller than the wavelength of ultrasound ($500\,\mu m$) so that the scattering is complex. In addition, ultrasound medical imaging systems often generate images from the complex near field (Fresnel zone) of the ultrasound transducer (Fig. 21.10). This becomes particularly confusing when tissues are moving laterally through an array of ultrasound beams. Because of the Moire effect of this system, tissue motions from left to right can cause speckle patterns to move right to left.

21.3.5 Fresnel Zone (Near Field), Transition Zone, and Fraunhofer Zone (Far Field)

The transition between the Fresnel and Fraunhofer zones can be computed from geometric considerations (Fig. 21.11). As in the computation of the basic wave equations, we assume that ultrasound propagation is a linear process and that superposition holds (pressure fluctuations and molecular velocity fluctuations can be added). Although some authors use Huygens' principle [21.44], dividing the transducer into tiny segments and adding the contribution of each to the wave, the computation is simplified if reciprocity is used (the transmitted ultrasound beam pattern and the received ultrasound beam pattern are the same), and the wave is
Fig. 21.11a−c Geometry of transition zone between near field (Fresnel zone) and far field (Fraunhofer zone) **(a)** A transducer consists of a piezoelectric element (PZT) with electrodes on the face with an impedance matching layer and on the back with a backing material. For computation, only the wave intersection with the matching layer face needs to be considered. **(b)** By geometry, the distance to the transition zone (Ψ) between the Fresnel zone and the Fraunhofer zone for a flat transducer can be estimated. The transition zone is located at the furthest distance from the transducer that the origin of a compression half-cycle of a wave can completely envelope the transducer face. r = transducer radius, Ψ = distance to transition zone, $\lambda/2$ = half wavelength, H = hypotenuse of transition radius. $H^2 = \Psi^2 + r^2$, $H - \Psi = \lambda/2$. If $\lambda/4 \ll \Psi$, then $\Psi = r^2/\lambda = d^2/4\lambda$, the accepted formula for the transition zone. A wave originating from a closer location (Fresnel zone), will always produce a combination of compressions and decompressions at the transducer surface. **(c)** Drawings can be made for focused transducers whether concave, lens or phased focus array, but the algebra is more complex. The equivalent concave curvature is shown by the *dotted circle*. F = transducer focal radius, J = hypotenuse of focal radius

assumed to be emitted from a test point in the ultrasound beam and received by the transducer.

A wave propagating from a stationary point will expand as a series of concentric spherical surfaces, spaced by the ultrasound wavelength with the source at the center. If the source is close to a planar transducer face, then at every time point some compressional spherical regions and some rarefactional spherical regions will simultaneously be present on the transducer face plane. This provides a mixed signal to the transducer, the compressions and rarefactions destructively interfering. There are some locations of the source point that result in equal areas of compression and decompression of the transducer surface at all times. These are locations where the transducer has no sensitivity, and are called null points. By reciprocity, if the transducer

emitted a wave, a null point will have no sound intensity from the transducer. Ultrasound transducer beam plots often show these null locations along the axis of the ultrasound beam. There may be several of these null points along the beam axis, and at other points in the beam pattern. The *near field* or *Fresnel zone* is the region of the ultrasound beam pattern where these null points are present. In the Fresnel zone, there is always some destructive interference of the ultrasound wave. The Fresnel zone is the region where beam focusing can be achieved.

When the source point is at a greater distance from the transducer plane, these regions of compression and rarefaction become nearly planar. There are times when the planar transducer surface can be completely contained in either a compression zone or a decompression zone. At this range, at least near the axis of the ultrasound beam pattern, there are no regions of destructive interference. This is the *far field* or *Fraunhofer zone*.

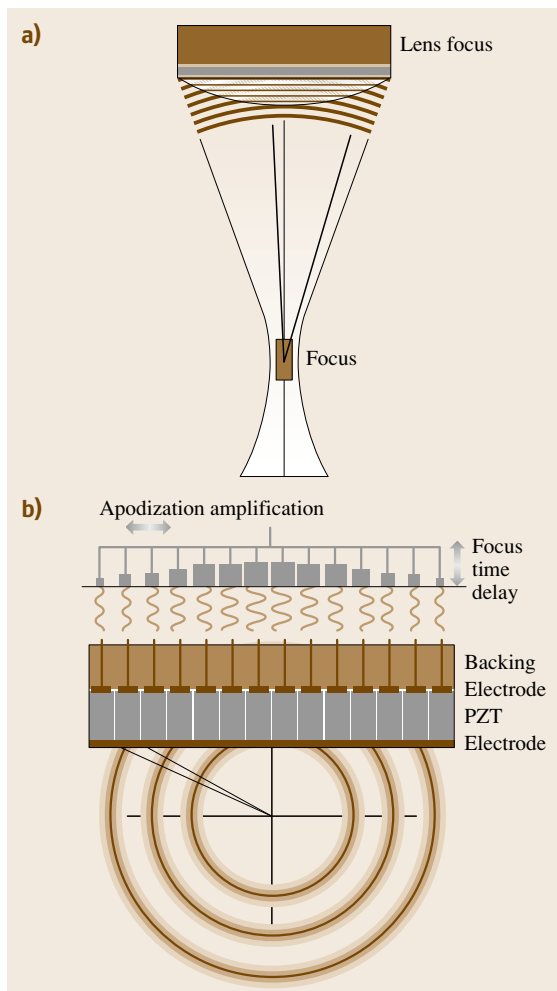
There is a transition between the Fresnel and Fraunhofer zones along the ultrasound beam axis, where it is first possible for the ultrasound transducer to be just barely completely contained in a compression half-wave region at some time within the ultrasound wave period. Half a period later, the transducer will be completely contained in a decompression half wave. This location is easily diagrammed geometrically (Fig. 21.11b) and the distance to the transition zone computed. Although the geometry for a similar computation for a concave transducer can be easily drawn (Fig. 21.11c), the algebraic solution for the focused


Fig. 21.12a,b Mechanical lens focusing and electronic delay focussing. (**a**) A low acoustic velocity in the lens allows the ultrasound traveling along the shorter central path to be delayed so that the ultrasound along the longer marginal paths can catch up, aligning the compressions and decompressions to provide the highest voltage excursions in the piezoelectric transducer element for ultrasound waves originating from the focal region. (**b**) Electronic delay lines in the signal path after the piezoelectric elements provide the same focusing function as the lens. Apodization *shading* of the sensitivity of the transducers at the edge of the aperture suppresses aperture diffraction side-lobes in the beam. The mechanical focus depth is determined at the time that the ultrasound transducer is manufactured; it cannot be altered by the examiner. The electronic focus depth can be adjusted to a different depth in a microsecond, the time that ultrasound travels 1.5 mm, so that the electronic focus can be adjusted to each depth during the time that the ultrasound is traversing the tissue ◄

transition, which is now retracted toward the transducer, is more difficult.

In addition to using a concave transducer, focusing of the ultrasound beam pattern can also be achieved by the use of a lens on the front of the transducer (Fig. 21.12a). The lens is often made of silicone rubber because of the low ultrasound propagation speed. Currently, most ultrasound scan heads consist of a linear array of 128 transducer elements; each element is 2 cm long and 0.5 mm wide arranged in a side-by-side row with a footprint of 2 cm by 6.4 cm. Focus is provided in the image thickness direction by a cylindrical

silicone rubber lens and in the lateral image direction by adjusting the relative phase of the adjacent transducers (Fig. 21.12b).

21.3.6 Measurement of Ultrasound Wavelength

Modern diagnostic ultrasound systems use sophisticated transducers and filters to improve resolution by shifting and broadening the ultrasound frequency band used for imaging, Doppler and other methods. It is possible, however, to use basic wave physics to measure the effective ultrasound wavelength of the system. In addition to refraction, ultrasound waves are also subject to diffraction. By placing a diffraction grating in the ultrasound image path in water, and imaging a point reflector, the diffraction pattern of the wave can be imaged and the wavelengths computed (Figs. 21.13, 21.14).

21.3.7 Attenuation of Ultrasound

As ultrasound passes through tissue as a pulse or as a *continuous wave* along the beam pattern, some of the ultrasound energy is converted to heat in the tissue and some is reflected or scattered out of the beam pattern. In addition, nonlinear propagation converts some of the energy to higher harmonics ($2f$, $3f$ ...) of the fundamental frequency (f) of the wave. Attenuation increases with frequency, and the harmonic frequencies also may be outside the bandwidth of the detection system. These factors contribute both to actual and apparent attenuation of the ultrasound energy in the pulse and the average power passing through a cross section of the ultrasound beam as a function of depth. Changes in intensity are related to these changes in power, but the
Fig. 21.13a–d Grating diffraction. Like any wave, an ultrasound beam can be tilted by a diffraction grating. The angle of tilt can be computed using Huygens' principle. If the pitch spacing of the grating is P, and the wavelength is λ, then the angle of deflection of the wave is expressed as $\sin \varphi = P/\lambda$. An ultrasound transducer array can act as a diffraction grating. This should be avoided. A diffraction grating in a water tank can be used to measure the wavelength of ultrasound. An image of a reflector deeper than the grating appears three times in the image, once at the true location and once for each of the diffraction orders. (a) Plane wave diffracted by grating. (b) Computaion of diffraction angle. (c) Ultrasound scanhead, diffraction grating and target. (d) Expected ultrasound image for a single frequency transducer ◄

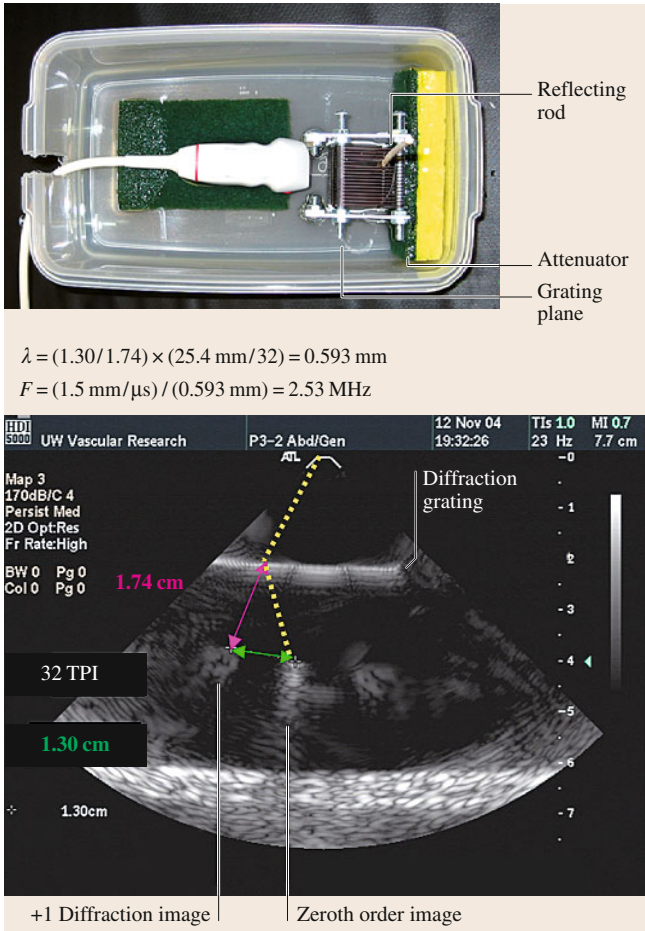
$$\lambda = (1.30 / 1.74) \times (25.4 \text{ mm} / 32) = 0.593 \text{ mm}$$
$$F = (1.5 \text{ mm}/\mu\text{s}) / (0.593 \text{ mm}) = 2.53 \text{ MHz}$$


Fig. 21.14 Measuring ultrasound frequency and bandwidth by viewing a reflecting rod through a diffraction grating. The cross section of a rod forms the zeroth-order spot in the image. In addition to passing the ultrasound beam pattern directly (the zeroth image) the diffraction grating forms a +1 branch of the beam pattern (shown in *yellow*), which makes an image of the rod to the *left* (+1 diffraction image) and a symmetrical −1 image on the *right*. By measuring the geometric sine of the deflection angle, (1.30/1.74), the ultrasound wavelength can be computed using the spacing of the grating. The grating is made of monofilament fishing line wound on a frame made of 10–32 threaded screws (32 threads per inch, pitch spacing = 0.8 mm)

intensity is power divided by the cross-sectional area of the beam, so changes in beam cross-sectional area cause intensity changes that are not related to attenuation. Focusing the beam pattern can decrease the area, increasing intensity; diffraction and refraction increase the area, decreasing intensity.

Ultrasound attenuation is usually expressed as a ratio of the output power divided by the input power. In linear systems, this ratio is constant for all ultrasound intensities. In nonlinear systems, the relationship is more complicated. The attenuation rate of ultrasound in tissue can be computed using base 10 (dB/cm, for engineers), base "e" (Np/cm, for scientists), compound percentage (% per cm, for physical therapists) or base 2 (half-value layers, for systems designers). The decibel, derived from the bel can be traced to Alexander Graham Bell, and the neper to John Napier. The bel is a factor of 10 in power, the neper is a factor of e (2.718) in amplitude. Ultrasound attenuation in soft tissue is between 3 dB/(MHz cm) and 0.3 dB/(MHz cm). Using intensity as the dependent variable in attenuation computations is complicated by changes in beam area. Some authors apply the bel to intensity. In acoustics the pressure amplitude of the wave, which is proportional to the square root of intensity (assuming constant impedance) is often used. The base 2 system is used to identify the thickness of tissue that attenuates the power by half, the intensity by half or the amplitude by half. The thickness is called the *half-value layer*, often without qualifying whether it is *half power*, *half intensity* or *half amplitude*. Intensity is proportional to the square of the amplitude, which is a multiplier of 2 in logarithms. If the cross-sectional area of the ultrasound beam is constant

$$
\begin{aligned}
0.7 \text{ nepers} &= 6 \text{ dB} \\
&= 1 \text{ half-amplitude layer} \\
&= 2 \text{ half-power layers .} \qquad (21.10)
\end{aligned}
$$

Often the attenuation rate is nearly proportional to frequency, and frequency is inversely proportional to wavelength, so the attenuation can be most easily

Table 21.4 Ultrasound attenuation

Tissue type	Half amplitude (quarter power) thickness in wavelengths	60 dB pulse-echo attenuation depth in wavelengths (10 bit dynamic range)	Attenuation dB/(cm MHz)
Bone	1	5	30
Cartilage	8	40	10
Tendon	8	40	10
Skin	25	125	3
Muscle	25	125	3
Fat	80	400	1
Liver	80	400	1
Blood	300	1500	0.25

expressed in wavelength (Table 21.4). The use of half-value layers has the advantage that it can be related directly to the number of bits in a digitizer, simplifying computation.

Because of the high instantaneous intensities used in pulse-echo diagnostic ultrasound, all of the ultrasound propagation is nonlinear. The commonly used linear equations do not apply. The beam patterns are not as predicted, because the wave propagation speed in the higher-pressure regions is faster than in the lower-pressure regions. The waves convert from sinusoidal to sawtooth, introducing a series of harmonic frequencies into the wave. The change in frequency (wavelength) affects the ultrasound beam pattern. The conversion of ultrasound energy into harmonic frequencies also increases the attenuation because the attenuation increases with frequency.

A significant development was the use of tissue-generated harmonic signals for diagnostic imaging. The utility of these harmonics was discovered by accident when investigators were searching for better methods of detecting ultrasound contrast agents. Ultrasound contrast agents consist of microbubbles that have natural oscillation frequencies near diagnostic frequencies. The bubbles therefore oscillate in response to incident ultrasound. The bubble oscillation stores some energy, which is reradiated at the original ultrasound frequency as well as at harmonics of that frequency. Older ultrasound systems were, by nature, insensitive to the second harmonic of the natural transducer frequency. By using a transducer with an increased bandwidth (3 MHz center frequency transducer manufactured with the quality factor reduced spreading the bandwidth to 1.9–4.1 MHz) then lowering the transmit frequency (2 MHz) and raising the receive frequency (4 MHz), a system sensitive to the harmonic emissions from the contrast bubbles can be achieved. Surprisingly, harmonic echoes are generated by tissues even when contrast bubbles are not present.

21.4 Methods of Medical Ultrasound Examination

Over the half century of ultrasonic medical examination, a variety of examination methods have been tried, discarded, with some to be resurrected and honed for use.

A passive method was evaluated to detect local ultrasound emissions above background due to local temperature elevations of cancerous tumors. The emissions of about 10^{-13} W/cm^2 (1 nW/m^2) are present in all warm tissues and provide a minimum intensity for the operation of active ultrasound systems. Transmission ultrasound systems have been developed using an ultrasound transmitter on one side of a body part and a receiver on the other side to detect differences in attenuation (like X-ray imaging). These systems determine ultrasound attenuation and ultrasound speed through the intervening tissues. One version of this system used an acousto-optical holographic system to form the image. Several systems have been explored to insonify tissue from one direction and gather the scattered ultrasound from another direction. Such systems usually require an array of receiving transducers.

The only ultrasound systems that have gained wide acceptance in clinical use are: (1) the continuous-wave (CW) backscatter Doppler system, and (2) common-axis pulse-echo backscatter imaging and Doppler systems. The reason for the failure of the other systems is due to two features of medical ultrasound examination: refraction of ultrasound in tissue and the cost of receiving and processing data from array receivers. The CW methods are used only for Doppler measurements. The first of these systems was constructed before
Fig. 21.15 Nondirectional continuous-wave Doppler. In a typical CW 5 MHz nondirectional Doppler, the incident ultrasound beam is scattered by stationary tissue forming a 5 MHz echo and by moving blood forming a 5.0004 MHz echo. The two echoes arrive at the receiving transducer simultaneously. By constructive and destructive interference between these waves, the received 5 MHz signal is amplitude modulated by the 5.0004 MHz echo. The frequency of the amplitude modulation is the difference frequency 5.0004 − 5 MHz or 400 Hz, which is amplitude demodulated, providing a 400 Hz audio signal to the speaker
Fig. 21.16a,b Interference between echoes to produce audio frequencies. Constructive interference between the Doppler frequency-shifted echo and the original frequency wave increases the resultant amplitude; destructive interference reduces the amplitude. This occurs whether the Doppler shift is downward (**a**) due to reflections from blood cells receding from the transducer, or is upward (**b**) due to reflections from blood cells advancing toward the transducer. By amplitude demodulating the result, an audio frequency signal results. Amplitude demodulation can be done by multiplying the two ultrasound frequency signals together and low-pass filtering the result or by squaring (rectifying) the sum of the two ultrasound signals and low-pass filtering the result

1960 [21.45, 46]; their application in medical diagnosis was well established by 1970 [21.47–52]. Pulse-echo methods have been under continuous development since 1950. The majority of medical diagnostic imaging examinations in the world are performed with pulse-echo instruments.

21.4.1 Continuous–Wave Doppler Systems

Continuous-wave Doppler was used in one of the earliest ultrasound systems to be commercialized. Developed independently in Japan in 1957 (Satamura and Koneko), and in the US in 1959 (Baker et al.), a system can be constructed from an radio frequency (RF) transmitter, transmitting piezoelectric transducer, receiving piezoelectric transducer and amplitude demodulating receiver (Fig. 21.15). In the region of tissue where the transmitting beam pattern overlaps with the receiving beam pattern, the reflected wave from moving tissue will combine to interfere with the reflected wave from stationary tissue. The reflected wave from moving tis-

sue has a Doppler shift. The Doppler-shifted frequency will interfere with the reflected wave from stationary tissue to cause an amplitude modulation in the combined wave. The frequency of that modulation is within the hearing range.

Ultrasonic Doppler examination produced an audible frequency by chance. The best ultrasound frequency to reflect by Rayleigh scattering from blood at a depth of 2 cm is 5 MHz. This frequency is shifted by the ratio of twice the blood speed (2×0.75 m/s $= 1.5$ m/s) to the ultrasound speed 1500 m/s ($1.5/1500 = 0.001$) to cause a downshift in the ultrasound frequency of 5 kHz. The interference between the unshifted and shifted waves causes a 5 kHz modulation in the amplitude of the 5 MHz wave. This modulation is converted to sound by common amplitude modulation (AM) radio circuitry.

The introduction of the transistor in 1960 allowed this simple circuit to be produced in a palm-size package so that convenient clinical examination could be done. Whether the blood is approaching the transducer or receding from the transducer (Fig. 21.16), the audio signal is the same, with audio frequency proportional to the blood velocity.

These CW Doppler systems allowed the detection of narrow arterial stenosis by the high velocities present in the stenotic lumen. Normal velocities are below 125 cm/s, causing a Doppler shift of 4 kHz if the
Fig. 21.17 Directional continuous-wave Doppler. By using a pair of reference waves at the transmitted ultrasound frequency, but phase shifted with respect to each other, the receiver Doppler demodulation can be performed against each of the reference waves. This allows the instrument to differentiate Doppler shifted echoes with increased frequency due to blood cells approaching the transducer from those with decreased frequency due to blood cells receding from the transducer

Fig. 21.18a,b Quadrature Doppler demodulation. (**a**) Demodulation of the of a Doppler down shifted echo against an-I reference and Q reference produces a quarter-wave advanced signal (shifted to the *right*) on the I product compared to the Q product. (**b**) Demodulation of the of a Doppler upshifted echo against an I reference and Q reference produces a quarter wave delayed signal (shifted to the *left*) on the I product compared to the Q product ▶

Doppler angle is 60°. The blood velocity in a stenosis is limited by the blood pressure via the Bernoulli effect; the velocity can be no greater than 500 cm/s for a systolic blood pressure of 100 mmHg. A blood velocity of 500 cm/s causes a Doppler shift of 16 kHz. These CW Doppler systems also allow the detection of venous obstruction by the loss of variations in venous velocity synchronized with respiration, and the testing of venous valve incompetence by the detection of reverse flow resulting from distal compression release or sudden proximal compression. An examiner with one year of training and experience can diagnose all superficial arterial obstructions and venous obstructions and reflux with accuracies exceeding 95% against any gold standard.

The addition of directional detection by Fran McLeod in 1968 simplified the separation of mixed arterial and venous flow, and allowed more-objective evaluation of velocities (Fig. 21.17). Directional detection was accomplished by providing a pair of quadrature signals derived from the transmitted frequency directly to the demodulator in the receiver. Quadrature signals differ only in phase by a quarter cycle. When the Doppler-shifted ultrasound echo is demodulated against each of the quadrature reference signals, the pair of difference waves produced are phase shifted by 90° (Fig. 21.18). If the reflecting blood is advancing toward the transducer then audio frequency (AF) I wave is advanced compared to the AF Q wave, if the reflecting blood is receding, then the AF I wave is delayed with respect to the Q wave. By further delaying the AF Q wave by a quarter cycle (the shift time is dependent on frequency), and adding or subtracting the resultant AF I and AF Q delayed, the sound channels can be separated (Fig. 21.19). After separation, the Doppler signal representing advancing flow can be delivered to one ear and the Doppler signal representing receding flow can be delivered to the other ear. Although these continuous-wave Doppler systems are simple and have not changed substantially since 1970, they still have tremendous clinical utility and are used by angiologists and vascular surgeons in daily practice. A CW Doppler transducer is provided with modern echo-cardiology

Fig. 21.18a,b (figure, right top)
systems (Fig. 21.20) for the measurement of cardiac output and for accurate velocity measurements of blood flow jets associated with valve disease.

During 1970–1985, several arterial mapping angiographs (Fig. 21.21) were developed to associate high-velocity Doppler signals, indicating stenoses with arterial landmarks such as bifurcations. These an-
Fig. 21.19a,b Audio direction separation. By retarding the I quadrature channel by 1/4 of the period of the audio frequency, and then adding or subtracting the resultant pairs, the directions of flow can be separated. (**a**) The added pair results in sound for only the downshifted Doppler signals representing receding flow. (**b**) The subtracted pair results in sound for only the upshifted Doppler signals representing advancing flow
Fig. 21.20 Dual-element continuous-wave Doppler transducer for cardiac output measurements. This transducer is designed to fit in the supersternal notch between the clavicles at the base of the neck. From this location, the Doppler ultrasound beam patterns can be nearly aligned with the axes of the cardiac valves. The ultrasound avoids the lungs by passing directly down through the mediastinum
Fig. 21.21 Doppler arteriography. By monitoring the position of a Doppler ultrasound transducer, transferring the position on a storage image screen, and marking the display screen only when the Doppler detects blood flow, an image of the flow can be generated. Most of these systems used continuous-wave Doppler; the Hokanson system used pulsed Doppler

giographs used mechanical or other methods to track the location of the ultrasound beam and display the results on an image that could be compared with an X-ray angiogram. Modern, large-field-of-view three-dimensional ultrasound imaging systems use extensions of this method.

21.4.2 Pulse–Echo Backscatter Systems

Pulse-echo ultrasound consists of sending a pulse of ultrasound into tissue and receiving the echoes from various depths. The length of the transmitted pulse may be as short as $0.5\,\mu s$ (for B-mode imaging) or as long as $5\,\mu s$ (for trans-cranial Doppler). Usually the same transducer or transducer aperture is used for both transmitting and receiving. The depth of each reflector is determined by the time of flight between the transmitted pulse and the received echo: a reflector 3 cm deep returns an echo at $40\,\mu s$; a reflector 15 cm deep returns an echo at $200\,\mu s$. If the system is examining to a depth of 18 cm, then a new pulse can be transmitted after $240\,\mu s$. In that case, an echo returning at $40\,\mu s$ after the later transmit pulse might come from 21 cm deep ($280\,\mu s$) rather than 3 cm. Tissue attenuation will suppress the echo from deep tissue by about 54 dB (3 MHz ultrasound) compared to the echo from 3 cm.

To perform a pulse-echo examination, an ultrasound transducer (or array of transducers) is positioned to form a beam pattern along an axis, which is assumed to penetrate tissue in a single straight line. A short ultrasound burst is launched along that line. After allowing for the round-trip travel time to the depth of interest (Table 21.5), the ultrasound echo from a segment of tissue in the beam pattern is received, demodulated and prepared for display (Fig. 21.22). The ultrasound transmit pulse can be adjusted for frequency, duration (Fig. 21.23), energy, and aperture size and shape to fine-tune the examination if needed. The ultrasound echo can be demodulated to yield the amplitude (Fig. 21.24) and/or the phase. The results of multiple pulse-echo cycles along a single beam pattern can be combined. The echo is usually amplified with a fast-slew programmed amplifier to increase the gain of later echoes coming from deeper tissues, because they will be attenuated more than shallow echoes. If tissue visualization is desired, the echo strength is displayed in an image along

Table 21.5 Ultrasound examination parameters

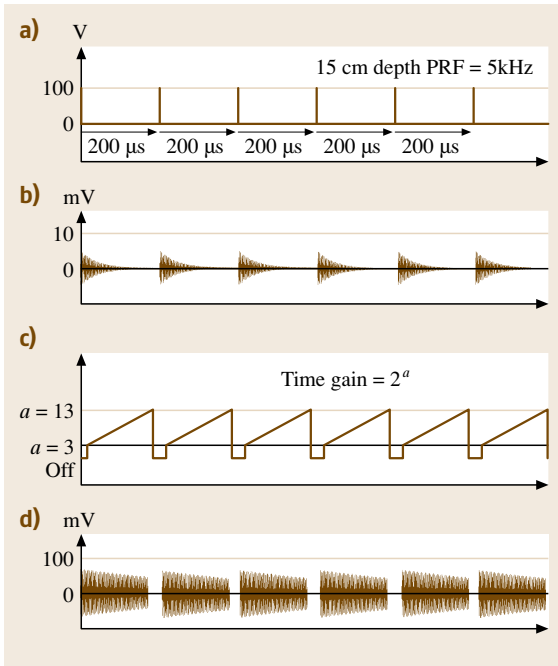
Maximum Examination depth (cm)	Ultra-sound wave-length (mm)	Ultra-sound frequency (MHz)	Pulse repetition Period (μs)	Frequency (kHz)
3	0.075	20	40	25
5	0.125	12	67	15
6	0.15	10	80	12.5
10	0.250	6	133	7.5
12	0.3	5	160	6.25
15	0.375	4	200	5
20	0.5	3	266	3.75


Fig. 21.22a–d Time gain compensation (TGC). (**a**) A new ultrasound pulse is transmitted each pulse repetition period (200 μs in this case). (**b**) Echoes from shallow and deep depths return at known times because of the speed of ultrasound and the expected round-trip travel time. The later echoes received from deeper tissues are weaker than the echoes received from shallow tissues because the echoes from deeper tissues have passed through more-attenuating tissue. (**c**) An amplifier programmed to increase the gain for deep echoes more than for shallow echoes is used to compensate for attenuation. This depth gain compensation (DGC) or TGC amplifier is under operator control. (**d**) The echoes, after TGC are ready for demodulation by analog or digital methods

Fig. 21.23 Different ultrasound transmit bursts for imaging and Doppler applications. Short broadband transmit bursts are used for B-mode imaging; long narrow-band transmit bursts are used for Doppler applications. A longer transmit burst contains more energy if the maximum acoustic negative pressure (mechanical index) are limiting factors. A short transmit burst allows better depth resolution and also spreads the diffraction side-lobes of the beam pattern, suppressing lateral ambiguity. A longer transmit burst is preferable for Doppler applications where echoes from blood are weak and coherence length is important for demodulation

a line representing the direction of the ultrasound beam, with the location along the line (representing depth) determined by the time after transmission that the echo returns. If a measurement of tissue motion is desired, then additional identical pulses are transmitted along the same beam pattern to obtain a series of nearly identical echoes from each depth of interest. These echoes are examined for changes in phase, which is the most sensitive indicator of displacement of the tissue reflecting the ultrasound.

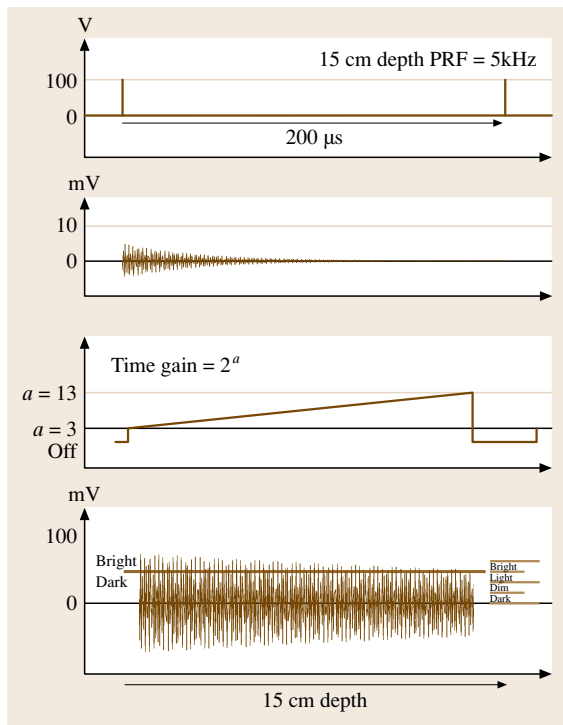
This simple model places constraints on the ultrasound examination. First, at any depth, the strongest echoes from a bone or air interface perpendicular to the beam are 10^6 (60 dB) stronger than the weakest echoes from cells in liquid (blood). So, a 10 bit digital echo-processing system is the minimum to handle the range of echo strengths expected in an image. Second, because the speed of ultrasound is about 1.5 mm/μs in most tissues, echoes returning from 15 cm deep arrive 200 μs after ultrasound pulse transmission. A new pulse cannot be sent into the tissue along the same line or along another line until all of the echoes from the first pulse have returned. So, the maximum pulse repetition frequency (PRF) for an examination to a depth of 15 cm is 5 kHz (1/200 μs). Ultrasound energy is attenuated to 1/4 of the incident energy in most body tissues after passing through a depth of 80 wavelengths. So after passing through a depth of 400 wavelengths and returning through 400 wavelengths, the echo strength is only 0.25^{10} or 10^{-6} of the strength of a similar echo from the shallowest tissue. To compensate for this attenuation, an amplifier must amplify the deep echoes 60 dB more than the shallow echoes (Fig. 21.22). An


Fig. 21.24 Preparing the amplitude demodulated brightness mode echo for display. The amplitude of the amplified echo can be converted into brightness values by a digitizer. In early B-mode scanners, the display could show bright (echo) or dark (no echo) based on a one bit threshold detector (*dark line*). A two-bit digitizer allows four levels of gray scale (scale on *right*), making the result less sensitive to the setting of the TGC amplifier. Modern ultrasound B-mode imaging systems use an eight-bit digitizer to display 256 levels of gray. Depending on the method of presentation, the eye can distinguish no more than 64 stepped levels of gray or 16 isolated levels of gray

alternative is to digitize the echoes with a 20 bit digitizer, 10 bits for the dynamic range of the echoes from different tissues and 10 bits to account for attenuation. In either case, the maximum depth of an examination is limited to 400 wavelengths of ultrasound. An ultrasound depth resolution cell (a pixel) is equal to about twice the wavelength of ultrasound. So, an ultrasound image can contain 200 pixels in the depth direction (Table 21.5). These considerations provide a practical relationship between the ultrasound frequency and the PRF, based on the attenuation of tissue. The PRF is 1/800 of the ultrasound frequency in most applications.
Fig. 21.25 B-mode static scanner. The traditional B-scanner restricted the transducer position and direction to movements in one plane that would form a cross-sectional image through the patient. The position of the transducer was located on the image display, and a line projected from the origin along the display in the direction of sound beam propagation. During the scan a marker was moved along the ultrasound beam direction at a speed of 0.75 mm/µs, representing the time that an echo would return after a round trip to each depth when traveling at 1.5 mm/µs. If a strong echo was detected, then a mark was stored on the screen to contribute to the image. The transducer was scanned across the skin to form an ultrasound scan cross-sectional image of the tissue

21.4.3 B-mode Imaging Instruments

A series of B-mode (brightness mode) ultrasound imaging methods have been developed over the last 40 years. The methods have used the latest electronic technologies to improve the speed, convenience, capability and utility of the systems. The original imaging systems were based on radar technology and analog electronic parts. Today, ultrasound systems are personal computers using standard operating systems with specialized display software coupled to custom ultrasound circuitry on the front end. A review of the history is useful because the modern instruments keep incorporating older methods.

Two-Dimensional Static B-mode
The original B-scanners (Figs. 21.25, 21.26) consisted of a single ultrasound transducer element coupled to
Fig. 21.26 B-mode calibration phantom. Analog electronics were not stable at the time that static B-scanners were constructed. Calibration phantoms were used to assure that a target would appear in the same location when viewed from different locations. Adjustments were provided to align the electronics

a mechanical system to track the origin and direction of the ultrasound beam. The systems had the advantage that large fields of view could be scanned, such as a plane through a full-term fetus, and the sonographer could return to portions of the image to *paint in* anatomical features by approaching each of the re-
Fig. 21.27 Real-time two-dimensional ultrasound images. Motor-driven ultrasound transducers were able to rapidly tilt to a series of angles obtaining data from a series of lines in a plane of tissue to form a new two-dimensional image 10 times or 30 times per second
Fig. 21.28 Two-dimensional B-mode (brightness mode) common carotid artery image. The lumen of the common carotid artery in longitudinal section appears as a darker streak (*wide arrow*) bounded by the superficial and deep walls separated by 6 mm. The walls appear brighter where the ultrasound scan lines are perpendicular to the walls (*narrow arrow*) because of the specular backscatter.

flecting interfaces from a perpendicular direction. As the image display system showed the brightest echo for each anatomic location, *compound scanning* was used to obtain echoes from a variety of directions at each tissue location to render a useful image. Since a scan
Fig. 21.29 Duplication of aorta (after [21.53]) in the image. Refractive tissues composed of fat ($c = 1.45$ mm/μs) and muscle ($c = 1.58$ mm/μs) at the midline of the abdomen form two prisms. Each prism allows the aorta to be viewed resulting in two images of the aorta. This effect has also caused double viewing of a single pregnancy
Fig. 21.30 Mechanical scan head. Three transducers are mounted around a rotating wheel encased in a cover filled with oil. Two of the 3 transducers can be seen in the image. Between the transducers is an air bubble in the oil; the air bubble must be removed through the oil filling port before scanning. Under the bubble is a rectangular shape that is the housing for a switch. Each of the transducers has a switch mounted opposite the transducer on the wheel which is activated magnetically to connect the transducer when the transducer is pointed toward the patient. The transducer wheel is driven by a motor in the white housing through a belt. A control knob on a joystick allows adjustment of the Doppler ultrasound beam, when needed; swinging the arm tilts the beam, rotating the knob advances the sample volume along the line. Electrical coupling to the transducer was accomplished by using a transformer aligned on the axle of the wheel with one coil stationary and one rotating. The magnet-activated switches mentioned above selected the proper transducer that was pointing at the patient

might take 5 min, movement of the patient during the scanning period was a problem, rendering the image useless. Because these systems used analog electronic devices, which were subject to deterioration over time, the stability and alignment of the instruments was important. In addition, since the same tissue was examined from multiple locations, the co-registered alignment of the tissue voxels (small volumes of tissue) on the image was critical. Regular testing of the instrument on alignment phantoms was required. The speed of ultrasound in the phantoms was controlled by the chemical
Fig. 21.31 Mechanically steered annular array scan head. The circular transducer is divided into concentric circles with each segment having the same area. By delaying by different amounts, the signals to the more central transducers, the depth of focus can be adjusted. A 10 ns delay between the transducer rings with the central transducer operating last will retract the focus a centimeter. The oil between the transducer and the dome shaped cap provides refractive focus in addition to the focus provided by the delays to the transducer. To point the ultrasound beam along different lines, the transducer wobbled back and forth rather than rotated. A rotating motion was not possible because the four coaxial cables could not cross the rotating axis. The arrow is pointing at the transducer along its axis

composition of the phantom at the time of fabrication and the temperature of the phantom at the time of use. Of course, because the speed of ultrasound is not the same in different tissues, the success of the phantom in controlling image distortions in the depth direction during actual examination was limited. In addition, because the ultrasound beam can bend due to refraction as it passes from tissue to tissue, a factor ignored in the phantom, preventing lateral image distortions was impossible. However the phantoms did serve to prevent huge errors. Modern real-time ultrasound scanners that complete a scan in 30 ms (Fig. 21.27) form each image without overlapping beams so object co-registration is not tested. Thus, the value of phantoms has diminished. They still retain educational value.

Two-Dimensional Real-Time B-mode Mechanical Scanning

The earliest real-time systems scanned the ultrasound beam by tilting the ultrasound transducer, tracking the position and direction of the ultrasound beam with timing or an optical encoding system. The images had

To provide acoustic coupling between the transducer and the housing, the scan head is filled with liquid. The transducer, at the left end of the image, is pointing out of the page. (**b**) Trans-esophageal (TEE) ultrasound scan head. The patient swallows the end with the transducer array (*upper right* in the picture) mounted in the end of the flexible esophageal probe. Marks every 10 cm (*arrows*) allow the cardiologist to monitor the location of the transducer array from the patient's teeth. (**c**) The trans-esophageal ultrasound transducer 5 MHz linear phased array has a circular boarder so that the array can be rotated to rotate the scan plane once the transducer is in the esophagus. A pair of control handles ((**b**) at *bottom*) allows the cardiologist to rotate the transducer array and to tilt the tip housing the array to examine the heart in different planes. Some patients tolerate this procedure well with little anesthesia, others require more sedation

tremendous utility (Fig. 21.28) in spite of the poor lateral resolution compared to the depth resolution. Unfortunately, neither phantoms nor digital tracking of the ultrasound beam direction avoid image distortions due to refraction of the ultrasound beam in tissue
Fig. 21.33 M-mode (motion-mode) examination. For the study of cardiovascular wall motion, a single ultrasound beam is directed through the heart or other tissue. A *horizontal mark* showing the depth of each reflecting tissue in the vertical direction is shown on each vertical image line. By transmitting a new ultrasound pulse every millisecond, the echoes from tissue interfaces can be plotted for each pulse with time on the *horizontal axis*. By placing the lines side by side, the trajectories of tissue motion along the ultrasound beam are displayed. Speed of the reflecting tissue interface along the direction of the ultrasound beam is shown as a tilt or slope of an interface displayed on the image

(Fig. 21.29). These distortions, which are still a problem in the lateral direction, are ignored.

The ultrasound scan heads were convenient, ergonomic and compact (Fig. 21.30), located at the end of a cable attached to the ultrasound scanner. A variety of scan heads were developed including some with electronic focusing (Fig. 21.31) and specialized shapes for placement in the esophagus, rectum, vagina (Fig. 21.32), and some 1 mm in diameter for insertion inside blood vessels.

M-mode Ultrasound

Among the early applications of ultrasound was the study of the motions of the heart using M-mode (motion mode) imaging [21.54, 55] (Fig. 21.33). By holding the ultrasound beam stationary and plotting the image width as a function of time, motions of the heart and other vascular structures could be documented. The velocity of a valve could be determined (Fig. 21.34) by measuring the slope of the trajectory on the M-mode tracing.

Two-Dimensional Real-Time B-mode Electronic Scanning

An alternative to moving the ultrasound transducer to point in different directions, is to have an array of transducers [21.56]. By switching to each transducer in turn to acquire echoes from the corresponding beam pattern, a two-dimensional (2-D) image is formed (Fig. 21.35).
Fig. 21.34 M-mode (motion mode). Motion of a tissue interface along the ultrasound beam line is shown as depth (*vertical*) versus time (*horizontal*). The speed of the heart structure can be computed from the slope of the tracing. In this example, the speed is $158 - 16\,\text{mm}/0.4\,\text{s} = 355\,\text{mm/s}$. The green line across the bottom of the image is the Electrocardiograph (ECG, EKG) timing signal

Several ultrasound scanners developed between 1970 and 1980 used low-density arrays like this. A scanhead with more transducer elements, spaced closely together (Fig. 21.36), could use groups of transducers to form
Fig. 21.35 Low-density linear-array two-dimensional B-mode. If the tissue does not move very much during the acquisition of an image, and the ultrasound beam pattern is moved across the tissue by successively activating different transducers and plotting the echoes with depth along the lines of the corresponding beam patterns, a two-dimensional image is formed. By convention in radiologic images, the images are usually displayed as if the patient is facing the physician. There is disagreement between clinics about how images should be oriented

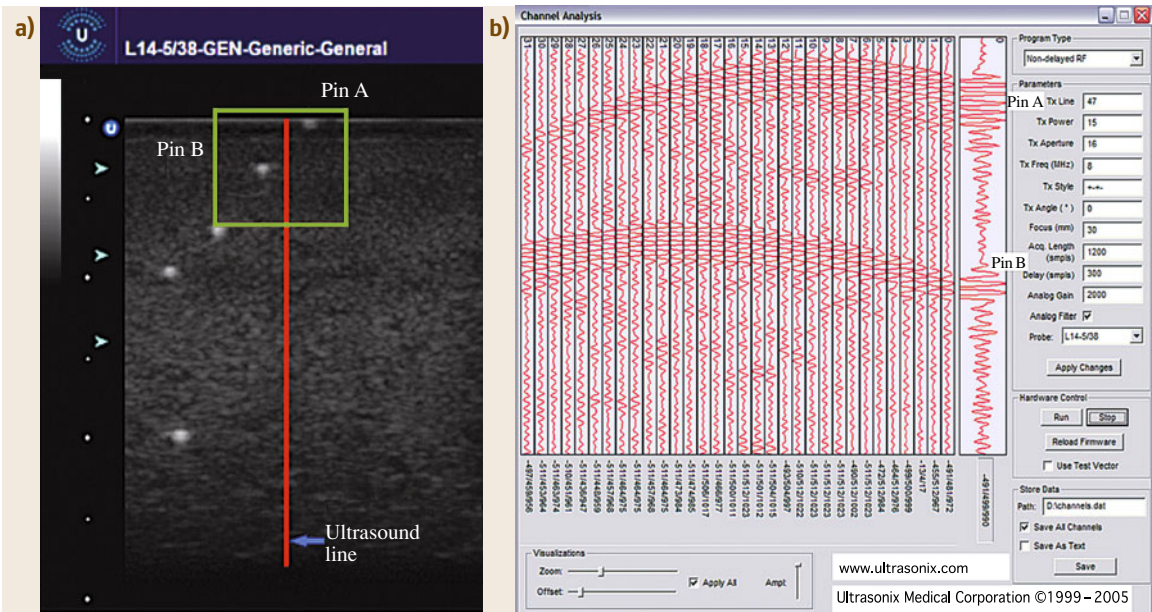
an aperture. These high-density arrays permit phase focusing to a series of depths (Figs. 21.36–21.38), phase tilting of the ultrasound beam patterns (Fig. 21.39) and apodization of the aperture to smooth the ultrasound beam pattern (Fig. 21.40). The transducer array is usually formed from a single rectangular piezoelectric crystal, cut into a row of thin rectangles to form an array in one direction. Because of the cuts, the array
Fig. 21.36 High-density linear-array scan head. The transducers can be spaced more closely than the width of the ultrasound beam. Then each ultrasound aperture is formed by multiple transducers at the scan head face. The beam patterns overlap. The use of multiple transducers in the aperture allows the shaping of the aperture and electronic focusing of the ultrasound beam pattern


Fig. 21.37a,b Echoes received by each transducer in an array. By imaging highly reflective pins in a phantom, the effect of distance on travel time from a reflector to each transducer element in an array can be appreciated. By applying an appropriate delay on each of the transducer signals so that the echoes from the target align in time, and then adding the transducer signals together, a receiver beam pattern is formed, which is focused on the target. The time delays can be adjusted in 6 ns steps. (**a**) The transmit pulse was launched along the *red ultrasound line*. The echoes are displayed for data gathered from within the *green box*. (**b**) Radio-frequency echoes from each of 32 transducers are displayed for the echoes returning from a single transmit pulse (courtesy Ultrasonix Medical Corp., Burnaby, www.ultrasonix.com)

becomes flexible in the long dimension and can be curved (Fig. 21.41) to form a sector scan. Each of the 128 elements is connected via an electrical impedance-matching network to a coaxial cable, which forms part of the scan-head cable running back to the scanner. The plug connecting the 128 coaxial connectors to the ultrasound scanner has separate contacts for all 128 cables. Behind the plug in the scanner are separate ultrasound transmitters and receivers for each transducer element.

Often each of the receivers will have a separate digitizer to convert the TGC-amplified signal into digital form. The receivers and digitizers together form the ultrasound beam former for receive mode. Early array transducers had 32 elements, and the electronics were located in the scan head. Current instruments have 128 elements, a number limited by the costly cable con-

Fig. 21.38 Adjustable focus with large aperture. Using a high-density linear array to generate a large aperture and focus at a deep depth
Fig. 21.39 Steering of the ultrasound beam pattern. Multiple transducers in the aperture allows the ultrasound beam to be steered at an angle for either imaging or Doppler by introducing phase delays in the signals to and from the transducers progressively along the transducer array
Fig. 21.40 Apodized aperture. Apodization is used to limit the side-lobes of the ultrasound beam pattern. Transducers near the edge of the aperture are excited with a low voltage during transmit compared to the central transducers and are amplified with a lower gain compared to the central transducers during receive. The drawing on the *right* shows the image line corresponding to the beam pattern with the superficial and deep echoes plus the mark on the *right*, indicating the focal depth ◄

taining 128 coaxial leads that connects the array to the receivers and transmitters in the console. The number of transducers will increase in the future as higher-capacity cables become available or, alternatively as it becomes possible to house the transmitting and receiving electronics in the ultrasound scan head.

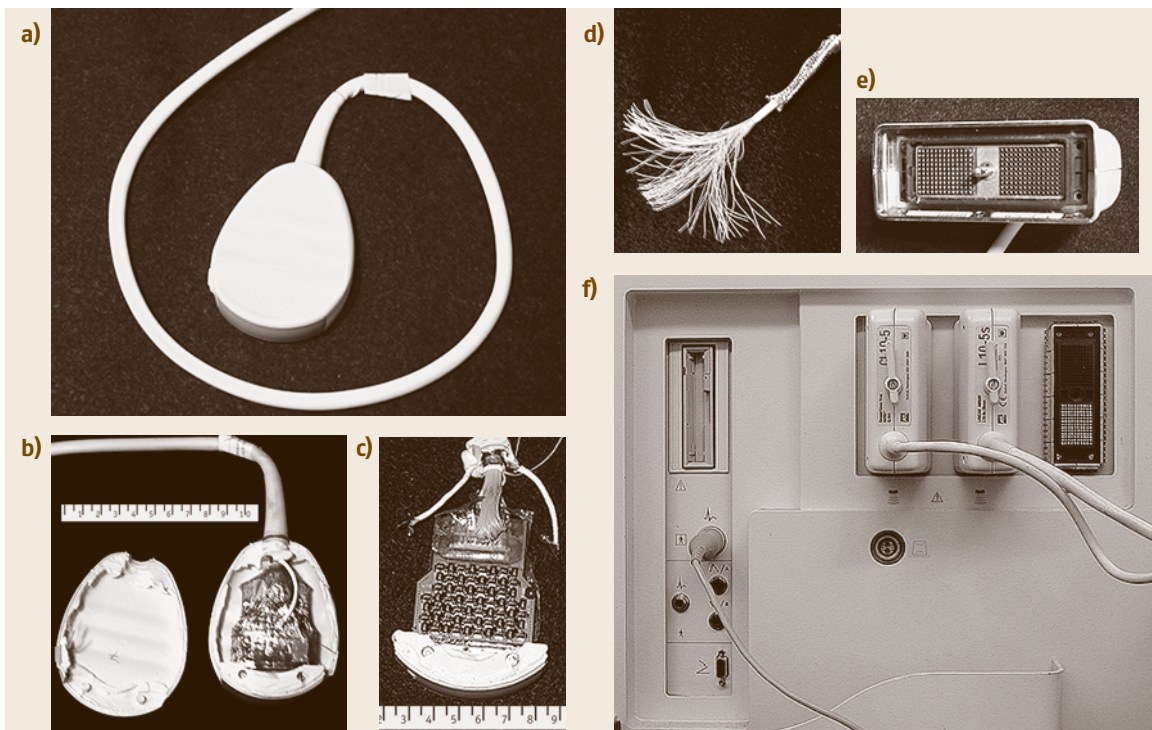
A linear array transducer allows for adjustment of the transmit focus and aperture separate from the receive focus and aperture (Fig. 21.42). Because during the receiving period the relationship between depth and time is 0.75 mm/μs, a system can change receive focus every 20 μs, advancing the focus 15 mm each time along


Fig. 21.41a–f Scan head details. This curved linear-array scan head consists of an array of 128 transducer elements cut from a single block of PZT piezoelectric ceramic. The array block is 64 mm long and 5 mm wide, cut into elements 0.4 mm long and 5 mm wide with a 0.1 mm kerf between. The block is curved to form a curved linear array. **(a)** Transducer in housing with cable; **(b)** Transducer housing removed showing the copper foil shielding over the internal electronics; **(c)** Shielding removed to show the 64 electronic matching circuits on this side of the circuit board; **(d)** 128 individual coaxial cables housed in the ultrasound scan head cable; **(e)** Scan head plug showing the connector electrodes for the 128 coaxial cables; **(f)** Front panel of the ultrasound scanner showing the sockets for the scan head connections. The front panel also shows connectors for other instruments including: electrocardiograph, plethysmograph, phonocardiograph microphone and computer disk drive for data exchange
Fig. 21.42 Adjustable focus with large aperture. Using a high = density linear array to generate a large aperture allows electronic adjustment of the focal depth by adjusting the electronic delay of the transmit and receive signals so that the signal at the center transducers is delayed more than the signal at the edge transducers in both transmit and receive. Dual transmit focal depths, indicated by the pair of *arrows* on the *right* of the image, require that separate transmit pulses be sent into tissue for each of the two focal depths. On receive, the focus can be changed between the time that shallow echoes are received and the time that deep echoes are received

with the corresponding aperture. This focal adjustment is called dynamic focusing and is similar in concept to time-gain compensation. It is also possible to acquire data along the ultrasound line using several pulse-echo cycles, each with a transmit burst that is focused at a different depth. Although dynamic receive focusing takes no more time than static focusing, using double transmit focusing to further improve the lateral resolution of the image at a greater range of depths does reduce the frame rate by half. The location of the transmit focus is indicated by a carrot on the right of the image.

Because a linear array can steer the ultrasound beam, it is possible to form an image of each voxel in the tissue plane from different views, combining the results into a compound image (Fig. 21.43). The algorithm for

combining the data from different angles is important in creating a pleasing image.

Phased Array Transducers. By applying a selected time delay to each transducer in an array, the ultrasound beam can be focused or tilted as desired (Fig. 21.39). Phased array transducers (Fig. 21.44) form the ultrasound image by tilting the ultrasound beam using selected delays on each transducer on transmit and receive to achieve the desired tilt. A scanhead with a transducer array of width D can tilt an ultrasound beam to an angle θ in tissue with an ultrasound velocity of c by applying a time delay gradient along the transducer of

$$\frac{tc}{D} = \sin\theta . \tag{21.11}$$

The time t is often represented as a function of the phase of the ultrasound ϕ for the ultrasound frequency f_{us}

$$t = \frac{\frac{\phi}{2\pi}}{f_{us}} . \tag{21.12}$$

To allow the ultrasound beam to tilt to θ degrees, the width of each transducer element must be less than $\lambda/2$ but the pitch ($w =$ center to center spacing of the elements) must be $\lambda/4$ in order that, at the maximum deflection angle, a single beam pattern is defined when

Fig. 21.43 Compound real-time imaging. By tilting the beam patterns to cross during acquisition of the image plane, system can take advantage of the specular backscatter of planar reflectors in the tissue
Fig. 21.44 Phased-array scan head. A phased-array scan head is able to use the same aperture for all ultrasound scan line beam patterns, directing the beam along different lines by adjusting the relative phase of the signals to the transducers

ultrasound intersects the array at angle θ

$$w < \frac{\lambda}{4 \sin \theta} = \frac{c}{4 f_{us} \sin \theta} . \qquad (21.13)$$

A 3 MHz scan head tilting the ultrasound beam 30° to the left and to the right requires a transducer element pitch of 0.3 mm.

Pulsed Doppler [21.57]

The series of echoes from a single ultrasound transmit pulse provides information about the echogenicity of the tissue along the ultrasound beam pattern at various depths. The echogenicity of the tissue at each depth is determined by amplitude demodulation (Fig. 21.45). The measurement of the velocity of blood or tissue requires pairs of echoes from two (or more) ultrasound transmit pulses along the same beam pattern line, separated by a short time (0.1 ms). By comparing a second echo series from the same transducer beam pattern from a later time to the echo series from the first pulse, motion of the echogenic tissue along the beam pattern can be detected and measured. If the second echo se-

ries is identical to the first echo series, then none of the tissue along the ultrasound beam pattern has moved or changed during the period. However, if the second echo series is different, then the tissue has moved or changed. Motion in the direction of ultrasound propagation causes a simple time shift in the echo series, lateral motion or a change in tissue properties results in a loss of coherence between the echoes.

If the tissue has moved toward the ultrasound transducer, then the second echo pattern will arrive earlier after the transmit pulse compared to the first (Fig. 21.46). If the difference is detected by Doppler processing, then the echoes from each region of tis-
Fig. 21.46 Phase demodulation. To measure blood velocity, or tissue displacement or strain, the change in phase (or echo displacement) between successive pulse-echo cycles at a particular depth must be determined. In this case, a phase change of $\pi/4$ of 5 MHz ultrasound represents an echo time shift of $0.05 \,\mu s/8 = 0.00625 \,\mu s$, which is equivalent to a displacement of the scatterers toward the transducer of $0.00625 \,\mu s \times 0.75 \, mm/\mu s = 0.0047 \, mm$ in the time between pulse-echo cycles or 0.1 ms, yielding a velocity of 0.047 mm/ms or 0.047 m/s. The Doppler equation, time-domain velocimetry and strain imaging are all based on this computation. In Doppler demodulation, the phase and amplitude of the echo at any depth can be represented as a vector on a phase diagram. These vectors can be represented as complex numbers if the vertical direction is represented as the *imaginary* ($\sqrt{-1}$) direction and the horizontal direction represents the *real* direction

Fig. 21.45 Amplitude demodulation. To create a B-mode image of tissue anatomy, the strength or amplitude of the received ultrasound echo is determined as a function of depth. The RF echo is rectified (converting 5 MHz to 10 MHz) and low-pass-filtered with a 1 MHz cutoff to yield a depth resolution of 0.75 mm. That is effective if the ultrasound transmit burst is shorter than 1 μs. Amplitude demodulation requires one pulse-echo cycle along each ultrasound beam pattern line

sue are characterized by a vector in a complex plane (Fig. 21.46). One rotation of the vector is equivalent to the reflector moving toward the transducer to shorten the round-trip path by one wavelength of the ultrasound. If the ultrasound is 5 MHz, then the wavelength is 320 μm so one rotation represents a shortening of the round trip ultrasound travel distance of 320 μm, or 160 μm each way. A phase rotation of one quarter of a cycle ($\pi/2$ rad) represents 40 μm of motion. Doppler processing cannot tell the difference between 20 and 180 μm of motion because the vector is pointed in the same direction after the 160 μm displacement. This is called aliasing and is responsible for a waveform with the highest forward velocities incorrectly shown as reverse velocities (Fig. 21.47). Doppler systems cannot tell the difference between displacements of 100 μm toward the transducer and 60 μm away from the transducer, because both are represented by the same phase shift. A motion of 20 μm will result in a rotation of the phase vector by 45° ($\pi/4$ rad). Often the interval between the first echo and the second echo is 0.1 ms. The velocity of the tissue in this case is $20/0.1\,\mu\text{m}/\text{ms} = 200\,\text{mm/s} = 20\,\text{cm/s} = 0.2\,\text{m/s}$.

The Doppler frequency is the phase change of the echo in cycles during the pulse interval divided by the pulse interval. In this case the phase change is 1/8 cycle, so the Doppler frequency is $0.125/0.1\,\text{ms} = 1250\,\text{cy/s} = 1.25\,\text{kHz}$.

Usually, pulsed Doppler systems are used to measure blood velocity. Unfortunately, it is rarely convenient to align the ultrasound beam pattern along the axis of a blood vessel so typically the angle between the ultrasound beam pattern and the vessel axis is 60°. This is called the Doppler angle. The ultrasound system can only measure the projection of the blood velocity vector along the ultrasound beam. That projection is the cosine of the angle between the velocity vector and the ultrasound beam. The Doppler equation relating velocity to the ultrasound echo is:

$$f = \frac{2v_f f_{us}\cos\theta_D}{c} \quad \text{or} \quad v_f = c\frac{\frac{f}{f_{us}}}{2\cos\theta_D} \ . \quad (21.14)$$

where f is the Doppler frequency that you hear, the factor of 2 accounts for the round-trip of the ultrasound, v_f is the velocity of the blood, f_{us} is the ultrasound frequency, θ_D is the angle between the blood velocity and the ultrasound beam, and c is the speed of ultrasound in tissue. The form

$$\frac{v_f}{c} = \frac{\frac{f}{f_{us}}}{2\cos\theta_D} \quad (21.15)$$
Fig. 21.47 Aliasing. Blood velocities that cause high phase shifts (greater than 180° or π radians) between pairs of pulsed Doppler echoes cause the Doppler system to mistake high-velocity forward flow for reverse flow. Continuity in blood flow allows the examiner to detect this error

emphasizes the relationship between the ratio of the blood velocity to the ultrasound velocity and the Doppler frequency to the ultrasound frequency. Since the ultrasound wavelength $\lambda = c/f_{us}$,

$$v_f = \frac{f\lambda}{2\cos\theta_D} \ . \quad (21.16)$$

To provide a measurement of blood velocity, ultrasound instruments have a cursor on the screen to align with the axis of the vessel under examination (Fig. 21.48). The associated Doppler data, here represented as a spectral waveform, is provided with a scale showing the angle-adjusted velocity based on the projection of the measured velocity onto the vessel axis. Although this adjustment is theoretically justified by the geometry, unfortunately, it does not provide a useful velocity value. If a Doppler angle of zero degrees is used, then the value is correct, however, if other angles between the ultrasound beam and the presumed velocity vector are used, then the value of the velocity is not correct. The reason is that blood velocity vectors are rarely aligned with the axis of the artery. Instead, blood velocities form helical patterns along the artery [21.58–60]. Angle-adjusted Doppler velocity measurements are systematically higher as the Doppler angle increases from zero to 70 degrees or more. Although at a Doppler angle of zero, velocities are accurately used to determine both the volume flow rate and the Bernoulli pressure drop, neither result is correct when Doppler angles other than zero are used [21.61–63].

Pulsed Doppler Range of Measurement. The highest Doppler frequency shift that can be measured with pulsed Doppler occurs when the phase change of the echoes during the interval between echo acquisitions (pulse repetition interval (PRI)) is 180° (half a cycle).
Fig. 21.48 Duplex Doppler image and waveform of a carotid artery. The axis of the ultrasound beam pattern used for Doppler is shown crossing the artery at an angle of 60° to the vessel axis. A cursor is aligned parallel to the vessel axis to provide θ_D for the Doppler equation. The Doppler frequency, which is produced by the speakers of the instrument, is shown by a scale drawn on the *left*. The scale showing the speed at which the blood is approaching the transducer is drawn adjacent to the frequency scale. The instrument computes the scale on the screen by dividing the cosine of the Doppler angle into the approach speed. Along the lower edge of the image is the electrocardiograph tracing (ECG) showing the *QRS complex* (small up and down) indicating the onset of ventricular contraction in each cardiac cycle. The lump in the trace 200 ms later is the T wave indication the end of ventricular contraction. The fourth beat is too early and the QRS has an odd shape. This is a premature ventricular contraction (PVC) originating from an abnormal spot on the ventricle. The PVC causes the ventricle to contract before filling is complete, producing a low-volume contraction, and low systolic blood velocities. The ventricle overfills before the next normal contraction, causing elevated systolic velocities

The Doppler frequency at that condition is half of the pulse repetition frequency (PRF, the Doppler sampling frequency). This is called the Nyquist limit, after Harry Nyquist. This establishes the highest velocity that the Doppler can detect, although since the signal is analyzed as a complex number with twice the data (half as a *real* number and half as an *imaginary* number) Doppler frequencies between $+0.5\,\mathrm{PRF}$ and $-0.5\,\mathrm{PRF}$ are reported. As long as there is no reverse flow the range of Doppler frequencies available is equal to the PRF. If the phase vector is characterized by a 2 bit complex number into four values, then the smallest phase change that can be classified is 1/4 cycle. So, a 5 MHz Doppler system with the data recorded as 2 bits, and a PRF of 10 kHz, can only report four Doppler frequency ranges, -1.25 to $+1.25\,\mathrm{kHz}$, $+1.25$ to $+3.75\,\mathrm{kHz}$, $+3.75$ to $+6.25\,\mathrm{kHz}$, and $+6.25$ to $+8.75\,\mathrm{kHz}$. $-1.25\,\mathrm{kHz}$ is equal to $+8.75\,\mathrm{kHz}$. Such a Doppler system would probably classify -1.25 to $+1.25\,\mathrm{kHz}$ as no motion. By increasing the number of

bits in the digitizers representing the phase vector, the resolution of the phase shift is increased, and the number of possible measured velocities is increased. This does not increase the Nyquist limit.

Another way to increase the number of velocities that can be measured is to increase the number of pulse-echo cycles or Doppler phase samples that are gathered. The number of samples used to resolve the velocity is called the ensemble length or packet length. In a typical spectral waveform pulsed Doppler system, Doppler samples will be gathered from a voxel at a PRF of 12.8 kHz for 10 ms to provide 128 Doppler samples for frequency analysis. The Nyquist limit (upper frequency limit) is 6.4 kHz. The lowest frequency that can be detected is 100 Hz, one full Doppler cycle in the 10 ms acquisition period. If the signals are digitized into 2 bit complex numbers, then each of the 128 possible frequencies can be tested to see whether each is present or absent, but no information is available about the strength of each frequency signal. To determine the

strength of each frequency, the signals must be digitized into numbers with more binary bits. Spectral waveform analysis assumes that there are many Doppler frequencies present in the Doppler signal from the voxel of interest.

Pulsed Doppler Pulse–Pair analysis. The Doppler frequency shift can be measured from just two echo samples separated by a known time. The assumption is that only a single Doppler frequency is present in the signal. The phase change divided by the sample interval time provides the Doppler frequency. The upper limit of the Doppler frequency is the Nyquist limit. To resolve the Doppler frequency, the phase angle change must be resolved. Representing the phase angle by a two bit complex number only resolves the phase angle into four divisions. For 5 MHz ultrasound, displacements of 40 μm can be resolved. For a 10 kHz PRF sample frequency, this allows a velocity of ±40 cm/s (±0.4 m/s) to be detected. However, if the phases are represented by 10 bit complex numbers, the phase angles can be resolved into 1000 divisions and the displacement and velocities can also be resolved. With 10 bit quadrature digitizers, velocities between plus and minus 80 cm/s can be measured with a resolution of 0.8 cm/s, equivalent to displacements of 80 nm during the pulse interval.

Pulsed Doppler Wall/Clutter Filtering. The measurement of blood velocity with ultrasound is complicated by the containment in vascular walls. The echogenicity of the blood is 60 dB less than the echogenicity of the walls at 5 MHz. The blood cells are Rayleigh scatterers because they are smaller (7 μm) than the wavelength of ultrasound (300 μm for 5 MHz). The strength of the echo from blood increases with the fourth power of the frequency. However, frequency-dependent attenuation of the ultrasound by overlying tissues limits most Doppler ultrasound studies to frequencies of 2–6 MHz. 5 MHz produces the strongest echoes for vessels under 2 cm of tissue, deeper vessels, and those behind the skull require 2 MHz ultrasound waves to penetrate these tissues [21.64–66].

In many examinations, Doppler measurements from blood adjacent to the wall are desired, so Doppler echoes from the voxel next to the wall will include strong wall echoes as well as weak echoes from the adjacent blood. Unfortunately, vascular walls move with velocities near 2 mm/10 ms or 0.2 m/s (20 cm/s). The strong echoes from these moving walls must be rejected to reveal the adjacent blood velocity, which may be only slightly higher than 20 cm/s. The strong echoes from the wall are called clutter. 10 bits of the system dynamic range are required to handle the clutter and the blood echoes must be resolved above that, so most ultrasound systems now utilize a 14–16 bit dynamic range, which is achieved by combining the outputs of separate digitizers (one for each transducer) and digitizing faster than the required four times the ultrasound center frequency, then filtering the result for processing.

Pulsed Doppler Spectral Analysis. To measure the Doppler frequency shift, any method of frequency analysis can be used. Zero-crossing rate meters and zero-crossing time interval histograms have been replaced with real-time spectrum analyzers. Although the time-compression analyzer produces identical results, the popular fast Fourier transform (FFT) analyzer is used to produce spectral waveforms of Doppler signals (Figs. 21.47, 21.48). The FFT analyzer is coupled to the pulsed Doppler so that the FFT analyzer receives a quadrature pair of data from the depth of interest for each pulse-echo cycle. The advantage of the spectral analysis is that if the voxel contains several flow velocities, the FFT spectrum will display the Doppler frequency for each velocity. Unfortunately, in blood flow, eddy oscillation frequencies up to 500 Hz occur; the typical FFT length of 10 ms (100 spectra per second) is only capable of resolving eddies of 50 Hz or lower. When a voxel contains higher-frequency eddies, the result appears as spectral broadening or as harmonics on the spectral waveform.

Pulsed Doppler Autocorrelation. Autocorrelation is a frequency analysis method which is an extension of pulse-pair analysis. Autocorrelation analysis assumes that there is only one valid Doppler frequency in the blood flow. Autocorrelation analysis identifies that frequency. However, to reject the stationary and slow moving strong echoes of the wall, a clutter filter must be applied. Clutter is a stationary echo superimposed on the changing Doppler echo. The analysis is based on an ensemble of N echoes, usually eight echoes. The difference between adjacent pairs of echoes n and $n-1$ (for $n = 2$, N) creates a new group of $N-1$ vectors (Fig. 21.49). By taking the average of the change in angles, a Doppler velocity can be obtained. Sometimes two filtering steps are required rather than one. Such filters are called finite impulse response (FIR) and infinite impulse response (IIR) filters.

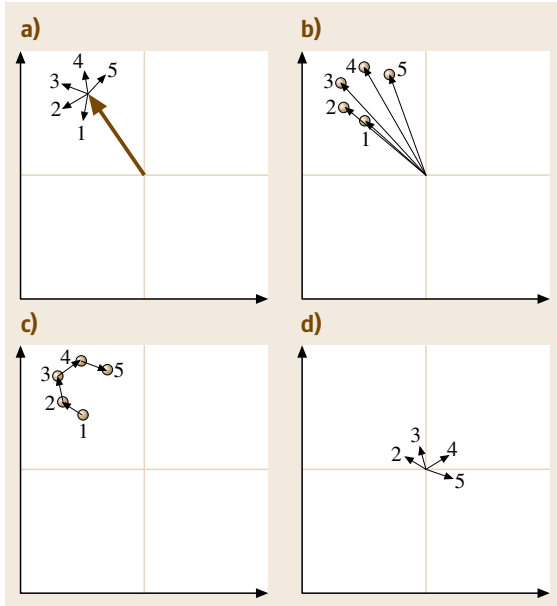
Time–Domain Velocimetry. The Doppler equation contains the Doppler frequency and the phase an-


Fig. 21.49a–d Autocorrelation clutter (high-pass) filter. By representing each pulse-echo from a particular depth as a point on a phase diagram, the trajectory of the echo phase in time can be plotted. (**a**) The Doppler echo comes from two types of reflectors, strong reflecting stationary structures (*clutter*) and weak reflecting moving blood cells. In each of the five pulse-echo cycles (ensemble or packet of 5), the contribution from the strong reflectors is the same. The moving blood cells reflect the same amplitude (vector length) but a different phase during each pulse-echo cycle. (**b**) The ultrasound receiver cannot differentiate the clutter contributed by the stationary structures from the signal contributed by the moving blood cells. High-pass filter. (**c**) By taking the difference between successive results, the effect of the clutter is eliminated. (**d**) By centering the resultant vectors on a new phase diagram, the phase angle change between each pulse-echo cycle can be used to compute the blood velocity

gle. Doppler signals are subject to aliasing when the between-pulse phase angle change ($\Delta\phi$, a circular variable) has a value greater than π. In addition, echoes from deep tissues have a lower center frequency than echoes from shallow tissues, causing confusion about the correct value of the ultrasound frequency f_{us} to use in the equation.

$$\frac{v_f}{c} = \frac{\frac{\Delta\phi}{\Delta t}}{2\cos\theta_D}\ . \tag{21.17}$$
Fig. 21.50 Time-domain demodulation removing clutter. To remove clutter in time-domain demodulation, the RF echo signal from each pulse-echo cycle is subtracted from the preceding RF echo signal to yield the residual due to tissue motion

Of course, the center frequency of deep echoes is still within the bandwidth of the transmitted ultrasound; the center frequency is depressed because of the greater attenuation of the higher-frequency portions of the transmitted bandwidth.
Fig. 21.51 Time-domain demodulation measuring the velocity component. By measuring the time shift between successive echo pairs, multiplying by half the ultrasound velocity and dividing by the pulse repetition interval time, the velocity of the tissue along the ultrasound beam results

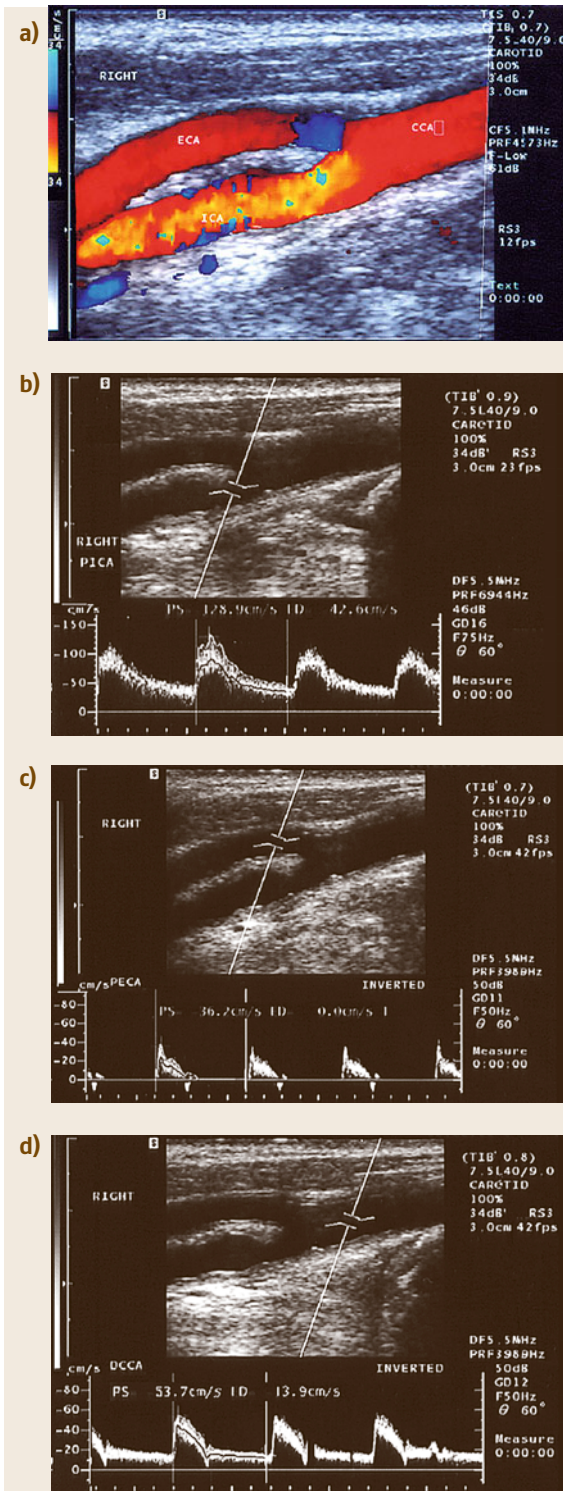

Fig. 21.52a–d Ultrasound images from a conventional carotid artery Doppler examination in the neck (after [21.67]). *Orientation*: a linear array transducer located at the top of each image acquires the 128 vertical scan lines in sequence across the 35 mm-wide image. Two of the monochrome B-mode images (**c**) and (**d**) were acquired in 24 ms (42 frames per second) so the scan lines progress across the image at a speed of $(35/24)$ 1.46 m/s, a speed similar to blood velocity. The color flow image (**a**) was acquired at 12 fps; the other monochrome image (**b**) was acquired at 23 fps. *Anatomy*: (**a**) ECA external carotid artery supplying the face, ICA internal carotid artery supplying the brain, CCA common carotid artery from the heart via the Brachiocephalic trunk. (**a**) Color Doppler image of the carotid bifurcation. The color scale on the left of the image shows that forward flow is shown as *red* and reverse flow is shown as *blue*. The flow directions are with respect to the transducer array at the top of the image rather than with respect to the heart to the *right* of the image. The blue region at the origin of the external carotid artery shows that the vertical component of the velocity vector is pointing toward the ultrasound transducer rather than showing that flow is reversed toward the heart. Notice that this region is bounded by black bands indicating *zero* velocity toward the transducer. The *blue spots* in the lumen of the internal carotid artery are aliasing (Fig. 21.47). Notice that each of those regions is surrounded by an *orange* color indicating high blood velocity components with respect to the transducer. *Doppler waveform orientation*: each of the three Doppler waveforms is acquired from an ultrasound beam pattern that is tilted at an angle with respect to the transducer, selected by the examiner to form an angle of 60° with respect to the artery axis. (**b**) *lower* Normal Doppler spectral waveform from the internal carotid artery with high diastolic flow. Because the brain continuously requires 10% (10 ml/s) of the cardiac output (100 ml/s), the peripheral resistance is low so blood flows to the brain during systole and diastole. (**c**) *lower* Normal Doppler spectral waveform from the external carotid artery with low diastolic flow. Because the face at rest requires little blood flow but when active (chewing, blushing) requires more blood flow, at rest the arteriolar sphincters are constricted, only accepting blood flow during systole. When the arteriolar resistance decreases, the external carotid also has flow during diastole. (**d**) *lower* Normal Doppler spectral waveform from the common carotid artery which has the combined internal and external flow waveform. A pulsatility index showing the ratio between the diastolic and systolic velocities is sometimes used to classify waveforms
Fig. 21.53 Stenotic internal carotid artery. Even after 25 years of exploring the meaning of carotid artery spectral wave-forms, there is no agreement on how the data should be interpreted. Although this color Doppler image shows an interruption in the color flow image of the lumen, the interruption is not due to an arterial occlusion, but to a local region of high ultrasound attenuation which causes the color Doppler signal to drop out. Thus, the diameter of the color Doppler streak cannot be used to assess the lumen. In this case, the vessel walls cannot be easily seen. A stenosis is present at the Doppler sample volume as indicated by the high velocity. The spectral waveform is confusing. The highest Doppler frequency shift which was measured by the examiner 220 ms after the onset of systole at 497.3 cm/s is probably not accurate because the measurement is at the time of greatest spectral broadening (SB), indicating eddies in the flow. Use of the Doppler equation is not appropriate for these eddy velocities because the heading of the vectors is not known. The true peak systolic (PS) velocity probably occurs 100 ms after the onset of systole where the measurement is near 4 m/s and the Doppler equation is probably accurate if the velocity vector is assumed to be parallel to the artery axis. An appreciating of the difference between the believed accuracy of 497.3 cm/s versus "bout 4 m/s" is important because of the clinical decisions that result. The PSV is used to decide whether a patient with symptoms of mini-stroke should have surgery. In this case, the end diastolic velocity (EDV) is measured at 135.2 cm/s. An EDV value exceeding 140 cm/s in a single measurement would cause a vascular surgeon to schedule the patient for carotid endarterectomy surgery even if the patient has no symptoms

Since bandwidth is inversely proportional to pulse duration and pulse duration is related to spatial resolution, it is desirable to have a short pulse duration so that spatial resolution is as small as possible. This means broadband pulses, permitting depression of the center frequency of the echo. The desire for improved resolution and the desire to avoid aliasing combine in the use of time-domain velocimetry as an alternative to Doppler.

$$\frac{v_f}{c} = \frac{\frac{\Delta\tau}{\Delta t}}{2\cos\theta_D} \ . \tag{21.18}$$

In time-domain velocimetry, two successive ultrasound echoes are compared to see if a time shift ($\Delta\tau$) has occurred in the echo in the intervening time (Δt),

which indicates tissue motion. By measuring the time shift, the velocity can be calculated. Of course, clutter from solid tissue in the voxel may provide a substantial stationary echo superimposed on the small shifted echo. To remove the clutter echo, subtraction of adjacent pairs of echoes (Fig. 21.50) provides the difference waveform containing the motion information. Then the time shift between difference waveforms can be measured (Fig. 21.51).

A comparison between the time-domain equation and the Doppler equation shows that $\Delta\tau = \Delta\phi/f_{us}$. This indicates that it is the demodulator frequency, not the frequency of the echo, that is relevant for the Doppler equation; the former must be close (and is usually equal) to the transmitted center frequency, i.e., the frequency required in the Doppler equation.

Fig. 21.54 Doppler spectral waveform signals from the inferior vena cava showing augmented flow. Doppler spectral waveforms show velocity (*vertical axis*) versus time (*horizontal axis*). In addition to the difference in flow direction, venous flow is differentiated from cardiac flow because the venous flow varies with respiration and with manual compressions of the tissues. Here the sudden increase in venous flow in the distal inferior vena cava was created by releasing an occlusion of the venous outflow from the legs. ECG tracing (*green*) shows cardiac timing. The heart beat to the right of center is due to a premature ventricular contraction, an abnormal heart rhythm which does not affect the venous flow ▶
There are substantial differences between the Doppler and time-domain systems. First the time-domain system usually transmits a broadband, short ultrasound pulse. The signal-to-noise ratio of the echo is determined by the transmit pulse energy. To achieve the same energy in a short pulse, the temporal peak power must be high, leading to a high acoustic pressure. When analyzing the time shift between the echoes, it is easiest to test for the time-lagged correlation by stepping one digitizing interval at a time. So, if the echo is digitized at a rate of 20 MHz, the digitizing interval is 50 ns ($\Delta \tau$), equivalent to a tissue displacement of 0.0375 mm. If
Fig. 21.55 Duplex echocardiogram of a heart with an atrial septal defect. The jet of blood from the left atrium to the right atrium can easily be seen on the color flow image. The Doppler spectral waveform taken at the center of the jet orifice at a Doppler angle of 25° to the jet shows velocities as high as 1.4 m/s when the inter-atrial pressure difference is the greatest. Correcting the velocity for the Doppler angle ($\cos 25 = 0.906$) increases the velocity value to 1.54 m/s. Cardiologists usually attempt to orient the Doppler transducer to align the jet with the Doppler ultrasound beam to achieve a *zero* Doppler angle. The pressure difference between the chambers can be computed using the Bernoulli equation for blood velocity $\Delta p[\text{mmHg}] = 4\,[\text{mmHg}/(\text{m/s})^2]\,V^2$. The pressure difference here is near 9 mmHg (courtesy Frances DeRook and Keith Comess)
Fig. 21.56 Vibration from the mitral valve. Signals from blood flow are mixed with signals from solid tissue motion. Here, the signal of solid tissue motion is suppressed by the wall filter, which suppresses clutter at frequencies below 400 Hz. However, in this case with the Doppler sample volume in the mitral orifice, as the mitral valve closes for the fourth time, the valve vibrates at a frequency of 2 kHz for a period of 8 ms causing the harmonic (Bessel function) spectral pattern with seven harmonic terms, indicating that the amplitude of the vibration is high (courtesy Frances DeRook and Keith Comess)

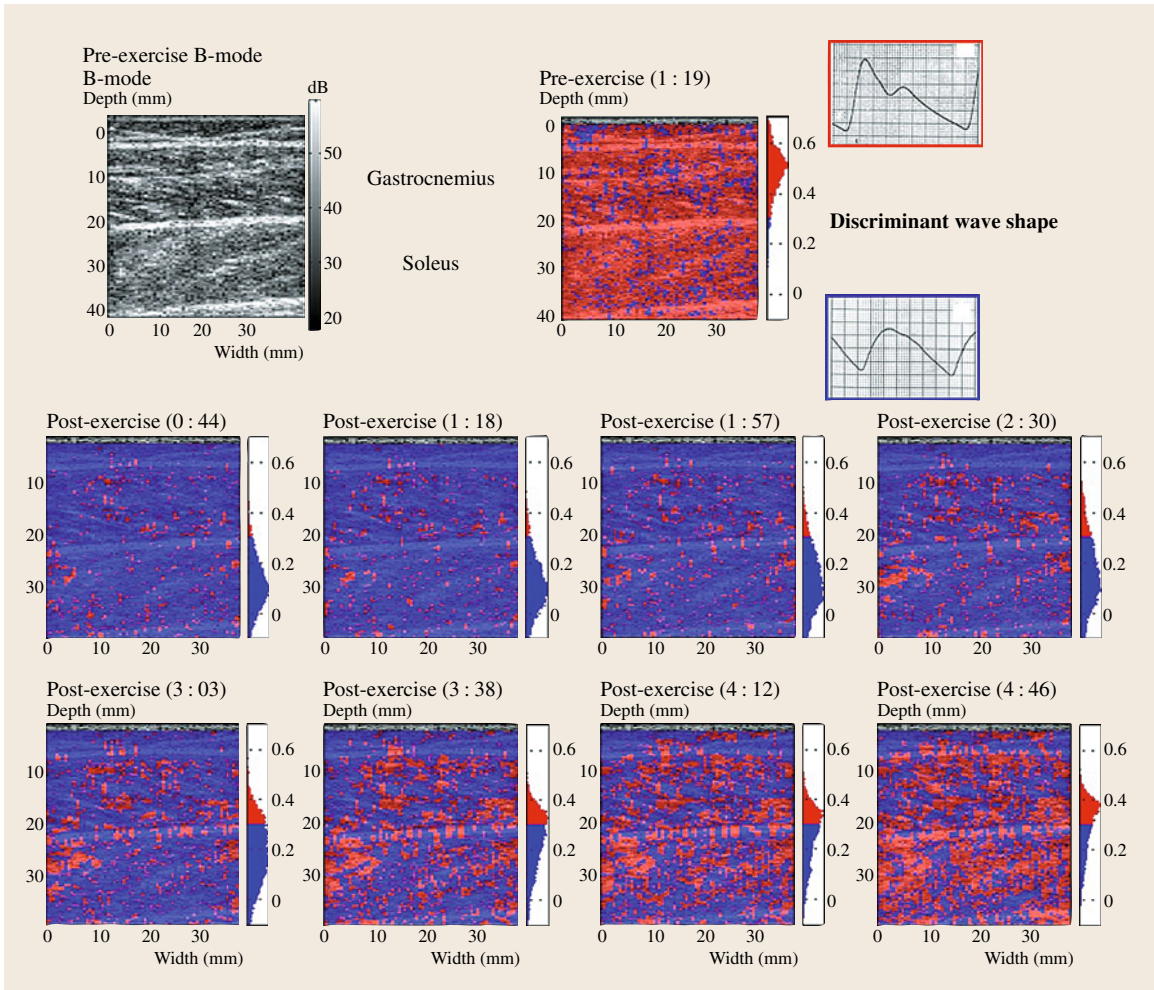
the pulse repetition frequency is 10 kHz, so the inter-pulse interval is 100 μs (Δt), the velocity resolution is 38 cm/s (0.4 m/s). Time-domain systems usually digitize at a higher frequency and usually interpolate the wave between the measurements to improve velocity resolution. For large time shifts, when noise is present, the time domain system usually has trouble with peak hopping, associating the wrong cycles in the wave when determining the time shift. This results in a measurement error identical to aliasing. So, the advantages of
Fig. 21.57 Duplex echocardiogram tissue Doppler of myocardium. Like velocity measurements from blood flow, velocities of solid tissues can also be measured. Low velocities of the intra-ventricular septum of the heart indicates abnormal muscle contraction (courtesy Frances DeRook and Keith Comess)


Fig. 21.58 Tissue strain in calf muscles. During tissue perfusion, different strain waveforms indicate resting perfusion (*red*) with high peripheral (arteriolar) resistance or hyperemic perfusion (*blue*) with low peripheral resistance. In this case, the calf muscle was imaged at rest, and then at intervals for a period of 5 min following a toe stand exercise. Immediately after exercise, the peripheral resistance is low to make up for the metabolic oxygen deficit after exercise. Five minutes after exercise, most of the muscle tissue has returned to the resting state (courtesy John Kucewicz)

time-domain processing over Doppler processing, while promising, have not been fulfilled.

Clinical Applications of Ultrasound Velocimetry

The most common application of pulse Doppler ultrasound spectral waveform analysis is the examination of the carotid arteries [21.68] for stenoses that might lead to stroke (Figs. 21.52, 21.53). The measurement of high systolic ($> 125\,\text{cm/s}$) carotid blood velocity is associated with a 20% chance of stroke in two years in a patient reporting stroke-like symptoms

(TIA = transient ischemic attack, RIND = reversible ischemic neurological deficit). The measurement of a high-end diastolic velocity ($> 140\,\text{cm/s}$) in any patient is associated with a 20% chance of stroke in two years from emboli released from the carotid stenosis. Such findings, by themselves, can direct a patient to treatment that will prevent devastating disability.

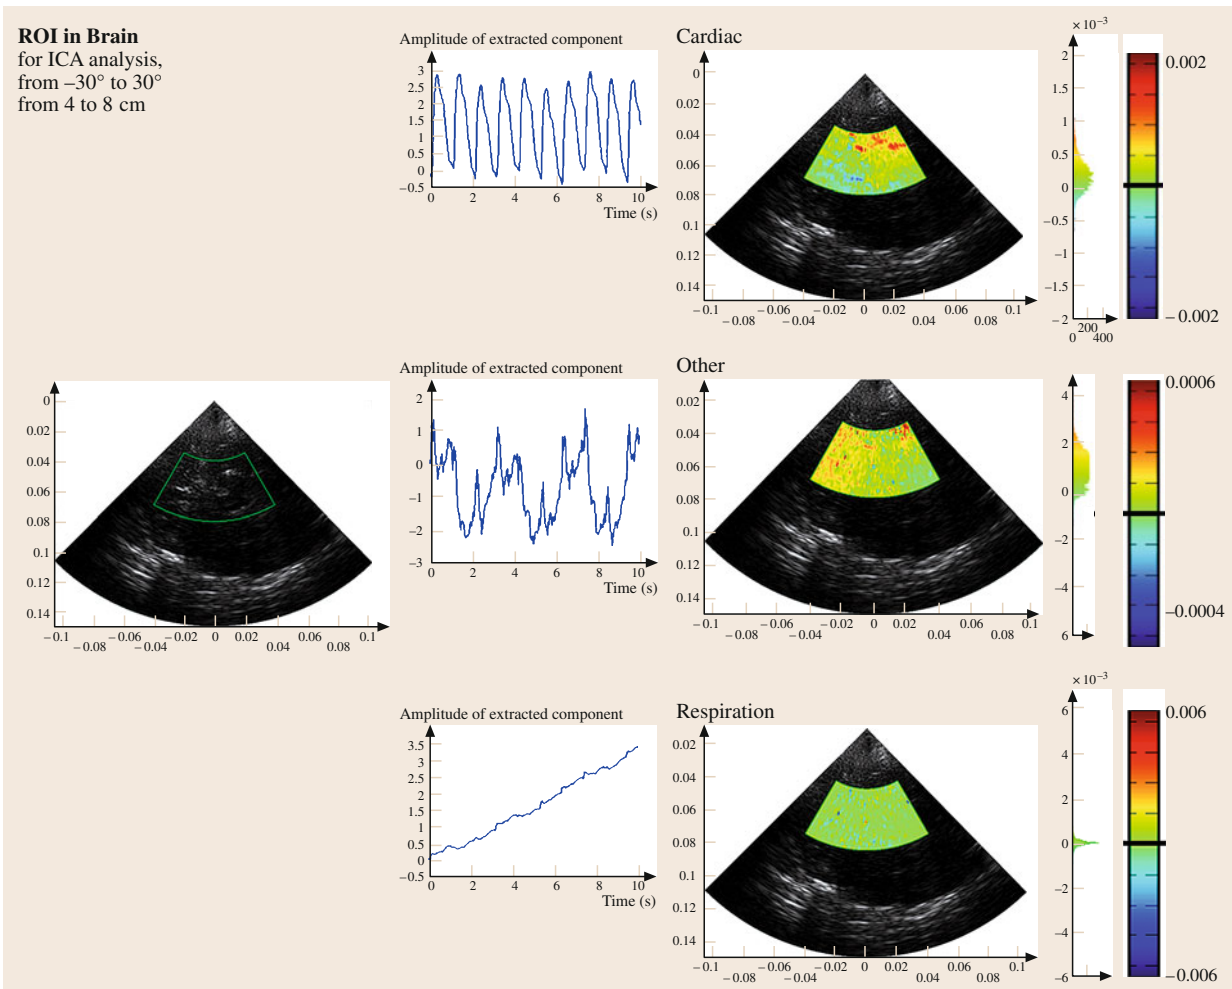
Examination of the veins of the legs with Doppler for the detection of deep venous thrombosis (DVT) is another popular examination that can lead to life saving therapy. Because venous pressures are near 5 mmHg


Fig. 21.59 Tissue pulsations in brain measured with ultrasonic phase gradient demodulation. Using ultrasound to measure tissue displacement over time with a resolution of 0.05 μm and differentiating motion with depth to measure strain, perfusion waveforms can be obtained. Independent component analysis of the brain perfusion signal reveals the cardiac and respiration contributions to the natural tissue strain (courtesy Lingyun Huang)

in the supine patient, normal venous flow is associated with respiration and minor local compression rather than pulsatile with the cardiac cycle (Fig. 21.54). Pulmonary embolus from venous emboli released from a DVT may account for one-third of sudden cardiac death cases [21.69]. A venous Doppler examination failing to show spontaneous venous flow with respiration indicates a venous obstruction that may be a DVT that could progress to threaten life if not treated with anticoagulation.

Cardiac Doppler examinations for blood flow are perfectly suited to characterize narrow holes between the cardiovascular structures in the chest (Fig. 21.55). By measuring the velocity of blood flow jets and applying the Bernoulli equation, the instantaneous pressure difference between the associated chambers of the heart can be measured. This works for all heart valves and wall defects so the method can be used to identify pulmonary artery hypertension as well as cardiac valve failure.

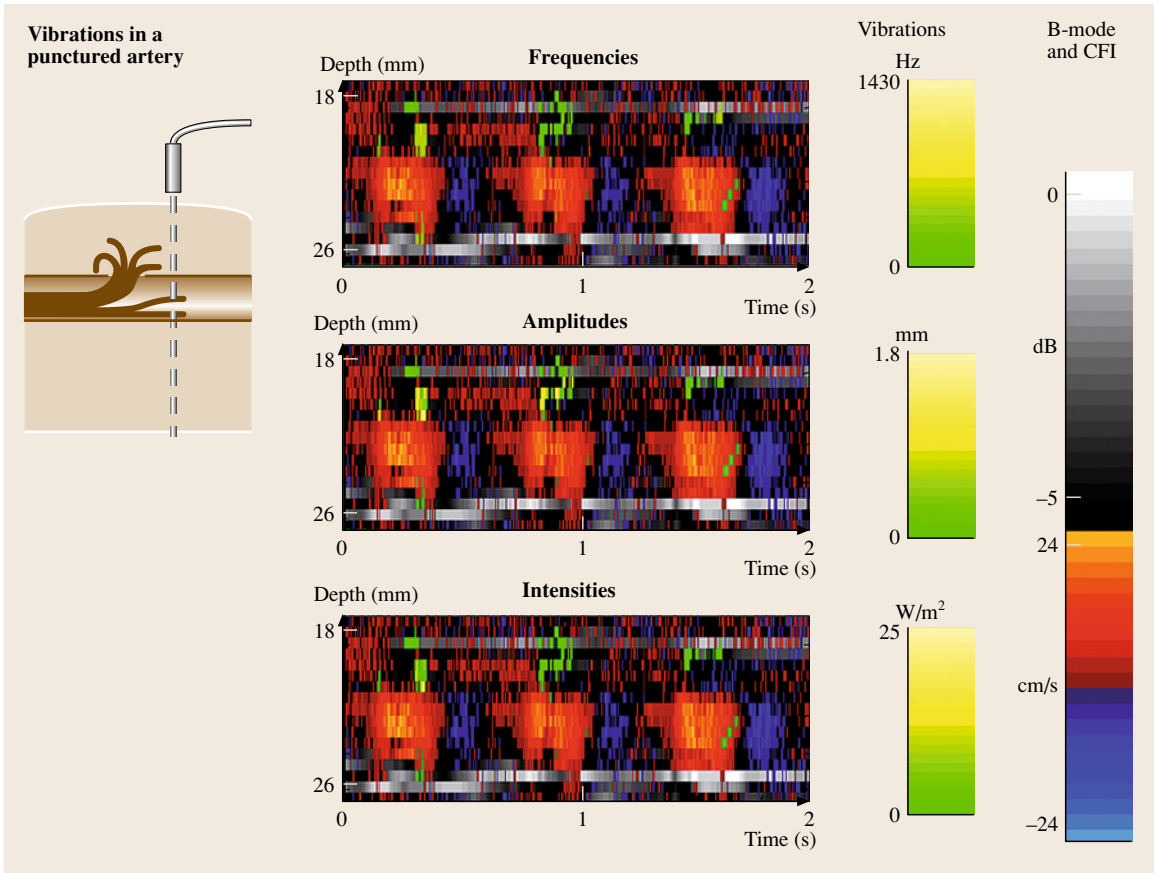
Although blood velocity through valves can be measured (Fig. 21.56), the dynamics of solid structures such as valve vibration, can also be characterized. By measuring the velocity of the cardiac wall, regions of poor myocardial function can be identified (Fig. 21.57).


Fig. 21.60 Tissue vibrations of a punctured artery. Flow through any small orifice which results in a pressure drop can cause vibrations. Arterial bleeding can be detected by searching Doppler signals for such vibrations (courtesy M. Paun, M. Plett)

Tissue Strain Imaging

A number of laboratories are exploring the ultrasound measurement of tissue strain [21.70] for diagnostic purposes. The most popular examinations involve the measurement of tissue response to externally applied vibration or pressure. These methods are called elastography or elastometry. During ultrasound examination,

Fig. 21.61 Vibration of a coronary artery stenosis. Flow through any small orifice which results in a pressure drop can cause vibrations. Flow though a stenosis causes a bruit (Fig. 21.2), or murmur which can be detected and measured with ultrasound. These 4.5 μm-amplitude 300 Hz vibrations on the surface of the heart at the location of a stenosis in the right coronary artery occur only in diastole when the coronary flow rates are the highest (courtesy S. Sikdar, T. Zwink, S. Goldberg) ▶

static or vibrating. By monitoring the relative motions of the tissues in response to the applied strain using Doppler or time-domain methods, the relative elastic properties of the tissues can be determined. The computation simply takes the derivative of the motion as a function of depth. To achieve 10% resolution on a 1% applied strain in 1 mm voxels requires that the ultrasound motion detection system resolve 1 μm tissue displacements. This requires a 1 GHz digitizing rate for a time-domain system without interpolation. A Doppler system with 6 bits of dynamic range can achieve a 1 μm displacement resolution.

More challenging is to examine the natural tissue strain that occurs as the tissue fills and empties of blood each cardiac contraction and each respiratory cycle. Normal tissue strain for arteriolar filling is 0.1%. To resolve 0.1% strain with 10% resolution in 1 mm voxels requires the resolution of 0.1 μm displacements. This requires Doppler demodulation of a 5 MHz echo with at least 9 bits of dynamic range. Ultrasound pulsatility images can be made of most body tissues including muscle (Fig. 21.58) showing physiological responses to stresses, and brain [21.71] (Fig. 21.59) showing the separate effects of pulse and respiration.

Tissue Vibration Imaging

Several pathological conditions are associated with the presence of tissue vibrations. These were discussed at the beginning of the chapter where the detection of the vibrations with a stethoscope was described. Of particular interest are vibrations associated with arterial stenosis and vibrations and motions associated with internal bleeding [21.72]. Using the same Doppler demodulation methods, but filtering for the cyclic motions of the highly echogenic solid tissues rather than the continuous motions of the poorly echogenic blood, vibrations can be detected and rendered as an image showing pathologies such as arterial bleeding (Fig. 21.60). The amplitude and frequency of the vibrations are characteristic of the rate of bleeding. Arterial stenoses including stenoses of the coronary arteries (Fig. 21.61) can be demonstrated in vibration images.

Fig. 21.62 Modern ultrasound imaging system. During the quarter century between 1975 and 2000, ultrasound systems retained the same exterior design, mounted on wheels, narrow enough to fit through a doorway, light enough that a sonographer could push the system, short enough so that a sonographer could see over the top and powered by a 1.5 kW outlet. To the right is the key to good ultrasound diagnosis, the well-trained, certified, experienced ultrasound examiner

Modern Ultrasound Scanners

Real-time diagnostic ultrasound scanners changed little on the outside between 1975 and 2000; they are narrow enough to fit through a doorway (Fig. 21.62) and draw less than 1.5 kW of electrical power from a standard power outlet in the hospital wall. However, inside the systems have evolved from analogue devices to digital devices (Fig. 21.63), with the conversion to digital processing determined by cutting-edge computer technology. Now an ultrasound scanner with a full array of functions is constructed from software, using a Windows laptop computer (Fig. 21.64) or a custom box. Ultrasound systems can be produced inexpensively and can obtain the diagnostic results automatically, so that a patient can use the system for self-management of some conditions (Fig. 21.64).

21.5 Medical Contrast Agents

Contrast agents are used in medical imaging to make invisible structures visible. Contrast agents can be classified by anatomic/application: intraluminal/intracavity, excretory, diffusional, and chemotactic. Contrast mechanisms include reflection, absorption, fluorescence, emission and nuclear resonance frequency shift.

Intraluminal/intracavity agents are used to visualize the cardiovascular system, gastrointestinal system,

reproductive system, body cavities, and other spaces. The contrast agent is injected into the space, where it spreads throughout the structure of interest. Excretory systems are used to visualize the renal system (excretory urogram or intravenous pyelogram (IVP)) or gall bladder and bile duct (cholangiopancreaticogram). The contrast agent is injected into the venous system and is excreted in concentrated form by the target organ. Because of the concentrating action of the kidney, a contrast agent in the urine will be 100 times more concentrated than in the blood. Diffusional agents are injected into the venous system and diffuse into the interstitial space through leaky capillaries. Newly formed capillaries are leaky, and such diffusion may mark local angiogenic factors secreted by tumors or retinopathy. Contrast magnetic resonance imaging (MRI) for breast tumor detection and fluorescene angiography of the retina are examples of diffusional agents. Chemotactic agents are injected into the veins and diffuse into the interstitial space through normal capillaries, where they bind to tissues of interest such as tumor cells. The time between the injection of a chemotactic contrast agent and the imaging study is several hours. This method is common in nuclear medicine imaging.

Ultrasound contrast agents cause increased backscatter of ultrasound and often cause the generation of harmonics. X-ray contrast agents contain heavy nuclei which absorb X-rays to provide contrast. Fluorescene, indocyanine green and other dyes are activated by high-energy (short-wavelength) photons and emit longer-wavelength photons, which are detected by optical camera systems. Chemotactic chemicals prepared with short-half-life (hours) nuclear isotopes are prepared and injected within a few hours. After allowing time for the agents to accumulate in the tissues of interest, the sources of radiation are imaged with pinhole or collimation nuclear radiation cameras. Gadolinium is used as a contrast agent in nuclear magnetic resonance imaging. The paramagnetism of gadolinium decreases the T_1 and T_2 relaxation times, which are displayed in the MR image.

21.5.1 Ultrasound Contrast Agents

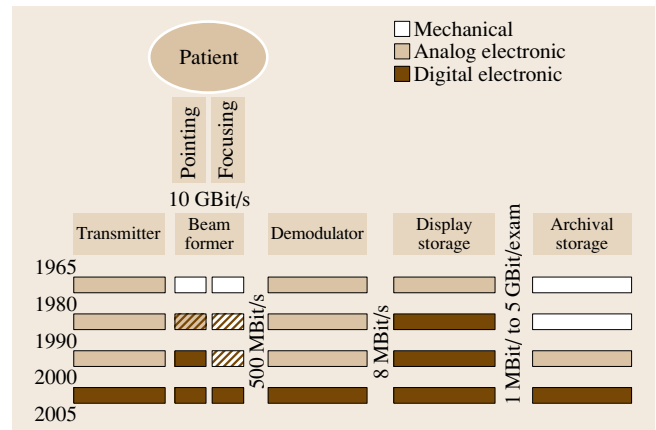
The first intravenous ultrasound contrast agents [21.73] were large bubbles generated by intravenous injection of indocyanine green [21.74], other injectable liquids including saline and blood [21.75–77], and finally agitated saline [21.78]. These bubbles were so large that they would not pass through capillaries, so appearance in the left heart or arteries was proof of a shunt


Fig. 21.63 Diagnostic ultrasound signal processing history. The amount of data transferred between the stages of the ultrasound signal-processing chain is a minimum around the display, the display systems were converted to digital processing during the early years of digital technology development. Beam forming occurs in two directions: in the plane of the image, where the evolution from mechanical to analog to digital proceeded with time, and perpendicular to the plane of the image, where mechanical focusing was replaced by digital electronic focusing and then steering with the advent of transducers segmented into two-dimensional arrays. Pointing of the ultrasound beam between 1980 and 1990 was done digitally in linear array raster scans by switching on selected transducers in the array, but in phased-array sector scans the direction of the beam was determined by adjusting the phase delay with nanosecond resolution on each transducer. Because analog signals have a continuum of possible signal levels, small differences in analog signals can be extracted as long as the differences are greater than the noise in the signal. Once a signal is digitized, no noise is added to the signal by processing. The 10 GBit/s data rate on the receiving path is based on the assumption that the transducer is divided into an array

bypassing the lungs. These bubbles were generated inadvertently or deliberately by flow-induced cavitation. The bubbles contained air that was dissolved in the blood. These bubbles generated strong ultrasound reflections because of the large difference in ultrasound impedance between the body (water) and the air in the bubbles. Small bubbles were not stable, so only large bubbles survived.

Currently, most commercial ultrasound contrast agents are small bubbles or particles, which are able to pass through the capillaries of the lungs but are confined to the vascular system. Some ultrasound contrast agents are solid particles smaller than a micron in diameter. These are Rayleigh scatters of ultrasound

monics because of the nonlinear properties of their oscillation.

21.5.2 Stability of Large Bubbles

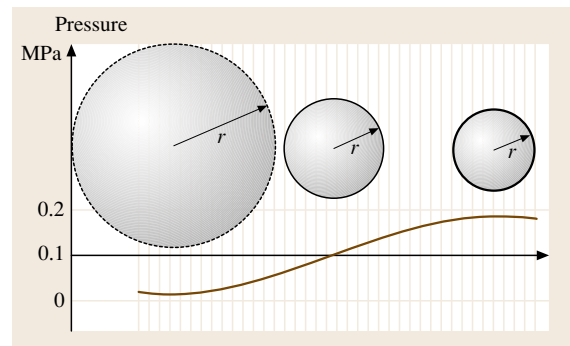
The size of stable bubbles can be estimated from physical principles. The gas inside a stable bubble of radius r (Fig. 21.65) is under a pressure equal to the sum of the ambient atmospheric pressure plus the fluid pressure (1 atm = 10 m of water), and the pressure generated by the surface tension of the interface between the contained gas and the external fluid (water). In the body and in carbonated beverages, the depth of the bubbles is small compared to 10 m of water, so the pressure added because of the depth of the fluid can be ignored compared to atmospheric pressure. A force balance on the


Fig. 21.65 Contrast agent bubble. An ultrasound contrast bubble is a system consisting of a gas inside the bubble, a surfactant, a surrounding liquid, and solutes including gases and surfactants in the liquid solvent. Thermodynamics and the transport of heat and of the dissolved gasses and dissolved surfactant materials all contribute to the response of a bubble to ultrasound exposure. Interactions between bubbles are also important factors in contrast agent dynamics. Here are the expected sizes for a bubble based on an isothermal ideal gas model without considering surface tension for an ultrasound intensity of 87.5 kPa

at the fundamental frequency. Most ultrasound contrast agents are bubbles about 3 μm in diameter (Fig. 21.65) so that they will pass through pulmonary capillaries and recirculate in the cardiovascular system. They are also Rayleigh scatters, but because they oscillate, they convert the fundamental ultrasound frequency into har-

equator of the bubble equates the pressure force $P\pi r^2$ to the surface tension force $\sigma 2\pi r$. Thus the pressure in the bubble above the ambient pressure is $P = 2\sigma/r$. In the absence of a surfactant, the surface tension of water is 70 d/cm. When $r = 1.4\,\mu m$, $P = 1$ atm; this is a huge chemical potential to drive the contained gas into solution. If a bubble is 0.14 mm in diameter, too large to pass through a capillary (red blood cells are 8 μm in diameter), then the pressure elevation in the bubble caused by surface tension is 0.01 atm and the gas contained in the bubble has a low driving force to diffuse into solution. So, large bubbles are more stable than small bubbles. If the surface tension is reduced by applying a surfactant (shell) to the bubble, then small bubbles become stable. If the gas contained in the bubble is less soluble in blood and/or has a low diffusion constant, then the bubble has a longer life.

21.5.3 Agitated Saline and Patent Foramen Ovale (PFO)

Agitated saline contrast bubbles are generated by forcing fluid rapidly through a small orifice, such as an injection needle. They have an important diagnostic application: to determine whether there is a shunt from the right heart to the left heart, bypassing the lungs. The most common of these shunts is the *patent foramen ovale* (PFO). PFO may be a cardiovascular defect of considerable medical importance. If a person under the age of 50 has a stroke due to occluded vessels in the brain (ischemic stroke), the most likely cause is a PFO. One affected group is divers, who return from great depths with large amounts of gas dissolved in their body tissues, especially in fat. Bubbles which form in the low-pressure venous system as the gas is transported toward the lungs, might pass through a PFO during a cough, releasing these large bubbles into the arterial system where they cause occlusion of arteries and ischemia of the tissues that were supplied by the arteries. Ischemia of some tissues might be unnoticed. Ischemia of other tissues might cause pain that is ignored. Ischemia of some portions of the brain might result in undetected changes in personality or memory. Only ischemia of the motor and sensory cortices of the brain causes loss of sensory and motor function that are recognized as stroke symptoms. In divers, these symptoms are called neurological symptoms of the bends, in others they are called transient ischemic attacks (TIA) or stroke, depending on whether the symptoms last less than 24 h or longer than 24 h, respectively.

The foramen ovale is a normal structure before birth, along with the ductus arteriosus, allowing the blood to circulate in parallel through the fetal body, lungs and placenta. At birth, with the muscular constriction of the ductus arteriosus to obliterate the lumen, pressure shifts cause the flap valve of the foramen ovale to close and over time it will seal in most people. However, in some people the foramen ovale does not seal, opening occasionally when the person coughs or strains. The prevalence of PFO in the general population is 30% at age 20 and 10% at age 70. The reason for the decline in prevalence is either because in some people the foramen seals after age 20 or because these people suffer repeated embolic events from the venous to the arterial circulation, which progressively damage body organs leading to failure and death. In the absence of PFO, such venous emboli pass to the lungs where they temporarily occlude portions of the lung, but resolve over time.

The importance of the diagnosis of PFO is currently disputed, but two factors may make testing for PFO a part of every physical examination:

1. The cost of the contrast agent is only the 2 min that it takes to handle off-the-shelf saline and
2. Recently catheter methods of sealing a PFO have been released for testing, avoiding the need for open-chest heart surgery to seal the defect. If 2/3 of the people with PFO at age 20 die before the age of 70, this diagnosis would be an issue of considerable importance.

21.5.4 Ultrasound Contrast Agent Motivation

The case for the development of stable ultrasound contrast bubbles small enough to pass through the capillaries of the lungs and appear in the systemic arteries is based on the wide use of ultrasound in medical imaging. Over half of all medical imaging is done with ultrasound, so there are many potential applications for contrast agents. Because these mechanical agents are confined to the vascular space, they cannot provide contrast in excretory, diffusional or extravascular chemotactic applications. Blood is a poor reflector of ultrasound, generating echoes 60 dB below the echoes from vascular walls. Contrast agents increase the backscatter. In most cases, the detection of blood flow is easy by Doppler methods which can reject the high-intensity stationary echoes from vascular walls and detect the moving echoes of blood using Doppler methods. However, in cases where the

blood is moving slowly, these methods are more diffi-
cult and there is an advantage from the increased echo
signals produced by contrast agents. Thus, in identi-
fying the exact location of endocardium (Fig. 21.66),
in regions deep within strong attenuators (such as
skull) and for blood flow in capillaries, contrast agents
promise to provide important additional diagnostic
information.

21.5.5 Ultrasound Contrast Agent Development

Ultrasound microbubble contrast agents have been un-
der development for a quarter century [21.79]. The first
task in the development of microbubble contrast agents
was to make stable bubbles small enough so that they
could pass through the capillaries of the lungs (about
$3\,\mu m$ in diameter) after injection into the venous system,
and stable enough to survive long enough to be useful
(more than 1 min, preferably 30 min). Three strategies
are available to stabilize the microbubbles:

1. Lower the surface tension,
2. Form bubbles of a gas with low solubility or diffu-
   sivity in water/blood and
3. Produce a gas-impermeable barrier at the gas–liquid
   interface.

Surfactants lower surface tension; fluorocarbons have
low solubility in water/blood; polymeric shells can be

impermeable to gas diffusion. A series of contrast agents
have been developed based on various combinations of
surfactant, contained gas and method of formation.

The behavior of ultrasound contrast agent mi-
crobubbles is complicated and can easily consume an
entire career. Only a few factors will be mentioned here.
A microbubble consists of three phases: the contained
gas, the surfactant, and the surrounding fluid. The size
distribution of the bubbles is determined by the method
of formation. Air-filled albumin-coated microspheres
can be formed by whipping a mixture of albumin and
water in a blender. This forms a broad distribution
of microspheres. The desired size can be selected by
centrifugation or flotation. A more nearly uniform mi-
crobubble size can be achieved by metering the relative
volume of surfactant and gas through a calibrated noz-
zle orifice. The relative amounts of gas and surfactant
are determined by the desired surface to volume ratio.
The speed of bubble extrusion is crucial to the forma-
tion of bubbles of stable size. If prepared for medical
use, in addition to a sterile preparation, formed using
Food and Drug Administration (FDA)-approved good
manufacturing practice, the agent must have sufficient
stability and shelf life to permit distribution, storage and
timely preparation for use.

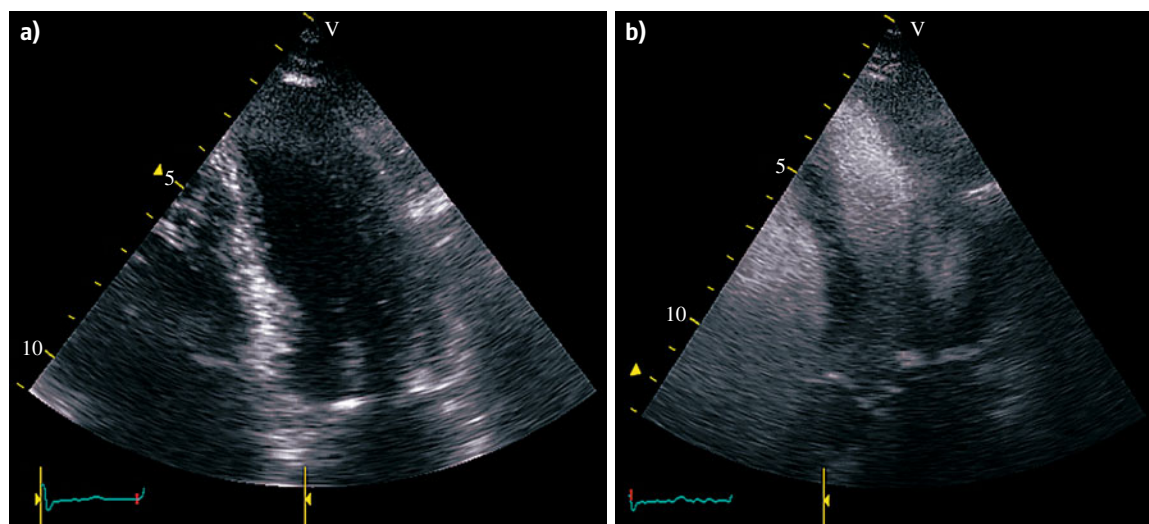
When released into blood, the contained gas is usu-
ally not at equilibrium with the dissolved gases in the
blood. A microbubble filled with fluorocarbon will take
up nitrogen, oxygen and carbon dioxide without releas-


Fig. 21.66a,b Two-dimensional B-mode real-time echocardiogram of the left ventricle. **(a)** Left ventricle without ultra-
sound contrast agent; **(b)** left ventricle with intravenously infused Optison ultrasound contrast agent (courtesy Frances
DeRook and Keith Comess)

ing much fluorocarbon, so the microbubble will swell after injection. The amount of swelling will depend, in part, on the amount and properties of the surfactant. If the bubble swells so that the surface area begins to exceed the available surfactant, the surface tension rises. This may favor bubble coalescence. As the microbubble passes through the lungs, some of the contained fluorocarbon will be released. Gas exchange between the microbubble and the dissolved gas in the blood is continuous during the life of the bubble. Some surfactants and some contained gases have chemical or physical affinities for the interior surfaces of the cardiovascular system of the lungs, arteries, capillaries or veins. The bubbles may become specifically adsorbed to the endoluminal surfaces of these vessels. This can be accidental or deliberate, and can become part of the functionality of the contrast agent. When specifically adsorbed, the surfactant may migrate to the vascular surface or may take on molecules from the vascular surface or surroundings. Of course, the contrast agent might be taken up by cells, transported by those cells and/or retained in particular tissues or organs.

21.5.6 Interactions Between Ultrasound and Microbubbles

When exposed to ultrasound at diagnostic frequencies (1–20 MHz), the contrast bubbles will oscillate at the driving frequency of the ultrasound, emitting the fundamental frequency as well as harmonics of the fundamental frequency. Microbubbles have a natural resonance frequency, primarily determined by their size, surface tension, shell rigidity (if any) and the density of surrounding material. If stimulated at a frequency near the resonant frequency, the amplitude of oscillations will be greater. The pressure of the interior gas varies with volume according to the rules of adiabatic compression and expansion, at least to the extent that the process is too fast for heat transfer. Although the waveform of the oscillation is primarily determined by the waveform of the driving ultrasound, the surfactant forces also play a great role in this process. When the ultrasound pressure is high (for 0.3 μs) the gas compresses, the temperature raises, the water vapor pressure increases as does the pressure of other gases. The gas pressures rise above the surrounding partial pressures of gas, providing a driving force to move gas out of the bubble into solution. Because the bubble is small, the surface area available for heat and mass transfer is small, and the amount of loss of heat and gas is small. Alternatively, when the ultrasound pressure is low (the subsequent 0.3 μs), the pressures and temperature drops, providing driving forces for heat and gas to enter the bubble. Now the surface area is large and it is easy for transport into the bubble, leading to rectified diffusion of gas and heat into the bubble.

At the body temperature of 37 °C, the vapor pressure of water is 6.2 kPa, 6% of atmospheric pressure. An acoustic wave of 285 mW/cm^2 SPTP (spatial peak temporal peak) intensity drops the pressure in a bubble below the vapor pressure of water (ignoring surface tension) which will cause the water to vaporize, filling the bubble with water vapor in addition to the other contained gasses. The latent heat of evaporation lowers the temperature of the bubble. On compression, the recondensing of the water adds heat to the bubble. When the ultrasound is compressing the bubble, the surfactant acts as a stable skin. The skin may even exhibit negative surface tension. Like the hull of a submarine deep in the ocean, the surfactant may hold the bubble gas pressure lower than the surrounding pressure. Similarly, when the ultrasound pressure has dropped below ambient, and the bubble expands to form a larger surface area, the surfactant, which is often a monolayer of molecules on the surface, will change in configuration, become patchy and result in increased surface tension, holding the internal gas pressure higher than expected from the surrounding pressure. As there is a driving force for the gaseous contents of the microbubble to experience rectified diffusion, there is also a driving force for the surface phase to experience rectified diffusion, changing the composition of the surface. A stable molecular monolayer on the surface of the bubble at one bubble volume will become compressed when the bubble becomes small, providing a driving chemical potential to both change the phase of the monolayer to a multilayer and to drive some of the surfactant into solution. The monolayer will be expanded when the bubble becomes large, providing a driving chemical potential to draw surfactant from solution. The solution my provide surfactant materials that are similar to or different from the original surfactant on the microbubble. Unless the concentration of potential surfactants in solution is high, this process is too slow to affect bubble behavior. In experimental solutions, such concentrations may be low, but the complex mixture of complex molecules in blood may favor such a process.

21.5.7 Bubble Destruction

The first experiments with microbubble contrast agents were disappointing. Contrast agents did not produce re-

flections as bright as expected. Increasing the transmit intensity did not improve the strength of the echoes coming from the agents. In an effort to improve the signal strength, broadband ultrasound transducers were used to form harmonic images. An ultrasound transducer oscillates at a resonant fundamental frequency determined by the thickness. The transducer has no efficiency or sensitivity at double the frequency, although it does have one-third the efficiency and sensitivity at triple the frequency. By damping the transducer, a transducer with a center resonant frequency of 3 MHz can be made to operate at frequenciesof 1.9–4.1 MHz. In harmonic imaging to detect contrast bubbles, a 2 MHz transmit burst is applied to this broadband transducer and the receiver is tuned to 4 MHz. Echoes from tissue are expected at 2 MHz, echoes from contrast microbubbles are expected at 2 MHz and 4 MHz. By selecting only echoes at 4 MHz, clear visualization of the contrast bubbles was expected. Unfortunately, for this application, because ultrasound transmit intensities are so high, ultrasound transmission in tissue is nonlinear, generating harmonics in the transmit beam on the way to the reflectors. So even without contrast microbubbles, tissue echoes contain 4 MHz, 6 MHz and 8 MHz components when exposed to 2 MHz transmit pulses. Even more disturbing, real-time B-mode images still did not show brighter echoes from contrast-filled blood spaces than from the same spaces before the introduction of the contrast agent. The reason for this puzzling result is that the transmitted ultrasound pulse destroys the echogenic bubbles, bleaching the contrast effect. Only bubbles of a particular size are bleached by the particular incident ultrasound frequency used, some becoming larger by coalescence and some dividing into smaller sizes, so they are not strongly echogenic at the incident frequency. The process of bubble destruction takes several milliseconds after exposure to a single ultrasound transmit burst. This provided the basis for two new methods of imaging with ultrasound contrast microbubbles: interrupted imaging and color Doppler imaging. If 2-D real-time B-mode imaging is used at a typical frame rate of 30 images per second, the interval between one pulse-echo cycle along an image line and the next is 33 ms, so the echogenic bubbles are gone after the first frame, and any new echogenic bubbles that enter the image field are destroyed as the imaging continues. This led to interrupted imaging of the heart muscle. In interrupted imaging, a series of ECG-triggered images is recorded for later analysis. Each image is acquired at the same time during the cardiac cycle so that successive images are separated by at least one cycle. During the sequence of ECG-triggered acquisition of images from a single plane, an initial image is obtained (i0), after an interval of five cardiac cycles a second image is obtained (i5), after the next interval of four cardiac cycles the next image is obtained (i4), then after three cycles (i3) and after two cycles (i2) and finally after an interval of one cycle the final image is obtained (i1). In theory, the prior image bleaches all of the contrast while acquiring the image. For contrast to appear in the next image, perfusion must carry the contrast bubbles into the image. By subtracting i5 from i0, all regions with significant perfusion are dark. By subtracting i1 from i2, only the regions that are filled with contrast within a second are dark, those that fill during the time between 1 and 2 s are bright. By subtracting i4 from i5, the bright regions showing contrast bubbles in the image i5 that are not present in i4 show the regions that are filling slowly with blood.

During a color Doppler or color power angiography ultrasound examination, the ultrasound system sends an ensemble of eight transmit bursts at intervals of 0.2 ms along the ultrasound beam pattern to measure the changes in phase of the ultrasound echoes. In that 1.6 ms period, the contrast bubbles will begin and complete the process of vanishing. Thus there will be a large change in the echoes received from each depth during the period of the ensemble. This will be interpreted by the ultrasound system as a Doppler signal and displayed as color in the image.

The exact role of ultrasound contrast agents in medical diagnosis remains to be developed. However, there are a number of efforts to develop nanoparticles for useful applications. These nanoparticles are the same size as ultrasound contrast agents and may contain gas as well as liquid. The National Cancer Institute Unconventional Innovations Program supports some of this work for the diagnosis, treatment and monitoring of cancer. Nanoparticles can act as machines, using ultrasound energy as the supply to do useful work. This can be achieved using protein mechanics. Protein folding confirmations can change in nanoseconds, the molecular volume is different for each conformation and the energy states of folding change under high and low pressure, so ultrasound can be used to drive proteins from one conformational state to another. Nanoparticles can be used to deliver drugs [21.80] to target tissues, with ultrasound serving to trigger the release of the drug at desired times.

21.6 Ultrasound Hyperthermia in Physical Therapy

One of the earliest medical applications of ultrasound was the therapeutic heating of deep tissue because absorption of ultrasound by tissue results in the conversion of ultrasound energy into heat. In common practice, an ultrasound transducer 3 cm in diameter transmitting 20 W at a frequency of 3 MHz is applied to the skin (Figs. 21.67, 21.68).

As a rule, the size of the treatment area should be less than twice the surface area of the transducer. Because of diffraction effects, the ultrasound field has

Fig. 21.68 Combined ultrasound diathermy and electrotherapy system. Deep heating of tissue can be achieved by using ultrasound or by using radio-frequency electric currents. This system is capable of delivering both kinds of heating. The two transducers shown are for ultrasound, but since the metallic surface is in contact with the patient, either can also apply RF diathermy when used with a counter-electrode

Fig. 21.67 Ultrasound therapy system
Fig. 21.69 5 MHz ultrasound is attenuated more in a short distance than 2 MHz ultrasound (*upper lines*). At shallow depths 5 MHz ultrasound delivers more heat because of greater absorption (*lower interrupted line*), but at the deepest depths, 2 MHz ultrasound provides greater heating (*lower solid line*). Because of the low absorption of ultrasound by fat, little heating occurs in fat

a complex pattern of peaks and valleys. The best transducers have a beam nonuniformity ratio (BNR) of 2 : 1 in intensity. A BNR of 6 : 1 is clinically acceptable. Some instruments have a BNR of 8 : 1.

The ultrasound passes through skin and subcutaneous fat to the muscles and connective tissues below. Because the attenuation of ultrasound in tendon is 10 times the attenuation in fat, the majority of the heating is in the tendon (Fig. 21.69). Heating is more superficial when a higher ultrasound frequency is used.

The attenuation in muscle and tendon is higher than in fat, favoring the heating of these tissues even when they are covered by fat. However, the attenuation of skin is quite variable; some reports show skin attenuation higher than tendon. The variability of the attenuation in skin results from two factors, the thin and nonuniform character of skin, and the variable air content of the stratum corneum, the outermost layer of skin. With careful application of ultrasonic gel, the air can be removed from the stratum corneum layer, lowering the attenuation.

Although ultrasound diathermy as well as other diathermy methods are often used in physical therapy, the effectiveness of the treatments beyond the placebo effect is questioned by some.

21.7 High-Intensity Focused Ultrasound (HIFU) in Surgery

Starting in 1950, William J. Fry and colleagues at the University of Illinois, Urbana, developed an ultrasound method to heat small volumes of deep tissue to high temperatures. Using a 10 cm-diameter transducer operating at 2 MHz focused at a depth of 10 cm, tissue the size of a grain of rice can be heated at 25 °C per second, causing the tissue to boil in 2.5 s. This method allowed Fry to create thermal lesions in the brain for the treatment of brain tumors and other neurological conditions.

The technology is still in evolution, but holds promise of allowing the cautery of deep tissue without
Fig. 21.70 3.5 MHz HIFU transducer used in abdominal surgery research. Notice that the black transducer face is concave (the reflection of the fluorescent light fixture is curved). The transducer is fitted with a signal cable (*black*), a pair of tubes to deliver and return cooling water (*clear*), and a thermocouple cable (*thin*) to monitor the temperature of the transducer. A plastic cone filled with water fits on the front of the transducer to conduct the sound to the tissue
Fig. 21.71 Histology of a HIFU lesion overlaid onto the ultrasound image. 5 s high-intensity focused ultrasound cautry at a depth of 5 cm under tissue in porcine spleen. Typical lesions are 10 mm long (in depth from the transducer) and 1 mm in diameter

damaging the overlying superficial tissue. A 35 mm-diameter 5 MHz concave ultrasound transducer focused at a depth of 35 mm (Fig. 21.70) delivering 30 W of acoustic power to a treatment volume 1 mm in diameter and 10 mm long can deliver an intensity of 3 kW/cm² (30 MW/m²) to form a lesion (Fig. 21.71). At such intensities the nonlinearity of the tissue causes much of the ultrasound to be converted to higher harmon-

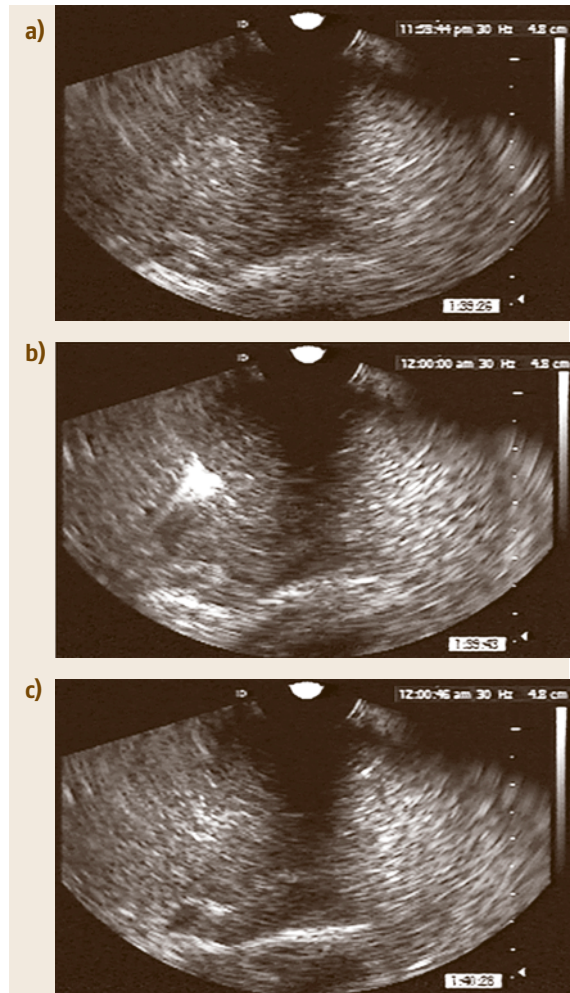
ics (Fig. 21.72), increasing the fraction of the incident power absorbed in the treatment volume. During HIFU treatment, ultrasound images of the treatment volume show a spot of increased echogenicity caused by bubbles filled with water vapor (boiling) or with gas coming out of solution. When the HIFU treatment stops, the hyper-echogenic zone quickly becomes anechoic. During treatment, the bubbles may act as a shield, restricting the delivery of ultrasound to deeper tissues (Figs. 21.73, 21.74).
Fig. 21.72 Computed central beam instantaneous pressures from a HIFU transducer. The high acoustic pressures in the focal zone create nonlinear effects that generate harmonics in the transmitted ultrasound beam (courtesy F. Curra)
Fig. 21.73 Typical HIFU ultrasound beam profile. High-intensity focused ultrasound beam profile showing increase in beam intensity, not accounting for attenuation. The small circles post focus represent bubbles formed by a combination of mechanical-index-induced cavitation boiling. They are pushed into the post-focus zone by radiation pressure. As the exposure continues, more bubbles will be formed at shallower depths. Post-focal bubbles may provide a safety shield, preventing HIFU exposure of deeper, healthy tissue


Fig. 21.74a–c B-mode imaging of high-intensity focused ultrasound lesion formation. Focal intensity 1000 W/cm2. **(a)** B-mode image of tissue before HIFU therapy. **(b)** Echogenic region at HIFU treatment zone after 15 s of exposure. **(c)** Echogenicity vanishes with time after cessation of HIFU exposure

HIFU treatment can coagulate blood to stop bleeding or to render tissue ischemic, causing necrosis. The method holds promise for:

1. Stopping internal bleeding of the liver or spleen,
2. Stopping bleeding due to catheter procedures,
3. Reducing the size of tissues such as uterine fibroids and prostate hypertrophy,
4. Destroying cancer cells and tumors,
5. Birth-control procedures such as vasectomy and tubal ligation,
6. Tissue welding, and
7. Pushing tissues using radiation force to stretch or compress them.

Thermal dose is one way to summarize hyperthermia treatment conditions. Thermal dose implies that tissue changes occur above 43 °C, and that the effect is increased with increasing time and increasing temperature. One empirical formula for thermal dose has been given [21.81] as:

$$D = \int_{t_1}^{t_2} n(T)^{(T-43)} \, dt \, ,$$

where t_1 and t_2 are the initial and final times of the heating profile, respectively, and $n(T)$ is 4 for $T < 43\,°C$ and 2 for $T > 43\,°C$. The temperature is determined by the rate of heat delivery per tissue volume, which is the product of the intensity times the attenuation minus the rate at which heat is removed from the tissue by conduction through tissues, and convection via the blood.

The most difficult issue with HIFU is the small treatment volume versus the relatively large access window. Under ideal conditions, the treatment of a single volume of tissue $10\,mm^3$ takes about 2 s. A cubic region 50 mm on a side has a volume of $125\,000\,mm^3$ and requires nearly 4 h to treat. These long treatment times present a considerable economic problem for the adoption of the technology.

21.8 Lithotripsy of Kidney Stones

Explosive ultrasound can be used to fracture kidney stones in the renal pelvis where the urine is collected from the kidney and directed down the ureter to the bladder. Stones which form in the renal pelvis from solutes in the urine are very painful. The pain occurs because urine is moved down the ureter by peristaltic action, and the peristalsis cannot handle a bolus the size of a stone. One type of ultrasound lithotripter uses a 10 cm-diameter concave reflector with a spark gap at the source focus. The elliptical curvature forms a target focus 12 cm from the face of the reflector. Equally intense ultrasound pulses can be formed using focused piezoelectric transducers or electromagnetically driven membranes with the ultrasound focused using an acoustic lens.

A water path is used to couple the reflector to the skin nearest the affected kidney so that the target focus can be positioned on the kidney stone. By firing the spark gap in the water at the source focus, pressures of $+100\,MPa$ followed by $-10\,MPa$ are achieved at the target focus. Treatment of a kidney stone may require 3000 shocks delivered over an hour. The object of the treatment is to break a large stone ($\geq 1\,cm$ in diameter) into smaller pieces ($\leq 2\,mm$ diameter) that the ureter can carry to the bladder. The mechanism of stone destruction includes erosion, spallation, fatigue, shear and circumferential compression associated with the primary shock wave or resulting cavitation. Erosion is caused by cavitation. Spallation is the ejection of the distal portion of the stone, resulting from a decompression wave reflected from the distal portion of the stone. Unfortunately, lithotripsy is often associated with injury to the kidney parenchyma [21.82].

21.9 Thrombolysis

A new therapeutic application of ultrasound is the destruction of blood clots occluding vessels. Two mechanical methods may contribute to clot destruction [21.83–85]: the formation of microbubbles in the clot (cavitation) and differential radiation force on the clot squeezing and expanding the clot like a sponge to take up thrombolytic drugs. There are research reports of successful thrombolysis in coro-

nary arteries [21.86], intracranial arteries [21.87, 88] and vascular access shunts for dialysis. The ultrasound intensities required for thrombolysis are similar to those used in diagnostic ultrasound. The mechanisms include streaming and disaggregation of the clot [21.89].

21.10 Lower-Frequency Therapies

Lower-frequency ultrasound is used for tissue disruption and cleaning purposes. To remove an opacified lens (cataract) from the eye through a small incision, a needle oscillating at 25–60 kHz is used to emulsify the lens (phacoemulsification), which is then removed by aspiration (suction).

Dental scaling is performed with a similar instrument operating at frequencies of 18–30 kHz and applied power of 30 W. Cavitation is an important mechanism in the cleaning process. Chemical additives such as toothpaste can suppress cavitation and degrade the cleaning efficiency.

21.11 Ultrasound Safety

Undoubtedly, ultrasound is safe. In over a half century of widespread use of diagnostic ultrasound, there are no currently accepted reports of harm to patients or examiners from the use of diagnostic ultrasound. However, in 1950, unamplified X-ray fluoroscopic imaging was considered so safe that it was used for shoe fitting in nearly all shoe stores, and for the entertainment of children waiting to be served. In 1950, smoking was considered to be so beneficial to health that nearly all doctors smoked. Although there are reports that ultrasound examination in pregnancy is associated with increased birth complications in retrospective studies where ultrasound was applied to high-risk pregnancies, a causative effect is unlikely. Fewer complications were found in pregnancies randomized to ultrasound examination compared to those with conventional care [21.90] because of the increased knowledge of physicians about the expected date of delivery. In one discussion of the safety of Doppler ultrasound examination of the ophthalmic artery through the eye, an experienced investigator stated *If the patient doesn't see flashes of light, I figure that the exam is safe*. Still today, diagnostic ultrasound is considered so safe that, although there are occasional disclaimers such as *to be used only under the supervision of a physician*, ultrasound examinations are performed for educational purposes on students, demonstrated on hired actors at trade shows, available for home use, and advertised for entertainment purposes. One prominent ultrasound safety expert warned that driving to the examination carried more risk than the risk associated with ultrasound examination.

In 1976, the United States congress passed the Medical Device Amendments providing that the Food and Drug Administration should have authority over medical devices [21.91]. At that time, any medical device in clinical use, in the absence of evidence of hazard, was considered safe. Any new medical device that was substantially equivalent to a pre-enactment device could be approved for distribution in interstate commerce and use by filing a 510k application showing equivalence. Devices that were not substantially equivalent required pre-market approval (PMA) as an investigational device. This started a search for existing ultrasound systems that had been sold across state lines so that the ultrasound output levels could be measured. These old systems are called pre-enactment systems. New ultrasound devices that had similar or lower acoustic outputs were considered equivalent and could be approved by the FDA under a 510k application, which was simpler and far less costly than the PMA process.

In 1976, continuous-wave (CW) Doppler systems were in use, pulsed Doppler systems were in use, M-mode, 2-D static B-mode and 2-D real-time B-mode systems were also in use. One CW Doppler system at the time caused red spots on the skin that were called *Doppler hickies*, but were still considered safe because there were no complaints.

The task was to characterize the equivalent acoustic output. Over the quarter century since enactment, various methods have been developed to describe the effect of ultrasound on tissue, to establish equivalence. Because of the common use of therapeutic ultrasound to create tissue hyperthermia, the first consideration was

the heating effect of the ultrasound; later mechanical effects were included in the analysis.

The heating of tissue is governed by the bioheat equation. This equation relates the increase in tissue temperature to the rate of heat deposit minus the rate of heat removal divided by the heat capacity of the tissue. The rate of heat deposit is proportional to the incoming ultrasound power minus the outgoing ultrasound power, per unit mass. In a simple computation, the heat capacity of tissue is the same as water, 1 cal/gm or $4.2\,\mathrm{J/gm\,°C} = 4.2\,\mathrm{J/cm^3\,°C} = 4.2\,\mathrm{W\,s/cm^3\,°C}$. So, if ultrasound at an intensity of $4.2\,\mathrm{W/cm^2}$ is completely absorbed by a layer of tissue (water) that is 1 cm thick, the temperature will rise 1 °C per second, if no heat is carried away. $42\,\mathrm{mW/cm^2}$ ($420\,\mathrm{W/m^2}$) will raise the temperature by only 0.01 °C per second, allowing 100 s of exposure to raise the temperature from the normal body temperature of 37 °C to 38 °C, well below fever temperature considered safe by most people. Since at 4 MHz, only half of the ultrasound power is converted to heat in one cm, the heating rate is half of the values above.

Until 1985, ultrasound exposure levels were quoted in terms of $\mathrm{W/cm^2}$ related to tissue heating. Based on pre-enactment levels, diagnostic ultrasound systems had a temporal average (TA) acoustic intensity at the transducer focal zone measured in a water-filled test tank of $100\,\mathrm{mW/cm^2}$ ($1\,\mathrm{kW/m^2}$) or less. The major exception was ultrasound systems for the examination of the eye, which had pre-enactment intensities of $7\,\mathrm{mW/cm^2}$ ($70\,\mathrm{W/m^2}$). So, the generally accepted temporal average allowable intensities became: $7\,\mathrm{mW/cm^2}$ ($70\,\mathrm{W/m^2}$) for the eye and $100\,\mathrm{mW/cm^2}$ ($1\,\mathrm{kW/m^2}$) for all other diagnostic applications. The maximum intensity of sunlight is about $50\,\mathrm{mW/cm^2}$ ($500\,\mathrm{W/m^2}$), but the attenuation of sunlight at the skin is near 100%. Acceptable physical therapy ultrasound intensities were about 30 times higher: $3\,\mathrm{W/cm^2}$ ($30\,\mathrm{kW/m^2}$).

Ultrasound beam patterns are not uniform, especially in the Fresnel zone (near field). The intensities at the focus in diagnostic ultrasound beams are often three times higher than the average intensities. Because of this, ultrasound intensities were reported as spatial peak (SP) intensities, to indicate the variations, or spatial average (SA) intensities.

With pulsed-echo ultrasound imaging, the transmitted ultrasound is on for less than 0.5 µs every millisecond along the same ultrasound beam pattern in M-mode examination; thus the ultrasound was on only 1/2000 of the time (duty factor or duty cycle of 0.05%). For a spatial peak temporal average intensity of $100\,\mathrm{mW/cm^2}$, ($1\,\mathrm{kW/m^2}$) the pulse average (PA) was 2000 times as great or $200\,\mathrm{W/cm^2}$ ($2\,\mathrm{kW/m^2}$) (SP PA) and the temporal peak (TP) intensity was twice that value (SPTP, Fig. 21.23, broadband pulse). A conventional pulsed Doppler examination with a 1 µs transmit burst every 50 µs has a duty factor of 2% and an SPTP intensity of $5\,\mathrm{W/cm^2}$ ($50\,\mathrm{kW/m^2}$). In both M-mode and Doppler examinations, the ultrasound beam pattern is held stationary for several seconds. But in real-time 2-D B-mode imaging, each successive beam axis is along a different line. Typically, the ultrasound is directed along the same line at the frame rate, about 30 times per second.

Over the next decade, the guidelines for ultrasound intensities in different applications became more sophisticated, separating application-specific output levels into four categories: general, cardiac, vascular, and ophthalmic. The motivation was to allow higher intensity levels to be used for Doppler blood velocity measurements because the echoes returned by blood were 0.000001 (60 dB) lower than those from tissue. Rather than accepting the intensities measured at the focal zone in a water tank, the intensities were derated by computing the expected intensity if the water were replaced by attenuating tissue with an attenuation rate of 0.3 dB/(MHz cm). Derating allows a 3 MHz cardiac Doppler system focused at a depth of 11 cm to derate the intensity by 10 dB, thus allowing a tenfold increase in transmit power. The derated SPTA limits were: fetal, neonatal and other general-purpose applications $-94\,\mathrm{mW/cm^2}$; cardiac $-430\,\mathrm{mW/cm^2}$; peripheral vascular $-720\,\mathrm{mW/cm^2}$; ophthalmic $-17\,\mathrm{mW/cm^2}$; the SPPA limits were $190\,\mathrm{W/cm^2}$ for the first three categories and $28\,\mathrm{W/cm^2}$ for ophthalmic exams.

Working together, the US Food and Drug Administration (FDA), National Electronic Manufacturers Association (NEMA) and the American Institute of Ultrasound in Medicine (AIUM) began to agreed on output display standards (ODS) for ultrasound instruments, including the thermal index (TI, the intensity required to raise the temperature of tissue by 1 °C) predictive of tissue heating, and the mechanical index (MI) predictive of cavitation and interactions with ultrasound contrast agents. The TI was further divided into subcategories for soft tissue (TIS), bone near the focus (TIB) and cranial bone near the skin (TIC) based on the expected absorption of ultrasound in the tissue. These values also include the fact that the ultrasound beam is scanning across the tissue in 2-D imaging. The computation of MI is based on the SPTP intensity values,

includes attenuation derating but not the scanning of the ultrasound beam.

To better understand the MI values, refer to Fig. 21.5 which indicates that the amplitude of the pressure fluctuation for a $0.3\,\mathrm{W/cm^2}$ wave is 1 atm, or $100\,\mathrm{kPa} = 100\,\mathrm{kN/m^2}$. The pressure increases by the square root of intensity, for a linear system (which this cannot be). So, for the M-mode SPTP intensity of $200\,\mathrm{W/cm^2}$, ($2\,\mathrm{MW/m^2}$) the pressure amplitude is 26 atm, making the peak positive pressure 27 atm (2.7 MPa) and the peak negative pressure (below zero) -25 atm (-2.5 MPa). The MI is defined as the negative pressure amplitude [MPa] divided by the square root of the ultrasound frequency [MHz]. This provides a basis for the estimation of the chance of an adverse nonthermal event. At 3 MHz, the MI for this case is 1.5. An MI less than 1.9 is acceptable for obstetrical examinations in the absence of ultrasound contrast agents our other sources of gas bubbles.

In 1991, the FDA released its 510k guidance [21.92], establishing a new track for approval of non-PMA devices, regulatory track 3. This permitted increased outputs for devices implementing the output display standard developed jointly by the AIUM and NEMA [21.93]. This standard recognized two general classes of mechanisms by ultrasound could adversely affect biological tissue, thermal and mechanical, and provided simple metrics for the likelihood of such effects, the thermal index (TI) and mechanical index (MI).

Similar standards have been addressed in other countries by organizations and agencies including Health Canada, the European Committee for Medical Ultrasound Safety (ECMUS), the British Medical Ultrasound Society (BMUS), the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB), the Australasian Society for Ultrasound in Medicine (ASUM), the Asian Federation for Societies of Ultrasound in Medicine and Biology (AFSUMB), the Latin American Federation of Ultrasound in Medicine and Biology (FLAUS), the Mediterranean and African Society of Ultrasound (MASU), and the World Federation for Ultrasound in Medicine and Biology (WFUMB).

In spite of the confidence that ultrasound is absolutely safe, all ultrasound agencies subscribe to the policy of using ultrasound exposure levels that are as low as reasonably achievable (ALARA) for diagnostic ultrasound examinations.

In the presence of ultrasound contrast agents or gas in the lungs or gut, there is a risk of damaging capillaries and creating interstitial hemorrhaging in tissues when high-MI examinations are performed.

However, there are some other considerations. In addition to heating tissue and the compression/decompression mechanical factors related to mechanical index, an ultrasound wave exerts radiation pressure on tissue as it passes through. The radiation pressure is proportional to intensity. Radiation force is used in the measurement of acoustic output. The body force is equal to the [power entering a region minus the power transmitted through and exiting the region] divided by the speed of sound. At a pulsed Doppler focus in the examination of the fetus, a temporal peak radiation pressure of 1700 Pa can be generated at a frequency equal to the pulse repetition frequency (PRF) of 5 kHz, which is well within the hearing range. If the ultrasound beam pattern is directed to intersect the ear, the radiation pressure oscillation can be heard by the fetus and cause increased fetal activity [21.94].

Of more serious concern is the increase in permeability in cell membranes and other biologic barriers to small and large molecules that can be induced by ultrasound [21.95]. This may prove useful for the delivery of therapeutic drugs through the skin (sonoporation) and genes across membranes including the placental barrier and the blood–brain barrier, but it might also allow the inadvertent transfer of pathogens. The effect is enhanced in the presence of gas and ultrasound contrast agents. It is possible that such effects have escaped detection by current monitoring methods.

The conceptual simplicity of the pulse-echo system has allowed instrument engineers to devote all efforts toward lowering the cost and improving the diagnostic utility of these instruments. Unlike most other medical imaging methods, ultrasound is low-cost, portable, real-time, and considered safe in most applications.

Part G

Structural

Part G Structural Acoustics and Noise

22. Structural Acoustics and Vibrations

Antoine Chaigne

This chapter is devoted to vibrations of structures and to their coupling with the acoustic field. Depending on the context, the radiated sound can be judged as desirable, as is mostly the case for musical instruments, or undesirable, like noise generated by machinery. In architectural acoustics, one main goal is to limit the transmission of sound through walls. In the automobile industry, the engineers have to control the noise generated inside and outside the passenger compartment. This can be achieved by means of passive or active damping. In general, there is a strong need for quieter products and better sound quality generated by the structures in our daily environment.

Structural acoustics and vibration is an interdisciplinary area, with many different potential applications. Depending on the specific problem under investigation, one has to deal with material properties, structural modifications, signal processing and measurements, active control, modal analysis, identification and localization of sources or nonlinear vibrations, among other hot topics.

In this chapter, the fundamental methods for the analysis of vibrations and sound radiation of structures are presented. It mainly focuses on general physical concepts rather than on specific applications such as those encountered in ships, planes, automobiles or buildings. The fluid–structure coupling is restricted to the case of light compressible fluids (such as air). Practical examples are given at the end of each section.

After a brief presentation of the properties of the basic linear single-degree-of-freedom oscillator, the linear vibrations of strings, beams, membranes, plates and shells are reviewed. Then, the structural–acoustic coupling of some elementary systems is presented, followed by a presentation of the main dissipation mechanisms in structures. The last section is devoted to nonlinear vibrations. In conclusion, a brief overview of some advanced topics in structural acoustics and vibrations is given.

In this chapter, the fundamental methods for the analysis of vibrations and sound radiation of structures are presented. It mainly focuses on general physical concepts rather than on specific applications such as those encountered in ships, planes, automobiles or buildings. The fluid–structure coupling is restricted to the case of light compressible fluid (such as air). The case of strong coupling with heavy fluid (water) is not treated.

If the magnitude of the vibratory and acoustical quantities of interest can be considered as sufficiently small, then the equations that govern the structural–acoustics phenomena can be linearized. The linear theory of vibrations applied to simple continuous elastic structures, such as bars, membranes, shells and plates, forms a reference framework for numerous studies involving more-complex geometries. In some practical situations, it is not necessary to know the exact vibratory shape at each point of a given system: to take advantage of this, a continuous structure can often be represented as a discrete system built with rigid masses connected to springs and dampers. The main results of the linear theory for the vibration of discrete and continuous systems are presented in Sects. 22.1–22.4. Section 22.1 is devoted to the linear single-degree-of-freedom (DOF) oscillator for which the fundamental results are derived with the help of the Laplace transform. In Sect. 22.2, the case of discrete systems with multiple DOFs is used to introduce the concepts of eigenmodes, eigenfrequencies, the admittance and modal analysis. As an illustration, one example of coupled oscillators is solved in detail. Also the fundamental energy equation of statistical energy analysis (SEA) that governs the mean power flow between coupled oscillators is summarized. Section 22.3 deals with the transverse vibrations of strings and membranes, which can be viewed as limiting cases of prestressed structures with negligible stiffness. In Sect. 22.4, longitudinal and transverse vibrations of bars are presented. The case of flexural vibrations is extended to two-dimensional (2-D) structures such as plates and

shallow shells. In this latter case, the influence of curvature is emphasized using the example of a spherical cap for which analytical results can be obtained.

The three remaining sections focus on specific problems of great significance in structural acoustics. The case of vibroacoustic coupling is treated in Sect. 22.5 through examples of increasing complexity. Starting from the simple case of a longitudinally vibrating bar coupled to a semi-infinite tube, it is shown that modes of the structure are coupled to the radiated field, and that eigenfrequencies and modal shapes of the in vacuo structure are modified by this coupling. An energetic approach to the structural–acoustic coupling allows the introduction of radiation filters and radiation efficiencies. A state-space formulation of the phenomena is presented, which is of particular interest for the control of radiated sound. The example of a single-DOF oscillator coupled to a tube illustrates the coupling between a structure and a cavity. Finally, attention is paid to fluid–plate coupling, with the introduction of the concept of the critical frequency. Section 22.6 is devoted to the presentation of important causes of damping in structures. Also some indications are given with regard to the validity of the modal approach for damped discrete and continuous systems.

For structures subjected to motion with large amplitude, most of the concepts and methods developed for linear vibrations no longer apply. Specific methods must be used to account for the observed phenomena of distortion, amplitude-dependent resonance, jump, hysteresis, instability and chaos. Section 22.7 introduces the basic concepts of nonlinear vibrations with some examples. The Duffing equation and the example of two nonlinearly coupled oscillators are analyzed in detail. These examples illustrate the use of perturbation methods for solving nonlinear equations of motion for vibrating systems. Finally, some equations for the vibrations of nonlinear continuous systems (strings, beams, shells and plates) are briefly reviewed.

22.1 Dynamics of the Linear Single-Degree-of-Freedom (1-DOF) Oscillator

In the low-frequency range, the linear motion of an electrodynamical loudspeaker, for example, can be described by a single-degree-of-freedom (SDOF) oscillator. This is also the case for any complex structure considered as a rigid body for which the equivalent stiffness is represented by a unique spring, and where all the dissipation mechanisms are approximated by a unique dashpot or *fluid damping* constant; one can think of the rigid-body mode of vibration of an automobile. Also the 1-DOF oscillator has fundamental mathematical properties of great interest in the field of vibrations, since linear vibrations of discrete and continuous structures can be represented by a set of oscillators, as will be shown in the following sections.

The motion of a standard 1-DOF oscillator is governed by a second-order differential equation involving an excitation force $F(t)$ and the response of the structure. Using a formulation with the velocity $v(t)$, we get

$$F = M\frac{dv}{dt} + Rv + K\int v\, dt\ . \tag{22.1}$$

This equation accounts for the motion of a mass M subjected to a restoring force due to a linear spring of stiffness K and a dashpot R which represents a linear viscous fluid damping (Fig. 22.1).

Equation (22.1) can be written alternatively, using the mass displacement $\xi(t)$ and the usual reduced parameters

$$F = M\left(\frac{d^2\xi}{dt^2} + 2\zeta_0\omega_0\frac{d\xi}{dt} + \omega_0^2\xi\right), \tag{22.2}$$

where $\omega_0 = \sqrt{M/K}$ is the eigenfrequency of the lossless system and $\zeta_0 = R/2M\omega_0$ is the nondimensional damping coefficient.
Fig. 22.1 Single-DOF oscillator

22.1.1 General Solution

One strategy for solving a linear equation such as (22.2) is to make use of the Laplace transform [22.1]. Using this transform, (22.2) becomes

$$s^2\mathcal{X}(s) - s\xi(0) - \dot{\xi}(0) + 2\zeta_0\omega_0\left[s\mathcal{X}(s) - \xi(0)\right]$$
$$+ \omega_0^2\mathcal{X}(s) = \frac{\mathcal{F}(s)}{M}\ , \tag{22.3}$$

where $\mathcal{X}(s)$ and $\mathcal{F}(s)$ are the Laplace transforms of $\xi(t)$ and $F(t)$, respectively. Using the tables and properties of the Laplace transforms, we obtain the general solution

$$\xi(t) = \frac{1}{M}\int_0^t F(\theta)G(t-\theta)\, d\theta$$
$$+ \left[2\zeta_0\omega_0\xi(0) + \dot{\xi}(0)\right]G(t) + \xi(0)\dot{G}(t)\ , \tag{22.4}$$

where $G(t)$ can take different forms, depending on the value of the damping coefficient ζ_0:

● If $\zeta_0 < 1$, which corresponds to the so-called *underdamped* case, then

$$G(t) = e^{-\zeta_0\omega_0 t}\frac{\sin\omega_0\sqrt{1-\zeta_0^2}\ t}{\omega_0\sqrt{1-\zeta_0^2}}\ . \tag{22.5}$$

● If $\zeta_0 = 1$, which corresponds to the *critical* case, we obtain

$$G(t) = t\, e^{-\omega_0 t}\ . \tag{22.6}$$

● Finally, if $\zeta_0 > 1$, which corresponds to the *overdamped* case, we get

$$G(t) = e^{-\zeta_0\omega_0 t}\frac{\sinh\omega_0\sqrt{\zeta_0^2-1}\ t}{\omega_0\sqrt{\zeta_0^2-1}}\ . \tag{22.7}$$

22.1.2 Free Vibrations

Free vibrations are characterized by the absence of an external force. With $F(t) = 0$ in (22.4), we get

$$\xi(t) = \left[2\zeta_0\omega_0\xi(0) + \dot{\xi}(0)\right]G(t) + \xi(0)\dot{G}(t)\ , \tag{22.8}$$

- if $\zeta_0 < 1$, the displacement $\xi(t)$ is given by

$$
\xi(t) = e^{-\zeta_0 \omega_0 t} \left\{ \xi(0) \cos \omega_0 \sqrt{1 - \zeta_0^2}\, t \right.
$$

$$
+ \left[\xi(0) \frac{\zeta_0}{\sqrt{1 - \zeta_0^2}} + \dot{\xi}(0) \frac{1}{\omega_0 \sqrt{1 - \zeta_0^2}} \right]
$$

$$
\left. \times \sin \omega_0 \sqrt{1 - \zeta_0^2}\, t \right\} . \qquad (22.9)
$$

In this case, the free regime is characterized by a damped sinusoid with oscillation frequency $\omega_0 \sqrt{1 - \zeta_0^2}$ and decay time $\tau = 1/\zeta_0 \omega_0$. The total energy of the system decreases with time.

- If $\zeta_0 = 1$, we obtain

$$
\xi(t) = e^{-\omega_0 t} [\xi(0)(1 + \omega_0 t) + \dot{\xi}(0) t] . \qquad (22.10)
$$

The motion exhibits no oscillation. This critical case corresponds to the situation where we get the fastest non-oscillatory motion toward equilibrium;

- if $\zeta_0 > 1$ the displacement $\xi(t)$ becomes

$$
\xi(t) = e^{-\zeta_0 \omega_0 t} \left\{ \xi(0) \cosh \omega_0 \sqrt{\zeta_0^2 - 1} t \right.
$$

$$
+ \left[\xi(0) \frac{\zeta_0}{\sqrt{\zeta_0^2 - 1}} + \dot{\xi}(0) \frac{1}{\omega_0 \sqrt{\zeta_0^2 - 1}} \right]
$$

$$
\left. \times \sinh \omega_0 \sqrt{\zeta_0^2 - 1}\, t \right\} . \qquad (22.11)
$$

Here again, no oscillation exists. The decay is governed by the combination of two exponentials with decay time τ such that $1/\tau = \omega_0 \left(\zeta_0 \pm \sqrt{\zeta_0^2 - 1} \right)$.

22.1.3 Impulse Response and Green's Function

Consider now the case where $\xi(0) = \dot{\xi}(0) = 0$ and where $F(t)$ is the Dirac delta function $\delta(t)$ whose fundamental property is

$$
\int_{-\infty}^{\infty} u(t) \delta(t - a)\, dt = u(a) , \qquad (22.12)
$$

where $u(t)$ is a test function. The response $\xi(t)$ can therefore be written as

$$
\xi(t) = \frac{1}{M} \int_0^t \delta(\theta) G(t - \theta)\, d\theta
$$

$$
= \frac{1}{M} \int_0^t \delta(t - \theta) G(\theta)\, d\theta = \frac{G(t)}{M} . \qquad (22.13)
$$

The function $G(t)$ defined in Sect. 22.1.1 can therefore be defined as the impulse response of the oscillator with mass equal to unity. This function is also referred to as the *Green's function* of the oscillator. For an oscillator initially at rest and excited by an arbitrary time function $F(t)$, the response is given by the convolution integral of $F(t)$ and the Green's function $G(t)$. Equation (22.4) shows, in addition, that for $F(t) = 0$ and $\xi(0) = 0$, the displacement is given by

$$
\xi(t) = \dot{\xi}(0) G(t) . \qquad (22.14)
$$

Therefore, we can see that the solution obtained with a Dirac delta force is proportional to the one obtained with an initial velocity $\dot{\xi}(0)$.

22.1.4 Harmonic Excitation

For harmonic excitation, $F(t) = F_M \sin \Omega t$, of the oscillator in the underdamped case, (22.4) gives

$$
\xi(t) = \frac{F_M}{M} \frac{(\omega_0^2 - \Omega^2) \sin \Omega t - 2\zeta_0 \omega_0 \Omega \cos \Omega t}{(\omega_0^2 - \Omega^2)^2 + (2\zeta_0 \omega_0 \Omega)^2}
$$

$$
+ \alpha G(t) + \beta \dot{G}(t) , \qquad (22.15)
$$

where α and β are constants that depend on the initial conditions. The Green's function $G(t)$ and its time derivative are proportional to $e^{-\zeta_0 \omega_0 t}$ and become negligible for $\zeta_0 \omega_0 t \gg 1$. With this assumption, the response to the forcing term at frequency Ω is given by the first term on the right-hand side of (22.15). This term can be written alternatively as

$$
\xi(t) = A(\Omega) \sin [\Omega t - \Phi(\Omega)] \qquad (22.16)
$$

with

$$
A(\Omega) = \frac{F_M}{M} \frac{1}{\sqrt{(\omega_0^2 - \Omega^2)^2 + (2\zeta_0 \omega_0 \Omega)^2}}
$$
Fig. 22.2 Magnitude and phase of the mass displacement for the forced underdamped oscillator as a function of the normalized frequency Ω/ω_0

and

$$\tan \Phi(\Omega) = \frac{2\zeta_0 \omega_0 \Omega}{\omega_0^2 - \Omega^2} . \tag{22.17}$$

Figure 22.2 shows the variations of A and Φ with Ω in the underdamped case. The amplitude A reaches its maximum for frequency $\Omega = \omega_0 \sqrt{1 - 2\zeta_0^2}$, which is very close to ω_0 for $\zeta_0 \ll 1$. The maximum is equal to $F_M/2M\zeta_0\omega_0\Omega$.

22.1.5 Energetic Approach

The instantaneous mechanical power $p_m(t)$ into the system is given by the scalar product of F and v, which yields

$$p_m = \frac{d}{dt}\left(\frac{1}{2}Mv^2 + \frac{1}{2}K\xi^2\right) + Rv^2 . \tag{22.18}$$

The terms on the right-hand side of (22.18) represent the kinetic energy of the mass M, the elastic energy of the spring K and the energy dissipated in the mechanical resistance R, respectively. In a number of applications, we are mostly interested in the time-averaged value of $p_m(t)$ rather than in details of its time evolution. In audio acoustics, for example, the human ear is sensitive to the sound level, which is correlated to the average value of the instantaneous acoustic power, after integration over a duration of nearly 50 ms. Therefore, after defining an integration duration T, whose appropriate

selection is discussed later in this section, we can define the average mechanical power $\mathcal{P}_m(T)$ as

$$\mathcal{P}_m(T)$$
$$= \frac{1}{2T}[Mv^2(T) + K\xi^2(T) - Mv^2(0) - K\xi^2(0)]$$
$$+ \frac{1}{T}\int_0^T Rv^2(t)\,dt . \tag{22.19}$$

In a conservative system, the sum of the kinetic and elastic energy remains constant over time, so that the term between the square brackets in (22.19) is equal to zero. As a consequence, the average input power becomes

$$\mathcal{P}_m(T) = \frac{1}{T}\int_0^T Rv^2(t)\,dt = \mathcal{P}_s(T) , \tag{22.20}$$

where $\mathcal{P}_s(T)$ represents the mean *structural* power dissipated in the mechanical resistance R.

22.1.6 Mechanical Power

A particular case of importance is the steady-state harmonic motion of the mechanical oscillator with angular frequency ω. Given an excitation force $F(t) = F_M \sin \omega t$, then, due to the assumed linearity of the system, the mass velocity is written $v(t) = V_M \sin(\omega t + \phi)$. Therefore, $\mathcal{P}_m(T)$ is given by

$$\mathcal{P}_m(T) = \frac{1}{T}\int_0^T F_M V_M \sin \omega t \sin(\omega t + \phi)\,dt . \tag{22.21}$$

Denoting the period of motion by $\tau = 2\pi/\omega$, we can write $T = n\tau + \tau_0$, where n is a positive integer. In this case, the mean power can be rewritten

$$\mathcal{P}_m(T) = \frac{1}{2}F_M V_M \cos \phi + \frac{F_M V_M}{4(2\pi n + \tau_0 \omega)}$$
$$\times [\sin \phi - \sin(2\omega\tau_0 + \phi)] . \tag{22.22}$$

Comment

This equation (22.22) shows that the mean (or average) power $\mathcal{P}_m(T)$ is nearly equal to $1/2 F_M V_M \cos \phi$ only if the average duration T contains a sufficiently large number n of periods. If T is equal to $n\tau$, then the previous result is strict. In what follows, it will be assumed that this condition is fulfilled, so that the dependence versus integration time T of the mean power terms will be suppressed. For a given force, the velocity amplitude

V_M and phase angle ϕ are given by

$$V_M = \frac{F_M}{M} \frac{\omega}{\sqrt{\left(\omega^2 - \omega_0^2\right)^2 + 4\zeta_0^2 \omega^2 \omega_0^2}} , \qquad (22.23)$$

$$\cos\phi = \frac{2\zeta_0 \omega_0 \omega}{\sqrt{\left(\omega^2 - \omega_0^2\right)^2 + 4\zeta_0^2 \omega^2 \omega_0^2}} , \qquad (22.24)$$

and the mean power becomes

$$\mathcal{P}_m = \frac{F_M^2}{2R} \frac{4\zeta_0^2 \omega_0^2 \omega^2}{\left(\omega^2 - \omega_0^2\right)^2 + 4\zeta_0^2 \omega^2 \omega_0^2} . \qquad (22.25)$$

Equation (22.25) shows that the maximum of the dissipated power, and thus the maximum of the input power, is obtained for $\omega = \omega_0$, i.e. when the excitation frequency is equal to the eigenfrequency of the oscillator. In this case, we obtain

$$\text{Max}(\mathcal{P}_m) = \frac{F_M^2}{2R} . \qquad (22.26)$$

Since F_M is known, in general, (22.26) can be used for estimating the mechanical resistance R.

Remark

Recall that (22.25) is only valid in the dynamic equilibrium, which does not correspond to many experimental (or numerical) situations where, for obvious causality reasons, the force is applied at a given instant of time, usually taken as origin. In this more realistic case, the force signal should be written as $F(t) = F_M H(t) \sin\omega t$, where $H(t)$ is the Heaviside function. In this case, the Laplace transform of the velocity is

$$V(s) = \frac{F_M}{M} \frac{s\omega}{(s^2 + \omega^2)(s^2 + 2\zeta_0\omega_0 s + \omega_0^2)} . \qquad (22.27)$$

From which the velocity is derived

$$v(t) = \frac{F_M \omega}{M\sqrt{D(\omega)}} + A(\omega) \exp(-\zeta_0\omega_0 t)$$
$$\times \sin\left[\omega_0\sqrt{1 - \zeta_0^2}\, t + \psi(\omega)\right] , \qquad (22.28)$$

where $D(\omega) = \left(\omega^2 - \omega_0^2\right)^2 + 4\zeta_0^2 \omega^2 \omega_0^2$. $A(\omega)$ and $\psi(\omega)$ are also functions of the excitation frequency whose exact expressions do not add significant matter to the present discussion. The first term in the expression of $v(t)$ corresponds to the steady-state regime. The important features of the second term are the following:

- It is non-negligible as long as the time is small compared to the decay time $(\zeta_0\omega_0)^{-1}$. For lightly damped structural modes, the decay time can be of

the order of 0.1 ms or more. The second term cannot then be neglected during the first $0.5–1.0$ s of the sound, if one wants to estimate the mean sound power correctly.
- When multiplying $v(t)$ by $F(t)$ and integrating over time, terms with frequencies $\omega + \omega_0\sqrt{1 - \zeta_0^2}$ and $\left|\omega - \omega_0\sqrt{1 - \zeta_0^2}\right|$ appear in the expression of $\mathcal{P}_m$. As a consequence, the mean power fluctuates at low frequency, which is another cause of difficulty for estimating its value properly.

22.1.7 Single-DOF Structural–Acoustic System

We now investigate the simple example of a mechanical oscillator acting as a piston at one end of an air-filled semi-infinite tube presenting an additional acoustical resistance $R_a = \rho c S$. The oscillator motion is now governed by the equation

$$F = M\frac{dv}{dt} + Rv + \int v\, dt + R_a v . \qquad (22.29)$$

The instantaneous input power is given by

$$p_m(t) = \frac{d}{dt}\left(\frac{1}{2}Mv^2 + \frac{1}{2}K\xi^2\right) + (R + R_a)v^2 . \qquad (22.30)$$

The average input power becomes

$$\mathcal{P}_m(T) = \frac{1}{T}\int_0^T Rv^2(t)\, dt + \frac{1}{T}\int_0^T R_a v^2(t)\, dt$$
$$= \mathcal{P}_s(T) + \mathcal{P}_a(T) , \qquad (22.31)$$

where $\mathcal{P}_a(T)$ is the acoustic mean power radiated in the tube. The acoustical efficiency of the system is given by

$$\eta = \frac{\mathcal{P}_a(T)}{\mathcal{P}_m(T)} = \frac{\mathcal{P}_a(T)}{\mathcal{P}_s(T) + \mathcal{P}_a(T)} = \frac{R_a}{R + R_a} \qquad (22.32)$$

Some remarks can be formulated with regards to (22.32).

- The expression for the acoustical efficiency is independent of the integration time T.
- Though (22.32) appears simple in form, the experimental (or numerical) determination of the efficiency is generally not straightforward. R can be estimated through calculation of the mechanical power in vacuo $\mathcal{P}_{mo}(T)$.
- In the simple example discussed here, the acoustical resistance, and hence the acoustic power, is known.

This does not include the case where the acoustic power is not known, and has to be estimated by measurements of the acoustic intensity in the fluid, for example.

Link Between Sound Power and Free-Vibration Decay Times

For a single-DOF system, an alternative method for estimating the sound power consists of estimating the decay times of free vibrations through experiments or numerical calculations. Let us take the example of the previously described oscillator loaded by the semi-infinite tube. We consider the case $F(t) = 0$, with the mass initially moved from equilibrium by a quantity $\xi(0) = \xi_0$ and released with zero velocity at $t = 0$. The equation of motion is written as

$$\frac{d^2\xi}{dt^2} + 2\zeta\omega_0\frac{d\xi}{dt} + \omega_0^2\xi = 0 \qquad (22.33)$$

with

$$\zeta = \frac{R + R_a}{2M\omega_0} \, .$$

The Laplace transform of the displacement is given by

$$\xi(s) = \xi_0\frac{s + 2\zeta\omega_0}{s^2 + 2\zeta\omega_0 s + \omega_0^2} \qquad (22.34)$$

from which the time evolution of the mass displacement is obtained (assuming $\zeta < 1$)

$$\xi(t) = \exp(-\zeta\omega_0 t)\left[\cos\left(\omega_0\sqrt{1 - \zeta^2}t\right) \right.$$
$$\left. + \frac{\zeta}{\sqrt{1 - \zeta^2}}\sin\left(\omega_0\sqrt{1 - \zeta^2}t\right) \right] . \qquad (22.35)$$

Equation (22.35) shows that the *decay factor* α (equal to the inverse of the decay time) is equal to $\zeta\omega_0 = (R + R_a)/2M$. The same mathematical derivations applied to the oscillator in vacuo yields $\alpha_0 = \zeta_0\omega_0 = R/2M$. In conclusion, this shows that, for the 1-DOF system studied here, the acoustical efficiency can
Fig. 22.3 Accelerometer

be estimated in the time domain by the expression

$$\eta = \frac{\alpha - \alpha_0}{\alpha} \, . \qquad (22.36)$$

22.1.8 Application: Accelerometer

Accelerometers are piezoelectric transducers which are widely used for vibration measurements. An accelerometer has a base, a piezoelectric crystal and a seismic mass (Fig. 22.3). It delivers an electric signal which is proportional to the compression force applied to the crystal. Such a device can be modeled by a 1-DOF oscillator equation. Let us denote by k the equivalent stiffness of the crystal, by m the seismic mass, and by $\omega_0 = \sqrt{k/m}$ the resonance frequency of the accelerometer. Internal damping is neglected here, for simplicity. For a sinusoidal excitation $A\sin\Omega t$ of the base, the compression force is [22.2]

$$F \simeq -\frac{k\Omega^2}{\omega_0^2 - \Omega^2}\, A\sin\Omega t \, . \qquad (22.37)$$

Therefore, we can see that if $\Omega \ll \omega_0$, then the signal delivered by the accelerometer is proportional to the acceleration of the base. The frequency response curve of an accelerometer is flat below its resonance frequency, which gives the upper limit of its valid frequency range.

22.2 Discrete Systems

In a number of applications, real structures can be approximated by an assembly of discrete rigid substructures, which leads to enormous computational simplifications. In fact numerical modeling (finite elements, finite differences) is such an example where continuous structures are replaced by an equivalent set of discretely connected elements. In experimental techniques, such as modal analysis, measurements are taken at discrete positions on the structure under study, and thus the measurements are treated by methods applicable to discrete systems.

22.2.1 Lagrange Equations

For a discrete system with n degrees of freedom, the kinetic energy E_k can be formulated as a function of the generalized coordinates q_n and velocities $\dot{q}_n$

$$E_k = E_k(q_1, q_2, \ldots, q_n, \dot{q}_1, \dot{q}_2, \ldots \dot{q}_n) = E_k(q, \dot{q})$$
(22.38)

Thus, given virtual vectors of displacements δq and velocities $\delta \dot{q}$, the variation of the kinetic energy is written

$$\delta E_k = \sum_{k=1}^{n} \frac{\partial E_k}{\partial q_k} \delta q_k + \frac{\partial E_k}{\partial \dot{q}_k} \delta \dot{q}_k .$$
(22.39)

Remark

Recall that δq has to be kinematically compatible with the system, though not necessarily equal to a real displacement, so that the partial derivatives of T versus δq and $\delta \dot{q}$ are independent.

Applying Hamilton's principle, with $\delta q = 0$ at t_1 and t_2, we can write the minimization integral as

$$\int_{t_1}^{t_2} (\delta E_k - \delta V + \delta W_{nc}) \, dt = 0$$
(22.40)

where V is the potential energy of the system and W_{nc} is the energy of the nonconservative applied external forces. Through integration by parts, we can write

$$\int_{t_1}^{t_2} \frac{\partial E_k}{\partial \dot{q}_k} \delta \dot{q}_k \, dt = \left[\frac{\partial E_k}{\partial \dot{q}_k} \delta q_k \right]_{t_1}^{t_2} - \int_{t_1}^{t_2} \frac{d}{dt} \left(\frac{\partial T}{\partial \dot{q}_k} \right) \delta q_k \, dt$$

$$= - \int_{t_1}^{t_2} \frac{d}{dt} \left(\frac{\partial E_k}{\partial \dot{q}_k} \right) \delta q_k \, dt .$$
(22.41)

Assuming that $V = V(q)$, which corresponds to a large class of problems in dynamics and vibrations,

$$\delta V = \sum_{k=1}^{n} \frac{\partial V}{\partial q_k} \delta q_k .$$
(22.42)

Finally, the virtual work δW_{nc} can be written as the scalar product of the vectors F of generalized forces and virtual displacement δq in the form $\delta W_{nc} = \sum_{k=1}^{n} F_k \delta q_k$, so that (22.40) becomes

$$\sum_{k=1}^{n} \int_{t_1}^{t_2} \left[\frac{\partial E_k}{\partial q_k} - \frac{d}{dt} \left(\frac{\partial E_k}{\partial \dot{q}_k} \right) - \frac{\partial V}{\partial q_k} + F_k \right] \delta q_k \, dt = 0 .$$
(22.43)

Since the integral in (22.43) must be equal to zero for any δq this implies, for each k

$$\frac{d}{dt} \left(\frac{\partial E_k}{\partial \dot{q}_k} \right) - \frac{\partial E_k}{\partial q_k} + \frac{\partial V}{\partial q_k} = F_k .$$
(22.44)

The set of n differential equations (22.44) are the Lagrange equations of the discrete system. This set yields the equations of motion in a very elegant and practical manner.

Small Displacements. Linearization

For small perturbations from equilibrium, we can write $q_k = Q_k + \varepsilon X_k$, where $\varepsilon \ll 1$. Assuming that Q is given by the Lagrange equations and that the generalized forces F are independent of q, a first-order approximation of (22.44), for each k, gives

$$\frac{\partial^2 E_k}{\partial \dot{q}_k \partial \dot{q}_j} \ddot{X}_k$$

$$+ \left[\frac{d}{dt} \left(\frac{\partial^2 E_k}{\partial \dot{q}_k \partial \dot{q}_j} \right) + \frac{\partial^2 E_k}{\partial q_k \partial \dot{q}_j} - \frac{\partial^2 E_k}{\partial \dot{q}_k \partial q_j} \right] \dot{X}_k$$

$$+ \left[\frac{d}{dt} \left(\frac{\partial^2 E_k}{\partial q_k \partial \dot{q}_j} \right) + \frac{\partial^2 V}{\partial q_k \partial q_j} - \frac{\partial^2 E_k}{\partial q_k \partial q_j} \right] X_k = 0 ,$$
(22.45)

which becomes in matrix form

$$\mathbf{M}\ddot{X} + \mathbf{C}\dot{X} + \mathbf{K}X = 0 .$$
(22.46)

1. Since the kinetic energy E_k is a positive quadratic form of the velocity, the mass matrix $\mathbf{M}$ is a symmetric positive operator.
2. The matrix $\mathbf{C}$ is a generalized damping matrix made up of three terms:
   – The first, with generic element $C_{kj1} = \frac{d}{dt} \times \left(\frac{\partial^2 E_k}{\partial \dot{q}_k \partial \dot{q}_j} \right)$ is associated with the temporal variation of the mass matrix;
   – The two other terms $\frac{\partial^2 E_k}{\partial q_k \partial \dot{q}_j} - \frac{\partial^2 E_k}{\partial \dot{q}_k \partial q_j}$ relate to gyroscopic forces. This part of the matrix $\mathbf{C}$ is antisymmetric and does not lead to dissipation.
3. The stiffness matrix $\mathbf{K}$ also is a sum of three terms:
   – The first is associated with the time variation of the first gyroscopic term in $\mathbf{C}$;
   – The second is governed by the q dependence of V;
   – The third is governed by the q dependence of E_k.

In what follows, we restrict our attention to conservative systems where E_k is independent of q and where

the mass matrix is taken to be constant with time. In this case, (22.46) becomes

$$\mathbf{M}\ddot{X} + \mathbf{K}X = 0 \tag{22.47}$$

with

$$\begin{cases} M_{kj} = M_{jk} = \dfrac{\partial^2 E_k}{\partial \dot{q}_k \partial \dot{q}_j} \\[4mm] K_{kj} = K_{jk} = \dfrac{\partial^2 V}{\partial q_k \partial q_j} \end{cases} \tag{22.48}$$

22.2.2 Eigenmodes and Eigenfrequencies

Natural modes (or eigenmodes) are the sinusoidal (or harmonic) solutions of (22.47) with frequency ω in the absence of a driving term. As a consequence, the natural modes are solutions of the equation

$$\left(-\omega^2\mathbf{M} + \mathbf{K}\right)X = 0 \tag{22.49}$$

with roots (or eigenvalue, or eigenfrequency) ω_n solutions of the characteristic equation

$$\det\left(-\omega^2\mathbf{M} + \mathbf{K}\right) = 0 . \tag{22.50}$$

The eigenvector $\boldsymbol{\Phi}_n$ associated to each eigenfrequency ω_n is given by

$$\left(-\omega_n^2\mathbf{M} + \mathbf{K}\right)\boldsymbol{\Phi}_n = 0 . \tag{22.51}$$

$\boldsymbol{\Phi}_n$ is defined with an arbitrary multiplicative constant. The natural modes are defined by the set of eigenvalues ω_n and associated eigenvectors $\boldsymbol{\Phi}_n$. Spectral analysis theory shows that the $\boldsymbol{\Phi}_n$ form an $\mathbf{M}$ and $\mathbf{K}$ orthogonal basis set, so that

$${}^t\boldsymbol{\Phi}_m\mathbf{M}\boldsymbol{\Phi}_n = 0$$

and

$${}^t\boldsymbol{\Phi}_m\mathbf{K}\boldsymbol{\Phi}_n = 0 \quad \text{for} \quad m \neq n \tag{22.52}$$

The orthogonality properties of the eigenmodes mean that the inertial (stiffness) forces developed in a given mode do not affect the motion of the other modes. The modes are mechanically independent. As a consequence, it is possible to expand any motion onto the eigenmodes. Given a force distribution F, the motion of the system is governed by the equation

$$\mathbf{M}\ddot{X} + \mathbf{K}X = F . \tag{22.53}$$

The modal projection is written in the form

$$X = \sum_n \boldsymbol{\Phi}_n q_n(t) . \tag{22.54}$$

The functions $q_n(t)$ in (22.54) are the modal participation factors. Inserting (22.54) into (22.53) and, after taking the scalar product of both sides of the equation with an eigenfunction $\boldsymbol{\Phi}_m$, we find

$$\langle \boldsymbol{\Phi}_n, \mathbf{M}\boldsymbol{\Phi}_n \rangle \ddot{q}_n + \langle \boldsymbol{\Phi}_n, \mathbf{K}\boldsymbol{\Phi}_n \rangle q_n = \langle \boldsymbol{\Phi}_n, F \rangle \tag{22.55}$$

where the notation $\langle A, B \rangle$ denotes the scalar product ${}^tA.B$ between vectors the A and B. Equation (22.55) shows that the generalized displacements are uncoupled. Each q_n is governed by a single-DOF oscillator differential equation. The quantity

$$m_n = \langle \boldsymbol{\Phi}_n, \mathbf{M}\boldsymbol{\Phi}_n \rangle \tag{22.56}$$

is the modal mass associated with the mode n. These coefficients are defined with an arbitrary multiplicative constant. Similarly,

$$\kappa_n = \langle \boldsymbol{\Phi}_n, \mathbf{K}\boldsymbol{\Phi}_n \rangle \tag{22.57}$$

is the modal stiffness, related to the modal mass through the relationship

$$\kappa_n = m_n\omega_n^2 . \tag{22.58}$$

Finally, the quantity

$$f_n = \langle \boldsymbol{\Phi}_n, F \rangle \tag{22.59}$$

is the projection of the nonconservative forces onto mode n. Each independent oscillator equation can then be rewritten as

$$\ddot{q}_n + \omega_n^2 q_n = \frac{f_n}{m_n} . \tag{22.60}$$

Remark

Since the eigenvectors are defined with arbitrary multiplicative constants C_n, (22.56) shows that the modal mass is proportional to C_n^2. In addition, (22.58) shows that f_n is also proportional to C_n. Therefore, through (22.60), q_n is proportional to C_n^{-1} and from (22.54), X is independent of C_n.

Normal Modes

The normal modes Ψ_n correspond to the case where the arbitrary constant is such that the modal masses become unity. In this case, we can write

$$\Psi_n = \frac{\Phi_n}{\sqrt{m_n}} . \tag{22.61}$$

Consequently, (22.57) becomes

$$\langle \boldsymbol{\Psi}_n, \mathbf{K}\boldsymbol{\Psi}_n \rangle = \omega_n^2 . \tag{22.62}$$

22.2.3 Admittances

In general, a given structure vibrates as a result of the action of localized and distributed forces and moments. For both numerical and experimental reasons, one often has to work on a discrete representation of the structure. In practice, the geometry of the structure is represented by a mesh consisting of a number N of areas with dimensions smaller than the wavelengths under consideration. This results in having to consider the structure as an N-DOF system. At each point of the mesh, the motion is defined by three translation components plus three rotation components. Similarly, the action of the external medium on the structure can be reduced to three force components plus three moment components, here denoted by F_l. The translational and rotational velocity components V_k at each point are thus related to the forces and moments through a 6×6 admittance matrix, such that

$$V = \mathbf{Y}F . \tag{22.63}$$

For each force component at a given point j on the structure, denoted $F_{j|l}$, a motion at another point i, denoted by $V_{i|k}$, can be generated. As a consequence one can define the transfer admittance

$$Y_{ij|kl} = \frac{V_{i|k}}{F_{j|l}} \quad \text{with} \quad 1 \le i, j \le N$$
$$\text{and} \quad 1 \le k, l \le 6 .$$

In summary, the transfer admittance matrix is defined by $6N \times 6N$ coefficients such as $Y_{ij|kl}$.

Notation
In what follows, the indices (k, l) are omitted, for the sake of simplicity. The transfer admittances are written as Y_{ij}, which reduces to Y_{ii} (or, even to Y_i) in the case of a driving-point admittance. Attention here is mostly focused on translation, though the formalism remains valid for rotation.

The previous results obtained on modal decomposition are now used to investigate the frequency dependence of the admittances. Here, $X(x_i) \equiv X_i$ is one component of displacement at point x_i and $F(x_j) \equiv F_j$ is one force component at point x_j. The structure is subjected to a forced motion at frequency ω. We have

$$(\mathbf{K} - \omega^2 \mathbf{M})X_i = F_j , \tag{22.64}$$

where $X_i = \sum \Phi_n(x_i)q_n(t)$ and

$$(\omega_n^2 - \omega^2)q_n = \frac{f_n}{m_n} = \frac{{}^t\Phi_n(x_j)F_j(\omega)}{m_n} . \tag{22.65}$$

For a structure discretized on N points, the displacement at point x_i is given by

$$X_i(\omega) = \sum_{n=1}^{N} \frac{\Phi_n(x_i) {}^t\Phi_n(x_j)}{m_n(\omega_n^2 - \omega^2)} F_j(\omega) . \tag{22.66}$$

The complete set of functions $X_i(\omega)$ given in (22.66) is the operating deflexion shape (ODS) at frequency ω. The transfer admittance between points x_i and x_j is written

$$Y_{ij}(\omega) = \mathrm{i}\omega \sum_{n=1}^{N} \frac{\Phi_n(x_i) {}^t\Phi_n(x_j)}{m_n(\omega_n^2 - \omega^2)} . \tag{22.67}$$

The driving-point admittance at point x_i becomes

$$Y_i(\omega) = \mathrm{i}\omega \sum_{n=1}^{N} \frac{[\Phi_n(x_i)]^2}{m_n(\omega_n^2 - \omega^2)} . \tag{22.68}$$

Remark
To include damping, (22.67) can be written

$$Y_{ij}(\omega) = \mathrm{i}\omega \sum_{n=1}^{N} \frac{\Phi_n(x_i) {}^t\Phi_n(x_j)}{m_n(\omega_n^2 + 2\mathrm{i}\zeta_n\omega_n\omega - \omega^2)} , \tag{22.69}$$

where ζ_n is a nondimensional damping factor. The physical origin of the damping terms will be presented in more detail in Sect. 22.6.1.

Frequency Analysis and Approximations
For weak damping, and low modal density, the modulus of $Y_{ij}(\omega)$ passes through maxima at frequencies close to the eigenfrequencies $\omega = \omega_n$ (Fig. 22.4).

- For $\omega \approx \omega_n$, the main term in $Y_{ij}(\omega)$ is equal to

$$\mathrm{i}\omega \frac{\Phi_n(x_i) {}^t\Phi_n(x_j)}{m_n(\omega_n^2 - \omega^2)} . \tag{22.70}$$

- For $\omega \gg \omega_n$, the admittance becomes

$$Y_{ij} \approx \mathrm{i}\omega \sum_{l>n} \frac{\Phi_l(x_i) {}^t\Phi_l(x_j)}{-m_l\omega^2} \approx \frac{1}{\mathrm{i}M\omega}$$

with

$$\frac{1}{M} = \sum_{l>n} \frac{\Phi_l(x_i) {}^t\Phi_l(x_j)}{m_l} . \tag{22.71}$$

It can be seen that the modes with a rank larger than a given mode n play the role of a mass M.
Fig. 22.4 Typical frequency dependence of an admittance modulus for a lightly damped structure (after Derveaux et al. [22.3])

- Similarly, for modes with a rank smaller than n, we find

$$Y_{ij} \approx i\omega \sum_{l<n} \frac{\Phi_l(x_i) \,^t\Phi_l(x_j)}{m_l \omega_l^2} \approx \frac{i\omega}{K}$$

with

$$\frac{1}{K} = \sum_{l<n} \frac{\Phi_l(x_i) \,^t\Phi_l(x_j)}{m_l \omega_l^2} . \qquad (22.72)$$

Here, the contribution of the modes is equivalent to a stiffness K.

In summary, in the vicinity of a resonance of mode n, the transfer admittance can be written

$$Y_{ij}(\omega) \approx i\omega \frac{\Phi_n(x_i) \,^t\Phi_n(x_j)}{m_n(\omega_n^2 - \omega^2)} + \frac{i\omega}{K} + \frac{1}{iM\omega} . \qquad (22.73)$$

22.2.4 Example: 2-DOF Plate–Cavity Coupling

To illustrate the previous concepts, a simple example of structural–acoustic coupling represented by a moving plate over a cavity with a hole is considered. This corresponds to a crude low-frequency model for stringed instruments or vented boxes [22.4]. V is the volume of the cavity, A_h is the section of the air piston of mass m_h and displacement x_h, and m_p is the mass of the plate with area A_p (Fig. 22.4). It is assumed that all points of the plate move in phase with the displacement x_p;
Fig. 22.5 Two-DOF plate–cavity coupling

k_p is the equivalent stiffness of the elastic plate and $\omega_{p,0} = \sqrt{k_p/m_p}$ denotes its eigenfrequency in the absence of coupling to the cavity. As the plate and piston are set in motion, the change of volume in the cavity is equal to $\Delta V = A_p x_p + A_h x_h$. Consequently, the pressure change in the cavity is $\Delta p = -\frac{\rho c^2 \Delta V}{V}$. F is the vertical external force applied to the plate, R_p and R_h are fluid damping coefficients. The equations that govern the motion of the coupled oscillators can be written

$$\begin{cases} m_p \ddot{x}_p = F - k_p x_p - R_p \dot{x}_p + A_p \Delta p , \\ m_h \ddot{x}_h = A_h \Delta p - R_h \dot{x}_h \end{cases} \qquad (22.74)$$

Let us write $\mu = c^2 \rho / V$. If the cavity is closed ($A_h = 0$), then the eigenfrequency of the plate is given by $\omega_p = \sqrt{(k_p + \mu A_p^2)/m_p}$. If the stiffness k_p of the plate tends to zero, then the eigenfrequency of the plate coupled to the cavity becomes $\omega_a = \sqrt{\mu A_p^2/m_p}$. Finally, if the plate is assumed to be completely rigid ($x_p = 0$), then the eigenfrequency of the cavity–hole system (Helmholtz resonance) is $\omega_h = \sqrt{\mu A_h^2/m_h}$. Solving (22.74) for a sinusoidal excitation $F e^{i\omega t}$, with $\gamma_p = R_p/m_p$ and $\gamma_h = R_h/m_h$, yields for the plate velocity u_p and air velocity u_h in the piston

$$u_p = i\omega \frac{F}{m_p} \frac{(\omega_h^2 - \omega^2 + j\omega\gamma_h)}{D} \qquad (22.75)$$

and

$$u_h = -i\omega \frac{F}{m_p} \frac{A_p}{A_h} \frac{\omega_h^2}{D} \qquad (22.76)$$

with

$$D = (\omega_p^2 - \omega^2 + i\omega\gamma_p)(\omega_h^2 - \omega^2 + i\omega\gamma_h) - \omega_{ph}^4 , \qquad (22.77)$$

where

$$\omega_{ph}^4 = \omega_h^2 \omega_a^2 .$$
Fig. 22.6 Driving-point admittance of a plate loaded by a cavity. $A_p = 0.01\,\mathrm{m}^2$; $V = 0.1\,\mathrm{m}^3$; $f_h = 100\,\mathrm{Hz}$; $f_p = 200\,\mathrm{Hz}$; $\gamma_h = 1.0\,\mathrm{s}^{-1}$; $\gamma_p = 2.0\,\mathrm{s}^{-1}$; $m_p = 0.4\,\mathrm{kg}$; Admittance Y (in dB) $= 20\log|u_p/F|$

The eigenfrequencies of the coupled system correspond to the roots of the denominator D. Neglecting the influence of losses, these eigenfrequencies are solutions of the equation

$$(\omega_p^2 - \omega^2)(\omega_h^2 - \omega^2) - \omega_{ph}^4 = 0\,. \tag{22.78}$$

The solutions ω_+ and ω_- satisfy the relation

$$\omega_+^2 + \omega_-^2 = \omega_p^2 + \omega_h^2\,, \tag{22.79}$$

which shows that the difference between the eigenfrequencies increases due to the coupling between the plate and the Helmholtz resonator, compared to the uncoupled case. Figure 22.6 shows the modulus of the driving-point admittance $|u_p/F|$ of the plate, showing two maxima at ω_+ and ω_- and a zero at ω_h.

In stringed instruments and vented boxes, the main effect of the open cavity is to enhance the radiated sound in the low-frequency range, below the lowest resonance of the moving structure (the top plate or loudspeaker diaphragm).

22.2.5 Statistical Energy Analysis

The aim of statistical energy analysis (SEA) is to use power flows as a means for estimating the responses of complex systems. It is of particular interest for the analysis of coupled structures such as those encountered in the transportation industry. It is often used for the preliminary design of structures, or for identifying energy transmission paths [22.5].

One main advantage of SEA is that it usually leads to a substantial reduction of the number of degrees of freedom. The price to pay is that results are only given in terms of average and variance over frequency and space. It is particularly suitable when structural details are not known, or when measurements yield uncertainty in the modal parameters. SEA techniques focus on the analysis of energy levels in resonant modes of dynamical systems. Its main principle is based on the property that the average power flow between two coupled systems (or subsystems) is proportional to the difference in the average modal energies of each system. In order to illustrate this basic concept of SEA, the case of two coupled 1-DOF oscillators is summarized below. Detailed developments can be found in [22.6].

To consider a general case, it is assumed that both oscillators are coupled by means of a coupling spring with stiffness coefficient k_{12} and a gyroscopic constant B. The equations of motion of this system are given by

$$\begin{cases} m_1\dfrac{\mathrm{d}^2\xi_1}{\mathrm{d}t^2} + r_1\dfrac{\mathrm{d}\xi_1}{\mathrm{d}t} + s_1\xi_1 + B\dfrac{\mathrm{d}\xi_2}{\mathrm{d}t} + k_{12}\xi_2 = F_1\,, \\[2mm] m_2\dfrac{\mathrm{d}^2\xi_2}{\mathrm{d}t^2} + r_2\dfrac{\mathrm{d}\xi_2}{\mathrm{d}t} + s_2\xi_2 - B\dfrac{\mathrm{d}\xi_1}{\mathrm{d}t} + k_{12}\xi_1 = F_2\,, \end{cases} \tag{22.80}$$

where m_1 and m_2 are the masses of the oscillators, $r_1 = 2\delta_1 m_1$ and $r_2 = 2\delta_2 m_2$ are the mechanical resistances, $s_1 = k_1 - k_{12}$ and $s_2 = k_2 - k_{12}$ are stiffness coefficients, and F_1 and F_2 are the magnitudes of the forces applied to each mass. For a harmonic motion with frequency ω, the power flow between the oscillators is given by

$$P_{12} = \frac{1}{2}\,\mathrm{Re}\left(F_{12}v_2^*\right)\,, \tag{22.81}$$

where v_2^* is the complex conjugate of the velocity for the second oscillator and F_{12} is the force applied by oscillator 1 to oscillator 2. Using (22.80), the power flow at frequency ω is written [22.6]

$$P_{12} = \frac{\omega^2 s_{12}^2 + \omega^4 B^2}{m_1^2 m_2^2 |D(\omega)|^2}\left(m_2\delta_2|F_1|^2 - m_1\delta_1|F_2|^2\right)\,, \tag{22.82}$$

where

$$D(\omega) = \omega^4 - 2i\omega^3(\delta_1 + \delta_2)$$
$$- \omega^2\left(\omega_1^2 + \omega_2^2 + 4\delta_1\delta_2 + \frac{B^2}{m_1 m_2}\right)$$
$$+ 2i\omega\left(\delta_1\omega_2^2 + \delta_2\omega_1^2\right) - \frac{k_{12}}{m_1 m_2} + \omega_1^2\omega_2^2 .$$

(22.83)

In (22.83), ω_1 and ω_2 are the natural frequencies of the undamped uncoupled oscillators. It can be shown that (22.82) can be generalized to a broadband excitation with frequency bandwidth $\Delta\omega$. One basic property of SEA follows from the fact that P_{12} is proportional to the energy difference $W_1 - W_2$ of the oscillators. For a broadband excitation, these energies are given by

$$W_i = \frac{m_i}{2\Delta\omega}\int_{-\infty}^{+\infty}|v_i(\omega)|^2\,d\omega$$

(22.84)

and the basic SEA equation becomes

$$P_{12} = \beta(W_1 - W_2)$$

with

$$\beta = \frac{2}{m_1 m_2}\frac{\left(\delta_1\omega_2^2 + \delta_2\omega_1^2\right)B^2 + (\delta_1 + \delta_2)k_{12}^2}{\left(\omega_1^2 - \omega_2^2\right)^2 + 2(\delta_1 + \delta_2)\left(\delta_1\omega_2^2 + \delta_2\omega_1^2\right)} .$$

(22.85)

Equation (22.85) shows that β is positive and depends on the parameters of the oscillators and on the coupling parameters B and k_{12}. This equation can be generalized to the coupling between any mode m_1 of a given subsystem with N_1 modes and a mode m_2 of another subsystem with N_2 modes. Considering a frequency band with central frequency ω_c, the generalization leads to the following expression for the power flow from subsystem 1 to subsystem 2

$$P_{12} = \omega_c(\eta_{12}W_1 - \eta_{21}W_2) ,$$

(22.86)

where η_{12} and η_{21} are the coupling loss factors obtained through averaging of the parameters $\beta_{m_1 m_2}$ analogous to that defined in (22.85)

$$\eta_{12} = \frac{N_2}{\omega_c}\langle\beta_{m_1 m_2}\rangle_{N_1 N_2}\ \text{and}\ \eta_{21} = \frac{N_1}{N_2}\eta_{12} .$$ (22.87)

$W_1 = N_1 W_{m_1}$ and $W_2 = N_2 W_{m_2}$ are the total modal energies in both subsystems, averaged over a frequency band, with the assumption that both energies are equally divided among the modes. The coupling loss factors give the rate at which energy is transferred from one subsystem to the other. The SEA theory can be used, for example, for predicting the vibration level of coupled plates over a large frequency range, where standard numerical methods, such as the finite-element method are too costly [22.6].

22.3 Strings and Membranes

Strings and membranes belong to that category of structures where the stiffness is due to external tension. This is sometimes called *geometrical* stiffness, in contrast with the *elastic* stiffness of most vibrating solids. In practice, strings and membranes also are made of elastic materials and, consequently, show more or less elastic stiffness due to their Young's moduli. This elastic stiffness will be neglected in the present section. The relative contributions of both stiffnesses will be discussed in Sect. 22.4 in the case of prestressed beams.

22.3.1 Equations of Motion

Consider a small element at a given point of Cartesian coordinates x on a stretched membrane of density $\rho(x)$. The membrane is assumed to be in equilibrium in the plane e_x, e_y and subjected to a tension field $\tau(x)$ so that the resulting forces per unit length are

(Fig. 22.7)

$$\begin{cases}\text{on both sides oriented in the } e_x \text{ direction:}\\ \quad \tau_x = \tau_{11}e_x + \tau_{21}e_y ,\\ \text{on both sides oriented in the } e_y \text{ direction:}\\ \quad \tau_y = \tau_{12}e_x + \tau_{22}e_y ,\end{cases}$$

(22.88)

where $\tau_{12} = \tau_{21}$ to ensure the moment equilibrium (reciprocity principle). In the general case, τ_{ij} are functions of the coordinates x. The membrane is subjected to a small displacement in the direction e_z and released, so that its vertical motion $u(x, y, t)$ is governed by the balance between inertial forces and elastic forces due to tension. Gravity is neglected. After balance of forces on the four sides of the membrane element and projection on the vertical axis, with the assumption of small dis-
Fig. 22.7 Balance of forces on a membrane element

placements, one obtains the equation that governs the flexural motion of a nonuniformly stretched membrane

$$\rho(\boldsymbol{x})h\ddot{u} = \frac{\partial}{\partial x}\left(\tau_{11}\frac{\partial u}{\partial x} + \tau_{12}\frac{\partial u}{\partial y}\right)$$
$$+ \frac{\partial}{\partial y}\left(\tau_{12}\frac{\partial u}{\partial x} + \tau_{22}\frac{\partial u}{\partial y}\right), \qquad (22.89)$$

where h is the thickness. The tension field

$$\boldsymbol{\tau} = \begin{bmatrix} \tau_{11} & \tau_{12} \\ \tau_{12} & \tau_{22} \end{bmatrix} \qquad (22.90)$$

is a symmetric tensor of order two, and

$$\mathbf{grad}\, u = \frac{\partial u}{\partial x}\boldsymbol{e}_x + \frac{\partial u}{\partial y}\boldsymbol{e}_y . \qquad (22.91)$$

The previous equation can be written in the more compact form

$$\text{div}\left(\boldsymbol{\tau} . \mathbf{grad}\, u\right) = \rho(\boldsymbol{x})h\ddot{u} , \qquad (22.92)$$

where this last formulation has the advantage of being independent of the selected system of coordinates.

One–Dimensional (1–D) Approximation: Transverse Motion of Strings

Strings can be viewed as membranes where one dimension (the length) is much larger than the other two, so that a 1-D approximation is justified. Thus, rewriting (22.89) after integrating mass and tension along the axis $\boldsymbol{e}_y$, one obtains the equation of transverse motion for a string with nonuniform tension

$$\mu(x)\ddot{u} = \frac{\partial}{\partial x}\left[T(x)\frac{\partial u}{\partial x}\right], \qquad (22.93)$$

where $\mu = \rho S$ is the linear mass density, S is the cross-sectional area and T is the tension.

Remark

1. A similar equation can be obtained for the transverse motion $v(x, t)$ of the string in the direction $\boldsymbol{e}_y$. Therefore, two transverse motions polarized in orthogonal directions can exist on a string.
2. In the absence of coupling terms, u and v are independent. However, induced motion at the ends and/or nonlinear terms usually lead to coupling between these motions (Sect. 22.7).
3. Strings and membranes are also subjected to longitudinal motion. This motion is due to the variation of tension resulting from the variation in strain associated with the motion.

Homogeneous and Uniformly Stretched Strings and Membranes

For a uniformly stretched and homogeneous membrane, (22.92) reduces to

$$\tau\,\text{div}\left(\mathbf{grad}\, u\right) = \tau\Delta u = \rho h\ddot{u} , \qquad (22.94)$$

where the Laplacian is written in Cartesian coordinates as

$$\Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} . \qquad (22.95)$$

For a string, we get the well-known wave equation

$$\mu\ddot{u} = T\frac{\partial^2 u}{\partial x^2} . \qquad (22.96)$$

22.3.2 Heterogeneous String: Modal Approach

Extending the previous results to continuous structures shows that, in the linear regime, these structures have an infinite number of eigenmodes with similar properties of orthogonality with respect to mass and stiffness to those presented in Sect. 22.2 for discrete systems. In this case, the previously defined eigenvectors $\boldsymbol{\Phi}_n$ become continuous functions of the space coordinates $\Phi(\boldsymbol{x})$. To illustrate the modal approach for continuous systems, consider the case of an heterogeneous string (i.e., a nonuniformly stretched string with variable density), rigidly fixed at both ends and subjected to a force density $f(x, t)$

$$\rho(x)S(x)\frac{\partial^2 y}{\partial t^2} - \frac{\partial}{\partial x}\left[T(x)\frac{\partial y}{\partial x}\right] = f(x, t) , \qquad (22.97)$$

$\Phi_n(x)$ are the eigenfunctions of the string, which account for the boundary conditions. We seek solutions of

the form

$$y(x, t) = \sum_n \Phi_n(x)q_n(t) \, . \tag{22.98}$$

Multiplying both sides of (22.97) by the eigenfunction $\Phi_m(x)$ and integrating over the length of the string yields

$$\sum_n \ddot{q}_n(t) \int_0^L \Phi_n(x)\Phi_m(x)\rho(x)S(x)\,\mathrm{d}x$$

$$-\sum_n q_n(t) \int_0^L \Phi_m(x) \frac{\mathrm{d}}{\mathrm{d}x}\left[T(x)\frac{\mathrm{d}\Phi_n(x)}{\mathrm{d}x}\right]\mathrm{d}x$$

$$= \int_0^L \Phi_m(x)f(x, t)\,\mathrm{d}x \, , \tag{22.99}$$

which can be written in symbolic form as

$$\mathcal{M}(\ddot{y}, \Phi_m) + \mathcal{K}(y, \Phi_m) = \langle f, \Phi_m \rangle \, . \tag{22.100}$$

Equation (22.100) is general and can be applied to all conservative systems. $\mathcal{M}$ denotes the mass operator and $\mathcal{K}$ the stiffness operator.

Orthogonality Properties of the Eigenmodes
Each eigenmode $\Phi_n(x)$ is a solution of the equation

$$-\omega_n^2 \rho(x)S(x)\Phi_n(x) = \frac{\mathrm{d}}{\mathrm{d}x}\left[T(x)\frac{\mathrm{d}\Phi_n(x)}{\mathrm{d}x}\right] . \tag{22.101}$$

These eigenfunctions are orthogonal with respect to the mass

$$\int_0^L \Phi_n(x)\Phi_m(x)\rho(x)S(x)\,\mathrm{d}x = 0 \tag{22.102}$$

and orthogonal with respect to the stiffness

$$\int_0^L T(x)\frac{\mathrm{d}\Phi_m(x)}{\mathrm{d}x}\frac{\mathrm{d}\Phi_n(x)}{\mathrm{d}x}\,\mathrm{d}x = 0 \, . \tag{22.103}$$

Generalized Coordinates
Taking the orthogonality properties of the eigenmodes into account, we can write

$$-\frac{\mathrm{d}}{\mathrm{d}x}\left[T(x)\frac{\mathrm{d}\Phi}{\mathrm{d}x}\right] = \omega^2 \rho(x)S(x)\Phi(x) \, , \tag{22.104}$$

so that (22.100) becomes

$$\ddot{q}_n(t) + \omega_n^2 q_n(t) = \frac{f_n(t)}{m_n} \, , \tag{22.105}$$

where the modal mass is given by

$$m_n = \int_0^L \Phi_n^2(x)\rho(x)S(x)\,\mathrm{d}x \tag{22.106}$$

with

$$f_n(t) = \int_0^L f(x, t)\Phi_n(x)\,\mathrm{d}x \, . \tag{22.107}$$

The equations that govern the generalized displacements are therefore formally identical to those obtained for discrete systems. For continuous systems, truncation of the theoretically infinite number of differential equations has to be performed. The truncation criteria are often determined by the frequency domain under consideration. For a lossless string of length L with perfect boundary conditions excited by a source term $f(x, t)$, the general solution can be written in the modal domain as

$$y(x, t) = \sum_n \Phi_n(x)q_n(t) \, , \tag{22.108}$$

where

$$\ddot{q}_n(t) + \omega_n^2 q_n(t) = \frac{f_n(t)}{m_n}$$

with

$$f_n(t) = \langle f(x, t), \Phi_n(x) \rangle = \int_0^L \Phi_n(x)f(x, t)\,\mathrm{d}x \, .$$

Let us assume an initial shape $y(0, t)$ and an initial velocity $\dot{y}(0, t)$. The initial values of the $q_n(t)$ are thus given by

$$\begin{cases} q_n(0) = \dfrac{1}{m_n} \displaystyle\int_0^L \rho(x)S(x)y(0, t)\Phi_n(x)\,\mathrm{d}x \\[2mm] \text{and} \\[2mm] \dot{q}_n(0) = \dfrac{1}{m_n} \displaystyle\int_0^L \rho(x)S(x)\dot{y}(0, t)\Phi_n(x)\,\mathrm{d}x \end{cases} \tag{22.109}$$

Denoting the Laplace transform of $q_n(t)$ by $Q_n(s)$, we have

$$Q_n(s) = \frac{1}{s^2 + \omega_n^2} \left[\frac{F_n(s)}{m_n} + s q_n(0) + \dot{q}_n(0) \right],$$

(22.110)

where $F_n(s)$ is the Laplace transform of $f_n(t)$. The first term of $Q_n(s)$ is a product of two transforms which, in the time domain, corresponds to a convolution. Using transform tables, we obtain

$$q_n(t) = \frac{1}{m_n \omega_n} \int_0^t f_n(\theta) \sin \omega_n (t - \theta) \, d\theta$$

$$+ q_n(0) \cos \omega_n t + \dot{q}_n(0) \frac{\sin \omega_n t}{\omega_n} .$$ (22.111)

If $f_n(t)$ is a Dirac delta function of the form $f_{n0}\delta(t)$, the Laplace transform reduces to $F_n(s) = f_{n0}$ Equation (22.111) can then be written

$$q_n(t) = \frac{f_{n0}}{m_n} \frac{\sin \omega_n t}{\omega_n}$$

$$+ q_n(0) \cos \omega_n t + \dot{q}_n(0) \frac{\sin \omega_n t}{\omega_n} .$$ (22.112)

From the above impulse response for mode n of the string, we note the following:

1. There is an equivalence between $q_n(t)$ from the impulse source term and the initial velocity term. In other words, the motion of the string induced by an initial velocity profile is equivalent if the string is excited by a spatial distribution of Dirac delta function forces.
2. A source term localized at a given point x_0 can be written $f(x, t) = A\delta(x - x_0)\delta(t)$. In this case, $f_n(t) = \langle f(x, t), \Phi_n(x) \rangle = A\Phi_n(x_0)\delta(t)$. Therefore, the mode n will not be excited if the force is applied on a node of vibration.
3. The first term of the function $g_n(t) = \sin \omega_n t / m_n \omega_n$ is the Green's function of mode n.

String with a Finite Mass at One End
To present general results, the string is still assumed to be heterogeneous. The purpose of this section is to give the orthogonality properties of the modes for a heterogeneous string terminated by a finite mass M. The boundary conditions are

$$y(0, t) = 0 \quad \text{and} \quad -T(x)\frac{\partial y}{\partial x} = M \frac{\partial^2 y}{\partial t^2},$$

$$\text{at} \quad x = L .$$ (22.113)

The eigenfunctions $\Phi(x)$ therefore have to satisfy

$$\rho(x)S(x)\omega^2 \Phi(x) = -\frac{d}{dx}\left[T(x)\frac{d\Phi(x)}{dx} \right] = 0,$$

for $0 < x < L$

with $\Phi(0) = 0$

and $T(x)\frac{d\Phi}{dx} = \omega^2 M \Phi(x),$

at $x = L .$

For $n \neq m$, the orthogonality condition with respect to mass becomes

$$\int_0^L \rho(x)S(x)\Phi(x)\Phi_m(x)\,dx + M\Phi_n(L)\Phi_m(L) = 0$$

(22.114)

and the orthogonality condition with respect to stiffness remains

$$\int_0^L T(x)\frac{d\Phi_n(x)}{dx}\frac{d\Phi_m(x)}{dx}\,dx = 0 .$$ (22.115)

For a homogeneous string with uniform tension and constant diameter, these conditions reduce to

$$\int_0^L \Phi_n(x)\Phi_m(x)\,dx = -\frac{M}{\rho S}\Phi_n(L)\Phi_m(L)$$ (22.116)

and

$$\int_0^L \frac{d\Phi_n(x)}{dx}\frac{d\Phi_m(x)}{dx}\,dx = 0 .$$ (22.117)

22.3.3 Ideal String

To solve initial-boundary problems in simple cases, we assume that the lossless string is homogeneous with density ρ, constant tension T and constant cross section S. In this case, the vertical displacement is given by the wave equation

$$\frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2},$$ (22.118)

where $c = \sqrt{T/\rho S}$ is the transverse wave velocity.

D'Alembert's Solution in the Time Domain
In order to show the correspondence between the wave and modal approaches, a time-domain method is used

first to solve the wave equation (22.118) with initial conditions [22.7]

$$u(x, 0) = f(x) \quad \text{and} \quad \frac{\partial u}{\partial t}(x, 0) = g(x). \quad (22.119)$$

Using the change of variables $\xi = x - ct$ and $\eta = x + ct$, we have

$$u(x, t) = U(\xi, \eta) \quad (22.120)$$

from (22.120), we obtain

$$\begin{cases} \dfrac{\partial^2 u}{\partial t^2} = c^2 \left(\dfrac{\partial^2 U}{\partial \xi^2} - 2 \dfrac{\partial^2 U}{\partial \xi \partial \eta} + \dfrac{\partial^2 U}{\partial \eta^2} \right) \\[2mm] \dfrac{\partial^2 u}{\partial x^2} = \dfrac{\partial^2 U}{\partial \xi^2} + 2 \dfrac{\partial^2 U}{\partial \xi \partial \eta} + \dfrac{\partial^2 U}{\partial \eta^2} \end{cases} . \quad (22.121)$$

Inserting (22.121) into (22.118) yields $(\partial^2 U)/(\partial \xi \partial \eta) = 0$ which implies

$$u(x, t) = F(x - ct) + G(x + ct), \quad (22.122)$$

where F and G are are two twice-differentiable functions. $F(x - ct)$ represents a travelling wave moving to the right (direction of increasing values for x), while $G(x + ct)$ is a travelling wave moving to the left. Using (22.119) implies that F and G must fulfill the conditions

$$\begin{cases} F(x) + G(x) = f(x) \\ -cF'(x) + cG'(x) = g(x) \end{cases} . \quad (22.123)$$

Solving (22.123) yields

$$\begin{cases} F(x) = \dfrac{1}{2} f(x) - \dfrac{1}{2} [-F(0) + G(0)] \\ \qquad\quad - \dfrac{1}{2c} \displaystyle\int_0^x g(s)\, \mathrm{d}s \\[4mm] G(x) = \dfrac{1}{2} f(x) + \dfrac{1}{2} [-F(0) + G(0)] \\ \qquad\quad + \dfrac{1}{2c} \displaystyle\int_0^x g(s)\, \mathrm{d}s \end{cases} . \quad (22.124)$$

Finally, the solution of the wave equation is written explicitly

$$u(x, t) = \frac{1}{2} [f(x - ct) + f(x + ct)] \\ + \frac{1}{2c} \int_{x-ct}^{x+ct} g(s)\, \mathrm{d}s . \quad (22.125)$$

Semi-infinite String. For a semi-infinite string rigidly fixed at $x = 0$, we have the boundary condition $u(0, t) = 0$. This requires

$$F(-ct) + G(ct) = 0 \quad (22.126)$$

and, finally, with the appropriate change of variables

$$u(x, t) = -G(x - ct) + G(x + ct) \\ = F(x - ct) - F(-x - ct). \quad (22.127)$$

Equation (22.127) expresses the fact that, due to the fixed end at $x = 0$, the left-traveling wave is reflected with a change of sign and becomes a right-traveling wave. The validity domain for (22.127) is $0 \leq x < +\infty$ and $t > 0$.

String of Finite Length. In the case of an ideal string fixed at both ends, the wave approach can still be used, with the additional boundary condition $u(L, t) = 0$, which yields

$$u(L, t) = -G(L - ct) + G(L + ct) \\ = F(L - ct) - F(-L - ct) = 0. \quad (22.128)$$

Equation (22.128) can be rewritten $F(z) = F(z - 2L)$, which shows that F (and G) are now periodic functions with spatial period $2L$ or, equivalently, temporal period $2L/c$. The validity domain of (22.128) is now $0 \leq x \leq L$ and $t > 0$. Equations (22.126)–(22.128) can be used for step-by-step constructions of the string shape at successive instants of time.

String Fixed at Both Ends. Eigenmodes

Injecting a harmonic wave of the form $u(x, t) = \mathrm{e}^{\mathrm{i}(\omega t - kx)}$ in (22.118), we find the dispersion equation $D(\omega, k)$ that governs the relationship between frequency ω and wavenumber k. Here, we obtain

$$D(\omega, k) = \omega^2 - c^2 k^2 = 0. \quad (22.129)$$

This equation shows that the ratio between the frequency and wavenumber is constant, which is a characteristic property of a nondispersive medium. If we assume further that the string is rigidly fixed at both ends, the eigenmodes must satisfy the equation

$$\frac{\mathrm{d}^2 \Phi(x)}{\mathrm{d}x^2} + \frac{\omega^2}{c^2} \Phi(x) = 0 \quad (22.130)$$

with the boundary conditions $\Phi(0) = \Phi(L) = 0$ from which we obtain

$$\Phi_n(x) = \sin k_n x. \quad (22.131)$$

The only possible values for the wavenumber are given by the discrete series

$$k_n = \frac{n\pi}{L} \quad \text{so that} \quad \omega_n = \frac{n\pi c}{L} \, . \tag{22.132}$$

Using (22.106), the modal mass is $m_n = \rho SL/2 = M_s/2$, where M_s is the total mass of the string. Recall, however, that the ratio $m_n/M_s = 1/2$ is purely arbitrary since the modal masses are defined with an arbitrary multiplicative constant. The important result here is that all modal masses are equal and do not depend on the rank n of the mode.

Application: Plucked String. Modal Approach

The particular case where the string is released from an initial triangular shape at the origin of time without initial velocity is now examined. With the assumption of no stiffness, the initial profile of the string is given by

$$u(0, t) = \begin{cases} \dfrac{hx}{x_0} & \text{for } 0 \le x \le x_0 \\[2mm] \dfrac{h(L-x)}{L-x_0} & \text{for } x_0 \le x \le L \end{cases} \, . \tag{22.133}$$

The modal method consists of looking for solutions of the form

$$u(x, t) = \sum_n \Phi_n(x) q_n(t) \, . \tag{22.134}$$

At the origin of time, we can write

$$u(0, t) = \sum_n \Phi_n(x) q_n(0) \, . \tag{22.135}$$

The unknowns of the problem are the functions $q_n(0)$. Exploiting again the orthogonality properties of the eigenmodes, we find

$$q_n(0) = \frac{2hL^2}{n^2\pi^2 x_0(L-x_0)} \sin k_n x_0 \, . \tag{22.136}$$

The functions $q_n(t)$ are given by the oscillator equations

$$\ddot{q}_n + \omega_n^2 q_n = 0 \tag{22.137}$$

which, in the case of zero initial velocity, leads to $q_n(t) = q_n(0) \cos \omega_n t$. In summary, the transverse displacement of the string is given by

$$u(x, t) = \sum_n \frac{2hL^2}{n^2\pi^2 x_0(L-x_0)} \\ \times \sin k_n x_0 \sin k_n x \cos \omega_n t \, . \tag{22.138}$$

Despite the simplicity of this example, a number of important issues can be derived from this result:

1. The eigenfrequencies are integer multiples of the fundamental $f_1 = c/2L$. The solution is periodic and the fundamental frequency is the inverse of the period of vibration.
2. The amplitudes of the modal components decrease as $1/n^2$ with the rank n of the modes.
3. Because the magnitude is proportional to $\sin k_n x_0$, a modal component n can be suppressed by selecting the plucking point $x_0 = pL/n$, where p is an integer $< n$.
4. The excitation point x_0 and observation point x can be interchanged in (22.138). This is an illustration of the reciprocity principle.

Moving End

To a first approximation, a vibrating string radiates as a dipole. Because of its small diameter compared to the acoustic wavelength, it is a poor radiator. If significant sound is to be radiated, one end of the string must be coupled to a component with a considerable vibrating area (plate, shell, etc.). In Sect. 22.3.2, the general properties of a heterogeneous string attached to a mass were obtained. In this section, the simple example of an ideal string coupled to a spring will be considered to illustrate the influence of such coupling on the eigenmodes, eigenfrequencies and modal masses. We consider a string fixed at point $x = 0$ to a spring of stiffness K_0. The boundary condition at this end is then

$$T\left(\frac{\partial u}{\partial x}\right)_{x=0} = K_0 \, u(0, t) \, . \tag{22.139}$$

The string is rigidly fixed at the other end, so that $u(L, t) = 0$. We look for solutions of the form $u(x, t) = \Phi(x) \cos \omega t$. Following (22.118), the eigenfunctions $\Phi(x)$ must satisfy the equation

$$\frac{d^2 \Phi}{dx^2} + k^2 \Phi = 0 \tag{22.140}$$

and the boundary conditions. Thus, we derive the equation for the eigenvalues k_n

$$\tan(k_n L) = -\frac{k_n T}{K_0} \quad \text{with } k_n > 0 \, . \tag{22.141}$$

The graphical representation of (22.141) shows that the k_n are no longer integer multiples of k_1 (Fig. 22.8). As a consequence, the free vibration of the string is no longer periodic. Note that the spring decreases the eigenfrequencies relative to those of a perfectly rigid end.

The eigenfunctions become

$$\Phi_n(x) = \sin k_n x + \frac{k_n T}{K_0} \cos k_n x = \frac{\sin k_n(L-x)}{\cos k_n L} \tag{22.142}$$
Fig. 22.8 Graphical resolution of the eigenvalue problem for a string attached to a spring (22.141)

from which the initial values $q_n(0)$ and the modal masses can be derived. We obtain

$$m_n = \int_0^L \rho S \left(\sin k_n x + \frac{k_n T}{K_0} \cos k_n x \right)^2 dx$$

$$= \frac{M_s}{2} \left[1 + \left(\frac{k_n T}{K_0} \right)^2 \right]. \tag{22.143}$$

Equation (22.143) shows here that the modal masses increase with the rank n of the mode. In the case of a mass termination, a similar procedure would lead to the eigenvalue equation

$$\tan(k_n L) = \frac{\rho S}{M_0 k_n}. \tag{22.144}$$

Here, the inertial load at the end leads to an increase of the eigenfrequencies.

Application to Stringed Instruments. In plucked and struck strings instruments (guitar, piano, harp, etc.), the main part of the sound is due to the free regime of vibration, and the spectrum is composed of the eigenfrequencies of the vibrating system. Previous considerations show that the coupling between the strings and the radiating body (top plate, soundboard) alters the frequencies, compared to the perfect harmonic case. Though this alteration is usually relatively small, it has the consequence that the waveform is not perfectly periodic anymore. This might have in turn some perceptual effects on the produced sound. See the chapter on musical acoustics (Chap. 15) in this Handbook for more details.

22.3.4 Circular Membrane in vacuo

Membranes are used in percussion instruments, microphones, loudspeakers and wall resonators. Because of their small thickness, the influence of air loading cannot be neglected in most applications. However, we limit ourselves here by solving the equation for transverse vibrations of a homogeneous membrane in vacuo. Fluid-loading effects on structures are discussed in later sections. From (22.94) the membrane equation, in circular geometry, is

$$\sigma \frac{\partial^2 u}{\partial t^2} = \tau \Delta u = \tau \left(\frac{\partial^2 u}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} + \frac{1}{r^2} \frac{\partial^2 u}{\partial \theta^2} \right), \tag{22.145}$$

where $\sigma = \rho h$. Equation (22.145) can be solved by using the method of separation of variables [22.8]. For zero displacement at the edge, $z(r = a, \theta, t) = 0$, and neglecting losses, the expansion of the displacement on the eigenmodes can be expressed as

$$u(r, \theta, t) = \sum_{m=1}^{\infty} \left[\sum_{n=0}^{\infty} U_{nm}(r, \theta) \right.$$
$$\times \left(A_{nm} \cos \omega t + B_{nm} \sin \omega t \right)$$
$$+ \sum_{n=1}^{\infty} \tilde{U}_{nm}(r, \theta)$$
$$\left. \times \left(\tilde{A}_{nm} \cos \omega t + \tilde{B}_{nm} \sin \omega t \right) \right]. \tag{22.146}$$

In (22.146), the eigenfunctions are

$$U_{nm}(r, \theta) = J_n(\beta_{nm} r) \cos n\theta$$

and

$$\tilde{U}_{nm}(r, \theta) = J_n(\beta_{nm} r) \sin n\theta, \tag{22.147}$$

where J_n is the order-n Bessel function of the first kind [22.9]. The indices n and m refer to the number of nodal lines and to the number of nodal circles, respectively (Fig. 22.9).

The fixed edge corresponds to one nodal circle. The symmetrical modes are those where there are no nodal diameters. In this case, the eigenfunctions are of the form $J_n(\beta_{0m} r)$. All other modes can be viewed as *pairs of modes* with the same eigenfrequency and the same dependence versus r. They only differ by an angle of $\pi/2n$. The discrete values β_{mn} of the wavenumbers are derived from the boundary condition at the edge, such that

$$J_n(\beta a) = 0. \tag{22.148}$$

For each value of n, we obtain an infinite series of roots β_{nm}. For $n = 0$, for example, $J_0(\beta a) = 0$ yields $\beta_{0m}a = 2.405,\ 5.520,\ 8.654,\ 11,792,\ 14,931, \ldots$. Similarly, the roots of $J_1(\beta a) = 0$ are given by $\beta_{1m}a = 3.832,\ 7.016,\ 10.173,\ 13.324,\ 16.471, \ldots$.

Finally, the eigenfrequencies ω_{nm} are obtained from the 2-D wave equation (22.145):

$$\omega_{nm} = c\beta_{nm}\ , \quad \text{where} \quad c = \sqrt{\frac{\tau}{\sigma}}\ . \tag{22.149}$$

Unlike the case of ideal strings, the eigenfrequencies of a circular membrane in vacuo are not harmonically related. It has been shown by different authors that the fluid and cavity loading both contribute to restore the harmonic character of timpani sound, although the fundamental is missing [22.10, 11].

Fig. 22.9 Eigenmodes (n, m) of a circular membrane in vacuo

22.4 Bars, Plates and Shells

In this section, we consider the flexural vibrations of bars, plates and shells, since these structures are of the most practical use for the radiation of sound. First, the longitudinal vibrations of bars are presented, to show the analogies with the string wave equation, and also because this example will be used in Sect. 22.5.1 to illustrate the basic concepts of fluid–structure interactions.

22.4.1 Longitudinal Vibrations of Bars

The longitudinal vibrations of a 1-D bar in vacuo, clamped at one end and free at the other, are governed by the equations

$$\begin{cases} \rho_s S \dfrac{\partial^2 \xi}{\partial t^2} = ES \dfrac{\partial^2 \xi}{\partial x^2}\ , \\[2mm] \xi(0, t) = 0\ ; \qquad \dfrac{\partial \xi}{\partial x}(L, t) = 0\ . \end{cases} \tag{22.150}$$

The eigenfunctions are

$$\phi_n(x) = \sin(2n - 1)\frac{\pi x}{2L} = \sin k_n x \tag{22.151}$$

with $k_n = \omega_n/c_L$ and thus the linear solution can be written as

$$\xi(x, t) = \sum_n \phi_n(x)q_n(t)\ , \tag{22.152}$$

where the generalized displacements obey

$$\ddot{q}_n + \omega_n^2 q_n = 0\ . \tag{22.153}$$

Equation (22.153) yields a harmonic solution with eigenfrequency ω_n.

22.4.2 Flexural Vibrations of Beams

The flexural vibrations of a slender isotropic beam are presented, within the framework of the Euler–Bernoulli assumptions [22.8]. The beam is oriented along the x-axis, and the cross section $S(x)$ is in the (y, z) plane. The flexural displacement $v(x, t)$ is in the direction of the y-axis. $E(x)$ is the Young's modulus, $\rho(x)$ is the density, and $I_z(x)$ is the moment of inertia of a cross section with respect to its neutral midplane. $f(x, t)$ represents a source term. Applying Hamilton's principle, we obtain the well-known equation

$$\rho(x)S(x)\ddot{v} + \frac{\partial^2}{\partial x^2}\left[E(x)I_z(x)\frac{\partial^2 v}{\partial x^2}\right] = f(x, t) \tag{22.154}$$

with the additional conditions to be satisfied

$$\left[E(x)I_z(x)\frac{\partial^2 v}{\partial x^2}\frac{\partial v}{\partial x}\right]_0^L = 0$$

and

$$\left[\frac{\partial}{\partial x}\left(E(x)I_z(x)\frac{\partial^2 v}{\partial x^2}\right)v\right]_0^L = 0\ . \tag{22.155}$$

Equation (22.154) is fourth order in the spatial coordinate. Therefore, four boundary conditions (two

conditions at each end) are necessary to solve the boundary-value problem. Following (22.155), four different situations are compatible at each end

Supported $\quad v = 0$

and $\quad \mathcal{M}(x) = E(x)I_z(x)\dfrac{\partial^2 v}{\partial x^2} = 0$;

Clamped $\quad \dfrac{\partial v}{\partial x} = 0$

and $\quad v = 0$;

Free $\quad \mathcal{T}(x) = \dfrac{\partial}{\partial x}\left[E(x)I_z(x)\dfrac{\partial^2 v}{\partial x^2}\right] = 0$

and $\quad \mathcal{M}(x) = E(x)I_z(x)\dfrac{\partial^2 v}{\partial x^2} = 0$;

Guided $\quad \mathcal{T}(x) = \dfrac{\partial}{\partial x}\left[E(x)I_z(x)\dfrac{\partial^2 v}{\partial x^2}\right] = 0$

and $\quad \dfrac{\partial v}{\partial x} = 0$,

where $\mathcal{M}(x)$ is the bending moment and $\mathcal{T}(x)$ is the shear force.

Free–Free Beam with a Constant Section

As a specific example of (22.154), we consider a homogeneous and isotropic beam of length L, thickness h, width b, with a constant rectangular section $S = bh$ whose moment of inertia with respect to the z-axis is $I_z = I = bh^3/12$ (Fig. 22.10).

In this case, (22.154) reduces to

$$EI\frac{\partial^4 v}{\partial x^4} + \rho S\frac{\partial^2 v}{\partial t^2} = 0 . \tag{22.156}$$

Looking for solutions for (22.156) of the form $v(x, t) = \Phi(x)\cos\omega t$ yields the general solution

$$\begin{aligned}\Phi(x) = {}&A\cosh\frac{\omega x}{c} + B\sinh\frac{\omega x}{c}\\ &+ C\cos\frac{\omega x}{c} + D\sin\frac{\omega x}{c}\end{aligned} \tag{22.157}$$
Fig. 22.10 Geometry of a beam with constant section

with

$$c = \sqrt{\omega c_L}\,\sqrt[4]{\frac{I}{S}} \quad \text{and} \quad c_L = \frac{E}{\rho} . \tag{22.158}$$

This expression shows that the phase velocity c of the flexural waves is proportional to $\sqrt{\omega}$. The dispersion relationship is given by

$$EIk^4 + \rho S\omega^2 = 0 . \tag{22.159}$$

From (22.159), we can see that the group velocity $c_g = d\omega/dk$ is also proportional to $\sqrt{\omega}$. The group velocity refers to the propagation velocity of wave energy and envelope of slowly varying amplitude. Flexural waves in the beam are thus dispersive with the higher frequencies propagating faster than the lower ones.

Remark

There is a paradox in (22.157) in the sense that the group velocity tends to infinity as the frequency tends to infinity. This results from the Euler–Bernoulli assumptions, where shear and rotation inertia of the cross sections are neglected. Introducing these two effects in the model (the Timoshenko model) leads to a bounded asymptotic value of the group velocity as frequency increases.

For a beam free at both ends, the boundary conditions are

$$\frac{\partial^2 y}{\partial x^2}(0, t) = \frac{\partial^2 y}{\partial x^2}(L, t) = 0 \tag{22.160}$$

and

$$\frac{\partial^3 y}{\partial x^3}(0, t) = \frac{\partial^3 y}{\partial x^3}(L, t) = 0 , \tag{22.161}$$
Fig. 22.11 Graphical resolution of the eigenfrequency equation for a free–free beam, with $X = \omega L/c$

which yields the equation of the eigenfrequencies (Fig. 22.11)

$$\cos \frac{\omega L}{c} \cosh \frac{\omega L}{c} = 1 . \tag{22.162}$$

The numerical resolution of (22.162) shows that the eigenfrequencies f_n (in Hz) are

$$f_n \approx \sqrt{\frac{EI}{\rho S}} \frac{\pi}{8L^2} \left[3.011^2, 5^2, 7^2, \dots, (2n+1)^2 \right] . \tag{22.163}$$

The eigenfrequencies are not harmonically related so that the impulse response of the beam is not periodic.

Beam with a Variable Cross Section

As another example, we consider the flexural vibrations for a beam with variable cross section. Here, we describe the Galerkin method [22.12]. It has the advantage that it remains valid even in the case of nonconservative systems. In this method, the eigenfunctions $\Phi(x)$ of (22.154) are approximated by a finite sum of p terms

$$\Phi^{(p)}(x) = \sum_{j=1}^{p} a_j \phi_j(x) , \tag{22.164}$$

where $\phi_j(x)$ are arbitrary functions that satisfy the boundary conditions at both ends of the beam. Inserting (22.164) in (22.154), and defining $\lambda^{(p)} = (\omega^2)^{(p)}$ as the approximate eigenvalues of order p, one can define the Galerkin residue

$$\mathcal{R} \left[\Phi^{(p)}(x) \right] = \frac{d^2}{dx^2} \left(EI(x) \frac{d^2 \Phi^{(p)}}{dx^2} \right)$$
$$- \lambda^{(p)} \rho(x) S(x) \Phi^{(p)} \tag{22.165}$$

following (22.164), this can be written as

$$\mathcal{R} \left[\Phi^{(p)}(x) \right] = \sum_{j=1}^{p} a_j$$
$$\times \left\{ \frac{d^2}{dx^2} \left[EI(x) \frac{d^2 \phi_j(x)}{dx^2} \right] - \lambda^{(p)} \rho(x) S(x) \phi_j(x) \right\} . \tag{22.166}$$

The weak formulation of the problem is given by

$$\int_0^L \phi_i(x) \sum_{j=1}^{p} a_j \left\{ \frac{d^2}{dx^2} \left[EI(x) \frac{d^2 \phi_j(x)}{dx^2} \right] \right.$$
$$\left. - \lambda^{(p)} \rho(x) S(x) \phi_j(x) \right\} dx = 0 . \tag{22.167}$$

The goal of the method is to find the coefficients a_j for which the residue $\mathcal{R} \left[\Phi^{(p)}(x) \right]$ is equal to zero. Thus (22.167) becomes

$$\sum_{j=1}^{p} k_{ij} a_j - \lambda^{(p)} \sum_{j=1}^{p} m_{ij} a_j = 0$$
$$\text{for} \quad i = 1, 2, \dots p , \tag{22.168}$$

where the mass and stiffness coefficients are

$$k_{ij} = \int_0^L \phi_i(x) \frac{d^2}{dx^2} \left[EI(x) \frac{d^2 \phi_j(x)}{dx^2} \right] dx \tag{22.169}$$

and

$$m_{ij} = \int_0^L \phi_i(x) \rho(x) S(x) \phi_j(x) \, dx . \tag{22.170}$$

Equation (22.168) can be written equivalently in matrix form

$$[\mathbf{K} - \lambda \mathbf{M}] \, \boldsymbol{a} = 0 , \tag{22.171}$$

where $\boldsymbol{a}$ is a vector with dimension p and $\mathbf{K}$ and $\mathbf{M}$ are matrices with dimension $p \times p$. The problem to be solved is therefore equivalent in form to the eigenvalue problem for a p-component discrete system (22.49).

Prestressed Beam or Stiff String

The flexural motion for a beam subjected to tension (or prestressed beam) is governed by the same equation as a string with stiffness. For a homogeneous and isotropic beam of constant section subjected to a uniform tension T, we have

$$\rho S \frac{\partial^2 v}{\partial t^2} = T \frac{\partial^2 v}{\partial x^2} - EI \frac{\partial^4 v}{\partial x^4} . \tag{22.172}$$

For a propagating wave of the form $y(x, t) = e^{i(\omega t - kx)}$, we obtain the dispersion relationship

$$\omega^2 = k^2 c^2 \left(1 + \frac{EI}{T} k^2 \right) . \tag{22.173}$$

For a stiff string of length L, the usual order of magnitude generally implies $\varepsilon = \frac{EI}{TL^2} \ll 1$ so that (22.173) can be written

$$\omega^2 = k^2 c^2 \left(1 + \varepsilon k^2 L^2 \right) . \tag{22.174}$$

For a stiff string with hinged ends the boundary conditions impose

$$\sin kL = 0 \quad \text{so that} \quad k_n L = n\pi \tag{22.175}$$

from which we can derive through (22.174) the eigenfrequencies

$$\omega_n \approx \frac{n\pi c}{L}\left(1 + \varepsilon\frac{n^2\pi^2}{2}\right) . \tag{22.176}$$

The eigenfrequencies are raised by the stiffness. The difference increases as n^2. The inharmonicity coefficient can be defined as

$$i = \varepsilon\frac{n^2\pi^2}{2} . \tag{22.177}$$

22.4.3 Flexural Vibrations of Thin Plates

The *thin plate*, or Kirchhoff–Love plate, described below is a generalization of the Euler–Bernoulli beam in 2-D [22.13]. The general case of orthotropic plates is treated here. The problem is solved in Cartesian coordinates, where $w(x, y, t)$ denotes the transverse displacement. It is assumed that the coordinates coincide with the symmetry axes of the material. The assumption of orthotropy leads to the following relations between plane stresses σ_{ij} and plane strains ε_{kl}

$$\begin{pmatrix}\sigma_{xx}\\\sigma_{yy}\\\sigma_{xy}\end{pmatrix} = \begin{pmatrix}\dfrac{E_x}{1-\nu_{xy}\nu_{yx}} & \dfrac{\nu_{yx}E_x}{1-\nu_{xy}\nu_{yx}} & 0\\[2ex]\dfrac{\nu_{yx}E_x}{1-\nu_{xy}\nu_{yx}} & \dfrac{E_y}{1-\nu_{xy}\nu_{yx}} & 0\\[2ex]0 & 0 & 2G_{xy}\end{pmatrix}$$

$$\times\begin{pmatrix}\varepsilon_{xx}\\\varepsilon_{yy}\\\varepsilon_{xy}\end{pmatrix} . \tag{22.178}$$

These relations involve two elastic moduli E_x and E_y, two Poisson's ratios ν_{xy} and one torsional modulus G_{xy}. In addition, we have the property $E_x\nu_{yx} = E_y\nu_{xy}$ [22.14]. The bending and twisting moments are obtained by integration of the elementary moments over the thickness h of the plate

$$\mathcal{M}_x = \int_{-h/2}^{h/2} z\sigma_{xx}\,\mathrm{d}z ;$$

$$\mathcal{M}_y = \int_{-h/2}^{h/2} z\sigma_{yy}\,\mathrm{d}z ;$$

$$\mathcal{M}_{xy} = \mathcal{M}_{yx} = \int_{-h/2}^{h/2} z\sigma_{xy}\,\mathrm{d}z \tag{22.179}$$

which leads to the matrix relation between the moments and curvatures

$$\begin{pmatrix}\mathcal{M}_x\\\mathcal{M}_y\\\mathcal{M}_{xy}\end{pmatrix} = -\begin{pmatrix}D_1 & \dfrac{D_2}{2} & 0\\[2ex]\dfrac{D_2}{2} & D_3 & 0\\[2ex]0 & 0 & \dfrac{D_4}{2}\end{pmatrix}\times\begin{pmatrix}\dfrac{\partial^2 w}{\partial x^2}\\[2ex]\dfrac{\partial^2 w}{\partial y^2}\\[2ex]\dfrac{\partial^2 w}{\partial x\partial y}\end{pmatrix} , \tag{22.180}$$

where

$$D_1 = \frac{E_x h^3}{12(1-\nu_{xy}\nu_{yx})} ;$$

$$D_2 = \frac{E_x\nu_{yx}h^3}{6(1-\nu_{xy}\nu_{yx})} = \frac{E_y\nu_{xy}h^3}{6(1-\nu_{xy}\nu_{yx})} , \tag{22.181}$$

$$D_3 = \frac{E_y h^3}{12(1-\nu_{xy}\nu_{yx})} ;$$

$$D_4 = \frac{G_{xy}h^3}{3} . \tag{22.182}$$

Again, the equation of motion can be obtained using Hamilton's principle [22.12]. Finally, given an external force density term $f(x, y, t)$, we obtain the equation of motion for the plate

$$\rho_\mathrm{p} h\frac{\partial^2 w}{\partial t^2}$$
$$= \frac{\partial^2\mathcal{M}_x}{\partial x^2} + \frac{\partial^2\mathcal{M}_y}{\partial y^2} + 2\frac{\partial^2\mathcal{M}_{xy}}{\partial x\partial y} + f(x, y, t) . \tag{22.183}$$

Boundary Conditions
As for the beam, the boundary conditions follow from integration by parts of the elastic energy. The number of possible conditions depends on the selected geometry. For rectangular plates, for example, Leissa lists 21 possible boundary conditions [22.15]. Along the principal directions, for example, the conditions of greatest practical interest are:

1. Clamped edge: displacement $w = 0$ and rotation $\frac{\partial w}{\partial x} = 0$.
2. Simply supported edge: displacement $w = 0$ and bending moment $\mathcal{M}_x = 0$.
3. Free edge: bending moment $\mathcal{M}_x = 0$ and shear force $\frac{\partial\mathcal{M}_x}{\partial x} + 2\frac{\partial\mathcal{M}_{xy}}{\partial y} = 0$.

Example: Homogeneous Rectangular Simply Supported Plate

From (22.180) and (22.183), we obtain for a homogeneous orthotropic plate

$$\rho_p h \frac{\partial^2 w}{\partial t^2} + D_1 \frac{\partial^4 w}{\partial x^4} + (D_2 + D_4)$$
$$\times \frac{\partial^4 w}{\partial x^2 \partial y^2} + D_3 \frac{\partial^2 w}{\partial y^4} = 0 . \qquad (22.184)$$

For a rectangular plate of length a and width b, simply supported at its edges, the boundary conditions are

$$\begin{cases} W(0, y, t) & = W(a, y, t) = W(x, 0, t) \\ & = W(x, b, t) = 0 , \\ \mathcal{M}_x(0, y, t) & = \mathcal{M}_x(a, y, t) = \mathcal{M}_y(x, 0, t) \\ & = \mathcal{M}_y(x, b, t) = 0 . \end{cases}$$
$$(22.185)$$

The eigenfunctions satisfying (22.185) are of the form

$$\Phi_{mn}(x, y) = \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \qquad (22.186)$$

and the associated eigenfrequencies are given by

$$\omega_{mn} = \pi^2 \sqrt{\frac{1}{\rho_p h}}$$
$$\times \sqrt{D_1 \frac{m^4}{a^4} + D_3 \frac{n^4}{b^4} + (D_2 + D_4) \frac{m^2 n^2}{a^2 b^2}} . \qquad (22.187)$$

In both expressions, m and n are positive integers. As for strings and beams, the eigenfunctions Φ_{mn} are orthogonal with respect to mass and stiffness, so that

$$\int_0^a \int_0^b \rho_p h \Phi_{mn}(x, y) \Phi_{m'n'}(x, y) \, dx \, dy$$
$$= \begin{cases} 0 & \text{if } m \neq m' \text{ or } n \neq n' , \\ M_{mn} & \text{if } m = m' \text{ and } n = n' ; \end{cases} \qquad (22.188)$$

where M_{mn} is the modal mass for the mode (m, n). The eigenfrequencies for the orthotropic plate are distributed between two limiting curves in the (k, f)-plane (Fig. 22.12).

Particular Case: Isotropic Plate

In the isotropic case, the rigidity coefficients become

$$D_1 = D_3 = D = \frac{Eh^3}{12(1 - v^2)} \qquad (22.189)$$
Fig. 22.12 Dispersion curves for an orthotropic plate made of carbon fibers with $D_1 = 8437$ MPa; $D_2 = 463$ MPa; $D_3 = 852$ MPa; $D_4 = 2267$ MPa; $h = 2$ mm; $\rho_p = 1540$ kg/m³; $a = 0.4$ m; $b = 0.2$ m

and

$$D_4 = \frac{Eh^3}{6(1 + v)} ,$$
$$D_2 = 2D_1 - D_4 = \frac{Evh^3}{6(1 - v^2)} . \qquad (22.190)$$

Here, the elastic behavior of the material is fully determined by two constants: the Young's modulus E and the Poisson's ratio v. The eigenfunctions $\Phi_{mn}(x, y)$ are the same as in (22.186). However, the eigenfrequencies now reduce to

$$\omega_{mn} = \pi^2 \sqrt{\frac{D}{\rho_p h}} \left(\frac{m^2}{a^2} + \frac{n^2}{b^2} \right) . \qquad (22.191)$$

Prestressed Isotropic Plate. If a tension (or compression) T_x in the x-direction and, simultaneously, a tension (or compression) T_y in the y-direction are applied in the plate plane, then the flexural equation is modified as follows [22.1]

$$\rho_p h \frac{\partial^2 w}{\partial t^2} + D \left(\frac{\partial^4 w}{\partial x^4} + 2 \frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^2 w}{\partial y^4} \right)$$
$$- T_x \frac{\partial^2 w}{\partial x^2} - T_y \frac{\partial^2 w}{\partial y^2} = 0 . \qquad (22.192)$$

In this case, the eigenfrequencies become

$$
\omega_{mn} = \sqrt{\frac{1}{\rho_{\mathrm{p}} h}}
$$
$$
\times \sqrt{D\left(\frac{\pi^2 m^2}{a^2} + \frac{\pi^2 n^2}{b^2}\right)^2 + T_x \frac{m^2 \pi^2}{a^2} + T_y \frac{n^2 \pi^2}{b^2}} \, .
$$

(22.193)

22.4.4 Vibrations of Thin Shallow Spherical Shells

One interest of presenting the vibrations of shallow spherical shells is to show the influence of curvature, compared to the case of flat plates. The present section focuses on the particular case of free edge, which is scarcely treated in the literature [22.16]. Linear vibrations of cymbals and gongs, for example, are conveniently described by such an idealized structure.

An isotropic spherical cap is considered, with thickness h, radius of curvature R and whose projection on a plane is a circle of radius a (Fig. 22.13). Using the Donnell–Mushtari–Vlasov assumptions for thin ($h \ll a$) and shallow ($a \ll R$) shells, the equations of motion for the free transverse displacement $w(r, \theta, t)$ of the cap is given by [22.17]

$$
D\nabla^6 w + \frac{Eh}{R^2}\nabla^2 w + \rho h \nabla^2 \ddot{w} = 0 \, ,
$$

(22.194)

where E is the Young's modulus, ρ is the density, ν is the Poisson's ratio and $D = Eh^3/12(1 - \nu^2)$ is the flexural rigidity of the shell. Equation (22.194) can be conveniently put into nondimensional form using the reduced variables $\overline{w} = w/w_0$, $\overline{r} = r/a$ and $\overline{t} = t/t_0$ with $t_0 = a^2 \sqrt{\rho h/D}$. In this case, (22.194) becomes

$$
\nabla^6 \overline{w} + \chi \nabla^2 \overline{w} + \nabla^2 \ddot{\overline{w}} = 0 \, ,
$$
Fig. 22.13 Spherical cap

where

$$
\chi = 12(1 - \nu^2)\frac{a^4}{R^2 h^2} \, .
$$

(22.195)

Notice that w_0 can be selected arbitrarily in the linear case. For nonlinear vibrations, this parameter should be selected in accordance with the order of magnitude of the nonlinear perturbation terms (Sect. 22.7).

Remark
In what follows, the nondimensional equation is solved but the overlines are removed from the variables, for convenience.

Eigenmodes of the Spherical Cap with Free Edge
We look for harmonic solutions of (22.195) of the form $w(r, \theta, t) = \Phi(r, \theta)q(t)$. The solutions must fulfill one of the two following cases [22.18]

$$
\begin{cases}
\text{if} & \omega^2 - \chi = \zeta^4 > 0 \\
\text{then} & \nabla^2\left(\nabla^4 - \zeta^4\right)\Phi = 0 \text{ case 1}, \\
\text{if} & \omega^2 - \chi = -\zeta^4 < 0 \\
\text{then} & \nabla^2\left(\nabla^4 + \zeta^4\right)\Phi = 0 \text{ case 2}.
\end{cases}
$$

(22.196)

In case 1, the eigenfunctions are given by

$$
\Phi_{nm}(r, \theta) =
$$
$$
\left[A_n r^n + B_n J_n(\zeta_{nm}r) + C_n I_n(\zeta_{nm}r)\right]\begin{vmatrix}\cos m\theta \\ \sin m\theta\end{vmatrix} \, ,
$$

(22.197)

where A_n, B_n and C_n are constants, ζ_{nm} are determined by the boundary conditions, J_n are the Bessel functions of the first kind and I_n are the modified Bessel functions of the first kind. In case 2, the eigenfunctions are given by

$$
\Phi_{nm}(r, \theta) =
$$
$$
\left[A_n r^n + B_n \mathrm{ber}_n(\zeta_{nm}r) + C_n \mathrm{bei}_n(\zeta_{nm}r)\right]\begin{vmatrix}\cos m\theta \\ \sin m\theta\end{vmatrix} \, ,
$$

(22.198)

where ber_n and bei_n are the Kelvin functions defined by [22.9]

$$
\mathrm{ber}_n(x) + \mathrm{i}\,\mathrm{bei}_n(x) = J_n\left[x \exp\left(\frac{3\mathrm{i}\pi}{4}\right)\right].
$$

(22.199)

For a free edge, the eigenvalues ζ_{mn} are determined from the equation obtained by expressing that forces and moments are equal to zero at the edge $r = a$. The

four possible situations for the eigenfrequencies are summarized below [22.19]

$$
\begin{cases}
\text{for} \quad n \in 0, 1, \quad \forall m \geq 1 \\
\qquad \omega_{nm} = \sqrt{\chi + \omega_{nm}^{(0)2}} \,, \\
\text{for} \quad n \geq 2, \quad m = 0 \quad \text{and} \quad \chi < \chi_n^{\text{lim}} \\
\qquad \omega_{n0} = \sqrt{\chi + \zeta_{n0}^4} \,, \\
\text{for} \quad n \geq 2, \quad m = 0 \quad \text{and} \quad \chi > \chi_n^{\text{lim}} \\
\qquad \omega_{n0} = \sqrt{\chi - \zeta_{n0}^4} \,, \\
\text{for} n \quad \geq 2, \quad m \geq 1, \\
\qquad \omega_{nm} = \sqrt{\chi + \zeta_{nm}^4} \,,
\end{cases}
\tag{22.200}
$$

where $\omega_{nm}^{(0)}$ are the eigenfrequencies obtained in the case of the circular plate with free edge, corresponding to the limiting case of the spherical shell with no curvature. The limiting value χ_n^{lim} that separates the Bessel from the Kelvin axisymmetric modes is given by [22.18]

$$
\chi_n^{\text{lim}} = \frac{(1-\nu)(3+\nu)n^2(n^2-1)}{1 + \frac{1}{4}(1-\nu)(n-2) - \frac{n^2(n-1)(1-\nu)(4n-\nu+9)}{16(n+2)^2(n+3)}} \,.
\tag{22.201}
$$

22.4.5 Combinations of Elementary Structures

Interesting and powerful models of complex structures can be obtained by combining together elementary components. One-dimensional models of intersecting walls, for example, can be modeled by means of connected bars, with appropriate boundary conditions at the junctions: equality of displacements, angles, forces and moments. This allows calculations of reflection and transmission coefficients in the different parts of a wall or a frame. Other examples of interest are sandwich plates. A sandwich is usually made of two plates with a thin viscoelastic (absorbing) layer between them. Again, the model contains the equation of motion for each layer plus additional boundary conditions. As a result, one can calculate, for example, the equivalent complex stiffness of the sandwich. One main advantage of such a configuration is that one can obtain a substantial increase of loss factor over a relatively wide frequency range, compared to a sytem of equal thickness composed by only one plate with a simple viscoelastic layer. However, the main drawback is that each application needs careful design of a specific sandwich in order to be effective in the frequency range of interest [22.13, 20].

Periodic structures can be found in many applications, such as ships, planes or roofs where a relatively light plate (or shell) is reinforced by stiffeners and ribs at uniform intervals. Such problems have been studied extensively in recent decades. A simple example of such a structure is the periodically supported infinite beam subjected to bending motion. By generalizing methods previously applied to atomic chains and crystals by Brillouin, different authors represent the spatial part of the wave propagation in such a beam by an equation of the form

$$
w(x + L) = \exp(\lambda)w(x) \,,
\tag{22.202}
$$

where w is the transverse displacement, L is the spatial period of the structure and λ is the propagation constant to be determined. The problem is solved by expressing the continuity and equilibrium equations at the junctions. Two situations may occur: if λ is purely imaginary, the bending wave can propagate freely in the periodic structure. The corresponding frequency range is called the *pass band*. If λ contains a real part, then the wave becomes evanescent, and the corresponding frequency range is called the *stop band*. Recently, some authors have shown that SEA can by useful for tackling such problems [22.21].

22.5 Structural–Acoustic Coupling

If the sound is generated by a light and flexible structure, then the effect of the acoustic loading back on the structure cannot be neglected, and the system has to be considered as a whole [22.22]. In the general case, the action of a fluid on a structure has several effects: radiation damping and modification of the eigenfrequencies. Approximations can be made in the case of a light fluid and weak coupling. These points are examined in Sect. 22.5.1. The simple example of a 1-D bar coupled to a semi-infinite tube is selected in order to facilitate the presentation of the various concepts. In a number of applications, the goal is to control the amount of energy radiated by a vibrating structure. This forms the heart of Sect. 22.5.2. In particular, the state-space formulation of structural–acoustic coupling facilitates the development of active noise-reduction systems [22.23]. The concept

of radiation modes and their link with sound power and efficiency is also presented in this section [22.24, 25].

In the case of structure–cavity coupling, the effects of the cavity field are different from those of the free field. Strong structural–acoustic modes can appear, which may contribute to a substantial modification of the radiated spectrum. These features are illustrated in Sect. 22.5.3 for the example of a 1-DOF oscillator coupled to a finite tube.

The concept of coincidence (or critical) frequency is essential in the radiation of sound by structures. By comparing the dispersion equations for the structure and fluid, respectively, one can make a distinction between frequency domains where the radiation efficiency of the structure is strong and where it is weak. This is treated in Sect. 22.5.4 for an isotropic plate.

22.5.1 Longitudinally Vibrating Bar Coupled to an External Fluid

Model and Modal Projection

We consider here the simple case of a longitudinally vibrating bar of length L coupled at one end to a 1-D infinite tube filled with air, which presents a resistive loading $R_a = \rho c S$ at the end of the bar. It is assumed throughout this section that the bar has a constant cross-sectional area S and that it is clamped at one end ($x = 0$) and free at the other ($x = L$). ρ_s is the density of the bar, E its Young's modulus, $c_L = \sqrt{E/\rho_s}$ is the longitudinal wave speed and $\xi(x, t)$ the longitudinal displacement at a point M at position x along the bar ($0 \leq x \leq L$). Similarly, ρ denotes the air density, c the speed of sound and $p(x, t)$ the sound pressure in the tube ($L < x < \infty$) (Fig. 22.14). In the absence of an exciting force (free vibration), the equations of the problem are

$$
\begin{cases}
\rho_s S \dfrac{\partial^2 \xi}{\partial t^2} = E S \dfrac{\partial^2 \xi}{\partial x^2} - S p(L, t)\delta(x - L) \\
\qquad \text{for } 0 \leq x \leq L \,, \\
p(L, t) = \rho c \dot{\xi}(L, t) \,, \\
\xi(0, t) = 0 \,, \\
p(x, t) = \rho c \dot{\xi}\left(L, t - \dfrac{x-L}{c}\right) \\
\qquad \text{for } L < x < \infty
\end{cases}
\tag{22.203}
$$

We look for the solution $\xi(x, t)$ expanded in terms of the in vacuo modes $\phi_n(x)$ of the bar. Both sides of the first equation in (22.203) are multiplied by any eigenfunction and integrated over the length of the bar. This

gives

$$
\int_0^L \rho_s S \left[\sum_m \phi_m(x)\ddot{q}_m(t) \right] \phi_n(x)\,\mathrm{d}x
$$

$$
- \int_0^L E S \left[\sum_m \phi_m{}''(x)q_m(t) \right] \phi_n(x)\,\mathrm{d}x
$$

$$
= \int_0^L S\rho c \left[\sum_m \phi_m(L)\dot{q}_m(t) \right] \phi_n(x)\delta(x - L)\,\mathrm{d}x \,.
$$

$$
\tag{22.204}
$$

This equation can be rewritten in a simpler form, by using the definition of the modal mass

$$
m_n = \int_0^L \rho_s S \phi_n^2(x)\,\mathrm{d}x \,.
\tag{22.205}
$$

Because of the mass orthogonality property of the eigenfunctions, the terms of the series in the first integral on the left-hand side of (22.204) are zero for $m \neq n$, so that the integral reduces to $m_n \ddot{q}_n(t)$. The second integral can be rewritten

$$
- \int_0^L E S \frac{\omega_m^2}{c_L^2} \left[\sum_m \phi_m(x)q_m(t) \right] \phi_n(x)\,\mathrm{d}x
\tag{22.206}
$$

which, due to stiffness orthogonality properties of the eigenfunctions, reduces to $-\omega_n^2 m_n q_n(t)$. Finally, due to the properties of the delta function, the third integral can be rewritten

$$
-R_a \phi_n(L) \sum_m \phi_m(L)\dot{q}_m(t) \,,
\tag{22.207}
$$

where $R_a = \rho c S$ is the acoustic radiation resistance.

Remark. In the case of the clamped–free bar, we would get $\phi_n(L) = (-1)^{n+1}$ and, similarly, $\phi_m(L) = (-1)^{m+1}$. However, in what follows, we choose to retain the more general formulation of (22.207) so that the equations remain general.

For a 1-D bar of length L coupled to a semi-infinite tube, the displacement is given by

$$
\xi(x, t) = \sum_n \phi_n(x)q_n(t) \,,
\tag{22.208}
$$

where the functions of times $q_n(t)$ obey the set of coupled equations

$$
m_n \ddot{q}_n(t) + m_n \omega_n^2 q_n(t)
$$

$$
= -R_a \phi_n(L) \sum_m \phi_m(L)\dot{q}_m(t) \,.
\tag{22.209}
$$

Once the displacement of the bar $\xi(x, t)$ is known, we can calculate the velocity $\dot{\xi}(x, t)$ at each point of the bar and, in particular, at the point $x = L$ and thus derive the radiated sound pressure inside the tube through (22.203). We now examine the consequences of the coupling on systems of small dimensions, to better understand its physical meaning.

Single-DOF System. Suppose that, for various reasons, we can reduce the previous system to one single mode. In this case, (22.209) reduces to

$$\ddot{q}_1(t) + \frac{R_a \phi_1^2(L)}{m_1} \dot{q}_1(t) + \omega_1^2 q_1(t) = 0 . \qquad (22.210)$$

This is simply the equation of a damped oscillator, where the dimensionless damping factor ζ_1 is given by

$$2\zeta_1 \omega_1 = \frac{R_a \phi_1^2(L)}{m_1} . \qquad (22.211)$$

Thus, for a single-DOF system, the acoustic coupling adds a radiation damping to the structure. This damping represents the amount of acoustic energy radiated by the vibrating bar.

Two-DOF System. Now, we truncate the system to the two lowest modes of the structure. In this case, (22.209) reduces to

$$\begin{cases} \ddot{q}_1 + 2\zeta_1 \omega_1 \dot{q}_1 + \omega_1^2 q_1 &= -\dfrac{R_a \phi_1(L) \phi_2(L)}{m_1} \dot{q}_2 \\ &= C_{12} \dot{q}_2 , \\ \ddot{q}_2 + 2\zeta_2 \omega_2 \dot{q}_2 + \omega_2^2 q_2 &= -\dfrac{R_a \phi_2(L) \phi_1(L)}{m_2} \dot{q}_1 \\ &= C_{21} \dot{q}_1 . \end{cases}$$
$$(22.212)$$

Several conclusions can be drawn from this last result:

- The acoustic radiation introduces damping terms $2\zeta_i \omega_i \dot{q}_i$ in each equation.
- The time functions are coupled by the radiation. In general, the coupling coefficients C_{12} and C_{21} are not equal.

Taking the Laplace transform of the system in (22.212) leads to the characteristic equation

$$(s^2 + 2\zeta_1 \omega_1 s + \omega_1^2)(s^2 + 2\zeta_2 \omega_2 s + \omega_2^2)$$
$$- 4\zeta_1 \zeta_2 \omega_1 \omega_2 s^2 = 0 . \qquad (22.213)$$

Equation (22.213) shows that the structural–acoustic coupling modifies the eigenfrequencies and damping factors of the system, compared to the in vacuo case.

Light–Fluid Approximation. For $\zeta_1 \omega_1 \ll 1$ and $\zeta_2 \omega_2 \ll 1$ one can find first-order approximations for both the eigenfrequencies and decay times, due to the air–structure coupling. Denoting $s = \sigma + i\omega$ and replacing it in (22.213) yields the new damping factors

$$\sigma_1 \approx -\left(\zeta_1 \omega_1 - \frac{\omega_2}{2\omega_1} C_{12}\right) ,$$

$$\sigma_2 \approx -\left(\zeta_2 \omega_2 - \frac{\omega_1}{2\omega_2} C_{21}\right) . \qquad (22.214)$$

Similarly, the new eigenfrequencies become

$$\begin{cases} \omega_1'^2 \approx \omega_1^2 - \left[2\zeta_1^2 \omega_1^2 - (\zeta_1 + \zeta_2)\omega_2 C_{12} \right. \\ \qquad\qquad \left. + \dfrac{\omega_1}{2\omega_2} C_{21} C_{12}\right], \\ \omega_2'^2 \approx \omega_2^2 - \left[2\zeta_2^2 \omega_2^2 - (\zeta_1 + \zeta_2)\omega_1 C_{21} \right. \\ \qquad\qquad \left. + \dfrac{\omega_2}{2\omega_1} C_{21} C_{12}\right]. \end{cases}$$
$$(22.215)$$

Forced Vibrations

The transfer function between the excitation force and the bar displacement is now examined. Equation (22.203) is modified through the introduction of a force term $F(x_0, t)$ at point x_0

$$\rho_s S \frac{\partial^2 \xi}{\partial t^2} = ES \frac{\partial^2 \xi}{\partial x^2} - S p(L, t)\delta(x - L)$$
$$+ F(x_0, t)\delta(x - x_0)$$
$$\text{for} \quad 0 \le x \le L$$
$$\text{and} \quad 0 \le x_0 \le L . \qquad (22.216)$$

Using the same modal projection as in the previous section, we find

$$\ddot{q}_n + 2\zeta_n \omega_n \dot{q}_n + \omega_n^2 q_n$$
$$= \sum_{m \ne n} C_{nm} \dot{q}_m + F(x_0, t) \frac{\phi_n(x_0)}{m_n} \qquad (22.217)$$

or, equivalently, using Laplace transforms, as

$$\tilde{q}_n(s) = H_n(s)\tilde{F}(x_0, s) + \sum_{m \ne n} K_{nm}(s)\tilde{q}_m(s) \quad (22.218)$$

with

$$H_n(s) = \frac{\phi_n(x_0)}{m_n(s^2 + 2\zeta_n \omega_n s + \omega_n^2)}$$

and

$$K_{nm}(s) = \frac{s C_{nm}}{s^2 + 2\zeta_n \omega_n s + \omega_n^2} . \qquad (22.219)$$

Finally, the displacement is

$$\tilde{\xi}(x, s) = \sum_n \tilde{q}_n(s)\phi_n(x)$$

$$= \tilde{F}(x_0, s) \sum_n \phi_n(x)H_n(s)$$

$$+ \sum_n \phi_n(x) \sum_{m \neq n} K_{nm}(s)\tilde{q}_m(s) . \quad (22.220)$$

Matrix Formulation. Equation (22.218) can then be rewritten (removing the tilde from the Laplace transforms, for convenience) as

$$\begin{pmatrix} 1 & -K_{12} & \dots & -K_{1n} \\ -K_{21} & 1 & \dots & -K_{2n} \\ \dots & \dots & \dots & \dots \\ -K_{n1} & -K_{n2} & \dots & 1 \end{pmatrix} \begin{pmatrix} q_1 \\ q_2 \\ \dots \\ q_n \end{pmatrix} = F \begin{pmatrix} H_1 \\ H_2 \\ \dots \\ H_n \end{pmatrix}$$

$$(22.221)$$

which can be formulated in the more compact form

$$\mathbf{K}Q = F\mathbf{H} . \quad (22.222)$$

The displacement of the bar is

$$\xi = Q^{\mathrm{t}}.\boldsymbol{\phi} = Q.\boldsymbol{\phi}^{\mathrm{t}} = (\mathbf{K}^{-1}\mathbf{H})^{\mathrm{t}}.\boldsymbol{\phi}F = (\mathbf{K}^{-1}\mathbf{H}).\boldsymbol{\phi}^{\mathrm{t}}F \quad (22.223)$$

In some applications, it is interesting to write (22.218) in a form that allows the characteristic equation to be determined immediately. In this case, (22.221) becomes

$$\begin{pmatrix} s^2 + \omega_1^2 \\ +2\zeta_1\omega_1 s & -sC_{12} & \dots & -sC_{1n} \\ -sC_{21} & s^2 + \omega_2^2 \\ +2\zeta_2\omega_2 s & \dots & -sC_{2n} \\ \dots & \dots & \dots & \dots \\ -sC_{n1} & -sC_{n2} & \dots & s^2 + \omega_n^2 \\ +2\zeta_n\omega_n s \end{pmatrix} \begin{pmatrix} q_1 \\ q_2 \\ \dots \\ q_n \end{pmatrix}$$

$$= F \begin{pmatrix} \beta_1 \\ \beta_2 \\ \dots \\ \beta_n \end{pmatrix} , \quad (22.224)$$

where $\beta_n = \dfrac{\phi_n(x_0)}{m_n}$. The equivalent matrix notation is

$$\mathbf{C}Q = F\boldsymbol{\beta} . \quad (22.225)$$

The displacement of the bar is given by

$$\xi = (\mathbf{C}^{-1}\boldsymbol{\beta})^{\mathrm{t}}.\boldsymbol{\phi}F = (\mathbf{C}^{-1}\boldsymbol{\beta}).\boldsymbol{\phi}^{\mathrm{t}}F . \quad (22.226)$$

Inversion of the Matrix **C.** Finding explicit solutions for the generalized displacements q_i in (22.224) requires inversion of the matrix **C**. An example is given below for a subsystem of order two, where we write for convenience $D_n = s^2 + 2\zeta_n\omega_n s + \omega_n^2$. We obtain easily

$$q_1 = \frac{\beta_1 D_2 + sC_{12}\beta_2}{D_1 D_2 - s^2 C_{12}C_{21}} F$$

and

$$q_2 = \frac{\beta_2 D_1 + sC_{21}\beta_1}{D_1 D_2 - s^2 C_{12}C_{21}} F . \quad (22.227)$$

Or, using the $(\mathbf{H}, \mathbf{K})$ formulation

$$q_1 = \frac{H_1 + K_{12}H_2}{1 - K_{12}K_{21}} F = L_1 F$$

and

$$q_2 = \frac{H_2 + K_{21}H_1}{1 - K_{12}K_{21}} F = L_2 F \quad (22.228)$$

from which the displacement ξ can be derived. The coupling appears in (22.224) through the fact that q_1 is not zero, even if β_1 vanishes. In other words, one can excite vibrations at ω_n even if the structure is excited at a node of the associated in vacuo mode. The new eigenfrequencies and damping factors modified by the coupling are now given by the roots of the denominator $D_1 D_2 - s^2 C_{12}C_{21}$.

Orthogonalization of the Matrix **C.** The question is now to study whether one can find an appropriate basis for decoupling the system. Approximate formulations in the case of weak coupling are derived below. We start with a 2-DOF system before generalization. The matrix **C** is

$$\begin{pmatrix} D_1 & -sC_{12} \\ -sC_{21} & D_2 \end{pmatrix}$$

with

$$D_i = s^2 + 2\zeta_i\omega_i s + \omega_i^2 . \quad (22.229)$$

The corresponding diagonal matrix $\boldsymbol{\Lambda}$ is written

$$\begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} , \quad (22.230)$$

where the λ_i are solutions of the equation

$$\begin{vmatrix} D_1 - \lambda & -sC_{12} \\ -sC_{21} & D_2 - \lambda \end{vmatrix}$$

$$= (D_2 - \lambda)(D_1 - \lambda) - s^2 C_{12}C_{21} = 0 . \quad (22.231)$$

Denoting by e_i the corresponding eigenvectors and $\mathbf{T} = (e_1 \ e_2)$, then we have the following matrix equations

$$\mathbf{T}\boldsymbol{\Lambda} = \mathbf{C}\mathbf{T} \quad \Leftrightarrow \quad \boldsymbol{\Lambda} = \mathbf{T}^{-1}\mathbf{C}\mathbf{T} . \tag{22.232}$$

In the general case, the λ_i are given by

$$\lambda_{1,2} = \frac{1}{2}\left[D_1 + D_2 \pm \sqrt{(D_1 - D_2)^2 + 4s^2 C_{12} C_{21}} \right]. \tag{22.233}$$

Weak–Coupling Approximation. It is convenient to define the nondimensional coupling parameter

$$\varepsilon = \frac{C_{12} C_{21}}{D_2 - D_1}$$
$$= \frac{C_{12} C_{21}}{\omega_2^2 - \omega_1^2 + 2s(\zeta_2 \omega_2 - \zeta_1 \omega_1)} \tag{22.234}$$

so that, for $\varepsilon \ll 1$, the eigenvalues of $\mathbf{C}$ can be written to first-order approximation as

$$\lambda_1 = D_1 - \varepsilon s^2 ; \quad \lambda_2 = D_2 + \varepsilon s^2 . \tag{22.235}$$

This approximation is justified if the C_{ij} are small, as in the case of a light fluid, or if the in vacuo eigenfrequencies ω_i and ω_j are not too close to each other (Sect. 22.6.1). In this case, the previously defined matrices become

$$\mathbf{T} = \begin{pmatrix} 1 & -\dfrac{\varepsilon s}{C_{21}} \\ \dfrac{\varepsilon s}{C_{12}} & 1 \end{pmatrix} \Rightarrow$$

$$\mathbf{T}^{-1} = \frac{C_{12} C_{21}}{C_{12} C_{21} + \varepsilon^2 s^2}$$
$$\times \begin{pmatrix} 1 & \dfrac{\varepsilon s}{C_{21}} \\ -\dfrac{\varepsilon s}{C_{12}} & 1 \end{pmatrix} . \tag{22.236}$$

Defining further the vectors $\boldsymbol{\gamma} = \mathbf{T}^{-1}\boldsymbol{\beta}$ and $\boldsymbol{R} = \mathbf{T}^{-1}\boldsymbol{Q}$, (22.225) and (22.226) can be rewritten as

$$\boldsymbol{\Lambda R} = F\boldsymbol{\gamma} \Rightarrow$$
$$\xi = \mathbf{T}\boldsymbol{\Lambda}^{-1}\boldsymbol{\gamma}\,\boldsymbol{\phi}^{\mathrm{t}}F . \tag{22.237}$$

Here, we have

$$\boldsymbol{\Lambda}^{-1} = \frac{1}{D_1 D_2 - s^2 C_{12} C_{21}}$$
$$\times \begin{bmatrix} D_2 + \varepsilon s^2 & 0 \\ 0 & D_1 - \varepsilon s^2 \end{bmatrix} , \tag{22.238}$$

$$\boldsymbol{\gamma} = \frac{C_{12} C_{21}}{C_{12} C_{21} + \varepsilon^2 s^2} \begin{pmatrix} \beta_1 + \dfrac{\varepsilon s}{C_{21}}\beta_2 \\ \beta_2 - \dfrac{\varepsilon s}{C_{12}}\beta_1 \end{pmatrix}$$

and

$$\boldsymbol{R} = \frac{C_{12} C_{21}}{C_{12} C_{21} + \varepsilon^2 s^2} \begin{pmatrix} q_1 + \dfrac{\varepsilon s}{C_{21}}q_2 \\ q_2 - \dfrac{\varepsilon s}{C_{12}}q_1 \end{pmatrix} . \tag{22.239}$$

To a first-order approximation, it can be shown that

$$\boldsymbol{\Lambda}^{-1} \approx \boldsymbol{\Lambda}_0^{-1} + \varepsilon \boldsymbol{\Lambda}_{\mathrm{c}}^{-1} , \tag{22.240}$$

where $\boldsymbol{\Lambda}_0^{-1}$ is the in vacuo diagonal matrix given by

$$\boldsymbol{\Lambda}_0^{-1} = \begin{pmatrix} \dfrac{1}{D_1} & 0 \\ 0 & \dfrac{1}{D_2} \end{pmatrix} \tag{22.241}$$

and $\boldsymbol{\Lambda}_{\mathrm{c}}^{-1}$ is the coupling diagonal matrix given by

$$\boldsymbol{\Lambda}_{\mathrm{c}}^{-1} = \begin{pmatrix} \left(\dfrac{s}{D_1}\right)^2 & 0 \\ 0 & -\left(\dfrac{1}{D_2}\right)^2 \end{pmatrix} . \tag{22.242}$$

This result is of particular interest for computing the perturbation due to air loading of all significant variables of the system.

Generalization. Equation (22.235) can be generalized to n coupled modes. In this case, the eigenvalues become

$$\lambda_i = D_i + \varepsilon_i$$
$$\text{with} \quad \varepsilon_i = -s^2 \sum_j \frac{C_{ij} C_{ji}}{D_j - D_i}$$
$$\text{and} \quad 1 \le j \le n$$
$$\text{and} \quad j \ne i . \tag{22.243}$$

Approximate Expressions for Displacement and Mode Shapes. From the above results, we can now find a first-order approximate expression for the bar displacement ξ. As in the previous sections, we start with the simple example of a 2-DOF system. Let us write first the in vacuo displacement

$$\xi_0 = \phi_{10} q_{10} + \phi_{20} q_{20} . \tag{22.244}$$

N.B. The notation ϕ_{i0}, denotes the eigenmode in vacuo and should not be confused with $\phi_i(x_0)$, which denotes

the value of this eigenmode at one particular point of the structure. For the structure vibrating in air, the displacement becomes

$$\xi = \phi_{10} q_1 + \phi_{20} q_2 \ . \tag{22.245}$$

From (22.226) one can derive a first-order approximation for the bar displacement

$$\xi = \phi_{10} \left(q_{10} + \frac{sC_{12}}{D_1} q_{20} \right) + \phi_{20} \left(q_{20} + q_{10} \frac{sC_{21}}{D_2} \right) \ . \tag{22.246}$$

Operating Deflexion Shapes. Equation (22.246) can be rewritten

$$\xi = q_{10} \left(\phi_{10} + \frac{sC_{21}}{D_2} \phi_{20} \right)$$
$$+ q_{20} \left(\phi_{20} + \phi_{10} \frac{sC_{12}}{D_1} \right)$$

$$\text{with} \quad q_{i0} = \frac{\phi_{i0}}{m_i D_i} F \ . \tag{22.247}$$

In experiments on structures, sinusoidal excitation is often used. Imagine that we apply a sudden harmonic force $F(t) = H(t) \sin \omega t$ at time $t = 0$ to the structure, with excitation location and frequency such that q_{20} is negligible compared to q_{10}. $H(t)$ is the Heaviside function. In this case, the spatial pattern of the structure is given by

$$\phi_1 = \phi_{10} + \phi_{20} \frac{sC_{21}}{D_2} \ . \tag{22.248}$$

Because of the time dependence of the second term (through the Laplace variable s), the spatial shape evolves with time. Here, we can use the Laplace limit theorem, which states that the value of $\phi(t)$ as time tends to infinity is given by the product of $s\phi(s)$ as s tends to zero. Since $s^2 C_{12}/D_2$ tends to zero as s tends to zero, the second term on the right-hand side of (22.248) vanishes after some time. Calculating the inverse Laplace transform shows that this decay time is of the order of the magnitude of the decay time of the second structural mode. After this transient regime, the spatial shape is nearly equal to the spatial shape in vacuo ϕ_{10}. In the more general case, (22.247) shows that F excites both q_{10} and q_{20}. After a transient regime, the bar displacement then finally converges to

$$\xi(\omega, x) = \left[\frac{\phi_{10}\beta_1}{D_1(\mathrm{i}\omega)} + \frac{\phi_{20}\beta_2}{D_2(\mathrm{i}\omega)} \right] \ . \tag{22.249}$$

The quantity between in square brackets is called the operating deflexion shape (ODS) of the structure at

frequency ω. Since it is very difficult in practice to excite a single q_{i0}, the ODS describes the multi-mode shapes that are observed for sinusoidal excitation of structures.

State–Space Formulation
The transfer function formulation is convenient if the system is initially at rest, and for time-invariant systems. For other applications, such as sound control, it is useful to express the results in terms of state-space variables [22.26–29]. In most cases, the mechanical state of the system is given by the position and the velocity of the DOFs. Since the unloaded structure is described by its eigenmodes ϕ_n, all useful information about the state of the system is contained in the modal participation factors q_n and in their first derivatives with time $\dot{q}_n$. This allows us to rewrite the equations for a 2-DOF coupled system as follows

$$\frac{\mathrm{d}}{\mathrm{d}t} \begin{pmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\omega_1^2 & 0 & -2\zeta_1\omega_1 & C_{12} \\ 0 & -\omega_2^2 & C_{21} & -2\zeta_2\omega_2 \end{pmatrix}$$
$$\times \begin{pmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \beta_1 \\ \beta_2 \end{pmatrix} F \ , \tag{22.250}$$

where

$$X_1 = q_1 \ ; \ \ X_2 = q_2 \ ; \ \ X_3 = \dot{q}_1 \ ; \ \ X_4 = \dot{q}_2 \ . \tag{22.251}$$

Equation (22.250) can then be formulated equivalently as

$$\dot{X} = \mathbf{A}X + \mathbf{B}F \ , \tag{22.252}$$

where F is the *input* and X is the *state vector*. The output Y depends on the investigated mechanical problem. If we decide, for example, to investigate the displacement, then we can write for the *output*

$$Y = \begin{pmatrix} \phi_1 & \phi_2 & 0 & 0 \end{pmatrix}^{\mathrm{t}} X = \mathbf{\Gamma} X \ . \tag{22.253}$$

Equations (22.252) and (22.253) are general expressions for a linear system expressed in terms of state-space variables.

Remark 1. The representation presented in (22.250) is not unique. Selecting, for example

$$X_1 = q_1; \ \ X_2 = \dot{q}_1; \ \ X_3 = q_2; \ \ X_4 = \dot{q}_2 \tag{22.254}$$

leads to different values for $\mathbf{A}$ and $\mathbf{B}$.
Fig. 22.14 Longitudinally vibrating bar coupled to a semi-infinite tube

Remark 2. Denoting by **M**, **R**, and **K**, the mass, resistance and stiffness matrices, respectively, of the 2-DOF system, the matrix **A** can be rewritten more generally using submatrices as

$$\mathbf{A} = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{R} \end{pmatrix}, \qquad (22.255)$$

where **I** is the identity matrix.

22.5.2 Energetic Approach to Structural–Acoustic Systems

Two–DOF System

We now consider a 2-DOF structure coupled to a radiating wave, but now include damping terms in the structure r_1 and r_2, to compare the power dissipated in vacuo and air, respectively. The damping terms r_{a1} and r_{a2} are due to radiation. Modal masses and stiffnesses are written explicitly, so that comparison with the case of a single oscillator becomes easier. We can then write

$$\begin{cases} m_1\ddot{q}_1 + (r_1 + r_{a1})\dot{q}_1 + k_1 q_1 + \gamma\dot{q}_2 = \phi_1(x_0)F , \\ m_2\ddot{q}_2 + (r_2 + r_{a2})\dot{q}_2 + k_1 q_2 + \gamma\dot{q}_1 = \phi_2(x_0)F , \end{cases}$$
$$(22.256)$$

where $\gamma = -C_{12}m_1 = -C_{21}m_2$. In what follows, we use the notations

$$\begin{cases} 2\zeta_1\omega_1 & = \frac{r_1 + r_{a1}}{m_1} ; \\ 2\zeta_{10}\omega_1 & = \frac{r_1}{m_1} ; \\ \omega_1^2 & = \frac{k_1}{m_1} \\ 2\zeta_2\omega_2 & = \frac{r_2 + r_{a2}}{m_1} ; \\ 2\zeta_{20}\omega_2 & = \frac{r_2}{m_2} ; \\ \omega_2^2 & = \frac{k_2}{m_2} \end{cases} \qquad (22.257)$$

to make a distinction between the damping factors in air and in vacuo. The force F is applied at point $x = x_0$ so that the mechanical input power is given by

$$p_m(t) = F\frac{d\xi}{dt}(x_0, t) = F[\phi_1(x_0)\dot{q}_1 + \phi_2(x_0)\dot{q}_2].$$
$$(22.258)$$

Using (22.256) allows $p_m(t)$ to be written as

$$\begin{aligned} p_m(t) = & m_1\ddot{q}_1\dot{q}_1 + (r_1 + r_{a1})\dot{q}_1^2 + k_1 q_1\dot{q}_1 \\ & + 2\gamma\dot{q}_1\dot{q}_2 \\ & + m_2\ddot{q}_2\dot{q}_2 + (r_2 + r_{a2})\dot{q}_2^2 + k_2 q_2\dot{q}_2 . \end{aligned}$$
$$(22.259)$$

Integrating $p_m(t)$ over a duration T and removing the conservative energy terms yields the mean input power

$$\begin{aligned} \mathcal{P}_m(T) = & \frac{1}{T}\int_0^T (r_1 + r_{a1})\dot{q}_1^2 + (r_2 + r_{a2})\dot{q}_2^2 \\ & + 2\gamma\dot{q}_2\dot{q}_1 \, dt . \end{aligned}$$
$$(22.260)$$

The input power is now seen as the sum of three terms:

1. The mean power

$$\mathcal{P}_s(T) = \frac{1}{T}\int_0^T r_1\dot{q}_1^2 + r_2\dot{q}_2^2 \, dt$$

   dissipated in the structure

2. The mean acoustic power

$$\mathcal{P}_a(T) = \frac{1}{T}\int_0^T r_{a1}\dot{q}_1^2 + r_{a2}\dot{q}_2^2 \, dt$$

   radiated in the air

3. The mean coupling power

$$\mathcal{P}_c(T) = \frac{2}{T}\int_0^T \gamma\dot{q}_2\dot{q}_1 \, dt$$

   due to the exchange of energy between the two oscillators via the fluid.

Let us denote the steady-state excitation frequency by ω. The transient regime is neglected, and the integration time T is supposed to be taken equal to an integer multiple of the period $T = n\tau = n2\pi/\omega$. The mean input power can then be written as

$$\begin{aligned} \mathcal{P}_m = & \frac{1}{2}\Big[(r_1 + r_{a1})|\dot{q}_1|^2 \\ & + (r_2 + r_{a2})|\dot{q}_2|^2 + 2\gamma|\dot{q}_2||\dot{q}_1|\Big]. \end{aligned} \quad (22.261)$$

$\mathcal{P}_m$ can be written in matrix form. Writing $\dot{Q} = \begin{pmatrix} \dot{q}_1 \\ \dot{q}_2 \end{pmatrix}$,

$$\mathbf{R}_s = \begin{pmatrix} r_1 & 0 \\ 0 & r_2 \end{pmatrix} \text{ and } \mathbf{R}_a = \begin{pmatrix} r_{a1} & \gamma \\ \gamma & r_{a2} \end{pmatrix}, \text{ we have}$$

$$\mathscr{P}_\mathrm{m} = \dot{\boldsymbol{Q}}^\mathrm{H}\,[\mathbf{R}_\mathrm{s} + \mathbf{R}_\mathrm{a}]\,\dot{\boldsymbol{Q}}\;, \tag{22.262}$$

where $\dot{\boldsymbol{Q}}^\mathrm{H}$ is the Hermitian conjugate (conjugate transpose) of $\dot{\boldsymbol{Q}}$.

Generalization
The mean power for a multiple-DOF system is written

$$\mathscr{P}_\mathrm{m}(T) =$$
$$\frac{1}{T}\int\limits_0^T \left[\sum_{i=1}^n (r_i + r_{ai})\dot{q}_i^2 + \sum_{i=1}^n \sum_{\substack{j=1\\j\neq i}}^n \gamma_{ij}\dot{q}_i\dot{q}_j \right]\mathrm{d}t$$

with $\quad \gamma_{ij} = -m_i C_{ij}\;.$ \hfill (22.263)

This mean power can be written in the same form as (22.262), where the resistance matrix is defined as

$$\begin{pmatrix}
r_1 + r_{a1} & \cdots & \gamma_{1i} & \cdots & \gamma_{1j} & \cdots & \gamma_{1n}\\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots\\
\gamma_{i1} & \cdots & r_i + r_{ai} & \cdots & \gamma_{ij} & \cdots & \gamma_{in}\\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots\\
\gamma_{j1} & \cdots & \gamma_{ji} & \cdots & r_j + r_{aj} & \cdots & \gamma_{jn}\\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots\\
\gamma_{n1} & \cdots & \gamma_{ni} & \cdots & \gamma_{nj} & \cdots & r_n + r_{an}
\end{pmatrix}.$$
\hfill (22.264)

Remark. The resistance matrix can again be viewed as the sum of a structural resistance matrix $\mathbf{R}_\mathrm{s}$ and an acoustical resistance matrix $\mathbf{R}_\mathrm{a}$. This leads to the expression for the mean acoustic power

$$\mathscr{P}_\mathrm{a} = \dot{\boldsymbol{Q}}^\mathrm{H}\mathbf{R}_\mathrm{a}\dot{\boldsymbol{Q}} \tag{22.265}$$

and acoustical efficiency

$$\eta_\mathrm{m} = \frac{\dot{\boldsymbol{Q}}^\mathrm{H}\,[\mathbf{R}_\mathrm{a}]\,\dot{\boldsymbol{Q}}}{\dot{\boldsymbol{Q}}^\mathrm{H}\,[\mathbf{R}_\mathrm{s} + \mathbf{R}_\mathrm{a}]\,\dot{\boldsymbol{Q}}} \tag{22.266}$$

which generalizes (22.32). Note that we have assumed that the structural resistance matrix $\mathbf{R}_\mathrm{s}$ is diagonal, which is usually a reasonable assumption for lightly damped structures. However, strong structural damping can also be the source of intermodal coupling. In this case, $\mathbf{R}_\mathrm{s}$ is no longer diagonal, but the general results expressed in (22.262) and (22.266) remain valid. A comparison of efficiencies between the cases of light and heavy fluids, respectively has been conducted by *Rumerman* [22.30].

Radiation Filter
Because $\mathbf{R}_\mathrm{a}$ is real, symmetric and positive definite, we can write this matrix in the form

$$\mathbf{R}_\mathrm{a} = \mathbf{P}^\mathrm{t}\boldsymbol{\Omega}\mathbf{P}\;, \tag{22.267}$$

where $\boldsymbol{\Omega}$ is a diagonal matrix [22.25]. As a consequence, the acoustic power becomes, removing for simplicity the integration time T,

$$P_\mathrm{a} = \boldsymbol{b}^\mathrm{H}\boldsymbol{\Omega}\boldsymbol{b}$$

where

$$\boldsymbol{b} = \mathbf{P}\dot{\boldsymbol{Q}}\;. \tag{22.268}$$

This can be written explicitly as

$$P_\mathrm{a} = \sum_n \Omega_n |b_n|^2\;. \tag{22.269}$$

Equation (22.269) shows that, defining the appropriate basis, the acoustic power can be expressed as a sum of quadratic terms, thus removing the cross products between the q_i in the previous subsections. Another interesting consequence of the properties of $\mathbf{R}_\mathrm{a}$ is that the acoustic power can be decomposed using the Cholesky method. This leads to the expression

$$P_\mathrm{a} = \dot{\boldsymbol{Q}}^\mathrm{H}\mathbf{R}_\mathrm{a}\dot{\boldsymbol{Q}}$$
$$= \dot{\boldsymbol{Q}}^\mathrm{H}\mathbf{G}^\mathrm{H}\mathbf{G}\dot{\boldsymbol{Q}} = \boldsymbol{z}^\mathrm{H}\boldsymbol{z} = \sum_n |z_n|^2\;, \tag{22.270}$$

where, by comparison with (22.269), the vector $\boldsymbol{z}(\omega)$ can be viewed as the output of a set of radiation filters whose transfer functions $\mathbf{G}(\omega)$ are given by

$$\mathbf{G}(\omega) = \sqrt{\boldsymbol{\Omega}(\omega)}\mathbf{P}(\omega) \tag{22.271}$$

with input vector $\dot{\boldsymbol{Q}}$, so that

$$\boldsymbol{z} = \mathbf{G}\dot{\boldsymbol{Q}}\;. \tag{22.272}$$

Impulsively Excited Structure: Total Radiated Energy
For an impulsively excited structure, the total radiated energy is given by

$$E_\mathrm{T} = \int\limits_0^\infty \dot{\boldsymbol{Q}}^\mathrm{H}\mathbf{R}_\mathrm{a}\dot{\boldsymbol{Q}}\,\mathrm{d}\omega = \int\limits_0^\infty \boldsymbol{z}^\mathrm{H}(\omega)\boldsymbol{z}(\omega)\,\mathrm{d}\omega \tag{22.273}$$

which, by Parseval's theorem, is equivalent to [22.31]

$$E_\mathrm{T} = \int\limits_0^\infty \boldsymbol{z}^\mathrm{t}(t)\boldsymbol{z}(t)\,\mathrm{d}t\;. \tag{22.274}$$

State-Space Analysis

The interest of formulating structural acoustic coupling in terms of state-space variables is now emphasized using an example. Denoting by r the internal state of filter G with input X (or $\dot{Q}$) and output z, we can use a state-space realization of the form

$$\begin{cases} \dot{r} = \mathbf{A}_G r + \mathbf{B}_G X \,, \\ z = \mathbf{C}_G r + \mathbf{D}_G X \,. \end{cases} \tag{22.275}$$

Combining these equations with the equations of motion of the structure gives

$$\begin{pmatrix} \dot{X} \\ \dot{r} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{B}_G & \mathbf{A}_G \end{pmatrix} \begin{pmatrix} X \\ r \end{pmatrix} + \begin{pmatrix} B \\ 0 \end{pmatrix} F \tag{22.276}$$

with the output

$$z = \begin{pmatrix} \mathbf{D}_G & \mathbf{C}_G \end{pmatrix} \begin{pmatrix} X \\ r \end{pmatrix} \,. \tag{22.277}$$

If, for example, the purpose is to minimize the total energy radiated by a source, then the cost function can be defined as

$$\mathcal{C}_f = \frac{\int_0^\infty z^t(t) z(t)\, \mathrm{d}t}{\max\{E_T\}} \,. \tag{22.278}$$

22.5.3 Oscillator Coupled to a Tube of Finite Length

Presentation of the Model

The purpose of this section is to present the fundamental concepts for a vibrating structure coupled to an acoustic cavity. As a simple example, we consider a single-DOF oscillator coupled to a 1-D tube of cross-sectional area S and finite length L loaded at its end $x = L$ by an impedance Z_L, defined here as the ratio between the pressure and acoustic velocity. The selected structure is a mechanical oscillator of mass M, stiffness $K = M\omega_0^2$ and dashpot $R = 2M\zeta_0\omega_0$ driven by a force $T(0, t)$ at
Fig. 22.15 Single-DOF mechanical oscillator coupled to a finite loaded tube

position $x = 0$ (Fig. 22.15). The amplitude of the motion of the mass is assumed to be small, so that the acoustic velocity $v(0, t)$ is equal to the mechanical velocity $\dot{\xi}(t)$. We assume lossless wave propagation in the tube itself. The set of equations for the model is written

$$\begin{cases} \dfrac{1}{c^2} \dfrac{\partial^2 p}{\partial t^2} = \dfrac{\partial^2 p}{\partial x^2} & \text{for } 0 < x < L\,; \\ \rho \dfrac{\partial v}{\partial t} = -\dfrac{\partial p}{\partial x} \\ p(L, s) = Z_L v(L, s)\,; \quad v(0, t) = \dot{\xi}(t) \\ M\left(\ddot{\xi} + 2\zeta_0\omega_0\dot{\xi} + \omega_0^2\xi\right) = -Sp(0, t) + T(t) \end{cases} \tag{22.279}$$

Mass Displacement

Using the Laplace transforms, we obtain

$$\begin{cases} p(x, s) = \exp\left(-\dfrac{sx}{c}\right) F(s) + \exp\left(\dfrac{sx}{c}\right) G(s)\,, \\ v(x, s) = \dfrac{1}{\rho c}\left[\exp\left(-\dfrac{sx}{c}\right) - \exp\left(\dfrac{sx}{c}\right) G(s)\right], \end{cases} \tag{22.280}$$

where $F(s)$ and $G(s)$ are two functions to be determined. The boundary condition at $x = L$ gives

$$G(s) = F(s)\frac{Z_L - \rho c}{Z_L + \rho c} \exp\left(-\frac{2Ls}{c}\right) \,. \tag{22.281}$$

The continuity of the displacement at position $x = 0$ yields

$$\begin{aligned} v(0, s) &= \frac{1}{\rho c} F(s)\left[1 - \frac{Z_L - \rho c}{Z_L + \rho c} \exp\left(-\frac{2Ls}{c}\right)\right] \\ &= s\xi(s)\,. \end{aligned} \tag{22.282}$$

Finally, the equation governing the oscillator motion becomes

$$\begin{aligned} &\left(s^2 + 2\zeta_0\omega_0 s + \omega_0^2\right)\xi(s) \\ &= \frac{T(s)}{M} - s\frac{R_a}{M}\frac{z_L + \tanh\left(\frac{sL}{c}\right)}{1 + z_L \tanh\left(\frac{sL}{c}\right)}\xi(s) \end{aligned} \tag{22.283}$$

with

$$z_L = \frac{Z_L}{\rho c} \quad \text{and} \quad R_a = \rho c S \,. \tag{22.284}$$

Equation (22.283) shows that, due to the loading of the oscillator by the finite tube, the damping term $2\zeta_0\omega_0$ becomes

$$2\zeta_0\omega_0 + 2\zeta_a\omega_0 Z(s)\,, \tag{22.285}$$

where

$$\frac{R_a}{M} = 2\zeta_a\omega_0$$

and

$$Z(s) = \frac{z_L + \tanh\left(\frac{sL}{c}\right)}{1 + z_L \tanh\left(\frac{sL}{c}\right)} \tag{22.286}$$

so that we can write

$$\xi(s) = \frac{T(s)}{M} \frac{1}{s^2 + 2\omega_0 \left[\zeta_0 + \zeta_a \, Z(s)\right] s + \omega_0^2} . \tag{22.287}$$

$F(s)$ is derived from (22.282)

$$F(s) = \frac{\rho c s \xi(s)}{\left[1 - \frac{z_L - 1}{z_L + 1} \exp\left(-\frac{2sL}{c}\right)\right]}$$

$$= \frac{\rho c s \xi(s) \exp\left(\frac{sL}{c}\right)(z_L + 1)}{2\left[z_L \sinh\left(\frac{sL}{c}\right) + \cosh\left(\frac{sL}{c}\right)\right]} . \tag{22.288}$$

Equations (22.280) and (22.281) yield the pressure in the tube

$$p(x, s) = \rho c s \xi(s)$$

$$\times \frac{z_L \cosh\left(\frac{s(x-L)}{c}\right) - \sinh\left(\frac{s(x-L)}{c}\right)}{\cosh\left(\frac{sL}{c}\right) + z_L \sinh\left(\frac{sL}{c}\right)} . \tag{22.289}$$

The pressure $p(0, s)$ acting on the oscillator is

$$p(0, s) = \rho c s \xi(s) \frac{z_L \cosh\left(\frac{sL}{c}\right) + \sinh\left(\frac{sL}{c}\right)}{\cosh\left(\frac{sL}{c}\right) + z_L \sinh\left(\frac{sL}{c}\right)}$$

$$= \rho c s \xi(s) Z(s) . \tag{22.290}$$

Taking the inverse Laplace transform of (22.289) and (22.287) yields the pressure in the tube and the mass displacement in the time domain.

Discussion of Z(s). Several interesting limiting cases can be examined:

- If the load at the end of the tube at $x = L$ is such that $Z_L = \rho c$, then $G(s) = 0$ and $F(s) = \rho c s \xi(s)$. This means that when the tube is loaded by its characteristic impedance there is no returning wave. In this case $Z(s) = 1$, and the only effect of the tube is to increase the damping of the oscillator, which becomes equal to $\xi_0 + \xi_a$. The increase of damping is entirely due to radiation and is, of course, identical to that obtained for the 1-DOF approximation of the vibrating bar loaded by the semi-infinite tube presented in Sect. 22.5.1.

- If the tube is closed at $x = L$, then z_L tends to ∞ so that $Z(s) = 1/\tanh(sL/c)$. If, in addition, the length L of the tube is sufficiently small so that we can make the approximation $\tanh(sL/c) \approx sL/c$, then the displacement can be written

$$\xi(s) = \frac{T(s)}{M} \frac{1}{s^2 + 2\omega_0\zeta_0 s + \omega_0^2 + \frac{2\omega_0\zeta_a c}{L}} . \tag{22.291}$$

This is equivalent to the tube acting as an added stiffness $K_a = 2\omega_0 M \zeta_a c/L$, which increases the eigenfrequency of the mechanical oscillator.

- If the tube is open at $x = L$ and if we neglect radiation, then $z_L = 0$ and $Z(s) = \tanh(sL/c)$. For a small tube, or more generally for $sL/c \ll 1$, we obtain

$$\xi(s) = \frac{T(s)}{M} \frac{1}{s^2 + 2\omega_0\zeta_0 s + \omega_0^2 + \frac{2\omega_0\zeta_a s^2 L}{c}} . \tag{22.292}$$

so that the tube acts as an added mass $M_a = 2M\omega_0\zeta_a L/c$, which decreases the eigenfrequency of the oscillator.

In the most general case, the coupling between a structure and a cavity yields new vibroacoustic (or structural–acoustic) modes that differ from the in vacuo modes of the structure and from the cavity modes with rigid walls [22.32]. For the present example, assuming light damping, these modes are the poles of $\xi(\omega)$, which are obtained from the equation

$$-\omega^2 + \omega_0^2 - 2\zeta_a\omega_0\omega \, \text{Im}[Z(\omega)] = 0 . \tag{22.293}$$

For a lossless tube closed at $x = L$, the eigenmodes are the solutions of

$$\left(\omega_0^2 - \omega^2\right) \tan\frac{\omega L}{c} + 2\zeta_a\omega_0\omega = 0 . \tag{22.294}$$

For high frequencies, i. e., for $\omega \gg \omega_0$, the displacement of the oscillator tends to zero and (22.294) reduces to

$$\tan\frac{\omega L}{c} \approx 0 . \tag{22.295}$$

In this regime, the eigenfrequencies tend to those of the tube closed at both ends.

22.5.4 Two–Dimensional Elasto–Acoustic Coupling

We now turn to the case of 2-D systems. First, the case of an infinite isotropic plate is examined to introduce the concept of critical frequency. The presentation used the wave formalism and is inspired from *Filippi* et al., [22.33] and *Lesueur* [22.34]. We then consider the case of a finite plate using the wavenumber Fourier-transform method [22.35, 36].

Infinite Isotropic Plate. Critical Frequency

The case of thin plates submerged in compressible fluids and subjected to a transverse flexural displacement $\xi(x, y, t)$ is considered. Kirchhoff–Love approximations are assumed, so that shear stresses and rotary inertia are neglected. The infinite plate is located in the plane $z = 0$. In what follows, h is the plate thickness, E the Young's modulus, ν the Poisson's ratio and ρ_s the density of the plate. In the half-space $z < 0$, the pressure field is $p_1(x, y, z, t)$ in fluid 1 of density ρ_1 where the speed of sound is c_1. For $z > 0$, the pressure field is $p_2(x, y, z, t)$ in fluid 2 of density ρ_2 with speed of sound is c_2. The motion of the plate is harmonic with frequency ω. The equations of the problem are written in Cartesian coordinates:

- For $z < 0$

$$\nabla^2 p_1 + \frac{\omega^2}{c_1^2} p_1 = 0 \qquad (22.296)$$

with the continuity condition

$$\frac{\partial p_1}{\partial z}(x, y, 0-) = \omega^2 \rho_1 \xi(x, y). \qquad (22.297)$$

- For $z > 0$

$$\nabla^2 p_2 + \frac{\omega^2}{c_2^2} p_2 = 0 \qquad (22.298)$$

with the continuity condition

$$\frac{\partial p_2}{\partial z}(x, y, 0+) = \omega^2 \rho_2 \xi(x, y). \qquad (22.299)$$

- For $z = 0$, we have the loaded-plate equation

$$p_1(x, y, 0-) - p_2(x, y, 0+)$$
$$= -\omega^2 \rho_s h \xi(x, y) + D \nabla^4 \xi(x, y), \qquad (22.300)$$

where $D = \dfrac{Eh^3}{12(1 - \nu^2)}$.

General Solution. The continuity conditions yields the following equalities for the wavenumber components

$$k_x^1 = k_x^2 = k_x \quad \text{and} \quad k_y^1 = k_y^2 = k_y. \qquad (22.301)$$

Therefore the general solution of the problem can be written in the form

$$\begin{cases} p_1(x, y, z) &= \left(A_x^1 e^{-ik_x x} + B_x^1 e^{ik_x x}\right) \\ & \quad \left(A_y^1 e^{-ik_y y} + B_y^1 e^{ik_y y}\right) B_z^1 e^{ik_z^1 z}, \\ p_2(x, y, z) &= \left(A_x^2 e^{-ik_x x} + B_x^2 e^{ik_x x}\right) \\ & \quad \left(A_y^2 e^{-ik_y y} + B_y^2 e^{ik_y y}\right) A_z^2 e^{-ik_z^2 z}, \\ \xi(x, y) &= \left(C_x e^{-ik_x x} + D_x e^{ik_x x}\right) \\ & \quad \left(C_y e^{-ik_y y} + D_y e^{ik_y y}\right), \end{cases} \qquad (22.302)$$

where the constants A, B, C, and D depend on the initial conditions. The wavenumbers in both fluids are written

$$k_1^2 = \frac{\omega^2}{c_1^2} = k_x^2 + k_y^2 + k_z^{1\,2}$$

and

$$k_2^2 = \frac{\omega^2}{c_2^2} = k_x^2 + k_y^2 + k_z^{2\,2}. \qquad (22.303)$$

From (22.296–22.303) we derive the dispersion equation for the fluid-loaded plate

$$i\omega^2 \left(\frac{\rho_1}{\sqrt{\frac{\omega^2}{c_1^2} - k_x^2 - k_y^2}} + \frac{\rho_2}{\sqrt{\frac{\omega^2}{c_2^2} - k_x^2 - k_y^2}} \right)$$
$$+ D\left(k_x^2 + k_y^2\right)^2 - \omega^2 \rho_s h = 0 \qquad (22.304)$$

and the expressions for the pressure fields

$$\begin{cases} p_1 &= -\frac{i\omega\rho_1 c_1 k_1}{\sqrt{k_1^2 - k_x^2 - k_y^2}} \xi(x, y) e^{+i\sqrt{k_1^2 - k_x^2 - k_y^2}\, z} \\ & \text{with} \quad k_1 = \frac{\omega}{c_1}, \\ p_2 &= +\frac{i\omega\rho_2 c_2 k_2}{\sqrt{k_2^2 - k_x^2 - k_y^2}} \xi(x, y) e^{-i\sqrt{k_2^2 - k_x^2 - k_y^2}\, z} \\ & \text{with} \quad k_2 = \frac{\omega}{c_2}. \end{cases} \qquad (22.305)$$

Equation (22.305) shows that the acoustic waves can be either progressive or evanescent, depending on the values of the wavenumber components k_x and k_y.

Radiated Power. The mean acoustic power in the fluids are given by

$$
\begin{cases}
\langle \mathcal{P}_1 \rangle & = \int_{(S)} \frac{1}{2} \operatorname{Re} \left(p_1 \left[\mathrm{i}\omega\xi \right]^* \right) \mathrm{d}S \\
& = -\frac{1}{2}\omega^2 \rho_1 c_1 \int_{(S)} \operatorname{Re} \left(\frac{k_1}{\sqrt{k_1^2 - k_x^2 - k_y^2}} \right) \\
& \quad \times \left| \xi(x, y) \right|^2 \mathrm{d}S \,, \\
\langle \mathcal{P}_2 \rangle & = \int_{(S)} \frac{1}{2} \operatorname{Re} \left(p_2 \left[\mathrm{i}\omega\xi \right]^* \right) \mathrm{d}S \\
& = +\frac{1}{2}\omega^2 \rho_2 c_2 \int_{(S)} \operatorname{Re} \left(\frac{k_1}{\sqrt{k_2^2 - k_x^2 - k_y^2}} \right) \\
& \quad \times \left| \xi(x, y) \right|^2 \mathrm{d}S \,.
\end{cases}
\tag{22.306}
$$

The minus sign in $\langle \mathcal{P}_1 \rangle$ follows from the fact that the acoustic intensity vector in fluid 1 is oriented towards the negative direction of the z-axis. The radiation efficiencies σ_i of the plate in both fluids (with $i \in [1, 2]$) are defined as

$$
\sigma_i = \left| \frac{\langle \mathcal{P}_i \rangle}{\rho_i c_i \langle V^2 \rangle} \right|
$$

with

$$
\langle V^2 \rangle = \frac{1}{2} \int_{(S)} \omega^2 \left| \xi(x, y) \right|^2 \mathrm{d}S
\tag{22.307}
$$

which gives

$$
\sigma_i = \operatorname{Re} \left(\frac{k_i}{k_z^i} \right) .
\tag{22.308}
$$

These quantities represent the ratio between the amount of acoustic energy radiated in fluid and the total kinetic energy of the plate. Equation (22.308) shows that, if k_i^z is real, we have a propagating acoustic wave and the mean radiated power is different from zero. In the opposite case, the acoustic wave is evanescent and the mean radiated power is equal to zero.

Particular Case of Two Identical Fluids. One particular case of interest corresponds to the practical situation where the plate is coupled to the same fluid on both sides. In this case, the dispersion equation becomes

$$
2\mathrm{i}\omega^2 \frac{\rho}{\sqrt{k^2 - k_F^2}} - \omega^2 \rho_s h + D k_F^4 = 0 \,,
\tag{22.309}
$$

where $k_x = k_F \cos\theta$ and $k_y = k_F \sin\theta$. k_F is the flexural wavenumber coupled to the fluid, θ is the angle of propagation and $k = \omega/c$ is the acoustic wavenumber.

For a plate vibrating in vacuo, the flexural wavenumber is written

$$
k_{F0} = \left(\frac{\omega^2 \rho_s h}{D} \right)^{1/4}
\tag{22.310}
$$

so that the dispersion equation can be rewritten

$$
\frac{k_F^4}{k_{F0}^4} = 1 - \frac{2\mathrm{i}\rho}{\rho_s h k_z}
\tag{22.311}
$$

Light–Fluid Approximation. The light-fluid approximation corresponds to

$$
\left| \frac{2\mathrm{i}\rho}{\rho_s h k_z} \right| \ll 1 \,.
\tag{22.312}
$$

In this case, the wavenumbers are given by

$$
k_F = k_{F0} \quad \text{or} \quad k_F = \mathrm{i} k_{F0} \,.
\tag{22.313}
$$

The case $k_F = k_{F0}$ corresponds to propagating waves. In this case, the radiation efficiency becomes

$$
\begin{cases}
\sigma & = \operatorname{Re} \left(\frac{k}{k_z} \right) = \frac{1}{\sqrt{1 - \frac{k_{F0}^2}{k^2}}} \\
& = \frac{1}{\sqrt{1 - \frac{\omega_c}{\omega}}} \quad \text{if} \quad \omega > \omega_c \\
\text{with} \quad \omega_c = \frac{c^2}{h} \sqrt{\frac{12(1 - \nu^2)\mu}{E}} \\
& = 0 \quad \text{if} \quad \omega < \omega_c \,;
\end{cases}
\tag{22.314}
$$
Fig. 22.16 Radiation efficiency σ for progressive flexural waves in an infinite isotropic plate submerged in a light fluid, ω_c is the critical frequency
Fig. 22.17 Radiation efficiency for evanescent flexural waves in an infinite isotropic plate submerged in a light fluid

ω_c is the critical (or coincidence) frequency of the plate coupled to the light fluid. For this frequency, the wavelength in the plate is equal to the wavelength in the fluid. For $\omega > \omega_c$ ($k_{F0} < k$), the flexural waves are *supersonic*. The radiation efficiency tends to infinity as ω tends to ω_c and tends to unity as ω tends to infinity (Fig. 22.16). σ tends to infinity for $\omega = \omega_c$ because we are dealing with an infinite plate.

For $\omega < \omega_c$, the flexural waves are *subsonic*. The radiation efficiency is equal to zero which means that the plate does not radiate sound. This result follows from the fact that acoustic pressure and velocity are in quadrature.

The solution $k_F = i k_{F0}$ corresponds to evanescent waves in the plate. In this case, the radiation efficiency becomes

$$\sigma = \mathrm{Re}\left(\frac{k}{k_z}\right) = \frac{1}{\sqrt{1 + \frac{k_{F0}^2}{k^2}}} = \frac{1}{\sqrt{1 + \frac{\omega_c}{\omega}}}. \quad (22.315)$$

Equation (22.315) shows that the radiation efficiency of a flexural evanescent wave increases with frequency and tends to unity as the frequency tends to infinity (Fig. 22.17).

Simply Supported Radiating Isotropic Plate

Equations of Motion. We address the problem of structural–acoustic interaction for a 2-D, rectangular, baffled, simply supported isotropic thin plate radiating in air (Fig. 22.18).

The system is described by the equations

$$
\begin{cases}
D\nabla^4 \xi(x, y, t) + \rho_s h \dfrac{\partial^2 \xi}{\partial t^2}(x, y, t) \\
\quad = p(x, y, 0-, t) - p(x, y, 0+) \\
\qquad \text{for} \quad 0 < x < L_x \quad \text{and} \quad 0 < y < L_y, \\
\xi(0, y, t) = \xi(L_x, y, t) = \xi(x, 0, t) \\
\quad = \xi(x, L_y, t) = 0, \\
\xi''(0, y, t) = \xi''(L_x, y, t) = \xi''(x, 0, t) \\
\quad = \xi''(x, L_y, t) = 0, \\
v_z(x, y, 0+, t) = -v_z(x, y, 0-, t) = \dot{\xi}(x, y, t) \\
\qquad \text{for} \quad 0 < x < L_x \quad \text{and} \quad 0 < y < L_y, \\
v(x, y, 0) = 0 \\
\qquad \text{for} \quad x \notin \,]0, L_x[\quad \text{or} \quad y \notin \,]0, L_y[, \\
\rho \dfrac{\partial v}{\partial t} + \nabla p = 0, \\
\nabla^2 p - \dfrac{1}{c^2} \dfrac{\partial^2 p}{\partial t^2} = 0,
\end{cases}
$$

$$(22.316)$$

where h is the thickness of the plate, $D = EI = \frac{Eh^3}{12(1-\nu^2)}$ is the flexural rigidity factor, E is the Young's modulus, ν is the Poisson's ratio and ρ_s is the plate's density. The transverse displacement of the plate is denoted by $\xi(x, y, t)$. The acoustic variables are the pressure $p(x, y, z, t)$ and the velocity $v(x, y, z, t)$. ρ is the air density and c is the speed of sound in air.

Eigenmodes in Vacuo. Solving the plate equations in vacuo with simply supported boundary conditions yields the eigenmodes

$$\phi_{mn}(x, y) = \phi_m(x)\phi_n(y) = \sin\frac{\pi m x}{L_x}\sin\frac{\pi n y}{L_y}$$

$$(22.317)$$

allowing the displacement to be expanded as follows

$$\xi(x, y, t) = \sum_{m,n} \phi_{mn}(x, y)q_{mn}(t)$$

$$= \phi_m(x)\phi_n(y)q_{mn}(t). \quad (22.318)$$

Defining the vectors

$$
\begin{cases}
\boldsymbol{Q}^t = (q_{01} \; q_{10} \; q_{11} \; \dots \; q_{MN}), \\
\text{and} \\
\boldsymbol{\Phi}^t = (\phi_{01} \; \phi_{10} \; \phi_{11} \; \dots \; \phi_{MN}),
\end{cases}
$$

$$(22.319)$$

(22.318) can be written

$$\xi(x, y, t) = \boldsymbol{Q}^{\mathrm{t}}\boldsymbol{\Phi} \tag{22.320}$$

which is similar in form to the 1-D systems studied in Sect. 22.5.1. In (22.318), the number of considered modes (with indices M and N in both directions, respectively) depends on the nature and frequency content of the practical problem to be solved.

Calculation of the Radiated Sound Field Using Wavenumber Fourier Transform. Using the spatial Fourier transform enables the pressure on the plate surface to be easily determined [22.36]. For any 2-D spatial function $f(x, y)$, the transform is defined by

$$\begin{cases} F(k_x, k_y) = \displaystyle\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(x, y)\,\mathrm{e}^{\mathrm{i}(k_x x + k_y y)}\,\mathrm{d}x\,\mathrm{d}y\,, \\[4pt] f(x, y) = \dfrac{1}{(2\pi)^2}\times \\[4pt] \qquad\displaystyle\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} F(k_x, k_y)\,\mathrm{e}^{-\mathrm{i}(k_x x + k_y y)}\,\mathrm{d}k_x\,\mathrm{d}k_y\,. \end{cases} \tag{22.321}$$

This allows us to transform the wave equation for a harmonic sound pressure in space as follows

$$\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} (\nabla^2 + k^2)\,p(x, y, z)\,\mathrm{e}^{\mathrm{i}(k_x x + k_y y)}\,\mathrm{d}x\,\mathrm{d}y = 0\,. \tag{22.322}$$

This leads to

$$\left(k^2 - k_x^2 - k_y^2 + \frac{\partial^2}{\partial z^2}\right) P(k_x, k_y, z) = 0 \tag{22.323}$$

with a solution given by

$$P(k_x, k_y, z) = \frac{\omega\rho\dot{\Xi}(k_x, k_y)}{k_z}\,\mathrm{e}^{-\mathrm{i}k_z z}$$
$$\text{with}$$
$$k_z = \sqrt{k^2 - k_x^2 - k_y^2}\,, \tag{22.324}$$

where $\dot{\Xi}(k_x, k_y)$ is the wavenumber transform of the transverse plate velocity $\dot{\xi}(x, y)$. The complex sound pressure in space is obtained by using the inverse trans-

form, so that

$$p(x, y, z) = \frac{\omega\rho}{(2\pi)^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\frac{\dot{\Xi}(k_x, k_y)}{k_z}$$
$$\times\,\mathrm{e}^{-\mathrm{i}(k_x x + k_y y + k_z z)}\,\mathrm{d}k_x\,\mathrm{d}k_y\,. \tag{22.325}$$

This equation can be solved by using the method of stationary phase or the fast Fourier transform algorithm [22.37].

Radiated Sound Power and the Radiation Impedance Matrix. In the harmonic case, the total sound power radiated by the plate is given by

$$\mathcal{P}_{\mathrm{a}} = \frac{1}{2}\,\mathrm{Re}\left[\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} p(x, y, 0)\,\dot{\xi}^*(x, y)\,\mathrm{d}x\,\mathrm{d}y\right], \tag{22.326}$$

where (*) denotes the complex conjugates. Using Parseval's theorem and (22.324) yields

$$\mathcal{P}_{\mathrm{a}} = \frac{\omega\rho}{8\pi^2}\,\mathrm{Re}\left[\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\frac{|\dot{\Xi}(k_x, k_y)|^2}{k_z}\,\mathrm{d}k_x\,\mathrm{d}k_y\right]. \tag{22.327}$$

Notice that this last result is only valid for wavenumbers such that $\sqrt{k_x^2 + k_y^2} \le k$. Alternatively, the sound power can be written in terms of the wavenumber transform of the acoustic pressure, such that

$$\mathcal{P}_{\mathrm{a}} = \frac{1}{8\omega\rho\pi^2}\iint_{k_x^2 + k_y^2 \le k^2} |P(k_x, k_y)|^2\,k_z\,\mathrm{d}k_x\,\mathrm{d}k_y\,. \tag{22.328}$$

Using (22.320) for the plate velocity and $\boldsymbol{\Phi}(k_x, k_y)$ as the wavenumber transform of $\boldsymbol{\Phi}(x, y)$ yields the squared modulus of the velocity field

$$|\dot{\Xi}(k_x, k_y)|^2 = |\dot{\boldsymbol{Q}}^{\mathrm{t}}\boldsymbol{\Phi}(k_x, k_y)|^2$$
$$= \dot{\boldsymbol{Q}}^{\mathrm{H}}\boldsymbol{\Phi}^*(k_x, k_y)\boldsymbol{\Phi}^{\mathrm{t}}(k_x, k_y)\dot{\boldsymbol{Q}}\,. \tag{22.329}$$

Finally, substituting this result into (22.327), the acoustic power can be written as

$$\mathcal{P}_{\mathrm{a}} = \dot{\boldsymbol{Q}}^{\mathrm{H}}\mathbf{R}_{\mathrm{a}}\dot{\boldsymbol{Q}}\,. \tag{22.330}$$
Fig. 22.18 Geometry of the thin isotropic baffled radiating plate

The radiation impedance matrix $\mathbf{R}_a$ is defined as

$$\mathbf{R}_a = \frac{\omega\rho}{8\pi^2}\,\mathrm{Re}\left(\iint \frac{\boldsymbol{\Phi}^*(k_x,k_y)\boldsymbol{\Phi}^{\mathrm{t}}(k_x,k_y)}{\sqrt{k^2-k_x^2-k_y^2}}\,\mathrm{d}k_x\,\mathrm{d}k_y\right) \tag{22.331}$$

which generalizes the results obtained in (22.265) to 2-D systems. Each element $(\mathbf{R}_a)_{ij}$ of the matrix $\mathbf{R}_a$ quantifies the mutual radiation resistance resulting from the interference between the fields of modes (m,n) and (m',n'), respectively. If $(m,n)=(m',n')$, we obtain the self-radiation resistances, which are the diagonal terms of the matrix $\mathbf{R}_a$. These terms can be written explicitly as

$$(\mathbf{R}_a)_{ij} = (\mathbf{R}_a)_{mn,m'n'}$$
$$= \frac{\omega\rho}{8\pi^2}\,\mathrm{Re}\iint \frac{\Phi_m^*(k_x)\,\Phi_n^*(k_y)\Phi_{m'}(k_x)\,\Phi_{n'}(k_y)}{\sqrt{k^2-k_x^2-k_y^2}}\,\mathrm{d}k_x\,\mathrm{d}k_y\,. \tag{22.332}$$

For a baffled simply supported plate (Fig. 22.18), the radiation resistances become

$$(\mathbf{R}_a)_{mn,m'n'} = \frac{mm'nn'\omega\rho\pi^2}{8L_x^2L_y^2}$$

$$\times\mathrm{Re}\left(\iint (f_{mm'}(k_xL_x)\,f_{nn'}(k_yL_y)\,\mathrm{d}k_x\,\mathrm{d}k_y\right.$$

$$\left./\left\{\left[k_x^2-\left(m\frac{\pi}{L_x}\right)^2\right]\left[k_x^2-\left(m'\frac{\pi}{L_x}\right)^2\right]\right.\right.$$

$$\left.\left.\times\left[k_y^2-\left(n\frac{\pi}{L_y}\right)^2\right]\left[k_y^2-\left(n'\frac{\pi}{L_y}\right)^2\right]\right\}\right), \tag{22.333}$$

where the functions of the form $f_{mm'}(k_xL_x)$ are given by

$$f_{mm'}(k_xL_x) =$$
$$\begin{cases} 2(1-\cos k_xL_x) & \text{for } m \text{ even,} \quad m' \text{ even} \\ 2(1+\cos k_xL_x) & \text{for } m \text{ odd,} \quad m' \text{ odd} \\ 2\mathrm{i}\sin k_xL_x & \text{for } m \text{ odd,} \quad m' \text{ even} \\ -2\mathrm{i}\sin k_xL_x & \text{for } m \text{ even,} \quad m' \text{ odd} \end{cases}. \tag{22.334}$$

For the application of the radiation modal expansion to active structural control of sound, see, for example, the work by *Gibbs* et al.[22.38]. In a recent work, *Kim* investigated structural–acoustic coupling for active control purpose, using an impedance/mobility approach [22.39]. Alternative techniques make use of multipole expansion of the radiated sound pressure [22.40].

22.6 Damping

In this section, we start by summarizing briefly the conditions for modal decoupling in discrete damped systems, and the concept of proportional damping is introduced. The modal approach is convenient for treating the case of localized damping (Sect. 22.6.1). The following example of a string with a dissipative end illustrates the limit of the modal approach, and shows that such a system cannot exhibit stationary solutions. A physical interpretation is presented in terms of damped propagating waves. Other authors use a state-space modal approach to address the analysis of damped structures [22.41, 42].

The section continues with the presentation of three damping mechanisms in plates: thermoelastic-ity, viscoelasticity and radiation, with emphasis on the time-domain formulation. The section ends with a brief presentation of friction, stick–slip vibrations and hysteretic damping, which are often encountered in structural damping models.

22.6.1 Modal Projection in Damped Systems

Discrete Systems
For a linear system with multiple degrees of freedom, with a dissipation energy of the form

$$\mathcal{E}_D = \frac{1}{2}\,{}^{\mathrm{t}}\dot{\boldsymbol{X}}\mathbf{C}\dot{\boldsymbol{X}}\,, \tag{22.335}$$

where $\mathbf{C}$ is a symmetric damping matrix with positive elements, the equations of motion can be written as

$$\mathbf{M}\ddot{X} + \mathbf{C}\dot{X} + \mathbf{K}X = F \ . \tag{22.336}$$

Denoting the eigenfrequencies and eigenfunctions of the associated conservative system by ω_n and $\boldsymbol{\Phi}_n$, respectively, we use the expansion $X = \sum_m \boldsymbol{\Phi}_m q_m(t)$. Denoting by ζ_{nm} the intermodal coefficients, the generalized coordinates are governed by the system of coupled differential equations

$$\ddot{q}_n + 2\omega_n\zeta_n\dot{q}_n + \omega_n^2 q_n = \frac{f_n}{m_n} - 2\omega_n \sum_{m \neq n} \zeta_{nm}\dot{q}_m \ . $$

$$\tag{22.337}$$

Weakly Damped Systems. In the case of weak damping, a first-order development of both the eigenfrequencies and eigenvectors of the form

$$\omega'_n = \omega_n + \Delta\omega_n \ ; \quad \boldsymbol{\Phi}'_n = \boldsymbol{\Phi}_n + \Delta\boldsymbol{\Phi}_n \tag{22.338}$$

in (22.336), with $F = 0$, leads to the matrix equation

$$\left(\mathbf{K} - \omega_n^2\mathbf{M}\right)\Delta\boldsymbol{\Phi}_n + \omega_n\left(-2\Delta\omega_n\mathbf{M} + \mathbf{C}\right)\boldsymbol{\Phi}_n \simeq 0 \tag{22.339}$$

from which we get

$$\Delta\omega_n \simeq \mathrm{i}\zeta_n\omega_n \ . \tag{22.340}$$

Equation (22.340) yields two significant results:

1. The correction frequency is purely imaginary. As a consequence, the eigenmode is transformed into a damped sinusoid of the form $\mathrm{e}^{\mathrm{i}\omega_n t}\,\mathrm{e}^{-\zeta_n\omega_n t}$.
2. To first order, the correction frequency is independent of the intermodal coefficients, thus the damping matrix is diagonal.

The perturbation of the eigenvectors due to damping is given by

$$\Delta\boldsymbol{\Phi}_n = \sum_{m \neq n} \alpha_m \boldsymbol{\Phi}_m$$

with

$$\alpha_m = 2\mathrm{i}\zeta_{mn}\frac{m_n\omega_n^2}{m_m\left(\omega_n^2 - \omega_m^2\right)} \ . \tag{22.341}$$

Consequently, in the presence of damping, the eigenvectors become

$$\boldsymbol{\Phi}'_n = \boldsymbol{\Phi}_n + 2\mathrm{i}m_n\omega_n^2 \sum_{m \neq n} \boldsymbol{\Phi}_m \frac{\zeta_{mn}}{m_m\left(\omega_n^2 - \omega_m^2\right)} \ . $$

$$\tag{22.342}$$

Equation (22.342) shows that

1. If the eigenfrequencies of the associated conservative system are sufficiently different from each other then, to first order, the perturbation of the eigenvectors are of the same order of magnitude as the intermodal damping ζ_{mn}. If $\omega_n \approx \omega_m$, terms of the form $\omega_n^2 - \omega_m^2$ in the denominator can lead to significant corrections.
2. The correction terms for the eigenvectors are also purely imaginary. Thus, the eigenmodes are no longer in phase (or in antiphase) as for the conservative case.

Proportional Damping. The system can be decoupled without any approximations if the damping matrix can be written in the form of a linear combination of mass and stiffness matrices $\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K}$ where α and β are real constants. This corresponds to the so-called proportional damping case. In this case, we obtain

$$\ddot{q}_n + 2\omega_n\zeta_n\dot{q}_n + \omega_n^2 q_n = \frac{f_n}{m_n}$$

with

$$\zeta_n = \frac{\alpha}{2\omega_n} + \frac{\beta\omega_n}{2} \ . \tag{22.343}$$

We therefore obtain a frequency-dependent modal damping that decreases with frequency below $\omega = \sqrt{\alpha/\beta}$, and increases with frequency above this value. This damping law does not correspond to particular physical phenomena, but is rather used for practical mathematical considerations. It can be useful in some cases for fitting experimental curves over a restricted frequency range.

Localized Damping in Continuous Systems

In some applications, the damping of the vibrations of continuous systems is localized at discrete points of the structure. In this section, this problem is illustrated by the case of a string of finite length L with eigenfrequencies ω_n and eigenfunctions $\boldsymbol{\Phi}_n(x)$. A *fluid damping* term is introduced at position $x = x_0$, with $0 < x_0 < L$, so that this term is of the form $-R\dot{y}(x, t)\delta(x - x_0)$. The equation of motion can therefore be written

$$\rho(x)S(x)\frac{\partial^2 y}{\partial t^2} + R\frac{\partial y}{\partial t}\delta(x - x_0)$$

$$- \frac{\partial}{\partial x}\left[T(x)\frac{\partial y}{\partial x}\right] = f(x, t) \ . \tag{22.344}$$

Applying the usual scalar products, we can write

$$\sum_m \ddot{q}_m(t) \int_0^L \Phi_m(x)\Phi_n(x)\rho(x)S(x)\,\mathrm{d}x$$

$$+ \sum_m \dot{q}_m(t) \int_0^L R\delta(x-x_0)\Phi_m(x)\Phi_n(x)\,\mathrm{d}x$$

$$- \sum_m q_m(t) \int_0^L \Phi_n(x)\frac{\mathrm{d}}{\mathrm{d}x}\left(T(x)\frac{\mathrm{d}\Phi_m(x)}{\mathrm{d}x}\right)\mathrm{d}x$$

$$= \int_0^L \Phi_n(x)f(x,t)\,\mathrm{d}x \ . \tag{22.345}$$

The generalized displacements are governed by the equations

$$\ddot{q}_n + 2\omega_n \sum_m \zeta_{nm}\dot{q}_m + \omega_n^2 q_n = \frac{f_n}{m_n} \ , \tag{22.346}$$

where the intermodal coefficients are written here

$$\zeta_{nm} = \frac{R\Phi_n(x_0)\Phi_m(x_0)}{2m_n\omega_n} \ . \tag{22.347}$$

For weak damping, we have

$$\ddot{q}_n + 2\omega_n\zeta_n\dot{q}_n + \omega_n^2 q_n \simeq \frac{f_n}{m_n} \ , \tag{22.348}$$

where the modal damping coefficient are given by

$$\zeta_n = \frac{R\Phi_n^2(x_0)}{2m_n\omega_n} \ . \tag{22.349}$$

Example. For a homogeneous string rigidly fixed at both ends, we have $\Phi_n(x) = \sin k_n x$ and $\omega_n = ck_n = n\pi c/L$. With a damper fixed at position $x_0 = L/2$, we get $\zeta_n = \frac{R\sin^2(n\pi/2)}{2m_n\omega_n}$. Two cases can be differentiated:

1. If n is odd, $\sin^2(n\pi/2) = 1$ and $\zeta_n = \frac{R}{2m_n\omega_n}$.
2. If n is even, $\zeta_n = 0$.

In this case, only the odd modes are damped.

String With a Dissipative End. The case of a dissipative end is slightly more delicate to handle since the dissipation is localized at a boundary, and thus is directly involved in the definition of the eigenmodes. The equations of the problem are

$$\rho S\frac{\partial^2 y}{\partial t^2} - T\frac{\partial^2 y}{\partial x^2} = 0 \tag{22.350}$$

with the boundary conditions

$$y(0,t) = 0 \quad \text{and} \quad T\frac{\partial y}{\partial x}(L,t) = -R\frac{\partial y}{\partial t}(L,t) \ . \tag{22.351}$$

One strategy consists of looking for complex solutions of the separate variables $y(x,t) = f(x)g(t)$. The time dependence is assumed to be of the form

$$g(t) = A\,\mathrm{e}^{-st} + B\,\mathrm{e}^{st} \ , \tag{22.352}$$

with A, B and $s \in \mathbb{C}$. Inserting (22.352) into (22.350), we find that $f(x)$ is of the form

$$f(x) = C\,\mathrm{e}^{-sx/c} + D\,\mathrm{e}^{sx/c}$$

$$\text{with} \quad c = \sqrt{\frac{T}{\rho S}} \ , \tag{22.353}$$

where C and $D \in \mathbb{C}$. The boundary solution at $x = 0$ yields $C = -D$. The boundary condition at $x = L$ yields two possible cases

$$\begin{cases} \cosh\dfrac{sL}{c} = r\sinh\dfrac{sL}{c} \text{ and } B = 0 \ , \\[2mm] \cosh\dfrac{sL}{c} = -r\sinh\dfrac{sL}{c} \text{ and } A = 0 \ , \end{cases} \tag{22.354}$$

where $r = R/Z_c$ and $Z_c = T/c$ is the characteristic impedance of the string. Defining $s = \mathrm{i}\omega + \alpha$, we find two sets of solutions depending on whether R is larger or smaller than Z_c.

1. For $r < 1$,

$$\begin{cases} \cos\dfrac{\omega L}{c} = 0 \ , & \tanh\dfrac{\alpha L}{c} = r \text{ and } B = 0 \ , \\[2mm] \cos\dfrac{\omega L}{c} = 0 \ , & \tanh\dfrac{\alpha L}{c} = -r \text{ and } A = 0 \ . \end{cases} \tag{22.355}$$

2. For $r > 1$,

$$\begin{cases} \sin\dfrac{\omega L}{c} = 0 \ , & \tanh\dfrac{\alpha L}{c} = \dfrac{1}{r} \text{ and } B = 0 \ , \\[2mm] \sin\dfrac{\omega L}{c} = 0 \ , & \tanh\dfrac{\alpha L}{c} = -\dfrac{1}{r} \text{ and } A = 0 \ . \end{cases} \tag{22.356}$$
Fig. 22.19 Temporal evolution of a string with one dissipative end

We focus on the case $r > 1$. Defining $a = AC$ and $b = BC$, and taking (22.355) into account, we obtain

$$y(x, t) = e^{-\alpha t} \sum_n a_n e^{-i\omega_n t}$$
$$\times \left(e^{-(i\omega_n + \alpha)x/c} - e^{(i\omega_n + \alpha)x/c} \right)$$
$$+ e^{-\alpha t} \sum_n b_n e^{i\omega_n t}$$
$$\times \left(e^{-(i\omega_n - \alpha)x/c} - e^{(i\omega_n - \alpha)x/c} \right)$$
(22.357)

which can be rearranged, in condensed form, as

$$y(x, t) = e^{-\alpha t} \left[e^{-\alpha x/c} F\left(t + \frac{x}{c} \right) - e^{\alpha x/c} F\left(t - \frac{x}{c} \right) \right]$$
(22.358)

with

$$F(t) = \sum_n \left(a_n e^{-i\omega_n t} - b_n e^{i\omega_n t} \right) .$$
(22.359)

The complex constants a_n and b_n are determined by the initial conditions of the problem. It can be shown that (22.359) yields a real function $F(t)$. Several conclusions can be drawn from this example:

1. The mechanical resistance R yields a decay time $1/\alpha$ which is independent of frequency.
2. The term in square brackets in (22.358) corresponds to two traveling waves in opposite directions with different amplitudes, except at $x = 0$ where the

rigidly fixed boundary condition must be fulfilled. As a consequence, we cannot get a steady-state solution.

In conclusion, as shown in Fig. 22.19, the string with a dissipative end cannot exhibit stationary wave solutions. We cannot make reference to nodes and antinodes, since the points of maximum (and minimum) amplitude are moving with time, though first-order approximations can be made for weak dissipation.

22.6.2 Damping Mechanisms in Plates

In vibrating structures, the dissipation of energy is partly due to radiation, and partly due to other internal damping mechanisms such as thermoelasticity and viscoelasticity. The relative prominence of these mechanisms is dependent on the material. In this section, models for these three mechanisms are briefly reviewed in the particular case of free rectangular plates, for which the losses at the boundaries are neglected.

Thermoelasticity

Thermoelastic damping affects the vibrations of plates with significant thermal conductivity, such as metallic plates. A model for such damping can be derived from the equations that govern the coupling between plate vibrations and the diffusion of heat [22.43, 44]. Here, the method previously used by *Cremer* for isotropic bars is extended to orthotropic plates to derive the expressions for the complex rigidity constants [22.20]. The temperature change θ is assumed to be sufficiently small, so that the stress–strain relationships can be linearized. The plate is located in the (x, y) plane and is subjected to transverse flexural vibrations. $w(x, y, t)$ is the transverse displacement. The stress components are given by

$$\sigma_{xx} = -12z \left(D_1 w_{,xx} + \frac{D_2}{2} w_{,yy} \right) - \phi_x \theta ,$$
$$\sigma_{yy} = -12z \left(D_3 w_{,yy} + \frac{D_2}{2} w_{,xx} \right) - \phi_y \theta ,$$
$$\sigma_{xy} = -6z D_4 w_{,xy} ,$$
(22.360)

where ϕ_x and ϕ_y are the thermal coefficients of the material. In the particular case of an isotropic material, we have $\phi_x = \phi_y = \phi$. Equation (22.360) has to be complemented by the heat diffusion equation. Assuming that θ only depends on z, we have

$$\kappa \theta_{,zz} - \rho C s \theta = -z T_0 s (\phi_x w_{,xx} + \phi_y w_{,yy}) ,$$
(22.361)

where T_0 is the absolute temperature, C is the specific heat at constant strain, and κ is the thermal conductivity. It is assumed that $\theta(z)$ is given by an equation of the form [22.20]

$$\theta(z) = \theta_0 \sin\frac{\pi z}{h} \text{ for } z \in \left[-\frac{h}{2}, \frac{h}{2}\right], \qquad (22.362)$$

which takes into account the fact that there is no heat transmission between plate and air. Through integration of $z\sigma_{ij}$ over the thickness h of the plate, one obtains, in the Laplace domain, the relationship between the bending and twisting moments M_{ij} and the partial derivatives of the transverse displacement w of the plate. The rigidity factors are now complex functions of the form [22.45]

$$\tilde{D}_1(s) = D_1 + \phi_x^2 \frac{s\zeta}{1+\tau s},$$

$$\tilde{D}_2(s) = D_2 + 2\phi_x\phi_y \frac{s\zeta}{1+\tau s},$$

$$\tilde{D}_3(s) = D_3 + \phi_y^2 \frac{s\zeta}{1+\tau s},$$

$$\tilde{D}_4(s) = D_4, \qquad (22.363)$$

where the thermoelastic relaxation time τ and the thermal constant ζ are given by

$$\tau = \frac{\rho C h^2}{\kappa \pi^2} \quad \text{and} \quad \zeta = \frac{8T_0 h^2}{\kappa \pi^6}. \qquad (22.364)$$

As a consequence of (22.364), the thermoelastic losses decrease as the thickness h of the plate increases. Notice also that D_4 is real. As a consequence, the particular flexural modes of the plate, such as the torsional modes, which involve this rigidity factor will be relatively less affected by thermoelastic damping than the other modes. In other words, the thermoelastic damping factors depend on the modal shapes [22.46]. The complex rigidities can be rewritten in the form

$$\tilde{D}_i(s) = D_i\left[1 + \tilde{d}_{it}(s)\right] = D_i\left[1 + \frac{sR_i}{s + c_1/h^2}\right],$$
$$i = [1, 2, 3],$$

$$\tilde{D}_4(s) = D_4. \qquad (22.365)$$

Because the thermoelastic damping is small for most materials, the $\tilde{d}_{it}(s)$ can often be considered as perturbation terms of the complex rigidities. For convenience, these terms are written in (22.365) using the following

nondimensional numbers

$$R_1 = \frac{8T_0\phi_x^2}{\pi^4 D_1 \rho C};$$

$$R_2 = \frac{16T_0\phi_x\phi_y}{\pi^4 D_3 \rho C};$$

$$R_3 = \frac{8T_0\phi_y^2}{\pi^4 D_3 \rho C}. \qquad (22.366)$$

The decay factor $1/\tau$ is written here in the form c_1/h^2 in order to highlight the fact that this factor is proportional to the inverse squared thickness of the plate.

Viscoelasticity

A large class of materials is subject to viscoelastic damping [22.47]. A convenient method for representing viscoelastic phenomena is to use a differential formulation between the stress σ and strain ε tensors of the form

$$\sigma + \sum_{w=1}^{N} q_w \frac{\partial^w \sigma}{\partial t^w} = E\left(\varepsilon + \sum_{v=1}^{N} q_v \frac{\partial^v \varepsilon}{\partial t^v}\right). \qquad (22.367)$$

As a consequence, the differential equations involving the flexural displacements and moments in thin plates contain time derivatives up to order N. By taking the Laplace transform of both sides in (22.367) and inserting it into the plate equation, one obtains the complex rigidities due to viscoelasticity

$$\tilde{D}_i(s) = D_i\left[1 + \tilde{d}_{iv}(s)\right] = D_i \frac{1 + \sum_{v=1}^{N} s^v p_{iv}}{1 + \sum_{w=1}^{N} s^w q_w}. \qquad (22.368)$$

Equation (22.368) is a particular class of representation for the complex rigidities. The operator is bounded by the condition [22.48]

$$q_N \neq 0. \qquad (22.369)$$

Another restrictive condition on the coefficients in (22.368) follows from the fact that the energy for deforming the material from its initial undisturbed state must be positive. For a generalized viscoelastic strain–stress relationship, the Laplace transform is given by

$$\tilde{\sigma}_{ij} = \sum_{k,l} \tilde{a}_{ijkl}(s)\tilde{\epsilon}_{kl}. \qquad (22.370)$$

Gurtin and *Sternberg* [22.48] have proven that one necessary condition for the model to be dissipative is

$$\text{Im}[X_{ij}\tilde{a}_{ijkl}(i\omega)X_{kl}] \geq 0 \quad \text{for} \quad \omega \geq 0 \qquad (22.371)$$

for any real symmetric tensor X_{ij}. For the viscoelastic orthotropic plate model, (22.371) together with (22.368) yield the following conditions

$$
\begin{cases}
p_{1N} > 0\,, \quad p_{3N} > 0\,, \quad p_{4N} > 0\,, \\
p_{1N}p_{3N} - \dfrac{D_2\,p_{2N}{}^2}{4D_1D_3} > 0\,.
\end{cases}
\tag{22.372}
$$

As for thermoelastic damping, if the viscoelastic losses in the materials are sufficiently small, the corresponding terms can be viewed as first-order corrections to the rigidity.

Time–Domain Model of Radiation Damping in Isotropic Plates

In this section, an approximate time-domain model for isotropic plates is presented that takes the effect of radiation into account. The leading idea is to use a differential operator for the radiation losses (i.e., a polynomial formulation in the Laplace domain), similar to that presented in the previous paragraphs for thermoelastic and viscoelastic damping. Experiments performed on freely suspended plates show that in the *low-frequency* domain (i.e., below the critical frequency), viscoelastic and/or thermoelastic losses are the main causes of damping [22.45]. Above the critical frequency, damping is mainly governed by radiation.

The equations that govern the flexural motion of an isotropic plate surrounded by air are given in (22.316). For a travelling wave of the form $w(x, y, t) = W(x, y)\exp[\mathrm{i}(\tilde{\omega}t - \boldsymbol{k}.\boldsymbol{x})]$, where k is the wavenumber and $\tilde{\omega} = \omega + \mathrm{i}\alpha_{\mathrm{r}}$ is the complex frequency, one obtains the dispersion equation

$$
-\tilde{\omega}^2 \left(1 + \frac{2\rho_{\mathrm{a}}}{\rho h} \frac{1}{\sqrt{k^2 - \frac{\tilde{\omega}^2}{c^2}}} \right) + \frac{Dh^2}{\rho}k^4 = 0\,.
\tag{22.373}
$$

With the assumption of a light fluid, one can derive the radiation decay factor α_{r} from (22.373) by reformulating this equation through the introduction of a rigidity modulus $\tilde{D}$ of the form

$$
\tilde{D} \simeq D \left(1 - \frac{2\rho_{\mathrm{a}}c}{\omega_{\mathrm{c}}\rho h} \frac{1}{\sqrt{\Omega - \Omega^2}} \right)
$$

with

$$
\omega_{\mathrm{c}} = c^2 \sqrt{\frac{\rho}{h^2 D}}
$$

and

$$
\Omega = \frac{\omega}{\omega_{\mathrm{c}}}\,.
\tag{22.374}
$$
Fig. 22.20 Comparison between damping model (*solid line*) and measurements (⬤) for a free rectangular aluminum plate. Damping factors (in s^{-1}) as a function of frequency (in kHz) (after *Chaigne* et al. [22.45])

The complex rigidity $\tilde{D}$ can be rewritten in the form of a third-order Padé development

$$
\begin{aligned}
\tilde{D}(s) &\hat{=} D \left(1 + \frac{2\rho_{\mathrm{a}}c}{\omega_{\mathrm{c}}\rho h} \frac{\sum_{m=1}^{3} b_m \left(\frac{s}{\omega_{\mathrm{c}}}\right)^m}{\sum_{n=0}^{3} a_n \left(\frac{s}{\omega_{\mathrm{c}}}\right)^n} \right) \\
&= D\left[1 + \tilde{d}_{\mathrm{r}}(s)\right]
\end{aligned}
\tag{22.375}
$$

with

$$
\begin{aligned}
&a_0 = 1.1669\,, \quad a_1 = 1.6574\,, \\
&a_2 = 1.5528\,, \quad a_3 = 1\,, \\
&b_1 = 0.0620\,, \quad b_2 = 0.5950\,, \\
&b_3 = 1.0272\,.
\end{aligned}
$$

Figure 22.20 shows a comparison between this asymptotic model and experimental data in the case of an aluminum plate. The present formulation of radiation damping cannot be easily generalized to anisotropic plates where the dispersion equation depends on the direction of wave propagation [22.14].

22.6.3 Friction

Elementary 1–DOF Oscillator with Coulomb Damping

The Coulomb damping corresponds to the simple modeling of a friction force applied to a solid sticking and/or sliding on dry surfaces. Figure 22.21 shows a 1-DOF oscillator subjected to Coulomb damping. For an initial
Fig. 22.21 One-DOF oscillator subjected to Coulomb damping

displacement $\xi(0) = \xi_0$, the motion of the mass M can occur under the condition that the restoring force $K\xi_0$ due to the spring is larger than the static friction force $F_s = \mu_s Mg$, where μ_s is the static friction coefficient with $0 < \mu_s < 1$. After the motion has started, the mass is subjected to a dynamic frictional force $F_d = \mu_d Mg$ where $\mu_d < \mu_s$. This force is in the opposite direction to the velocity, so that the equation of motion can be written [22.12]

$$M\frac{d^2\xi}{dt^2} + F_d \operatorname{sgn}\left(\frac{d\xi}{dt}\right) + K\xi = 0$$

$$\text{where} \quad \operatorname{sgn}\left(\frac{d\xi}{dt}\right) = \frac{\frac{d\xi}{dt}}{\left|\frac{d\xi}{dt}\right|}. \tag{22.376}$$

During the initial part of the motion, we have

$$\frac{d^2\xi}{dt^2} + \omega_0^2 \xi = \omega_0^2 \frac{F_d}{K} \tag{22.377}$$

whose solution is

$$\xi(t) = \left(\xi_0 - \frac{F_d}{K}\right)\cos\omega_0 t + \frac{F_d}{K}$$

$$\text{for} \quad 0 \le t \le t_1 = \frac{\pi}{\omega_0}. \tag{22.378}$$

The solution (22.378) remains valid until the time $t_1 = \pi/\omega_0$ where the velocity reduces to zero. At that time, the displacement is $\xi(t_1) = \xi_1 = 2F_d/K - \xi_0$. If $K\xi_1 > \mu_s Mg$, then the motion is governed by

$$\frac{d^2\xi}{dt^2} + \omega_0^2 \xi = -\omega_0^2 \frac{F_d}{K} \tag{22.379}$$

whose solution is

$$\xi(t) = \left(\xi_0 - 3\frac{F_d}{K}\right)\cos\omega_0 t - \frac{F_d}{K}$$

$$\text{for} \quad t_1 \le t \le t_2 = \frac{2\pi}{\omega_0}. \tag{22.380}$$

At the time $t_2 = 2\pi/\omega_0$, the displacement is $\xi(t_2) = \xi_2 = \xi_0 - 4F_d/K$. The motion decreases linearly with time and the equation of the envelope is $\xi_0 - (2F_d)/(\pi\sqrt{KM})t$. The motion stops abruptly at time t_n where $\xi(t_n) < \mu_s F_d/\mu_d K$.

Stick–Slip Vibrations

A number of acoustic sources are due to frictional effects [22.49]. The sounds produced can be perceived as noise (such as squeal) or music (like for violin bowed strings). In all cases, the vibrations are the result of self-sustained oscillations. The simplest example of such systems is a 1-DOF oscillator whose mass is resting on a belt moving at constant velocity V_0 (Fig. 22.22).

The equation of motion of such an oscillator can be written in a general form

$$M\ddot{\xi} + R\dot{\xi} + K\xi = F(v_r, \xi)$$

$$\text{with} \quad v_r = V_0 - \dot{\xi}. \tag{22.381}$$

The previous Coulomb model presented in Sect. 22.6.3 does not account for the energy exchange between oscillator and belt. One widely used semi-empirical model assumes a friction force $F(t) \le F_s = \mu_s Mg$ during the sticking phase, while the sliding frictional force decreases with relative mass-belt velocity (Fig. 22.23). Various mathematical formulations have been proposed for such frictional forces. *Leine* et al. [22.50], for example, make use of the following model

$$F(v_r, \xi) = \begin{cases} F(\xi) &= \min(|K\xi|, F_s)\operatorname{sgn}(K\xi), \\ v_r &= 0 \quad \text{stick}, \\ F(v_r) &= \dfrac{F_s \operatorname{sgn} v_r}{1 + \delta|v_r|} \\ v_r &\ne 0 \quad \text{slip}, \end{cases} \tag{22.382}$$

where δ is an arbitrary constant. In fact, the energy exchange depends on many factors: material properties,
Fig. 22.22 One-DOF oscillator in stick–slip vibrations
Fig. 22.23 Typical frictional force versus relative mass/belt velocity

surface roughness, thermal properties of the materials in contact [22.51], etc. See, for example, [22.52] and [22.49] for a review of friction models.

A periodic oscillation can be obtained for specific ranges of belt velocity and friction parameters. In many cases, such a complex system leads to bifurcations and chaos [22.53].

22.6.4 Hysteretic Damping

Hysteretic damping is a widely used model of structural damping. In the frequency domain, it corresponds to the case of a frequency-dependent dashpot that leads to a loss factor independent of frequency. Recall that the loss factor η is defined as the ratio between the energy lost in the system during a period and the maximum of the potential energy [22.54]. For a 1-DOF system, the equation of motion is written in the frequency domain

as

$$[-M\omega^2 + i\omega R(\omega) + K]\varXi(\omega) = F(\omega) \qquad (22.383)$$

or, equivalently,

$$\left\{-M\omega^2 + K\left[1 + i\eta\,\text{sgn}(\omega)\right]\right\}\varXi(\omega) = F(\omega)\,. \qquad (22.384)$$

This formulation accounts for steady-state oscillations of the system. However, its major drawback follows from the fact that the corresponding time-domain description is not causal. In the frequency domain, the dashpot force is $F_{\text{d}}(\omega) = i\omega R(\omega)\varXi(\omega) = iK\eta\,\text{sgn}(\omega)\varXi(\omega)$. Taking the inverse Fourier transform of $F_{\text{d}}(\omega)$ yields [22.54]

$$f_{\text{d}}(t) = \frac{iK\eta}{2\pi}\int_{-\infty}^{+\infty}\text{sgn}(\omega)e^{i\omega t}\,d\omega\int_{-\infty}^{+\infty}\xi(\tau)e^{-i\omega\tau}\,d\tau\,. \qquad (22.385)$$

Inverting (22.385) yields the displacement of the mass

$$\xi(t) = \frac{1}{2\pi K\eta}\int_{-\infty}^{+\infty}\frac{e^{i\omega t}}{i\,\text{sgn}(\omega)}\,d\omega\int_{-\infty}^{+\infty}f_{\text{d}}(\tau)e^{-i\omega\tau}\,d\tau\,. \qquad (22.386)$$

Selecting, for example, $f_{\text{d}}(t) = \delta(t)$ where $\delta(t)$ is the Dirac delta function leads to

$$\xi(t) = \frac{1}{\pi K\eta}\frac{1}{t}\qquad -\infty < t < +\infty \qquad (22.387)$$

which is clearly not causal, since the response anticipates the excitation [22.54]. Thus, hysteretic damping is generally not appropriate in the time domain, and one has to find other strategies for modeling frequency-dependent damping while preserving the causality.

22.7 Nonlinear Vibrations

Nonlinearities in structures can be either due to nonlinear properties of the material or to large amplitude of vibration affecting the equations of motion. We limit our attention to this latter case, which is called *geometrical nonlinearity*. The most frequently encountered nonlinear terms are cubic and quadratic. These nonlinearities are responsible for many important phenomena: existence of harmonics of the excitation frequency in the response, combination of modes, jumps and hysteresis in response curves, instability and chaos. The purpose of this section is to introduce most of these properties for simple systems: single and coupled nonlinear oscillators. Finally, a number of nonlinear equations for continuous structures are briefly reviewed.

22.7.1 Example of a Nonlinear Oscillator

Equation of Motion

To introduce the fundamental concepts of nonlinear vibrations, we start with a simple example of a nonsymmetrical oscillator: the interrupted pendulum (Fig. 22.24). The oscillator consists of a point mass m suspended by a massless thread of length L and subjected to gravity g. The length of the thread varies with time, as it moves around the pulley of radius R [22.55].

The equation of motion can be derived from the Lagrange equations (Sect. 22.2). Selecting the angle θ
Fig. 22.24 Interrupted pendulum (after *Denardo* [22.55])
Fig. 22.25 Interrupted pendulum (after *Denardo*). Waveform: exact solution (*solid line*). Perturbative solution to the third order (*dashed line*)

between the vertical axis and the actual direction of the thread as the parameter of the system, the kinetic energy is written $E_k = 1/2 m (L - R\theta)^2 \dot{\theta}^2$ and the equation of motion becomes

$$\ddot{\theta} + \omega_0^2 \sin \theta = \rho \frac{d}{dt}(\theta \dot{\theta}) , \qquad (22.388)$$

where $\omega_0^2 = g/L$ and $\rho = R/L$. As R tends to zero in (22.388), we find the well-known equation for a pendulum where the only nonlinear term is due to $\sin \theta$. The nonlinear right-hand side member of the equation is due to the rigid support. The validity domain of this equation is $\theta \in [0, \theta_{\max}]$ where $\theta_{\max} = \min(1/\rho, \pi/2)$. We assume that the pendulum is released at time $t = 0$ from its initial position θ_0 with zero initial velocity.

Resolution with the Harmonic Balance Method

It is observed experimentally that the solution is periodic for small amplitudes with $\rho < 1$, with a period of oscillation that depends on amplitude (Fig. 22.25). With increasing amplitude, the solution departs more and more from the linear harmonic reference motion. This encourages us to look for solutions of the form

$$\begin{cases} \theta & = \varepsilon A \cos \omega t + \varepsilon^2 B \cos 2\omega t \\ & \quad + \varepsilon^3 C \cos 3\omega t + \dots \\ & = \varepsilon \theta_1 + \varepsilon^2 \theta_2 + \varepsilon^3 \theta_3 + \dots \\ \omega^2 & = \omega_0^2 + \varepsilon \omega_1^2 + \varepsilon^2 \omega_2^2 + \varepsilon^3 \omega_3^2 + \dots \end{cases} \qquad (22.389)$$

In (22.389), the solution is expanded in the form of a Fourier series, where the amplitudes of the expansion terms are proportional to increasing powers of a nondimensional parameter $\varepsilon \ll 1$. Similarly, the frequency ω is expanded in terms of increasing power of ε. The basic principle of the harmonic balance method used here for solving this nonlinear equation consists of inserting (22.389) in (22.388) and matching sinusoidal terms to calculate the unknowns $(A, B, C, \omega_1, \omega_2, \omega_3)$ from the equations, obtained separately for each power of ε [22.55]. An example up to the third order in ε is given below. We start by defining a nondimensional time variable $\tau = \omega t$. Limiting the development of $\sin \theta$ to the third order, we obtain

$$\omega^2 \frac{d^2 \theta}{d\tau^2} + \omega_0^2 \left(\theta - \frac{\theta^3}{6} \right) = \rho \omega^2 \frac{d}{d\tau} \left(\theta \frac{d\theta}{d\tau} \right) . \qquad (22.390)$$

Inserting (22.389) in (22.390) and equating terms of equal power in ε, we find

$$\frac{d^2 \theta_1}{d\tau^2} + \theta_1 = 0 \qquad (22.391)$$

whose solution is $\theta_1 = A \cos \omega \tau$. With the same procedure applied to the term in ε^2, one obtains

$$\frac{d^2\theta_2}{d\tau^2} + \theta_2 = \frac{\omega_1^2}{\omega_0^2}\theta_1 + \rho \frac{d}{d\tau}\left(\theta_1 \frac{d\theta_1}{d\tau}\right). \qquad (22.392)$$

Equation (22.392) yields the following relation

$$-3B\cos 2\tau = \frac{\omega_1^2}{\omega_0^2}A\cos\tau - \rho A^2 \cos 2\tau. \qquad (22.393)$$

Using the harmonic balance method for each component $n\tau$ leads to

$$\omega_1 = 0 \quad \text{and} \quad B = \frac{\rho A^2}{3}. \qquad (22.394)$$

At this stage, (22.394) shows that the pulley is responsible for a nonlinear quadratic perturbation. To first order, the quadratic nonlinearity has no effect on the frequency. However, extending the calculations to the third order in ε, we get

$$\frac{d^2\theta_3}{d\tau^2} + \theta_3 = \frac{\omega_2^2}{\omega_0^2}\theta_1 + \frac{\theta_1^3}{6} + \rho\frac{d^2}{d\tau^2}(\theta_1\theta_2). \qquad (22.395)$$

Using the harmonic balance method in (22.395) now yields

$$C = \frac{A^3}{192}(36\rho^2 - 1)$$

and

$$\frac{\omega_2^2}{\omega_0^2} = \frac{A^2}{24}(4\rho^2 - 3). \qquad (22.396)$$

In summary, by defining $\theta_{10} = \varepsilon A$ as the amplitude of the fundamental, we find the third-order perturbation solution

$$\begin{cases} \theta & = \theta_{10}\cos\omega t + \dfrac{\rho\theta_{10}^2}{3}\cos 2\omega t \\ & \quad + (36\rho^2 - 1)\dfrac{\theta_{10}^3}{192}\cos 3\omega t \\ \text{and} \\ \omega^2 & = \omega_0^2\left[1 + \dfrac{\theta_{10}^2}{24}(4\rho^2 - 3)\right] \end{cases} \qquad (22.397)$$

The following comments can be made:

- To third order, θ_{10} is linked to the initial angle θ_0 by the relation

$$\theta_0 \simeq \theta_{10} + \frac{\rho\theta_{10}^2}{3} + (36\rho^2 - 1)\frac{\theta_{10}^3}{192}. \qquad (22.398)$$

- Figure 22.25 shows that the third-order approximation yields a good estimation of the period. In addition, the waveform is also correctly predicted for $\theta > 0$. However, the estimation is less good for $\theta < 0$.
- For $\rho = 0$, we have $\omega \simeq \omega_0(1 - \theta_{10}^2/16)$, and the term $\cos 2\omega t$ is equal to zero. The system exhibits a cubic nonlinearity due to gravity.
- For $0 < \rho < \sqrt{3}/2$, the oscillation frequency decreases as the amplitude increases. A softening effect is obtained.
- For $\rho > \sqrt{3}/2$, the oscillation frequency increases with amplitude we have an hardening effect.
- For $\rho = \sqrt{3}/2$, it is observed that the frequency is independent of the magnitude. The softening effect due to gravity is compensated by the hardening effect due to the rigid pulley. This result remains valid up to fourth order.

Many of the nonlinear effects derived for this simple oscillator, such as amplitude-dependent frequency and softening/hardening effects, are found in more-complex systems.

22.7.2 Duffing Equation

A number of nonlinear vibrations are governed by the Duffing equation. This presentation starts with the example of an elastic pendulum. General results for this cubic nonlinearity are then discussed.

Elastic Pendulum
To illustrate the Duffing equation, the elastic pendulum shown in Fig. 22.26 is considered [22.56]. The mass M moves horizontally due to the harmonic force $F\cos\Omega t$. Two springs with stiffness k, and length L_0 at rest, are
Fig. 22.26 Elastic pendulum

stretched to the length L when attached to the mass. The displacement of the mass from its equilibrium position is x. We introduce the dimensionless parameters $\lambda = L_0/L < 1$ and $y = x/L$. During the motion, the actual length of the spring is $l(y) = L\sqrt{1+y^2}$ and the elastic potential energy is $V = 1/2k(l - L_0)^2$. By differentiating this expression with respect to y, the elastic force is obtained from which the equation of motion for the mass is derived

$$M\frac{d^2 y}{dt^2} + 2ky\left(1 - \frac{\lambda}{\sqrt{1+y^2}}\right) = \frac{F}{L}\cos\Omega t \,. \tag{22.399}$$

With the additional assumption of small amplitude ($y_{max} \ll 1$), and defining further $\omega_0^2 = 2k/M$ we obtain the first-order approximation

$$\frac{d^2 y}{dt^2} + \omega_0^2(1-\lambda)y + \frac{\omega_0^2\lambda}{2}y^3 = \frac{F}{ML}\cos\Omega t \tag{22.400}$$

which can be written in nondimensional form, after defining $\tau = \omega t$ with $\omega^2 = \omega_0^2(1-\lambda)$ and $\gamma = \Omega/\omega$, as

$$\frac{d^2 y}{d\tau^2} + y + \eta y^3 = \alpha\cos\gamma\tau \,, \tag{22.401}$$

where $\eta = \lambda/(2(1-\lambda))$ and $\alpha = F/ML\omega^2$. Equation (22.401) is a forced Duffing equation with a hardening cubic coefficient ($\eta > 0$).

Forced Vibrations

We consider the case where $\eta > 0$ and α defined in (22.401) are small compared to unity. By analogy with the linear case, a first approximation of the solution is $y_1(t) = A\cos\gamma\tau$, where A is the unknown. Inserting y_1 into (22.401), we get the differential equation that governs the second-order approximation $y_2(t)$

$$\frac{d^2 y_2}{d\tau^2} = -A\cos\gamma\tau - \eta A^3\cos^3\gamma\tau + \alpha\cos\gamma\tau \,. \tag{22.402}$$

Using the equality $4\cos^3\gamma\tau = 3\cos\gamma\tau + \cos 3\gamma\tau$ and selecting the appropriate origin of time to avoid constant terms, we get

$$y_2(t) = \frac{A + \frac{3\eta A^3}{4} - \alpha}{\gamma^2}\cos\gamma\tau + \frac{\eta A^3}{36\gamma^2}\cos 3\gamma\tau \,. \tag{22.403}$$
Fig. 22.27 Frequency response curve of the undamped Duffing equation with $\eta > 0$. $\gamma = \Omega/\omega$ is the reduced frequency

Using the method originally used by Duffing, we look for the value of A that is equal to the lowest terms of the series in (22.403), which yields

$$(1 - \gamma^2)A + \frac{3\eta A^3}{4} = \alpha \,. \tag{22.404}$$

In order to plot the resonance curve, this can be written as

$$(\gamma^2 - 1) = \frac{3\eta A^2}{4} \pm \frac{\alpha}{|A|} \,. \tag{22.405}$$

With $\alpha = 0$, the free regime is obtained. For $\alpha \neq 0$, two branches of solution are obtained, depending on whether A is positive or negative. A nonlinear oscillator of the hardening type is obtained here, since the resonance frequency increases with the amplitude (Fig. 22.27).

Duffing Equation with a Viscous Damping Term. With the introduction of a viscous damping term, we obtain the nondimensional equation

$$\frac{d^2 y}{d\tau^2} + \beta\frac{dy}{d\tau} + y + \eta y^3 = \alpha\cos\gamma\tau \,. \tag{22.406}$$

In this case, the response curves are governed by the equation

$$\left[(1 - \gamma^2)A + \frac{3\eta A^3}{4}\right]^2 + \beta^2 A^2 = \alpha^2 \tag{22.407}$$

which corresponds to the curves shown in Fig. 22.28.
Fig. 22.28 Response curves of the damped Duffing equation

Jump and Hysteresis. It can be seen from Fig. 22.28 that a frequency range exists where three different values for $|A|$ correspond to one single value of the reduced frequency γ. Only the two extreme solutions are stable, while the intermediate value is unstable. As a consequence, on decreasing or increasing the frequency, a jump phenomenon is observed at points corresponding to the vertical tangents. The hysteresis cycle include these two jumps in addition to the stable portions of the upper and lower resonance curves.

Generation of Subharmonics. An important property of nonlinear oscillators is that they exhibit spectral components that are not present in the forcing terms, and which are also distinct from their eigenfrequencies. The generation of subharmonics is examined here. The Duffing equation with a forcing term at reduced frequency 3γ is considered

$$\frac{d^2 y}{d\tau^2} + y + \eta y^3 = \alpha \cos 3\gamma\tau \tag{22.408}$$

with $\eta \ll 1$. We look for solutions of the form

$$y(\tau) = y_0(\tau) + \eta y_1(\tau) \quad \text{with} \quad \gamma^2 = 1 + \eta\gamma_1^2 . \tag{22.409}$$

By inserting (22.409) in (22.408) and eliminating the higher-order terms in η, we get

$$\frac{d^2 y_0}{d\tau^2} + \gamma^2 y_0 - \eta\gamma_1^2 y_0 + \eta\frac{d^2 y_1}{d\tau^2} + \eta\gamma^2 y_1 + \eta y_0^3$$
$$= \alpha \cos 3\gamma\tau . \tag{22.410}$$

The linear solution (zero-order term) is obtained by imposing $\eta = 0$ in (22.410), which yields

$$\frac{d^2 y_0}{d\tau^2} + \gamma^2 y_0 = \alpha \cos 3\gamma\tau . \tag{22.411}$$

With the appropriate initial conditions, we obtain the zero-order solution $y_0(\tau) = A \cos \gamma\tau + C \cos 3\gamma\tau$ with $C = -\alpha/8\gamma^2$. By pursuing the mathematical derivations iteratively, we obtain the first-order approximation y_1

$$\frac{d^2 y_1}{d\tau^2} + \gamma^2 y_1 = \gamma_1^2 y_0 - y_0^3 . \tag{22.412}$$

Inserting the expression for $y_0(\tau)$ in (22.412) it is found that $y_1(\tau)$ must be a solution of the equation

$$\frac{d^2 y_1}{d\tau^2} + \gamma^2 y_1$$
$$= A\left[\gamma_1^2 - \frac{3}{4}\left(A^2 + \frac{3\alpha^2}{64\gamma^4} - \frac{A\alpha}{8\gamma^2}\right)\right]\cos \gamma\tau$$
$$+ \text{terms in } 3\gamma, \ 5\gamma, \ 7\gamma, \ 9\gamma . \tag{22.413}$$

The first term on the right-hand side of (22.413) is a resonant excitation term or *secular term*, which leads to an infinitely growing solution. As such a solution is not physically possible, this secular terms must be eliminated, which leads to the condition

$$\gamma_1^2 = \frac{3}{4}\left(A^2 + \frac{3\alpha^2}{64\gamma^4} - \frac{A\alpha}{8\gamma^2}\right) . \tag{22.414}$$

Equation (22.414) yields the condition of existence, in terms of amplitude A and nonlinear strength η, for subharmonics of order three

$$\gamma^6 - \gamma^4 - \frac{3\eta}{256}(64A^2\gamma^4 - 8A\alpha\gamma^2 + 2\alpha^2) = 0 . \tag{22.415}$$

Similarly, one can show that the Duffing oscillator can yield superharmonics of order three. The method consists of imposing a forcing term with reduced frequency γ and looking for the condition of existence of solutions with frequency 3γ.

22.7.3 Coupled Nonlinear Oscillators

Continuous systems and discrete systems with several degrees of freedom subjected to large amplitude of motion show multiple nonlinear coupling effects. In this section, we limit ourselves to nonlinear coupling between two oscillators, which represents a significant step forward in terms of complexity compared to the single-DOF nonlinear oscillator.

Example of a Quadratic Nonlinear Coupling

Here, the case of a quadratic nonlinear coupling between two oscillators is investigated using the multiple-scales method [22.57]. The equations are

$$
\begin{cases}
\ddot{x}_1 + \omega_1^2 x_1 = \varepsilon(-\beta_{12} x_1 x_2 - 2\mu_1 \dot{x}_1) \,, \\
\ddot{x}_2 + \omega_2^2 x_2 = \varepsilon\left(-\beta_{21} x_1^2 - 2\mu_2 \dot{x}_2 + P \cos \Omega t\right) \,,
\end{cases}
\tag{22.416}
$$

where x_1 and x_2 are the displacements, ω_1 and ω_2 are the eigenfrequencies of the oscillators in the linear range. The perturbation terms are grouped on the right-hand side of (22.416). The nondimensional parameter $\varepsilon \ll 1$ indicates that these terms are small. The quadratic nonlinear coupling is due to the presence of the terms $\beta_{12} x_1 x_2$ and $\beta_{21} x_1^2$. It is assumed that the system has a so-called *internal resonance* in the sense that $\omega_2 = 2\omega_1 + \varepsilon\sigma_1$, where σ_1 is the internal detuning parameter. The forcing frequency Ω is close to ω_2 so that we can write $\Omega = \omega_2 + \varepsilon\sigma_2$ where σ_2 is the external detuning parameter, and μ_1 and μ_2 are viscous damping parameters.

Resolution with the Method of Multiple Scales

Solving the above equations involves calculating the amplitudes a_1 and a_2 of both oscillators as a function of the external detuning parameter σ_2. Another goal is to determine the values of the threshold in terms of amplitude and frequency, at which the nonlinear set of oscillators exhibit bifurcations and unstable behavior. The present example contains most of the concepts and methods used in the theory of multiple scales applied to nonlinear oscillators. The main steps of the calculations are the following:

1. Definition of time scales and general form of the solution
2. Solvability conditions. Elimination of secular terms
3. Autonomous system and fixed points
4. Stability of the system
5. Amplitudes and phases of the solution.

Definition of Time Scales and General Form of the Solution. The time scales are defined as

$$
T_j = \varepsilon^j t \quad \text{with} \quad j \geq 0
\tag{22.417}
$$

and the solutions are expanded into

$$
\begin{cases}
x_1(t) = x_{10}(T_0, T_1) + \varepsilon x_{11}(T_0, T_1) + O(\varepsilon^2) \\
x_2(t) = x_{20}(T_0, T_1) + \varepsilon x_{21}(T_0, T_1) + O(\varepsilon^2)
\end{cases} ,
\tag{22.418}
$$

where the expansion is limited here to the first order in ε. The differentiation operators can be written

$$
\begin{cases}
\dfrac{\partial}{\partial t} = \dfrac{\partial}{\partial T_0} + \varepsilon \dfrac{\partial}{\partial T_1} \,, \\[2mm]
\dfrac{\partial^2}{\partial t^2} = \dfrac{\partial^2}{\partial T_0^2} + 2\varepsilon \dfrac{\partial}{\partial T_0} \dfrac{\partial}{\partial T_1} \,.
\end{cases}
\tag{22.419}
$$

In what follows, we write $D_j = \partial/\partial T_j$. Inserting (22.419) into (22.416) and matching the coefficients of terms with the same power in ε yields:

- For the zero-order term $\varepsilon^0 = 1$

$$
D_0^2 x_{10} + \omega_1^2 x_{10} = 0 \,; \quad D_0^2 x_{20} + \omega_2^2 x_{20} = 0 \,;
\tag{22.420}
$$

- For the first-order term ε

$$
\begin{cases}
D_0^2 x_{11} + \omega_1^2 x_{11} \\
\quad = -2D_0 D_1 x_{10} - \beta_{12} x_{10} x_{20} - 2\mu_1 D_0 x_{10} \,, \\
D_0^2 x_{21} + \omega_2^2 x_{21} \\
\quad = -2D_0 D_1 x_{20} - \beta_{21} x_{10}^2 \\
\quad\quad - 2\mu_2 D_0 x_{20} + P \cos \Omega t \,.
\end{cases}
\tag{22.421}
$$

The solutions of (22.420) can be written

$$
\begin{aligned}
x_{10}(t) &= A_1(T_1)\,\mathrm{e}^{\mathrm{i}\omega_1 t} + A_1^*(T_1)\,\mathrm{e}^{-\mathrm{i}\omega_1 t} \,; \\
x_{20}(t) &= A_2(T_1)\,\mathrm{e}^{\mathrm{i}\omega_2 t} + A_2^*(T_1)\,\mathrm{e}^{-\mathrm{i}\omega_2 t} \,,
\end{aligned}
\tag{22.422}
$$

where the (*) indicates the complex conjugate.

Solvability Conditions. In order to calculate the complex terms $A_1(T_1)$ and $A_2(T_1)$, the expressions (22.422) are inserted into (22.421). Then, conditions are determined so that no secular terms, such as $t \cos \omega t$, exist in the solution. This leads to the so-called solvability conditions

$$
\begin{cases}
-2\mathrm{i}\omega_1\left(\dfrac{\partial A_1}{\partial T_1} + \mu_1 A_1\right) - \beta_{12} A_1^* A_2\, \mathrm{e}^{\mathrm{i}\sigma_1 T_1} = 0 \,, \\[3mm]
-2\mathrm{i}\omega_2\left(\dfrac{\partial A_2}{\partial T_1} + \mu_2 A_2\right) - \beta_{21} A_1^2\, \mathrm{e}^{-\mathrm{i}\sigma_1 T_1} \\[2mm]
\quad + \dfrac{P}{2}\, \mathrm{e}^{\mathrm{i}\sigma_2 T_1} = 0 \,.
\end{cases}
\tag{22.423}
$$

Equations (22.423) are usually written in polar form

$$A_1(T_1) = \frac{a_1}{2} e^{i\theta_1} ;$$
$$A_2(T_1) = \frac{a_2}{2} e^{i\theta_2} ,$$
(22.424)

where the amplitudes a_i and phases θ_i are functions of T_1. Substituting (22.424) in (22.423) yields the system that governs the slow temporal evolution of the response, with scale $T_1 = \varepsilon t$

$$\begin{cases} \dfrac{\partial a_1}{\partial T_1} = -\mu_1 a_1 - \dfrac{\beta_{12} a_1 a_2}{4\omega_1} \\ \qquad\qquad \sin(\sigma_1 T_1 + \theta_2 - 2\theta_1) , \\[2mm] a_1 \dfrac{\partial \theta_1}{\partial T_1} = \dfrac{\beta_{12} a_1 a_2}{4\omega_1} \cos(\sigma_1 T_1 + \theta_2 - 2\theta_1) , \\[2mm] \dfrac{\partial a_2}{\partial T_2} = -\mu_2 a_2 + \dfrac{\beta_{21} a_1^2}{4\omega_2} \sin(\sigma_1 T_1 + \theta_2 - 2\theta_1) \\ \qquad\qquad + \dfrac{P}{2\omega_2} \sin(\sigma_2 T_1 - \theta_2) , \\[2mm] a_2 \dfrac{\partial \theta_2}{\partial T_2} = \dfrac{\beta_{21} a_1^2}{4\omega_2} \cos(\sigma_1 T_1 + \theta_2 - 2\theta_1) \\ \qquad\qquad - \dfrac{P}{2\omega_2} \cos(\sigma_2 T_1 - \theta_2) . \end{cases}$$
(22.425)

Autonomous System and Fixed Points. Now, the system is written in autonomous form, i.e. in the form $\dot{X} = F(X)$. In practice, this is achieved with the changes of variables $\gamma_1 = \sigma_2 T_1 - \theta_2$ and $\gamma_2 = \sigma_1 T_1 + \theta_2 - 2\theta_1$. As a consequence (22.425) becomes

$$\begin{cases} \dfrac{\partial a_1}{\partial T_1} = -\mu_1 a_1 - \dfrac{\beta_{12} a_1 a_2}{4\omega_1} \sin \gamma_2 , \\[2mm] \dfrac{\partial \gamma_1}{\partial T_1} = \sigma_2 - \dfrac{\beta_{21} a_1^2}{4\omega_2 a_2} \cos \gamma_2 + \dfrac{P}{2\omega_2 a_2} \cos \gamma_1 , \\[2mm] \dfrac{\partial a_2}{\partial T_2} = -\mu_2 a_2 + \dfrac{\beta_{21} a_1^2}{4\omega_2} \sin \gamma_2 + \dfrac{P}{2\omega_2} \sin \gamma_1 , \\[2mm] \dfrac{\partial \gamma_2}{\partial T_2} = \sigma_1 - \dfrac{\beta_{12} a_2}{2\omega_1} \cos \gamma_2 + \dfrac{\beta_{21} a_1^2}{4\omega_2 a_2} \cos \gamma_2 \\ \qquad\qquad - \dfrac{P}{2\omega_2 a_2} \cos \gamma_1 . \end{cases}$$
(22.426)

The fixed points correspond to the steady-state solutions, which are those of interest in the case of forced vibrations. These solutions are obtained through cance-

lation of the time derivatives in (22.426), which gives

$$\begin{cases} a_1 \left(\mu_1 + \dfrac{\beta_{12} a_2}{4\omega_1} \sin \gamma_2 \right) = 0 , \\[2mm] \sigma_2 - \dfrac{\beta_{21} a_1^2}{4\omega_2 a_2} \cos \gamma_2 + \dfrac{P}{2\omega_2 a_2} \cos \gamma_1 = 0 , \\[2mm] -\mu_2 a_2 + \dfrac{\beta_{21} a_1^2}{4\omega_2} \sin \gamma_2 + \dfrac{P}{2\omega_2} \sin \gamma_1 = 0 , \\[2mm] \sigma_1 + \dfrac{\beta_{21} a_1^2}{4\omega_2 a_2} \cos \gamma_2 - \dfrac{P}{2\omega_2 a_2} \cos \gamma_1 \\ \qquad - \dfrac{\beta_{12} a_2}{2\omega_1} \cos \gamma_2 = 0 . \end{cases}$$
(22.427)

Imposing $a_1 = 0$ in (22.427) yields the response curve a_2 of the second oscillator in the linear case (Fig. 22.29)

$$a_2 = \frac{P}{2\omega_2 \sqrt{\sigma_2^2 + \mu_2^2}} .$$
(22.428)

Stability of the Nonlinear Coupled System. Intuitively, a physically unstable system behaves in such a way that, subjected to a small departure from equilibrium, its motion will never bring it back to its initial position but will rather continue its deviation. From a mathematical point of view, the deviations from an equilibrium position for a system with multiple variables such as (22.427) are calculated from the partial derivatives of each equation with regard to all variables of the system. This leads to
Fig. 22.29 Frequency response curves of the nonlinearly coupled oscillators as a function of the external detuning parameter

the definition of the Jacobian matrix $\mathcal{J}$ of the system

$$
\mathcal{J} = \begin{vmatrix} \dfrac{\partial f_1}{\partial a_1} & \dfrac{\partial f_1}{\partial \gamma_1} & \dfrac{\partial f_1}{\partial a_2} & \dfrac{\partial f_1}{\partial \gamma_2} \\[2mm] \dfrac{\partial f_2}{\partial a_1} & \dfrac{\partial f_2}{\partial \gamma_1} & \dfrac{\partial f_2}{\partial a_2} & \dfrac{\partial f_2}{\partial \gamma_2} \\[2mm] \dfrac{\partial f_3}{\partial a_1} & \dfrac{\partial f_3}{\partial \gamma_1} & \dfrac{\partial f_3}{\partial a_2} & \dfrac{\partial f_3}{\partial \gamma_2} \\[2mm] \dfrac{\partial f_4}{\partial a_1} & \dfrac{\partial f_4}{\partial \gamma_1} & \dfrac{\partial f_4}{\partial a_2} & \dfrac{\partial f_4}{\partial \gamma_2} \end{vmatrix} . \tag{22.429}
$$

In our case, the eigenvalues of this Jacobian are

$$
\begin{cases}
\lambda_1 = -\mu_2 + \mathrm{i}\sigma_2 \, ; \\[2mm]
\lambda_2 = -\mu_2 - \mathrm{i}\sigma_2 \, ; \\[2mm]
\lambda_3 = -\dfrac{\beta_{12}a_2}{4\omega_1}\sin\gamma_2 - \mu_1 \, ; \\[2mm]
\lambda_4 = \dfrac{\beta_{12}a_2}{2\omega_1}\sin\gamma_2 \, .
\end{cases} \tag{22.430}
$$

The system is unstable if the real part of any one of these eigenvalues is positive. In (22.430), the real parts of λ_1 and λ_2 are negative, because of the damping term μ_2. However, calculating the product of the two other eigenvalues yields

$$
\lambda_3\lambda_4 = -\frac{\mu_1\beta_{12}a_2}{2\omega_1}\sin\gamma_2 - \frac{\beta_{12}^2 a_2^2}{8\omega_1^2}\sin^2\gamma_2 \, . \tag{22.431}
$$

This product can be negative, leading to an instability, if

$$
a_2 > \frac{2\omega_1}{|\beta_{12}|}\sqrt{4\mu_1^2 + (\sigma_1 + \sigma_2)^2} \, . \tag{22.432}
$$

The instability domain corresponding to (22.432) is the shaded area in Fig. 22.29.

Amplitudes and Phases of the Solution. Solutions for the nonlinear coupled system are obtained by combining (22.422) with (22.424), taking the definitions of T_1, σ_1, σ_2 γ_1 and γ_2 into account. We then obtain

$$
\begin{cases}
x_{10} & = a_1\cos(\omega_1 t + \theta_1) \\[2mm]
& = a_1\cos\left(\dfrac{\Omega}{2}t - \dfrac{\gamma_1 + \gamma_2}{2}\right) , \\[2mm]
x_{20} & = a_2\cos(\omega_2 t + \theta_2) = a_2\cos(\Omega t - \gamma_1) ,
\end{cases} \tag{22.433}
$$

where, by solving the system (22.427), the amplitudes of the oscillators are given by

$$
\begin{cases}
a_2 = \dfrac{2\omega_1}{|\beta_{12}|}\sqrt{(\sigma_1 + \sigma_2)^2 + 4\mu_1^2} \, , \\[3mm]
a_1 = 2\left[-\Gamma_1 \pm \sqrt{P^2 \big/ \left(4\beta_{21}^2\right) - \Gamma_2^2}\,\right]^{1/2} , \\[3mm]
\text{with} \quad \Gamma_1 = \dfrac{2\omega_1\omega_2}{\beta_{12}\beta_{21}}\left[2\mu_1\mu_2 - \sigma_2(\sigma_1 + \sigma_2)\right] , \\[3mm]
\text{and} \quad \Gamma_2 = \dfrac{2\omega_1\omega_2}{\beta_{12}\beta_{21}}\left[2\mu_1\sigma_2 - \mu_2(\sigma_1 + \sigma_2)\right] .
\end{cases} \tag{22.434}
$$

Equation (22.433) shows that, for steady-state oscillations, the forcing frequency Ω is the same as the oscillation frequency of the second oscillator whereas, for appropriate conditions of instability, the first one oscillates with frequency $\Omega/2$, as a result of the nonlinear coupling. Figure 22.29 shows the resonance curves of the coupled nonlinear oscillators as a function of σ_2. By increasing this parameter progressively, successive phenomena occur:

1. First the resonance curve is that of the second oscillator. No subharmonics are observed as long as the amplitude remains below the instability region.
2. As the amplitude of the second oscillator reaches the instability limit given in (22.432), the first oscillator starts to oscillate. In our example, its magnitude a_1 is larger than a_2.
Fig. 22.30 Experimental response curves for two nonlinearly coupled degrees of freedom of a harmonically forced spherical shell (after *Thomas* et al. [22.19])

3. As the amplitude reaches the top of the resonance curve 1, it suddenly jumps back to the resonance curve 2, and oscillation at $\Omega/2$ disappears.
4. Following the frequency axis in the reverse direction, similar phenomena are observed, although the jumps do not occur at the same frequencies. Also the values of the instability thresholds are different.

To illustrate this theoretical part, Fig. 22.30 shows an example of experimental results for nonlinear coupling between two particular degrees of freedom of a spherical shell with free edge subjected to large-amplitude motion [22.19].

22.7.4 Nonlinear Vibrations of Strings

As an example of nonlinear coupling in a continuous system, the forced vibrations of a homogeneous elastic string is examined. Following the presentation by *Murthy* and *Ramakrishna*, only the coupling between the two polarizations $y(x, t)$ and $z(x, t)$ is presented [22.58, 59]. Other complicating effects such as torsional and longitudinal motions are neglected. See, for example, [22.60] for a more complete description of the nonlinear vibrating string.

Equations of Motion
As a result of the initial tension T_0 applied to the string, the length of a small element dx increases by a relative quantity λ, so that the actual length ds is given by

$$ds - dx = \lambda \, dx .\tag{22.435}$$

As a result, for a string with a Young's modulus of E and cross-sectional area of A, the actual tension becomes

$$T = T_0 + EA\lambda .\tag{22.436}$$

In the general case, we have $ds = [\,dx^2 + dy^2 + dz^2\,]^{1/2}$, which, by means of a second-order development is written

$$ds = dx\left\{1 + \frac{1}{2}\left[\left(\frac{\partial y}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial x}\right)^2\right]\right.$$
$$\left. - \frac{1}{8}\left[\left(\frac{\partial y}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial x}\right)^2\right]^2 + \dots\right\} .\tag{22.437}$$

With the additional assumption that $EA \gg T_0$, the potential energy of the string of length L rigidly fixed at both ends is written [22.58]

$$V = \int_0^L \left\{ \frac{T_0}{2}\left[\left(\frac{\partial y}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial x}\right)^2\right] \right.$$
$$\left. + \frac{EA}{8}\left[\left(\frac{\partial y}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial x}\right)^2\right]^2 \right\} dx .\tag{22.438}$$

The kinetic energy of the string is given by

$$E_k = \frac{\mu}{2}\int_0^L \left[\left(\frac{\partial y}{\partial t}\right)^2 + \left(\frac{\partial z}{\partial t}\right)^2\right] dx .\tag{22.439}$$

Using Hamilton's principle, and considering further that a sinusoidal force $f(x) \cos \omega t$ is applied to the string in the y-direction, we get the coupled equations of motion, where the derivatives are written with subscripts for convenience

$$\begin{cases} y_{tt} - c_0^2 y_{xx} &= \dfrac{c_1^2}{2}\left[3y_{xx}y_x^2 + \dfrac{\partial}{\partial x}\left(y_x z_x^2\right)\right] \\ &\quad + \dfrac{f(x)}{\mu}\cos \omega t , \\ z_{tt} - c_0^2 z_{xx} &= \dfrac{c_1^2}{2}\left[3z_{xx}z_x^2 + \dfrac{\partial}{\partial x}\left(z_x y_x^2\right)\right] , \end{cases}\tag{22.440}$$

where $c_0 = \sqrt{T_0/mu}$ and $c_1 = \sqrt{EA/\mu}$ are the transverse and longitudinal velocities in the linear case. It can be seen that the nonlinear terms on the right-hand side of (22.440) are negligible, as long as the slopes y_x and z_x are small. The terms on the left-hand side of (22.440) correspond to the linear case. The coupling between the two polarizations is due to the presence of the nonlinear terms. As a consequence, a force applied in the y-direction can give rise to a motion in the z-direction.

Forced Vibrations
Neglecting the nonlinear terms in (22.440) is generally not justified near resonance. We assume that the excitation frequency ω is close to one particular (linear) eigenfrequency $\omega_n = n\pi c_0/L$ of the string. If the coupling between the modes is neglected (which might not always be justified, see [22.59]) then the motion of the string can be described, to a first approximation by

$$y(x, t) = a_{ny} \sin \frac{n\pi x}{L} \cos \omega t$$

and

$$z(x, t) = a_{nz} \sin \frac{n\pi x}{L} \sin \omega t .\tag{22.441}$$

This leads to the following relations between the amplitudes a_{ny} and a_{nz}

$$
\begin{cases}
(\omega_n^2 - \omega^2)a_{ny} + \dfrac{9c_1^2}{32}\left(\dfrac{n\pi}{L}\right)^4 a_{ny}^3 \\
+ \dfrac{3c_1^2}{32}\left(\dfrac{n\pi}{L}\right)^4 a_{ny}a_{nz}^2 = \dfrac{\alpha_n}{\mu}, \\
(\omega_n^2 - \omega^2)a_{nz} + \dfrac{9c_1^2}{32}\left(\dfrac{n\pi}{L}\right)^4 a_{nz}^3 \\
+ \dfrac{3c_1^2}{32}\left(\dfrac{n\pi}{L}\right)^4 a_{nz}a_{ny}^2 = 0,
\end{cases} \tag{22.442}
$$

where α_n is the projection of the excitation force onto the nth mode of the string.

Planar Motion. The case of planar motion for the string is obtained by setting $a_{nz} = 0$ in (22.442). In this case, the amplitude in the y-direction is governed by the nonlinear equation

$$
(\omega_n^2 - \omega^2)a_{ny} + \dfrac{9c_1^2}{32}\left(\dfrac{n\pi}{L}\right)^4 a_{ny}^3 = \dfrac{\alpha_n}{\mu} \tag{22.443}
$$

which is similar in form to (22.404), obtained in the case of a discrete Duffing oscillator. Therefore, all properties of Duffing oscillators of the hardening type presented in Sect. 22.7.2 can be transposed here.

Nonplanar Motion. Eliminating a_{nz} between the two equations in (22.442) yields first for a_{ny}

$$
(\omega_n^2 - \omega^2)a_{ny} + \dfrac{3c_1^2}{8}\left(\dfrac{n\pi}{L}\right)^4 a_{ny}^3 = \dfrac{\alpha_n}{\mu}, \tag{22.444}
$$

which is similar in form to (22.443) except that the nonlinear term has increased by a factor of 4/3 compared to the planar case. The second equation can be written in the form

$$
a_{nz}^2 = a_{ny}^2 - \dfrac{16}{3}\dfrac{\alpha_n}{\mu c_1^2\left(\frac{n\pi}{L}\right)^4 a_{ny}}. \tag{22.445}
$$

Equation (22.445) shows that the string can exhibit nonplanar motion under the condition

$$
a_{ny} > a_{ny}^{\text{crit}} = \left(\dfrac{16\alpha_n}{3\mu c_1^2\left(\frac{n\pi}{L}\right)^4}\right)^{1/3}. \tag{22.446}
$$

This condition can be obtained either by increasing the excitation force or by varying the frequency to come closer to resonance.

22.7.5 Review of Nonlinear Equations for Other Continuous Systems

Beams

In this paragraph, the influence of amplitude on the flexural equations of beams is summarized. For more-extensive developments, one can refer to the review by *Nayfeh* [22.57]. The same notations as in Sect. 22.4.2 are used. The case of a homogeneous beam with constant cross section is considered. The plane cross sections remain plane during the motion. The radius of gyration $r = \sqrt{I_z/S}$ is assumed to be small compared to the wavelength so that transverse shear and rotary inertia are neglected. We assume planar motion, and the losses are simply modeled by a linear viscous term. Given an arbitrary characteristic length w_0, we can define the set of dimensionless variables [22.57]

$$
x^* = \dfrac{x}{w_0}, \quad w^* = \dfrac{w}{w_0}, \quad L^* = \dfrac{L}{w_0},
$$

$$
r^* = \dfrac{r}{w_0}, \quad t^* = t\dfrac{r}{w_0^2}\sqrt{\dfrac{E}{\rho}}. \tag{22.447}
$$

In this case, the nonlinear flexural equation of a beam hinged at both ends is written in nondimensional form (removing the asterisk for convenience)

$$
r^2\big(w_{tt} + \mu w_t + w_{xxxx}\big)
$$

$$
= \left(\dfrac{1}{2L}\int_0^L w_x^2\,dx\right)w_{xx} + f(x, t), \tag{22.448}
$$

where μ is the dimensionless viscous damping parameter, and where the indices refer to the derivatives. Equation (22.448) shows that the nonlinear term is due to the increase in axial tension consecutive to large-amplitude motion. Expanding the solution on the linear eigenmodes $w(x, t) = \sum_n \Phi_n(x)q_n(t)$, we obtain, for the special case of the hinged–hinged beam, the following set of nonlinearly coupled differential equations

$$
\ddot{q}_n + \omega_n^2 q_n = -\varepsilon\left(\mu\dot{q}_n + \dfrac{\omega_n^2}{2n^2}q_n\sum_{m=1}^{\infty} m^2 q_m^2\right) + f_n(t), \tag{22.449}
$$

where ε is a small dimensionless parameter indicating that the slenderness ratio of the beam is small. Equation (22.449) generalizes (22.416) obtained for two nonlinearly coupled oscillators, though an important difference is that we have to deal here with cubic nonlinear terms, instead of the quadratic terms in the previously mentioned 2-DOF nonlinear system.

Shallow Spherical Shells and Plates

Similarly, the case of large deflections for transverse vibrations of shallow spherical shells is now examined. The same notations and assumptions as in Sect. 22.4.4 are used. The only difference is that we assume here large displacements and moderate rotations. Moderate rotations mean that it is justified to linearize the angular functions $\sin\theta$ and $\cos\theta$ in the equations. The definition of large displacement depends on the order of magnitude of the characteristic length used for obtaining the dimensionless equations of motions (see below). These standard assumptions lead to the well-known von Kármán equations, also called Marguerre's or Koiter's equations in the literature [22.19, 61]. *Hamdouni* and *Millet* have shown recently that these equations can also be obtained through an asymptotic method applied to the general equations of elasticity [22.62]. Like in the linear case (Sect. 22.4.4), the assumption of thin shallow shell allows one to write the equations of motion as a function of the circular coordinates (r, θ) that refer to the projection of a current point of the shell on the horizontal plane. Finally, we obtain [22.19]

$$
\begin{cases}
\nabla^4 w + \dfrac{\nabla^2 F}{R} + \rho h \ddot{w} = L(w, F) - \mu \dot{w} + p \,, \\[2mm]
\nabla^4 F - \dfrac{Eh}{R} \nabla^2 w = -\dfrac{Eh}{2} L(w, w) \,,
\end{cases}
$$

(22.450)

where F is the Airy stress function, and where L is a bilinear quadratic operator which is written in circular coordinates as

$$
L(w, F) = w_{rr}\left(\frac{F_r}{r} + \frac{F_{\theta\theta}}{r^2}\right) + F_{rr}\left(\frac{w_r}{r} + \frac{w_{\theta\theta}}{r^2}\right) \\
- 2\left(\frac{w_{r\theta}}{r} - \frac{w_\theta}{r^2}\right)\left(\frac{F_{r\theta}}{r} - \frac{F_\theta}{r^2}\right) .
$$

(22.451)

In (22.450), F contains linear and quadratic terms in w. Therefore, $L(w, F)$ contains quadratic and cubic terms in w. In total, the nonlinear equations of the shell contain linear, quadratic and cubic terms. With $R \to \infty$, (22.450) reduces to the nonlinear plate equations. In this case, only cubic terms are present.

Equation (22.450) can be put into nondimensional form with the change of variables [22.19]

$$
r = a\bar{r} \,,
$$

$$
t = a^2\sqrt{\frac{\rho h}{D}}\,\bar{t} \,,
$$

$$
w = \frac{h^3}{a^2}\,\bar{w} \,,
$$

$$
F = \frac{Eh^7}{a^4}\,\bar{F} \,,
$$

$$
\mu = \left(\frac{2Eh^4}{Ra^2}\right)\sqrt{\frac{\rho h}{D}}\,\bar{\mu} \,,
$$

$$
p = \frac{Eh^7}{Ra^6}\,\bar{p} \,.
$$

(22.452)

Equation (22.450) becomes, with the overbars dropped for convenience,

$$
\begin{cases}
\nabla^4 w + \varepsilon_q \nabla^2 F + \ddot{w} \\
\quad = \varepsilon_c L(w, F) + \varepsilon_q\left(-\mu \dot{w} + p\right), \\[2mm]
\nabla^4 F - \dfrac{a^4}{Rh^3}\nabla^2 w = -\dfrac{1}{2} L(w, w) \,.
\end{cases}
$$

(22.453)

Equation (22.453) has the advantage of highlighting a quadratic perturbation coefficient $\varepsilon_q = 12(1 - v^2)h/R$ and a cubic perturbation coefficient $\varepsilon_c = 12(1 - v^2)h^4/a^4$. In view of the assumptions of a thin shallow shell, the cubic nonlinear terms are much smaller than the quadratic ones. The quadratic terms are due to the curvature of the shell.

Expanding the solution on the linear eigenmodes

$$
w(r, \theta, t) = \sum_n \Phi_n(r, \theta) q_n(t)
$$

(22.454)

yields the set of coupled differential equations

$$
\ddot{q}_n + \omega_n^2 q_n = \varepsilon_q\left(-\sum_p \sum_q \alpha_{npq} q_p q_q - \mu \dot{q} + p_n\right) \\
+ \varepsilon_c \sum_q \sum_q \sum_r \beta_{npqr} q_p q_q q_r \,,
$$

(22.455)

which shows multiple cubic and quadratic coupling. For a plate, the coefficients α_{npq} are equal to zero. For shells, one can see an analogy with the interrupted pendulum presented in Sect. 22.7.1 in the sense that the quadratic nonlinearity is due to the asymmetry arising from the curvature.

22.8 Conclusion. Advanced Topics

A number of applications of interest in the field of structural acoustics and vibrations were not described in this chapter, since they are exhaustively presented in other chapters; this is, for example, the case of near-field acoustical holography and modal analysis. Also the area of active control of sound was only briefly mentioned, since the presentation of this technique would need a significant part devoted to signal processing.

In recent years, new theories have been developed in order to allow better prediction and modeling of structures and the related acoustic field in the medium frequency range, i. e., when modes overlap due to both damping and increasing modal density. In this context, a new model and the associated numerical method based on the theory of structural fuzzy has been given by *Soize* [22.63]. Fuzzy structures are systems composed by a well-defined *master* structure with other smaller subsystems attached on it, whose location, geometry and material properties are not known with certainty. One can think of the main body of a ship (or of a plane), with some attached equipment and/or ribs. The general idea is to describe the behavior of the subsystems with a probabilistic law; the input data are given in terms of mean value and dispersion. The advantage of such a technique is to greatly reduce the number of degrees of freedom. A recent paper by *Lyon* shows the analogy between SEA and structural fuzzy framework [22.64].

Several analytical models of structural acoustics and vibrations have been presented in this chapter. However, one should be aware of the fact that analytical solutions are generally hard to obtain in engineering applications. Therefore, numerical methods are required, and considerable work has been done in the field of computational structural dynamics over the last decades. Notice that analytical results are nonetheless very useful for testing the validity of numerical models. One can refer, for example, to the review by *Wachulec* et al. in order to get a comprehensive overview of the advantages and drawbacks of the main numerical methods applied to structure-borne sound, depending on the frequency range and structural complexity [22.65].

Finally, the design of smart materials for the active control of vibrations and sound is an active field and a good example of interdisciplinary work in structural acoustics. The goal in this area is often to use appropriate actuators and sensors in order to reduce the noise generated by structures. However, other applications such as enhancing or modifying intentionally some modal parameters, for example in musical instruments, are also potential applications. One difficulty is finding the appropriate locations for the actuators. Another problem is to find transducers that are insensitive to external electromagnetic fields. The interested reader can refer to a recent work by *Shih* et al. for more information [22.66].

Noise

George C. Maling Jr.

Noise is discussed in terms of a source–path–receiver model. After an introduction to sound propagation and radiation efficiency, the quantities measured for noise control are defined, and the instruments used for noise measurement and control are described.

The noise emission of sources is discussed with emphasis on the determination of the sound power level of a variety of sources. The properties of two very significant sources of environmental noise, aircraft and motor vehicles, are presented. Tire noise is identified as a major noise source for motor vehicles. Criteria for the noise emission of sources are given, and the basic principles of noise control are presented. A section on active control of noise is included.

The path from the source to the receiver includes propagation in the atmosphere, noise barriers, the use of sound–absorptive materials, and silencers. Guidance is given on the determination of sound pressure level in a room when the sound power output of the source is known.

At the receiver, the effects of noise are presented, including both hearing damage and annoyance. A brief section is devoted to sound quality.

Finally, noise regulations and policies are discussed. Many activities of the US government are discussed, and information on both state and local noise policies and regulations are presented. The activities of the European Union are included, as are the noise policies in many countries.

23.1 Fundamentals

23.1.1 The Source–Path–Receiver Model

The standard definition of noise is *unwanted sound*. This definition implies that there is an observer who hears the noise and makes a judgment based on a number of factors that what is heard is not wanted. This judgment may be made because the sound is too loud, is annoying, or has an unpleasant quality. In all cases, the receiver applies some metric to what is heard in order to characterize sound as noise. In other cases, the level of the sound is high enough to cause hearing damage, and the listener may accept the noise levels, as in an industrial situation, or may actually want the sound, as at a loud concert or in an automobile with a very loud audio system. The concept of *unwanted sound* also implies that there is a person who wants the sound level reduced; hence, the field of noise control has been developed to satisfy these needs. In some cases, control of noise is an administrative matter such as setting hours of operation for noisy outdoor activities or otherwise managing noise sources to make the levels acceptable. In most cases, however, a technical analysis of the source, an understanding of the propagation of sound from the source to the receiver, and application of one or more psychoacoustic metrics is required to find a solution to a noise problem. This process may be called *noise control engineering*. This source–path–receiver model was first proposed by *Bolt* and *Ingard* in 1956 [23.1], and has proved to be very useful as a systematic way to approach noise control problems. There are many situations where the distinction between a source and a path is not clear; for example when sound travels from a source through a structure and is radiated by the structure Chap. 22. Nevertheless, the above model has proved to be useful in many practical situations.

Another concept that has proved to be useful is the distinction between *emission* and *immission*. The verb emit is common in the English language, and means to send out. The verb *immit* is currently much less common, but has a long history, and means to receive [23.2]. Noise control then deals with noise emission from sources – using a variety of metrics – and noise immission is the reception of sound by an observer – expressed as some metric based on sound pressure level.

23.1.2 Properties of Sound Waves

Noise propagation, for the purposes of this chapter, can be described in terms of linear acoustics Chap. 3.

Exceptions include propagation of sonic booms and very-high-amplitude sound waves such as in gas turbines and other devices. For such problems, nonlinear acoustical theory is needed Chap. 8, which will not be covered here. The physical quantities most often used in noise control are sound pressure, particle velocity, sound intensity and sound power. A one-dimensional treatment serves to illustrate the principles involved. The linear one-dimensional wave equation may be expressed in terms of sound pressure as

$$\frac{\partial^2 p}{\partial x^2} - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = Q \ , \tag{23.1}$$

where p is the sound pressure, x is distance, and t is time. The speed of sound c is given by

$$c = 20.05\sqrt{T} \ , \tag{23.2}$$

where T is the temperature in Kelvin. At $20\,°C$, $c = 343.3\,m/s$, rounded to $344\,m/s$ for most noise control problems.

The *source term* Q in (23.2) represents the various sources of sound, and may be in the form of fluctuations in mass, force, or heat introduced into the medium. Or, it may be nonlinear terms placed on the right-hand side of the equation as in the *acoustic analogy* proposed by *Lighthill* [23.3] which explains the generation of sound by turbulence Chap. 3.

For $Q = 0$ in an unbounded medium at rest, any function $f(x - ct)$ a propagating wave, satisfies the wave equation. The exact solution is determined by the nature of the sources and the boundary conditions. The particle velocity (for one-dimensional propagation) is found from

$$\rho\frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} \ . \tag{23.3}$$

Where u is the particle velocity. As will be shown below, the sound pressure and particle velocity in almost all cases are small compared with atmospheric pressure and the speed of sound, respectively. Therefore, air can be considered a linear medium for the propagation of sound waves, and the sound pressures as a function of time from two (or more) sources can be added to find the total pressure p

$$p(t) = p_1(t) + p_2(t) \ . \tag{23.4}$$

However, the quantity measured by sound level meters and other analyzers is the root-mean-square (RMS) pressure over some time interval, which may be very short. In this case, the way two sound pressures are com-

bined depends on the correlation coefficient between them. The total mean-square pressure is

$$\overline{p^2} = \overline{p_1^2} + \overline{p_2^2} + \overline{2 p_1 p_2} \,, \tag{23.5}$$

where the overbars represent time averages. When p_1 and p_2 are uncorrelated, the cross-term in (23.5) is zero, and it is the mean square pressures that add. This is the case in most noise control situations where the noise comes from one or more different sources. When $p_1 = p_2$, it is the pressures that add. When $p_1 = -p_2$, generally the objective in active noise control, the resulting mean-square pressure is zero. For sinusoidal signals, the mean-square pressure depends on the amplitudes of the waves and the phase difference between them.

Other quantities of importance are the intensity I of the sound wave, a vector in the direction of propagation that is the sound energy per unit of area perpendicular to an element of surface area dS, Chap. 6. For a source of sound, the total sound power W radiated by the source is given by

$$W = \int_S \boldsymbol{I} \cdot d\boldsymbol{S} \,, \tag{23.6}$$

where the integral is over a surface that surrounds the source. Sound power is a widely used measure of the noise emission of the source. Its determination using sound intensity is advantageous in the presence of background noise because, in the absence of sound-absorptive materials inside the surface, any sound energy that enters the surface from the outside also leaves the surface from the inside, and thus does not affect the radiated power. In practice, the sound intensity on the surface is determined by scanning or by measurements at a finite number of measurement positions, and only an approximation to the ideal situation is obtained Chap. 6. Other techniques for the determination of the sound power of sources depend on an approximation of the intensity in terms of mean-square pressure, and are discussed later in this chapter.

The Decibel as a Unit of Level

As will be shown below, the magnitude of the quantities associated with a sound wave described above vary over a very wide range, and it is convenient to use logarithms to compress the scale. Logarithms are also useful in many noise transmission problems because quantities that are multiplicative in terms of the quantities themselves are additive using logarithms. The decibel is a unit of level, and is defined as

$$L_x = 10 \log \frac{X}{X_0} \,, \tag{23.7}$$

where X is a quantity related to energy, X_0 is a reference quantity, and log is the logarithm to the base 10. In the case of sound pressure $X = p^2$ the mean square pressure and $X_0 = p_0^2$. The reference pressure p_0 is standardized at $20\,\mu\text{Pa}$ ($2 \times 10^{-5}\,\text{N/m}^2$). The sound pressure level can then be written as

$$L_p = 10 \log \frac{p^2}{(2 \times 10^{-5})^2} \,\text{dB} \,. \tag{23.8}$$

For sound power and sound intensity, the reference levels are $10^{-12}\,\text{W}$ and $10^{-12}\,\text{W/m}^2$, respectively, and the corresponding sound power and sound intensity levels are

$$L_W = 10 \log \frac{W}{10^{-12}} \,\text{dB} \,, \tag{23.9}$$

$$L_I = 10 \log \frac{I}{10^{-12}} \,\text{dB} \,. \tag{23.10}$$

Note that all three quantities above are expressed in decibels; the decibel is a *unit of level*, and may be used to express a variety of quantities related to energy relative to a reference level. This fact often causes confusion because the quantity being expressed in decibels is often not stated (*The level is* 75 dB.), and the meaning of the statement is not clear. The wide use of sound power level as a measure of noise emission can easily cause confusion between sound power level and sound pressure level. In this situation, it is convenient, and common in the information technology industry, to omit the 10 before the logarithm in (23.9), and express sound power level in bels, where one bel = 10 dB.

Relative Magnitudes

As mentioned above, the quantities associated with a sound wave are small. For example, a sound pressure level of 90 dB is relatively high and corresponds to an RMS sound pressure of

$$p_A = \sqrt{[(4 \times 10^{-10}) \times 10^{90/10}]} = 0.63\,\text{Pa} \,. \tag{23.11}$$

Since atmospheric pressure p_{at} is nominally $1.01 \times 10^5\,\text{Pa}$, the ratio p_0/p_{at} is very small: 0.62×10^{-5}.

The particle velocity can be determined from (23.3) assuming plane wave propagation of a sinusoidal wave having a radian frequency ω ($\omega = 2\pi f$). In this case, (23.3) reduces to $p = \rho c u$ where ρ is the density of air, nominally $1.18\,\text{kg/m}^2$. The particle velocity is then

$$u = \frac{0.63}{(1.18 \times 344)} = 1.6 \times 10^{-3}\,\text{m/s} \tag{23.12}$$

and the ratio u/c is 4.7×10^{-6}. The particle velocity is very small compared with the speed of sound, and the model of a wave traveling with speed c and having a particle velocity u is justified. When this is not the case, the

compressional portion of the wave travels with speed $c + u$ and the rarefaction travels with speed $c - u$. This phenomenon is important when considering the propagation of sonic booms and other finite-amplitude waves.

23.1.3 Radiation Efficiency

The radiation efficiency of ideal sources is best described in terms of the sound power radiated by higher-order sources relative to monopole radiation, as
Fig. 23.1a–c Schematic of loudspeakers in an enclosure. (**a**) Two loudspeakers operating in phase to form a monopole. (**b**) Two loudspeakers operating out of phase to form a dipole. (**c**) Four speakers that form a quadrupole

discussed below. For actual sources, the radiation efficiency can be expressed in terms of the sound power output of the source relative to the mechanical power input. As shown below, the acoustic power radiated by an actual source is a very small fraction of the mechanical power of the source.

Radiation Efficiency of Ideal Sources
One way of classifying sources and determining the efficiency of the radiation of sound is in terms of a monopole and higher-order sources. If a sinusoidal source, such as two small baffled loudspeakers operating in phase having a radian frequency $\omega = 2\pi f$ injects mass per second with amplitude Q_o into the air, the power W_m radiated by the combination of the two sources can be shown to be [23.6]

$$W_m = \frac{(\omega^2 Q_o^2)}{8\pi\rho c} .$$ (23.13)

The situation is illustrated in Fig. 23.1.

The plus signs indicate that the two loudspeakers are operating in phase. The distance between all loudspeak-

Typical outdoor setting

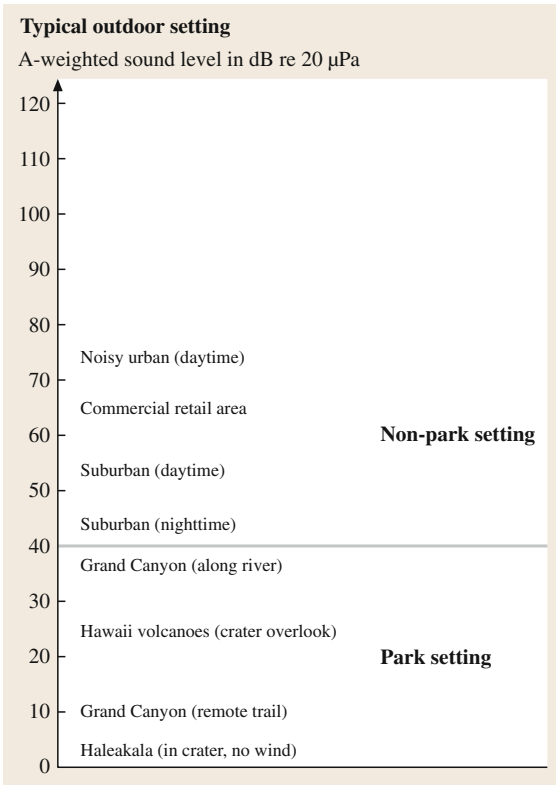
A-weighted sound level in dB re 20 μPa


Fig. 23.4 Comparison of outdoor A-weighted levels in different environments (after *Miller* [23.7], with permission)

ers is d. In the second case (b) the two loudspeakers are operated out of phase and form a dipole with a dipole moment in the direction shown. In this case, the total power radiated relative to monopole radiation can be shown [23.6] to be

$$W_{\mathrm{d}} = \frac{1}{24}\,(kd)^2\,W_{\mathrm{m}}\,, \qquad (23.14)$$

where k is the wave number (ω/c) and d is the distance between the two sources. If two dipoles with opposite dipole moments are combined, the result is

a quadrupole – as illustrated in (c). In this case, the total power radiated relative to monopole radiation can be shown [23.6] to be

$$W_{\mathrm{q}} = \frac{1}{120}\,(kd)^4\,W_{\mathrm{m}}\,. \qquad (23.15)$$

It can be seen that at small values of kd (low frequencies), dipole and quadrupole sources of sound are much less efficient in radiating sound than monopoles. The dipole case is especially important because one way to reduce the source noise level is to create a secondary source of opposite phase near the primary sources. The sound radiated by the secondary source partially cancels the sound radiated by the primary source, and the radiation efficiency is reduced.

Radiation Efficiency of Machines

The sound power radiated by a source is also a very small fraction of the mechanical power driving the source. *Shaw* [23.4] studied the radiation efficiency of a number of practical sources, and found that only a small fraction of the mechanical power was converted to sound. Figure 23.2 shows the relationship between A-weighted sound power and mechanical power for a wide variety of sources.

23.1.4 Sound Pressure Level of Common Sounds

Many authors have shown the relationship between sound pressure level and many common sounds. Data adapted from *Burgé* [23.5] are shown in Fig. 23.3. A-weighted sound pressure levels range from about 25 to 110 dB, which is a range in sound pressure of approximately 1 : 18 000. Similar data, but at lower sound pressure levels, have been adapted from Miller and are shown in Fig. 23.4. The vertical scales are labeled differently to conform to the practice of each author. As can be seen, there is a considerable difference for certain common terms; environmental levels may vary greatly in urban and suburban areas.

23.2 Instruments for Noise Measurements

23.2.1 Introduction

The most common quantity for control and assessment of noise is the frequency-weighted sound level, as measured by a sound level meter. Exponential time weighting may also be employed for measurements of frequency-

weighted sound level. Sound pressure levels are usually measured through constant-percentage-bandwidth filters. Sound intensity is commonly used for localization of noise sources and for direct determination of sound power level. As discussed in Sect. 23.3.1, measurements of time-average sound pressure levels are also

widely used for the determination of sound power levels. The time-average sound level is also known as the equivalent-continuous sound level.

23.2.2 Sound Level

Sound pressure almost always varies with the position of the receiver in space and with time. When measured by a sound level meter, the instantaneous sound pressure signal is frequency weighted, squared, time integrated, and time averaged before the logarithm is taken to display the result in decibels relative to the standard reference pressure. The process is illustrated by the following expression for a time-averaged frequency-weighted sound level L_{wT} in decibels

$$L_{wT} = 10 \log \left(\frac{\left[\left(\frac{1}{T} \right) \int_{-T}^{t} p_w^2(\xi) \, d\xi \right]^{1/2}}{p_0} \right)^2,$$

(23.16)

where T is the duration of the averaging time interval, ξ is a dummy variable for time integration over the averaging time interval ending at the time of observation t, $p_w(\xi)$ is the instantaneous frequency-weighted sound pressure signal in Pascals, and p_0 is the standard reference pressure of 20 μPa.

The numerator of the argument of the logarithm in (23.16) represents the root-mean-square frequency-weighted sound pressure over the duration of the averaging time interval. In principle, there is no time weighting involved in a determination of a root-mean-square sound pressure.

The frequency weighting applied to the instantaneous sound-pressure signal could be either the standard A or C weighting described below, or the weighting of a bandpass filter, in which case the result is a band sound pressure level. When reporting the result of a measurement of sound level, the frequency weighting should always be stated.

In general, for measurements of time-average sound level, it is important to record both the duration of the averaging time interval and the time of observation at the end of the averaging time. Sound level meters that display time-average sound levels are integrating–averaging sound level meters.

For applications such as determining estimates of the sound level that would have been indicated if the contaminating influence of background noise had not been present, for combining narrow-band sound pressure levels into wider-bandwidth sound pressure level,

or for calculating sound power levels from measurements of corresponding sound pressure levels, it is necessary to work with mean-square sound pressures, not with root-mean-square sound pressures.

Before the development of digital technology, sound level meters utilized a dial-and-pointer system to display the level of the sound pressure signal. These instruments employ exponential time weighting as illustrated by the following expression for exponential-time-weighted frequency-weighted sound level $L_{w\tau}(t)$ in decibels

$$L_w \tau(t) =$$
$$\times 10 \log \left(\frac{\left[\left(\frac{1}{\tau} \right) \int_{-\infty}^{t} p_w^2(\xi) \, e^{-(t-\xi)/\tau} \, d\xi \right]^{1/2}}{p_0} \right)^2,$$

(23.17)

where τ is one of the standardized time constants, ξ is a dummy variable of time integration from some time in the past, as indicated by the $-\infty$ for the lower limit of the integral, to the time t when the level is observed, and the other terms are as described above for the time-average sound level. The numerator in the argument of the logarithm in (23.17) represents an exponentially-time-weighted quasi-RMS sound pressure. The exponential time weighting de-emphasizes the contributions to the integral from sound-pressure signals at earlier times, with the degree of de-emphasis increasing as the time constant increases.

By international agreement, the two standardized exponential time constants are 125 ms for *fast* or F time weighting and 1000 ms for *slow* or S time weighting. The time weighting is applied to the square of the instantaneous frequency-weighted sound-pressure signal. Instruments that measure time-weighted sound levels are conventional sound level meters.

Note that in contrast to a time-average sound level, indications of exponential-time-weighted sound level vary continuously on the display device of the sound level meter.

A maximum sound level is the highest time-weighted sound level occurring within a stated time interval. A *hold* capability is needed to display an indication of a maximum sound level on a conventional sound level meter. Maximum sound levels are not the same as peak sound levels.

Although a proper description of a measurement of a sound level is, for example, *the A-weighted sound level was* 90 dB, the statement *the sound level was* 90 dB(A) is widely used, and implies that the level is

A-weighted. The instantaneous sound pressure signal is frequency weighted, not the decibel.

23.2.3 Sound Exposure and Sound Exposure Level

For transient sounds (including the sounds produced by many different kinds of machines, the sound of the pass by of an automobile or motorcycle or the overflight of an aircraft, the sound from blasting or explosions, and sonic booms), the most appropriate quantity to measure is sound exposure or sound exposure level. Instruments that measure sound exposure level are integrating sound level meters. Sound exposure may be measured with one of the standardized frequency weightings.

Sound exposure encompasses the magnitude or level of the sound pressure and its duration in a single quantity. The expression for a frequency-weighted sound exposure E_w, in Pascal-squared seconds, is as follows

$$E_w = \int_{t_1}^{t_2} p_w^2(t)\, dt \qquad (23.18)$$

with running time in seconds. In principle, no time weighting is involved in a determination of sound exposure according to (23.18).

The frequency-weighted sound exposure level L_{wE} in decibels, is given by

$$L_{wE} = 10 \log \left(\frac{E_w}{E_0} \right), \qquad (23.19)$$

where E_0 is the reference sound exposure equal to $(p_0^2 T_0) = (20\,\mu\text{Pa})^2 \times (1\,\text{s})$ or the product of the square of the reference pressure and the reference time for sound exposure of $T_0 = 1$ s.

It is often necessary to make use of the link between a measurement of the sound exposure level for a transient sound occurring in a given time interval and the corresponding time-average sound level. For a given frequency weighting, the relation is given by the following

$$L_{wT} = L_{wE} - 10 \log \left(\frac{T}{T_0} \right), \qquad (23.20)$$

where T is the averaging time for the determination of time-average sound level, in seconds, and T_0 is the reference time of 1 s. The relationship of (23.20) may be extended to the determination of the time-average sound level corresponding to the total sound exposure of a series of transient sounds occurring within a given time interval such as 8 h or 24 h.
Fig. 23.5 Design goals for A- and C-frequency weightings

23.2.4 Frequency Weightings

Specifications for A- and C-weighting as well as a new Z-weighting are given in IEC 61672-1:2002 [23.8]. Design goals for the A- and C-weightings are shown in Fig. 23.5. The design goal for the Z-weighting is flat (transmission level = 0 dB) over the frequency range 10–20 kHz.

23.2.5 Octave and One–Third–Octave Bands

In general, frequency-weighted sound levels are not adequate for the diagnosis of noise problems and the design and implementation of engineering controls. Sound levels do not contain enough information to calculate measures of human response such as loudness level or ratings of room noise such as those obtained from noise criterion (NC) and other criteria by means of a curve-tangent method (Chap. 11). In these cases, a set of bandpass filters covering octave- or one-third-octave frequency bands should be used. The filters may be implemented by analog or digital techniques. Idealized octave-band filter shapes are shown in Fig. 23.6 for the 125 Hz to 8 kHz range of nominal midband frequencies. This range is adequate for many noise problems. Sound pressure levels in the octave bands with nominal midband frequencies of 31.5 Hz and 63 Hz are important for many applications, e.g., noise from heating, ventilating, and air-conditioning equipment in rooms.

There are three one-third-octave bands in each octave band. Nominal midband frequencies are shown in Table 23.1. The standardized midband frequencies increase by a factor of ten in each decade. Specifications

for octave-band and fractional-octave-band filters are given in IEC 61260:1995.

23.2.6 Sound Level Meters

A sound level meter consists of a microphone, an amplifier and means to process the waveform of the sound-pressure signal from the microphone according to the equations above. There may be an analog or a digital readout or other device to indicate the measured sound levels. Extensive analog, or digital, or a combination of analog and digital signal processing may be utilized. Storage devices may include digital memory, computers, and printers.

A sound level meter should conform to the requirements of IEC 61672-1:2002 [23.8]. This standard provides design goals for various electroacoustical requirements along with appropriate tolerance limits around the design goals for class 1 and class 2 perfor-

mance categories. The two performance classes differ mainly in the tolerance limits and the ranges of environmental conditions over which an instrument conforms to the requirements within the tolerance limits.

Sound level meters are intended for measurement of sounds that are audible to humans, generally assumed to be in the frequency range from 20 Hz to 20 kHz.

Microphones are covered in detail in Chap. 24. Sound level meters generally use a condenser microphone, either with a direct-current (DC) polarizing voltage or pre-polarization to provide the electrostatic field between the diaphragm and back plate.

The acoustical sensitivity of a measuring system should be checked using a class 1 or class 2 sound calibrator that produces a known sound pressure level at a specified frequency in the cavity of a coupler into which the microphone is inserted [23.9]. More details on means to establish the sensitivity of acoustical instruments may be found in Chap. 15.

In the presence of turbulent airflow, pressure fluctuations at the microphone diaphragm will occur that are not related to the sound pressure in the sound field. In this case, a windscreen – which may be made from an open-cell material, a metal, or a nonmetallic fabric – may be used. The insertion loss of a windscreen is the difference between the sound pressure level measured without and with the windscreen (in the absence of airflow), and may be determined in a free or a diffuse sound field. A standard for measurement of windscreen performance is available [23.10]. The insertion loss of windscreens that do not have spherical shapes may vary with sound incidence angle.

Microphones are generally designed to have their best frequency response from a specified reference direction of sound incidence in a free sound field or in response to sounds incident on the microphone from random directions, i.e., so-called free-field or random-incidence microphones. The specifications in IEC 61672-1:2002 apply equally to either microphone type when installed on a sound level meter.

A free-field microphone should be used when there is a principal direction from which the sound is incident on the microphone. A random-incidence microphone is preferred for applications where the direction of sound incidence is unknown, unpredictable, or varies with time, a situation commonly encountered when measuring noise levels in a factory or community.

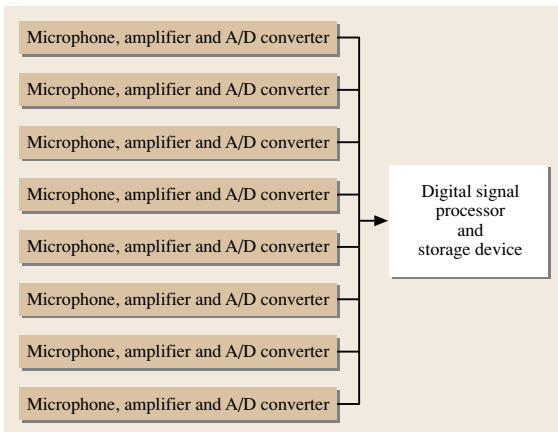
In addition to the time-average, time-weighted, and peak sound levels described above, many sound level meters can record maximum and minimum levels in a given time interval, as well as statistical measures


Fig. 23.7 Block diagram of a multichannel instrument using digital signal processing

such as the sound level exceeded at various percentages of a time interval, e.g., 10% of the time in an hour of observations. Performance specifications for the measurement of percentile sound level are not standardized, and the results may vary depending on the manufacturer of the instrument and the percentile of interest, with the greatest variations at the extremes of the percentiles.

23.2.7 Multichannel Instruments

Many applications for noise control are best satisfied by use of a microphone array. These include measurement of sound pressure level at multiple positions on a measurement surface for determination of sound power, and measurements at several locations around a time-varying sound source. In the first case, several microphones may be connected to a multiplexer, and the outputs sampled sequentially. In the second case, the

microphones may each be connected to an amplifier and analog-to-digital (A/D) converter. High sampling rates (e.g., greater than 40 kHz) are required. The data are sent to a digital signal processor and storage device, for example, a digital computer. A block diagram of such a system is shown in Fig. 23.7.

The number of samples of sound pressure level data that can be stored in a multichannel measurement system depends on the available storage capacity, which can be quite large in the case of systems used for monitoring noise in the community and around airports.

23.2.8 Sound Intensity Analyzers

Sound intensity is covered in detail in Chap. 25. Sound intensity analyzers often use two closely spaced microphones to approximate the pressure gradient in a sound field. Particle velocity is found by integration of the time derivative of the sound-pressure gradient (23.3). Sound pressure is the average of the pressures at the two microphones. A block diagram of a sound intensity meter is shown in Fig. 23.8. Processing of the sampled signals may be accomplished either with analog circuits or digitally. Standards for sound intensity analyzers are available [23.11, 12].

23.2.9 FFT Analyzers

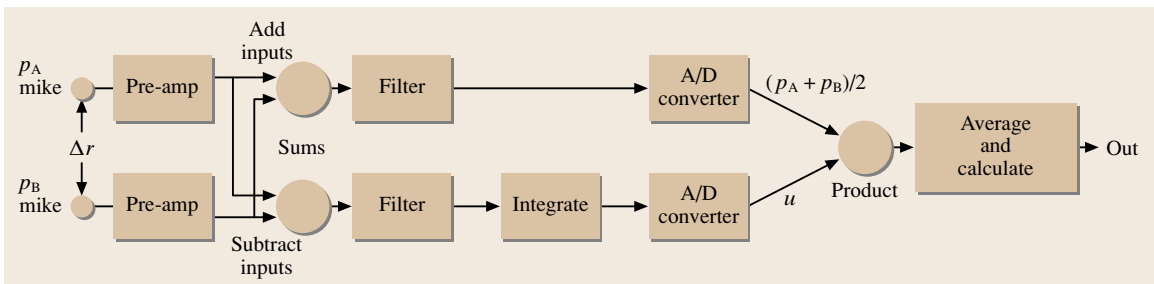
Unlike octave-band and one-third-octave band filters, which are proportional (or constant-percentage) bandwidth filters, a fast Fourier transform (FFT) analyzer is essentially a set of fixed-bandwidth filters. The FFT is a computational implementation of the discrete Fourier transform that produces a set of discrete-frequency spectral lines. The number of spectral lines in a given frequency interval depends on the number of samples of the time series obtained from digital sampling of the


Fig. 23.8 Block diagram of an analog-to-digital sound intensity analyzer with octave-band filters. Alternatively, the preamplifier outputs of the microphones could be suitably amplified and converted to digital format; all further processing would then be done digitally

sound-pressure signal. If a periodic wave is sampled with a sampling period that is not an integral number of wavelengths of the wave, spectral *leakage* occurs. FFT analyzers contain *windows* to improve spectral estimates – the Hanning window is the most common.

There are no national or international standards for the performance of FFT analyzers. The results of measurements by FFT analyzers may vary depending on the design implementation by the manufacturer or computer programmer.

23.3 Noise Sources

In this section, methods for the specification of noise emissions are given, noise emission criteria are described, and some basic principles of noise control are presented. A general description of noise control for stationary sources is presented, and some information on vehicle noise and aircraft noise is given. A short section on the principles of active noise control is included.

23.3.1 Measures of Noise Emission

This section is an edited version of a textbook chapter of [23.13].

Two quantities are needed to describe the strength of a noise source, its *sound power level* and its *directivity*.

The sound power level is a measure of the total sound power radiated by the source in all directions and is usually stated as a function of frequency, for example, in one-third octave bands. The sound power level is then the preferred descriptor for the emission of sound energy by noise sources.

The directivity of a source is a measure of the variation in its sound radiation with direction. Directivity is usually stated as a function of angular position around the acoustical center of the source and also as a function of frequency.

From the sound power level and directivity, it is possible to calculate the sound pressure levels produced by the source in the acoustical environment in which it operates. In Sect. 23.4.2, a classical method for this calculation is presented – as is an alternative method for long and flat rooms.

A source may set a nearby surface into vibration if it is rigidly attached to that surface, causing more sound power to be radiated than if the source were vibration isolated. Both the operating and mounting conditions of the source therefore influence the amount of sound power radiated as well as the directivity of the source. Nonetheless, the sound power level alone is useful for: comparing the noise radiated by machines of the same type and size as well as by machines of different types and sizes; determining whether a machine complies with a specified upper limit of noise emission; planning

in order to determine the amount of transmission loss or noise control required; and engineering work to assist in developing quiet machinery and equipment.

Expanding the dot product in (23.6) allows the surface integral to be written in terms of scalar quantities

$$W = \int_S I_n \, dS \,, \tag{23.21}$$

where $I_n = I \cos(\theta)$ is the component of sound intensity *normal* to the surface at the location of dS; dS is the magnitude of the elemental surface area vector.

The integral may be carried out over a spherical or hemispherical surface that surrounds the source. Other regular surfaces, such as a parallelepiped or a cylinder, are also used in practice, and, in principle, any closed surface can be used. If the source is nondirectional and the integration is carried out over a spherical surface having a radius r and centered on the source, sound intensity and sound power are related by

$$I(\text{at } r) = I_n(\text{at } r) = \frac{W}{S} = \frac{W}{4\pi r^2} \,, \tag{23.22}$$

where I is the magnitude of intensity on the surface (at radius r), I_n is the normal component of intensity on the surface (at radius r), W is the sound power, S is the area of spherical surface ($4\pi r^2$), and r is the radius of the sphere.

In general, a source is directional, and the sound intensity is not the same at all points on the surface. Consequently, an approximation must be made to evaluate the integral of (23.21). It is customary to divide the measurement surface into a number of subsegments, each having an area S_i, and to approximate the normal component of the sound intensity on each surface subsegment. The sound power of the source may then be calculated by a summation over all of the surface subsegments

$$W = \sum_i I_{ni} S_i \,, \tag{23.23}$$

here I_{ni} is the normal component of sound intensity averaged over the i-th area segment, S_i is the i-th area segment, and i is the number of segments.

When each segment of the measurement surface has the same area,

$$W = S \sum_i I_{ni} = S \langle I_n \rangle , \qquad (23.24)$$

where $\langle I_n \rangle$ is the average value of the normal sound intensity over the measurement surface, and S is the total area of the measurement surface.

The sound power level is then

$$L_W = 10 \log \frac{W}{W_0} , \qquad (23.25)$$

where W_0 is the standard reference power, 10^{-12} W.

Equation (23.24) is usually used to determine the sound power of a source from the sound intensity level except when the source is highly directional. For directional sources, the subareas of the measurement surface may be selected to be unequal and (23.23) should be used.

Table 23.2 A-frequency weightings for octave- and one-third-octave bands

A-Weighted Sound Power

All procedures described in this section apply to the determination of sound power levels in octave or one-third-octave bands. The techniques are independent of bandwidth. The A-weighted sound power level is obtained by summing (on a mean-square basis) the octave-band or one-third octave-band data after applying the appropriate A-weighting corrections. A-weighting values are listed Table 23.2.

Measurement Environments

Three different types of laboratory environments in which noise sources are measured are found in modern acoustics laboratories: anechoic rooms (free field), hemi-anechoic rooms (free field over a reflecting plane), and reverberation rooms (diffuse field). In an anechoic room, all of the boundaries are highly absorbent, and the free-field region extends very nearly to the boundaries of the room. Because the floor itself is absorptive, anechoic rooms usually require a suspended wire grid or other mechanism to support the sound source, test personnel, and measurement instruments. A hemi-anechoic room has a hard, reflective floor, but all other boundaries are highly absorbent. Both anechoic and hemi-anechoic environments are used to determine the sound power level of a source, but the hemi-anechoic room is clearly more practical for testing large, heavy sources.

In a reverberation room, where all boundaries are acoustically hard and reflective, the reverberant field extends throughout the volume of the room except for a small region in the vicinity of the source. The sound power level of a source may be determined from an estimate of the average sound pressure level in the diffuse field region of the room coupled with a knowledge of the absorptive properties of the boundaries, or by comparison with a reference sound source of known sound power output. A standard for the calibration of reference sound sources is available [23.14].

Free-Field Approximation for the Determination of Sound Power

For the far field of a source radiating into free space, the magnitude of the intensity at a point a distance r from the source is

$$I(\text{at } r) = \frac{p_{RMS}^2(\text{at } r)}{\rho c} , \qquad (23.26)$$

where ρc is the characteristic resistance of air equal to about 406 MKS Rayl at normal room conditions, and p_{RMS} is the root-mean-square sound pressure, at r.

Strictly speaking, this relationship is only correct in the far field of a source radiating into free space. Good approximations to free-space, or free-field, conditions can be achieved in properly designed anechoic or hemi-anechoic rooms, or outdoors. Hence, (23.26) is approximately correct in the far field of a source over a reflecting plane, provided that the space above the reflecting plane remains essentially a free field at distance r. Even if the free field is not perfect, and a small fraction of the sound is reflected from the walls and ceiling of the room, an environmental correction may be introduced to allow valid measurements to be taken in the room. The relations below are widely used in standards that determine the sound power of a source from a measurement of sound pressure level.

If a closed measurement surface is placed around a source so that all points on the surface are in the far field, and if the intensity vector is assumed to be essentially normal to the surface so that $I = I_n$ at all points on the surface, then (23.23) and (23.26) can be combined to yield

$$W = \frac{1}{\rho c} \sum_i p_i^2 S_i \,, \tag{23.27}$$

here p_i is the average RMS sound pressure over area segment S_i.

The sound power level is as expressed in (23.25). If all segments are of equal area,

$$W = \frac{S}{\rho c} \frac{1}{N} \sum_i p_i^2 = \frac{S}{\rho c} \langle p^2 \rangle \,, \tag{23.28}$$

where S is the total area of the measurement surface, N is the number of area segments, and $\langle p^2 \rangle$ is the average mean square pressure over the measurement surface.

In logarithmic form with reference power 10^{-12} W and reference pressure 20 µPa, the sound power level is

$$L_W = L_p + 10 \log \frac{S}{S_0} + 10 \log \frac{400}{\rho c} \,, \tag{23.29}$$

where $S_0 = 1\,\mathrm{m}^2$.

For $\rho c = 406$ MKS Rayl, the last term in (23.29) is -0.064, and can usually be neglected.

Hence, the sound power level of a source can be computed from sound pressure level measurements made in a free field. Equation (23.29) is widely used in standardized methods for the determination of sound power levels in a free field or in a free field over a reflecting plane.

Sound Power Determination in a Diffuse Field

The sound power level of a source can also be computed from sound pressure level measurements made in an enclosure with a diffuse sound field because in such a field the sound energy density is constant; it is directly related to the mean-square sound pressure and, therefore, to the sound power radiated by the source. The sound pressure level in the reverberant room builds up until the total sound power absorbed by the walls of the room is equal to the sound power generated by the source. The sound power is determined by measuring the mean-square sound pressure in the reverberant field. This value is either compared with the mean-square pressure of a source of known sound power output (*comparison method*) or calculated directly from the mean-square pressure produced by the source and a knowledge of the sound-absorptive properties of the reverberant room (*direct method*).

The procedure for determining the sound power level of a noise source by the comparison method requires the use of a reference sound source of known sound power output. The procedure is essentially as follows.

With the equipment being evaluated at a suitable location in the room, determine, in each frequency band, the average sound pressure level (on a mean-square basis) in the reverberant field using the microphone array or traverse described above.

Replace the source under test with the reference sound source and repeat the measurement to obtain the average level for the reference sound source.

The sound power level of the source under test L_W for a given frequency band is calculated from

$$L_W = L_{Wr} + \big(\langle L_p \rangle - \langle L_p \rangle_r \big) \tag{23.30}$$

where L_W is the one-third-octave band sound power level for the source being evaluated, $\langle L_p \rangle$ is the space-averaged one-third octave band sound pressure level of source being evaluated, L_{Wr} is the calibrated one-third-octave band sound power level of the reference source, and $\langle L_p \rangle_r$ is the space-averaged one-third-octave band sound pressure level of the reference sound source.

The direct method does not use a reference sound source. Instead, this method requires that the sound-absorptive properties of the room be determined by measuring the reverberation time in the room for each frequency band. Measurement of T_{60} is described in Chap. 11.

With this method, the space-averaged sound pressure level for each frequency band of the source being evaluated is determined as described above for the com-

parison method. The sound power level of the source is found from

$$
\begin{aligned}
L_W = \overline{L_p} + \Big[& 10 \log \frac{A}{A_0} + 4.34 \frac{A}{S} \\
& + 10 \log \left(1 + \frac{S\,c}{8Vf} \right) \\
& - 25 \log \left(\frac{427}{400} \sqrt{\frac{273}{273+\theta} \frac{B}{B_0}} \right) - 6 \Big] \\
& \times \mathrm{dB\ re}\ 10^{-12}\ \mathrm{W} ,
\end{aligned}
\tag{23.31}
$$

where L_W is the band sound power level of the sound source under test, $\overline{L_p}$ is the band space-averaged sound pressure level of the sound source under test, A is the equivalent absorption area of the room, given by

$$
A = \frac{55.26}{c} \left(\frac{V}{T_{\mathrm{rev}}} \right) ,
$$

V is the room volume, T_{rev} is the reverberation time for the particular band, A_0 is the reference absorption area, S is the total surface area of the room, f is the midband frequency of the measurement, c is the speed of sound at temperature θ in $^\circ C$, B is the atmospheric pressure, with $B_0 = 1.013 \times 10^5$ Pa, $V_0 = 1\,\mathrm{m}^3$, $T_0 = 1$ s.

Diffuse sound fields can be obtained in laboratory reverberation rooms. Sufficiently close engineering approximations to diffuse-field conditions can be obtained in rooms that are fairly reverberant and irregularly shaped. When these environments are not available or when it is not possible to move the noise source under test, other techniques valid for the in situ determination of sound power level may be used and are described later in this section.

Non-steady and impulsive noises are difficult to measure under reverberant-field conditions. Measurements on such noise sources should be made under free-field conditions.

Sound Power Determination in an Ordinary Room

The sound pressure field in an ordinary room such as an office or laboratory space that has not been designed for acoustical measurements is neither a free-field nor a diffuse field. Here the relationship between the sound intensity and the mean-square pressure is more complicated. Instead of measuring the mean-square pressure, it is usually more advantageous to use a sound intensity analyzer that measures the sound intensity directly (Sect. 23.2.8). By sampling the sound intensity at defined locations in the vicinity of the source, the sound

power level of the source can be determined. A standard for the in situ determination of sound power is also available, and is described below.

Source Directivity

Most sources of sound [23.15, 16] of practical interest are directional to some degree. If one measures the sound pressure level in a given frequency band a fixed distance away from the source, different levels will generally be found for different directions. A plot of these levels in polar fashion at the angles for which they were obtained is called the *directivity pattern* of the source.

The directivity factor Q_θ is defined as the ratio of the mean-square sound pressure p_θ^2 at angle θ and distance r from an actual source radiating W and the mean-square sound pressure p_S^2 at the same distance from a nondirectional source radiating the same acoustic power W. Alternatively, Q_θ is defined as the ratio of the intensity in the direction of propagation $\mathrm{W/m}^2$ at angle θ and distance r from an actual source to the intensity at the same distance from a nondirectional source, both sources radiating the same sound power W. It must be assumed that the directivity factor is independent of distance from the source.

The directivity index DI_θ of a sound source on a rigid plane (radiating into hemispherical space) at angle θ and for a given frequency band is computed from

$$
DI_\theta = L_{p\theta} - \langle L_p \rangle_H + 3\,\mathrm{dB} ,
\tag{23.32}
$$

where $L_{p\theta}$ is the sound pressure level measured a distance r and angle θ from the source, and $\langle L_p \rangle_H$ is the sound pressure level of the space-averaged mean-square pressure averaged over a test hemisphere of radius r (and area $2\pi r^2$) centered on and surrounding the source.

The 3 dB in this equation is added to $\langle L_p \rangle_H$ because the measurement was made over a hemisphere instead of a full sphere. The reason for this is that the intensity at radius r is twice as large if a source radiates into a hemisphere as compared to a sphere. That is, if a nondirectional source were to radiate uniformly into hemispherical space, $DI_\theta = DI = 3$ dB. Equations are available for sound radiation into a sphere and into a quarter sphere [23.15, 16].

23.3.2 International Standards for the Determination of Sound Power

The International Organization for Standardization (ISO) has published a series of international standards, the ISO 3740 series [23.17–26], which describes several methods for determining the sound power levels of

Table 23.3 Description of the ISO 3740 series of standards for determination of sound power

ISO standard	Test environment	Criteria for suitability of test environment	Volume of source	Character of noise	Limitation on background noise	Sound power levels obtainable	Optional information available
ISO 3741 precision (grade 1)	Reverberation room meeting specified requirements	Room volume and reverberation time to be qualified	Preferably less than 2% of room volume	Steady, broadband, narrow-band, or discrete-frequency	$\Delta L \geq 10\,dB$ $K_1 \leq 0.5\,dB$	A-weighted and in one-third-octave or octave bands	Other frequency-weighted sound power levels
ISO 3743-1 Engineering (grade 2)	Hard-walled room	Volume $\geq 40\,m^3$ $\alpha \leq 0.20$	Preferably less than 1% of room volume	Any, but no isolated bursts	$\Delta L \geq 6\,dB$ $K_1 \leq 1.3\,dB$	A-weighted and in octave bands	Other frequency-weighted sound power levels
ISO 3743-2 Engineering (grade 2)	Special reverberation room	$70\,m^3 \leq V$ $\leq 300\,m^3$ $0.5\,s \leq T_{nom}$ $\leq 1.0\,s$	Preferably less than 1% of room volume	Any, but no isolated bursts	$\Delta L \geq 4\,dB$ $K_1 \leq 2.0\,dB$	A-weighted and in octave bands	Other frequency-weighted sound power levels
ISO 3744 Engineering (Grade 2)	Essentially free field over a reflecting plane	$K_2 \leq 2\,dB$	No restrictions; limited only by available test environment	Any	$\Delta L \geq 6\,dB$ $K_1 \leq 1.3\,dB$	A-weighted and in one-third-octave or octave bands	Source directivity; SPL as a function of time; single-event SPL; Other frequency-weighted sound power levels
ISO 3745 Precision (Grade 1)	Anechoic or hemi-anechoic room	Specified requirements; measurement surface must lie wholly inside qualified region	Characteristic dimension not greater than 1/2 measurement surface radius	Any	$\Delta L \geq 10\,dB$ $K_1 \leq 0.5\,dB$	A-weighted and in one-third-octave or octave bands	Same as above plus sound energy level
ISO 3746 Survey (Grade 3)	No special test environment	$K_2 \leq 7\,dB$	No restrictions; limited only by available test environment	Any	$\Delta L \geq 3\,dB$ $K_1 \leq 3\,dB$	A-weighted	Sound pressure levels as a function of time
ISO 3747 Engineering or Survey (Grade 2 or 3)	Essentially reverberant field in situ, subject to stated qualification requirements	Specified requirements	No restrictions; limited only by available test environment	Steady, broadband, narrow-band, or discrete-frequency	$\Delta L \geq 6\,dB$ $K_1 \leq 1.3\,dB$	A-weighted from octave bands	Sound pressure levels as a function of time

Notes:
1. ΔL is the difference between the sound pressure levels of the source-plus-background noise and the background noise alone
2. K_1 is the correction for background noise, defined in the associated standard
3. V is the test room volume
4. α is the sound absorption coefficient
5. T_{nom} is the nominal reverberation time for the test room, defined in the associated standard
6. K_2 is the environmental correction, defined in the associated standard
7. SPL is an abbreviation for *sound pressure level*

noise sources. Table 23.3 summarizes the applicability of each of the basic standards of the ISO 3740 series. The most important factor in selecting an appropriate noise measurement method is the ultimate use of the sound power level data that are to be obtained.

In making a decision on the appropriate measurement method to be used, several factors should be considered:

1. The size of the noise source
2. The moveability of the noise source
3. The test environments available for the measurements
4. The character of the noise emitted by the noise source
5. The grade (classification) of accuracy required for the measurements.

The methods described in this chapter are consistent with those of the ISO 3740 series. A set of standards with the same objectives is available from the American National Standards Institute (ANSI) or the Acoustical Society of America (ASA).

Determination of Sound Power in a Free Field

The basis for sound power level in a free field using sound pressure is the approximate relationships in (23.28) and (23.29) above. Essentially, a measurement surface is chosen and microphone positions are defined over this surface. Sound pressure level measurements are taken at each microphone position for each frequency band, and from these, the sound power levels are computed. The relevant ISO standards are ISO 3744, ISO 3745, and ISO 3746.

Selection of a Measurement Surface. The international standards allow a variety of measurement surfaces to be used; some are discussed here. In selecting the shape of the measurement surface to be used for a particular source, an attempt should be made to choose one where the direction of sound propagation is approximately normal to the surface at the various measurement points. For example, for small sources that approximate a point source, the selection of a spherical or hemispherical surface may be the most appropriate; the direction of sound propagation will be essentially normal to this surface. For machines in a hemi-anechoic environment that are large and in the shape of a box, the parallelepiped measurement surface may be preferable. For tall machines in a hemi-anechoic environment having a height much greater than the length and depth, a cylin-
Fig. 23.9 Microphone positions for a hemispherical measurement surface according to ISO 3744 (ISO CD 3744 (N1497)) (courtesy of the International Organization for Standardization, Geneva, Switzerland)

drical measurement surface [23.27, 28] may be the most appropriate.

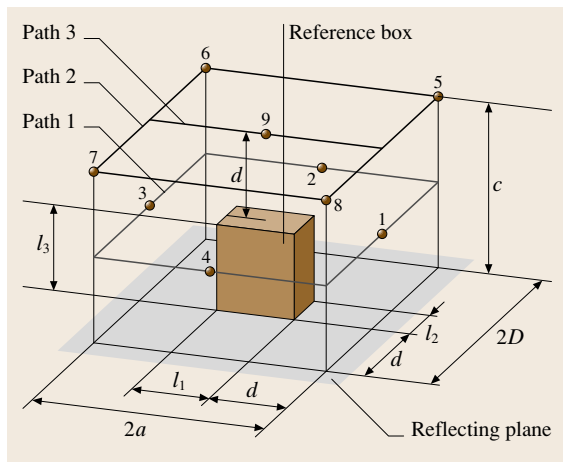
Measurement in Hemi-anechoic Space. The sound power determination in a hemi-anechoic space may be performed according to ISO 3744 for engineering-grade accuracy or according to ISO 3745 for precision-grade accuracy. ISO 3744 is strictly for hemi-anechoic environments, while ISO 3745 includes requirements for both hemi-anechoic and fully anechoic environments. These standards specify requirements for the measurement surfaces and locations of microphones, procedures for measuring the sound pressure levels and applying certain corrections, and the method for computing the sound power levels from the surface-


Fig. 23.10 Microphone positions for a rectangular measurement surface according to ISO 3744 (ISO CD 3744 (N1497)) (courtesy of the International Organization for Standardization, Geneva, Switzerland)

Fig. 23.11 Microphone positions for a cylindrical measurement surface

average sound pressure levels. In addition, they provide detailed information and requirements on criteria for the adequacy of the test environment and background noise, calibration of instrumentation, installation and operation of the source, and information to be reported. Several annexes in each standard include information on measurement uncertainty and the qualification of the test rooms. ISO 3746 is a survey method.

As examples, microphone positions for a hemispherical measurement surface, a rectangular measurement surface, and a cylindrical measurement surface are shown in Figs. 23.9–23.11, respectively.

Determination of Sound Power in a Diffuse Field

ISO 3741 is a precision method for the determination of sound power level in a reverberant test environment. The standard includes both the direct method and the comparison method described above. Requirements on the volume of the reverberation room are specified. Qualification procedures for both broadband and discrete frequency sound, are included, the minimum distance between the source and the microphone(s) are specified, and other measurement details are given.

Determination of Sound Power in Situ

In ISO 3747, engineering or survey methods are given for determination of the sound power of a source in situ, when the source cannot be moved.

Determination of Sound Power Using Sound Intensity

Sound intensity is discussed in detail in Chap. 25. The fundamental procedures for the determination of sound power from sound intensity are discussed above. The sound intensity is measured over a selected surface enclosing the source. In principle, the integral over any surface totally enclosing the source of the scalar product (dot product) of the sound intensity vector and the associated elemental area vector provides a measure of the sound power radiated directly into the air by all sources located within the enclosing surface.

The use of sound intensity to determine sound power has several advantages over the free-field methods described above using sound pressure.

1. It is not necessary to make the approximation $I = p^2/\rho c$. Therefore, it is not necessary to make any assumption about the direction of sound intensity relative to the measurement surface. What is required is proper orientation of the intensity probe.
2. If there is no sound absorption within the measurement surface, the sound energy that enters the measurement surface from the outside also exits. Therefore, the sound power measurement is less sensitive to background noise levels and reflections from room surfaces than the pressure methods described above. The pressure methods require corrections for background noise and, in some cases, environmental corrections for reflections from room surfaces.

3. Measurements can often be made in an ordinary room.

There are, however, disadvantages to the intensity method.

An intensity analyzer is more complex than a sound level meter in the sense that the two channels required for the measurements (Sect. 23.2.8) must be carefully matched in phase. When using discrete microphone positions, a very large number of microphone positions may be required to obtain a specified accuracy in the measurements. Mean square sound pressures on a measurement surface are always positive, whereas sound intensity may be outward from the measurement surface (positive) or inward (negative). Thus, the summation of sound intensities over the measurement surface may produce a small number, and the accuracy of the measurement may be difficult to determine.

Standards have been developed to overcome these disadvantages. Instrument standards have been developed [23.11, 12] and there are standards available for the determination of sound power via sound intensity both for fixed intensity-probe positions [23.29] and for scanning [23.30–32] with an intensity probe over the measurement surface. The standards also describe *field indicators* that can be used to estimate the accuracy of the sound power determination, and technical information on the use of field indicators is available [23.33,34].

After substantial experience with the determination of sound power via sound intensity has been achieved, it is expected that these standards will be revised.

Determination of Sound Power in a Duct

The most common application of in-duct measurements is to determine the sound power radiated by air-moving devices. The sound power level of a source in a duct can be determined according to ISO 5136 [23.35] from sound pressure level measurements, provided that the sound field in the duct is essentially a plane progressive wave, using the equation

$$L_W = L_p + 10 \log \frac{S}{S_0} \,, \tag{23.33}$$

where L_W is the level of total sound power traveling down duct, L_p is the sound pressure level measured just off centerline of duct, S is the cross-sectional area of duct, and $S_0 = 1 \, \text{m}^2$.

The above relation assumes not only a nonreflecting termination for the end of the duct opposite the source but also a uniform sound intensity across the duct. At frequencies near and above the first cross resonance of

the duct the latter assumption is no longer satisfied. Also, when following the measurement procedures of ISO 5136, several correction factors are incorporated into (23.33) to account for microphone response and atmospheric conditions.

Equation (23.33) can still be used provided L_p, is replaced by a suitable space average $\langle L_p \rangle$ obtained by averaging the mean square sound pressures obtained at selected radial and circumferential positions in the duct, or by using a traversing circumferential microphone. The number of measurement positions across the cross section used to determine $\langle L_p \rangle$ will depend on the accuracy desired and the frequency [23.36].

In practical situations, reflections occur at the open end of the duct, especially at low frequencies. The effect of branches and bends must be considered [23.37]. When there is flow in the duct, it is also necessary to surround the microphone by a suitable windscreen. This is necessary to reduce turbulent pressure fluctuations at the microphone, which can cause an error in the measured sound pressure level.

23.3.3 Emission Sound Pressure Level

Another measure of the noise emission of a source is the *emission sound pressure level*. The sound pressure level measured in the vicinity of a noise source is dependent not only on its operating condition, but also the distance from the source and the acoustical environment – primarily reflections from the room surfaces – but also on the presence of other nearby sources. There are, however, cases where the noise emissions of a source can be described using sound pressure levels. These levels may be specified at an operator's position and at selected bystander positions, and in a controlled acoustical environment. Peak C-weighted sound levels (Sect. 23.2.4) may also be important when the levels are high enough to cause hearing damage, and these levels are not determined when using sound power level as a measure of noise emissions.

A series of international standards has been developed to ensure consistency in the measurement process and to estimate emission sound pressure levels when only sound power level information is available. ISO 11200 [23.38] provides an introduction and overview of the series. ISO 11201 [23.39] provides guidance for measurements at the operating position and bystander position when the acoustical environment is a free field over a reflecting plane. If the measurements cannot be made in a free field over a reflecting plane, it may be necessary to use a semi-reverberant

environment. Using this method, A-weighted or C-weighted peak sound levels may be measured using ISO 11202 [23.40]. When only the sound power level of the source is available, it may be necessary to make estimates of the emission sound pressure level, and this procedure is covered in ISO 11203 [23.41]. As in the case of engineering and survey methods for determination of sound power level, environmental corrections may be needed in the measurement of emission sound pressure level, and this subject is covered in ISO 11204 [23.42]. Sound intensity level may be used to determine sound power level of a source, as described in the previous section. Sound intensity measurement may also be used in the determination of emission sound pressure level. The procedures are standardized in ISO 11205 [23.43].

23.3.4 Other Noise Emission Standards

Many standards organizations, trade associations, and other organizations have developed standards to determine the noise emissions of specific sources. This section is devoted to a brief description of such standards.

ISO Standards
The ISO has many standards for specific noise sources:

- Noise emitted by road vehicles [23.44–50]
- Information technology equipment [23.51–53]
- Noise emitted by rotating electrical machinery [23.54]
- Shipboard noise [23.55, 56]
- Aircraft noise [23.57, 58]
- Industrial plants [23.59, 60]
- Construction machinery [23.61]
- Agricultural machinery [23.62, 63]
- Earth-moving machinery [23.64–67]
- Lawn care equipment [23.68]
- Air terminal devices [23.69]
- Pipes and valves [23.70]
- Brush saws [23.71].

For other equipment, the ISO has published standards related to the writing of noise test codes [23.72].

American National Standards
The determination of noise emissions from a wide variety of mechanical equipment is the subject of two American national standards. ANSI S12.15-1992 [23.73] defines microphone positions and other information for determining noise emissions from a wide variety of tools. It defines measurement surfaces for portable tools and gives information on determination of sound power level for stationary tools. The tools covered include the following.

Portable Electric Tools.

- Circular hand saws
- Drills
- Grinders
- Polishers
- Reciprocating saws
- Nibblers
- Screwdrivers
- Nut settlers and tappers
- Hedge trimmers
- Shears
- Grass shears
- Routers
- Planers
- Edge trimmers
- Rotary cultivators.

Stationary and Fixed Electric Tools.

- Drill presses
- Scroll saws
- Scroll saws
- Disk sanders
- Joiner/planers
- Bench grinders
- Belt sanders
- Radial saws
- Hacksaws
- Band saws.

A second American national standard, ANSI S12.16-1992(R2002) [23.74], gives guidance to users on how to request noise emission data for machinery, and refers to industry standards for a wide variety of equipment. The applicable standard is given and the data to be reported. Examples of equipment included in the standard are:

- Fans
- Hydraulic fluid power pumps
- Hydraulic fluid power motors
- Pneumatic tools
- Gear drives and gear motors
- Mechanical equipment (general)
- Liquid immersed transformers
- Dry type ventilated and non ventilated and sealed transformers
- Control valves and associated piping

- Air-conditioning equipment; refrigeration equipment, chillers, etc.
- Stationary heavy duty internal combustion engines
- Electric motors, turbines, and generators
- Machine tools.

23.3.5 Criteria for Noise Emissions

Criteria for noise emissions can be divided into standards for making a noise declaration, specific criteria for both indoor and outdoor sources, and criteria for obtaining an environmental label for a product.

General Noise Declaration Standards

After the sound power level of a product has been determined, the results are usually communicated to users either in the form of a product noise declaration published in product literature, on the manufacturer's web site, or a physical label attached to the product. The emission sound pressure level may also be declared (Sect. 23.3.3). Noise declarations are generally in terms of a statistical upper limit determined according to national or international standards. The basic statistical procedures are contained in ISO 7574, a four-part series of standards [23.75–78].

The preferred descriptor of product noise emissions is the *declared A-weighted sound power level*, L_{WAd}. A widely used international standard is ISO 4871:1996 [23.79] for machinery in general. This standard is an implementation of ISO 7574 and must be followed by noise test codes. ISO 9296:1998 [23.80] is an example of such a code specifically for computer and business equipment (information technology equipment).

Noise Emission Limits

Below, two examples of upper limits for noise emissions are given, one for office equipment widely used for specification of noise emissions of information technology equipment, and the other for specification of outdoor equipment.

Indoor Equipment. Since the middle of the 1980s, recommended limits for equipment in the information technology industry have been published by the Swedish Agency for Public Management, Statskontoret [23.81]. The recommended upper limits are given in Table 23.4. The limits are in terms of the statistical upper-limit A-weighted sound power level of the equipment in bels. Since a wide variety of products are produced in this industry, it is necessary, in addition to upper limits, to specify the environment in which the

equipment will be operated. A category 1 product is intended for use in a large data-processing installation, either generally attended or generally unattended, where the installation noise level is determined by a large number of machines. Category 2 products are intended for use in a business office where many persons operate workstations. A category 3 product is intended for use in a private office where, for example, personal computers or low-noise copiers are operated. Users are encouraged to obtain the latest version of the standard; it contains a great deal of information in addition to the recommended upper limits in the table below. Information on the presence of impulsive noise and prominent discrete tones is also required in the version below, and there is information on determination of the emission sound pressure level determined according to the ISO 11200 series of international standards [23.38–43]. While the limits in the table below are recommended, they can become a requirement when written into a purchase contract or other document.

Note that in the table below, the sound power level is expressed in bel (1 bel = 10 decibel).

Outdoor Equipment. A source of noise emission requirements for outdoor equipment may be found in European Union directive 2000/14/EC [23.82]. The directive specifies demanding noise limits and noise markings for about 55 different types of equipment (Table 23.5). The intent is that the state of the art in noise reduction permits manufacturers to meet these limits without excessive additional costs. The limits are stated in terms of the A-weighted sound power level L_{WA} and the measurements are to be made according to European standards (EN) that correspond to ISO standards 3744 and 3746 [23.17–26].

The permissible sound power level shall be rounded to the nearest whole number (less than 0.5 use the lower number, greater than or equal to 0.5 use the higher number).

Fig. 23.12 German *Blue Angel* logo

Environmental Labels

An alternative to the declaration of a specific noise level is the submission of product noise emission data to an independent body, which makes a judgment of the data relative to other similar products and allows an environmental label to be used. Such labels are not limited to noise levels, but are issued to products that display a variety of favorable environmental characteristics. The general objective of environmental labels (eco-labels) is to provide a voluntary system to both allow manufacturers to identify environmentally friendly products and to provide the public with a recognizable label that designates environmental quality.

The first eco-label was the German *Blue Angel* label [23.83]. Noise as a requirement to obtain the *Blue Angel* label, illustrated in Fig. 23.12, is covered in

Fig. 23.13 European Union (EU) *Flower* logo

specific documents for a number of products. The verification criteria are prepared by the German Institute for Quality Assurance and Certification (RAL).

Table 23.4 Recommended upper limits of declared A-weighted sound power level (after [23.81, Table 1])

Product description	Recommended upper limit A-weighted sound power level in bel	
	L_{WAd} **Operating**	L_{WAd} **Idle**
Category I: Equipment for use in data processing (DP) areas		
A. Products in unattended DP areas	$8.0 + L$	$8.0 + L$
B. Products in generally attended DP areas	$7.5 + L$	$7.5 + L$
Category II: Equipment for use in general business areas		
A. Fully-formed character typewriters and printers	7.2	5.5
B. Printers and copiers more than 4 m distance from workstations	7.2	6.5
C. Tabletop printers and tabletop copiers	7.0	5.5
D. Processors, controllers, disk and tape drives, etc. (more than 4 m distant from workstations)	$7.0 + L$	$7.0 + L$
E. Processors, controllers, disk and tape drives, etc. (less than 4 m distant from workstations)	6.8	6.6
Category III: Floor-standing use in quiet office areas		
A. Printers, typewriters, plotters	6.5	5.0
B. Keyboards	6.2	N/A
C. Processors	6.0	5.5
D. Tabletop processors, controllers, system units including built-in disk drives and/or tapes, display units with fans [4]	5.8	5.0
E. Display units (no moving parts)	4.5	4.5

Notes:
1. $L = \log(S/S_0)$. S is the footprint area of the product, in square meters. S_0 is the reference footprint area, equal to $1\,m^2$. If $S < 1\,m^2$, S shall be set equal to 1.0. (Thus the specification will not get lower than 8.0 and 7.5 and 7.0 bels for Category IA and IB and IID, respectively)
2. For products comprised of multiple racks or frames of equal footprint areas linked together, the reference footprint area S_0 shall be set equal to the footprint area of the individual racks or frames, or to $1.0\,m^2$, whichever is smaller
3. The calculated value of the recommended upper limit (for Category IA, IB, and IID) may be rounded to the nearest upper 0.1 bel
4. For Category IIID products, especially for personal computers to be used in the home, lower values are often recommended (e.g., $L_{WAd} = 5.5\,B$ operating and $L_{WAd} = 4.8\,B$ idle; see, for instance, European Commission decision 2001/686/EC and Swedish TCO 99)

Table 23.5 Table of limit values from EU directive 2000/14/EC

Type of equipment	Net installed power P (in kW); Electric Electric power P_{el} in kW; Mass of appliance m in kg; cutting width L in cm	Permissible sound power level (dB/1 pW)	
		Stage I as from **3 January 2002**	**Stage II** as from **3 January 2006**
Compaction machines (vibrating rollers, vibrating plates, vibratory hammers	$P \leq 8$ $8 < P \leq 70$ $P > 70$	108 109 $89 + 11 \log P$	105 106 $86 + 11 \log P$
Tracked dozers, tracked loaders, tracked excavators–loaders	$P \leq 55$ $P > 55$	106 $87 + 11 \log P$	103 $84 + 11 \log P$
Wheeled dozers, wheeled loaders, dumpers, graders, loader-type landfill compactors, combustion-engine driven counterbalanced lift trucks, mobile cranes, compaction machines (non-vibrating rollers) paver finishers, hydraulic power packs	$P \leq 55$ $P > 55$	104 $85 + 11 \log P$	101 $82 + 11 \log P$
Excavators, builder's hoists for the transport of goods, construction winches motor hoes	$P \leq 15$ $P > 15$	96 $83 + 11 \log P$	93 $80 + 11 \log P$
Hand-held concrete breakers and picks	$m \leq 15$ $15 < m < 30$ $m \geq 30$	107 $94 + 11 \log P$ $96 + 11 \log P$	105 $92 + 11 \log m$ $94 + 11 \log m$
Tower cranes		$98 + \log P$	$96 + \log P$
Welding and power generators	$P_{el} \leq 2$ $2 < P_{el} \leq 10$ $P_{el} > 10$	$97 + \log P_{el}$ $98 + \log P_{el}$ $97 + \log P_{el}$	$95 + \log P_{el}$ $96 + \log P_{el}$ $95 + \log P_{el}$
Compressors	$P \leq 15$ $P > 15$	99 $97 + 2 \log P$	97 $95 + 2 \log P$
Lawnmowers, lawn trimmers/ lawn edge trimmers	$L \leq 50$ $50 < L \leq 70$ $70 < L \leq 120$ $L > 120$	96 100 100 105	$94(^2)$ 98 $98(^2)$ $103(^2)$

Notes:
1. P_{el} for welding generators: conventional welding current multiplied by the conventional load voltage for the lowest value of the duty factor given by the manufacturer
2. P_{el} for power generators: prime power according to ISO 8528-1:1993, point 13.3.2
3. Indicative figures only. Definitive figures will depend on amendment of the directive following the report required in article 20(3). In the absence of any such amendment, the figures for stage I will continue to apply for stage II

Table 23.6 shows product categories and document numbers for products with noise emission requirements.

A review of *Blue Angel* requirements specifically for noise emissions of construction equipment is available [23.84].

A more recent eco-label is the European Union *EU Flower* designation [23.85]. Currently, only personal computers [23.86] and portable computers [23.87] have noise emissions included with other environmental requirements. The *EU Flower* label is illustrated in Fig. 23.13.

Other European countries with eco-label programs include Austria, France, and the Nordic countries.

23.3.6 Principles of Noise Control

As illustrated in the previous section, the noise emissions of a wide variety of equipment are of importance,

Part G | 23.3

Table 23.6 German *Blue Angel* product categories with noise criteria

Product category	Relevant document
Automobile tires, low noise	RAL-UZ 89
Commercial vehicles and buses	RAL-UZ 59a and RAL-UZ 59b
Workstation computers	RAL-UZ 78
Construction machinery	RAL-UZ 53
Garden shredders	RAL-UZ 54
Portable computers	RAL-UZ 93
Printers	RAL-UZ 85
Copiers	RAL-UZ 62
Low-noise and low-pollutant chain saws	RAL-UZ 83
Low-noise waste-glass containers	RAL-UZ 21

and it is not possible to present noise reduction on each type here. It is however, possible to present general principles of noise reduction. A widely distributed set of principles was prepared by *Ingemansson* [23.88]. One principle and its application is shown in Fig. 23.14.

The text below is partly organized according to those principles. In the following section, examples of the control of stationary noise sources are given.

As discussed in Sect. 23.1.2, sources of sound in the wave equation include mass introduced into a region, the application of a fluctuating force, transfer of heat, or stresses induced by turbulence. A fluctuating force or excess force produced by the speed of moving mechanical parts produce noise, and reduction of this force will reduce noise levels. In particular, high-frequency noise is generated by abrupt changes in force. Lower-frequency noise is produced by more gradual changes in force. Heavy objects impacting at high speeds generally produce less noise than lighter objects at low speeds.

Forces transmitted to large radiating surfaces also cause sound to be radiated, and these forces can be reduced by vibration isolation. Practical vibration isolators include rubber–plastic materials, cork, and various types of springs.

A reduction in the area of vibrating surfaces also reduces noise levels. When a plate, such as a cover over a portion of a rotating machine is not used to provide transmission loss, a perforated plate will reduce the vibrating area and reduce the radiation from the plate. Sound cancelation takes place between the front and back of a vibrating device such as a loudspeaker or a plate. Cancelation is more effective for a long narrow plate than for a square plate having the same area. This may have applications, for example, in the design of belt

drives. Cancelation is also more effective for plates with free edges rather than edges which are clamped. Plates may also be covered with materials with a high degree of internal damping, thus producing absorption of sound that might otherwise be radiated as sound. This may apply, for example to objects that resonate such as saw blades. In general, damping is most effective at high frequencies.

In solid structures, structure-borne sound may travel over long distances, and its effect on radiated sound can be reduced by vibration isolation. Flexible connections are useful for prevention of noise transmission from a machine into a pipeline. Separate isolation pads may be used for mounting machinery, and heavy rigid foundations are generally most effective.

When the wavelength of sound is small (high-frequency sound), sound-absorptive materials are most effective, and enclosures may be an effective means of noise control. The sound attenuation in air is also greater for high-frequency sound than low-frequency sound, which means that there can be additional attenuation due to the distance between a source and an observer (Sect. 23.4.1 and Chap. 4). However, a high-frequency sound pressure level is perceived to be louder than a low-frequency sound of the same level. This difference is expressed in the A-weighting curves in Sect. 23.2.4. Thus, conversion of a high-frequency sound to a low-frequency sound may result in a reduction in perceived noise level, and a reduction measured using A-weighting on a sound level meter.

Tones can be produced when air flows past an object. An example is wind passing over high tension wires. Vortices are shed from the wire (Karman vortex street), and this produces a fluctuating force on the wire, which results in radiation of sound. Adding an irregular structure to the object may reduce the strength of such forces and reduce the noise level. Tones can also be generated by wind passing over resonators, and noise levels may be reduced by altering the geometry of the resonator.

In pipes carrying fluid, constrictions, as may be produced by a valve, bends, and other obstructions generate forces in the system which lead to sound radiation. Noise can be reduced by gradual changes in bends, cross sections, and pipe lengths that are long enough to allow the levels of turbulence to be reduced. Lower exhaust air flows also result in reduced noise levels, especially in high-Mach-number regions where the noise is generated aerodynamically, and the radiated noise is proportional to the eighth power of the Mach number. Another way to reduce noise from ex-

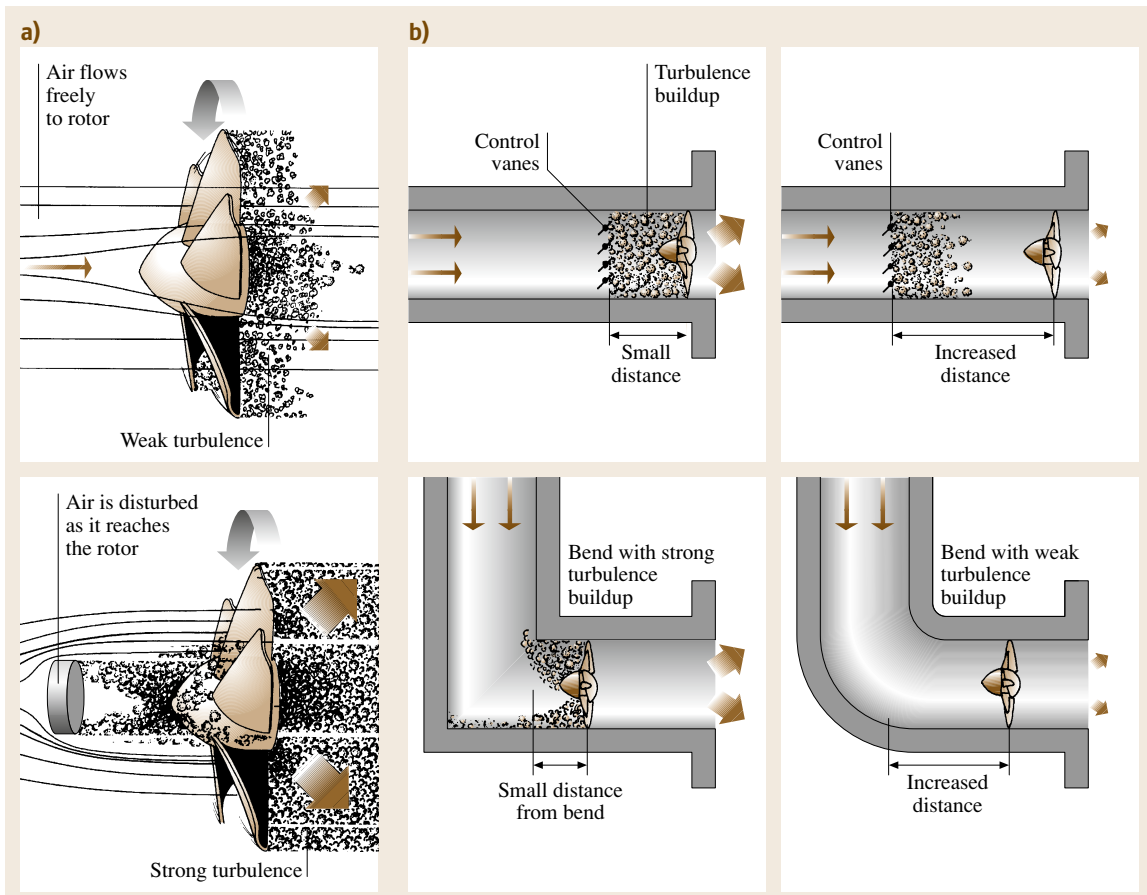

Fig. 23.14a,b An example of how fans make less noise when placed in smooth undisturbed air streams. Illustrations courtesy of Ingemansson Technology, Gothenburg, Sweden. (**a**) Principle, (**b**) application with ventilation

haust air flows is to add secondary flow of a lower speed around a high-speed exhaust jet. This is the principle of the high-bypass-ratio jet engine, and may also apply to compressed-air nozzles when used as part of a cleaning system in industrial applications. In air-moving devices, particularly axial flow fans, turbulence in the inlet air stream causes the angle of attack of the flow incident on the fan blades (airfoils) to vary, and generates fluctuating lift forces on the blades. Thus, obstructions in inlet air streams should be avoided.

The presence of solid surfaces affects the radiation of sound. For idealized sources such as monopoles, dipoles, and quadrupoles (Sect. 23.1.3), the reflected pressure from one or more surfaces may be in phase with the particle velocity of the source on a small surface surrounding the source and thus produce a radiated sound power that is greater than the sound power that

would be radiated by the source in a free field [23.89]. For actual machines, placement in, for example, a corner results in reflected sound waves that increase the measured sound pressure level. Thus, machines should be spaced a distance from walls and corners to reduce noise level. This effect is included in the prediction algorithm described in Sect. 23.4.3.

Acoustical materials for noise reduction are described in Sect. 23.4.3. Because good sound absorption requires a particle velocity in the material, and the particle velocity in a sound wave is small near a rigid surface, thick materials tend to be better sound absorbers than thin materials when placed on a rigid surface. Also, an air gap between a rigid wall and sound-absorptive material tends to increase sound absorption (Sect. 23.4.3). A layer of perforated metal with relatively large perforations is effective in protecting the

surface of the material from abrasion, and has relatively little effect on the sound-absorptive performance of the material. The shape of the perforations may take many different forms. Sound-absorptive material is also effective when used on ceilings in conjunction with screens in an office environment, since sound transmitted over the screen may be reflected before reaching an observer on the other side of the screen.

When sound travels in a tube, an expansion chamber as part of the tube may reduce noise levels. This principle may be used in reactive silencers. An example of a generic reactive silencer is given in Sect. 23.4.4. Such silencers with added sound-absorptive material may provide additional sound absorption. Dissipative silencers contain sound-absorptive materials, as discussed in the same section. Sound cancelation at selected frequencies may be achieved by using a tube with a side path which is long enough to produce sound cancelation between the wave that travels down the duct and the wave that travels over the side path.

The effect of wall constructions on noise reduction is covered in Chap. 11.

23.3.7 Noise from Stationary Sources

One of the most pervasive sources of noise is noise generated by air-moving devices. The general principles of control of noise from these devices is described below. Noise from other stationary sources is the subject of current research.

Air–Moving Device Noise

Air moving devices (AMDs) (e.g., fans and blowers) are widely used in a variety of equipment, and are a pervasive source of noise. These devices (AMDs) may have a very large diameter, and used in ventilating systems for buildings as well as in industrial processes. Large fans are usually axial devices and large blowers are centrifugal devices that may have either forward-curved or backward-curved blades. Smaller units may be used for home heating and ventilating as well as in industrial equipment such as that produced for the information technology industry. Axial fans are most common, but centrifugal blowers are also used when the system resistance (see below) is relatively high. Other air-moving devices, such as cross-flow fans, motorized impellers, or mixed-flow devices may also be used.

The primary source of noise is fluctuating lift forces on the blades as turbulent air passes through the unit. For high values of inlet turbulence, there is a fluctuating angle of attack on the blades, and this leads to

fluctuating lift forces. Forces are also produced by flow separation from the blade, and by vortices being shed from the blades. The radiated noise is broadband in character with discrete frequency components at the blade passage frequency and its harmonics. The blade passage frequency is

$$f = B\frac{N}{60} \, , \tag{23.34}$$

where f is the frequency in Hz, B is the number of blades and N is the device speed in revolutions per minute (rpm).

A performance curve is common to all types of air-moving devices, illustrated in Fig. 23.15 for a small centrifugal device. All systems have a resistance to air flow, and the system resistance can generally be defined as a quadratic function of air flow, as illustrated in the figure. The intersection of these two curves is the operating point for the device. If the flow rate is zero, the condition is known as *shutoff*, and when the static pressure is zero, the condition is known as *free delivery*. The air flow through the blades under either condition is poor, the noise level tends to rise as discussed below.

The static efficiency of an air-moving device is generally defined as

$$\eta_s = \frac{PQ}{W_{in}} \, , \tag{23.35}$$

where P is the static pressure rise in Pa (N/m^2), Q is the volume flow rate in m^3/s, and W_{in} is the input power to the device in W. The static efficiency is a maximum at some point on the performance curve, as illustrated in Fig. 23.16 for a constant input power. An operating
Fig. 23.15 Performance curve for a small centrifugal blower

Static efficiency normalized to its maximum value
Fig. 23.16 Illustration of air-moving device static efficiency for a constant input power

point near the point of maximum static efficiency is desirable for low noise radiation, and is usually a design goal for large devices. In the design of small ventilating systems, the system resistance is often not known accurately, and optimal design may be difficult to achieve. However, an operating point to the left of the point of maximum static efficiency is usually undesirable, both from the viewpoint of flow instability and increased noise.

The choice of a type of air-moving device is usually dictated by the desired *specific speed* N_s defined as

$$N_s = \frac{NQ^{1/2}}{P^{3/4}} \,, \tag{23.36}$$

where N is the rotational speed of the air moving device, and P and Q are defined above. Axial flow devices are generally used at low pressures and high-volume flow rates (high specific speed), and centrifugal devices are usually used at relatively high pressures and low-volume flow rates (low specific speed).

For noise radiation from large air-moving devices, it is often useful to use a sound law first proposed by *Madison* [23.90]. Its validity depends on the point of rating for a homologous series of air-moving devices. For such a series, it is useful to define dimensionless parameters, the *pressure coefficient* ψ and the *flow coefficient* ϕ as

$$\psi = \frac{2P}{\rho (\pi DN)^2} \,, \tag{23.37}$$

$$\phi = \frac{Q}{\pi D^3 N} \,, \tag{23.38}$$

where D is a characteristic dimension (diameter), and N is the rotational speed of the device. Then, the performance curve for any device in the series can be expressed as a single curve of ψ versus ϕ and the operating point discussed above becomes the point of rating for the series.

The sound law is then

$$W = W_s \frac{P^2 Q}{P_0^2 Q_0} \,, \tag{23.39}$$

where W_s is the specific sound power, and W is the radiated sound power of the device P_0 and Q_0 are 1 Pa and $1\,\mathrm{m^3/s}$, respectively.

No frequency dependence was given in (23.39), but values of W_s are often published in octave bands. It must be emphasized that (23.39) is valid only at a given point of rating. If the operating point goes from shutoff ($P = 0$) to free discharge ($Q = 0$), the point of rating is changing, and the radiated sound power does not go to zero at these extremes; in fact, it generally increases, as illustrated in Fig. 23.17. The above sound law is most useful in the design of large systems when the system resistance is known and the air-moving device operates near its point of maximum static efficiency. Using (23.37), (23.38), and (23.39), it can be shown that at a given point-of-rating, the sound power is proportional to the fifth power of the speed of the device.

For small air-moving devices, it is most meaningful to obtain sound power level data on the device itself, usually as a function of speed, operating point, or both. An apparatus for determination of sound power of small devices has been standardized both nationally and internationally [23.91, 92] and is shown in Fig. 23.18 [23.93]. The AMD is mounted on a flexible membrane for airborne noise tests. Small fans mounted on lightweight structures are known to transmit energy into the structure, which can then be radiated as sound. The same test apparatus can also be used for evalu-

Relative A-weighted sound power level (dB)

Fig. 23.18 Test plenum for determination of the sound power level of small air-moving devices (In 1962, an early version of this apparatus was first used to determine the sound power output of centrifugal blowers (after [23.93]))

ation of the structure-borne vibration of small AMDs if the membrane is replaced by a specially designed plate [23.94].

A history of noise control in small air-moving devices is available [23.95]. The following guidelines have proved to be useful for the design of cooling systems for electronic equipment [23.96].

1. Design the system to be cooled to have the lowest possible static pressure rise for the required air flow. A low static pressure rise indicates that the AMD can operate at a low tip speed, resulting in a low noise level. The static pressure rise across a system is caused by several sources of resistance such as the devices being ventilated and finger guards which may be required for safety. If unnecessary sources of resistance can be eliminated, the air flow will increase. It should then be possible to reduce the tip speed of the device (speed of the outer edge of the AMD blade) to obtain the desired air flow at a lower noise level.

2. Select an AMD so that it operates near its point of maximum static efficiency, considering the required air flow rate and the pressure drop through the system. Operation away from the point of maximum static efficiency should be in the direction of lower static pressure rise and higher air flow (see point 3).

3. Select a point of operation of a fan that is away from the best efficiency point in the direction of higher air flow and lower static pressure rise. Small fans are often unstable when operated at air flow rates less than the air flow rate at the best efficiency point. They are often very noisy under conditions of high static pressure rise and low air flow rate.

4. Select a fan or blower with a low sound power level and avoid devices that have high level peaks in their one-third-octave-band sound power spectrum. Such peaks usually indicate the presence of discrete frequency tones in the spectrum. Such tones can be difficult to eliminate and are generally a source of annoyance.

5. Select a fan or blower having the lowest speed and largest diameter consistent with the other requirements.

6. Minimize system noise levels by designing the system so that obstructions are not present within one fan diameter of the inlet to axial-flow fans so that the airflow into the inlet of axial-flow fans [23.97] is as spatially uniform as possible. Avoid the direct attachment of the AMD to lightweight sheet-metal parts.

7. Axial-flow fans should generally be mounted so that the air-flow direction is *toward* the equipment being cooled. *Pulling* air over equipment being cooled usually causes undesirable turbulence at the fan inlet, and produces an increase in noise level. See also item 6 above.

8. When possible, consider operating the AMD at a lower rotational speed. Then noise generally varies as the fifth power of the rotational speed, speed reductions produce significant reductions in noise level.

Active Noise Control

As shown in Sect. 23.1.2, in a linear medium sound pressures at a given point in space add. Therefore, in theory, if one sound pressure is created by a source and another pressure equal in amplitude and of opposite sign is created by a second source, the resulting sound pressure is zero. This is the principle of active control of noise. In practice, active control is difficult to achieve, and there are many technical issues involved.

The electronic sound absorber of *Olson* and *May* [23.98] was a very early attempt to produce active noise control. At the time, only analog circuits were available, it was necessary to control the low-frequency phase shift of both the loudspeaker and microphone used in the experiments – a subject of interest to both of the authors. With the introduction of signal processing techniques in the late 1960s and 1970s, and its

rapid development in the 1980s and 1990s, active control became more practical, in spite of many limitations which still exist. Nevertheless, there have been successful applications. Good results are obtained only at low frequencies (long wavelengths) and for sources that are small compared with the wavelength of sound. In general, discrete-frequency noise is easier to cancel than broadband noise.

There are several configurations of a source and one or more loudspeakers that can produce active noise reduction:

1. Noise control in a duct. This generally requires a microphone to determine the sound coming along the duct, a loudspeaker mounted at the side of the duct, an error microphone, and signal processing to determine the signal to the loudspeaker which will reduce the sound pressure level at the error microphone (ideally) to zero. This configuration is most successful for low-frequency sound and for plane-wave propagation in the duct.
2. Reduction of radiation efficiency. Placement of one or more canceling sources very close to the noise source. In the case of a single canceling source, the effect of the canceling source is to create a dipole source and to reduce the radiation efficiency of the combined noise source – canceling source. In principle, one could use three canceling sources which, with proper phasing, reduces the radiation efficiency even further by creating a quadrupole source.
3. Creation of an outgoing wave field. Using several loudspeakers around a source, and processing the driving signals to the loudspeakers in such a way as to produce an outgoing wave equal in amplitude and opposite in phase to the wave field of the source.
4. Creation of a *zone of silence*. Using one or more loudspeakers to cancel the noise generated by a source at a point in space, creating a *zone of silence* in the vicinity of the point. Such zones are small compared with the wavelength of sound, and in any practical application, many loudspeakers are needed.
5. Global reduction inside an enclosed space. Investigation of the modal structure of an enclosed space and placement of a large number of microphones and cancelation sources within the space. A complex signal-processing system is then used to create a net noise reduction in the space. This technique has been used in the cabins of small turboprop aircraft.
6. Active headsets. A cancellation field is created in the ear canal when a headphone is worn, thereby creating a noise-canceling headset. Such headsets are commercially available.

The literature on active noise control includes books [23.99, 100], articles [23.101, 102], conference papers [23.103–107], and collected works [23.108].

Other Stationary Sources

Noise from other stationary sources covers a very wide variety of machinery and equipment. Many examples of noise control may be found in the *Noise Control Engineering Journal* and in the INTER-NOISE and NOISE-CON series of international congresses and conferences on noise control engineering(Sect. 23.7).

23.3.8 Noise from Moving Sources

Vehicle Noise

Noise emissions from motor vehicles are an important source of environmental noise in almost every industrialized country in the world, and many steps have been taken to reduce these levels. Unlike aircraft noise, vehicle noise affects populations in a very wide geographical area, and is pervasive in any area with a well-defined roadway network. In recreational areas, noise from snowmobiles and other recreational vehicles is a major source of annoyance. However, in this section, emphasis is on road vehicles – passenger cars, buses, and trucks. Aside from reduction of the noise emissions of the vehicles themselves, noise barriers and buffer zones are the primary methods of shielding persons from motor vehicle noise. The properties of noise barriers are discussed briefly in Sect. 23.4.1, and in more detail in Chap. 4.

The major sources of vehicle noise can be divided into power-train noise (cooling fan, engine, drive train, exhaust), tire–road interaction noise, and wind noise. The latter is not a major source of noise. Fan noise has been described in Sect. 23.3.7. Engine noise is produced by pressure fluctuations within the engine due to combustion, their interactions with mechanical components, transmission into the engine block and subsequent radiation. Gear noise is produced by the drive train, and exhaust noise is attenuated by the muffler. The relative importance of these sources is highly dependent on the type of vehicle and its design. Considerable progress has been made in the reduction of all of these sources, partly because of the development of regulatory limits on pass-by noise in nearly every industrialized country in the world, but also because of the desire of manufacturers to reduce the interior noise in vehicles. As

a result, tire–road interaction noise has become a major source of exterior vehicle noise, especially at high speeds.

As part of a study on the effect of noise regulations on traffic noise [23.109], the International Institute of Noise Control Engineering summarized some of the noise reduction measures that have been taken to reduce the noise emissions of motor vehicles. Examples are given in Table 23.7 below.

The international standard for the determination of pass-by noise, a common descriptor of vehicle noise emissions, is ISO 362 [23.110], which specifies measurement methods, including microphone position, the characteristics of the test area in the immediate vicinity of the vehicle, driving mode, and the area of the site that must be free from obstructions. In summary, this document specifies that the test vehicle is driven over a designated test area with a standardized road surface. Fixed microphones are located 7.5 m from the vehicle path center line (In the United States, the microphone distance is 15 m and the relevant standards are SAE J986 and SAE J366.). Vehicles approach the test area at a constant speed, usually 20–50 km/h, but the throttle

is fully open when the vehicle is within ±10 m of the microphone positions. The maximum A-weighted fast sound level during the acceleration is measured.

The relative importance of power train and tire/road interaction noise has been studied by *Sandberg* and *Ejsmont* [23.111]. The relative importance of these sources depends on the year of vehicle manufacture, the type of vehicle (cars, heavy trucks), and engine speed. The characteristics of the tire itself (tread, sidewall stiffness, etc.) are also important – as is the character of the road surface. The relative importance of these sources may be described in terms of a crossover speed – the speed at which tire–road noise becomes more important than power train (power unit) noise.

It can be seen from Table 23.8 that at normal speeds on major highways, tire–road interaction noise is the dominant source of vehicle noise emissions. In the table caption, *SMA* refers to a stone mastic asphalt surface and *chippings* refers to stones in an asphalt concrete surface that also consists of sand, filler, and an asphalt binder.

A qualitative description of the sources of noise radiation from tires includes radial and tangential vibra-

Table 23.7 Examples of noise reduction measures in motor vehicles (after [23.109, Table 1])

Engine in general	Other vehicle components
• Switchover to turbo-charged engines • Optimization of the engine combustion process, e.g., by using electronics or by improving the shape of the combustion chamber • Encapsulation or shielding of entire engines or especially noisy parts of them • Use of hood blankets or laminated covers • Sound-absorptive material in the engine compartment • Optimization of the stiffness of the cylinder block • Use of structure-borne noise-reducing material	• Improvement of gearboxes, damped propeller shafts • Improved rear-axle transmission • Shielding of transmission components • Regulation of the fan by thermostat • Decreased speed of fan by using a larger fan or optimization of fan shape • Silencers for air compression outlet noise • Improvements of brakes for reduction of brake squeal • Improved aerodynamics • Selection of suitable tires (low noise at acceleration)
Exhaust system	**Induction system**
• Minimization of outlet and mantle emission of exhaust silencers, e.g., by increased volume • Introduction of more than one silencer • Optimization of pipes to/from the silencer, e.g., by equal length pipes or air gap pipes • Dual-mode mufflers • Use of absorptive materials • Active noise control	• 1/4-wave tuners or other resonators • Thicker duct walls, and/or lined ducts • Increased volume of air cleaner • Intake covers or shields • Active noise control

Table 23.8 Crossover speeds for various cases. According to *Sandberg* [23.111]: *The table assumes that normal tires are used, and that the road surface is a dense asphalt concrete or an SMA with max 10–14 mm chippings.* Cruising *is constant speed, and* Accelerating *means an average way of accelerating after a stop, but not as much as in the ISO 362 driving mode.* (after [23.111, Table 5.1])

Vehicle type	Cruising	Accelerating
Cars made 1985–1995	30–35 km/h	45–50 km/h
Cars made 1996–	15–25 km/h	30–45 km/h
Heavy trucks made 1985–1995	40–50 km/h	50–55 km/h
Heavy trucks made 1996–	30–35 km/h	45–50 km/h

tion of the tire treads, axial vibrations of the sidewalls, *air pumping* due to the deformation of the tread by irregularities in the road surface, and possibly vibration of the rim of the tire. At low frequencies, there is evidence that the tire treadband can be considered to be a cylindrical beam elastically supported by the sidewall [23.112].

A quantative description of tire–road noise is best obtained by development of a model of the sound radiation. A history of past modeling attempts has been given by *Kuijpers* and *van Blokland* [23.113], and more generalized models are also available [23.114, 115].

The road surface itself has a significant effect on the generation of tire noise. The roughness of the surface affects the excitation of the tire and subsequent generation of noise; the porosity of the surface effectively changes the compressibility of trapped air, and if the acoustic impedance is in the range to absorb sound, energy can be absorbed by the surface. Information on the characteristics of porous surfaces is given in [23.111].

Tire–road interaction noise is currently the subject of intensive research. *Bernhard* et al. have given a summary of research [23.116], *Sandberg* et al. [23.117] have discussed poroelastic road surfaces, and *Thornton* et al. [23.118] have studied the variability of existing pavements. Although porous surfaces have been shown to provide noticeable reductions in traffic noise levels, questions remain about the durability of these surfaces, especially in cold climates. The durability of such surfaces in a warm climate has been studied by *Donavan* et al. [23.119].

Traffic Noise Prediction Models. The US Federal Highway Administration has released version 2.5 of the *traffic noise model*, which may be used for a wide variety of calculations related to traffic noise. The char-

acteristics of the model are described in Sect. 23.4.1 on *outdoor noise barriers*.

Aircraft Noise

Exterior noise emissions of aircraft are of major importance to persons on the ground, and interior noise emissions are a concern of both airline passengers and crews.

Aircraft Noise Emissions. Noise emissions from civil aircraft have been regulated for more than 35 years, first by the Federal Aviation Administration in the United States, and later, internationally, by the International Civil Aviation Organization (ICAO). Nevertheless, although the noise from individual airplanes has been significantly reduced, the total exposure to aircraft noise for residents in communities near many airports has increased because of the growth in the number of aircraft operations at airports throughout the world. Consequently, operators of the airplanes and the airports continue to face limitations because of aircraft noise. This section discusses the noise emissions of aircraft; noise at the receiver is discussed in Sect. 23.5.4. Requirements for the noise levels that may be produced by aircraft are given in title 14 of the US Code of Federal Regulations, 14CFR part 36 [23.120] and in annex 16 to the Convention on International Civil Aviation (ICAO annex 16) [23.121].

The methodology of determining the noise emission of aircraft for certification purposes is well developed. Certification noise levels are not intended to, and do not, represent noise levels that may be measured in communities around airports.

Certification noise limits, in terms of effective perceived noise level (EPNL), are specified at three points – known as *lateral*, *flyover*, and *landing approach*. The limits are a function of the maximum design takeoff gross mass, and apply to both jet-powered and propeller-driven transport-category airplanes, business/executive airplanes, and helicopters. The limits apply to new-design airplanes and to retrofit modifications of old-design aircraft.

Perceived noise levels are determined from 500 ms-average one-third-octave-band sound pressure levels, at 500 ms intervals, and are adjusted for the additional noisiness caused by prominent tones, if present, or other spectral irregularities. For each of the three noise-measurement points, effective perceived noise levels are determined from the time integral of tone-corrected perceived noisiness and adjusted to reference atmospheric conditions, reference flight paths, reference airspeeds, and reference engine power settings.

The first issue of 14CFR part 36 became effective in 1969; ICAO annex 16 was first issued in 1971. The main objective of those regulations was to ensure that noise produced by new aircraft designs would be less than the noise produced by earlier designs. In the years since the initial issue, the certification noise level limits have been gradually reduced in stages.

Stage 1 airplanes are the noisiest, and include the as-manufactured versions of the Boeing 707 and McDonnell Douglas DC8 and various business/executive jets. Stage-2-compliant airplanes have lower noise levels than stage 1 airplanes. Noise levels from airplanes that comply with stage 3 requirements are even lower. An airplane that complies with the Stage 1, 2, or 3 requirements of 14CFR Part 36 also complies with the corresponding Chap. 1, 2 or 3 requirements of ICAO Annex 16.

ICAO Annex 16 recently introduced the Chapter 4 requirements for jet-propelled airplanes and for propeller-driven airplanes having a takeoff gross mass of more than 8618 kg. The FAA is considering adoption of similar stage 4 requirements. Noise-level limits for chapter 4 compliance are the same as for chapter 3 compliance but compliance was made more stringent by eliminating the *tradeoff provisions* that had

been part of the chapter 2 and 3 (or stage 2 and 3) requirements.

As an example of the changes to the certification noise-level limits, the effective perceived noise level limit at the lateral position for a takeoff gross mass of 200 000 kg (441 000 lbf) is 107.1 dB for a chapter 2/stage 2 airplane at 650 m to the side of the takeoff flight path, and 100.4 dB for a chapter 3/stage 3 airplane (or a chapter 4 airplane) at 450 m to the side of the takeoff flight path. Changes in lateral noise levels are representative of improvements in the technology of aircraft noise reduction.

Figure 23.19 illustrates trends in the progress in reducing the noise emission from commercial jet aircraft. There are no chapter 1/stage 1 airplanes operating in most of the industrialized countries of the world and only a few chapter 2/stage 2 airplanes.

For jet-powered and propeller-driven airplanes, the engines are the principal sources of noise during ground roll, climb-out, and landing. Sound produced by vortices shed by the extended landing gear and by wing leading-and trailing-edge devices (flaps) contributes to the noise level under landing-approach flight paths, and is an important consideration as engine noise is reduced.
Fig. 23.19 Progress in aircraft noise reduction. Effective perceived noise level at the 450 m lateral noise-measurement point normalized to a total static thrust of 444 800 N for the noted airplane/engine configurations at the time of initial service. (After *Willshire* [23.122]; adopted from *Condit* [23.123])

Reduction of airplane engine noise during departure operations (as illustrated in Fig. 23.19) was achieved primarily by increasing the bypass ratio, and hence the diameter of the fan stage at the front of the turbofan engines. Bypass ratio is the ratio of the mass flow rate of the air that passes through the fan-discharge ducts to the mass flow rate through the turbine stages in the core of the engine. Thrust is provided by moving a large amount of air at a lower exhaust-gas velocity and hence with lower levels of jet-mixing noise at high engine-power settings. Higher bypass ratios also result in better fuel efficiency for the same thrust, although at an increase in engine weight and diameter.

Discrete-frequency noise from the fan, compressor, and turbine stages is reduced by means of sound-absorptive linings in the engine inlet and discharge ducts. Tonal components in the sound from the fan stages are minimized or eliminated by careful selection of the number of blades and vanes and by increasing the spacing between the fan stage and the fan-outlet guide vanes. Inlet guide vanes ahead of the fan blades are no longer used in modern turbofan engines.

A summary of technology for engine noise-control designs is available [23.124]. A summary of retrofit applications intended to allow chapter 2/stage 2 airplanes to meet a phase-out deadline of the year 2000 for stage 3 (ICAO chapter 3) compliance has been published [23.125].

Interior Aircraft Noise. The engines and pressure fluctuations in the turbulent boundary layer outside the fuselage of an aircraft during flight are sources of noise in the interior of an airplane. Vibration from jet engines or propellers can cause the fuselage to vibrate and be radiated as sound into the cabin of an aircraft or helicopter. The air-conditioning system is often a source of noise in the interior of an aircraft.

Noise from external sound sources can be partially controlled by the design and construction of the fuselage. Sound-absorptive material is installed between the skin of the fuselage and the interior trim panels; this material also acts as a thermal insulation barrier to the cold outside air. Some propeller-driven airplanes have successfully used active noise and vibration control systems.

Control of noise in the interior of an aircraft requires a balance between the desire to achieve low cabin interior noise levels for the comfort of the passengers and the flight and cabin crews, while maintaining a degree of privacy, and an increase in airplane empty weight and maintenance costs.

Cabin noise levels vary greatly with seat location and operation of the aircraft (takeoff, cruise, and landing). Standardized test methods are now available for the specification of procedures to measure aircraft interior noise under specified cruise conditions [23.126, 127].

23.4 Propagation Paths

23.4.1 Sound Propagation Outdoors

Sound propagation in the atmosphere is discussed in Chap. 4, and only general information will be presented here. Geometrical spreading is the most important effect that reduces the sound pressure level as distance from a source is increased. There are, however, several other factors which influence outdoor sound propagation.

1. Atmospheric absorption. At long distances and at high frequencies, the effects of atmospheric absorption are significant. These effects are usually described by an attenuation coefficient in decibels per meter Chap. 4.
2. Ground effects. When the sound source is located above a ground surface, sound waves that reflect from the ground will constructively and destructively interfere with those propagating directly from the source. In general, the ground is partially reflecting; the reflected wave is modified in amplitude and phase by its interaction with the ground surface. The amount of attenuation attributable to this ground interaction, and its variation with frequency, depend on the surface characteristics, the source and receiver heights, and their separation. The effects of the ground are largest for intermediate frequencies ($\approx 500\,\mathrm{Hz}$) when the source is above the ground (1 m or more). If the source is very close to the ground, all frequencies above about $500\,\mathrm{Hz}$ are highly attenuated.
3. Temperature gradients and wind speed gradients. The speed of sound is proportional to the square root of the absolute temperature of the medium. The normal temperature lapse with height above the ground means that a sound wavefront moves more rapidly near the ground surface. This causes the wavefront

to bend upwards, creating a *shadow zone* of low sound pressure level near the surface. The opposite effect occurs when the temperature lapse is abnormal. Wind velocity gradients have a similar effect since the speed of the wave is the wind speed plus the speed of sound. Since the wind speed is usually lower close to the ground, propagation upwind tends to bend the wavefront upwards, creating a shadow zone similar to that produced by a normal temperature lapse. For sound propagation downwind, the opposite effect occurs, and the wavefront is bent toward the ground; there is no significant attenuation of the sound wave relative to the attenuation in the absence of wind.

4. Turbulence. Since turbulence always accompanies wind outdoors, the effects of atmospheric turbulence must be included in any analysis of sound propagation outdoors. There are three major effects of turbulence. First, at single frequencies, atmospheric turbulence affects the coherence between waves that propagate directly from the source and waves that are reflected from the ground surface. This results in sound pressure levels that are higher than would be expected in the absence of turbulence at those points where destructive interference between the waves occurs. Second, atmospheric turbulence produces scattering into the shadow zones caused by air-temperature and wind-speed gradients that tends to raise the sound pressure level in these areas. Third, in a highly directive sound beam, the presence of turbulence results in an excess attenuation produced by sound scattering out of the beam.

A review of sound propagation outdoors has been given by *Embleton* [23.128].

Outdoor Noise Barriers

Information on the design of noise barriers may be found in Chap. 4. In this section, the current use of outdoor noise barriers is described, and a summary of the effectiveness of these barriers is given. Barriers are widely used for the control of highway traffic noise, and are also used to control noise from rail vehicles and airport ground operations. Two common alternatives to barriers exist: sound insulation of buildings when noise indoors is the problem, and the use of quiet (porous) road surfaces. Information on tire–road interaction noise is presented in Sect. 23.3.8. However, noise barriers are currently the preferred solution for the reduction of traffic noise, and they have been constructed along many highways, as described below.

Barrier Characteristics. A typical noise barrier is shown in Fig. 23.20.

The most important parameter to describe the effectiveness of the noise barrier is the Fresnel number N

$$N = \frac{(d_1 + d_2 - d_3)}{\frac{\lambda}{2}} . \tag{23.40}$$

The distances d_1, d_2, and d_3 are defined in Fig. 23.20; λ is the wavelength of sound. The noise reduction performance of the barrier for single source and receiver points may be described in terms of its insertion loss L_i; $L_i = L_{pb} - L_{pa}$.

L_{pb} is the sound pressure level before installation of the barrier, and L_{pa} is the sound pressure level after installation. These levels may be described in octave- or one-third-octave bands, or for an overall sound level with frequency weightings such as A or C. Since the insertion loss depends on the location of both the sound source and the receiver, standardization of the measurement procedures must be available to allow specification of barrier performance (see below). Large Fresnel numbers lead to high insertion loss, and therefore performance is best at high frequencies. A technical assessment of the performance of many noise barriers [23.129] found insertion losses (A-weighted sound levels) to be in the range 5–25 dB. Barrier heights are typically 3–8 m. The performance of a barrier depends on its height, thickness, shape, edge conditions at the top of the barrier, and ground impedance on both sides of the barrier (because ground reflections contribute to the insertion loss). The transmission loss of the barrier material itself should exceed about 25 dB, but it is often of secondary importance because structural considerations usually require massive walls.
Fig. 23.20 A basic schematic showing the source of noise, barrier, and receiver

A variety of materials are used to construct barriers – precast concrete, block, earth berms, wood, metal, and plastics (including transparent plastics). Barriers with sound-absorptive surfaces have two advantages: the sound at the receiver point may be lowered, and reflections from the barrier are reduced. The latter may be of importance where barriers are installed on both sides of a highway and multiple reflections between the barriers can compromise insertion loss. Also, absorptive surfaces are useful where a barrier is installed on only one side of a highway, and neighbors on the opposite side may perceive increased noise due to reflections.

Determination of Barrier Insertion Loss. One method to determine the insertion loss of barriers is described in ANSI S12.8 [23.130]. The most reliable method is the direct method that uses data measured at the same site before and after construction of the barrier. Two *indirect* methods are described – one using *before* data at an equivalent site, and a second using a prediction method to obtain *before* data.

Steps must be taken to ensure that the source level is the same for the *before* and *after* measurements by using a reference microphone position not influenced by the barrier. The atmospheric conditions must be constant, the microphones must be calibrated, and corrections must be applied for calibration differences before and after a series of measurements. The standard specifies microphone heights and distances at which measurement must be made to determine the insertion loss.

Noise Barrier Construction. Data on noise barrier performance in many countries is available [23.129]. In the United States, construction of noise barriers is the responsibility of State Departments of Transportation guided by criteria specified by the US Federal Highway Administration (FHWA). According to the FHWA [23.131], by the end of 2001, the 10 states with the most noise barriers had constructed $8.53 \times 10^6 \, \text{m}^2$ of noise barriers (1993 linear km) at a cost of 1.89 billion US dollars (2001 dollars). Many of the barriers have been constructed using a combination of materials. However, the materials most used in single-material barriers are:

- Concrete/precast
- Block
- Wood/post and plank
- Concrete
- Berm
- Wood/glue laminated

- Metal and
- Other wood construction.

A more detailed analysis of barrier construction by state, including area, length, and cost has been made by *Polcak* [23.132]. He concluded that cost figures are reliable only in general terms, and that many costs are variable from project to project. These include drainage, excavation, guard rails, utility relocation, landscaping, and the cost of the barrier system itself.

Noise Barrier Prediction Methods. Prediction of the performance of noise barriers is included in a more general noise model used to predict traffic noise, the *Traffic Noise Model* (TNM). According to the sponsor of the model, the US FHWA [23.133], the model contains the following components:

- Modeling of five standard vehicle types, including automobiles, medium trucks, heavy trucks, buses, and motorcycles, as well as user-defined vehicles
- Modeling of both constant-flow and interrupted-flow traffic using a 1994/1995 field-measured database
- Modeling of the effects of different pavement types, as well as the effects of graded roadways
- Sound level computations based on a one-third-octave-band database and algorithms
- Graphically interactive noise barrier design and optimization
- Attenuation over/through rows of buildings and dense vegetation
- Variable ground impedance
- Multiple diffraction analysis
- Parallel barrier analysis
- Contour analysis, including sound level contours, barrier insertion loss contours, and sound level difference contours.

The TNM replaced the STAMINA/OPTIMA program, and several early versions were produced. Experience with the TNM and elements of its design have been described by *Menge* et al. [23.134], and comparisons of model predictions with experimental data have been made by *Rochat* [23.135].

23.4.2 Sound Propagation Indoors

In this section, the primary objective is to relate the sound pressure level measured in a room having specified acoustical characteristics to the sound power radiated by one or more sources in the room. Sound

transmission through walls, window and other building elements is discussed in Chap. 11.

Classical Theory of Sound Propagation in Rooms

It is important to relate the sound pressure level in rooms to the sound power output of a source, and therefore the path indoors between the source and receiver should be discussed. In the classical theory of room acoustics, reflections from all of the surfaces in the room are equally important, and the difference between the sound pressure level L_p, and sound power level L_W at a distance r from a source emitting sound power L_W may be expressed as

$$L_p - L_W = 10 \log \left(\frac{Q}{4\pi r^2} + \frac{4}{R} \right), \tag{23.41}$$

where Q is the directivity of the source in the direction of the receiver point (Sect. 23.3.1), and R is the room constant (Chap. 9). The first term on the right of the equation is the direct sound, and the second term is the reverberant sound – the sound reflected from all of the room surfaces. For an omnidirectional source ($Q = 1$), the difference between sound pressure level and sound power level is as shown in Fig. 23.21.

In many rooms of practical interest, reflections from the room surfaces are not of equal importance, and the noise emission of one or more sources in the room has been determined according to the methods described earlier in this chapter. Rooms almost always contain objects that scatter the sound waves, and this scattering
Fig. 23.21 Difference between sound pressure level and sound power level as a function of distance from an omnidirectional source

is not taken into account in (23.41). Therefore, a more detailed theory must be used to characterize the path between the source and the receiver.

Prediction of Installation Noise Levels

One procedure for determining the path attenuation in real rooms has been published by the European Computer Manufacturers' Association (ECMA) [23.136]. This method allows for the prediction of sound levels in rooms, and, while it was developed for use with information technology equipment, it is applicable to other noise sources when the A-weighted sound power level of the source is known. The method predicts A-weighted sound pressure levels, and the sound-absorptive properties are described in terms of a sound absorption coefficient α, which is the average of the absorption coefficients in the 250, 500, 1000, and 2000 Hz octave bands.

Three different shapes of rooms are defined in the procedure:

An *ordinary room* has a length L and a width W, smaller than $3H$, where H is the height of the room. For this room, classical theory is used with the modifications described below.

A *flat room* has $L > 3H$ and $W > 3H$. For such a room, it is assumed that the sound absorption of only the floor and ceiling is important.

A *long room* has $L > 3H$ and $W < L/2$. For such rooms, reflections from the sidewalls are assumed to be important.

For an ordinary room, the classical theory is used with the following modifications.

In a free field, the radiation from the source is through a hemispherical surface, since widely used methods for the determination of sound power level depend on sound pressure level measurements on the surface of a hemisphere.

The measured directivity of the source itself is assumed to be unity because the source directivity is not normally reported with the sound power level. However, a directivity Q is included in the calculations if the source is near a wall ($Q = 2$) or in a corner ($Q = 4$).

With these modifications, the difference $L_{pA} - L_{WA}$ as a function of distance r from the source in an ordinary room is

$$L_{pA} - L_{WA} = 10 \log \left(\frac{Q}{2\pi r^2} + \frac{4}{S\alpha} \right), \tag{23.42}$$

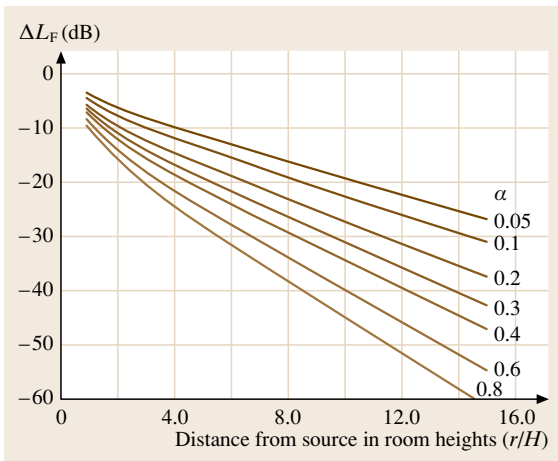
where $S\alpha$ is the total absorption in the room weighted according to the area and absorption of each room sur-


Fig. 23.22 Correction term for a furnished flat room having a density factor $q = 2$ as a function of distance from the source for several values of α

face and piece of furniture. Curves similar to those shown in Fig. 23.21 above may be plotted for this case.

Similar, but more complex equations are given in [23.136] for flat rooms and long rooms. As an example, in a flat room with scattering objects, the absorption of the scatterers is assumed to be $\alpha_s = 0.1$ and the density factor of scattering objects q is given by

$$q = \frac{S_E}{4S_F},$$

where S_E is the total area of scatterers as viewed from the source in m^2, and S_F is the surface area of the room floor in m^2.

The difference $L_{pA} - L_{WA}$ in a flat furnished room is then given by

$$L_{pA} - L_{WA} = -20 \log H + \Delta L_F, \qquad (23.43)$$

where ΔL_F is a complicated function of distance from the source, density factor, and average absorption of the ceiling and floor. As an example, ΔL_F is given in Fig. 23.22 as a function of absorption coefficient for a density factor $q = 2$.

Other equations are given in [23.136], and correction terms are defined, both as equations and in graphical form.

Calculations for Multiple Sources

In general, there are several sources in a room at different distances from the receiver. In this case, the A-weighted sound pressure level is calculated for each source and distance, and converted to mean-square pressure. These mean-square pressures are added and converted to a total A-weighted sound pressure level at a given receiver position.

23.4.3 Sound-Absorptive Materials

Sound-absorptive materials are widely used for the control of noise in a variety of different situations. These include addition of absorptive materials to room surfaces to control reverberant sound generated by machinery and other equipment, installation of duct liners to increase the sound attenuation in air-conditioning ducts, liners for machine enclosures to reduce the sound radiated from the machine, hanging baffles for reduction of reverberant sound, and other applications.

Sound-absorptive materials exist in many different forms. These include:

- Glass-fiber materials
- Open-cell acoustical foams (urethane and similar materials, reticulated and partially reticulated)
- Fiber board as frequently used for acoustical ceilings
- Hanging baffles used to reduce reverberation in factories, and other enclosed spaces
- Felt materials
- Curtains and drapes
- Thin porous sheets, often mounted on a honeycomb structure
- Hollow concrete blocks with a small opening to the outside – to create a Helmholtz resonator
- Head liners for automobiles – of various materials, and
- Carpets.

One characteristic common to nearly all sound-absorptive materials is that they are porous. That is, there is air flow through the material as a result of a pressure difference between the two sides of the material. Porous materials are frequently fragile, and, as a result, it is necessary to protect the exposed surface of the material. Typical protective surfaces include:

- Thin impervious membranes of plastic or other material
- Perforated facings of metal, plastic, or other material
- Fine wire-mesh screens
- Sprayed-on materials such as neoprene, and
- Thin porous surfaces.

A full description of propagation in porous materials, the relationship between the propagation parameters

and the physical properties of materials, and the matching of boundary conditions when composite structures are created is beyond the scope of this chapter. However, some of the properties of sound-absorptive materials will be discussed, methods of measurement of normal impedance will be presented, and some results of calculations on composite structures will be shown.

A key parameter is the flow resistance r which can be defined as the ratio of the pressure drop across a sample of a material and the velocity through it

$$r = \frac{\Delta p}{u} \,. \tag{23.44}$$

The flow resistance is usually measured for steady flow through the material, the assumption being made that this value is equivalent, at least at low frequencies, for the particle velocity in a sound wave.

The unit of of flow resistance is $\mathrm{N\,s/m^3}$, the MKS Rayl. Actual values are often specified as a dimensionless quantity, the specific flow resistance r_s, where $r_s = r/\rho c = r/406$ for a density of air ρ of $1.18\,\mathrm{kg/m^3}$ and a speed of sound c of $344\,\mathrm{m/s}$. It is also common to specify the flow resistance per unit thickness.

Another property of sound-absorptive materials is that they can often considered to be *locally reacting*. When a sound wave is incident on a locally reacting material, the local pressure at the surface produces a particle velocity normal to the surface. When the two are sinusoidal and expressed as complex numbers the ratio is the normal impedance of the surface

$$z_N = \frac{p}{u} \,. \tag{23.45}$$

The normal impedance is independent of the angle of incidence of the sound wave.

Two mechanisms are mainly responsible for the absorption of sound. First, friction in the boundary layer between the air and the internal structure of the material absorbs energy, and a large particle velocity is needed for effective absorption. Second, the temperature rise during the compression phase of the sound wave results in conduction of heat into the material, further absorbing energy from the sound wave. The former is generally most important.

The sound absorption coefficient α is the ratio of the sound energy absorbed by the surface and the incident sound energy. In general, it is a function of the angle of incidence of the sound wave on the material. It varies from 0 to 1.0, although some measurement methods – described later in the section – result in values of $\alpha > 1$. The unit of sound absorption is the metric Sabine, S.
Fig. 23.23 Normal incidence sound absorption coefficient for a thin, rigid sound absorber having a flow resistance ρc placed 50 mm from a rigid termination. Calculated using a program by *Ingard* [23.137]

Material with an area of $1\,\mathrm{m^2}$ and $\alpha = 1$ has 1 Sabine of sound absorption (10.8 Sabins in English units). The sound-absorptive properties of, for example, hanging baffles are frequently expressed in Sabins.

Sound absorption coefficients are frequently measured in octave bands, and the noise reduction coefficient (NRC) is the average absorption in the 250, 500, 1000, and 2000 Hz octave bands.

The importance of particle velocity can be illustrated for the case where a thin sound absorber having a flow resistance ρc is placed in a tube at a distance 50 mm from a rigid termination. The normal incidence absorption coefficient calculated as a function of frequency is shown in Fig. 23.23. It can be seen that the absorption coefficient is highest when the distance from the rigid termination is an odd multiple of one-quarter wavelength of the sound. It is at these distances that the particle velocity in the absorber is highest.

Galaitsis [23.138] showed that multiple resistive sheets can be used to improve the sound absorption at normal incidence, and *Ingard* [23.137] extended the analysis to diffuse fields for both locally and non-locally reacting materials. As an example, Fig. 23.24 shows the absorption coefficients for two resistive sheets having a flow resistance $1.5\,\rho c$ and a total absorber thickness of 50 mm. The first sheet is 33 mm from a rigid surface, and the spacing between the two sheets is 17 mm. The structure can be made approximately locally reacting by, for example, using a honeycomb material between the resistive layers.
Fig. 23.24 Sound absorption coefficient for a two-screen sound absorber for normal incidence, a locally reacting structure, and a nonlocally reacting structure (after [23.139])

Fig. 23.25 Normal incidence sound absorption coefficient calculated for a porous material 25 mm-thick with a total flow resistance of ρc. The spacing between the material and the rigid backing is shown in the figure. Calculated using a program by *Ingard* [23.139]

Most sound-absorptive materials are relatively thick (e.g., 25 mm), and in this case, it is beneficial to have an air gap behind the material when it is mounted near a rigid surface. In the figure below, the sound-absorptive material is 25 mm thick, and has a total flow resistance of ρc. It is assumed that the material itself does not move. The normal incidence sound absorption coefficient as a function of spacing is shown in Fig. 23.25.

The sound-absorptive properties of flexible materials can be calculated [23.140], but this requires a knowledge of properties of the material other than flow resistance, and is beyond the scope of this chapter.

Measurement of Sound Absorption Coefficients

Two methods are commonly used to measure the performance of sound-absorptive materials, the impedance tube method and the reverberation room method.

The classic impedance tube method involves two tubes to cover two frequency ranges, a 100 mm-diameter tube and a 30 mm-diameter tube. A sample of the material is mounted at one end of the tube, and a loudspeaker at the other end is used to create a plane-wave sound field in the tube. A moving probe is used to detect the sound pressure an any point. The absorption coefficient is determined from

$$\alpha = 1 - \left| R^2 \right|, \tag{23.46}$$

where $|R|$ is the magnitude of the pressure reflection coefficient in the tube, the ratio of the incident and re-flected pressure. R is determined from the maximum and minimum pressures detected in the tube. The distance to the first minimum of sound pressure can also be measured, and together with R, can be used to determine the normal impedance of the material at its surface [23.141].

This method is useful to demonstrate plane-wave propagation and the interference of sound waves upon reflection, but it has several disadvantages:

1. The absorption coefficient is determined at single frequencies; it is therefore time consuming to determine its value as a function of frequency.
2. The sample size is small; 100 mm in diameter or 30 mm in diameter depending on the frequency of interest. The properties of a small sample may not be representative of a large sample of the same material.
3. The sample must be cut very accurately and very carefully mounted to achieve consistent results.

The first disadvantage may be eliminated by using the two-microphone method [23.142, 143] for probing the sound field. This method uses broadband excitation of the tube and two closely spaced phase-matched microphones; a digital signal processor is used to determine the transfer function between them. The absorption coefficient can then be calculated.

The reverberation room method [23.144] uses a large sample of material in a reverberation room,

usually with rotating diffusers. The sound absorption coefficient is determined from the difference in reverberation time in the room with and without the sample present. The results approximate the diffuse-field absorption coefficient.

One additional method for measuring the spherical-wave absorption coefficient in a free field over a reflecting plane has been proposed by *Nobile* [23.146]. The method uses the two-microphone technique referenced above, and makes it possible to measure the absorption coefficient as a function of the angle of incidence of the sound wave for samples of absorptive materials, which can be very large. The method therefore overcomes the disadvantages of the impedance tube method and provides more information than the reverberation room method.

23.4.4 Ducts and Silencers

Attenuation of sound in heating, ventilating, and air-conditioning ducts is covered in Chap. 11. There are, however, many other applications for devices to reduce noise between the source and the receiver. These include:

- Pumps
- Compressors
- Fans
- Cooling towers
- Engines (diesel and gas)
- Power plants and
- Gas turbines.

A general schematic of a *silencer* is shown in Fig. 23.26.

It is not always appropriate to describe input and output parameters in terms of impedances, but is is convenient for the purposes of illustration. Sources of sound have an internal impedance which is Z_{int} in the figure. This can be used to quantify the effect that an acoustic load has on the power output of a source [23.6]. For example, if a monopole source is characterized by a volume velocity that is independent of load, then a re-

flected pressure at the source which is in phase with the particle velocity will increase the power output of a source. In the figure below, the conditions at the inlet to the silencer are represented by Z_{in}. The conditions at the output of the silencer looking down the duct are characterized by Z_d. The radiation of sound into a reverberation room, hemi-anechoic environment, or an environment in which reflections are present is characterized by Z_{rad}.

When the silencer does not contain any sound-absorptive materials (a *packless* silencer), the only mechanism that can produce an insertion loss (the ratio of the sound power radiated with the silencer in place and the sound power radiated with the silencer removed) is to create a Z_{in} which, in combination with Z_{int}, reduces the sound power input to the silencer. Such a reactive silencer works best at low frequencies, and clearly depends on the internal impedance of the source, a topic that has been studied for internal combustion engines. At low frequencies, the silencer itself can often be represented by transmission matrices [23.138]. Transmission matrices for a variety of duct elements have been defined by *Ingard* [23.145]. Characterization of the silencer in terms of lumped parameters (mass, compliance, resistance) is not generally effective. A tube, for example, is a mass element only if its end is open (low-impedance termination) whereas it is a compliance when the end is closed (high-impedance termination). Thus, a description using transmission lines in the form of *T* networks is an alternative. Characterization of the

Fig. 23.26 Schematic diagram of a *silencer*
Fig. 23.27 Transmission loss in a duct as a function of frequency for two thicknesses of duct liner. Calculated using the program DuctMltl by *Ingard* [23.145]

silencer for complex geometries and high frequencies requires a computer program.

In most practical applications, the silencer contains sound-absorptive materials and usually protective facings. The input impedance of the muffler is usually such that reflections back to the source are not important. At high frequencies, the radiation impedance is high enough that there is little sound power reflected back down the outlet duct, and the transmission loss of the silencer (the ratio of the sound power at the outlet and the sound power at the inlet) is a good measure of silencer performance. This may not be true at low frequencies.

Duct silencers are manufactured in a wide variety of sizes, with linings, with splitters, and with aerodynamic shapes on the inlet and outlet. Standards are available for the measurement of silencer performance and guidance on their use [23.147–151]. The insertion loss of the silencer is usually measured, and its value may depend on the direction of air flow relative to the direction of propagation of sound. When the two are in the same direction (outlet duct), a sound wave is bent toward

the lining whereas when the two are in opposite directions (inlet duct), sound is bent toward the center of the duct [23.152].

Calculation of Duct Transmission Loss

Computer programs for the determination of the transmission loss of ducts are available [23.145]. The duct lining may consist of air gaps, one or more layers of porous material, resistive sheets and perforated facings. As one example, Fig. 23.27 shows the transmission loss for a duct 2.5 m long having a cross section of 0.6 m × 0.6 m. The sound-absorptive material has a steel perforated facing 1.6 mm thick with perforations 3 mm in diameter and a 30% open area. The duct liner is 200 mm thick in one case, and 100 mm thick in the second. The transmission loss shown in the figure is from 50 Hz to 500 Hz because the calculation is for plane-wave transmission only. It can be seen that the peak attenuation is about the same for both cases, but the thicker liner provides a much higher transmission loss at low frequencies.

23.5 Noise and the Receiver

Section 23.3 was devoted to the characterization of sources in terms of their noise emission. The third part of the source–path–receiver model involves immission of sound at the receiver. The sound may not be *unwanted*, and is therefore not technically noise, but this section is generally devoted to the effects of noise on people. Section 23.5.5 is devoted to *sound quality*, a subject of increasing importance in the design of products.

23.5.1 Soundscapes

As discussed in Sect. 23.1.2, a sound field may be described in terms of a sound pressure $p(r, t)$ that varies both in space and time. In practice, it is the RMS pressure that is measured since the time average of the pressure itself is zero, and several quantities measured by modern sound level meters are discussed in Sect. 23.2. The sound field can be described in the time domain or the frequency domain, or as a short-time spectrum that varies with time. Other descriptions are also possible.

The sound field $p(r, t)$ may, for the purposes of this section, be called a *soundscape*, an overall acoustical environment – both indoors and outdoors – that includes all sound, both wanted and unwanted. The interaction between an observer and this *physical* soundscape can

then be described in terms of *immission* of sound. In some cases, it has been found that this interaction depends not only on the properties of the soundscape itself, but on the visual environment of the observer (the landscape). A discussion of this effect is beyond the scope of this chapter.

The soundscape includes indoor environments such as living space and industrial plants, urban and suburban areas, parks, and wilderness areas. The effects of the sound field on observers in different portions of the soundscape are varied, and in many cases difficult to quantify. These effects include hearing damage, annoyance in various forms – which can range from mild dissatisfaction to frustration and anger – as well as interference with speech communication in many settings, including meeting rooms and classrooms. Other effects include interference with sleep, and loss of productivity. Since the soundscape includes both wanted and unwanted sound, the soundscape, when properly managed can induce a sense of well-being in the observer which can have a positive effect on the quality of life. Examples include listing to natural sounds in remote areas where unwanted sound is either nonexistent, or has been reduced to an acceptable level. It is a fact that *acceptable* means different things to different persons.

A further complication is that using conventional measures of noise immission, the acceptability of a sound may depend on the source. For example, it has been found that the same level of noise from aircraft, road traffic, and rail traffic produces different human reactions. In recent years, the quality of the sound has become an important factor in the design of machinery, particularly in automobiles and other motor vehicles. The soundscape created by a snowmobile may, for example, be quite acceptable to the operator, but unacceptable to an observer some distance from the machine.

In this section, various measures of noise level will be discussed, and generally accepted criteria for the magnitude of the level will be discussed. The management of the soundscape can be thought of as a policy issue that is partly the responsibility of individuals and partly the responsibility of federal, state, and local governments.

23.5.2 Noise Metrics

The effects of noise on people is a complicated subject, and extensive research is still in progress. Several metrics are commonly used to describe noise immission at the receiver, and most of these are in terms of the A-weighted sound pressure level. These metrics work well, both indoors and outdoors provided that the spectrum of the noise, measured in octave or one-third-octave bands is somewhat neutral in character; that is, it is not perceived as *rumbly* or *hissy*, does not contain discrete frequency components (tones), is broadband, and steady without impulsive or time-varying characteristics. Other, more complex, metrics are required when any of the above characteristics are present.

The A-weighted sound level as a function of time can be expressed as L_{Af} or L_{As}, where the subscripts f and s refer to the dynamic characteristics of a sound level meter: *fast* or *slow*. These dynamic characteristics are defined in Sect. 23.2.2.

In the early 1970s, the day–night average sound level (DNL, L_{dn}) was selected as a long-term measure of noise exposure. The day–night level is the time-weighted average level over a 24 hour period, but with 10 dB added to the level during the nighttime hours from 10:00 to 07:00.

Another time-weighted average level used in Europe is the day–evening–night level (LDEN, L_{den}) where the evening hours are normally between 19:00 and 23:00, the nighttime hours are from 23:00 to 07:00, and the daytime hours are from 07:00 to 19:00. In this case, 5 dB is added to the level in the evening hours, and 10 dB is added to the level in the nighttime hours. According to the European environmental noise directive, 2002/49/EC, the evening interval may be shortened by one or two hours, with corresponding lengthening of the day and/or night periods.

Other metrics for the sound level include, L_{10}, L_{50}, and L_{90}, the levels exceed 10%, 50%, and 90% of the time, respectively. Single events may be described in terms of the sound exposure level (Sect. 23.2.3).

Indoors, other metrics are commonly used to describe noise immission. In most of the world, the equivalent sound level over an eight hour period is the metric used to relate noise level to hearing loss. This level is usually described as having a 3 dB exchange rate because an equivalent level over a time interval T_1 is the same as for a level 3 dB higher over a time interval of $T_1/2$. In the United States, the Occupational Safety and Health Administration (OSHA) has adopted a 5 dB exchange rate. In this case, the time-weighted average level over a time interval T_1 is equivalent in noise dose to a level 5 dB higher measured over a time interval of $T_1/2$.

23.5.3 Measurement of Immission Sound Pressure Level

Before presenting criteria for noise immission, it is necessary to have procedures for the measurement of sound pressure level, both indoors and outdoors. For occupational noise exposure, ANSI S12.19 [23.153] defines terms used in occupational noise exposure, including noise dose, exchange rates, and the criterion sound level used in some cases. The use of sound level meters and dosimeters are also described.

ANSI S1.13 [23.154] is a very general standard for description of noise levels. The quantities discussed in Sect. 23.2 are defined as are various temporal characteristics of noise – continuous and steady, continuous sound, fluctuating sound, impulsive and intermittent sound, and other characteristics. Characteristics in the frequency domain are also described – broadband and narrow-band noise, and noise containing discrete-frequency sound. The relationship between discrete-frequency components in a spectrum and the critical bands (Chap. 14) is discussed, and the *prominence ratio* and *tone-to-noise ratio*, measures of the prominence of discrete tones in noise, are defined.

For the measurement and description of environmental noise, there is a complete series of standards [23.155–160] available. This series covers such

topics as basic quantities to be measured, measurement positions, definition of noise zones, categories of land use, land-use criteria, treatment of prominent discrete tones, and measuring positions for determination of the effect of aircraft noise exposure on sleep.

23.5.4 Criteria for Noise Immission

In this section, criteria are divided into criteria for hearing damage, criteria for annoyance, and other currently used criteria.

Hearing Damage Criteria

In the United States, permissible levels for industrial noise exposure are set by the US Department of Labor, and are described in 29 CFR 1910.95. In summary, an employer shall administer a hearing conservation program when the eight hour time-weighted average level exceeds 85 dB. The requirements of such a program are described in detail in the above document – as is the requirements on audiometers for the determination of hearing loss, personnel conducting the tests, and hearing protectors when used to satisfy the requirements below. More details may be found in the *Hearing Conservation Manual* [23.161].

Permissible noise exposures are given in the regulation in Table G-16, reproduced below (Table 23.9) with an explanation of how the permissible levels are to be determined.

Currently, engineering controls are required only if the eight hour noise exposure exceeds 100 dB. For lower levels, hearing protection is an alternative.

The problem of specifying upper limits for noise in the workplace has been studied by a technical study group of the International Institute of Noise Control Engineering, and a report has been prepared and approved by the member societies of that organization [23.162]. Most countries in the world allow a time-weighted average sound level over eight hours of 85–90 dB as the upper limit, and an exchange rate of 3 dB. Selection of this exchange rate is widely believed to be the best alternative, and it greatly simplifies the measurement of levels that fluctuate during the working day. Table 23.10, from [23.162], shows hearing damage criteria in a number of countries as of 1997.

I-INCE publication 97-1 [23.162] makes specific recommendations with respect to allowable levels, exchange rate, and hearing conservation programs:

1. It is desirable for jurisdictions without regulations, or with currently higher limits, to set a limit on the level of exposure over a workshift, A-weighted and normalized to eight hours, of 85 dB as soon as may be possible given the particular economic and sociological factors that are pertinent.

2. This exposure level should include the contribution from all sounds that are present including short-term, high-intensity sounds. If such sounds are further limited in regulations to a maximum sound pressure level, then regulations should set a limit of 140 dB for C-weighted peak sound pressure level.

3. An exchange rate of 3 dB per doubling or halving of exposure time should be used. This exchange rate is implicit when the exposure level is stated in terms of eight-hour-average sound pressure level;

4. Efforts should be made to reduce levels of noise in the workplace to the lowest economically and technologically reasonable values, even when there may be no risk of long-term damage to hearing. Such action can reduce other negative effects of noise such as reduced productivity, stress and disturbed speech communication.

5. At the design stage of any new installation, consideration should be given to sound and vibration isolation between noisier and quieter areas of activity. Rooms normally occupied by people should have a significant amount of acoustical absorption in order to reduce the increase of sound due to excessive reverberation.

Table 23.9 Criteria from Table G-16 of 29 CFR 1910.95. Permissible noise exposures[a]

Duration in hours per day	Sound level (dBA) slow response
8	90
6	92
4	95
3	97
2	100
1 1/2	102
1	105
1/2	110
1/4 or less	115

[a] When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the following fractions: $C_1/T_1 + C_2/T_2 + \ldots C_n/T_n$ exceeds unity, then, the mixed exposure should be considered to exceed the limit value. C_n indicates the total time of exposure at a specified noise level, and T_n indicates the total time of exposure permitted at each level. Exposure to impulsive noise should not exceed 140 dB peak sound pressure level

Table 23.10 Some features of legislation in other countries in 1997. After *Embleton* [23.162]. See the notes following the table*

Some features of legislation in various countries					
Country (Jurisdiction)	Eight hour average A-weighted sound pressure level (dB)	Exchange rate(dB)	8h average A-wtd limit for engineering or administrative controls (dB)	Eight hour average A-wtd limit for monitoring hearing (dB)	Upper limit for peak sound pressure level (dB)
Argentina	90	3			110 A slow
Australia (varies by State)	85	3	85	85	140 unwgtd peak
Austria[a,c]	85		90		
Brazil	85	5	90, no exposure > 115 if no protection, no time limit	85	130 unwgtd peak or 115 A slow
Canada (Federal)	87	3	87	84	
(ON, PQ, NB)	90	5	90	85[b]	140 C peak
(Alta, NS, NF)	85	5	85		
(BC)	90	3	90		
Chile	85	5			140 unwgtd peak or 115 A slow
China	70–90	3			115 A slow
Finland[c]	85	3	90		
France[c]	85	3	90	85	135 C peak
Germany[c,d]	85	3	90	85	140 C peak
Hungary	85	3	90		140 C peak or 125 A slow
India	90				140 A peak
Israel	85	5			140 C peak or 115 A slow
Italy[c]	85	3	90	85	140 C peak
Japan	90		85 hearing protection mandatory at 90	85	
Netherlands[c]	85	3	90	80	140 C peak
New Zealand	85	3	85	85	140 unwgtd peak
Norway	85	3		80	110 A slow
Poland	85	3			135 C peak or 115 A slow
Spain[c]	85	3	90	80	140 C peak
Sweden[c]	85	3	90	80	140 C peak or 115 A fast
Switzerland	85 or 87	3	85	85	140 C peak or 125 ASEL
United Kingdom	85	3	90	85	140 C peak
USA[e]	90 (TWA)	5	90	85	140 C peak or
USA (army and air force)	85	3		85	115 A slow 140 C peak
Uruguay	90	3			110 A slow

Table 23.10 (continued)

Some features of legislation in various countries					
Country (Jurisdiction)	Eight hour average A-weighted sound pressure level (dB)	Exchange rate(dB)	8h average A-wtd limit for engineering or administrative controls (dB)	Eight hour average A-wtd limit for monitoring hearing (dB)	Upper limit for peak sound pressure level (dB)
This Report recommends	85 for 8 hour normalized exposure level limit	3	85, see also text under recommended engineering controls	on hiring, and at intervals thereafter, see text under audiometric programs	140 C peak

* Information for Austria, Japan, Poland and Switzerland was provided directly by these member societies of I-INCE. For other countries not represented by member societies participating in the working party the information is taken with permission from [23.14]
[a] Austria also proposes 85 dB AU-weighted according to IEC 1012 as a limit for high-frequency noise, and a separate limit for low-frequency noise varying inversely as the logarithm of frequency
[b] A more complex situation is simplified to fit this tabulation
[c] All countries of the European Union require the declaration of emission sound power levels of machinery, the use of the quietest machinery where reasonably possible, and reduced reflection of noise in the building, regardless of sound pressure or exposure levels. In column 4, the limit for other engineering or administrative controls is 90 dB or 140 dB C-weighted peak (or lower) or 130 dB A-weighted impulse
[d] The rating level consists of time-average, A-weighted sound pressure level plus adjustments for tonal character and impulsiveness.
[e] TWA is the time-weighted average. The regulations in the USA are unusually complicated. Only A-weighted sound pressure levels of 80 dB or greater are included in the computation of TWA to determine whether or not audiometric testing and noise exposure monitoring are required. A-weighted sound pressure levels less than 90 dB are not included in the computation of TWA when determining the need for engineering controls

6. The purchase specifications for all new and replacement machinery should contain clauses specifying the maximum emission sound power level and emission sound pressure level at the operator's position when the machinery is operating.
7. A long-term noise control program should be established and implemented at each workplace where the level of the daily exposure, normalized to eight hours, exceeds 85 dB. This program should be re-assessed periodically in order to exploit advances in noise control technology.
8. The use of personal hearing protection, either earplugs or other hearing protection devices, should be encouraged when engineering and other noise control measures are unable to reduce the daily A-weighted exposure level of workers normalized to eight hours to 85 dB. The use of hearing protection devices should be mandatory when the exposure level is over 90 dB.
9. All employers should conduct audiometric testing of workers exposed to more than 85 dB at least every three years, or at shorter intervals depending on current exposure levels and past history of the individual worker. Records of the results of the audiometric tests should be preserved in the employee's permanent file.

Effect of High Noise Levels on Hearing

The result of exposure to high levels of noise is first a temporary shift in the hearing threshold (TTS), and eventually permanent hearing damage called noise-induced permanent threshold shift (NIPTS). Quantitative data have been published in ISO 1999 [23.163], and in ANSI S3.44-1996 [23.164]. The two standards contain the same information except that the ANSI standard allows exchange rates other than 3 dB through the calculation of an equivalent level. As one example (informative), exposure to an A-weighted sound level of 95 dB for 20 years is said to result in a NIPTS greater than 23 dB at 4 kHz in 50% of the population.

Noise Levels and Annoyance

It is difficult to specify criteria for annoyance, even when the descriptor for the noise is selected – usually the day–night average sound level L_{dn}. There is a high variability in the response of individuals to noise, and it is difficult to describe a physical soundscape in terms of a single number. Reporting guidelines for community noise were published in 1998 [23.165] – after many surveys were performed. However, the classic work of *Schultz* [23.166] resulted in the *Schultz curve* that related the percent of persons highly annoyed and the day–night sound level. More recent data are also avail-
Fig. 23.28 USAF logistic curve – together with data from *Schultz* [23.166], *Fidell* et al. [23.168] (after *Finegold* et al. [23.167], reprinted with permission)

able, and a logistic curve has been developed by the US Air Force [23.167]. Figure 23.28 shows this curve together with data from *Schultz* [23.166] and *Fidell* et al. [23.168].

Fidell et al. [23.168] showed that annoyance also depends on the source of sound (e.g., road traffic noise, railway noise, aircraft noise), and more recently studies by *Miedma* [23.169] and *Midema* and *Oudshoorn* [23.170] have quantified this effect with 95% confidence limits on the data. Their results are shown in Fig. 23.29.

In spite of the progress that has been made, there are doubts about the current approach to developing relationships between noise exposure and annoyance [23.171], and there may be improved methods for prediction of community response [23.172].

Criteria for Annoyance from Noise

While the figures above relate day–night average sound level and the percentage of a population annoyed, there is still the question of criteria that can be used for land-use planning and other activities for which noise control is needed.

ANSI standard S12.9 [23.155–160] contains information on noise levels appropriate for various categories of land use. The data are a combination of recommendations from various sources. Table 2 from the standard is reproduced in Table 23.11.

Schomer [23.173] has studied the recommendations of several federal agencies in the United States, the World Health Organization, and the National Research Council. His recommendation is:

> For residential areas and other similarly noise sensitive land uses, noise impact becomes significant in urban areas when the DNL exceeds 55 dB. In suburban areas where the population density is between 1250 and 5000 inhabitants per square mile, noise impact becomes significant when the DNL exceeds 50 dB. And in rural areas where the population density is less than 1250 inhabitants per square mile, noise impact becomes significant when the DNL exceeds 45 dB.

Noise in Recreational Areas

Noise immission in recreational areas presents special problems. Many individuals expect a very quiet environment in parks and other recreational areas whereas others – particularly those who enjoy the use of motorized vehicles such as snowmobiles and off-road vehicles – enjoy sound levels, particularly if they are of good quality. Others enjoy recreational areas from a distance – such as in helicopters and airplanes, and the noise of these sources of concern to those on the ground. Other problems include the measurement of sounds which are often of very low level (Fig. 23.4), and may be intermittent. Measurement location is also a problem because the areas of interest are frequently very large.

A collection of 16 papers covering a variety of topics related to recreational noise is available. The papers were presented at a symposium on recreational noise held in New Zealand in 1998. *Miller* [23.7] has given a summary of the state of the art in recreational noise as of 2003.

Other Noise Criteria

A wide variety of noise criteria are discussed in a document on community noise prepared for the World Health Organization.

23.5.5 Sound Quality

In Sect. 23.1.1, noise was defined as *unwanted sound*. The field of sound quality or sound quality engineering has become important for two reasons. Noise often has characteristics that may make the sound more annoying than sounds of equivalent level using conventional measures. These include the presence of discrete-frequency sound, sound which is impulsive in character, and
Fig. 23.29 Percentages of highly annoyed (HA), annoyed (A), and lightly annoyed (LA), with 95% confidence limits, for aircraft noise, road noise, and railway noise (after *Miedema* [23.169] and *Miedema* and *Oudshoorn* [23.170], reprinted with permission)

Table 23.11 A-weighted day, night, and day–night average sound levels in decibels and corresponding approximate population densities in people per square kilometer or square mile. *Reprinted by permission of the Acoustical Society of America from ANSI S12.9/part 3, annex D* [23.157]. *This annex is for information, and is not part of the standard*

	Land-use category	DNL range dB	Typical DNL dB	Day level dB	Night level dB	Approximate population density per km²	per sq.mi.
1	Very noisy urban	> 67	70	69	61	24 650	63 840
2	Noisy urban residential	62–67	65	64	57	7722	20000
3	Urban and noisy suburban residential	57–62	60	58	52	2465	6384
4	Quiet urban and normal suburban residential	52–57	55	53	47	772	2000
5	Quiet suburban residential	47–52	50	48	42	247	638
6	Very quiet suburban and rural residential	< 47	45	43	37	77	200

sounds that create a negative image – such as a noisy bearing which may indicate that a machine is failing. Reduction or elimination of such sounds improves the quality of the noise.

More recent work, particularly in the automobile industry has focused on the sound of engines and other automotive components to create a desirable sound for the consumer. Similarly, consumer products such as sewing machines and vacuum cleaners have been studied in an effort to eliminate sounds that the consumer finds objectionable and emphasize sounds that give a good impression of the quality of the product. There have been two sound-quality symposia that cover a wide range of topics in this field. In addition, Lyon has described the sound-quality design process [23.174], and has described a methodology by which various attributes of sound can be used to define the quality of that sound [23.175].

23.6 Regulations and Policy for Noise Control

In this section, an overview of noise policies and regulations is given. First, an overview of noise policy in the United States is given, and then information on noise policies in other countries and in the European Union is presented.

23.6.1 United States Noise Policies and Regulations

This material has been adapted from paper 302 titled *A Review of Untied States Noise Policy* by G. C. Maling, Jr. and L. S. Finegold. The paper was presented an INTER-NOISE 04, Czech Republic (2004).

The policies of the United States with respect to noise emission and noise immission have a long history. Many of the historical environmental noise documents produced in the US in the past are well known throughout the world, and have been reviewed elsewhere [23.176–182].

Funding for the US Office of Noise Abatement and Control of the US Environmental Protection Agency was discontinued in 1982, and since then there has been a lack of focus in the implementation of US noise policy. Since then, noise policies and regulations have been promulgated by a number of different federal agencies. There is a variety of state and local noise regulations; information on selected policies is given below.

Federal Government Noise Policies
The noise policies of the US federal government have been reviewed in detail elsewhere [23.181, 182]. A database of US noise policy documents has been published on CD-ROM [23.183].

Federal Aviation Administration. A number of policies related to aviation noise were in existence before 1969, but the first FAR 36 regulation [23.184] issued in 1969 by the Federal Aviation Administration, an agency of the US Department of Transportation. This regulation implemented a certification procedure for the noise emissions of aircraft, and has been amended many times to reduce noise emissions as the technology of aircraft engine design improved. More information may be found in Sect. 23.3.8.

US Environmental Protection Agency. The National Environmental Policy Act of 1969 established the Office of Noise Abatement and Control (ONAC) of the US Environmental Protection Agency (EPA), and in the early 1970s, ONAC held a series of public hearings to discuss the noise problem. These hearings led to the passage of the Noise Control Act of 1972 (NCA 72), which was landmark legislation in which the US Congress declared that it is

> the policy of the United States to promote an environment for all Americans free from noise that jeopardizes their health and welfare.

The program included:

- Development of standards and criteria
- Identification of major sources of noise
- Regulation of the noise emissions of certain vehicles, machinery, and equipment
- Product noise labeling
- Interactions with other federal agencies
- The establishment of regional noise technical centers
- Support of research in noise control and
- Assistance to state and local governments.

Funding for ONAC was discontinued in 1982. *Finegold, Finegold* and *Maling* [23.181, 182] discussed the successes and failures of the program, and a history of the program has been prepared by *Maling* [23.185]. A re-

view of administrative procedures related to NCA 72 and ONAC, and recommendations for future noise abatement were prepared by the Administrative Conference of the United States in 1991 [23.186].

US Department of Housing and Urban Development. It is the policy of the US Department of Housing and Urban Development (HUD) (24 CFR part 51) to provide minimum national standards applicable to HUD programs to protect citizens against excessive noise in their communities and places of residence. HUD has defined noise exposure standards for new construction, interior noise goals, and acoustical privacy in multifamily buildings. These standards must be met if federal financing assistance is to be provided for new construction or residential rehabilitation. It is also HUD's policy to apply standards to prevent incompatible development around civil airports and military airfields. HUD requires that grantees give adequate consideration to noise exposures and sources of noise as an integral part of the urban environment when HUD assistance is provided for planning purposes. Particular emphasis is placed on the importance of compatible land-use planning in relation to airports, highways and other sources of high levels of noise exposure. HUD assistance for the construction of new noise sensitive uses is prohibited generally for projects with unacceptable noise exposures and is discouraged for projects with normally unacceptable noise exposure. Noise exposure by itself will not result in the denial of HUD support for the resale and purchase of otherwise acceptable existing buildings. However, environmental noise is a marketability factor, which HUD will consider in determining the amount of insurance or other assistance that may be given.

The Federal Energy Regulatory Commission. The Federal Energy Regulatory Commission (FERC) is an agency of the US Department of Energy, and has issued a regulation that controls noise emitted by compressors and other sources of noise related to the power industry. The regulation 18 CFR 157.206(d)(5) states that:

> 5. *The noise attributable to any compressor facility installed pursuant to the blanket certificate shall not exceed a day–night sound level (L_{dn}) of 55 dB(A) at any noise-sensitive area unless the noise-sensitive areas (such as schools, hospitals, or residences) are established after facility construction.*

US Department of Labor, Occupational Safety and Health Administration. Within the US Department of Labor, OSHA has regulations on occupational noise exposure which are detailed in the US code of federal regulations, 29 CFR 1910.95. Additional information may be found in the hearing conservation manual [23.187]. Noise policy for exposure to industrial noise is generally covered by the text in Sect. 23.5.4.

US Department of Labor, Mine Safety and Health Administration. The Mine Safety and Health Administration (MSHA) is part of the US Department of Labor. Regulations for the control of the noise exposure of miners is covered in 30 CFR 62. The basic requirements are:

- The eight hour time-weighted, A-frequency-weighted sound pressure level shall not exceed 90 dB. Levels below 90 dB and above 140 dB are not included in the integration.
- A 5 dB exchange rate is used.
- Above an *action level* of 85 dB, hearing protection must be used, and the individual must be enrolled in a hearing conservation program.

Additional information on the policies of other government agencies vis à vis occupational noise may be found in a paper by *Bruce* and *Wood* [23.188].

Federal Highway Administration. The primary activity of the Federal Highway Administration is to coordinate state efforts with regard to the construction of highway noise barriers. Noise barrier design in discussed in Chap. 4. Additional information on noise barriers is in Sect. 23.4.1, in the section on state policies below, and in [23.132]. More recently, there have been efforts to design highways so that tire–road noise is reduced.

State Government Policies

Policies of the state governments can generally be divided into policies with respect to exposure to occupational noise, transportation noise, and noise emissions from industrial plants. In the first case, states may establish occupational noise policies that are at least as stringent as federal regulations (see the section on OSHA).

Highway Noise Barriers. Many State governments have established noise policies with regard to the erection of noise barriers along highways [23.132]. Noise barrier policy is based on a cooperative arrangement between the federal government and state governments. Federal policy is set by the Federal Highway Administration, an agency of the US Department of Transportation, and is

detailed in an FHWA policy document [23.189]. It is, however, the responsibility of each State Department of Transportation (SDoT) to determine the extent of noise abatement measures and to balance costs and environmental benefits in determining where noise barriers are to be erected.

Industrial Noise Emissions. The policy situation with regard to industrial noise immissions varies from state-to-state. The Internet site maintained by the Noise Pollution Clearing House [23.190] lists 12 states (with links to the requirements) with regulations on noise. One of the states not listed is the state of Maine – whose noise requirements have been described as the most complex in the United States [23.191]. These requirements show evidence of being carefully written. *Brooks* [23.192] has identified two other states, Illinois [23.193] and Connecticut [23.194] as two other states with carefully crafted environmental noise regulations.

The Maine text is in the Department of Environmental Protection regulations 375.10, and is approximately 6000 words in length. The requirements are written in terms of hourly A-weighed sound levels. Daytime levels are between 7 a.m. and 7 p.m., and nighttime levels are between 7 p.m. and 7 a.m. The key elements are:

- In protected locations that are not predominantly commercial, transportation, or industrial, 60 dB daytime and 50 dB nighttime.
- In other areas, the required levels are 10 dB higher.
- Where pre-development levels are less than 45 dB in the daytime and 35 dB at night, the required levels are 5 dB lower.
- There are penalties for repetitive sounds and requirements on blast noise.
- Maximum levels are specified for construction activities.

Local Noise Regulations and Policies. A large number of cities and towns in the United States have ordinances and building codes to deal with local noise issues. For example, noise ordinances from cities and towns in 31 states have been posted on the Internet by the Noise Pollution Clearing House [23.189]. A model noise ordinance published by the EPA and dating from 1975 September has also been posted [23.195]. However, there is no consistency in how local noise ordinances are structured. Some use subjective noise exposure criteria, while others use objective, quantitative criteria. As described by *Finegold* and *Brooks* [23.196], an American

National Standards Institute (ANSI) working group is currently developing a new ANSI standard with an updated model community noise ordinance for use by local jurisdictions to provide the needed guidance. There is a strong preference for objective noise standards as opposed to subjective standards. For example, a requirement for the prohibition of *excessive and unreasonable noises* without objective limits is difficult to enforce.

As one example of the purpose of local noise ordinances, the noise policy statement in the March 1998 New York City noise code [23.197] is reproduced below (this noise code is being revised):

> 24-202 Declaration of policy. *It is hereby declared to be the public policy of the city to reduce the ambient noise level in the city, so as to preserve, protect and promote the public health, safety and welfare, and the peace and quiet of the inhabitants of the city, prevent injury to human, plant and animal life and property, foster the convenience and comfort of its inhabitants, and facilitate the enjoyment of the natural attractions of the city. It is the public policy of the city that every person is entitled to ambient noise levels that are not detrimental to life, health and enjoyment of his or her property. It is hereby declared that the making, creation or maintenance of excessive and unreasonable noises within the city affects and is a menace to public health, comfort, convenience, safety, welfare and the prosperity of the people of the city. For the purpose of controlling and reducing such noises, it is hereby declared to be the policy of the city to set the unreasonable noise standards and decibel levels contained herein and to consolidate certain of its noise control legislation into this code. The necessity for legislation by enactment of the provisions of this chapter is hereby declared as matter of legislative determination.*

Noise Policies in Other Countries. Most industrialized countries have published noise regulations for a variety of sources. *Gottlob* [23.198] as well as *Flindell* and *McKenzie* [23.199] have presented information on community noise regulations in a large number of countries, and have listed the noise descriptors in use. More recently, technical study group 3 of the International Institute of Noise Control Engineering (I-INCE) prepared a comprehensive draft report on noise policies and regulations worldwide [23.200]. This report documents the results of an international survey on current environmental noise policies and regulations, and describes some similarities and differences

in noise policies that exist at the global level. It also provides recommendations for a follow-on project to estimate national noise exposures in the I-INCE participating member countries as a next step towards the long-term goal of assessing the effectiveness of noise policies.

23.6.2 European Noise Policy and Regulations

Early European noise policy emphasized *old approach* directives that covered specific noise sources such as motor vehicles, construction equipment, lawnmowers, aircraft, and other equipment. The original safety directive, 89/392/EC, contained requirements on emission sound pressure level (Sect. 23.3.3). This document was superseded by directive 98/37/EC [23.201], but with the same acoustical requirements. This directive has been implemented throughout the European Union – the details being in European standards (EN). There are now several hundred of these standards covering a wide variety of machine types [23.202].

More recently, *new approach* directives give requirements, but are much more general in their approach to regulation of noise. There are still specific requirements on machines – as discussed in Sect. 23.3.5. These approaches have been summarized by *Higginson* et al. [23.203] in 1996, the European Union published a green paper that recognized the fact that in spite of limits on the noise emissions of individual machines, the noise to which persons are exposed has been increasing, and that more emphasis should be placed on noise in communities. A summary of the future noise policy as presented in the green paper is available [23.204], as is the green paper itself [23.205] and an edited version [23.206]. This activity led to directive 2002/49EC designed to understand noise problems in communities through noise mapping and other activities, and to prepare action plans. The directive instructs the member states to develop a long-range plan to establish common assessment methods, to develop noise maps, to develop action plans to combat noise, to keep the public informed about noise issues. It also requires that the European Commission make regular evaluations of the implementation of the directive.

Some key action items and implementation dates in the directive are:

1. Common noise assessment methods will be established by the European Commission.
2. By 2005 July 18, the European Commission will be informed of limit values in force by the member states.
3. By 2005 June 30 and every five years thereafter, the member states will inform the European Commission of the major roads that have more than six million vehicle passages per year, major railways that have more than 60 000 train passages per year, and airports and the agglomerations with more than 250 000 inhabitants within their territories.
4. By 2007 June 30, the member states will ensure that strategic noise maps showing the situation in the previous year have been made and approved by competent authorities. By 2008 June 30, all agglomerations, major roads, and major railways shall be identified and by 2012 June 30, noise maps for these areas will be prepared and updated every five years.
5. By 2008 July 18, competent authorities shall draw up action plans to manage noise issues in areas defined by item 3 above.
6. By 2013 July 18, action plans for those areas defined by item 4 above shall be developed.
7. Action plans shall be reviewed whenever the existing noise situation changes, and at least every five years.
8. The public will be kept informed about noise maps and action plans.
9. By 2004 January 18, the European Commission will submit a report to the European parliament which reviews existing measures related to sources of environmental noise. A summary report of strategic noise maps and action plans will be prepared by 2009 July 18 and every five years thereafter. By this date, a report on the implementation of the directive will also be submitted.

Six annexes to the directive cover noise indicators, assessment methods for the noise indicators, assessment methods for harmful effects, minimum requirements for strategic noise mapping, minimum requirements for action plans, and definitions of data to be sent to the European Commission.

There are a number of ongoing projects related to this directive. Further information on EU noise policies can be found at http://europa.eu.int/comm/environment/noise/home.htm.

23.7 Other Information Resources

The following information will be helpful in locating many of the references below.

American National Standards are available from the Acoustical Society of America, asa.aip.org.

International Standards on electroacoustics (sound level meters, etc.) are published by the International Electrotechnical Commission (IEC), www.iec.ch.

International Standards on noise are published by the International Organization for Standardization (ISO), www.iso.ch.

The sponsor of the INTER-NOISE series of international congresses on noise control engineering is the International Institute of Noise Control Engineering, www.i-ince.org.

A technical journal, Noise Control Engineering Journal (NCEJ), has been published by Institute of Noise Control Engineering (INCE/USA) since 1973, and all technical papers from that journal are now available on CD-ROM and on the Internet. For more information, go to www.inceusa.org.

The organizer of the INTER-NOISE series when the congresses are held in North America is the Institute of Noise Control Engineering of the USA (www.inceusa.org). The institute also sponsors the NOISE-CON series of national conferences on noise control engineering. Technical papers on CD-ROM for both of these series are available from the institute (www.atlasbooks.com/marktplc/00726.htm).

The Institute of Noise Control Engineering has also published two public information documents available for free download: *Noisy Motorcycles: An environmental quality of life issue* (2013) [23.207] and *Cost-Benefit Analysis: Noise barriers and quieter pavements* (2014) [23.208].

The National Academy of Engineering has prepared a report titled *Technology for a Quieter America* which has been published by the National Academies Press (NAP) [23.209]. The NAP has also published *Protecting National Park Soundscapes* [23.210].

Part H Engineering Acoustics

24. Microphones and Their Calibration

George S. K. Wong

The condenser microphone continues to be the standard against which other microphones are calibrated. A brief discussion of the theory of the condenser microphone, including its open-circuit voltage, electrical transfer impedance, and mechanical response, is given. The most precise method of calibration, the reciprocity pressure calibration method for laboratory standard microphones is discussed in detail, beginning with the principles of the reciprocity method. Corrections for heat conduction, equivalent volume, capillary tube, wave motion, barometric pressure and temperature are necessary to achieve the most accurate open-circuit sensitivity of condenser microphones.

Free-field calibration is discussed briefly, and in view of the difficulties in obtaining more accurate results than those provided by the reciprocity method, references are given for more detailed consideration. Secondary microphone calibration methods by comparison are described. These methods include interchange microphone comparison, comparison with a calibrator, comparison pressure and free-field, and comparison with a precision attenuator. These secondary calibration methods, which are adequate for most industrial applications, are economically attractive and less time consuming.

The electrostatic actuator method for frequency response measurement of working standard microphones is discussed with some pros and cons presented. An example to demonstrate the stability of laboratory standard microphones and the stability of a laboratory calibration system is described.

Appendix A discusses acoustic transfer impedance evaluation, while appendix B contains physical properties of air, which are necessary for microphone calibration.

Nomenclature

A_1' numerical coefficient

$\tilde{A}_1, \tilde{A}_2$ complex quantities

a the radius of the capillary tube (m)

a_0 to a_{12} coefficients

$B = (\eta/\rho\alpha_t)^{\frac{1}{2}}$ coefficient

B_1' numerical coefficient

C fixed capacitance (F)

C_1' shunt capacitance (F)

C_p specific heat capacity at constant pressure (kJ kg^{-1} K^{-1})

C_r reference capacitance (F)

C_v specific heat capacity at constant volume (kJ kg^{-1} K^{-1})

C_t shunt capacitance (F)

c_c large shunt capacitance (F)

c sound speed (m/s)

c_0 reference dry air sound speed at $0\,^\circ$C, 101.325 kPa and 400 ppm CO_2 content (m/s)

c_i input capacitance of the preamplifier (F)

c_{stat} static capacitance (F)

c_s stray capacitance (F)

$c_t(t)$ variable capacitance (F)

Δ_c capillary correction ($\Delta_{c(AB)}$, $\Delta_{c(BC)}$, and $\Delta_{c(CA)}$ are the capillary corrections for the microphone pairs)

D complex function

D_1 function for computation of R'

D_1' numerical coefficient

D_2 function for computation of R'

d diameter of microphone cavity (m)

E voltage across the microphone (V)

E_0 polarizing voltage (V)

E_v complex temperature transfer function

e_A, e_B, e_C open-circuit voltage (V)

e_o output voltage (V)

e_{oc} output voltage as function of the varying capacitor c_t (V)

$e_{i(B)}$ sinusoidal insert voltage (V)

$e(t)$ time-varying voltage (V)

e_B' microphone output voltage with microphone shunting capacitance

e_{Bref}, e_{Aref} open-circuit voltage and the source driving voltage when the reference microphone is in position

e_{Bx}, e_{Ax} open-circuit voltage and the source driving voltage when the test microphone is in position

e_1 driving voltage across Z_x (V)

e_2 preamplifier output voltage (V)

f frequency (Hz)

f_e $= 1.00062 + p_s(3.14 \times 10^{-8})$ $+ t^2(5.6 \times 10^{-7})$, enhancement factor

f_0 resonance frequency (Hz)

g_1 gain of the preamplifier

H relative humidity, %

h_0 static deflection of diaphragm (m)

h_a air gap between the diaphragm and the backplate when the polarizing voltage is applied (m)

$h_s = \frac{p_{sv}}{p_0}\frac{H}{100}$ fractional molar concentration of moisture

h_c CO_2 content (%)

$h = H/100$ humidity (dimensionless)

ΔH humidity correction (dB/100%)

Δ_H complex correction factor

I input current (A)

i_t time varying current generated by the microphone (A)

K wave number of sound in the membrane (m^{-1})

k $= i\omega Z_x/(\gamma P_s)$

k_0 constant

k_c $= (-i\omega\rho/\eta)^{1/2}$ complex wave number (m^{-1})

L_r level reading of the reference microphone (dB)

L_t level reading of the test microphone (dB)

ℓ volume to surface ratio of the coupler (m)

ℓ_c length of the capillary tube (m)

l_0 length of the cavity, i.e. distance between the two diaphragms (m)

M microphone sensitivity

M_A, M_B, M_C open-circuit sensitivity of microphone A, B, C (V/Pa)

M_m mechanical response (m/Pa)

M_e electrical transfer impedance

M_A', M_B', M_C' modified microphone A, B, C sensitivity (V/Pa)

M_t open-circuit sensitivity of the test microphone (dB re 1 V/Pa)

M_r open-circuit sensitivity of the reference microphone (dB re 1 V/Pa)

M_{dB} microphone sensitivity (dB re 1 V/Pa)

M_{corr} microphone sensitivity with correction (V/Pa)

M_{com} combined level sensitivity of microphone and preamplifier (dB)

n number of capillary tubes

P_s barometric pressure (Pa)

p alternating pressure inside the cavity (Pa)

p_i incident sound pressure (Pa)

p_0 reference pressure = 101.325 kPa

p_{sv} saturation water vapor pressure (Pa)

p_s static pressure (during calibration) (Pa)

ΔP_c capacitance correction (dB)

ΔP_v microphone sensitivity level pressure correction (dB)

ΔP $= (p_s - p_0)$ pressure difference (kPa)

R Universal gas constant, $8.31451\,J\,mol^{-1}\,K^{-1}$. For dry air, $0\,°C$, 400 ppm CO_2 content and 101 325 Pa

R' parameter for computation of heat conduction correction

R_p impedance parallel with R_c and R_i (Ω)

R_c high resistance (Ω)

R_i input resistance of the preamplifier (Ω)

r_a radius of microphone diaphragm (m)

24.1 Historic References on Condenser Microphones and Calibration

In 1917, *Wente* [24.1] described a microphone close to what we find today as the modern condenser microphone. The theory of absolute pressure calibration for condenser microphones and some of the modern analyses and implementations including the early im-

plementation of the Western Electric 640AA condenser microphone have been described [24.2–30]. In 1995, a comprehensive discussion on the history of condenser microphone development and calibration was published [24.29].

24.2 Theory

The theory of condenser microphone operation has been investigated [24.1–30], and a brief summary is discussed in the following.

24.2.1 Diaphragm Deflection

The basic condenser microphone consists of a stretched diaphragm (Fig. 24.1) over a backplate that is polarized with a voltage E_0, usually 200 V. Due to the small air gap h_a (approximately 20 µm for a 25 mm diameter microphone) between the backplate and the thin (approximately 1–5 µm) metallic diaphragm, the latter is deflected by electrostatic charge of the backplate. With the diameter of the planar (flat) backplate ($2r_b$) smaller than that of the diameter ($2r_a$) of the diaphragm, the relatively complex initial deflection (y_0) of the diaphragm shape was analyzed by *Hawley* et al. [24.29, Chap. 2]. It has been shown by *Fletcher* and *Thwaites* [24.30] that it is an advantage to modify the backplate to have a parabolic profile to accommodate the curvature of the diaphragm and, according to their analysis, this eliminates distortion and increases the microphone

sensitivity. Until this idea is further developed, the following will concentrate on condenser microphones with planar backplates.

24.2.2 Open-Circuit Voltage and Electrical Transfer Impedance

For functional implementation of a condenser microphone, *Zuckerwar* gave a detailed analysis [24.29, Chap. 3], and the electrical circuit is shown in Fig. 24.2. A microphone is represented by a variable capacitance c_t with a static value of c_{stat}, and a stray capacitance of c_s. The polarizing voltage E_0 is applied to the microphone backplate via a high resistance R_c. The preamplifier is represented by an input impedance consisting of a capacitance c_i and a resistance R_i; c_c is a large blocking capacitor to prevent the polarizing voltage from overloading the preamplifier.

When a time-varying sound pressure is applied to the diaphragm, the diaphragm vibrates and the microphone capacitance c_t and the voltage E across the
Fig. 24.1 Schematic diagram of a condenser microphone
Fig. 24.2 Electrical circuit of a condenser microphone
Fig. 24.3 Equivalent small-signal circuit

microphone are represented by their corresponding static and time-varying components

$$c_t = c_{stat} + c_t(t) \,, \tag{24.1}$$

$$E = E_0 + e(t) \,. \tag{24.2}$$

The time-varying current i_t generated by the microphone is

$$i_t = E_0 \frac{dc_t}{dt} + c_{stat} \frac{de}{dt} \,. \tag{24.3}$$

For small electrical signals, Fig. 24.2 can be represented by an equivalent circuit shown in Fig. 24.3 and for small time-varying (ω) pressure at the diaphragm, the microphone can be represented by a fixed capacitance C and a current source i_t, and the output voltage e_o is

$$e_o = E_0 \frac{c_t}{C} \frac{i\omega C R_p}{1 + i\omega C R_p} \,, \tag{24.4}$$

where R_p is the impedance of R_c in parallel with R_i, and C is the sum of c_{stat}, c_i and c_s. The microphone open-circuit voltage e_{oc} as a function of the varying capacitance c_t is

$$e_{oc} = E_0 \frac{c_t}{c_{stat}} \left(1 + \frac{c_i + c_s}{c_{stat}}\right)^{-1} \,. \tag{24.5}$$

Based on an approximate equation derived by *Hawley* [24.29, Chap. 2, Eq. 5.8] for the capacitance of a microphone under the influence of the polarizing voltage, and assuming that the diaphragm can be modeled as a piston-like displacement, *Zuckerwar* [24.29, Chap. 3, Eq. 2.23] has shown that the electrical transfer impedance M_e is

$$M_e = \frac{E_0}{h_0} \left(1 + \frac{r_b^2}{2r_a^2}\right) \left(1 + \frac{c_i + c_s}{c_{stat}}\right)^{-1} \,, \tag{24.6}$$

where r_a and r_b are the radii of the diaphragm and the backplate, respectively.
Fig. 24.4 Sample amplitude and phase response of a one-inch microphone (Brüel Kjær 4146). *Solid lines*: theoretical. *Symbols*: experimental (after *Zuckerwar* [24.29, Chap. 3])

Both *Hawley* et al. [24.29, Chap. 2] and *Zuckerwar* [24.29, Chap. 3] arrived at the conclusion that the optimum backplate size is

$$\frac{r_a}{r_b} = \left(\frac{2}{3}\right)^{1/2} = 0.8165 \,. \tag{24.7}$$

24.2.3 Mechanical Response

The membrane motion is coupled to the air between the diaphragm and the backplate. The system exhibits damping due to the damping holes in the backplate. *Zuckerwar* [24.29, Chap. 3, Eq. 3.51] arrived at a solution for the mechanical response as

$$M_m = \frac{[y(r)]}{p_i} = \frac{1}{TK^2} \frac{J_2(K_a)}{J_0(K_a) + D} \,, \tag{24.8}$$

where K is the wave number of sound in the membrane, given by

$$K = \omega \left(\frac{\sigma_M}{T_m}\right)^{1/2} \,, \tag{24.9}$$

ω is angular frequency, σ_M is the membrane surface mass density, and T_m is the membrane tension. D is a complex function [24.29, Chap. 3, Eq. 3.50]. With (24.8) the amplitude and phase response can be realized; some examples [24.29, Chap. 3, Fig. 3.8] are shown in Fig. 24.4.

24.3 Reciprocity Pressure Calibration

24.3.1 Introduction

High precision in acoustical measurements is needed even though the human ear cannot discern a change in sound level much smaller than 1 dB. For example, to certify aircraft for regulations, it is necessary to obtain measurements with a known uncertainty, usually 0.1–0.2 dB (Unless otherwise stated, the uncertainties referred to in this chapter, may be taken as better than two standard deviations. However, in most cases, the quoted statements on uncertainty are unclear in the source documents. Further complications are introduced when the original data are converted to decibels. For a more rigorous treatment of uncertainties, one should consult [24.31]). It is reasonable to assume that laboratory standard microphones (working standards) should be approximately an order of magnitude better than this, say with an uncertainty ranging from 0.01 to better than 0.1 dB. For research and development purposes, including the study of microphones and monitoring their stability, the primary calibration of condenser microphones should have an uncertainty no larger than several thousandths of a decibel.

One of the most accurate techniques to calibrate a primary standard condenser microphone is the absolute method of reciprocity pressure calibration (sometimes called the coupler method), which currently has a best uncertainty of less than 0.01 dB at 250 Hz, under a fully controlled environment under reference conditions [24.20]. If the calibration were to be performed on a laboratory bench without any control on the environment, such as barometric pressure, temperature and humidity, the estimated uncertainty of the coupler method is approximately 0.05 dB at lower and middle frequencies.

The theory of absolute pressure calibration methods for condenser microphones and some of the relatively modern implementations have been described in [24.1–29].

24.3.2 Theoretical Considerations

The reciprocity method measures the product of the sensitivities of each pair of a set of three microphones in terms of related electrical and mechanical quantities, from which the absolute sensitivity of each microphone can be deduced.

The acoustic impedance Z_{AB}, of a cavity with a pair of microphones A and B, as shown in Fig. 24.5

is

$$Z_{AB} = \gamma P_s [i\omega(V + V_{eA} + V_{eB})]^{-1} ,   \text{(24.10)}$$

where γ is the ratio of specific heats of the gas in the coupler, P_s is the barometric pressure, ω equals $2\pi f$, where f is the frequency of the driving sinusoidal signal, and V, V_{eA} and V_{eB} are the equivalent volumes of the cavity and of microphone A and microphone B, respectively. Equivalent volumes, as the name implies, are volumetric measures that represent the physical volumes of the cavity and of the coupled microphones modified by thermal and finite impedance factors.

The relationship between the alternating pressure p inside the cavity and the volume velocity u is

$$p = u Z_{AB} = u\gamma P_s (i\omega V_{AB})^{-1} ,   \text{(24.11)}$$

where the equivalent volume of the cavity with microphones A and B is

$$V_{AB} = (V + V_{eA} + V_{eB}) .   \text{(24.12)}$$

The reciprocity theorem states that, in a passive linear reversible (reciprocal) transducer, the ratio of the volume velocity u in the cavity to the input current I when used as a sound source is equal to the ratio of the open-circuit voltage e_A across the electrical terminals to the sound pressure p acting on the diaphragm when used as a receiver. The theorem enables one to write the
Fig. 24.5 Calibrating condenser microphones by the reciprocity method (after *Wong* [24.29, Chap. 4])

following equations

$$M_A = \frac{u}{I} = \frac{e_A}{p} , \tag{24.13}$$

$$M_B = \frac{e_B}{p} , \tag{24.14}$$

$$M_C = \frac{e_C}{p} , \tag{24.15}$$

where M_A, M_B and M_C are the open-circuit sensitivities of the microphones.

Multiplying (24.13) and (24.14), and substituting p from (24.11) gives

$$M_A M_B = \frac{e_B i \omega V_{AB}}{I \gamma P_s} . \tag{24.16}$$

Since

$$I = \frac{e_A}{Z_x} \tag{24.17}$$

and Z_x is an electrical impedance, substitution of (24.17) into (24.16) gives

$$M_A M_B = V_{AB} k \beta_{AB} , \tag{24.18}$$

where

$$k = \frac{i \omega Z_x}{\gamma P_s} \tag{24.19}$$

and

$$\beta_{AB} = \frac{e_B}{e_A} . \tag{24.20}$$

By using the microphones A, B and C, configured in pairs to give equivalent volumes V_{AB}, V_{BC} and V_{CA}, and by measuring the corresponding voltage ratios β_{AB}, β_{BC}, and β_{CA}, respectively, the sensitivity product of three pairs of microphones can be obtained

$$M_A M_B = k \beta_{AB} V_{AB} ,$$
$$M_B M_C = k \beta_{BC} V_{BC} ,$$
$$M_C M_A = k \beta_{CA} V_{CA} . \tag{24.21}$$

From (24.21), the open-circuit sensitivities of the individual microphones can be derived

$$M_A = [(V_{CA} V_{AB}/V_{BC})(\beta_{CA} \beta_{AB}/\beta_{BC})k]^{1/2} ,$$
$$M_B = [(V_{AB} V_{BC}/V_{CA})(\beta_{AB} \beta_{BC}/\beta_{CA})k]^{1/2} ,$$
$$M_C = [(V_{BC} V_{CA}/V_{AB})(\beta_{BC} \beta_{CA}/\beta_{AB})k]^{1/2} . \tag{24.22}$$

It can be seen from (24.22) that the sensitivity of each microphone can be deduced by measuring the voltage ratios if the equivalent volumes for each of the three

pairs of microphones and the numerical value of the constant k are known.

Similarly, the open-circuit sensitivity shown in (24.22) can be expressed in terms of the acoustic impedance of the cavity (24.10)

$$M_A = \{[Z_{BC}/(Z_{CA} Z_{AB})](\beta_{CA} \beta_{AB}/\beta_{BC})Z_x\}^{1/2} ,$$
$$M_B = \{[Z_{CA}/(Z_{AB} Z_{BC})](\beta_{AB} \beta_{BC}/\beta_{CA})Z_x\}^{1/2} ,$$
$$M_C = \{[Z_{AB}/(Z_{BC} Z_{CA})](\beta_{BC} \beta_{CA}/\beta_{AB})Z_x\}^{1/2} , \tag{24.23}$$

where Z_{AB}, Z_{BC} and Z_{CA} are the acoustic impedances of the cavities.

An equation for calculating the acoustic impedance of a coupler is given in Appendix 24.A.

24.3.3 Practical Considerations

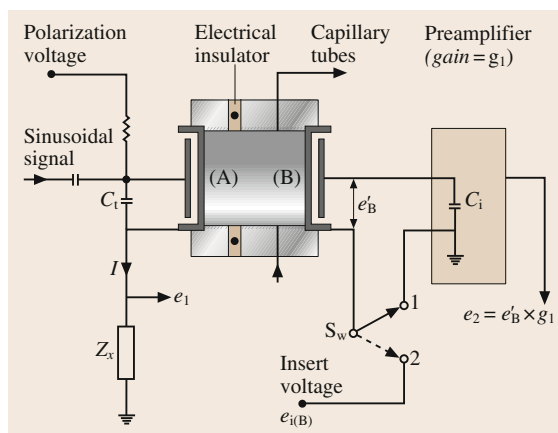
The general arrangement for implementation of pressure reciprocity calibration of condenser microphones is shown in Fig. 24.6. To simplify electrical measurements, it is necessary that the driving microphone A should be isolated electrically from the receiving microphone B. The preamplifier has a gain of g_1 and an input capacitance of C_i. Since the receiving microphone is shunted by C_i the microphone output voltage is modified to e'_B. When the switch S_w is at position 2, an insert voltage can be applied in order to obtain the open-circuit voltage. For both microphones, a polarization voltage (usually 200 V) is applied via a high resistance. A small shunt capacitor C_t, which closely approximates C_i, modifies the driving voltage e_A to e_1.


Fig. 24.6 Pressure reciprocity calibration method with provision for insert voltage (after *Wong* [24.29, Chap. 4])

The cavity usually has two capillary tubes for atmospheric pressure equalization and for the insertion of gases other than air. Hence the sensitivities of the microphones shown in (24.22) are modified to

$$M'_A = [(V'_{CA} V'_{AB}/V'_{BC})(\beta_{CA}\beta_{AB}/\beta_{BC})k]^{1/2} \,,$$
$$M'_B = [(V'_{AB} V'_{BC}/V'_{CA})(\beta_{AB}\beta_{BC}/\beta_{CA})k]^{1/2} \,,$$
$$M'_C = [(V'_{BC} V'_{CA}/V'_{AB})(\beta_{BC}\beta_{CA}/\beta_{AB})k]^{1/2} \,,$$

$$(24.24)$$

where the cavity equivalent volume is marked with a prime to indicate the inclusion of the equivalent volume of the capillary tubes. The voltage ratio e_B/e_A becomes e_2/e_1 and it is represented by β_{AB} in (24.24). The next section discusses the parameters shown in (24.24).

Open–Circuit Sensitivity

The open-circuit sensitivity of the microphones is obtained with the insert voltage method [24.8]. From Fig. 24.6, the measurement procedure is as follows.

With the switch S_w at position 1, measure the output voltage e_2 from the preamplifier. Next, remove the drive sinusoidal signal from microphone A, and with the switch at position 2, apply a sinusoidal insert voltage $e_{i(B)}$ to drive the diaphragm of microphone B. The magnitude of $e_{i(B)}$ is adjusted such that the voltage e_2 is repeated at the output of the preamplifier. As the circuit shows, the insert voltage is identical to the desired open-circuit voltage of microphone B if the loading of the preamplifier's input impedance were to be removed. The open-circuit sensitivity of the microphones can be obtained from (24.24) with the voltage ratio $e_{i(B)}/e_1$, for each pair of microphones, substituted into (24.20). Alternatively, the insert voltage can be computed from an injected voltage when the switch is at position 2, and then measuring the corresponding output voltage e_2 to obtain the overall gain that enables the computation of the proper insert voltage.

Electrical Circuit for Measurement

The basic electrical measurement for pressure reciprocity calibration is that of the amplitude ratio of two sinusoidal signals (e_1 and e_2 in Fig. 24.6) that may not be in phase. The uncertainty of direct measurement of each of the two signals is limited by the uncertainty of the alternating-current (AC) voltmeter. Several practical circuits for this purpose have been described [24.27]. A higher accuracy can be achieved with voltage ratio measurements. Two examples are described below to give some insight into the diversity of the methods of implementation.

Rectified Signal Null Method

In this method, used in commercial reciprocity calibration apparatus, one of the AC signals is applied to both inputs (Fig. 24.7). With the attenuator removed but with the bypass connection in place, the signal is balanced at the amplifier–rectifier circuit, such that a null reading is indicated by the null-meter. With the two sinusoidal signals connected to the inputs, the attenuator is adjusted for a null reading. The attenuator reading gives the voltage ratio. The uncertainty of the voltage ratio is theoretically dependent on the uncertainty of the precision attenuator. However, the linearity and matching of the amplifiers, amplifier–rectifiers (with RC time constants, not shown) together with the amplitude difference of the two signals, also affect the uncertainty of the circuit. Even with good design, the uncertainty of the voltage ratio measured is approximately 0.003 dB. With some modifications, the user of the apparatus may reduce the uncertainty of measurements by exchanging the signals at the input, and by shifting the attenuator from positions A and B to positions C and D, then taking the mean of the ratio readings for the two attenuator positions.

Variations on this method have been used; for example, the insert voltage (Fig. 24.6) can be derived from a precision attenuator driven by the same source as the driving microphone [24.25].

Interchange Reference Method

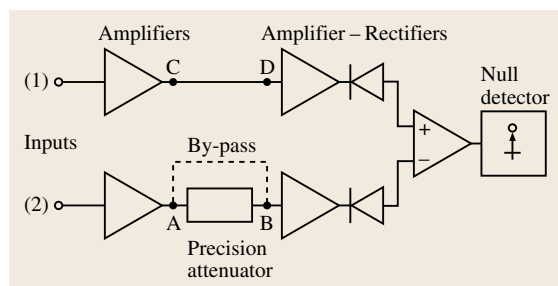
The amplitude ratio R and the phase θ of two sinusoidal signals can be measured very precisely with the interchange reference method [24.32] (Fig. 24.8). Signals e_1 and e_2 are presented to the differential inputs of a lock-in amplifier via the switch S_w and the attenuators. When the switch is in position 1, e_1 is selected to be the reference signal for the lock-in amplifier. The attenuator readings β_1 and α_1 are adjusted for a null condition. Using the vector diagram in Fig. 24.9,


Fig. 24.7 Rectified signal null circuit (after *Wong* [24.29] Chap. 4)
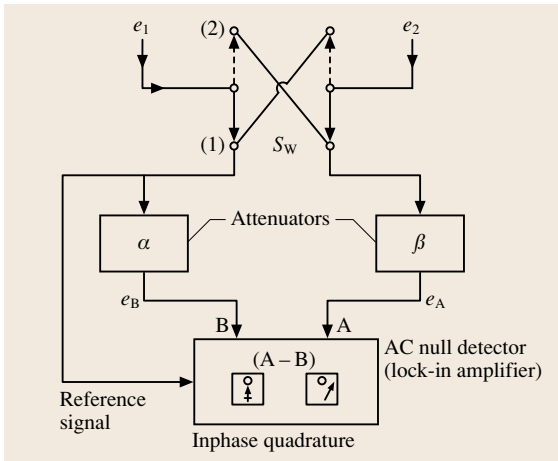

Fig. 24.8 Interchange reference method (after *Wong* [24.29, Chap. 4])

Fig. 24.9 Vector diagram for the in-phase null condition (after *Wong* [24.29, Chap. 4])

we have

$$e_2\beta_1 \cos\theta - e_1\alpha_1 = 0 . \tag{24.25}$$

Similarly, when e_2 is selected as the reference by the switch at position 2, the null condition with attenuator readings β_2 and α_2 provides the following

$$e_1\beta_2 \cos\theta - e_2\alpha_2 = 0 . \tag{24.26}$$

From (24.5) and (24.6), the general equations for the amplitude ratio $R = e_2/e_1$ and $\cos\theta$ are found

$$R = [(\alpha_1/\alpha_2)(\beta_2/\beta_1)]^{1/2} , \tag{24.27}$$

$$\cos\theta = [(\alpha_1\alpha_2)/(\beta_1\beta_2)]^{1/2} . \tag{24.28}$$

Although for symmetry, Fig. 24.8 shows two attenuators, in practice only one attenuator is required. For the condition in Fig. 24.9, where $e_2 > e_1$, $\alpha_1 = \beta_2 = 1$.

The uncertainty of the attenuator that can be a seven-decade ratio transformer (inductive voltage dividers) is of the order of 0.1 ppm. The uncertainty of the measured amplitude ratio is of the order of 1 ppm. Other circuits employing inductive voltage dividers for voltage ratio measurements are given in [24.17, 23].

Reference Impedance Selection

The reference impedance Z_x shown in Fig. 24.6 needs to be carefully selected. The nature of the impedance, either purely resistive or purely capacitive, or a combination of electrical impedances, dictates the mode of evaluation of the factor k, which is required for the computation of microphone sensitivity in (24.24). If Z_x is a resistance, the angular frequency ω, shown in (24.19), has to be measured. When the impedance is a capacitance C_r the term $Z_x = 1/(i\omega C_r)$, and the frequency terms are canceled. The numerical value of Z_x is chosen such that the magnitudes of e_1 and e_2 are nearly equal in order to enhance the measurement of voltage ratios using null measurement techniques. For precise measurement of Z_x, the capacitance of the connecting cables to the impedance should be taken into consideration.

24.4 Corrections

24.4.1 Heat Conduction Correction

The alternating sound pressure induces compression and expansion in the gas medium inside the closed cavity. At sufficiently low frequencies, the induced temperature changes occur isothermally, and the heat exchange at the walls of the cavity has to be included when computing the acoustic impedance of the cavity. As the frequency increases, heat conduction between

the gas and the walls decreases. Gradually, isothermal conditions change to adiabatic conditions, at which virtually no heat is exchanged with the walls.

Classical analytical approaches to calculate heat conduction in cavities are given by *Ballantine* [24.2] and *Daniels* [24.33]. Correction factors for heat conduction were obtained by *Biagi* and *Cook* [24.34]. Theoretical and experimental data, based on thermal diffusion, on the acoustic impedance of the cavity, are

The numerical values given are considered accurate to 0.00001

given by *Gerber* [24.35]. *Ballagh* [24.36] took into consideration heat loss effects due to the microphone diaphragms at the ends of the cavity. *Jarvis* [24.37] pointed out the need to include the impedance of the driver microphone during computation of the heat conduction correction. It is difficult to decide accurately at which middle frequencies the isothermal–adiabatic transition occurs, and which portions of the cavity to include in the impedance of the microphone. The exact nature of this transition depends upon the frequency of the calibration and the dimensions of the coupler. The sound pressure generated by the transmitter microphone, i. e. a constant-volume displacement source, will change accordingly. The effect can be considered as an apparent increase in the coupler volume expressed by a complex correction factor Δ_H to the geometrical volume V in Sect. 24.A or to the cross-sectional area S_0 defined in $Z = \rho c S_0^{-1}$ in Sect. 24.B.

The heat conduction correction factor is given by

$$\Delta_H = \frac{\gamma}{1 + (\gamma - 1)E_v} , \qquad (24.29)$$

where E_v is the complex temperature transfer function defined as the ratio of the space average of the sinusoidal temperature variation associated with the sound pressure to the sinusoidal temperature variation that would be generated if the walls of the coupler were perfectly nonconducting (24.30), and γ is the ratio of

specific heats of the gas inside the coupler. Tabulated values for E_v can be found in Table 24.1 [24.35] as a function of the parameters R' and X', where R' is the length-to-diameter ratio of the coupler, $X' = f\ell^2/(\gamma \alpha_t)$, f is the frequency, ℓ is the volume-to-surface ratio of the coupler and α_t is the thermal diffusivity of the gas enclosed.

For finite cylindrical couplers as described in [24.38], annex C, the approximation described below for the complex quantity E_v will be satisfactory

$$E_v = 1 - S + D_1 S^2 + \left(\frac{3}{4}\right) \sqrt{\pi} D_2 S^3 , \qquad (24.30)$$

where

$$S = \left(-i\frac{1}{2\pi X'}\right)^{1/2} = \frac{1 - i}{2\sqrt{\pi X'}} ,$$

$$D_1 = \frac{\pi R'^2 + 8R'}{\pi (2R' + 1)^2} ,$$

$$D_2 = \frac{R'^3 - 6R'^2}{3\sqrt{\pi}(2R' + 1)^3} .$$

The modulus of E_v, as calculated from (24.30), is accurate to 0.01% within the range $0.125 < R' < 8$ and for $X' > 5$. The first two terms in (24.30) constitute an approximation that may be used for couplers that are not right circular cylinders.

24.4.2 Equivalent Volume

The equivalent volume without heat conduction correction, as defined in (24.12), consists of the volume of the cavity plus the equivalent volumes of the microphones. The volume of the cavity is usually measured with traditional methods offered by mechanical metrology. The equivalent volume of a standard microphone, which includes a small volume occupied by a screw thread and an effective volume caused by the non-rigidity of the microphone diaphragm, is very difficult to measure precisely with conventional mechanical means. Various methods for the measurement of the equivalent volume of microphones are available [24.39]. Optical techniques, such as the traveling microscope, have been used to measure the cavity length [24.25]. For higher precision, interferometric procedures can be applied.

An acoustical resonance method can be used to determine the front cavity volume of a standard microphone. A three-port coupler accommodates two smaller microphones (e.g. 1/4 inch microphones), and the standard microphone. The smaller microphones are used as a driver–receiver combination to give the electrical transfer impedance including the cavity volume with the standard microphone in place. The standard microphone is replaced with a movable plunger; the displacement of the plunger is calibrated to indicate volumetric changes covering the range of actual microphone volumes. The equivalent front volume of the test microphone can be deduced from the calibrated position of the plunger at which the two smaller microphones indicate the same electrical transfer impedance as when the test microphone is in place. See [24.12] for a similar three-port procedure and [24.16] for precise measurement of volumetric changes.

Wong and *Embleton* [24.20] developed a very precise method that assesses the equivalent volume with the heat conduction correction and includes the impedance of the capillary tubes for the coupler and two microphones in one procedure. The length of the cavity can be varied with a removable spacer to replace the electrical insulation, and the voltage ratio $\beta = e_2/e_1$, as shown in Fig. 24.6, is assessed at the frequency of interest with the interchange reference method [24.32]. From (24.10) and (24.11), the equivalent volume of the cavity can be expressed in terms of the volume velocity u and the alternating pressure p

$$V = (\gamma P_s / \mathrm{i}\omega)(u/p) . \tag{24.31}$$

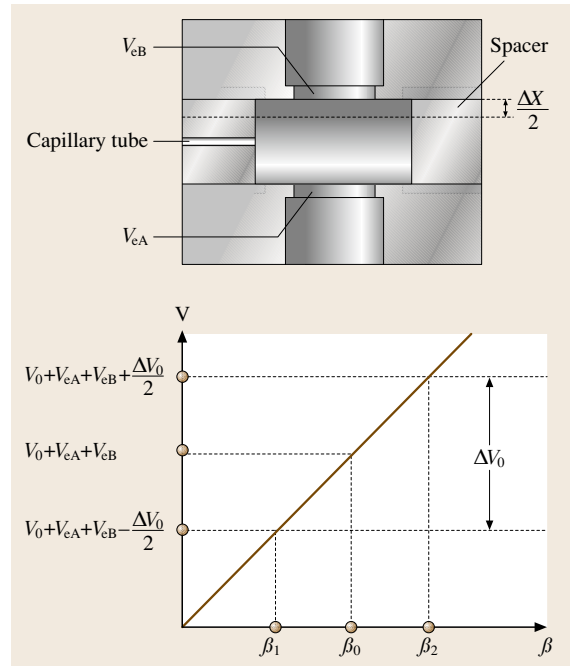
Since the voltage ratio β is inversely proportional to the pressure p inside the cavity (an increase of sig-


Fig. 24.10 Arrangement for determining the equivalent volume, including corrections for capillary tubes, and heat conduction (after [24.20])

nal magnitude requires a decrease in ratio reading to maintain a null condition), (24.31) can be modified to

$$V = k_0 \beta , \tag{24.32}$$

where k_0 is a constant.

Three readings, β_0, β_1 and β_2 corresponding to cavity volume $(V_0 + V_{eA} + V_{eB})$, volume $(V_0 + V_{eA} + V_{eB} - \Delta V_0/2)$ and volume $(V_0 + V_{eA} + V_{eB} + \Delta V_0/2)$, are obtained. Here ΔV_0 is a small variation in volume corresponding to a small variation Δx in spacer thickness. Figure 24.10 illustrates the relationship between changes in volume and the ratio readings. The equivalent volume of the cavity is

$$V = (V_0 + V_{eA} + V_{eB}) = \Delta V_0 [\beta_0/(\beta_2 - \beta_1)] . \tag{24.33}$$

From Fig. 24.10,

$$V = [\beta_0/(\beta_2 - \beta_1)] d^2 \Delta x \pi / 4 , \tag{24.34}$$

where d and Δx are the diameter and the variation in depth of the cavity.

For highly accurate measurements, the spacers are implemented with optical flats whose thicknesses are

measured by interferometry. The cavity is manufactured with precision optical fabrication. The uncertainty in the equivalent volume of such a cavity is estimated to be approximately 20 ppm. For less stringent applications the three optical flats can be replaced with adaptor rings [24.25] or with three cavities of known volumes. The equivalent volume of the cavity can then be determined by interpolation. This method has been commercialized with a similar procedure that relied on two couplers (long and short couplers) in the Brüel and Kjær 5998 reciprocity apparatus. With the sensitivities of the microphone pairs obtained with the two couplers, the microphone cavity depths are then adjusted numerically until the final microphone sensitivities obtained with the two couplers are nearly identical or very close.

24.4.3 Capillary Tube Correction

For microphone calibration, the preferred expression [24.38, 40] adopted for the acoustic input impedance of an open capillary tube is

$$Z_c = Z_t \tanh(\zeta L_c) \,, \tag{24.35}$$

where Z_t is the complex characteristic impedance of a capillary tube with infinite length, L_c is the length of the capillary tube, ζ is the complex propagation coefficient for plane waves in a tube, and

$$Z_t = \left(\tilde{A}_1/\tilde{A}_2\right)^{1/2} \,, \tag{24.36}$$

$$\zeta = \left(\tilde{A}_1\tilde{A}_2\right)^{1/2} \,. \tag{24.37}$$

$\tilde{A}_1$ and $\tilde{A}_2$ are complex quantities; $\tilde{A}_1$ represents viscosity loss at the walls and inertia of the gas medium, and $\tilde{A}_2$ represents heat conduction loss at the walls and the compliance of the gas medium, where

$$\tilde{A}_1 = i\frac{\omega\rho}{\pi r_c^2}\left(1 - \frac{2J_1(k_c r_c)}{k_c r_c J_0(k_c r_c)}\right)^{-1} \,, \tag{24.38}$$

$$\tilde{A}_2 = i\omega\frac{\pi r_c^2}{\rho c^2}\left(1 + \frac{2}{Bk_c r_c}(\gamma - 1)\frac{j_1(Bk_c r_c)}{j_0(Bk_c r_c)}\right) \,, \tag{24.39}$$

J_0 and J_1 are, respectively, the zeroth- and first-order cylindrical Bessel functions of the first kind for complex arguments, r_c is tube radius (m), $k_c = (-i\omega\rho/\eta)^{1/2}$ is the complex wave number (m^{-1}), $B = [\eta/(\rho\alpha_t)]^{1/2}$, α_t is the thermal diffusivity of the gas media (m^2/s).

The data used for this table are: $c = 345.7\,\text{m/s}$, $\gamma = 1.40$, $\rho = 1.186\,\text{kg/m}^3$, $\eta = 18.3 \times 10^{-6}\,\text{Pa s}$, $\alpha_t = 21 \times 10^{-6}\,\text{m}^2/\text{s}$

The values given in this table are valid at the reference environmental conditions: 23 °C, 101.325 kPa and 50% RH

For n capillary tubes the correction factors $\Delta_{c(AB)}$, $\Delta_{c(BC)}$ and $\Delta_{c(CA)}$ for the respective cavity impedances in (24.23) are

$$\Delta_{c(AB)} = 1 + n(Z_{AB}/Z_c) ,$$
$$\Delta_{c(BC)} = 1 + n(Z_{BC}/Z_c) ,$$
$$\Delta_{c(CA)} = 1 + n(Z_{CA}/Z_c) . \tag{24.40}$$

Equation (24.40) assumes that the heat conduction correction (Sect. 24.4.1) has been applied.

At a temperature of 23 °C, a relative humidity of 50% and a static pressure of 101.325 kPa, for a typical range of parameters and frequencies, the real and imaginary parts of Z_c are as shown in Table 24.2, respectively. The computation of the air density ρ, sound speed c in humid air and other physical quantities are discussed in Sect. 24.B.3.

It should be noted that the numerical values given in these tables are relatively sensitive to the change in the viscosity of air η. For example, when η deviates by 0.5%, the numerical values changes by approximately 1% in the real part of Z_c and approximately 8% in the corresponding imaginary part. Since the original data for the computation of η (Sect. 24.B.4) may have an uncertainty of several percent, the Table 24.2a,b should be used with caution.

24.4.4 Cylindrical Couplers and Wave–Motion Correction

Two types of couplers (cavities) are used for microphone calibration: plane-wave couplers, where the diameter of the cavity equals the diameter of the microphone diaphragm; and large-volume couplers, where the cavity diameter is larger than that of the diameter of the microphone diaphragm and the cavity volume is much larger than the sum of the equivalent volume and front volumes of the microphones. In reciprocity calibration, the dimensions of the large-volume coupler are chosen such that the pressure increase at the diaphragm of the receiving microphone, due to the first longitudinal mode, is partially canceled by the pressure decrease due to the lowest radial mode, whose maximum pressures occur at the side walls of the cavity and hence are removed from the vicinity of the microphone diaphragm. A generally accepted rule to ensure that the pressure is sufficiently uniform over the microphone diaphragm is that the maximum dimension of the cavity should not exceed $\lambda/20$, where λ is the wavelength in the gas. With a large-volume coupler there is less influence from the equivalent volumes of the capillary tubes and the microphones. However, with larger di-

mensions, the coupler is restricted to lower-frequency applications. In a plane-wave coupler with relatively dimensions there are smaller wave-motion effects, and the coupler can be used at higher frequencies. To extend the range of calibration frequency, a gas with a higher sound speed should be used. Theoretical and experimental data [24.38, 42–44] on wave motion in couplers have been published. In practice, it is difficult to obtain a precise theoretical expression for wave-motion correction. However, for experimental determination, the following method [24.44] has been used.

Assuming that the sensitivity of the microphones remains constant, the microphone sensitivity is measured with air as the gas at relatively high frequencies for which the pressure distribution in the cavity is nonuniform. The measurements are repeated with hydrogen or helium, which have higher sound speeds and for which the wave motion correction is correspondingly smaller. Changes in the apparent sensitivity of the microphones

Table 24.3 Experimental data on wave-motion corrections for the air-filled large-volume coupler used with type LS1P microphones (ANSI S1.15: 2005, IEC 61094-2:1992-03). give the wave-motion correction W for microphones calibrated in air.

Recommended [24.38] dimensions for the plane-wave and large-volume couplers are shown in Fig. 24.11, Table 24.4 and Fig. 24.12, Table 24.5, respectively. Representative wave-motion corrections [24.38] for both couplers used with LS1P (one-inch) microphones are shown in Table 24.3. These corrections should be added to the pressure sensitivity level measured with the coupler filled with air. When the coupler is filled with a gas other than air, the same correction can be used when the frequency scale is multiplied by a factor equal to the ratio of the velocity of sound in the gas to the corresponding velocity in air.

For LS1P microphones, the following empirical equation [24.25] for the wave-motion correction W, in decibels, may be used

$$W = -0.2242F^2 + 1.2145F - 1.6473 , \qquad (24.41)$$

where F equals $\log f$, and W should be added to the pressure sensitivity level of the microphone.

24.4.5 Barometric Pressure Correction

The sensitivity of a condenser microphone ([24.38], annex D) is inversely proportional to the acoustic impedance of the microphone. In a lumped parameter representation, the impedance is given by a serial connection of the impedance of the diaphragm (due primarily to its mass and compliance) and the impedance of the air behind the diaphragm is mainly determined by the following: (a) the thin air film between the diaphragm and the backplate, introducing loss and mass; (b) the air in slots or holes in the backplate, introducing loss and mass; and (c) the air in the cavity behind the backplate, acting at low frequencies as a compliance but at high frequencies as a mass due to wave motion in the cavity.

The density and the viscosity of air are considered linear functions of temperature and/or static pressure. Consequently the acoustic impedance of the microphone also depends upon the static pressure and the temperature. The resulting static pressure and temperature coefficients of the microphone are then considered

Table 24.6 Coefficients of the polynomial for calculating the microphone sensitivity pressure corrections using (24.42) or (24.43), and temperature corrections using (24.44) for specific LS1P and LS2P microphones (ANSI S1.15: 2005)

Fig. 24.13 Examples of static pressure coefficient of LS1P and LS2P microphones relative to the low-frequency value as a function of the relative frequency f/f_0 (ANSI S1.15: 2005, and IEC 61094-2:1992-03)

to be determined by the ratio of the acoustic impedance at reference conditions to the acoustic impedance at the relevant static pressure and temperature, respectively.

Both the mass and the compliance of the enclosed air depend on the static pressure, while the resistance can be considered independent of static pressure. The static pressure coefficient generally varies with frequency as shown in Fig. 24.13. For frequencies higher than about $0.5 f_0$ (f_0 being the resonance frequency of the microphone), the frequency variation depends strongly upon the wave motion in the cavity behind the backplate. In general, the pressure coefficient depends on constructional details in the shape of the backplate and back volume, and the actual values may differ considerably for two microphones of different manufacture although the microphones may belong to the same type, say LS1P. Consequently the pressure coefficients shown in Fig. 24.13 should not be applied to individual microphones.

The low-frequency values of the static pressure coefficient generally lie between -0.01 and -0.02 dB/kPa for LS1P microphones, and between -0.003 and -0.008 dB/kPa for LS2P microphones.

For the Brüel and Kjær type 4160 LS1P microphones, an empirical equation based on precise measurement of the microphone sensitivity [24.45] at various static pressures to derive the pressure coefficient, may be used to correct for microphone sensitivity variation with static pressure

$$\Delta P = \left(a_0 + a_1 f + a_2 f^2 + a_3 f^3 + a_4 f^4 + a_5 f^5 + a_6 f^6 \right) \Delta_{\mathrm{p}}, \qquad (24.42)$$

where ΔP is the microphone sensitivity level pressure correction (dB), (to be added to the sensitivity level of a microphone), a_0–a_6 are constant coefficients listed in Table 24.6, f is the frequency (Hz), $\Delta_{\mathrm{p}} = (p_{\mathrm{s}} - p_0)$ is the pressure difference (kPa), p_{s} is the static pressure during calibration (kPa), and p_0 is 101.325 kPa.

The variation of the pressure sensitivity correction with frequency is shown in Fig. 24.14. At a particular frequency, if the difference between the standard pressure and the barometric pressure during calibration is known, the sensitivity pressure correction can be obtained from the above equation. Over a pressure range 94–106 kPa, if (24.42) is used for sensitivity level pressure correction for a type 4160 microphone, the maximum deviation between the corrected microphone sensitivity level and the corresponding measured microphone sensitivities level is within 0.0085 dB over the frequency range 250–8000 Hz. For a wider frequency range of 63–10 000 Hz, the corresponding deviation is within 0.013 dB. Similar corrections can be obtained for LS2P (half-inch) microphones by applying the coefficients [24.46] given in Table 24.6.

Users of condenser microphones, particularly for very precise measurements such as during aircraft certification that involves huge resources, should be fully aware of the fact that the sensitivities of condenser microphones change with frequencies (frequency response) and these changes are functions of barometric pressure [24.45, Fig. 3]. Therefore for two sets of measurements at different barometric pressures, pressure corrections, such as with (24.43), can be applied at each frequency to arrive at more-precise measurements.

For LS2P microphones Brüel and Kjær type 4180 and GRAS-type 40AG, the pressure correction curves similar to that shown in Fig. 24.14 have been published [24.46]. With (24.42) their corrections can be computed from the coefficients shown in Table 24.6.

Alternatively, a similar equation for pressure correction developed at a later date also based on measurement [24.47], may be used

$$\delta_p = a_0 + a_1 x + a_2 x^2 + \ldots + a_9 x^9 \,, \tag{24.43}$$

where δ_p is the microphone sensitivity pressure correction (dB/kPa), a_0–a_9 are the constants listed in Table 24.6, $x = f/f_0$ is the frequency normalized to the resonance frequency f_0 of the individual microphone, and f is the frequency (Hz).

With (24.43), it is necessary to determine the resonant frequency f_0 of the microphones. With the assumption of a mean value for f_0, the numerical values obtained with (24.43) and (24.42) differ by a few thousandths of a decibel per kPa.

24.4.6 Temperature Correction

Both the mass and the resistance of the enclosed air depend on the temperature, while the compliance can
Fig. 24.14 Variation of the slopes of sensitivity correction curves with frequency for three Brüel and Kjær type 4160 microphones. The curve is obtained with an empirical equation for the computation of microphone sensitivity pressure correction. See (24.42). Similar corrections can be obtained for Brüel and Kjær Type 4180 and GRAS 40AG microphones with the coefficients shown in Table 24.6 (after [24.48])

be considered independent of temperature. The dependence on temperature is of secondary when compared with the pressure dependence. The resulting frequency dependence of the temperature coefficient is shown in Fig. 24.15.

In addition to the influence on the enclosed air, temperature variations also affect the mechanical parts of the microphone. The main effect will generally be a change in the tension of the diaphragm and thus
Fig. 24.15 General frequency dependence of the part of the temperature coefficient for LS1P and LS2P microphones caused by the variation in the impedance of the enclosed air (ANSI S1.15: 2005, and IEC 61094-2:1992-03)

Table 24.7 A numerical example for the calculation of estimated expanded uncertainty of microphone sensitivity level with a particular microphone calibration arrangement at 250 Hz (ANSI S1.15: 2005)

Source	Type	Estimated contribution (dB)	Distribution	Sensitivity coefficient	Standard uncertainty (dB)
Acoustic transfer impedance	B	0.025	Rectangular	1	0.0144

Expanded uncertainty ($k = 2$)					0.0412
Rounded expanded uncertainty					**0.042**

a change in its compliance. This results in a constant change in sensitivity in the stiffness-controlled range and a slight change in the resonance frequency.

The low-frequency values of temperature coefficient generally lie close to $+0.005\,\text{dB/K}$ for both LS1P and LS2P microphones.

An equation developed for the normalized temperature coefficient based on measurements of LS1P and LS2P microphones [24.47, 49], may be used

$$\Delta T = (a_0 + a_1 x + a_2 x^2 + \ldots + a_9 x^9)\Delta t , \quad (24.44)$$

where ΔT is the microphone sensitivity temperature correction (dB), $a_0 - a_9$ are the constants listed in Table 24.6, $x = f/f_0$ is the frequency normalized by the resonance frequency f_0 of the individual microphone, f is the frequency (Hz), $\Delta t = (T - 273.15)$, the temperature difference from the reference condition (K).

24.4.7 Microphone Sensitivity Equations

In general, based on (24.22) or (24.23), the open-circuit sensitivity of a microphone expressed in decibels relative to 1 V/Pa is

$$M_{\text{dB}} = 20 \log M + 10 \log \Delta_{\text{c}} + 10 \log \Delta_{\text{H}}$$
$$+ 10 \log \Delta P_{\text{v}} + 10 \log \Delta T + 10 \log \Delta h + W , \quad (24.45)$$

where M is the microphone sensitivity, and Δ_{c}, Δ_{H}, ΔP, ΔT, Δh and W are the corrections for capillary, heat conduction, pressure, temperature, humidity and wave motion, respectively. For LS1P and LS2P microphones, the humidity corrections of the order of $0.0025\,\text{dB/100\% RH}$ may be ignored.

When expressed in the format of volts per pascal, and including corrections, the microphone sensitivity is

$$M_{\text{corr}} = 10^{M_{\text{dB}}/20} . \quad (24.46)$$

24.4.8 Uncertainty on Pressure Sensitivity Level

The uncertainty of the pressure sensitivity level, expressed as a function of frequency, should be stated as the expanded uncertainty of measurement obtained by multiplying the derived standard uncertainty by a coverage factor of two.

It should be noted that not all of the contributing uncertainty components are known. Some of the uncertainty components that may be necessary for consideration for a given calibration arrangement are: (a) the electrical transfer impedance: series impedance, voltage ratio, cross-talk and noise, distortion etc., (b) the acoustic transfer impedance related to the coupler: coupler dimensions and surface area, capillary tube

parameters and environmental conditions, and (c) the microphone parameters, such as loss factor, diaphragm: mass, compliance, resistance and heat conduction related to front cavity etc. Details of some of these uncertainties have been published [24.50].

For the determination of the pressure sensitivity level, it is estimated [24.33, 39] that a reciprocity calibration carried out under laboratory conditions can achieve an uncertainty of approximately 0.05 dB

at low and middle frequencies. The uncertainty increases to about 0.1 dB at 10 kHz and 20 kHz for LS1P and LS2P laboratory standard microphones, respectively.

In order to clarify the computation process, a numerical example is given in Table 24.7 for the calculation of estimated expanded uncertainty of the microphone sensitivity level with a particular microphone calibration arrangement at 250 Hz.

24.5 Free–Field Microphone Calibration

The theory and procedure for free-field calibration have been discussed in detail [24.51, 52]. Similarly to pressure reciprocity calibration, one microphone is driven as a sound source and the microphone pair faces each other in a free field at a fixed distance. One of the major uncertainties in free-field calibration is to measure the positions of the acoustic centers of the microphones accurately so that the distance between them can be deduced. Procedures for measuring and estimating values of the positions of the acoustic centers

for laboratory standard microphones have been published ([24.52], annex A). For free-field calibration of half-inch microphones, over a frequency range from about 1.25 kHz to more than 20 kHz the uncertainty (three standard deviations) [24.51] is approximately 0.1−0.2 dB.

The manufacturers of the microphones usually supply free-field corrections for their microphones, to be added to the pressure reciprocity measurements, for free-field applications.

24.6 Comparison Methods for Microphone Calibration

Reciprocity microphone calibration discussed in Sect. 24.3 is a primary method that provides high accuracy but requires stringent procedures and is relatively time consuming. A more economical approach to microphone calibration is by means of comparison methods with which the performance of the test microphone is compared with that of a standard microphone that has been calibrated with a primary method. Secondary methods, such as using comparison, have higher uncertainties but offer several advantages, such as simplicity in procedure, are less time consuming and, depending on the method, require little or no correction, and are very economically attractive.

24.6.1 Interchange Microphone Method of Comparison

This economically attractive method was developed to compare microphones in a cavity or in a small anechoic box (*Wong* and *Embleton* [24.53] and *Wong* and *Wu* [24.54]). The technique can be applied to microphone phase comparison calibration (*Wong* [24.55]).

The method has been standardized in an international standard [24.56].

When two microphones with their diaphragms facing in close proximity to each other are excited in a sound field, the difference of level readings, L_{C12} between the two channels, where microphone 1 is connected to preamplifier 1, and microphone 2 is connected to preamplifier 2, is

$$L_{C12} = (L_1 + L_{m1} + L_d + L_{WA})$$
$$- (L_2 + L_{m2} + L_d + L_{WB}) , \qquad (24.47)$$

where L_1 and L_2 are the sensitivity levels of the microphones 1 and 2, respectively, L_{m1} and L_{m2} are the gain sensitivity levels of the measuring systems 1 and 2, respectively, L_d is the level of the sound excitation, and L_{WA} and L_{WB} are the wave pattern effects at the microphone positions A and B, respectively.

When the microphones are interchanged so that microphone 1 is now connected to preamplifier 2 and microphone 2 is now connected to preamplifier 1, the difference of level readings between the two channels

becomes

$$L_{C21} = (L_2 + L_{m1} + L_d + L_{WA})$$
$$- (L_1 + L_{m2} + L_d + L_{WB}) \,. \tag{24.48}$$

Subtracting (24.48) from (24.47), the difference in level between the two microphones is

$$(L_1 - L_2) = 1/2(L_{C12} - L_{C21}) \,. \tag{24.49}$$

If either L_1 or L_2 is the sensitivity level of a calibrated reference microphone, then the sensitivity level of the other microphone (the test microphone) can be deduced. It is interesting to point out that with this method, the level L_d of the driving sound need not have a flat response or known levels.

The above relatively simple theoretical consideration has assumed that the input capacitances of the two microphones are identical, i. e. the same model of microphones, and the same model of preamplifiers used for both channels such that their input capacitances have the same value.

If the input capacitances C_m of the preamplifiers are the same but the two models of microphones are different, then a correction L_{corr} should be added to the right-hand side of (24.49), where

$$L_{corr} = 20 \log[C_2/(C_m + C_2)]$$
$$- 20 \log[C_1/(C_m + C_1)] \,. \tag{24.50}$$

The two terms in (24.50) are the capacitance corrections for the two microphones; and C_1 and C_2 are the capacitances of microphone 1 and microphone 2, respectively.

It is important to realize that the physical positions of the reference microphone should be repeated accurately before and after the microphones are interchanged such that the sound field at the reference microphone is unchanged. The difference in level readings shown in (24.47) and (24.48) can be measured with the ratio provision of a precision AC voltmeter.

Uncertainties

The uncertainty for the above method depends on the reference microphone uncertainty that may be of the order of 0.05 dB. With very sophisticated measuring methods such as phase-lock amplifiers the uncertainty introduced by this comparison method to be added to the uncertainty of the reference microphone [24.57] is estimated to be less than 0.1 dB.

24.6.2 Comparison Method with a Calibrator

In general, there are five components and three basic steps in this comparison method [24.57]. The components are the reference microphone, the test microphone, a stable sound source, which is usually an acoustical calibrator that generates a constant sound pressure level, a microphone preamplifier and an acoustical level indicator such as a measuring amplifier or a voltmeter. Since the calibrator is used as a transfer standard, its sound pressure level need not be known.

The three basic steps are as follows

1. The reference microphone which is connected to the preamplifier is inserted into the acoustical calibrator and a level reading L_r is noted.
2. The reference microphone is replaced with the test microphone. With the same acoustical calibrator, a second level reading L_t is noted.
3. The test microphone is removed, and again with the reference microphone, step 1 is repeated to give a third level reading.

The agreement between the first and third level readings with the reference microphone is a confirmation of the validity of the second level reading obtained with the test microphone, that is, to assure that nothing has changed after the first level reading is taken. The difference between the level readings, $(L_t - L_r)$ is the difference in open-circuit sensitivities (expressed in decibels) between the two microphones if the following conditions are satisfied:

1. The equivalent volumes of the two microphones are identical, or the equivalent volume of the sound calibrator is much larger than that of the microphones, such that any difference in the front volumes of the microphones does not produce a significant change in the sound pressure levels measured in steps 1 and 2 above.
2. The capacitances of the two microphones are identical. Since the preamplifier has a finite input impedance (a very high resistance in parallel with a small known capacitance), the loading on the microphone will be different if the microphone capacitances were to be different, and this will produce a small change in the overall combined sensitivity of the microphone and preamplifier.
3. The environmental conditions remain constant during the measurements.

Corrections

When it is not possible to satisfy all of the above conditions during the implementation of the comparison procedure, the following corrections can be applied.

Equivalent Volume Correction

Depending on the type of microphones, the equivalent volume of the test microphone, as specified by the manufacturer, can differ substantially from that of the reference microphone. The following correction can be applied.

$$\Delta P_v = 20 \log[V/(V + \Delta V)] \text{dB} ,\qquad (24.51)$$

where ΔP_v is the volume correction to be added to the calibrated sensitivity of the microphone, V is the effective coupler volume of the acoustical calibrator, ΔV is the difference between the equivalent volumes of the microphones, i. e., the equivalent volume of the reference microphone minus the equivalent volume of the test microphone.

When the combined volume of the calibrator and the equivalent volume of the microphone increases, the sound pressure level inside the acoustical calibrator decreases. For example, if ΔV is negative, i. e., the equivalent volume of the test microphone is larger than that of the reference microphone the volume correction ΔP_v has a positive sign in order to compensate for the decrease in sound pressure level when the test microphone is measured. When the correction is added to the microphone sensitivity (24.45), the apparent sensitivity of the test microphone increases.

Depending on the frequency of the acoustical calibrator, the effective coupler volume V should include the additional volume due to heat conduction (Sect. 24.4.1). For example at a frequency of 250 Hz, the additional volume to account for heat conduction for the Brüel and Kjær type 4220 pistonphone is 0.16 cm³. There are other acoustical calibrators that have relatively large cavity volumes, such as the Brüel and Kjær model 4230 (94 dB at 1 kHz, with an equivalent volume of > 100 cm³ between 10 and 40 °C); and the Larson–Davis model CA250. In these cases, from (24.51), the correction is negligible since V is much larger than ΔV. Most calibrators are supplied with adaptors to accommodate microphones of various diameters, and these adaptors are designed to include the volume correction for the particular types of microphones when used with the calibrator. If the adaptors and the calibrator are from different manufacturers, the instruction manual of the calibrator should be consulted to ensure proper usage.

Capacitance Correction

The combined level sensitivity of the microphone and preamplifier is

$$M_{com} = M_o + g_1 + 20 \log[C/(C + C_i)] ,\qquad (24.52)$$

where M_o is the open-circuit sensitivity of the microphone (dB re 1 V/PA), g_1 is the gain of the preamplifier (dB), C is the capacitance of the microphone, C_i is the input capacitance of the preamplifier. The input capacitance of the preamplifier would load the microphone and the overall sensitivity decreases. With this comparison method, if the capacitances of the two microphones are different, the capacitance correction is

$$\Delta P_c = 20 \log[C_r/(C_r + c_i)] - 20 \log[C_t/(C_t + c_i)] ,\qquad (24.53)$$

where ΔP_c is the capacitance correction to be added to the calibrated sensitivity of the microphone (dB), C_r is the capacitance of the reference microphone, c_i is the input capacitance of the preamplifier, and C_t is the capacitance of the test microphone.

The first and the second term on the right-hand side of (24.53) are the capacitance corrections for the reference microphone and the test microphone, respectively.

Environmental Conditions

One of the advantages of a comparison method is that environmental effects usually remain constant during measurements outlined in the above three basic steps. Changes in temperature and humidity affect both microphones. A rapid variation in barometric pressure may affect some acoustical calibrators, and precaution should be taken to avoid opening or closing the doors of the calibration laboratory during measurements.

Uncertainties

From the above discussion, the open-circuit sensitivity of the test microphone is

$$M_t = M_r + (L_t - L_r) + \Delta P_v + \Delta P_c ,\qquad (24.54)$$

where M_r is the open circuit sensitivity of the reference microphone (dB re 1 V/Pa), L_t is the level reading obtained with the test microphone (dB), and L_r is the level reading obtained with the reference microphone (dB).

The uncertainty of M_r depends on the primary reciprocity procedure that calibrates the reference microphone (Sect. 24.3). If the environmental conditions are controlled [24.20], the uncertainty of the open-circuit sensitivity can be less than 0.005 dB. The uncertainty expectation for reciprocity calibrations based on international standard [24.38, 40] is approximately 0.05 dB.

If the magnitudes of the levels L_t and L_r are nearly identical, the uncertainty can be much less than 0.05 dB. However, if it is necessary for the level-measuring device, such as a measuring amplifier, to engage different instrument ranges during the measurement of the above levels, the uncertainties can be up to ± 0.1 dB. The uncertainties of ΔP_v and ΔP_c are estimated to be approximately 0.01 dB each, and the overall uncertainty of calibrator comparison method is estimated to be 0.05–0.2 dB.

For this comparison method, the preamplifier should have very high input impedance, usually in the order of gigaohms with a parallel capacitance of a fraction of a picofarad.

24.6.3 Comparison Pressure and Free–Field Calibrations

The coupler method described in Sect. 24.3 for primary reciprocity microphone calibration can be utilized to implement comparison pressure calibration. A laboratory standard microphone of unknown pressure response can be calibrated against a reference microphone with a known pressure response. One example of the coupler arrangement shown in Fig. 24.6 with which microphone A is the driver that serves as a sound source. The reference microphone and the test microphone replace microphone B in succession on the right-hand side of the coupler. The ratio of the driving voltage e_A applied to the driver microphone to the open-circuit output voltage of the receiving microphones e_B, is measured as described in Sect. 24.3.3. The sensitivity of the test microphone can be calculated as follows

$$M_t = M_r - 20\log(e_{Bref}/e_{Aref}) + 20\log(e_{Bx}/e_{Ax}) , \tag{24.55}$$

where M_t and M_r are the sensitivities of the test and the reference microphones, respectively, e_{Bref} and e_{Aref} are the open-circuit voltage and the source driving voltage when the reference microphone is in position, e_{Bx} and e_{Ax} are the open-circuit voltage and the source driving voltage when the test microphone is in position.

With (24.55), unless the equivalent volume of the coupler is large compared to those of the reference microphone and the test microphone, and the equivalent volumes of the reference microphone and the test microphone are similar, suitable volume correction should be applied such that the equivalent sound pressure levels are identical for both the reference and the test microphones.

Uncertainties

The uncertainties of the coupler pressure comparison method are very similar to those described in Sect. 24.6.2 with the exception that the open-circuit voltage measurements with the insert voltage method, capacitance corrections are unnecessary. The uncertainty of the coupler comparison method may approach approximately two times the uncertainty of the reference microphone plus the uncertainty involved with the equivalent volume corrections; assuming that the reference microphone has been calibrated with a similar method for open-circuit voltage measurement.

The uncertainty for free-field comparison method is higher and is due to electrical and mechanical air-transmitted interferences. Even with narrow-band filtering, the overall uncertainty for free-field comparison is of the order of 0.5 dB.

24.6.4 Comparison Method with a Precision Attenuator

A more precise method than that described in Sect. 24.6.2, comparison with a calibrator, is comparison with an attenuator. The acoustical level indicator is replaced with a calibrated attenuator [24.58]. Over the usable range of 5–100 mV/Pa of the open-circuit sensitivity of a microphone, the attenuator, i. e., a precision ten-turn potentiometer, is calibrated with a resolution of better than 0.05 mV/Pa. The comparison procedure is as follows:

1. The reference microphone is inserted into a calibrator. The sensitivity of the reference microphone is entered into the calibrated attenuator, say 50 mV/Pa. An indicator reading is taken.
2. The reference microphone is replaced with the test microphone, and the calibrated attenuator is adjusted until the indicator gives the same reading. The new attenuator reading gives the sensitivity of the test microphone.

With this method, it is still necessary to correct for capacitances and equivalent volumes of the microphones. However, the uncertainty is reduced by the precision of the attenuator, which may have an uncertainty of a few thousandths of a decibel. If the test microphone is of the same type and model as the reference microphones, the uncertainty of this method is the uncertainty of the reference microphone plus a few thousandths of a decibel, if the indicator has a resolution of a thousandth of a decibel.

24.7 Frequency Response Measurement with Electrostatic Actuators

Electrostatic actuators were used by *Ballantine* [24.2] to investigate microphone calibration and *Koidan* [24.59] gave a comprehensive discussion of the uncertainties between measurements obtained with electrostatic actuators compared with those measured with the coupler pressure reciprocity method. The description and analyses of some commercially available electrostatic actuators for microphone calibration have been published [24.60–62] and standardized [24.63] for frequency response measurement for working standard (WS) microphones. The electrostatic actuator method, Fig. 24.16, consists of a metal grid polarized with a high voltage direct-current (DC) supply (usually 800 V). An AC time-varying sweep signal provides the electrostatic pressure on the microphone diaphragm. With the usual amplification and a recorder, the frequency response is displayed graphically.

Madella [24.64] and *Nedzelnitsky* [24.65] pointed out that with electrostatic actuator measurements the effective mechanical radiation impedance loading of the microphone diaphragm in the presence of the electrostatic actuator is different from that of those used in a coupler or in a free field. Consequently, at higher frequencies the absolute values of the difference between the actuator-determined response of type L microphones and pressure calibrations determined in couplers by reciprocity can be as large as about 1.5 dB [24.65]. In practice, the design of the metal grid can be optimized for a particular microphone type. According to the IEC standard [24.63], the expanded uncertainty of the method is 0.1–0.2 dB for frequencies up to 10 kHz for WS1 (1-inch) and WS2 (half-inch) type microphones. Since the air gap between the metal grid and the microphone diaphragm is very small (nominally approximately 0.5 mm) the use of electrostatic actuators for models of microphones other than those specified is not recommended. Since the motion of the microphone diaphragm, caused by electrostatic pressure produce by the actuator, creates a sound pressure on the outer surface of the diaphragm that adds to the electrostatic pressure and influences the measure response, precautions should be taken to avoid blocking the actuator space that opens to the atmosphere.

Apart from being economically attractive, there are some salient features to the electrostatic actuator method.

1. The method is ideal for comparing the frequency responses of microphones, such as those in a production line, at which only changes from a nominal value is important.
2. Since the actuator method is unaffected by atmospheric pressure, humidity and temperature (assuming the air gap remains constant) [24.63], the method may be used to measure the change in microphone responses with respect to variations in the environment.

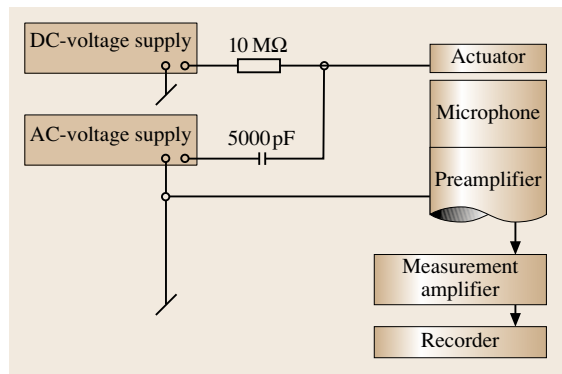
Given the fact that the international standard [24.63] only discusses type WS1 and WS2 working standard microphones and not the laboratory types LS1 and LS2 microphones, it is obvious that the electrostatic actuator method still requires further development to reduce uncertainties.


Fig. 24.16 Frequency response measurement with an electrostatic actuator (after *Frederiksen* [24.29, Chap. 15])

24.8 Overall View on Microphone Calibration

Primary microphone calibrations, such as those performed with the reciprocity method, provide uncertainty estimations. One may wonder what is the contribution to the calibration uncertainty from two major sources: (a) the stability of the microphones and (b) the stability of the calibration system that performed the microphone calibration. It is very difficult to separate these two sources of uncertainties.
Fig. 24.17 Deviation from the mean sensitivity level of a transfer standard microphone s/n 907045 (after [24.67])
Fig. 24.19 Deviation from the mean sensitivity level of a transfer standard microphone s/n 907039 (after [24.67])
Fig. 24.18 Deviation from the mean sensitivity level of a transfer standard microphone s/n 1734004 (after [24.67])

In connection with an international microphone calibration comparison [24.66] that involved five National Metrology Institutes (NMIs), the pilot laboratory (Canada) had the opportunity to calibrate the same set of three laboratory standard LS1P microphones five times over a period of 31 months. The calibrations were made in a chamber with a controlled environment [24.45] at the reference condition of 23 °C, 101.325 kPa and 50% RH. The microphone sensitivity levels were measured at seven frequencies from 125 Hz to 8 kHz. Two of the microphones (the transfer standards) were *hand carried* to and from the pilot laboratory in a *star* con-

figuration, i. e., the microphones were calibration by the pilot laboratory before and after delivery to each of the participating NMIs. The average of five sets of readings obtained by the pilot laboratory was taken as the mean sensitivity level. The deviation from the mean sensitivity level of the transfer standard microphones (LS1P Brüel and Kjær type 4160 microphones, s/n 907045 and s/n 1734004) are shown in Fig. 24.17 and Fig. 24.18, and are within approximately 0.011 dB. It is interesting to show that, for the above reciprocity calibration, the third type 4160 LS1P microphone s/n 907039 which remained at the pilot laboratory without the need to endure air transportation to and from the participating laboratories over the test period, the deviations shown in Fig. 24.19 were significantly smaller for frequencies below 8000 Hz, and are within +0.007 and −0.006 dB. It should be noted that the deviations shown for the three microphones are the combined contributions from the sensitivity level stability of the microphones and the stability of the primary calibration system. Since the specifications for laboratory standard microphones [24.41] states that the type 4160 LSIP microphone has a long-term stability coefficient of < 0.02 dB per year from 250 Hz to 1000 Hz, and the manufacturer Brüel and Kjær indicated the stability of their LS1P microphones may have a stability coefficient of approximately 0.01 dB per year, one may conclude that the primary microphones and the calibration system of the pilot laboratory have an excellent stability of approximately 0.01 dB over the period of 31 months.

24.A Acoustic Transfer Impedance Evaluation

Assume the sound pressure to be the same at any point inside the coupler (this will take place when the physical dimensions of the coupler are very small compared to the wavelength) the acoustic transfer impedance can be evaluated theoretically [24.38]. The air in the coupler then behaves as a pure compliance and assuming adiabatic compression and expansion of the gas

$$\frac{1}{Z'_{AB}} = i\omega \left(\frac{V}{\gamma p_s} + \frac{V_{eA}}{\gamma_0 p_0} + \frac{V_{eB}}{\gamma_0 p_0} \right), \qquad \text{(24.A1)}$$

where values for γ and γ_0 can be derived from the equations given in Sect. 24.B.

The computation of the acoustic transfer impedance becomes complicated at high frequencies when the dimensions of the coupler are not small compared with the wavelength. When the shape of the coupler is cylindrical and the cavity diameter is the same as that of the microphone diaphragm [24.38], and at frequencies where plane-wave transmission and adiabatic conditions can be assumed, the acoustic transfer impedance is

$$\frac{1}{Z'_{AB}} = \frac{1}{Z} \left[\left(\frac{Z}{Z_A} + \frac{Z}{Z_B} \right) \cosh(\xi \ell_0) \right.$$
$$\left. + \left(1 + \frac{Z}{Z_A} \frac{Z}{Z_B} \right) \sinh(\xi \ell_0) \right], \qquad \text{(24.A2)}$$

where ξ is the complex propagation coefficient (m^{-1}), and $\xi = i(\omega/c)$, approximately.

Allowance should be made for the air volume associated with the microphones that is not enclosed by the circumference of the coupler and the two diaphragms.

24.B Physical Properties of Air

Certain physical properties, characterizing the enclosed gas in the coupler, enter into the expressions for calculating the sensitivity of the microphones, see (24.A1) and Sects. 24.4.1 and 24.4.3. These properties are: the speed of sound in the gas; the density of the gas; the ratio of the specific heats of the gas; the viscosity of the gas; and the thermal diffusivity of the gas. These properties depend on one or more of the variables: temperature, static pressure and humidity.

A large number of investigations have been published in the literature where reference values for the physical properties can be found for specified environmental conditions, i.e. for standard dry air [24.68] at $0\,^\circ$C and at a static pressure of 101.325 kPa. In the following, unless otherwise stated, the recommended calculation procedures with the corresponding estimated uncertainties are valid over the temperature range 0–$30\,^\circ$C; barometric pressure of 60–110 kPa, and relative humidity from 10% to 90%.

24.B.1 Density of Humid Air

An equation for the determination of the density of moist air was first published by *Giacomo* [24.69] and some constants were modified by *Davies* [24.70]. The following equation may be used to compute the density of humid air ρ based on a CO_2 content of 400 ppm, which is slightly higher than the 314 ppm specified for the ISO standard air [24.68] constituents.

$$\rho = [3.48349 + 1.44 \, (x_c - 0.0004)]$$
$$\times 10^{-3} \frac{p_s}{ZT} \, (1 - 0.3780 x_w), \qquad \text{(24.B1)}$$

where x_c and x_w are the mole fractions of carbon dioxide and water vapor in air, respectively; p_s is the static pressure, Z is the compressibility factor for humid air, T is the thermodynamic temperature, and

$$Z = 1 - \frac{p_s}{T} \big[a_0 + a_1 t + a_2 t^2 + (a_3 + a_4 t) \, x_w$$
$$+ (a_5 + a_6 t) \, x_w^2 \big] + \frac{p_s^2}{T^2} \big(a_7 + a_8 x_w^2 \big) ,$$

$$x_w = \frac{p_{sv}}{p_s} f_e h ,$$
$$p_{sv} = \exp \left(A'_1 T^2 + B'_1 T + C'_1 + D'_1 T^{-1} \right) ,$$
$$f_e = 1.00062 + p_s(3.14 \times 10^{-8}) + t^2(5.6 \times 10^{-7}) .$$

For Z the numerical coefficients are

$a_0 = 1.58123 \times 10^{-6}$,	$a_1 = -2.9331 \times 10^{-8}$,
$a_2 = 1.1043 \times 10^{-10}$,	$a_3 = 5.707 \times 10^{-6}$,
$a_4 = -2.051 \times 10^{-8}$,	$a_5 = 1.9898 \times 10^{-4}$,
$a_6 = -2.376 \times 10^{-6}$,	$a_7 = 1.83 \times 10^{-11}$,
$a_8 = -0.765 \times 10^{-8}$.	

For p_{sv} the numerical coefficients are

$$A'_1 = 1.2378847 \times 10^{-5} ,$$
$$B'_1 = -1.9121316 \times 10^{-2} ,$$
$$C'_1 = 33.93711047 ,$$
$$D'_1 = -6.3431645 \times 10^3 .$$

Within the normal range of environmental conditions during calibrations, the following simplified equation for the density of humid air may be used

$$\rho = \rho_0 \frac{p_s}{p_0} \frac{T_0}{T} (1 - 0.378 h_s) , \qquad (24.B2)$$

where ρ and ρ_0 are the densities of air, p_0 and p_s are the reference and static pressure, respectively; T_0 and T are the temperatures in Kelvin and h_s is the fractional molar concentration of moisture.

Uncertainties in ρ

The uncertainty in ρ obtained with (24.B1) has been estimated [24.69, 70] at approximated 100 ppm. At the reference conditions of 101.325 kPa and 50% relative humidity, ρ obtained with (24.B2) are 239 ppm and 293 ppm larger than those obtained with (24.B1) at 23 °C and 30 °C, respectively.

24.B.2 Computation of the Speed of Sound in Air

Method 1

The speed of sound in air varies with temperature, carbon dioxide content, relative humidity and barometric pressure. The sequence of the above parameters is listed roughly in decreasing order of their influence on the speed of sound with respect to the day-to-day encounter of environmental conditions. A large number of investigations related to the speed of sound [24.50, 71–80] had been published, detailed references have been given [24.75], and an updated and comprehensive bibliography [24.80, Chap. 17, pp. 265–284], and references therein) on publications relating to sound speed in air is included at the end of this appendix. It can be shown that the speed of sound remains relatively constant with barometric pressure [24.72]: at 23 °C and 50% RH, over the barometric pressure range 60–110 kPa, the sound speed varies by less than 76 ppm. In view of this, the following equation has a relatively small overall uncertainty, is based on a steady barometric pressure of 101.325 kPa and may be used to compute the variation of the speed of sound with temperature, carbon dioxide content and relative humidity.

A general empirical equation has been obtained [24.71] for calculation of the variation of c/c_0 with relative humidity h, temperature t and carbon dioxide content h_c

$$c/c_0 = a_0 + a_1 t + a_2 t^2 + a_3 h_c + a_4 h_c t + a_5 h_c t^2$$
$$+ a_6 h + a_7 ht + a_8 ht^2 + a_9 ht^3 + a_{10}(h_c)^2$$
$$+ a_{11} h^2 + a_{12} ht h_c , \qquad (24.B3)$$

where c and c_0 are the sound speed and the reference dry-air sound speed, respectively; a_0–a_{12} are coefficient constants listed in Table 24.8. With Table 24.8, the sound speed can be deduced by multiplying c/c_0 with the corresponding reference dry-air sound speed c_0.

For h_c values from 0% to 1%, and for t from 0 °C to 30 °C, for h from 0 to 1 (relative humidity 0% to 100%), and at a barometric pressure of 101.325 kPa, the sound speed computed using the numerical coefficients in Table 24.8 fits the theoretical data with a standard uncertainty of ± 48 ppm.

Uncertainties in c_0

Over the temperature range 0–30 °C, (24.B3) is fitted to a computation [24.71] for a real gas at 101.325 kPa at which the value $C_p - C_v$ is not greatly different from the universal constant R [24.75]. Based on this approximate assumption, the dry-air sound speed c_0 is 331.29 m/s, with an uncertainty of approximately 200 ppm [24.75], which encompasses sound speeds from 331.224 to 331.356 m/s [24.50].

Table 24.8 Coefficient constants for the computation of c/c_0 and γ/γ_0 (after [24.71])

Coefficient constants	c/c_0 (24.B3)	γ/γ_0 (24.B5)
a_0	1.000100	1.000034
a_1	1.8286×10^{-3}	-2.8100×10^{-6}
a_2	-1.6925×10^{-6}	-2.1210×10^{-7}
a_3	-3.1066×10^{-3}	-1.01223×10^{-3}
a_4	-7.9762×10^{-6}	-5.2500×10^{-6}
a_5	3.4000×10^{-9}	1.1290×10^{-8}
a_6	8.9180×10^{-4}	-3.4920×10^{-4}
a_7	7.7893×10^{-5}	-2.8560×10^{-5}
a_8	1.3795×10^{-6}	-5.9000×10^{-7}
a_9	9.5330×10^{-8}	-2.9710×10^{-8}
a_{10}	1.2990×10^{-5}	4.23427×10^{-6}
a_{11}	4.8016×10^{-5}	8.0000×10^{-7}
a_{12}	-1.4660×10^{-6}	5.1000×10^{-7}

Method 2

Alternatively, over the temperature range 0–30 °C, with a computation [24.72–74] that is based on the derivation of real-gas sound speed from virial coefficients, the dry-air sound speed c_0 calculated with 16 coefficients similar to those shown in Table 24.8, is 331.46 m/s. The uncertainty is approximately 545 ppm [24.73, 74], which encompasses sound speeds c_0 from 331.279 to 331.641 m/s. It should be noted that the sound speed of 331.29 m/s obtained with the first method is within the uncertainty range of the second method [24.50].

Within the normal range of environmental conditions during calibration, the following simplified equation [24.38, 40, 50] for the sound speed in humid air may be used

$$c = c_0 \left(\frac{T}{T_0} \right)^{1/2} (1 + 0.165 h_s) \Delta , \qquad (24.B4)$$

where h_s is the fractional molar concentration of moisture, and Δ is a factor to compensate for dispersion. Values of $\Delta = 0.99935$ and $\Delta = 0.99965$ are found in [24.81] and [24.82], respectively. A value of 1.0001 has also been obtained [24.72].

Over a frequency range of 10 Hz to 10 kHz, by ignoring the dispersion factor Δ, the uncertainty in the sound speeds obtained with methods 1 and 2 increases by approximately 300 ppm.

By ignoring dispersion, at the reference conditions of 23 °C, 101.325 kPa and 50% relative humidity, the sound speed obtained with (24.B4) is 196 ppm higher than that obtained with (24.B3).

24.B.3 Ratio of Specific Heats of Air

There have been several experimental [24.83, 84] and theoretical [24.71–74, 85, 86] investigations into the variation of the ratio of specific heats of air with temperature, humidity, pressure and carbon dioxide content [24.75], [24.86, pp. 36–39]. A general empirical equation has been obtained [24.71] for the calculation of the variation of γ / γ_0 with relative humidity h, temperature t and carbon dioxide content h_c

$$\gamma / \gamma_0 = a_0 + a_1 t + a_2 t^2 + a_3 h_c + a_4 h_c t + a_5 h_c t^2$$
$$+ a_6 h + a_7 h t + a_8 h t^2 + a_9 h t^3 + a_{10} (h_c)^2$$
$$+ a_{11} h^2 + a_{12} h t h_c , \qquad (24.B5)$$

where $a_0–a_{12}$ are coefficient constants listed in Table 24.8. With (24.B5), the above normalized ratio of specific heats can be deduced by multiplying γ / γ_0 by the corresponding reference dry-air ratio of specific

heats γ_0. For CO_2 content h_c values from 0% to 1%, and for temperatures of 0–30 °C, humidity from 0 to 1 (relative humidity 0% to 100%), and at a barometric pressure of 101.325 kPa, the ratio of specific heats computed using the numerical coefficients in Table 24.8, fit the theoretical data with a standard uncertainty of ±17 ppm.

Uncertainties in γ_0

Based on method 1 above [24.71], the dry-air specific heat ratio γ_0 is 1.3998. The standard uncertainty in γ_0 is approximately 400 ppm.

Similarly, based on method 2 [24.72–74], the dry-air specific heat ratio γ_0 is 1.4029; the standard uncertainty in γ_0 is over 760 ppm.

24.B.4 Viscosity and Thermal Diffusivity of Air for Capillary Correction

The viscosity η of air, in the parameters in (24.39) of Sect. 24.4.3, is a function of temperature t. An empirical equation which is based on a least-squares fit to published data [24.87] is

$$\eta = [17.26797 + (5.0756 \times 10^{-2})t$$
$$- (4.4028 \times 10^{-5})t^2 + (5.0000 \times 10^{-8})t^3]$$
$$\times 10^{-6} \, \text{Pa s} . \qquad (24.B6)$$

The equation for the thermal diffusivity α_t of air [24.38, 40] is

$$\alpha_t = \eta(9\kappa - 5)/(4\kappa\rho) \text{m}^2/\text{s} . \qquad (24.B7)$$

Uncertainties in η

Over the temperature range from −80 °C to 100 °C, when compared with the published data [24.87], the maximum deviation in η obtained with (24.B6) is ±1 ppm from the data points. However, the data point uncertainty may be several percent [24.87].

For standard dry air at a pressure of 101.325 kPa, the numerical values calculated with the above equations for the viscosity are 1.7268×10^{-5} Pa s and 1.8413×10^{-5} Pa s, at 0 and 23 °C, respectively; and the corresponding values for the thermal diffusivity are 1.81234×10^{-5} m²/s and 2.09549×10^{-5} m²/s, respectively.

Examples. Aiming at the highest accuracies (method 1), Table 24.9 gives the recommended values of the quantities given in (24.B2)–(24.B4) for the reference

Table 24.9 Recommended values for some physical quantities in (24.A1)–(24.B5) (ANSI S1.15: 2005)

Environmental conditions	Density of air ρ (kg/m^3)	Speed of sound c (m/s)	Ratio of specific heats γ	Viscosity of air η (Pa s)	Thermal diffusivity of air α_t (m^2/s)
$T = 23\,°C$ $p_s = 101325\,Pa$ $H = 50\%$	1.1859997	345.677519	1.39836198	1.841268×10^{-5}	2.105344×10^{-5}

Table 24.10 Recommended reference values applicable to dry air at 0 °C and 101.325 kPa. (ANSI S1.15: 2005)

Environmental conditions	Density of air ρ (kg/m^3)	Speed of sound c (m/s)	Ratio of specific heats γ	Viscosity of air η (Pa s)	Thermal diffusivity of air α_t (m^2/s)
$T = 0\,°C$ $p_0 = 101325\,Pa$	1.29296	331.28	1.3998	1.7268×10^{-5}	1.8123×10^{-5}

conditions. The values in Table 24.9 are shown with more decimals than necessary and are intended for testing computation programs that are used to calculate these quantities.

Again, aiming at the highest accuracies (method 1) and in view of the need to have reference values c_0 and γ_0 in (24.B3), (24.B4) and (24.B5), Table 24.10 gives the recommended values for dry air.

25. Sound Intensity

Finn Jacobsen

Sound intensity is a vector that describes the flow of acoustic energy in a sound field. The idea of measuring this quantity directly, instead of deducing it from the sound pressure on the assumption of some idealized conditions, goes back to the early 1930s, but it took about 50 years before sound intensity probes and analyzers came on the market. The introduction of such instruments has had a significant influence on noise control engineering.

This chapter presents the *energy corollary*, which is the basis for sound power determination using sound intensity. The concept of reactive intensity is introduced, and relations between fundamental sound field characteristics and active and reactive intensity are presented and discussed.

Measurement of sound intensity involves the determination of the sound pressure and the particle velocity at the same position simultaneously. The established method of measuring sound intensity employs two closely spaced pressure microphones. An alternative method is based on the combination of a pressure microphone and a particle velocity transducer.

Both methods are described, and their limitations are analyzed. Methods of calibrating and testing the two different measurement systems are also described. Finally the state of the art in the various areas of practical application of sound intensity measurement is summarized. These applications include the determination of the sound power of sources, identification and rank ordering of sources, and the measurement of the transmission of sound energy through partitions.

Sound waves are compressional oscillatory disturbances that propagate in a fluid. Moving fluid elements have kinetic energy, and changes in the pressure imply potential energy. Thus, there is a flow of energy involved in the phenomenon of sound; sources of sound emit sound power, and sound waves carry energy. In most cases the oscillatory changes undergone by the fluid are very small compared with the equilibrium values, from which it follows that typical values of the sound power emitted by sources of sound, which is an acoustic second-order quantity, are extremely small. The radiated sound power is a negligible part of the energy conversion of almost any source. However, energy considerations are nevertheless of great practical importance in acoustics. Their usefulness is mainly due to the fact that a statistical approach where the energy of the sound field is considered turns out to give extremely useful approximations in room acoustics and in noise control. In fact determining the sound power of sources is a central point in noise control engineering. The value and relevance of knowing the sound power radiated by a source is due to the fact that this quantity is largely independent of the surroundings of the source in the audible frequency range.

Sound intensity is a measure of the flow of acoustic energy in a sound field. More precisely, the sound in-

tensity is a vector that describes the time average of the net flow of sound energy per unit area. The units of this quantity are power per unit area (W/m^2).

The advent of sound intensity measurement systems in the early 1980s had a significant influence on noise control engineering. One of the most important advantages of this measurement technique is that sound intensity measurements make it possible to determine the sound power of sources in situ without the use of costly special facilities such as anechoic and reverbera-

tion rooms, and sound intensity measurements are now routinely used in the determination of the sound power of machinery and other sources of noise in situ. Other important applications of sound intensity include the identification and rank ordering of partial noise sources, the determination of the transmission losses of partitions, and the determination of the radiation efficiencies of vibrating surfaces. Because the intensity is a vector it is also more suitable for visualization of sound fields than, for instance, the sound pressure.

25.1 Conservation of Sound Energy

In the absence of mean flow the instantaneous sound intensity is the product of the sound pressure $p(t)$ and the particle velocity $\boldsymbol{u}(t)$

$$I(t) = p(t)\boldsymbol{u}(t) . \tag{25.1}$$

By combining the fundamental equations that govern a sound field, the equation of conservation of mass, the adiabatic relation between changes in the sound pressure and in the density, and Euler's equation of motion, one can show that the divergence of the instantaneous intensity equals the (negative) rate of change of the sum of the potential and kinetic energy density $w(t)$,

$$\nabla I(t) = -\frac{\partial w(t)}{\partial t} . \tag{25.2}$$

This is the equation of conservation of sound energy [25.1, 2], expressing the simple fact that if there is net flow of energy away from a point in a sound field then the sound energy density at that point is reduced at a corresponding rate. Integrating this equation over a volume V enclosed by the surface S gives, with Gauss's divergence theorem,

$$\int_S I(t)\,\mathrm{d}S = -\frac{\partial}{\partial t}\left(\int_V w(t)\,\mathrm{d}V\right)$$
$$= -\frac{\partial E(t)}{\partial t} , \tag{25.3}$$

in which $E(t)$ is the total sound energy in the volume as a function of time. The left-hand term is the total net outflow of sound energy through the surface, and the right-hand term is the rate of change of the total sound energy in the volume. In other words, the net flow of sound energy out of a closed surface equals the (negative) rate of change of the sound energy in the volume enclosed by the surface because energy is conserved.

In practice we are often concerned with stationary sound fields and the time-averaged sound intensity rather than the instantaneous intensity, that is,

$$\langle I(t)\rangle_t = \langle p(t)\boldsymbol{u}(t)\rangle_t . \tag{25.4}$$

For simplicity the symbol I is used for this quantity in what follows rather than the more precise notation $\langle I(t)\rangle_t$. If the sound field is harmonic with angular frequency $\omega = 2\pi f$ the complex representation of the sound pressure and the particle velocity can be used, which leads to the expression

$$I = \frac{1}{2}\,\text{Re}(p\boldsymbol{u}^*) , \tag{25.5}$$

where $\boldsymbol{u}^*$ denotes the complex conjugate of $\boldsymbol{u}$.

A consequence of (25.3) is that the integral of the normal component of the time-averaged sound intensity over a closed surface is zero,

$$\int_S I \cdot \mathrm{d}S = 0 , \tag{25.6}$$

when there is neither generation nor dissipation of sound energy in the volume enclosed by the surface, irrespective of the presence of steady sources *outside* the surface. If the surface encloses a steady source then the surface integral of the time-averaged intensity equals the sound power emitted by the source P_a, that is,

$$\int_S I \cdot \mathrm{d}S = P_a , \tag{25.7}$$

irrespective of the presence of other steady sources outside the surface. This important equation is the basis for sound power determination using sound intensity.

In a plane wave propagating in the r-direction the sound pressure p and the particle velocity u_r are in phase and related by the characteristic impedance of air ρc, where ρ is the density of air and c is the speed of

sound,

$$u_r(t) = \frac{p(t)}{\rho c} \, . \tag{25.8}$$

Under such conditions the intensity is

$$I_r = \langle p(t)u_r(t)\rangle_I = \frac{\langle p^2(t)\rangle_t}{\rho c} = \frac{p_{\text{rms}}^2}{\rho c} = \frac{|p|^2}{2\rho c} \, , \tag{25.9}$$

where p_{rms}^2 is the mean square pressure (the square of the root-mean-square pressure) and p in the rightmost expression is the complex amplitude of the pressure in a harmonic plane wave. In the particular case of a plane propagating wave the sound intensity is seen to be simply related to the rms sound pressure, which can be measured with a single microphone. Under free-field conditions the sound field generated by any source of finite extent is *locally plane* sufficiently far from the source. This is the basis for the free-field method of sound power determination (which requires an anechoic room); the sound pressure is measured at a number of points on a sphere that encloses the source [25.3].

A practical consequence of (25.9) is the following extremely simple relation between the sound intensity level ($I_{\text{ref}} = 1\,\text{pW/m}^2$) and the sound pressure level ($p_{\text{ref}} = 20\,\mu\text{Pa}$),

$$L_I \simeq L_p \, . \tag{25.10}$$

This is due to the fortuitous fact that

$$\rho c \simeq \frac{p_{\text{ref}}^2}{I_{\text{ref}}} = 400\,\text{kg/(m}^2\,\text{s)} \tag{25.11}$$

in air under normal ambient conditions. At a static pressure of 101.3 kPa and a temperature of 23 °C the error of (25.10) is about 0.1 dB.

However, it should be emphasized that in the general case there is *no* simple relation between the sound intensity and the sound pressure, and both the sound pressure and the particle velocity must be measured simultaneously and their instantaneous product time-averaged as indicated by (25.4). This requires the use of a more complicated device than a single microphone.

25.2 Active and Reactive Sound Fields

Some typical sound field characteristics can be identified. For example, the sound field far from a source under free-field conditions has certain well-known properties (dealt with above); the sound field near a source has other characteristics, and some characteristics are typical of a reverberant sound field. One of the characteristics of the sound field near a source is that the sound pressure and the particle velocity are partly out of phase. To describe such a phenomenon one may introduce the concepts of *active* and *reactive* sound fields.

It takes four second-order quantities to describe the distributions and fluxes of sound energy in a stationary sound field completely [25.4–6]: potential energy density, kinetic energy density, active intensity (the quantity given by (25.4) and (25.5), usually simply referred to as the intensity), and the reactive intensity. The last of these quantities represents the non-propagating, oscillatory sound energy flux that is characteristic of a sound field in which the sound pressure and the particle velocity are in quadrature (90° out of phase), as for instance in the near field of a small source. The reactive intensity is a vector defined as the imaginary part of the product of the complex pressure and the complex conjugate of the particle velocity,

$$\boldsymbol{J} = \frac{1}{2}\text{Im}(p\boldsymbol{u}^*) \tag{25.12}$$

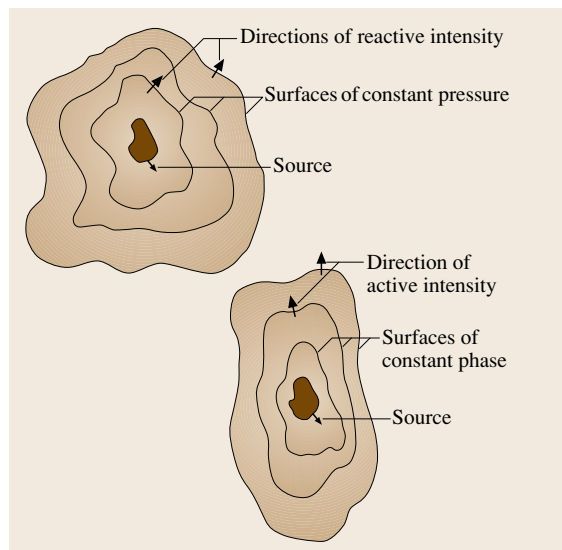
with the $\mathrm{e}^{i\omega t}$ sign convention (cf. (25.5)). Units: power per unit area (W/m^2). More-general time-domain formulations based on the Hilbert transform are also available [25.7]. Unlike the usual active in-


Fig. 25.1 Surfaces of constant phase and surfaces of constant pressure (after [25.4])
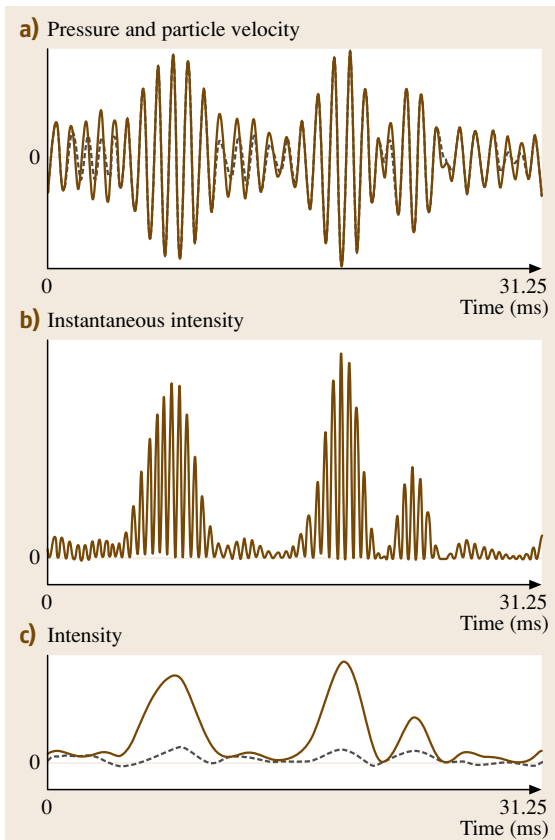

Fig. 25.2a–c Measurement 30 cm from a loudspeaker driven with one-third octave noise with a center frequency of 1 kHz. **(a)** Instantaneous sound pressure (*solid line*); instantaneous particle velocity multiplied by ρc (*dashed line*); **(b)** instantaneous sound intensity; **(c)** the real part of the complex instantaneous intensity (*solid line*); the imaginary part of the complex instantaneous intensity (*dashed line*) (after [25.7])

Fig. 25.3a–c Measurement in the near field of a loudspeaker driven with one-third octave noise with a center frequency of 250 Hz. *Key* as in Fig. 25.2 (after [25.7])

tensity, the reactive intensity remains a somewhat controversial issue although the quantity was introduced more than sixty years ago [25.8], perhaps because the vector J has no obvious physical meaning [25.9], or perhaps because describing an oscillatory flux by a time-averaged vector seems peculiar to some. However, even though the reactive intensity is of no obvious direct practical use it is nevertheless quite convenient that we have a quantity that makes it possible to describe and quantify the particular sound field conditions in the near field of sources in a precise manner. This will become apparent in Sect. 25.3.2.

It can be shown from (25.5) that the active intensity is proportional to the gradient of the phase of the sound pressure [25.10],

$$I = -\frac{|p|^2}{2\rho c} \frac{\nabla \varphi}{k} \, , \tag{25.13}$$

where $k = \omega/c$ is the wavenumber. Thus the active intensity is orthogonal to surfaces of equal phase, that is, the wavefronts [25.4]. Likewise it can be shown from (25.12) that the reactive intensity is proportional to the gradient of the mean square pressure [25.11],

$$J = -\frac{\nabla(|p|^2)}{4\rho ck} \, , \tag{25.14}$$

a) Pressure and particle velocity

b) Instantaneous intensity

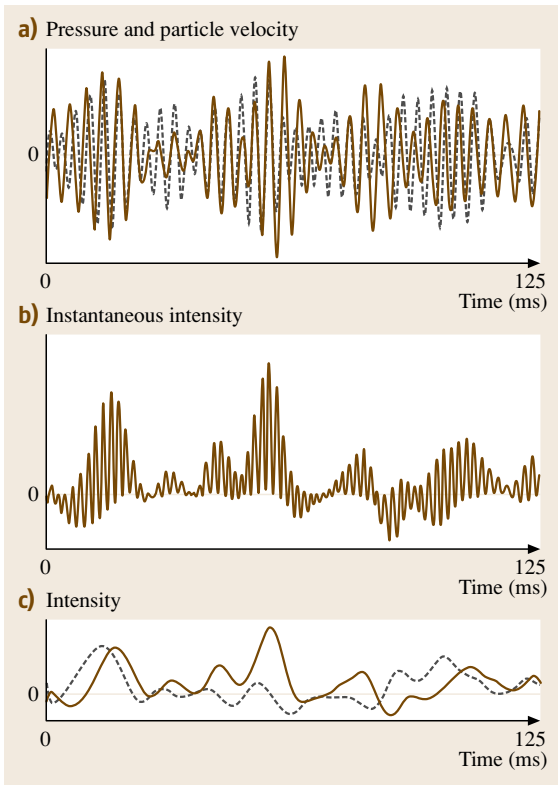
c) Intensity


Fig. 25.4a–c Measurement 30 cm from a vibrating steel box driven with one-third octave noise with a center frequency of 250 Hz. *Key* as in Fig. 25.2 (after [25.7])

a) Pressure and particle velocity

b) Instantaneous intensity

c) Intensity

Fig. 25.5a–c Measurement in a reverberation room driven with one-third octave noise with a center frequency of 500 Hz. *Key* as in Fig. 25.2 (after [25.7])

and thus is orthogonal to surfaces of equal pressure [25.4] (Fig. 25.1).

Very near a sound source the reactive field is often stronger than the active field at low frequencies. However, the reactive field dies out rapidly with increasing distance to the source. Therefore, even at a fairly moderate distance from the source, the sound field is dominated by the active field. The extent of the reactive field depends on the frequency and the radiation characteristics of the sound source. In practice, the reactive field may usually be assumed to be negligible at a distance greater than, say, half a wavelength from the source.

The fact that I is the real part and J is the imaginary part of the product of the pressure and the complex conjugate of the particle velocity has led to the concept of complex sound intensity [25.5, 10],

$$I + iJ = \frac{1}{2} p u^* \,. \tag{25.15}$$

Note that

$$\frac{I_r + iJ_r}{\frac{1}{2}|u_r|^2} = \frac{\frac{1}{2}|p|^2}{I_r - iJ_r} = \frac{p}{u_r} = Z_s \,, \tag{25.16}$$

which shows that there is a simple relation between the complex intensity and the wave impedance of the sound field Z_s [25.6, 10]. It is also worth noting that

$$\frac{I_r^2 + J_r^2}{\frac{1}{4}|p|^2|u_r|^2} = 1 \,. \tag{25.17}$$

Figures 25.1–25.4 demonstrate the physical significance of the active and reactive intensities. The figures show the sound pressure and a component of the particle velocity as functions of time, the corresponding instantaneous sound intensity, and the real and imaginary part of the *complex instantaneous intensity*, that is,

the quantity

$$I_c(t) = \frac{1}{2} (p(t) + i \tilde{p}(t)) (u(t) - i \tilde{u}(t)) , \qquad (25.18)$$

where $\tilde{p}(t)$ and $\tilde{u}(t)$ are the Hilbert transforms of the pressure and the particle velocity [25.12]. The time average of this quantity in a steady sound field is the complex intensity given by (25.15).

In a narrow-band sound field the real and imaginary parts of the complex instantaneous intensity are low-pass signals that represent short-time average values of the two components of (25.15) [25.7].

Figure 25.2 shows the result of a measurement at a position 30 cm (about one wavelength) from a small loudspeaker driven with a band of one-third octave noise. The sound pressure and the particle velocity (multiplied by ρc) are almost identical; therefore the instantaneous intensity is always positive, and the real part of the complex instantaneous intensity is much larger than the imaginary part. This is an active sound field.

Figure 25.3 shows the result of a similar measurement at a distance of a few centimeters (less than one tenth of a wavelength) from the loudspeaker cone. In this case the sound pressure and the particle velocity are almost in quadrature, and as a result the instantaneous intensity fluctuates about zero, that is, sound energy flows back and forth, out of and into the loudspeaker, and the imaginary part of the complex instantaneous intensity is much larger than the real part. This is an example of a strongly reactive sound field. Figure 25.4 shows data measured about 30 cm from a vibrating box made of 3 mm steel plates. It is apparent that the vibrating structure generates a much more complicated sound field than a loudspeaker does. And finally Fig. 25.5 shows the result of a measurement in a reverberant room several meters from the loudspeaker generating the sound field. Here the sound pressure and the particle velocity appear to be uncorrelated signals; this is neither an active nor a reactive sound field; this is a diffuse sound field.

25.3 Measurement of Sound Intensity

Acousticians have attempted to measure sound intensity since the early 1930s, but measurement of sound intensity is more difficult than measurement of the sound pressure, and it took almost 50 years before sound intensity measurement systems came on the market. The first international standards for measurements using sound intensity and for instruments for such measurements were issued in the middle of the 1990s. A description of the history of the development of sound intensity measurement up to the middle of the 1990s is given in *Fahy*'s monograph *Sound Intensity* [25.2].

Measurement of sound intensity involves determination of the sound pressure and the particle velocity at the same position simultaneously. In the general case at least two transducers are required. There are three possible measurement principles: (i) one can determine the particle velocity from a finite-difference approximation of the pressure gradient using two closely spaced pressure microphones and use the average of the two microphone signals as the pressure [25.2, 13] (the *two-microphone* or *p–p* method); (ii) one can combine a pressure microphone with a particle velocity transducer [25.2] (the *p–u* method); and (iii) one can determine the pressure from a finite-difference approximation of the divergence of the particle velocity [25.14] (the *u–u* method). The first of these methods is well es-

tablished. The second method has been hampered by the absence of reliable particle velocity transducers, but with the advent of the Microflown particle velocity sensor in the mid-1990s [25.15, 16] it seems to have potential [25.17]. The third method, which involves three matched pairs of particle velocity transducers, has never been used in air and is mentioned here for the sake of completeness.

25.3.1 The *p–p* Measurement Principle

For more than 25 years the *p–p* method based on two closely spaced pressure microphones (or hydrophones) has dominated sound intensity measurement. This method relies on a finite-difference approximation to the sound pressure gradient. Both the International Electrotechnical Commission (IEC) standard on instruments for the measurement of sound intensity and the corresponding American National Standards Institute (ANSI) standard deal exclusively with *p–p* measurement systems [25.18, 19]. The success of this method is related to the fact that condenser microphones are more stable and reliable than any other acoustic transducer.

Two pressure microphones are placed close together. The particle velocity component in the direction of the axis through the two microphones r is obtained

from Euler's equation of motion

$$\frac{\partial p(t)}{\partial r} + \rho \frac{\partial u_r(t)}{\partial t} = 0 \,, \qquad (25.19)$$

where the gradient of the pressure is approximated by a finite difference. Thus the particle velocity is determined as

$$\hat{u}_r(t) = -\frac{1}{\rho} \int\limits_{-\infty}^{t} \frac{p_2(\tau) - p_1(\tau)}{\Delta r} \, \mathrm{d}\tau \,, \qquad (25.20)$$

where p_1 and p_2 are the signals from the two microphones, Δr is the microphone separation distance, and τ is a dummy time variable. The caret indicates that the result is an estimate, which of course is an approximation to the true particle velocity. The sound pressure at the center of the probe is estimated as

$$\hat{p}(t) = \frac{p_1(t) + p_2(t)}{2} \,, \qquad (25.21)$$

and the time-averaged intensity component in the r-direction is

$$\begin{aligned}\hat{I}_r &= \langle \hat{p}(t)\hat{u}_r(t) \rangle_t \\ &= \left\langle \frac{p_1(t) + p_2(t)}{2} \int\limits_{-\infty}^{t} \frac{p_1(\tau) - p_2(\tau)}{\rho \Delta r} \, \mathrm{d}\tau \right\rangle_t \,.\end{aligned}$$
$$(25.22)$$

Some sound intensity analyzers use (25.22) to measure the intensity in frequency bands (usually one-third octave bands). Another type calculates the intensity from the imaginary part of the cross spectrum of the two microphone signals $S_{12}(\omega)$,

$$\hat{I}_r(\omega) = -\frac{1}{\omega \rho \Delta r} \mathrm{Im}\,[S_{12}(\omega)] \,. \qquad (25.23)$$

The frequency-domain formulation is equivalent to the time-domain formulation, and (25.23) gives exactly the same result as (25.22) when the intensity spectrum is integrated over the frequency band of concern [25.20, 21]. The frequency-domain formulation makes it possible to determine sound intensity with a dual-channel fast Fourier transform (FFT) analyzer.

Some sound intensity analyzers use The most common microphone arrangement is known as *face-to-face*, but another called *side-by-side* is occasionally used. The latter arrangement has the advantage that the diaphragms of the microphones can be placed very near a radiating surface, but the disadvantage that the microphones disturb each other acoustically more than they do in the other configuration. Figure 25.6 shows a three-dimensional (3-D) intensity probe produced by Ono-Sokki with yet another configuration. At high frequencies the face-to-face con-
Fig. 25.6 Three-dimensional sound intensity probe for vector measurements (Ono Sokki, Japan)

Fig. 25.7 Sound intensity probe with the microphones in the *face-to-face* configuration (Brüel & Kjær, Nærum)

figuration with a solid plug between the microphones is superior [25.22]. Such a sound intensity probe produced by Brüel & Kjær is shown in Fig. 25.7. The *spacer* between the microphones tends to stabilize the *acoustic distance* between them.

Sources of Error in Measurement of Sound Intensity with $p-p$ Measurement Systems

It is far more difficult to measure sound intensity than to measure sound pressure, and a surprisingly large part of the literature on sound intensity is concerned with identifying and studying the sources of error. One confusing problem is that the accuracy of any sound intensity measurement system depends strongly on the sound field

under study; sometimes such measurements are not very difficult, but under certain conditions even very small imperfections of the measuring equipment can have a significant influence on the results. Another complication is that small local errors are sometimes amplified into large global errors when the intensity is integrated over a closed surface [25.23]. The opposite may also happen. Yet another problem is that the distribution of the sound intensity in the near field of a source of sound often is far more complicated than the distribution of the sound pressure, indicating that sound fields can be much more complicated than earlier realized [25.2]. The problems are reflected in the fairly complicated international and national standards for sound power determination using sound intensity, ISO 9614-1, ISO 9614-2, ISO 9614-3, and ANSI S12.12 [25.24–27].

The most important limitations of sound intensity measurement systems based on the p–p approach are caused by the finite-difference approximation, scattering and diffraction, and instrumentation phase mismatch.

The Finite-Difference Error

The accuracy of the finite-difference approximation obviously depends on the separation distance and the wavelength. For a plane wave of axial incidence the finite-difference error can be shown to be [25.22]

$$\frac{\hat{I}_r}{I_r} = \frac{\sin k\Delta r}{k\Delta r} \ . \tag{25.24}$$

This expression is shown in Fig. 25.8 for various values of the microphone separation distance. More complicated expressions for other sound field conditions are available in the literature [25.30]. The upper frequency limit of p–p intensity probes has generally been considered to be the frequency at which the finite-difference error for axial plane-wave incidence is acceptably small. With 12 mm between the microphones (a typical value) this gives an upper limiting frequency of about 5 kHz.

Scattering and Diffraction

It is evident that the effect of scattering and diffraction depends on the geometry of the microphone arrangement. Several configurations are possible, but in the early 1980s it was shown experimentally that the face-to-face configuration with a solid spacer between the two microphones is particularly favorable [25.22]. About 15 years later it was discovered that the effect of scattering and diffraction in combination with the resonance of the small cavity between the spacer and
Fig. 25.8 Finite-difference error of an ideal p–p sound intensity probe in a plane wave of axial incidence for different values of the separation distance: 5 mm (*solid line*); 8.5 mm (*dashed line*); 12 mm (*dotted line*); 20 mm (*long dashes*); 50 mm (*dash-dotted line*) (after [25.28])

the diaphragm of each microphone not only tends to counterbalance the finite-difference error but in fact for a certain length of the spacer cancels it almost perfectly over a wide frequency range under fairly general sound field conditions [25.28]. (This finding had been antic-
Fig. 25.9 Pressure increase on the two microphones of a sound intensity probe with $\frac{1}{2}$ inch microphones separated by a 12 mm spacer for axial sound incidence. Experimental results (*solid line*); numerical results (*dashed line*) (after [25.29])
Fig. 25.10 Error of a sound intensity probe with $\frac{1}{2}$ inch microphones in the face-to-face configuration in a plane wave of axial incidence for different spacer lengths: 5 mm (*solid line*); 8.5 mm (*dashed line*); 12 mm (*dotted line*); 20 mm (*long dashes*); 50 mm (*dash-dotted line*) (after [25.28])

ipated much earlier [25.31].). Figure 25.9 shows the increase of the pressure on two $\frac{1}{2}$ inch microphones in the face-to-face configuration for axial sound incidence, and Fig. 25.10, which corresponds to Fig. 25.8, shows the error of the resulting sound intensity estimate. A practical consequence is that the upper frequency limit of a sound intensity probe based on two $\frac{1}{2}$ inch microphones separated by a 12 mm spacer in the face-to-face arrangement is about 10 kHz, which is an octave higher than the frequency limit determined by the finite-difference approximation. The combination of $\frac{1}{2}$ inch microphones and a 12 mm spacer is now regarded as optimal, and longer spacers are only used when the focus is exclusively on low frequencies. With a longer spacer between $\frac{1}{2}$ inch microphones the resonance occurs at too high a frequency to be of any help and the finite-difference error will dominate; thus an intensity probe with a 50 mm spacer has an upper frequency limit of about 1.2 kHz.

Phase Mismatch

Unless the measurement is compensated for phase mismatch the microphones for measurement of sound intensity with the p–p method have to be phase-
Fig. 25.11 Error due to a phase error of 0.3° in a plane propagating wave (after [25.32])

matched extremely well, and state-of-the-art sound intensity microphones are matched to a maximum phase response difference of 0.05° below 250 Hz and a phase difference proportional to the frequency above 250 Hz (say, 0.2° at 1 kHz) [25.33] The proportionality to the frequency is a consequence of the fact that phase mismatch in this frequency range is caused by differences between the resonance frequencies and the damping of the two microphones [25.34].

Phase mismatch between the two measurement channels is the most serious source of error in measurement of sound intensity with p–p measurement systems, even with the best equipment that is available today. It can be shown that a small (positive or negative) phase mismatch error φ_{pe} gives rise to a bias error that can be approximated by the following expression,

$$\hat{I}_r \simeq I_r - \frac{\varphi_{pe}}{k\Delta r}\frac{p_{rms}^2}{\rho c} = I_r\left(1 - \frac{\varphi_{pe}}{k\Delta r}\frac{p_{rms}^2/\rho c}{I_r}\right),$$

(25.25)

where I_r is the true intensity (unaffected by phase mismatch) [25.35]. This expression shows that the effect of a given phase error is inversely proportional to the frequency and the microphone separation distance and is proportional to the ratio of the mean square sound pressure to the sound intensity. If this ratio (which in logarithmic form is known as the *pressure-intensity index*) is large, say, more than 10 dB, then the true phase difference between the two pressure signals in the sound

field is small and even the small phase errors mentioned above will give rise to significant bias errors. Because of phase mismatch it will rarely be possible to make reliable measurements below, say, 80 Hz unless a longer spacer than the usual 12 mm spacer is used.

Figure 25.11 shows the effect of a positive phase error of 0.3° in a plane wave of axial incidence, calculated for different values of the microphone separation distance Δr. It is apparent that large underestimation errors occur at low frequencies. Note, however, that still larger errors will occur when the ratio of the mean square pressure to the sound intensity takes a larger value than unity, which is likely to happen unless the measurement takes place in an anechoic room. It should also be noted that a frequency-independent value of the phase error φ_{pe} is very unlikely [25.34]. Finally it is worth mentioning again that state-of-the-art microphone pairs for sound intensity measurements are much better matched now than within 0.3°.

Inspection of (25.25) shows that the simple expedient of reversing a p–p probe makes it possible to eliminate the influence of p–p phase mismatch; the intensity changes sign but the error does not [25.20, 36]. Unfortunately, most p–p intensity probes are not symmetrical and are therefore not suitable for real measurements with the probe reversed.

The ratio of the phase error to the product of the frequency and the microphone separation distance can be measured (usually in the form of the so-called *pressure-residual intensity index*) by exposing the two pressure microphones to the same pressure. The residual intensity is the *false* sound intensity indicated by the instrument when the two microphones are exposed to the same pressure p_0, for instance in a small cavity driven by a wide-band source. A commercial example of such a device is shown in Fig. 25.12. When the pressure on the two microphones is the same (in amplitude as well as in phase) the true intensity is zero, and the magnitude of the indicated, residual intensity,

$$I_0 = -\frac{\varphi_{pe}}{k\Delta r}\frac{p_0^2}{\rho c} ,$$
(25.26)

should obviously be as small as possible. Expressed in terms of this quantity (25.25) takes the form

$$\hat{I}_r = I_r + \left(\frac{I_0}{p_0^2}\right)p_{rms}^2 = I_r\left(1 + \frac{I_0}{p_0^2}\frac{\frac{p_{rms}^2}{\rho c}}{\frac{p_0^2}{\rho c}}\frac{1}{I_r}\right).$$
(25.27)

An alternative form that follows directly from (25.27) has the advantage of expressing the error in
Fig. 25.12 Coupler for measurement of the pressure-residual intensity index of p–p sound intensity probes (Brüel & Kjær, Denmark)

terms of the available, biased intensity estimate [25.37],

$$\hat{I}_r = I_r\left(1 - \frac{I_0}{\frac{p_0^2}{\rho c}}\frac{\frac{p_{rms}^2}{\rho c}}{\hat{I}_r}\right)^{-1} .$$
(25.28)

The pressure-residual intensity index of the measurement system can be measured once (and should be checked occasionally). Combined with the pressure-intensity index of the actual measurement it makes it possible to estimate the error. Some analyzers can give warnings when the error due to phase mismatch as predicted by (25.28) exceeds a specified level. The bias error predicted by (25.28) is less than $\pm 10\log(1 \pm 10^{-K/10})$dB if the pressure-intensity index of the measurement, δ_{pI}, is less than the pressure-residual intensity index, δ_{pIo}, minus the *bias error index K*, that is

$$\delta_{pI} = 10\log\left(\frac{\frac{p_{rms}^2}{\rho c}}{|I_r|}\right) < \delta_{pIo} - K$$

$$= 10\log\left(\frac{\frac{p_0^2}{\rho c}}{|I_0|}\right) - K .$$
(25.29)

The larger the value of K the smaller the maximum error that can occur and the stronger and more restrictive on the range of measurement is the requirement, as demonstrated by Fig. 25.13. Note that a negative residual intensity (which leads to underestimation of a positive intensity component) gives larger errors (in decibels) than a corresponding positive residual intensity (which leads to overestimation of a positive intensity component) unless the error is small. A bias error index of 7 dB corresponds to the error due to phase mismatch being less than 1 dB (*survey*
Fig. 25.13 Maximum error due to phase mismatch as a function of the bias error index K for negative residual intensity (*upper curve*) and for positive residual intensity (*lower curve*) (after [25.38])

Fig. 25.14 Pressure-intensity index on a surface enclosing a noise source determined under three different conditions: measurement using a reasonable surface (*solid line*); measurement using an eccentric surface (*dashed line*); measurement with strong background noise at low frequencies (*long dashes*) (after [25.39])

accuracy [25.25]), and a bias error index of 10 dB corresponds to the error being less than 0.5 dB (*engineering accuracy* [25.25]). These values correspond to the phase error of the equipment being five and ten times less than the actual phase angle in the sound field, respectively. The quantity $\delta_{pIo} - K$ is known as the *dynamic capability* of the measurement system.

Many applications of sound intensity measurements involve integrating the normal component of the intensity over a surface. The global versions of (25.27) and (25.28) are found by integrating the normal component over a surface that encloses a source. The result is the expressions

$$\hat{P}_a = \int_S \hat{I}\, dS \simeq P_a \left(1 - \frac{\varphi_{pe}}{k\Delta r} \frac{\int_S \left(\frac{p_{rms}^2}{\rho c} \right) dS}{\int_S I\, dS} \right)$$

$$= P_a \left(1 + \frac{I_0 \rho c}{p_0^2} \frac{\int_S \left(\frac{p_{rms}^2}{\rho c} \right) dS}{\int_S I\, dS} \right)$$

$$= P_a \left(1 - \frac{I_0 \rho c}{p_0^2} \frac{\int_S \left(\frac{p_{rms}^2}{\rho c} \right) dS}{\int_S \hat{I}\, dS} \right)^{-1}, \qquad (25.30)$$

where P_a is the true sound power of the source within the surface [25.35]. The condition expressed by (25.29)

still applies, although the pressure-intensity index now involves averaging over the measurement surface.

Sources outside the measurement surface do not contribute to the surface integral of the true intensity (the denominator of the second term on the right-hand side of (25.30)), but they invariably increase the surface integral of the mean square pressure (the numerator of the second term), as demonstrated by the results shown in Fig. 25.14. It follows that even a very small phase error imposes restrictions on the amount of extraneous noise that can be tolerated in sound power measurement with a p–p sound intensity measurement system.

Other Sources of Error

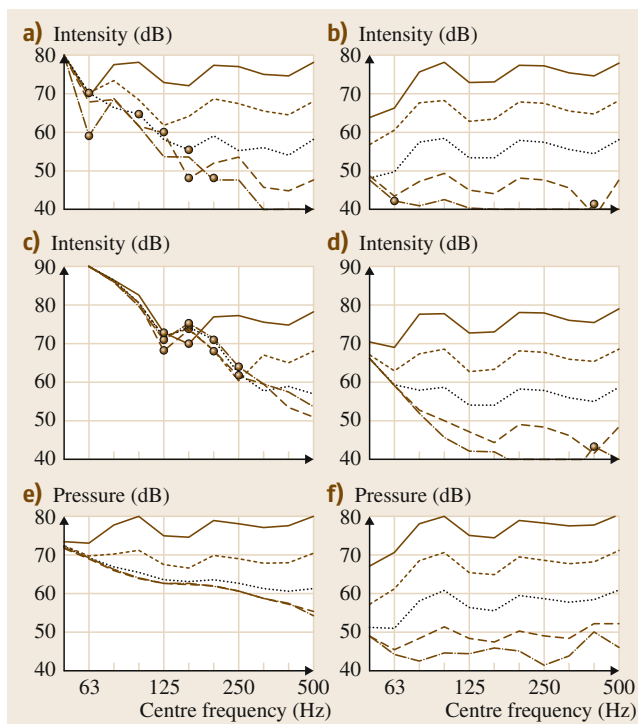
It can be difficult to avoid that the intensity probe is exposed to airflow, for example in measurements near air-cooled machinery. Strictly speaking the p–p measurement principle is simply not valid in such circumstances [25.40]. However, practice shows that the resulting fundamental error is insignificant in airflows of moderate velocities (say, up to 10 m/s), and that the false, low-frequency intensity signals produced by turbulence are a more serious problem under such conditions. Turbulence generates pressure fluctuations (flow noise, unrelated to the sound field) that contaminate the signals from the two microphones, and at low frequencies these signals are correlated and thus interpreted by the measurement system as intensity. The resulting false intensity is unpredictable and can be positive or negative. This is mainly a problem below 200 Hz [25.41]. A longer spacer helps reducing


Fig. 25.15a–f Measurement 60 cm from a loudspeaker and a fan producing airflow of about 4 m/s at the measurement position. **(a,b)** 50 mm spacer; **(e,f)** 12 mm spacer; **(a,c,e)** no windscreen; **(b,d,f)** windscreen. Asterisk: negative intensity estimate. Nominal sound power level of source: 100 dB (*solid line*); 90 dB (*dashed line*); 80 dB (*dotted line*); 70 dB (*long dashes*); 60 dB (*dash-dotted line*) (after [25.41])

the problem, but the most efficient expedient is to use a windscreen of porous foam, as demonstrated by the results shown in Fig. 25.15. However, windscreens give rise to errors at low frequencies in highly reactive sound fields, because the losses of the foam modify Euler's equation of motion (25.19) [25.42, 43]. Thus measurements with windscreened probes very near sources should be avoided.

The finite averaging time used in any measurement results in a random error, and this random error is usually larger in sound intensity measurements than in sound pressure measurements – sometimes much larger [25.44–46]. Thus to maintain the same random error as in measurement of the sound pressure one will usually have to average over a longer time. However, most applications of sound intensity involve integrating over a measurement surface, and since it can be shown that it is the total averaging time that matters [25.47],

the problem is less serious in practice than one might expect from observations at discrete positions.

Yet another source of error is the electrical self-noise from the microphones and preamplifier circuits. Although the level of such noise is very low in modern $\frac{1}{2}$ inch condenser microphones it can have a serious influence on sound intensity measurement at low levels. The noise increases the random error associated with a finite averaging time at low frequencies, in particular if the pressure-intensity index takes a large value. The problem reveals itself by poor or nonexistent repeatability [25.48].

Calibration of *p−p* Sound Intensity Measurement Systems

Calibration of *p−p* sound intensity measurement systems is fairly straightforward: the two pressure microphones are calibrated with a pistonphone in the usual manner. However, because of the serious influence of phase mismatch the pressure-residual intensity index should also be determined. The IEC standard for sound intensity instruments and its North American counterpart [25.18, 19] specify minimum values of the acceptable pressure-residual intensity index for the probe as well as for the processor; according to the results of a test the instruments are classified as being of class 1 or class 2. The test involves subjecting the two microphones of the probe to identical pressures in a small cavity driven with wide-band noise. A similar test of the processor involves feeding the same signal to the two channels. The pressure and intensity response of the probe should also be tested in a plane propagating wave as a function of the frequency, and the directional response of the probe is required to follow the ideal cosine law within a specified tolerance.

According to the two standards a special test is required in the frequency range below 400 Hz: the intensity probe should be exposed to the sound field in a standing-wave tube with a specified standing wave ratio (24 dB for probes of class 1). When the sound intensity probe is drawn through this interference field the sound intensity indicated by the measurement system should be within a certain tolerance.

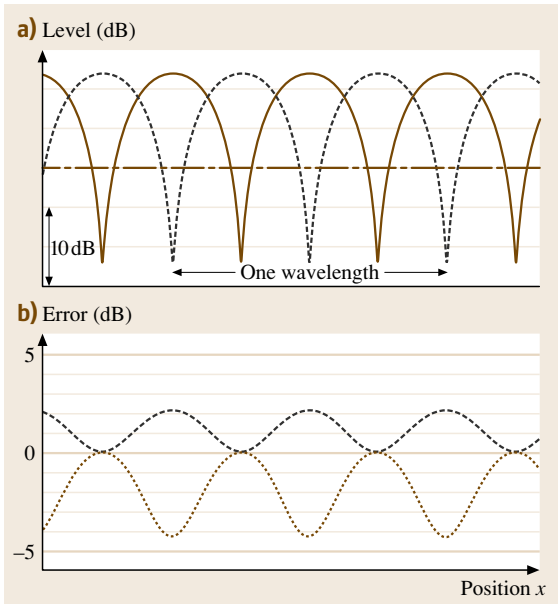
Figure 25.16a illustrates how the sound pressure, the particle velocity and the sound intensity vary with position in a one-dimensional interference field with a standing-wave ratio of 24 dB. It is apparent that the pressure-intensity index varies strongly with the position in such a sound field. Accordingly, the influence of a given phase error depends on the position, as shown in the calculations presented in Fig. 25.16b. Fig-


Fig. 25.16 (a) Sound pressure level (*solid line*), particle velocity level (*dashed line*), and sound intensity level (*dash-dotted line*) in a standing wave with a standing-wave ratio of 24 dB **(b)** Estimation error of a sound intensity measurement system with a residual pressure-intensity index of 14 dB (positive and negative residual intensity) (after [25.50])

ure 25.17 shows an example of measurements with an intensity probe drawn through a standing-wave tube. The standing-wave test will also reveal other sources of error than phase mismatch, for example, the influence of an unacceptably high vent sensitivity of the microphones [25.49].

25.3.2 The *p–u* Measurement Principle

A *p–u* sound intensity measurement system combines two fundamentally different transducers, a pressure microphone and a particle velocity transducer. The sound intensity is simply the time average of the instantaneous product of the pressure and particle velocity signal,

$$I_r = \langle p(t)u_r(t)\rangle_t = \frac{1}{2}\,\mathrm{Re}\left(pu_r^*\right)\;, \tag{25.31}$$

where the latter expression is based on the complex exponential representation. In the frequency domain the expression takes the form

$$I_r(\omega) = S_{pu}(\omega). \tag{25.32}$$

Equation (25.32) gives the same result as (25.31) when the intensity spectrum is integrated over the frequency band of concern.

A *p–u* sound intensity probe that combined a pressure microphone with a transducer based on the convection of an ultrasonic beam by the particle velocity flow was produced by Norwegian Electronics
Fig. 25.17 Response of a sound intensity probe exposed to a standing wave: sound pressure, particle velocity, intensity, and phase-corrected intensity (after [25.51])

Fig. 25.18 A *p–u* sound intensity probe (by Microflown Technologies, The Netherlands)

Fig. 25.19 Sound power of a source measured using a *p–u* intensity probe produced by Microflown and *p–p* intensity probe produced by Brüel & Kjær. Brüel & Kjær probe on large measurement surface (*solid line*); Microflown probe on large measurement surface (*dashed line*); Microflown probe on small measurement surface (*dotted line*) (after [25.17])

for some years [25.2, 52], but the device was somewhat bulky, very sensitive to airflow, and difficult to calibrate, and production was stopped in the middle of the 1990s. More recently, a micromachined transducer called the *Microflown* has become available for measurement of the particle velocity [25.15], and an intensity probe based on this device in combination with a small pressure microphone is now in commercial production [25.16]; see Fig. 25.18. The Microflown particle velocity transducer consists of two short, thin, closely spaced wires, heated to about 300 °C [25.15]. Their resistance depends on the temperature. A particle velocity signal in the perpendicular direction changes the temperature distribution instantaneously, because one of the wires will be cooled more than the other by the airflow. The frequency response of this device is relatively flat up to a corner frequency of the order of 1 kHz caused by diffusion effects related to the distance between the two wires. A second corner frequency at about 10 kHz is caused by the thermal heat capacity of the wires. Between 1 and 10 kHz there is a roll-off of 6 dB per octave. The particle velocity transducer is combined with a small electret condenser microphone in the $\frac{1}{2}$ inch sound intensity probe shown in Fig. 25.18. The velocity transducer is mounted on a small, solid cylinder, and the condenser microphone is mounted inside another, hollow cylinder. The geometry of this arrangement increases the sensitivity of the velocity transducer. Unlike Norwegian Electronics' intensity probe the Microflown probe is very small – in fact much smaller than a standard *p–p* probe. Thus it is possible to measure very

close to a vibrating surface with this device. At the time of writing there is still relatively little experimental evidence of the practical utility of the Microflown intensity probe, but it seems to be promising if difficult to calibrate [25.17]. Figure 25.19 shows the results of sound power measurements with a Microflown intensity probe in comparison with similar results made with a Brüel & Kjær *p–p* sound intensity probe.

A variant of the *p–u* method, the *surface intensity method*, combines a pressure microphone with a transducer that measures the vibrational displacement, velocity or acceleration of a solid surface, for example with an accelerometer or a laser vibrometer [25.53–55]; see Fig. 25.20. Obviously, this method can only give the normal component of the sound intensity near vibrating surfaces. A disadvantage of the surface intensity method is that sound fields near complex sources are often very complicated, which makes it necessary to measure at many points.

Sources of Error in Measurement of Sound Intensity with *p–u* Measurement Systems

Evidently, some of the limitations of any *p–u* intensity probe must depend on the particulars of the particle velocity transducer. However, some general problems are described in the following.
Fig. 25.20 Hand-held probe for surface intensity measurement (after [25.53])

Phase Mismatch

Irrespective of the measurement principle used in determining the particle velocity there is one fundamental problem: the pressure and the particle velocity transducer will invariably have different phase responses. One must compensate for this p–u phase mismatch, otherwise the result may well be meaningless. In fact even a small residual p–u mismatch error can have serious consequences under certain conditions. This can be seen by introducing such a small phase error, φ_{ue}, in (25.31). The result is

$$\hat{I}_r = \frac{1}{2} \operatorname{Re} \left(p u_r^* e^{-i\varphi_{ue}} \right)$$
$$= \operatorname{Re} \left[(I_r + iJ_r)(\cos \varphi_{ue} - i \sin \varphi_{ue}) \right]$$
$$\simeq I_r + \varphi_{ue} J_r , \qquad (25.33)$$

where J_r is the reactive intensity, cf. (25.12). Equation (25.33) demonstrates that even a small uncompensated p–u phase mismatch error will give rise to a significant bias error when $J_r \gg I_r$. On the other hand it also shows that substantial p–u phase errors can be tolerated if $J_r \ll I_r$. For example, even a phase mismatch of 35° gives a bias error of less than 1 dB under such conditions. In other words, phase calibration is critical when measurements are carried out under near-field conditions, but not at all critical if the measurements are carried out in the far field of a source. The *reactivity* (the ratio of the reactive to the active intensity) indicates whether this source of error is of concern or not.

Whereas phase-mismatching of a p–p sound intensity measurement system can in principle be eliminated simply by reversing the probe and measuring again, it can be seen from (25.33) that reversing a p–u probe simply changes the sign of the result, including the bias

error. In other words, probe reversal does not provide any new information.

The global version of (25.33) is found by integrating over a surface that encloses a source,

$$\hat{P}_a = \int_S \operatorname{Re} \left[(\boldsymbol{I} + i\boldsymbol{J})(\cos \varphi_{ue} - i \sin \varphi_{ue}) \right] \cdot d\boldsymbol{S}$$

$$\simeq P_a + \varphi_{ue} \int_S \boldsymbol{J} \cdot d\boldsymbol{S}$$

$$= P_a \left(1 + \varphi_{ue} \frac{\int_S \boldsymbol{J} \cdot d\boldsymbol{S}}{\int_S \boldsymbol{I} \cdot d\boldsymbol{S}} \right)$$

$$= P_a \left(1 - \varphi_{ue} \frac{\int_S \boldsymbol{J} \cdot d\boldsymbol{S}}{\int_S \hat{\boldsymbol{I}} \cdot d\boldsymbol{S}} \right)^{-1} , \qquad (25.34)$$

and this shows that uncompensated p–u phase mismatch is a potential source of error when the reactivity (which in the global case is the ratio of the surface integral of the reactive intensity to the surface integral of the active intensity) is large. This will typically occur at low frequencies when the measurement surface is close to the source. Thus the reactivity is an important error indicator for p–u probes [25.17]. In contrast the pressure-intensity index is not relevant for p–u probes.

Sources outside the measurement surface do not in general increase the reactivity, and thus they do not in general increase the error due to p–u phase mismatch.

Other Sources of Error

Airflow, and in particular unsteady flow, is a more serious problem for p–u than for p–p sound intensity measurement systems, irrespective of the particulars of the particle velocity transducer, since the resulting velocity cannot be distinguished from the velocity associated with the sound waves. Windscreens of porous foam reduce the problem.

Calibration of p–u Sound Intensity Measurement Systems

Calibration of p–u sound intensity measurement systems involves exposing the probe to a sound field with a known relation between the pressure and the particle velocity, for example a plane propagating wave, a simple spherical wave or a standing wave [25.15, 16]. One cannot calibrate a particle velocity transducer in a coupler. There are no standardized calibration procedures and no standards for testing such instruments. However,

recent experimental results seem to indicate the possibility of calibrating the particle velocity channel of the Microflown intensity probe in the far field of a loudspeaker in an anechoic room, in the near field of a very small source (sound emitted from a small hole in a plane or spherical baffle), and in a rigidly terminated standing wave tube [25.17, 56].

25.3.3 Sound Field Indicators

A sound field indicator may be defined as a normalized, energy-related quantity that describes a local or global property of the sound field [25.39]. The pressure-intensity index defined by (25.29) is an example. The concept of sound field indicators is closely related to sound intensity. The idea is that useful information about the nature of the sound field might be derived from the signals from an intensity probe. The purpose can be to derive information that may be helpful in interpreting experimental data, with a view, for example, to improving measurement accuracy in intensity-based sound power estimation by choosing another measurement surface, by shielding the surface from extraneous sources, etc. The international standards on sound

power determination using sound intensity [25.24–26] prescribe initial measurements of a number of indicators and specify corrective actions on the basis of the values of these quantities. The corresponding ANSI standard [25.27] is more pragmatic; no less than 26 indicators are described, but their use is optional and it is left to the user to interpret the data and decide what to do.

It is clear from the considerations in Sect. 25.3.1 that the (global) pressure-intensity index reflects the amount of extraneous noise in sound power measurements and, combined with the pressure-residual intensity index of a p–p sound intensity measurement system, makes it possible to predict the bias error due to p–p phase mismatch. Likewise, the considerations in Sect. 25.3.2 show that the reactivity reflects whether the measurement takes place in the near field of the source under test or not and, combined with knowledge about the residual phase mismatch of a p–u sound intensity measurement system, makes it possible to predict the bias error due to the mismatch. In comparison, most of the many quantities suggested in [25.27] are, as shown in [25.57], difficult to interpret and only vaguely related to the measurement accuracy.

25.4 Applications of Sound Intensity

Some of the most important practical applications of sound intensity measurements are now briefly discussed. In view of the relative lack of experimental evidence of the performance of p–u sound intensity measurement systems it is assumed in the following that p–p measurement systems are used unless otherwise mentioned.

25.4.1 Noise Source Identification

A noise reduction project usually starts with the identification and ranking of noise sources and transmission paths. Before sound intensity measurement systems became available this was often a difficult task, but now it is relatively straightforward since intensity measurements make it possible to determine the sound power contribution of the various components separately. Plots of the sound intensity normal to a measurement surface can be used in locating noise sources. Figure 25.21 shows the results of 3-D sound intensity measurements near a chain saw, and Fig. 25.22 shows an example of intensity measurements near a ship window. It should be mentioned, though, that sound intensity measurement

can give misleading results; for example, the intensity vector will point to a position between two uncorrelated sources where no source actually exists.

Visualization of sound fields contributes to our understanding of the sound radiation of complicated sources, and sound intensity is more suitable for visualizing sound fields than sound pressure, which is a scalar. Figure 25.23 shows a map of the sound intensity in the sound field generated by a rectangular plate driven in a certain mode, measured with a microphone array using near-field acoustic holography. It is apparent that the generated sound field is fairly complicated. Note in particular the recirculation of sound energy; a region of the plate acts as a sink. This phenomenon is typical of vibrating panels of low radiation efficiency and demonstrates that spatial averaging of the sound intensity very near such sources is problematic. The circulation of sound energy, which implies that some regions act as sources without actually radiating to the far field, has led Williams to introduce the concept of *supersonic intensity*, which is the part of the sound intensity associated with wavenumber components within the *radiation circle*, in other words, the part of the in-

tensity associated with radiation to the far field [25.58]. One cannot determine the supersonic intensity with an ordinary sound intensity probe, though; wavenumber processing of near-field holographic data is required.

25.4.2 Sound Power Determination

One of the most important applications of sound intensity measurement is the determination of the sound power of operating machinery in situ. Sound power determination using intensity measurements is based on (25.7), which shows that the sound power of a source is given by the integral of the normal component of the intensity over a surface that encloses the source, also in the presence of other sources outside the measurement surface. The analysis of errors and limitations presented in Sect. 25.3.1 leads to the conclusion that the sound intensity method is suitable for determining the sound power of stationary sources in stationary back-

ground noise provided that the pressure-intensity index is within the dynamic capability of the measurement system. On the other hand, the method is *not* suitable

Fig. 25.22 Sound intensity distribution (tangential component) near a single cabin window (after [25.60])

Fig. 25.23 Intensity vector map of the sound field generated by a rectangular plate excited in its (4, 2) mode (after [25.61])

in nonstationary background noise (because the sound field will change during the measurement); it cannot be used for determining the sound power of very weak sources of low-frequency noise (because of large random errors caused by electrical noise in the microphone signals); and the absorption of the source under test should be negligible compared with the total absorption in the room where the measurement takes place (otherwise the sound power will be underestimated because the measurement gives the *net* sound power).

The surface integral can be approximated either by sampling at discrete points or by scanning manually or with a robot over the surface. With the scanning approach, the intensity probe is moved continuously over the measurement surface. A typical scanning path is shown in Fig. 25.24. The scanning procedure, which was introduced by Chung in the late 1970s on a purely empirical basis, was regarded with much skepticism for more than a decade [25.63], but is now generally regarded as more accurate and very much faster and more convenient than the procedure based on fixed points [25.62, 64, 65]. A moderate scanning rate, say 0.5 m/s, and a reasonable scan line density should be used, say 5 cm between adjacent lines if the surface is very close to the source, 20 cm if it is further away. However, whereas it may be possible to use the method based on discrete positions if the source is operating in cycles (simply by measuring over a full cycle at each position) one cannot use the scanning method under such conditions; both the source under test and possible extraneous noise sources must be perfectly stationary.

Usually the measurement surface is divided into a number of segments that are convenient to scan. The pressure-intensity index of each segment and the accuracy of each partial sound power estimate depends on whether (25.29) is satisfied or not, but it follows from (25.30) that it is the global pressure-intensity index associated with the entire measurement surface that determines the accuracy of the estimate of the (total) radiated sound power. It may be impossible to satisfy (25.29) on a certain segment, for example because the net sound power passing through the segment takes a very small value because of extraneous noise, but if the global criterion is satisfied then the total sound power estimate will nevertheless be accurate.

Theoretical considerations seem to indicate the existence of an optimum measurement surface that minimizes measurement errors [25.66]. In practice one uses a surface with a simple shape at some distance, say 25–50 cm, from the source. If there is a strong reverberant field or significant ambient noise from other sources, the measurement surface should be chosen to be somewhat closer to the source under study. One particular problem is that one might be tempted to forget to close a measurement surface that is very close to, say, a panel or a window by measuring only the component of the intensity normal to the source. This can lead to serious errors in cases where the panel radiates very weakly, because the radiation will be nearly parallel to the source plane.

The three ISO standards for sound power determination using intensity measurement have been designed for sources of noise in their normal operating conditions, which may be very unfavorable [25.24–26]. In order to ensure accurate results under such general conditions the user must determine a number of field indicators and check whether various conditions are satisfied, as mentioned in Sect. 25.3.3. *Fahy*, who was the convener of the working group that developed ISO 9614-1 and 9614-2, has described the rationale, background, and principles of the procedures specified in these standards [25.65].

25.4.3 Radiation Efficiency of Structures

The radiation efficiency of a structure is a measure of how effectively it radiates sound. This dimensionless quantity is defined as

$$\sigma = \frac{P_a}{\rho c \langle v_n^2 \rangle S} , \tag{25.35}$$

where P_a is the sound power radiated by the structure, S is its surface area, v_n is normal velocity of the surface, and the angular brackets indicate averaging over time as well as space. Comparing with (25.16) shows the close relation between this quantity and the real part of the specific impedance, which can be measured directly

Fig. 25.24 Typical scanning path on a measurement surface (after [25.62])

with a sound intensity probe if it can be placed sufficiently close to the structure [25.67]. The Microflown *p–u* probe has an advantage in this respect. However, measurements very near weak radiators of sound are difficult because of the circulating energy flow mentioned in Sect. 25.4.1.

25.4.4 Transmission Loss of Structures and Partitions

The transmission loss of a partition is the ratio of incident to transmitted sound power in logarithmic form. The traditional method of measuring this quantity requires a transmission suite consisting of two vibration-isolated reverberation rooms. The sound power incident on the partition under test in the source room is deduced from the spatial average of the mean square sound pressure in the room on the assumption that the sound field is diffuse, and the transmitted sound power is determined from a similar measurement in the receiving room where, in addition, the reverberation time must be determined. The sound intensity method makes it possible to measure the transmitted sound power directly. In contrast one cannot measure the incident sound power in the source room using sound intensity, since the method gives the *net* sound intensity. If the intensity method is used for determining the transmitted sound power it is not necessary that the sound field in the receiving room is diffuse, from which it follows that only one reverberation room is necessary. Thus sound intensity is suitable for field measurements of transmission loss. There are international standards both for laboratory and field measurements of transmission loss based on sound intensity [25.69, 70].

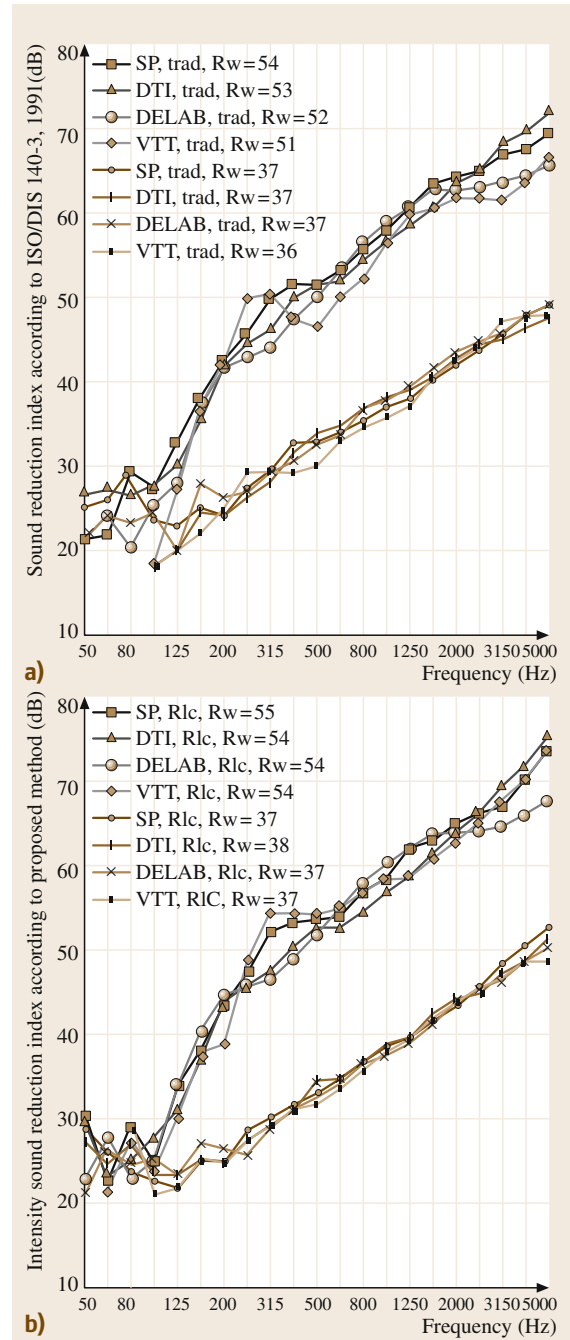
Figure 25.25 shows the results of a *round robin* investigation in which a single-leaf and a double-leaf construction were tested by four different laboratories using the conventional method and the intensity-based method. Apart from the fact that only one reverberation room is needed the main advantage of the intensity method is that it makes it possible to evaluate the transmission loss of individual parts of the partition. However, to be reliable each sound power measurement must obviously satisfy the condition expressed by (25.29). There are other sources of error than phase mismatch. If a significant part of the absorption in the receiving room is due to the partition under test then the net power is less than the transmitted power because a part of the transmitted sound energy is absorbed or retransmitted by the partition itself [25.71]. Under such conditions one must increase the absorption of


Fig. 25.25a,b Inter-laboratory comparison of measured transmission loss of a single metal leaf window (*lower curves*) and a double metal leaf window (*upper curves*). **(a)** Conventional method; **(b)** intensity method (after [25.68])

Part H | 25.4

the receiving room; otherwise the intensity method will overestimate the transmission loss because the transmitted sound power is underestimated. In contrast, the conventional method measures the transmitted sound power irrespective of the distribution of absorption in the receiving room.

Deviations between results determined using the traditional method and the intensity method led several authors to reanalyze the traditional method in the 1980s [25.72] and point out that the Waterhouse correction [25.73], well established in sound power determination using the reverberation room method [25.74], had been overlooked in the standards for conventional measurement of transmission loss. Only recently it has been showed that a correction very similar to the Waterhouse correction should be used not only for the source room [25.75].

25.4.5 Other Applications

The fact that the sound intensity level is considerably lower than the sound pressure level in a diffuse, reverberant sound field has led to the idea of replacing a measurement of the *emission sound pressure level* generated by machinery at the operator's position by a measurement of the sound intensity level, because the latter is less affected by diffuse background noise [25.76]. This method, which involves measuring three components of the intensity at a specified position near the source, has recently been standardized [25.77].

In principle, sound intensity may be used for measuring sound absorption in situ. As in measurement of transmission losses the incident sound power must be deduced from a spatial average of the mean square pressure in the room on the assumption that the sound field is diffuse, and the absorbed sound power is measured by integrating the normal component of the intensity over a surface that encloses the specimen under test [25.2]. In practice, however, this is one of the least successful applications of sound intensity, partly because of the assumption of diffuse sound incidence and partly because estimation errors in the absorbed power will be translated to relatively large fractional errors in the resulting absorption coefficients.

26. Acoustic Holography

Yang–Hann Kim

One of the subtle problems that make noise control difficult for engineers is the invisibility of noise or sound. A visual image of noise often helps to determine an appropriate means for noise control. There have been many attempts to fulfill this rather challenging objective. Theoretical (or numerical) means for visualizing the sound field have been attempted, and as a result, a great deal of progress has been made. However, most of these numerical methods are not quite ready for practical applications to noise control problems. In the meantime, rapid progress with instrumentation has made it possible to use multiple microphones and fast signal–processing systems. Although these systems are not perfect, they are useful. A state-of-the-art system has recently become available, but it still has many problematic issues; for example, how can one implement the visualized noise field. The constructed noise or sound picture always consists of bias and random errors, and consequently, it is often difficult to determine the origin of the noise and the spatial distribution of the noise field. Section 26.2 of this chapter introduces a brief history, which is associated with *sound visualization*, acoustic source identification methods and what has been accomplished with a line or surface array. Section 26.2.3 introduces difficulties and recent studies, including de–Dopplerization and de–re-

verberation methods, both essential for visualizing a moving noise source, such as occurs for cars or trains. This section also addresses what produces ambiguity in realizing real sound sources in a room or closed space. Another major issue associated with sound/noise visualization is whether or not we can distinguish between mutual dependencies of noise in space (Sect. 26.2.4); for example, we are asked to answer the question, *Can we see two birds singing or one bird with two beaks?*

26.1 The Methodology of Acoustic Source Identification

The famous article written by *Kac* [26.1], *Can one hear the shape of the drum?* clearly addresses the essence of the inverse problem. It can be regarded as an attempt to obtain what is *not* available, using what *is* available, using the example of the relationship between sound generation by membrane vibration and its reception in space. One can find many other examples of inverse problems [26.2–8]. Often, in the inverse prob-

lem, it is hard to predict or describe data that are not measured because the available data are insufficient. This circumstance is commonly referred to as an *ill-posed problem* in the literature [26.1–19]. Figure 26.1 demonstrates what might happen in practice; the prediction depends on how well the basis function (the elephants or dogs in Fig. 26.1) mimics what happens in reality. When we try to see the shape of noise/sound
Fig. 26.1 The inverse problem and basis function. Are the measured data the parts of elephants or dogs?

sources, how well we see the shape of a noise source completely depends on this basis function, because we predict what is not available by using this selected basis function.

One of the common methods of classifying methods used in noise/sound source identification, is by the type of basis function. According to this classification, one approach is the nonparametric method, which uses basis functions that do not model the signal. In other words, the basis functions do not map the unmeasured sound field; all orthogonal functions fall into this category. One of the typical methods of this kind uses Fourier transforms. Acoustic holography uses this type of basis function, mapping the sound field of interest

with regard to every measured frequency; it therefore sees the sound field in the frequency domain. In fact, the ideas of acoustic holography originated from optics [26.20–30]. Acoustic holography was simply extended or modified from the basic idea of optical holography. Near-field acoustic holography [26.31,32] has been recognized as a very useful means of predicting the true appearance of the source Fig. 26.2. (The near-field effect on resolution was first introduced in the field of microwaves [26.33].) The basis of this method is to include or measure exponentially decaying waves as they propagate from the sound source so that the sources can be completely reconstructed.

Another class of approaches are based on the parametric method, which derives its name from the fact that the signal is modeled using certain parameters. In other words, the basis function is chosen depending upon the prediction of the sound source. A typical method of this kind is the so-called *beam-forming method*. Different types of basis functions can be chosen for this method, entirely depending on the sound field that the basis function is trying to map [26.34, 35]. In Fig. 26.1, we can select either the elephants or dogs (or another choice), depending on what we want to predict. This type of mapping gives information about the source location. As illustrated in Fig. 26.1, the basis function maps the signal by changing its parameter; in the case of forming a plane-wave beam, the incident angle of the plane wave can be regarded as a parameter. The main issues that have been discussed for this kind of mapping method
Fig. 26.2 Illustration of acoustic holography. Near-field acoustic holography measures evanescent waves on the measurement plane. The measurement plane is always finite, i. e. there is always a finite aperture. Therefore, we only get limited data
Fig. 26.3 The beam-forming method

are directly related to the structure of the correlation matrix that comes from the measured acoustic pressure vector and its complex conjugate (see Fig. 26.3 for the details). In this method, each scan vector has a multiplicative parameter; for the plane wave in Fig. 26.3 it is the angle of arrival. The correlation matrix is given as illustrated in Fig. 26.3. The scan vector is a basis function in this case. As one can see immediately, this problem is directly related to the structure of the correlation matrix and the basis function used. The signal-to-noise (*S/N*) ratio of the measured correlation matrix determines the effectiveness of the estimation. There have been many attempts to improve the estimator's performance with regard to the signal-to-noise ratio [26.35, 36]. These methods have mainly been developed for applications in the radar and underwater communities [26.37]. This technique has also been applied to a noise source location finding problem; high-speed-train noise source estimation [26.38–40] is one such example. Various shapes of arrays have been tried to improve the spatial resolution [26.41–43]. However, it is obvious that these methods cannot sense the shape of the sound or noise source; they only provide its location. Therefore, we will not discuss the beam-forming method in this chapter. In the next section, the problems that we have discussed will be defined.

26.2 Acoustic Holography: Measurement, Prediction and Analysis

26.2.1 Introduction and Problem Definitions

Acoustic holography consists of three components: measurement, which consists of measuring the sound pressure on the hologram plane, prediction of the acoustic variables, including the velocity distribution, on the plane of interest, and analysis of the holographic reconstruction. This last component was not recognized as important as the others in the past. However, it yields the real meaning of the sound picture: visualization.

The issues associated with measurement are all related to the hologram measurement configuration; we measure the sound pressure at discrete measurement points over a finite measurement area (finite aperture), as illustrated in Fig. 26.2. References [26.44–52] explain the necessary steps to avoid spatial aliasing, wrap-around errors, and the effect of including evanescent waves on the resolution (near-field acoustic holography). If sensors are incorrectly located on the hologram surface, errors result in the prediction results. Similar errors can be produced when there is a mag-

nitude and phase mismatch between sensors. This is well summarized in [26.53]. There have been many attempts to reduce the aperture effect. One method is to extrapolate the pressure data based on the measurements taken [26.50, 52]. Another method allows the measurement of sound pressure in a sequence and interprets the measured sound pressures with respect to reference signals, assuming that the measured sound pressure field is stationary during the measurement and the number of independent sources is smaller than the number of reference microphones [26.54–61]. Another method allows scanning or moving of the microphone array, thereby extending the aperture size as much as possible [26.62–65]. This also allows one to measure the sound pressure generated by moving sound sources, such as a vehicle's exterior noise.

The prediction problem is rather well defined and relatively straightforward. Basically, the solution of the acoustic wave equation usually results in the sound pressure distribution on the measurement plane. Prediction can be attempted using a Green's function, an example of which may be found in the Kirchhoff–Helmholtz integral equation. It is noteworthy, however, that the prediction depends on the shape of the measurement and prediction surfaces, and also on the presence of sound reflections [26.54, 66–87].

The acoustic holography analysis problem was introduced rather recently. As mentioned earlier in this section, this is one of the essential issues connected to the general inverse problem. One basic question is whether what we see and imagine is related to what happens in reality. There are two different sound/noise sources, one of which is really radiating the sound, and the another that is reflecting the sound. The former is of-

ten called *active sound/noise*, while the latter is called *passive sound/noise*. This is an important practical concept for establishing noise control strategies; we want to eliminate the active noise source. Another concern is whether the sources are independently or dependently correlated (Fig. 26.23). The concept of an independent and dependent source has to be addressed properly to understand the issues.

26.2.2 Prediction Process

The prediction process is related to how we predict the unmeasured sound pressure or other acoustic variables based on the measured sound pressure information. The following equation relates the unmeasured and measured pressure

$$P(\boldsymbol{x}; f) = \int_{S_\mathrm{h}} \left[G(\boldsymbol{x}|\boldsymbol{x}_\mathrm{h}; f) \left. \frac{\partial P}{\partial n} \right|_{(\boldsymbol{x}=\boldsymbol{x}_\mathrm{h}; f)} \right.$$
$$\left. - P(\boldsymbol{x}_\mathrm{h}; f) \frac{\partial G(\boldsymbol{x}|\boldsymbol{x}_\mathrm{h}; f)}{\partial n} \right] \mathrm{d}S_\mathrm{h} . \qquad (26.1)$$

Equation (26.1) is the well-known Kirchhoff–Helmholtz integral equation, where $G(\boldsymbol{x}|\boldsymbol{x}_\mathrm{h}; f)$ is the free-space Green's function. This equation essentially says that we can predict the sound pressure anywhere if we know the sound pressures and velocities on the boundary Fig. 26.4. However, it is noteworthy that measuring the velocity on the boundary is more difficult than measuring the sound pressure. This rather practical difficulty can be solved by introducing a Green's function that

Fig. 26.4 The geometry and nomenclature for the Kirchhoff–Helmholtz integral (26.1)
Fig. 26.5 Illustration of the planar acoustic holography
Fig. 26.6 Propagating and exponentially waves in acoustic holography
Fig. 26.7 The data-processing procedure for acoustic holography

satisfies the Dirichlet boundary condition: $G_D(x|x_h; f)$. Then, (26.1) becomes

$$P(x; f) = \int_{S_h} \left[-P(x_h; f) \frac{\partial G_D(x|x_h; f)}{\partial n} \right] dS_h . \quad (26.2)$$

This equation allows us to predict the sound pressure on any surface of interest. It is noteworthy that we can choose a Green's function as long as it satisfies the linear inhomogeneous wave equation, or the inhomogeneous Helmholtz equation in the frequency domain. That is,

$$\nabla^2 G(x|x_h; f) + k^2 G(x|x_h; f) = -\delta(x - x_h) . \quad (26.3)$$

Therefore, we can select a Green's function in such a way that we can eliminate one of the terms on the right-hand side of (26.1); (26.2) is one such case.

To see what essentially happens in the prediction process, let us consider (26.2) when the measurement and prediction plane are both planar. Planar acoustic holography assumes that the sound field is free from reflection (Fig. 26.5); then we can write (26.2) as

$$P(x, y, z; f) = \int_{S_h} P(x_h, y_h, z_h; f)$$
$$\times K_{PP}(x - x_h, y - y_h, z - z_h; f) dS_h , \quad (26.4)$$

$$K_{PP}(x, y, z; f) = \frac{1}{2\pi} \frac{z}{r^3} (1 - ikr) \exp(ikr) , \quad (26.5)$$

$$\text{where} \quad r = \sqrt{x^2 + y^2 + z^2} ,$$
$$k = \frac{2\pi f}{c} ,$$
$$x = (x, y, z) ,$$
$$x_h = (x_h, y_h, z_h) .$$

K_{PP} can be readily obtained by using two free-field Green's functions that are located at z_h and $-z_h$, so that it satisfies the Dirichlet boundary condition.

This is a convolution integral, and therefore we can write this in the wave-number domain as

$$\hat{\hat{P}}(k_x, k_y, z; f)$$
$$= \hat{\hat{P}}(k_x, k_y, z_h; f) \exp[ik_z(z - z_h)] , \quad (26.6)$$
Fig. 26.8 The error due to discrete measurement: the spatial aliasing problem. The microphone spacing determines the Nyquist wave number. This wave number has to be smaller than the maximum wave number of the acoustic pressure distribution on the hologram plane. The microphone spacing, therefore, has to get smaller as the distance between the hologram (the measurement plane) and source decrease. The rule of thumb is $\delta < d$ ◄

where

$$\hat{\hat{P}}(k_x, k_y, z; f)$$

$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} P(x, y, z; f) e^{-i(k_x x + k_y y)} \, dx \, dy \,, \quad (26.7)$$

$$k_z = \sqrt{k^2 - k_x^2 - k_y^2} \,.$$

This equation essentially predicts the sound pressure with respect to the wave number (k_x, k_y). If $k^2 \geqslant k_x^2 + k_y^2$, the wave in z-direction (k_z) is propagating in space. Otherwise, the z-direction wave decays exponentially, i.e. it is an evanescent wave (Fig. 26.6).

We have derived the formulas that can predict what we did not measure based on what we measured, by using a Green's function. It is noteworthy that we can get the same results if we use the characteristic solutions of the Helmholtz equation; the Appendix describes the details. The Appendix also includes discrete expressions for the formula, which are normally used in the computation.

Equation (26.6) also allows us to predict the sound pressure on the source plane, when $z = z_s$. This is an inverse problem because it predicts the pressure distribution on the source plane based on the hologram pressure (Figs. 26.3 and 26.6).

Figure 26.7 essentially illustrates how we can process the data for predicting what we did not measure based on what we measure. There are four major areas that cause errors in acoustic holography prediction. One is related to the integration of (26.4). Equation (26.4) has to be implemented on the discretized surface Fig. 26.8. This surface, therefore, has to be spatially sampled according to the selected surface. This spatial sampling can produce spatial aliasing, depending on the spatial distribution of the sound source: the sampling wave number must be larger than twice the maximum wave number of interest. It is noteworthy that, as illustrated in Fig. 26.8, the distance between the
Fig. 26.9 The effect of a finite aperture: the rapid change at the aperture edges produces high-wave-number noise ◄

hologram and source planes is usually related to the sampling distance d. The closer one is to the source, the smaller the sampling distance needs to be. We must also note that the size of the aperture determines the wave-number resolution of acoustic holography. The finite aperture inevitably produces very sharp data truncation, as illustrated in Fig. 26.9. This produces unrealistic high-wave-number noise (see *without window* in Fig. 26.9). Therefore, it is often required that we use a window, which can result in a smoother data transition from what is on the measurement plane to what is not measured (Fig. 26.9).

The spatial Fourier transform that has to be done in the prediction process (26.6) has to be carried out in the domain for which data is available, i. e. a finite Fourier transform. It therefore produces a ghost hologram, as illustrated in Fig. 26.10 [26.46, 50]. This effect can be effectively removed by adding zeros to the hologram data (Fig. 26.11). The last thing to note is what can happen when we do backward propagation. As we can see in (26.6), when we predict the sound pressure distribution on a plane close to the sound source ($z < z_h$ (Fig. 26.5)) and k_z has an imaginary value (evanescent wave), then the sound pressure distribution of the exponentially decaying part will be unrealistically magnified (Fig. 26.11) [26.47]. Figure 26.12 graphically summarizes the entire processing steps of acoustic holography.

The issues related with the evanescent wave and its measurement are well addressed in the literature [26.88]. The measurement of evanescent waves essentially allows us to achieve higher resolution than conventional acoustic holography [26.89–94]. However, it is noteworthy that the evanescent-wave component is substantially smaller than the other propagating components. Therefore, it is easy to produce errors that are associated with sensor or position mismatch [26.53]; in other words, it is very sensitive to the signal-to-noise ratio. Errors due to position and sensor mismatch are bias errors and random errors, respectively. It has been shown [26.53] that the bias error due to the mismatches is negligible, but the random error is significant in backward prediction. This is related to the measurement spacing on the hologram plane (Δ_h), prediction plane (Δ_z), and the distance between the hologram plane and the prediction plane (d). It is approximately proportional to $24.9(d/\Delta_z) + 20\log_{10}(\Delta_h/\Delta_z)$ in a dB scale. The signal-to-noise ratio can be amplified when we try to reconstruct the source field: a typical ill-posed phenomena. There have been many attempts to reduce this effect by using a spatial filter [26.47, 95–99], which is often called the *regularization* of acoustic holography [26.100–115].
Fig. 26.10 The effect of the finite spatial Fourier transform on acoustic holography: the ghost image is due to the finite Fourier transform; circular convolution can be eliminated by adding zeros

Depending on the separable coordinates that we use for acoustic holography, we can construct cylindrical or spherical coordinates [26.54, 67, 69] (Figs. 26.13 and
Fig. 26.11 Wave-number filtering in backward prediction. Evanescent wave components are magnified without filtering (after [26.47])

26.14). These methods predict the sound field in exactly the same manner as in planar holography but with respect to different coordinates. As expected, however, these methods have some advantages. For example, the wrap-around error is negligible – in fact, there is no such error in spherical acoustic holography – and there is no aperture-related error [26.54]. Recently, the advantage of using spherical functions has also been noted [26.79, 81, 86, 87, 113].

26.2.3 Measurement

To construct a hologram, we commonly measure the sound pressure at discrete positions, as illustrated in Fig. 26.2. However, if the sound generated by the source, and therefore the sound field, can be assumed

Fig. 26.15a,b Two measurement methods for the pressure on the hologram plane: **(a)** step-by-step scanning **(b)** continuous scanning

to be stationary, then we do not have to measure them at the same time.

Figure 26.15 illustrates one way to accomplish this measurement. This method normally measures the sound pressure field using a stepped line array (Fig. 26.15a). To understand the issues associated with this measurement system for the sake of its simplicity, let us see how we process a signal of frequency f when there is a single source. The relationship between the sound source and sound pressure in the field, or measurement position (x_h), can be written as

$$P(x_h; f) = H(x_h; f)Q(f), \tag{26.8}$$

where $Q(f)$ is the source input signal and $H(x_h; f)$ is the transfer function between the source input and the measured pressure. This means that, if we know the transfer function and the input, we can find the magnitude and phase between the measured positions. Because it is usually not practical to measure the input, we normally use reference signals (Fig. 26.15a). By using a reference signal, the pressure can be written as

$$P(x_h; f) = H'(x_h; f)R(f), \tag{26.9}$$

where $R(f)$ is the reference signal. We can obtain $H'(x_h; f)$ by

$$H'(x_h; f) = \frac{P(x_h; f)}{R(f)}. \tag{26.10}$$

The input and reference are related through

$$R(f) = H_R(f)Q(f), \tag{26.11}$$

where $H_R(f)$ is the transfer function between the input and the reference. As a result, we can see that (26.9) has the same form as (26.8).

It is noteworthy that (26.8) holds for the case that we have only one sound source and the sound field is stationary and random. However, if there are two sound sources, then (26.8) becomes

$$P(x_h; f) = H_1(x_h; f)Q_1(f) + H_2(x_h; f)Q_2(f), \tag{26.12}$$

where $Q_i(f)$ is the i-th input and $H_i(x_h; f)$ is its transfer function. There are now two independent sound fields. This requires, of course, two independent reference signals. It has been well accepted that the number of reference microphones has to be greater than the number of independent sources [26.57]. However, if this is strictly true, then it means that we have to somehow know the number of sources, and this, in some degree, contradicts the the acoustic holography approach.
Fig. 26.16 Application result of the step-by-step scanning method to the wind noise of a car. This figure is the pressure distribution at $710 \sim 900\,\mathrm{Hz}$ in a source plane when the flow velocity is $110\,\mathrm{km/h}$. In this experiment, 17 reference microphones are randomly located in the car, to see the coherence between interior noise and what are measured by the array microphone system. The array microphone system was initially located at $3\,\mathrm{m}$ forward from the middle point of a car, and moved $6\,\mathrm{cm}$ in step until it reached at $3\,\mathrm{m}$ backward from the middle point ◄

A recent study [26.61] demonstrated that the measured information, the location of the sources, and the number of independent sources converge to their true values as the number of reference microphones increases. This study also showed that high-power sources are likely to be identified even if the number of reference microphones is less than the number of sources.

Figure 26.16 shows an example of this method when there are many independent sound fields. On the other hand, one study showed that we can even continuously scan the sound field by using a line array of microphones (Fig. 26.15b) [26.62–65]. This method essentially allows us to extend the aperture size without any limit as long as the sound field is stationary. In fact, [26.65] also showed that this method can be used for a slowly varying (quasi-stationary) sound field.

This method has to deal with the Doppler shift. For example, let us consider a plane wave in the $(k_{x_0}, k_{y_0}, k_{z_0})$ direction and a pure tone of frequency f_{h_0}. Then the pressure on the hologram plane can be written as

$$
\begin{aligned}
&p(x_h, y_h, z_h; t) \\
&= P_0 \exp\left[\mathrm{i}(k_{x_0} x_h + k_{y_0} y_h + k_{z_0} z_h)\right] \exp(-\mathrm{i}, f_{h_0} t) ,
\end{aligned}
\tag{26.13}
$$

where P_0 denotes the complex magnitude of the plane wave. Spatial information about the plane wave with respect to the x-direction can be represented by a wavenumber spectrum, and can be described as

$$
\begin{aligned}
\hat{P}(k_x, y_h, z_h; t) &= \int_{-\infty}^{\infty} p(x_h, y_h, z_h; t)\, \mathrm{e}^{-\mathrm{i} k_x x_h}\, \mathrm{d}x_h \\
&= P_0 \exp\left[\mathrm{i}(k_{y_0} y_h + k_{z_0} z_h)\right] \\
&\quad \times \delta(k_x - k_{x_0}) \exp(-\mathrm{i} 2\pi f_{h_0} t) \\
&= P(k_{x_0}, y_h, z_h) \delta(k_x - k_{x_0}) \\
&\quad \times \exp(-\mathrm{i} 2\pi f_{h_0} t) ,
\end{aligned}
\tag{26.14}
$$

where $P(k_{x_0}, y_h, z_h) = P_0 \exp[\mathrm{i}(k_{y_0} y_h + k_{z_0} z_h)]$ is the wave-number spectrum of the plane wave at $k_x = k_{x_0}$.

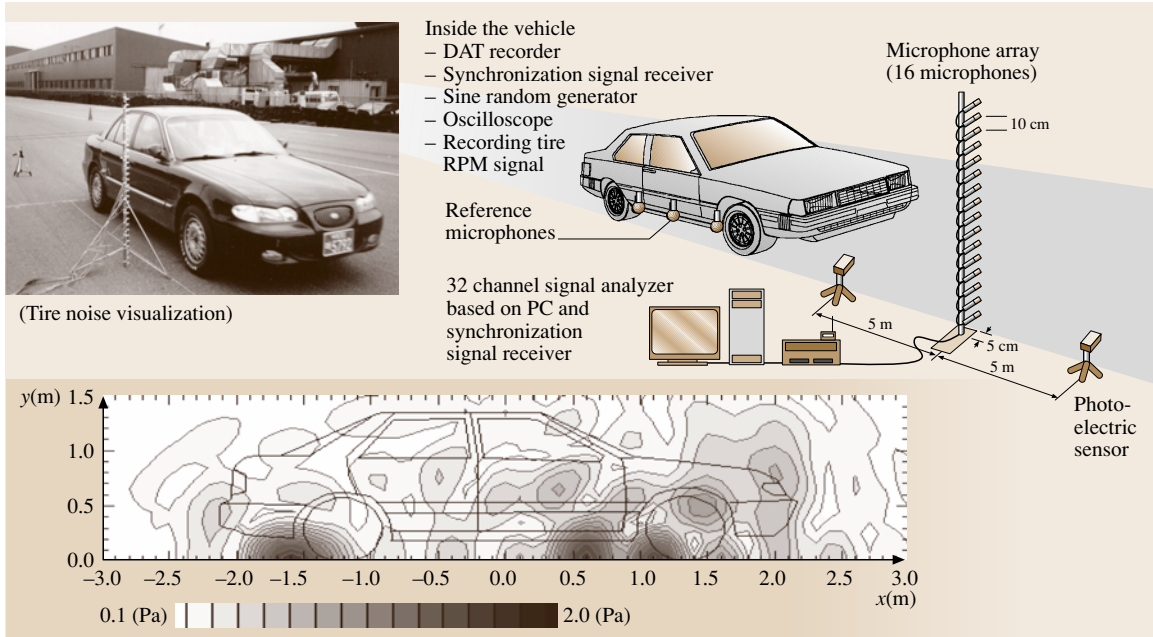
Fig. 26.17 The continuous scanning method for a plane wave and a pure tone (one-dimensional illustration). f_{h_0} is the source frequency, f is the measured frequency, u_m is the microphone velocity, c is the wave speed, k_{x_0} is the x-direction wave number, and P_0 is the complex amplitude of a plane wave ◄
Fig. 26.18 De-Dopplerization procedure for a line spectrum
Fig. 26.19 The continuous scanning method for a more general case (one-dimensional illustration)


Fig. 26.20 Experimental configuration and result of the continuous scanning method to vehicle pass-by noise. The tire pattern noise distribution (pressure) on the source plane is shown when the car passed the microphone array with constant speed of 50 km/h
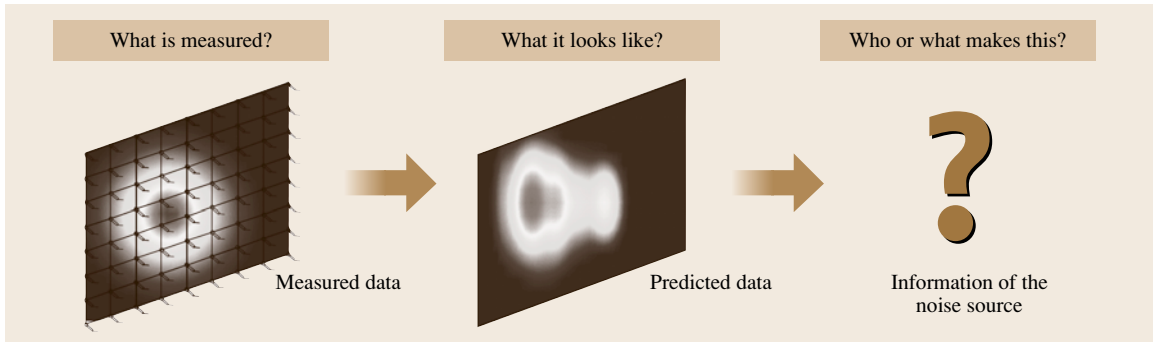

Fig. 26.21 Illustration of analysis problem in acoustic holography

If a microphone is moving at an x-velocity u_m, the measured signal $p_m(x_h, y_h, z_h; t)$ is

$$p_m(x_h, y_h, z_h; t) = p(u_m t, y_h, z_h; t).\qquad(26.15)$$

The Fourier transform of (26.15) with respect to time F_T, using (26.13), can be expressed as

$$F_T[p_m(u_m t, y_h, z_h; t)]$$
$$= \int_{-\infty}^{\infty} p_m(u_m t, y_m, z_h; t)\, e^{i2\pi ft}\, dt$$

$$= P_0 \exp[i(k_{y_0} y_h + k_{z_0} z_h)]$$
$$\times \delta\left(\frac{u_m}{2\pi} k_{x_0} - f_{h_0} + f\right)$$
$$= P(k_{x_0}, y_h, z_h)\delta\left(\frac{u_m}{2\pi} k_{x_0} - f_{h_0} + f\right).\qquad(26.16)$$

Equation (26.16) means that the complex amplitude of the plane wave is located at the shifted frequency $f_{h_0} - u_m k_{x_0}/2\pi$, as shown in Fig. 26.17. In general, the relation between the shifted frequency f and x-direction wave number k_x is expressed as

Fig. 26.18

$$k_x = \frac{2\pi(f_{h_0} - f)}{u_m} \, . \qquad (26.17)$$

We can measure the original frequency f_{h_0} by a fixed reference microphone. Using the Doppler shift, we can therefore obtain the wave-number components from the frequency components of the moving microphone signal. Figure 26.19 illustrates how we obtain the wave-number spectrum.

This method essentially uses the relative coordinate between the hologram and microphone. Therefore, it can be used for measuring a hologram of moving noise sources (Fig. 26.20), which is one of the major contributions of this method [26.62–65].

26.2.4 Analysis of Acoustic Holography

Once we have a picture of the sound (acoustic holography), the questions about its meaning are the next topic of interest. What we have is usually a contour plot of the sound pressure distribution or a vector plot of the sound intensity on a plane of interest. This plot may help us to imagine where the sound source is and how it radiates into space with respect to a frequency of interest. However, in the strict sense, the only thing we can do from the two-dimensional expression of sound pressure or intensity distribution is to guess what was really there. We do not know, precisely, where the sound sources are (Fig. 26.21).

As mentioned earlier, there are two types of sound sources: active and passive sound source. The former is the source that radiates sound itself, while the latter only radiates reflected sound. These two different types of sound sources can be distinguished by eliminating reflected sound [26.116]. This is directly related to the way boundary conditions are treated in the analysis.

The boundary condition for a locally reacting surface can be written as [26.116–118]

$$V(\mathbf{x}_s; f) = A(\mathbf{x}_s; f)P(\mathbf{x}_s; f) + S(\mathbf{x}_s; f) \, , \quad (26.18)$$

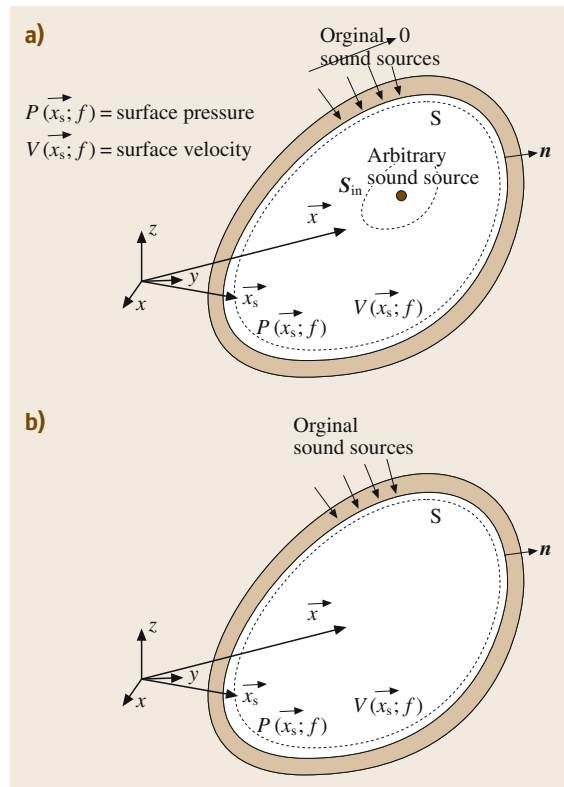
where $V(\mathbf{x}_s; f)$ and $P(\mathbf{x}_s; f)$ are the velocity and pressure on the wall. $A(\mathbf{x}_s; f)$ is the wall admittance and $S(\mathbf{x}_s; f)$ is the source strength on the wall. The active sound source is located at a position such that the source strength is not zero. This equation says that we can estimate the source strength if we measure the wall admittance. To do this, it is necessary to first turn off the source or sources, and then measure the wall admittance by putting a known source in the desired position (Fig. 26.22a). The next step is to turn on the


Fig. 26.22a,b Two steps to separate the active and passive source: (**a**) Admittance measurement, (**b**) source strength measurement

Fig. 26.23 Spatially independent or dependent sources

sources and obtain the sound pressure and velocity distribution on the wall, using the admittance information (Fig. 26.22b). This provides us with the location and strength of the source (i. e. the source power; for example, see Fig. 26.24).

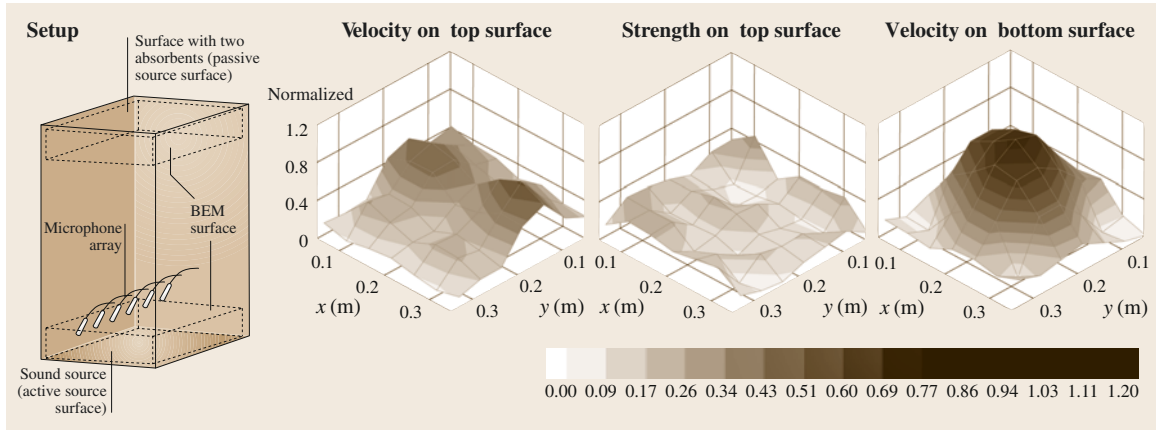
Another very important problem is whether or not we can distinguish between independent or dependent sources, i. e. two birds singing versus one bird with two


Fig. 26.24 Experiment results that separate the active and passive sources. The top surface is made by the sound absorption material. The speaker on the bottom surface, which is reflecting sound, is eliminated by this separation

– If inputs are independent (incoherent),
$$S_{PP}(f) = S_{P_1 P_1}(f) + S_{P_2 P_2}(f)$$

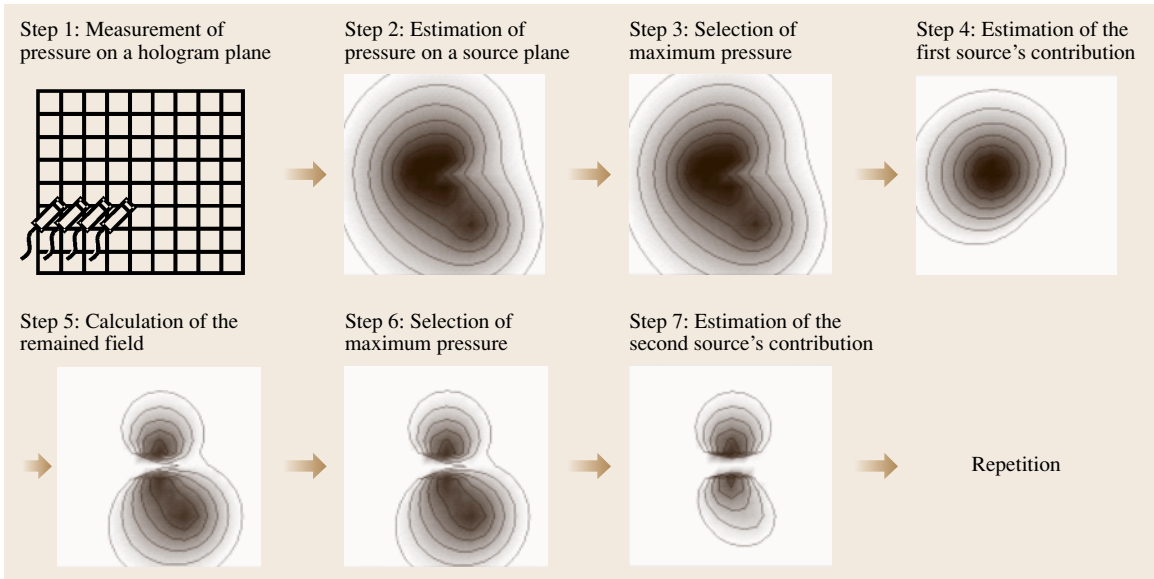

Fig. 26.28 The procedure to separate the independent and dependent sources
Fig. 26.29 The separation method applied to a vortex experiment

beaks (Fig. 26.23). This has a rather significant practical application. For example, to control noise sources effectively, we only need to control independent noise sources. This can be achieved by using the statistical differences between signals that are induced by independent and dependent sound sources.

For example, let us consider a two-input single-output system (Fig. 26.25). If the two inputs are independent, the spectrum $S_{PP}(f)$ of the output $P(f)$ can be expressed as

$$S_{PP}(f) = |H_1(f)|^2 S_{Q_1 Q_1}(f) + |H_2(f)|^2 S_{Q_2 Q_2}(f) \,, \tag{26.19}$$

where $S_{Q_i Q_i}(f)$ is the spectrum of the i-th input $Q_i(f)$, and $H_i(f)$ is its transfer function. The first and second terms represent the contributions of the first and second input to the output spectrum, respectively. If we can obtain a signal as

$$W_1(f) = C(f) Q_1(f) \,, \tag{26.20}$$

then we can estimate the contribution of the first source as [26.119]

$$S_{P_1 P_1}(f) = |H_1(f)|^2 S_{Q_1 Q_1}(f) = \gamma_{W_1 P}^2(f) S_{PP}(f) \,, \tag{26.21}$$

where $\gamma_{W_1 P}^2(f)$ is the coherence function between $W_1(f)$ and $Q_1(f)$ (Fig. 26.26).

We can simply extend (26.21) to the case of multiple outputs, as in the case of acoustic holography (Fig. 26.27). The main problem is how to obtain a signal that satisfies (26.20). We can generally say that, by putting sensors closer to the source or sources [26.57, 58, 120–123], we may have a better signal that can be used to distinguish between independent or dependent sources. However, this is neither well proven nor practical, as it is not always easy to put the sensors close to the sources. Very recently, a method that does not require this [26.124, 125] was developed. Figure 26.28 explains the method's procedures. The first and second steps are the same as in acoustic holography: measurement and prediction. The third step is to search for the maximum pressure on the source plane. This method assumes that the maximum pressure satisfies (26.20). The fourth step is to estimate the contribution of the first source by using the coherence functions between the maximum pressure and other points, as in (26.21). The fifth step is to calculate the remaining spectrum by subtracting the first contribution from the output spectrum. These steps are repeated until the contributions of the other sources are estimated (Fig. 26.29).

26.3 Summary

As expected, it is not simple to answer the question of whether we can see the sound field. However, it is now understood that the analysis of what we obtained, acoustic holography, needs to be properly addressed, although little attention was given to this problem in the past. We now understand better how to obtain informa-

tion from the sound picture. Making a picture is the job of acoustic holography, but the interpretation of this picture is the responsibility of the observer. This paper has reviewed some useful guidelines for better interpretation of the sound field to deduce the right impression or information from the picture.

26.A Mathematical Derivations of Three Acoustic Holography Methods and Their Discrete Forms

We often use the Kirchhoff–Helmholtz integral equation to explain how we predict what we do not measure based on what we do measure. It is noteworthy, however, that the same result can be obtained by using the characteristic solutions of the Helmholtz equation. The following sections address how these can be obtained. Planar, cylindrical, and spherical acoustic holography are derived using characteristic equations in terms of a corresponding coordinate system. The equations for holography are also expressed in a discrete form.

26.A.1 Planar Acoustic Holography

If we see solutions of the Helmholtz equation

$$\nabla^2 P + k^2 P = 0 \,, \tag{26.A1}$$

in terms of Cartesian coordinate, then we can write them as

$$P(x, y, z; f) = X(x) Y(y) Z(z) \,, \tag{26.A2}$$

where $k = \frac{\omega}{c} = \frac{2\pi f}{c}$. We assume then P is separable with respect to X, Y and Z. Equations (26.A1) and

(26.A2) yield the characteristic equation

$$\psi(x, y, z; k_x, k_y, k_z)$$
$$= \begin{pmatrix} e^{ik_x x} \\ e^{-ik_x x} \end{pmatrix} \begin{pmatrix} e^{ik_y y} \\ e^{-ik_y y} \end{pmatrix} \begin{pmatrix} e^{ik_z z} \\ e^{-ik_z z} \end{pmatrix}, \qquad (26.A3)$$

where

$$k^2 = k_x^2 + k_y^2 + k_z^2 . \qquad (26.A4)$$

Now we can write

$$P(x, y, z; f) = \int \hat{P}(\boldsymbol{k}) \psi(x, y, z; k_x, k_y, k_z) \, d\boldsymbol{k} , \qquad (26.A5)$$

where

$$\boldsymbol{k} = (k_x, k_y, k_z) . \qquad (26.A6)$$

Let us assume that the sound sources are all located at $z < z_s$ and we measure at $z = z_h > z_s$. Then we can write (26.A5) as

$$P(x, y, z; f)$$
$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \hat{\hat{P}}(k_x, k_y) e^{i(k_x x + k_y y + k_z z)} \, dk_x \, dk_y . \quad (26.A7)$$

It is noteworthy that we selected only $+ik_z z$. This is because of the assumptions we made ($z < z_s$ and $z = z_h > z_s$). The k_x and k_y can be either positive or negative. Therefore it is not necessary to include $-ik_x x$ or $-ik_y y$ in (26.A3).

In (26.7),

$$k_z = \begin{cases} \sqrt{k^2 - k_x^2 - k_y^2}, & \text{when} \quad k^2 > k_x^2 + k_y^2 \\ i\sqrt{k_x^2 + k_y^2 - k^2}, & \text{when} \quad k^2 < k_x^2 + k_y^2 . \end{cases}$$
$$\qquad (26.A8)$$

Figure 26.6 illustrates what these two different k_z values essentially mean. We measure $P(x, y, z = z_h; f)$, therefore we have data of the sound pressure data on $z = z_h$. A Fourier transform of (26.A7) leads to

$$\hat{\hat{P}}(k_x, k_y)$$
$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} P(x, y, z; f) e^{-i(k_x x + k_y y + k_z z)} \, dx \, dy . \qquad (26.A9)$$

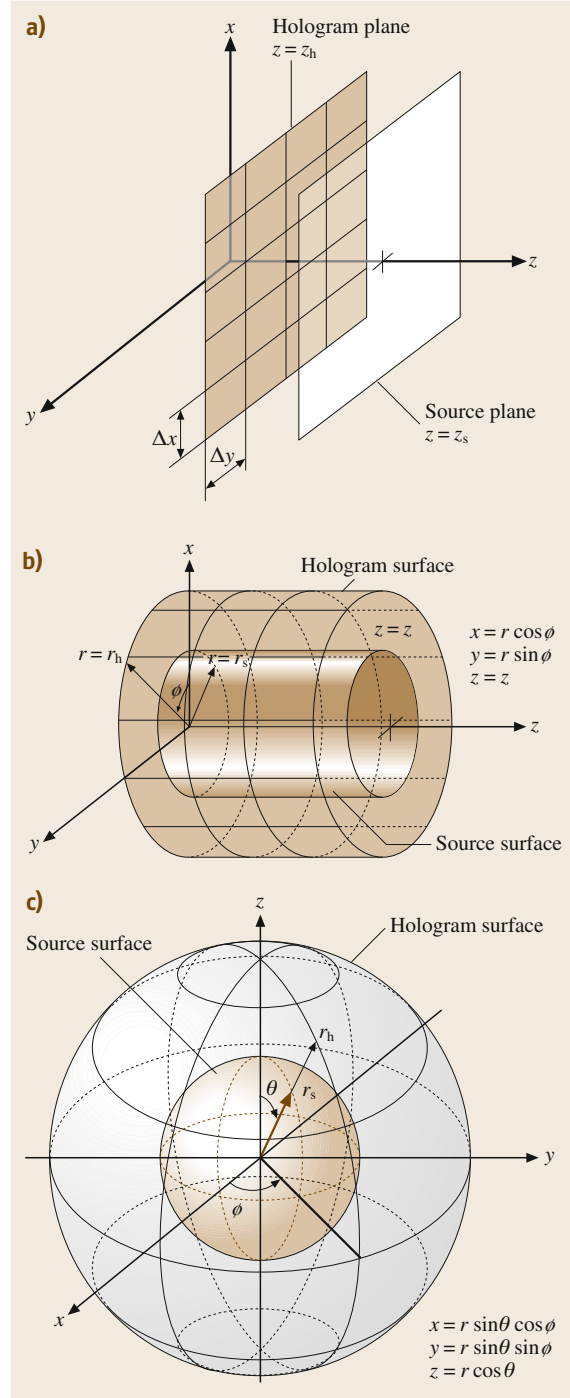
Using (26.A9) and (26.A7), we can always estimate the sound pressure on z, which is away from the source.


Fig. 26.30a−c Coordinates system for acoustic holography: (a) planar acoustic holography (b) cylindrical acoustic holography (c) spherical acoustic holography

It is noteworthy that (26.A9) has to be preformed in the discrete domain. In other words, we have to use a finite rectangular aperture, which is spatially sampled (26.8 and 26.30a). If the number of measurement points along the x-and y-directions are M and N, respectively, and the corresponding sampling distances are Δx and Δy, then (26.A9) can be rewritten as

$$
\hat{\hat{P}}(k_x, k_y) = \frac{1}{(2\pi)^2} e^{-ik_z z_h} \Delta x \Delta y
$$

$$
\sum_{m=0}^{M-1} \sum_{n=0}^{N-1} P(x_m, y_n, z_h) e^{-ik_x x_m} e^{-ik_y y_n} . \quad (26.A10)
$$

where

$$
x_m = \left(m + \frac{1-M}{2} \right) \Delta x ,
$$

$$
y_n = \left(n + \frac{1-N}{2} \right) \Delta y . \quad (26.A11)
$$

M and N are the number of data points in the x- and y-directions, respectively.

26.A.2 Cylindrical Acoustic Holography

A solution can also found in cylindrical coordinate, that is

$$
P(r, \phi, z) = R(r)\Phi(\phi)Z(z) . \quad (26.A12)
$$

Figure 26.1 shows the coordinate systems. Then, its characteristic solutions are

$$
\psi(r, \phi, z; k_r, k_z)
$$
$$
= \begin{pmatrix} H_m^{(1)}(k_r r) \\ H_m^{(2)}(k_r r) \end{pmatrix} \begin{bmatrix} e^{im\phi} \\ e^{-im\phi} \end{bmatrix} \begin{bmatrix} e^{ik_z z} \\ e^{-ik_z z} \end{bmatrix} , \quad (26.A13)
$$

where

$$
k^2 = k_r^2 + k_z^2 . \quad (26.A14)
$$

It is noteworthy that m is a nonnegative integer. $H_m^{(1)}$ and $H_m^{(2)}$ are first and second cylindrical Hankel functions, respectively. $e^{im\phi}$ and $e^{-im\phi}$ express the mode shapes in the ϕ-direction.

Using the characteristic function (26.A6), we can write a solution of the Helmholtz equation with respect to cylindrical coordinate as

$$
P(r, \phi, z; f) = \int \hat{P}_m(\boldsymbol{k})\psi_m(r, \phi, z; k_r, k_z) \, d\boldsymbol{k} ,
$$
$$
(26.A15)
$$

where

$$
\boldsymbol{k} = (k_r, k_z) . \quad (26.A16)
$$

Assuming that the sound sources are all located at $r < r_s$ and that the hologram surface is situated on the surface $r = r_h$, and that $r_h > r_s$, then no waves propagate into the negative r-direction, in other words, toward the sources. Then (26.A15) can be rewritten as

$$
P(r, \phi, z; f)
$$
$$
= \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} \hat{P}_m(k_z) e^{im\phi} e^{ik_z z} H_m^{(1)}(k_r r) \, dk_z ,
$$
$$
(26.A17)
$$

and k_r has to be

$$
k_r = \begin{cases} \sqrt{k^2 - k_z^2} , & \text{when } k^2 > k_z^2 \\ i\sqrt{k_z^2 - k^2} , & \text{when } k^2 < k_z^2 . \end{cases} \quad (26.A18)
$$

We measure the acoustic pressure at $r = r_h$, therefore $P(r_h, \phi, z)$ is available. $\hat{P}_m(k_z)$ can then be readily obtained.

That is

$$
\hat{P}_m(k_z) = \frac{1}{(2\pi)^2} \int_0^{2\pi} \int_{-\infty}^{\infty} P(r_h, \phi, z) e^{-m\phi} e^{-ik_z z}
$$

$$
\times \left\{ H_m^{(1)}(k_r r_h) \right\}^{-1} dz \, d\phi . \quad (26.A19)
$$

Inserting (26.A19) into (26.A17) provides us with the acoustic pressure at the unmeasured surface at r.

Discretization of (26.A19) leads to a formula that can be used in practical calculations

$$
\hat{P}_m(k_z) = \frac{1}{(2\pi)^2 H_m^{(1)}(k_r r_h)} \frac{2\pi}{L} \Delta z
$$

$$
\times \sum_{l=0}^{L-1} \sum_{n=0}^{N-1} P(r_h, \phi_l, z_n) e^{-im\phi_l} e^{-ik_z z_n} ,
$$
$$
(26.A20)
$$

where

$$
\phi_l = \frac{(2l+1)\pi}{L} ,
$$

$$
z_n = \left(n + \frac{1-N}{2} \right) \Delta z . \quad (26.A21)
$$

L and N are the number of data points in the ϕ- and z-directions, respectively.

26.A.3 Spherical Acoustic Holography

The Helmholtz equation can also be expressed in spherical coordinate (Fig. 26.30c). Assuming again that the separation of variable also holds in this case, we can write

$$P(r, \theta, \phi) = R(r)\Theta(\theta)\Phi(\phi) . \qquad (26.A22)$$

Substituting this into (26.A1) gives the characteristic equation

$$\psi_{mn}(r, \theta, \phi; k) =$$
$$\begin{pmatrix} h_m^{(1)}(kr) \\ h_m^{(2)}(kr) \end{pmatrix} \begin{pmatrix} P_m^n \cos \theta \\ Q_m^n \cos \theta \end{pmatrix} \begin{pmatrix} e^{in\phi} \\ e^{-in\phi} \end{pmatrix} . \qquad (26.A23)$$

m is a nonnegative integer and n can be any integer between 0 and m. $h_m^{(1)}$ and $h_m^{(2)}$ are first and second spherical Hankel functions. It is also noteworthy that P_m^n and Q_m^n are first and second Legendre polynomials.

Then we can write the solution of the Helmholtz equation as

$$P(r, \theta, \phi) = \sum_{m=0}^{\infty} \sum_{n=-m}^{m} \hat{P}_{mn} \psi_{mn}(r, \theta, \phi; k) . \qquad (26.A24)$$

Suppose that we have sound sources at $r < r_s$ and the hologram is on the surface $r = r_h > r_s$; then (26.A24) can be simplified to

$$P(r, \theta, \phi) = \sum_{m=0}^{\infty} \sum_{n=-m}^{m} \hat{P}_{mn} Y_{mn}(\theta, \phi) h_m^{(1)}(kr) , \qquad (26.A25)$$

where

$$Y_{mn}(\theta, \phi) = P_m^{|n|}(\cos \theta) e^{in\phi} . \qquad (26.A26)$$

This is a spherical harmonic function. It is noteworthy that we only have first spherical harmonic functions because all waves propagate away from the sources. The second Legendre function was discarded because it would have finite acoustic pressure at $\theta = 0$ or π.

Similarly, as previously stated, the sound pressure data on the hologram is available, therefore we can obtain $\hat{P}_{mn}$ in (26.A25) by

$$\hat{P}_{mn} = \frac{2m+1}{4\pi h_m^{(1)}(kr_h)} \frac{(m-|n|)!}{(m+|n|)!}$$
$$\times \int_0^\pi \int_0^{2\pi} P(r_h, \theta, \phi) Y_{mn}^*(\theta, \phi) \sin \theta \, d\phi \, d\theta , \qquad (26.A27)$$

where we have used the orthogonality property of Y_{mn}. The $*$ represents the complex conjugate. Using (26.A27) and (26.A25), we can estimate the acoustic pressure anywhere away from the sources.

The discrete form of (26.A27) can be written as

$$\hat{P}_{mn} = A_{mn} \frac{2\pi^2}{LQ} \sum_{l=0}^{L-1} \sum_{q=0}^{Q-1} P(r_h, \theta_l, \phi_q)$$
$$\times P_m^{|n|}(\cos \theta_l)(\sin \theta_l) e^{-in\phi_q} , \qquad (26.A28)$$

where

$$\theta_l = \frac{(2l+1)\pi}{2L} ,$$
$$\phi_q = \frac{(2q+1)\pi}{Q} . \qquad (26.A29)$$

where L is the number of data points in θ and Q is what is in ϕ-direction.

27. Optical Methods for Acoustics and Vibration Measurements

Nils-Erik Molin

Modern optical methods applicable to vibration analysis, monitoring bending-wave propagation in plates and shells as well as propagating acoustic waves in transparent media such as air and water are described. Field methods, which capture the whole object field in one recording, and point measuring (scanning) methods, which measure at one point (small area) at a time (but in that point as a function of time), will be addressed. Temporally, harmonic vibrations, multi-frequency repetitive motions and transient or dynamic motions are included.

Interferometric methods, such as time-average and real-time holographic interferometry, speckle interferometry methods such as television (TV) holography, pulsed TV holography and laser vibrometry, are addressed. Intensity methods such as speckle photography or speckle correlation methods and particle image velocimetry (PIV) will also be treated.

27.1 Overview

27.1.1 Chladni Patterns, Phase-Contrast Methods, Schlieren, Shadowgraph

Visualization of vibration patterns in strings, plates and shells and propagating acoustic waves in transparent objects such as air and water have been of great importance for the understanding and description of different phenomena in acoustics. *Chladni* [27.1] (1756–1824) sprinkled sand on vibrating plates to show the nodal lines. His beautiful figures challenged the research community for a theoretical description and Napoleon provided a prize of 3000 francs for someone that could give a satisfactory explanation; historical introduction by Lindsay in Lord Rayleigh's, *Theory of Sound* [27.2].

Chladni patterns are in some applications a simple, cost-effective way to visualize vibration patterns, often competitive to and an alternative to modern optical methods. In certain cases, such as for curved surfaces, the Chladni patterns may however, give completely misleading results.

Transparent or semitransparent objects such as cells and bacteria in microscopy, air flow and pressure fields in fluid mechanics, sound fields in acoustics etc. are objects that was not readily observed with the unaided eye. *Zernike* [27.3] developed phase-contrast microscopy, one of many optical, spatial-filtering techniques that operate in the Fourier-transform plane of imaging systems, to obtain images of such normally invisible objects. These techniques became very important in medicine and biology and are today used both in routine investigations and in research. In *Atlas de phénomènes d'optique* (Atlas of optical phenomena) [27.4] a collection of beautiful photographs of interference, diffraction, polarization and phase-contrast experiments are found. In *An Album of Fluid Motion* [27.5] different kinds of fluid flows are visualized. Classical optical filtering methods such as shadowgraph and Schlieren [27.6] are, together with interferometric methods, used to illustrate phenomena in turbulence, convection, subsonic and supersonic flow, shock waves, etc. Some of them, such as shock waves in air and water, certainly also generate sound fields. Still, most of those more classical methods only find limited application in acoustics since they mostly give qualitative pictures only. Practical optical methods with higher sensitivity, higher spatial resolution and that also give quantitative data have therefore been developed.

27.1.2 Holographic Interferometry, Acoustical Holography

In 1965 *Horman* [27.7], *Burch* [27.8], *Powell* and *Stetson* [27.9, 10] proposed to use holography [27.11] for optical interferometry. With holography a method was invented by which a wavefront, including phase and amplitude information, could be recorded and stored in a hologram. Subsequently a copy of the recorded wavefront could be reconstructed from the hologram for later use. At that time most holograms were recorded on special, high-resolution photographic plates. In ordinary photography it is the intensity (the irradiance distribution) that is recorded and displayed. This quantity is proportional to the amplitude squared. In that operation the phase is lost. And it is the phase that carries the information of the optical path: that is the distance to the

object, or the direction, for light passing through a transparent medium. Now, assume for instance that a hologram was exposed twice in the same setup (a double-exposed hologram) of an object in two different states, for instance with a small deformation introduced between the exposures. Then in the reconstruction both these two fields were reconstructed and displayed simultaneously. The total reconstruction then showed the object covered with a set of interference fringes (dark and bright bands) that display the difference in phase. A measure of the deformation field was thus obtained by letting an object interfere with itself. The techniques were called holographic interferometry or just hologram interferometry. Three sub-techniques evolved: two-exposure (or double exposure), time-average and real-time holographic interferometry. The research area evolved rapidly. A thorough, self-contained description of holographic interferometry of that time, including pulsed (two-exposure) holographic interferometry, is found in *Vest* [27.12]. For the first time diffusely scattering objects and transparent objects could be subjected to interferometric analysis. Holograms were, however, mostly recorded on photographic plates or film. The reconstruction of the recorded field was done optically and to evaluate data often a new set of photographs had to be made. All together, this was a quite time-consuming and complicated task and this fact stopped or hindered many attempts for industrial use of the technique. Holographic interferometry methods were also applied in acoustics quite early on [27.13], in what was called acoustical holography (see also Chap. 26).

27.1.3 Speckle Metrology: Speckle Interferometry and Speckle Photography

Speckle Interferometry and Shearography
The use of video systems to record holograms and speckle patterns was proposed by several groups in the early 1970s [27.14–17]. Several different names for such systems were proposed, among them, electronic speckle-pattern interferometry (ESPI). But these new holographic techniques also had quite limited commercial success. One drawback was the rather poor quality of the interferograms (poor resolution, noisy images); furthermore quantitative evaluation of deformation and vibration fields was still difficult to obtain. Any diffuse object that is illuminated by coherent laser light will normally appear very grainy (speckled) to an observer. These randomly distributed spots are called speckles. They carry information about the fine structure of the

objects micro-surface and of the optical system (the illumination and the observation system) used. The smaller aperture of the imaging system is set, the larger the speckles are. Speckles are of course also present in ordinary holographic interferometry but, as the apertures used here normally are much larger, the effects of speckles are not too severe. However, sometimes the speckles lowered the quality of the interferograms significantly, especially in early speckle interferometry. Vibration analysis using speckle interferometry was, however, developed quite far by a group in Trondheim [27.18–21]. With the improved capabilities during the 1980s of computers, sophisticated high-resolution charge-coupled device (CCD) cameras, fiber optics and ingenious piezoelectric devices, quantitative fringe interpretation became feasible. ESPI became digital and was renamed digital speckle-pattern interferometry (DSPI). Other names are electro-optic holography (EOH) and television (TV) holography. These methods are *all electronic* and they capture images at TV rate (25 pictures/s). Interferograms are also updated at such a rate that, for the human eye, they seem to be displayed in real time even if they are really time-average interferograms displayed at high rate, all in one system. Such systems work well both for sinusoidal vibrations and two-step motions. The quality of the interferograms was improved with the introduction of phase stepping [27.22–25] and speckle averaging methods [27.18, 19], which largely eliminated the noisy, speckled background.

Pulsed TV holography [27.12, 26–28] has a pulsed laser as a light source instead of continuous laser as in the ordinary TV holography system. It was used mainly for the study of transient and dynamic events both for solids and transparent objects.

Shearography or speckle shearing interferometry [27.29–31] is another branch of speckle metrology that can directly measure derivatives of surface displacements (without numerical differentiation of deformation fields) of surfaces undergoing a deformation. It is, for instance, used for nondestructive testing (NDT) of parts for the airplane industry and for tire testing. It is a much more robust technique than DSPI or TV holography. The laser-illuminated object is imaged twice, usually before and after some load or deformation is introduced, in such a way that two nearby object points in the image plane will overlap and interfere. This shearing effect can, for instance, be accomplished by letting the camera look at the object through a Michelson interferometer setup with the two mirrors slightly tilted with respect to each other, thus forming two overlapping

sheared images. A more traditional method is to cover one half of the imaging aperture (the camera lens) with a thin prism so that two sheared images will overlap each other in the image plane. Since both these sheared fields have traveled almost along the same path from the object to the image plane, they will both be submitted to about equal disturbances caused by the surroundings. In the sheared interferogram, these two fields are subtracted and therefore such equal disturbances will disappear and not affect the final interferogram. If, however, local disturbances exist, for instance an opening crack causing large in-plane, local deformations, such events will show up in the interferogram. The setup is thus quite robust and can be used in the workshop. Another advantage is that the measuring sensitivity can easily be changed by changing the amount of shear (tilt of mirrors in the Michelson setup) that is introduced. Even very large deformations or vibration amplitudes can be measured but since the instrument measures slope change (surface derivatives) the measured result has to be integrated to give deformation or vibration amplitudes. In [27.31–33] shearography is compared to TV holography and applied to measure vibration fields.

Several different kinds of speckle interferometry systems manufactured in Germany, US, Norway etc. are available on the market.

Laser Doppler Anemometry (LDA)

Parallel to full-field methods, point-measuring, interferometric methods were developed quite early. Laser Doppler anemometry (LDA, also named LDV where V stands for velocimetry) is a technique that measures flow velocities in seeded fluids such as air or water. It can also be used to measure the in-plane motion of solid surfaces. It was proposed as early as 1964 [27.34, 35]. A single laser beam is split into two beams. The beams are focused at an angle to each other into a common small volume in the flow, where they interfere so an interference pattern is formed in this small volume. Particles moving through this striped interference pattern scatter light with varying intensities when moving through it. The frequency of this intensity variation is measured. The distance between the interference stripes is given by the angle between the interfering beams and the laser wavelength. A measure of the velocity component of the flow at a right angle to the striped pattern is therefore obtained. With several crossing beams at different wavelengths in one point, it is possible to obtain several velocity components. Another explanation of the same phenomenon states that laser-illuminated, moving particles will scatter light

with a shifted frequency, a Doppler shift, relative to particles that have zero velocity. The frequency of this intensity variation is detected despite the very large difference in frequency between this Doppler signal and the frequency of undisturbed light by combining interferometry with heterodyne detection. It can be shown that this frequency shift is proportional to the flow-velocity component at a right angle to the interference pattern.

Laser Doppler vibrometry or just vibrometry [27.36] is a related interferometric point-measuring method that also uses a heterodyne technique. It is used to measure vibration amplitudes, or rather vibration velocities of vibrating surfaces instead of flow velocities. Here it is the Doppler shift that laser light experiences when it is reflected from a moving surface that is detected. It gives a measure of the out-of-plane velocity component of the moving object point if it is illuminated also at a right angle. Both LDA and vibrometry systems can be equipped with scanning facilities that allow whole-field measurements. To preserve relative phase information in the signals when moving from one measuring point to the next, some kind of reference signal from a microphone, accelerometer or other transducer is necessary. Hardware and software of point-measuring techniques are sold by several manufacturers and the equipment is today quite user-friendly but also rather expensive.

Digital Speckle Photography (DSP) Speckle Correlation, Particle Image Velocimetry (PIV)

Another branch of speckle metrology [27.37–40] in addition to speckle interferometry, is speckle photography or speckle correlation methods. Speckle photography measures the bulk motion of the speckle pattern, the random noisy pattern that is present. This random pattern is either created artificially (i.e. sprayed dots of paint), present naturally (i.e. as fibers in a wood sample) or caused by laser-light illumination of diffuse objects. In speckle interferometry it is the phase coded in intensity of the speckles (assumed more or less stationary in space) and in speckle photography it is the position of the speckles that is detected. Speckle photography is based upon the fact that, if the laser-illuminated object is moved or deformed, then the speckles in the image plane will also move. So speckle photography in its simplest form gives a measure of the in-plane motion of the object surface. In particle image velocimetry (PIV) a sheet of light illuminates a flow seeded with suitable scattering particles [27.41]. These particles follow the flow. They are imaged twice with a CCD camera at a known

time interval. The distance the particles have moved is determined with a correlation technique. In this way a measure of the flow velocity field is obtained [27.42].

27.1.4 Moiré Techniques

The Moiré effect, sometimes also named mechanical interference, shows up in many practical viewing situations. It is called mechanical interference since it is not optical interference between light fields that is studied; instead two or more striped, meshed, physical intensity patterns are overlaid and imaged most often in white light illumination. Folded fine-meshed curtains, suits of people appearing on TV, netting along roads etc. sometimes become modulated by a coarse pattern overlapping the finer mesh itself; in many cases this finer mesh is not resolved at all only the coarse, so-called Moiré patterns remain. Moiré as a measuring technique is quite old [27.43, 44]. It is related to the more modern speckle photography technique with the great difference that, instead of a random pattern, a regular pattern, a grating or a mesh, is used. If two identical gratings are overlapped and imaged a regular pattern of so called Moiré fringes will show up. If one of the gratings is glued onto an object and this object is deformed a modulation of the Moiré fringes will appear when this grating is compared to the stationary grating. This exemplifies an in-plane measuring technique using the Moiré effect. Combined with high-speed photography this technique has been used for the study of very fast events in engineering mechanics [27.45].

Techniques to measure out-of-plane deformations, vibrations, shape (contouring) are also in use as well as shadow Moiré, projected fringe techniques etc. These techniques are also named triangulation techniques since they rely on the fact that, if a regular striped pattern is projected onto a curved object surface, initially straight fringes will appear curved. A viewer will record different curved fringe patterns from different positions in the room. Knowing the geometrical parameters it is then possible to determine, e.g., the shape of a body illuminated by the projected fringes. One great advantage of Moiré methods is that the sensitivity can be chosen at will by proper selection of the line separation of the grating lines. This distance can be compared to the wavelength in optical interferometry. Quite small up to very large deformation fields can therefore be studied. A good overview of Moiré techniques can be found in [27.46], a book in which many other different phenomena and methods in optical metrology are described.

27.1.5 Some Pros and Cons of Optical Metrology

In the following, measuring principles for holographic interferometry, speckle metrology, vibrometry, pulsed TV holography, Moiré methods and PIV are discussed together with some applications. The main advantages of these methods are:

- There are no contact probes. They are non-disturbing.
- Most of them are whole-field, all-electronic methods. They give pictures.
- They give not only qualitative but also quantitative measures.
- The (digital) processing is often very fast, sometimes as if in real time.

- Pulsed lasers give very short light pulses (exposure times ≈ 10 ns), that *freezes* propagating sound fields and vibrations as if stationary.

Some disadvantages are:

- Optical equipment and lasers are, in many cases, still quite expensive.
- Trained personnel are needed to get full use of high-technology equipment.
- Speckle interferometry methods such as TV holography (DSPI, ESPI) most often need auxiliary equipment such as vibration-isolated optical tables placed in rooms that are not too dusty or noisy. Others, such as pulsed TV holography and vibrometry instruments, work well in more hostile environments without vibration isolation.
- Lasers are used and must be handled in a safe way.

27.2 Measurement Principles and Some Applications

27.2.1 Holographic Interferometry for the Study of Vibrations

With the introduction of holographic interferometry in 1965, amplitude fields of vibrating, diffusely reflecting surfaces could be mapped. Earlier only mirror-like, polished objects were used in interferometry but now suddenly all kinds of objects could be studied. The interest in holographic methods increased dramatically. The most often used technique for vibration studies was time-average holographic interferometry [27.9, 10]. A hologram of the vibrating object was recorded while the object was vibrating. The exposure time of the photographic plates was quite long, often about one second. This time was long compared to the period time of the object vibration so light fields from many cycles contributed to the total exposure of the photographic plate. After development this plate is called a hologram. In the optical reconstruction of the hologram, these object fields were reconstructed simultaneously. Now, a sinusoidally vibrating object spends most of its time in each cycle at the turning points, where the velocity is momentarily zero. These parts (at a distance of twice the amplitude of vibration) therefore contribute the most (spend the longest time) to the total exposure and therefore these parts will also dominate the reconstructed fields. A time-average field is therefore reconstructed, and essentially light beams from the turning points in-

terfere with each other. Iso-amplitude fringes that cover the object surface are mapped using this technique. The intensity of the reconstructed image of a sinusoidally vibrating surface can be described by

$$I(x, y) = I_0(x, y)J_0^2(\Omega) , \tag{27.1}$$

where $I_0(x, y)$ is the intensity of the object at rest and J_0 is the zero-order Bessel function of the first kind. The exposure does not have to span many cycles to get the J_0^2 function in time-average techniques. It is also possible to record time-average interferograms of low-frequency vibrations.

The argument

$$\Omega = \boldsymbol{K} \cdot \boldsymbol{L} , \tag{27.2}$$

where $\boldsymbol{K}$ is a sensitivity vector defined as

$$\boldsymbol{K} = \boldsymbol{k}_1 - \boldsymbol{k}_2 , \tag{27.3}$$

and $\boldsymbol{L}(x, y)$ is the vibration amplitude field. $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ are the illumination and observation directions, respectively, measured relative to the normal of the object surface. With normal illumination and observation directions the maximum sensitivity becomes

$$|\boldsymbol{K}| = \frac{4\pi}{\lambda} , \tag{27.4}$$

where λ is the laser wavelength used.

A deformation field or a vibration field $\boldsymbol{L}(x, y)$ is however vectorial, that is, it has three components.

Equation (27.2) implies that it is the projected component of $L(x, y)$ along the sensitivity vector K that is measured. With normal illumination and observation directions only the out-of-plane component is therefore measured. To obtain the in-plane components the measurements can be performed with two or more inclined illumination and observation directions. Several reference beams may also be used; see for instance [27.12, 47, 48]. With two symmetrically placed and inclined illumination directions and with observation along the object normal, the sensitivity will be zero for the out-of-plane component and optimal for one in-plane component [27.49]. A device for planning and evaluation of holographic interferometry measurements is called a holo-diagram [27.50], proposed by Abramson and in [27.23], Kreis presents computer methods to optimize holographic arrangements for different purposes.

For a two-step (double-exposure or double-pulsed) motion the squared zero-order Bessel function in (27.1) is replaced by a squared-cosine function with half the argument, that is, $\cos^2(\Omega/2)$. $L(x, y)$ is now the displacement of the object field that has taken place between the two recordings (pulses).

Most studies of vibrating objects, however, involve a combination of the time-average and real-time holographic interferometry technique [27.10]. Real-time observation of the vibration field gives very useful information to the experimentalist. A search for resonant modes can be made in real time to find the settings of frequency, amplitude and position of exciters etc. The vibration pattern is then recorded by the time-average technique, which often gives very nice interferograms that allow a more detailed analysis of the vibration field. Vibration modes of a violin recorded at different steps in making the violin [27.51–53] used this combined technique.

To illustrate these combined traditional techniques, the following experiment is sketched. The setup used is pictured in Fig. 27.1.

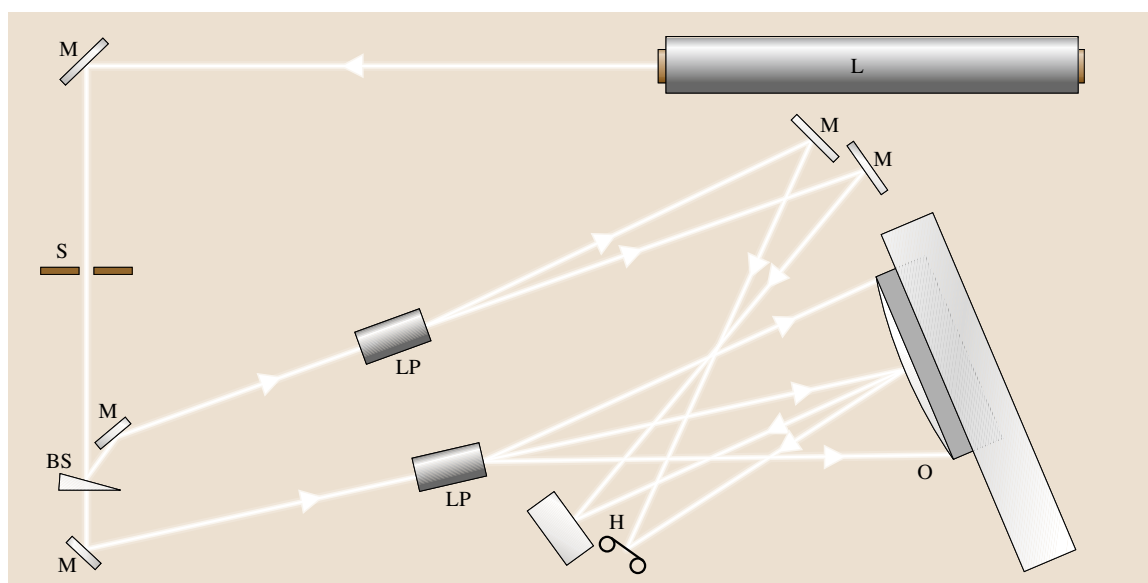
The laser, optical and mechanical components and the object are placed on a vibration isolated optical table in an off-axes holographic setup. In the off-axes technique there is an angle at the hologram plate between the object-observation direction and the reference-beam direction so that the object appears against a dark background. This way an observer does not have to look into the bright laser light from the reference beam to see the object. Beautiful reconstructions are thus obtained [27.54]. First a hologram is recorded of the object at rest, in this case the bottom of a herring can. The hologram is recorded on a high-resolution photographic plate in a special holder, a liquid gate hologram plate


Fig. 27.1 A combined real-time and time-average hologram interferometry setup. Abbreviations: laser (L), front surface mirrors (M), glass wedge beam splitter (BS), beam expander lens–pinhole system (LP), shutter (S), a liquid gate hologram plate holder and a holder for 35 mm film (H) and an object (O), for instance a herring can or a guitar clamped to a rigid, heavy jig (J)
Fig. 27.2 (a) The test object, the bottom of a white-painted herring can, observed in its rest position in the real-time hologram interferometer using the liquid gate hologram holder (H) in Fig. 27.1, (after [27.55]). The object field emanating from the herring can is transmitted through the hologram and interferes with the field reconstructed by the hologram. These fields are so similar that no interference fringes are seen (actually it is the same broad white fringe that is covering the whole object). **(b)** Real-time interferogram obtained by taking a photo through the liquid gate when the herring can is vibrating in its fundamental mode. **(c)** Time-average interferogram obtained from a time-average hologram recording (using the film holder at H in Fig. 27.1) of the same vibration pattern as in Fig. 27.2b. (courtesy of IOP)

holder [27.55]. It is exposed to the interfering light from the reference and object beam. The object field at rest is reconstructed by illuminating the hologram with the former reference wave or a laser wave proportional to it, in the same setup as before. The reconstructed stationary object field is then observed by looking through the hologram by eye or with a camera. Compare Fig. 27.2a which shows the bottom of the elliptical herring can at rest.

Now, if the original object is also illuminated by laser light in the same setup as before and observed through the hologram, the observer will see two images of the same object through the hologram, one as it is in real time and one as it was when the hologram was recorded. As both fields are coherent (the same laser reconstructs and illuminates the object), they will interfere. If the two fields are identical, no fringes will appear. To be more correct, since a negative hologram plate (a high irradiation gives a high exposure of a photographic plate, which is dark (high absorbing) and not bright) is used for the real-time holographic reconstruction and this field is added to the direct field observed through the hologram, the total object field should appear dark since the two fields are identical but out of phase (one field is negative and the other positive). If however the hologram plate holder or the object itself is moved slightly so that the first white cosine fringe covers the whole object, then the whole field will appear bright. Actually Fig. 27.2a is such a recording. The object is at rest but slightly translated from its initial position. When the object is vibrating it will become covered with interference fringes – compare Fig. 27.2b. The contrast of such real-time fringes are, however, quite low. It is also difficult, without special techniques, to avoid spurious fringes caused by

rigid-body motions, emulsion shrinkage etc. of the real-time interferogram. Therefore a time-average hologram of interesting patterns is recorded; compare the time-average interferogram of the same vibrating herring can in Fig. 27.2c. This time-average hologram is recorded on 35 mm holographic film in a hologram film holder (a camera house without lenses), at H in Fig. 27.1. It is placed close to the real-time hologram liquid gate on the hologram table. The time-average interferogram contains twice as many fringes with higher contrast than the corresponding real-time one. The distance from peak to peak in a sinusoidal vibration is also twice as great as the distance from the peaks to the average (the amplitude) value. This is why the number of fringes is doubled. This combined real-time and time-average technique has been applied to many different structures, such as musical instruments, turbine blades, aircraft and car structures etc. Figure 27.3 shows an example of

Fig. 27.3 Time-average interferogram of a guitar top plate vibrating at 505 Hz (Bolin guitar from 1969)

a time-average recording of a vibration mode of a guitar front plate identified using the real-time technique and recorded by time-average hologram interferometry. This picture was used as a Christmas card interferogram and it appeared in a number of physics textbooks, see also [27.56, 57]. It may be pointed out that the quality of interferograms as well as the spatial resolution, obtained in this way was high but it was a time-consuming task to obtain them compared to today's methods.

Practical resolution of vibration modes by visual observation in real time is often better than 100 nm ($\lambda/10$) – compare Fig. 27.2b. Practical maximum measurement range for time-average recordings as in Fig. 27.2c is about 4 µm, otherwise the fringe density might be too high to be resolved. The maximum possible object size in width and depth depends very much upon the laser used, both its output energy and its coherence length. The coherence length of the laser determines how big a difference in path length between the reference wave and the object beam is allowed if recording high-quality holograms. The difference in path length between the reference beam, from the laser via mirrors to the hologram, and the object beam, from the laser via the object to the hologram, should therefore not exceed the coherence length. This is easily determined with a soft string fastened at the laser and at the hologram. The power of the laser and the object reflectivity determines the width of the object and the coherence length, and thus the depth of the object volume. Objects that absorb light might be dusted with

chalk or painted white. In difficult cases retro-reflective paint or tape might be used. The guitar interferogram shown in Fig. 27.3 was recorded using a 20 mW HeNe laser having a wavelength of 633 nm and a coherence length of about 25 cm, the guitar shown in Fig. 27.3 was recorded. Remember that a holographic setup is sensitive to disturbances; an optical vibration-isolated table is recommended. Powerful lasers shorten the exposure time and lower the requirements for vibration isolation.

Holographic interferometry has been further developed using pulsed or stroboscopic techniques, temporal phase modulation as well as for studies of transparent objects such as flames, pressure waves in air and water. The books by *Vest* [27.12], *Kreis* [27.23] and *Hariharan* [27.48] are recommended. In practice today, all electronic, digital speckle interferometry methods have more or less replaced wet-processing photographic holographic interferometry, at least for industrial use. The fundamental ideas are, however, still the same.

27.2.2 Speckle Interferometry – TV Holography, DSPI and ESPI for Vibration Analysis and for Studies of Acoustic Waves

Speckles [27.32–35, 46, 47] are the granular, speckled appearance that a laser-illuminated diffusely reflecting object gets, when imaged by an optical system such as the eye or a camera. The speckles can be viewed as a fingerprint that is as a unique, random pattern
Fig. 27.4 The optical unit of TV holography (electro-optic holography, DSPI). Abbreviations: beam splitter (BS), speckle average mechanism (SAM), mirrors on piezoelectric devices used for phase stepping (PS) and sinusoidal phase modulation (PM), relay lenses (R). The distance between the optical head to the left and the object to the right can vary considerably depending of object size, magnification etc.

generated by the fine structure of the object surface. One technically important property of the speckles is that the speckles seem to move as if glued to the object surface when the object is moved or deformed. A change in illumination or observation directions of the object will however also change the speckle pattern. Two different observers both see speckles but with different distributions. The speckles were earlier looked upon as unwanted noise but as they also carry information; they also form the basis for techniques such as speckle photography (SP) and speckle interferometry (SI). They both belong to a group of methods named speckle metrology [27.32–34]. In SP the in-plane motion of the speckles themselves is measured, and in SI the change in intensity of the speckles (i.e. the phase change of interfering beams) are used. Hologram interferometry is also based on recording the information of the same speckles.

The optical arrangement of a speckle interferometer setup called TV holography or electro-optic holography [27.25] (also named DSPI or ESPI) is shown in Fig. 27.4. A special computer board is developed that allows real-time presentations of phase-stepped interferograms.

Laser light is divided by a beam splitter (BS) into an object illumination part and a reference wave part. The object space, situated to the right, is illuminated and imaged almost along the z-axis of the object. The measuring sensitivity of this configuration therefore also becomes highest along the same direction and consequently zero along the x–y-axes. The object light amplitude field, E_{obj}, is imaged by a video lens and some transferring optics onto the photosensitive surface of the CCD chip, where the smooth reference beam, E_{ref}, also emanating from the end of an optical reference fiber is added. Each pixel of the CCD camera pictures a small area in the object space, i.e. this can be described as an in-line, image-plane holographic setup. Via a special personal computer (PC) image-processor board, results are presented at the rate allowed by the digital camera (25 or 30 Hz) on a monitor, which is a highly valuable feature in many experimental situations. In the setup there are mirrors mounted on piezoelectric crystals, allowing phase modulation (PM) and phase stepping (PS). These options are used to determine the relative phase of vibration fields and to extract quantitative data from the interferograms.

The optical detectors are so-called quadratic detectors. They measure intensity or irradiance which in turn is proportional to the square of the sum of the two interfering electromagnetic amplitude fields. The instantaneous intensity $I(x, y)$ at a pixel of the CCD detector can therefore be written

$$I(x, y) = |(E_{obj} + E_{ref})|^2 = I_0 + I_A \cos(\Delta\Phi),$$
(27.5)

where I_0 is the background intensity and I_A the modulating intensity. The desired information however, is found in $\Delta\Phi$, the relative optical phase difference between the (constant) reference and the object field in each pixel. A difficulty exists since there are three unknowns in (27.5); $\Delta\Phi$, I_0 and I_A but only one equation. This can be solved by Fourier-filtering methods or phase-stepping (shifting) techniques [27.22–24]. In the phase-stepping technique, PS in Fig. 27.3 is used to shift the phase with, for instance, $\pi/2$ in steps between consecutive recorded frames to obtain four equations. With four equations and three unknowns, $\Delta\Phi$ can be calculated with good accuracy. In double-exposure and pulsed TV holography two series of recordings are made, one before and one after some deformation or change is introduced to the object. The corresponding phase changes $\Delta\Phi(x, y)$ for each of the two states are determined as above and then subtracted. Since the same reference beam is used in the recording of both states, ideally only the difference in object phase will remain after subtraction. The change in object phase, $\Omega = \Delta\Phi_1 - \Delta\Phi_2$, between the two objects fields are thus obtained. This quantity, Ω in turn is defined as the change (Δ) of the product of refractive index n, the geometrical path length l and the laser wave number k. That is, the measured change in optical phase between two object states can be written as

$$\Omega = \Delta(knl) = k(n\Delta l + l\Delta n).$$
(27.6)

The wave number, $k = 2\pi/\lambda$, is (most often) a constant since λ, the laser wavelength, is the same in all recordings. Equation (27.6) illustrates two main application areas: one where the optical phase change is proportional to the change in path length (i.e. vibration amplitudes, deformation fields etc.) and one where it is proportional to the change in refractive index (caused by, for instance, wave propagation in fluids, flames etc.).

The TV holography system, shown in Fig. 27.4, illuminating and observing the object along its normal, is highly sensitive to out-of-plane vibrations or object motions and insensitive to in-plane motions. A frequency doubled, continuous-wave Nd:YAG laser with a wavelength of 532 nm, is often used. Such lasers often have a higher output power and a longer coherence length than most comparable He–Ne lasers, say 50 mW and
Fig. 27.5 Interferograms of four modes of vibration of the bottom of the same herring can as in Fig. 27.2, now recorded using TV holography. Both real-time observation to find the settings and time-average recordings are made at once

a few meters in coherence length. The object size can now vary from a few mm up to meter-sized objects both in width and depth. With visual observation of the monitor in real time, the resolution of the vibration amplitude is often better than 100 nm and, if the phase-stepping technique is used, the resolution limit is of the order of 20 nm, compare Fig. 27.5. The practical maximum amplitude range for vibration modes is about 2.5 μm. To be able to unwrap (numerically evaluate) fringe patterns automatically without problems, fringe densities should be kept low; not less than 15–20 pixels/fringe is recommendable. For example, a CCD camera may have 512×512 pixels or more. If the imaged object covers all 512 pixels this would allow about 25 fringes or more over the whole object field to be analyzed automatically. So it is preferable that as much as possible of the CCD chip is used to image the object. This is favorable both for the unwrapping and also for the spatial resolution of the imaged object. It is also a great advantage if a vibration-isolated optical table is used for the experiments.

The TV holography system, like many other commercial systems can also be arranged for maximum sensitivity for motion in the plane or in some other direction. Dual-beam, symmetric illumination directions about the object normal and normal object observation direction are used to achieve maximum in-plane motion sensitivity and no sensitivity to out-of-plane motions [27.47–49]. Practical resolution (adjusted for noise) is now about 30 nm with phase-stepped interferograms. The maximum measurement range for the vibration mode is about 2.5 μm. The object size in this

case is often limited by the size of the illuminating lenses if equal sensitivity (with collimated light) over the whole object area is important. So, object diameters smaller than 5–10 cm are often the case, but much larger objects can be studied if varying sensitivity over the object field is allowed. Other 2-D (two-dimensional) and 3-D (three-dimensional) arrangements that measure two or three vibration components are also commercially available.

Interferograms of Vibration Modes Using TV Holography

In normal use the TV holography setup is used for sinusoidally vibrating, diffusely reflecting objects, such as the bottom of the elliptical herring can in Fig. 27.5. This is the same can that was used in Fig. 27.2, 35 years earlier. Since then the ravage of time has changed the can somewhat. It has been dropped from the shelf etc. and despite its rigid construction the mechanical shape and behavior has changed somewhat during the years. It is not as symmetrical as before. This experiment is also an example of nondestructive testing of components, which is a large application area of TV holography where vibration analysis is used.

In Fig. 27.5 the setup is arranged so that the change in index of refraction can be neglected; only the first part, $\Omega = kn \Delta l$, of (27.6) remains. In this way we get a measure of the change in geometrical path length Δl. A complication with sinusoidally vibrating objects such as the herring can is that the modulation of the interference fringes is, as in time-average holographic interferometry, not cosinusoidal as with two-step motions (i. e. double exposure, double-pulsed holographic and pulsed speckle interferometry) but instead modulated by a zero-order Bessel function squared $J_0^2(\Omega)$, (27.1). As before, this has to do with the integrated exposure during several cycles that the detector gets when the period time of the sinusoidally vibrating object is much shorter than the exposure time of the detector (about 1/25 s at a video rate of 25 frames per second). It is, however, also possible to record time-average interferograms of low-frequency vibrations. It is only at the start that the fringe function is somewhat dependent on which part of the vibration the integration spans – after 2–3 periods the difference between the recorded fringe function and the theoretical is negligible. The white closed line (fringe) along the rim of the can, in some higher modes connected to vertical white fringes, indicates zero amplitude, i. e. a nodal line. The bright and the dark closed loop fringes connect points with equal vibration amplitude, increasing towards the center towards a hill
Fig. 27.6 TV holography interferogram of a baritone guitar showing a top-plate mode at 262 Hz (after [27.58])

Fig. 27.7 A phase map of the same guitar mode as in Fig. 27.6 measured by phase-modulated TV holography. The units for the phase values at the z-axis are radians (after [27.58])

or a valley. Measurements such as this are quite simple to perform since the equipment works well in real time. Quantitative values of the vibration amplitude and phase in each pixel is also possible using the modulation options in the setup. This is exemplified in Figs. 27.6 and 27.7 [27.58]. Figure 27.6 shows an ordinary TV holography recording of a mode shape of a baritone guitar mode at 262 Hz. Since this is a normal vibration mode of the front plate, the phase on each side of the vertical nodal line at the bridge should be in anti-phase.

It must, however, be stressed that, in many practical vibration situations, normal modes are often replaced by combinations or superpositions of a number of different modes. A loudspeaker, for instance, often only shows uniform, normal-mode behavior at the lowest modes. At higher frequencies the phase may vary quite a lot over the field of view; not only object areas vibrating in anti-phase are present but there is a continuous change of phase over the loudspeaker membrane. A simple test to see if mode combinations are present is to observe if nodal lines are stationary when the driving amplitude is increased from zero upwards or when the frequency is varied slightly about an amplitude resonance peak. If the nodal lines start to move sideways or twist, or so that nodal points or other peculiar phenomena occur, then mode combinations can be the source. If the experimentalist is not sure that it is a real normal mode that he has detected, i.e. one that does not have neighboring vibrating areas vibrating in anti-phase, he often calls it an operation deflection shape (ODS). So, there is a need for the experimentalist to measure not only the amplitude distribution but also the phase variation over the field of
view to be sure. One technique is to set the mirror (PM in Fig. 27.4) in vibration at the same frequency and in phase with one of the vibrating areas of the object. If the amplitude of the mirror is then increased from zero, the white nodal line will start to move to new object points where the difference between the object amplitude and the mirror amplitude is zero. If, as in Fig. 27.6, a normal mode is studied, one vibrating area gets smaller (that is, there are fewer fringes in the area which is in phase with the mirror) and one area gets larger as the nodal line moves. Another technique is to use a small frequency difference, a *beat*, between the object frequency and the mirror frequency. By visual inspection, moving nodal lines are seen. A review of a number of different measurement techniques of mechanical vibrations is given by *Vest* in [27.12], by *Kreis* in [27.47] and by *Stetson* in [27.59].

The vibration phase can also be determined quantitatively using phase modulated TV holography (again using PM in Fig. 27.4). The phase difference between the upper and lower bouts, as shown in Fig. 27.7, was measured as π with such a method. Phase modulated TV holography is a technique used to measure phase and amplitude of small vibrations [27.21]. The method uses Bessel-slope evaluation of small amplitudes. Here the vibrating mirror and the object itself are given such small amplitudes such that the total maximum amplitude is kept within the linear part of the J_0^2 fringe function at low arguments. The vibrating reference wave is given such amplitude that it forms a working point, where the slope of the fringe function is the largest and around which the object amplitude may

vary. By changing the phase in steps of the reference wave relative to the object wave a number of recordings are made with a known phase difference. From this the phase and amplitude distribution can be estimated. A review of such recent developments in speckle interferometry is given by *Lökberg* as one chapter in [27.37]. Visual use of the phase-modulated techniques works in near real time, but calculations based on phase-modulation take a short time.

Visualization of Aerial Waves Using TV Holography

To get a measure of the sound field, the geometrical path length l in (27.6), is kept constant so that the first part $kn\Delta l$, equals zero. Then only the $kl\Delta n$ part remains. Since an increased air density or air pressure gives an increase to the refractive index Δn the way to see the sound is simply to let the index of refraction vary along the probing length l in a measuring volume. This distance l has to be kept constant to be able to quantify the results. Figure 27.8 illustrates the measuring principle.

Inside the box a standing aerial wave is generated by a loudspeaker. The incident plane light wave is modulated by the aerial pressure and density field in the box. A curved wavefront is generated to the right of the box. This phase change may also be measured by the TV holography system in Fig. 27.4.

Projections of the box are shown in Figs. 27.9 and 27.10. Laser light travels through the measuring vol-

Fig. 27.9a–c Air mode $(2, 0, 0)$ in the rectangular transparent box in Fig. 27.8 (after [27.60]). (**a**) View along the shortest side (1 dm); (**b**) View along the next shortest side (3 dm); (**c**) phase along the x-axis in (**a**) measured by phase-modulated TV holography (courtesy of S. Hirzel Verlag)

ume, in the simplest case a rather flat, 2-D, transparent box. The light field is phase modulated by a standing aerial wave inside the box. To increase the modulation the field is reflected back again by a rigid diffuse wall (not seen in Fig. 27.8) to pass through the box twice and then pass on into the interferometer (Fig. 27.4) as the object beam. The instantaneous phase shift compared to the undisturbed air (no standing wave) with index of refraction n_0 can then be written as

$$\Omega(t, y) = \frac{4\pi}{\lambda} \int_L [n(t, x, y) - n_0] \, dx$$

$$\cong 2k[n(t, y) - n_0]L \,. \qquad (27.7)$$

Since L can be measured, the integrated product of L and $\Delta n = n - n_0$ in (27.3) is known. The refractive index n is related to the air density ρ by the Gladstone–Dale equation, $n - 1 = K\rho$, where K is the Gladstone–Dale constant [27.12]. If, for instance, adiabatic conditions are assumed $(p/p_0) = (\rho/\rho_0)^\gamma$, then the relations between air density ρ and pressure p are also known. By combining these equations, a quantitative measure of the sound pressure $p(x, y, t)$ at all points in the projected field of view can be obtained.

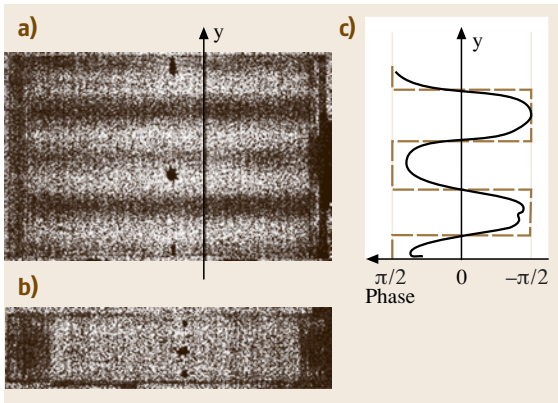
Fig. 27.8 A plane laser wave is traveling through a transparent box with dimensions $10\,\text{cm} \times 30\,\text{cm} \times 50\,\text{cm}$; the geometrical path length L is $10\,\text{cm}$ (after [27.60], courtesy of S. Hirzel Verlag)


Fig. 27.10a–c Air mode (0, 4, 0) in the rectangular transparent box in Fig. 27.8 (after [27.60]). **(a)** View along the shortest side; **(b)** view along the next shortest side; **(c)** phase along the x−axis in **(a)** measured by phase-modulated TV holography (courtesy of S. Hirzel Verlag)

Observe that it is the integrated field that is measured; thus when we have a 2-D distribution of the sound field like the one in Fig. 27.8, it can be assumed that the integral in (27.3) is reduced to the simple product $2k(n − n_0)L$. If not, the integral equation in (27.7) remains and tomography has to be used to reveal the distribution, see for instance Appendix B in [27.23]. Figs. 27.9 and 27.10 show measured standing waves inside the transparent box in Fig. 27.8 for two different

air modes [27.60]. Fig. 27.11 shows standing waves inside a guitar body with a transparent top and back plate measured by phase-modulated TV holography [27.61].

If instead a probing laser ray is passing through the box in Fig. 27.8 in the x-direction, it will experience a time-varying phase change. A small frequency shift is thus generated by the standing aerial waves inside the box. This shift can be detected by a laser vibrometer; compare Sect. 27.2.5.

27.2.3 Reciprocity and TV Holography

An indirect pointwise method to measure the sound distribution from an instrument is to use reciprocity [27.62] combined with, for instance, TV holography [27.63]. An advantage of this method is that, even in a quite large spatial volume, radiativity [27.64] can be recorded. This is valuable since audible acoustical waves at low frequencies can have very long wavelengths.

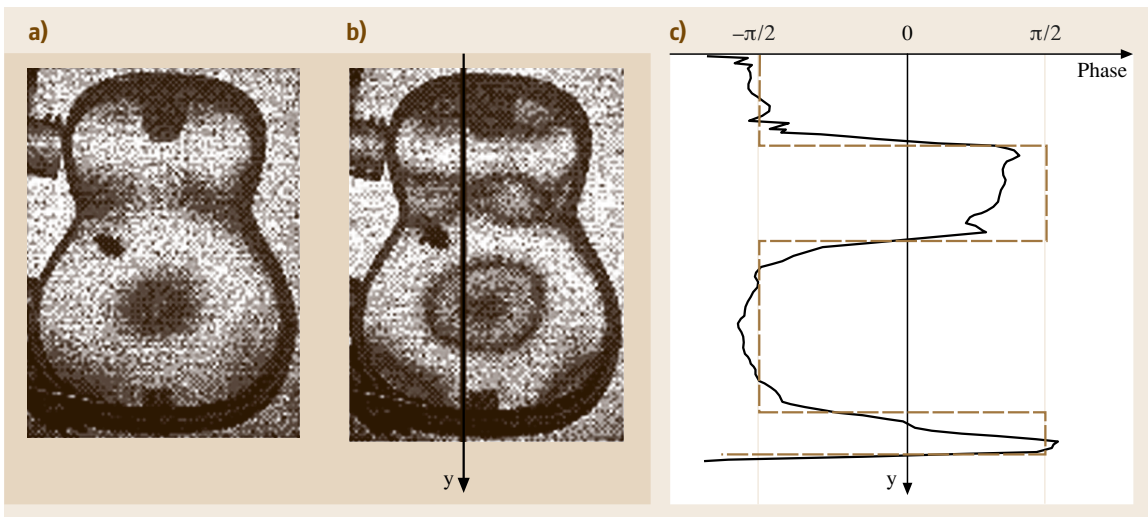
An experiment using reciprocity and TV holography can be performed as follows. A movable loudspeaker at constant (unit) driving conditions excites, say a stringed instrument, from different positions outside it. The corresponding out-of-plane velocity component at the bridge foot is measured by TV holography for the specific excited vibration pattern. Then, it can be argued using reciprocity that, if a constant (unit) driving force now instead is acting at the bridge foot, it will create a sound pressure of the same magnitude as the measured


Fig. 27.11a–c Standing aerial waves inside a transparent guitar cavity measured by phase-modulated TV holography (after [27.61]); **(a)** covered sound hole (1195 Hz); **(b)** open sound hole (1182 Hz); **(c)** phase distribution along the y-axis in **(b)** (courtesy of S. Hirzel Verlag)

velocity component at the same place as the loudspeaker was placed. By moving the loudspeaker around when measuring the vibration amplitude at the bridge foot, the radiativity is estimated.

Experiences from the violin experiments in [27.63] were:

- Radiativity is measured in an ordinary laboratory both close to and at quite large distances from the instrument.
- The mode shape is simultaneously recorded.
- The violin radiativity is measured as being almost spherical up to the 500 Hz.
- Complicated radiativity patterns result at higher modes.

Important conditions for dynamic reciprocity measurements are that the system is linear, passive and that the vibration system has stable equilibrium positions.

27.2.4 Pulsed TV Holography – Pulsed Lasers Freeze Propagating Bending Waves, Sound Fields and Other Transient Events

Pulsed lasers, like the traditional Q-switched ruby laser, emit one, two or more very short pulses (each pulse only some tenths of a ns long) of coherent laser light with a very high intensity. Most mechanical or acoustical events are frozen at such short exposure times. The time between the pulses can be set from about 10 μs to 800 μs with a ruby laser (during the burning time of the laser exciting flash lamps) and over a much broader range with a twin-cavity Nd:YAG laser. By double exposing a photographic plate of a transient event with two such pulses, one pulse of the object in the start position and another some time after the start, a double-exposed hologram is obtained. Both fields are reconstructed simultaneously with a continuous He–Ne laser. The technique is called pulsed holographic interferometry [27.12] and compares two states of an object. The optical setups used with pulsed lasers are in principle the same as with continuous ones with an object and a reference beam, compare Figs. 27.1 and 27.4. Both traditional recording on photographic plates (double-exposed hologram interferometry) and all-electronic methods (pulsed TV holography using a CCD chip for the recording as in TV holography) are available, although there are some differences. First, positive lenses are avoided and usually replaced by negative ones, since gas ions may otherwise occur at

125 μs

Fig. 27.12 Transient bending wave propagation in a violin body, 125 μs after impact start. The top of the bridge is impacted horizontally by a 5 mm steel ball at the end of a 30 cm-long pendulum (seen in the figure as a thin line). In the top plate a *hill and a valley* centered on the two bridge feet can be seen. In the back plate the fringes are centered at the soundpost, which rapidly transfers the impact from the bridge to the back of the violin (after [27.65], courtesy of AIP)

the focal points of positive lenses with the very strong light irradiances. With negative lenses light rays can be arranged so they seem to emanate from a virtual focal point. Secondly, to use the temporal phase-stepping technique with a moving mirror, such as PM in Fig. 27.4 is not applicable; there is simply not enough time to move them to record a sequence. Instead quantitative measuring data are obtained with a Fourier method where a small angle between the reference light and the object light is introduced to produce a modulated carrier wave at the CCD detector [27.66]. By Fourier filtering it is then possible to extract quantitative data.

In Fig. 27.12 [27.65], the transient bending wave response of a violin body to an impact is visualized with pulsed hologram interferometry. The instrument is impacted at the top of the bridge with a small pendulum. This is a crude and simple model of one of the pulses from the pulse train that is produced by the stick–slip bow–string interaction when the instrument is played. It is obvious that energy is effectively transferred to the back plate by the soundpost of the instrument and that the back is acting more like a monopole source. The top plate, on the other hand, is excited by the rocking motion of the bridge with a *hill* at one foot and a *valley* at the other, more like a dipole source. Interesting information about the violin is pictured in this way.
Fig. 27.13 Measured traveling bending waves on an impacted steel plate surface 7 μs, 32 μs, 57 μs and 82 μs after impact start. These were recorded with a four-pulse TV holography technique (after [27.67]). The pattern at the upper right side is a shadow in the illumination path and can be ignored

The pulsed TV holography setup is quite similar to ordinary TV holography (Fig. 27.4) in that it is all electronic, it uses fast CCD cameras and is computer operated. In an experiment [27.67], see Fig. 27.13, a pulsed TV holography setup using a four-pulse Nd:YAG laser technique is used that presents four in-

Fig. 27.14 The transient sound field outside an impacted cantilever steel beam 1 mm × 30 mm × 190 mm, clamped at the bottom. The 1 mm side is seen in the figure. The laser light passes outside and parallel to the cantilever surface along the 30 mm side. It is impacted at the *top right* by an air gun bullet. The interferogram is obtained 230 μs after impact start by pulsed hologram interferometry. Supersonic bending waves travel down the beam and create sound waves, *bow waves*, moving faster than the spherical sound wave, centered at the impact point

terferograms of the same transient event. This is in contrast to double-pulse experiments with, for instance, the double-pulsed ruby laser, where the experiment must be repeated at increasing time delays. With the four pulse technique a short sequence from one single event is obtained. (Another way to get a time sequence of the motion but now only in one point at a time is to use a vibrometer, see the next section.)

What kind of sound field does an impacted plate or played violin create? It is difficult to measure that in one projection since it is a 3-D sound distribution. In principle however it is possible to create a tomographic picture from many projections [27.68, 69] but such an experiment is quite complicated to perform. A much simpler and quite informative way is to use a 2-D structure instead. A simple cantilever beam or cantilever plate, much longer than it is wide and thick is used, as shown from the thinnest side in Fig. 27.14. The transient sound field outside the cantilever beam [27.70], which is impacted at the top end by an air gun bullet at about 100 m/s is shown. It is obtained by pulsed hologram interferometry. It is interesting to note that the impact causes a spherical sound wave to propagate (at about 340 m/s) around the impact point and also fast bending waves that move down the cantilever to act as secondary supersonic sound sources. They create a pattern that looks like a bow wave behind a ship. It differs from that however, since the waves have opposite phases on each side of the cantilever, as could be expected. Bending waves are dispersive, that is, fast waves preceding the slow ones have shorter wavelength than the slower ones. The figure also shows that the signal detected by a microphone or the ear from the impacted plate depends strongly upon the position of the detector. At some positions the sound from the supersonic

Fig. 27.15 The figure shows the density fields that are produced by an air-gun bullet traveling to the *right*. It emerged from the muzzle, which is situated at the left border. It has traveled in open air for 305 μs. Both the air that is pushed out by the bullet in front of the bullet in the barrel and the compressed air column behind it are seen, as well as the almost spherical and faster sound fields produced when the bullet emerged from the muzzle. Behind the bullet patterns reminiscent of vortex streets may be seen. The bullet speed is about 1/3 the speed of sound. Recorded by pulsed TV holography (after [27.71], courtesy of SPIE)

bending waves will reach the ear earlier than the direct impact sound.

Figure 27.15 shows the quite complicated density fields that are produced when an air gun bullet at 100 m/s leaves the muzzle [27.39, 71]. The air column pressed out from the barrel preceding the bullet as well as the air column behind it is seen. The almost spherical sound wave produced when the bullet is leaving the muzzle is also seen. Behind the bullet another pattern, reminiscent of vortex streets, is seen. A number of fluid mechanics and acoustical phenomena are thus visualized in the figure.

27.2.5 Scanning Vibrometry – for Vibration Analysis and for the Study of Acoustic Waves

Laser vibrometers are a family of accurate, versatile, non-contact, optical vibration transducers. They are used in applications where it is impractical or impossible to use transducers mounted on the object and they quickly map the structural response at many measurement points in sequence. They are easy-to-use, turnkey
Fig. 27.16 Principle of laser vibrometer in a Mach–Zehnder-type arrangement. BS is the beam splitter, while M is the mirror. A laser emits light at a frequency f onto an object and into a reference beam. The target/object to the top right, is moving with velocity $v(t)$, causing a Doppler shift of the reflected light of $\Delta f(t)$. The photodetector receives a time-varying signal, the interference between the object and the reference light, which is processed to give a measure of the target velocity. The Bragg cell in the reference beam introduces a known and constant frequency shift f_b to the reference light using which the sign of the target velocity is determined

systems that include optical and electronic hardware. With optional software many possibilities exist for advanced modal analysis, animations etc. Compared to TV holography scanning laser Doppler vibrometry is more of an off-the-shelf instrument, developed for industrial use. One drawback in that comparison is that it is not a real-time instrument. It is not as simple as with TV holography to find settings for unknown, interesting vibration patterns in a frequency scan. On the other hand it is highly sensitive and operates well not only with harmonic object motions but also with multi-frequency, repeatable object motions. Interesting vibration modes can be found by exciting the object with, for instance, a band-limited random signal and then performing modal analysis; compare Fig. 27.17. With scanning it is a full-field method but it has to be

remembered that the measurements of different object points are made sequentially. In one measuring point, very fast events can be recorded as a function of time. One manufacturer however, makes a special unit that takes measurements at a limited number of points simultaneously. Informative, animated visualizations of vibrations and sound fields can be obtained. For more technical information the reader may visit the home pages of the manufacturers, since a wide variety of options are available.

Laser light of wavelength λ that is scattered back from a moving surface with velocity $v(t)$ undergoes a shift in frequency, a Doppler shift Δf

$$\Delta f(t) = 2v(t)/\lambda . \tag{27.8}$$

In an interferometer, often of the Mach–Zehnder type, the scattered light from a moving object is mixed with a reference light from the same laser. In Fig. 27.16 the optical unit of such a heterodyne vibrometer is pictured with the Bragg cell mounted in the reference arm of the interferometer. This instrument is commonly used for measuring displacement and velocity fields of vibrations of solid objects. The first beam splitter (BS) splits the laser beam into measuring and reference beams. The reference beam reaches the photodetector via a mirror (M) and a second beam splitter. The measuring beam hits the moving target/object, gets reflected, frequency shifted and guided by two beam splitters to the photodetector. There, the measuring and the reference beams interfere to give a signal that varies with time.

A fast photodetector measures the time-dependent intensity, the beat frequency, of the mixed light,

$$i(t) = I_{av} + 2I_{mod} \cos(2\pi \Delta ft + \Phi) . \tag{27.9}$$

I_{av} and I_{mod} are the average and modulating intensities, respectively, and Φ is the difference in optical phase between the diffuse object surface and the smooth reference beam. The Doppler frequency shift $\Delta f(t)$ is measured with high accuracy. Using (27.8) the target velocity is calculated. However, a sign ambiguity is present, that is, it is not obvious from to the sinusoidal nature of the signal whether the object is mowing towards or away from the detector. This sign problem is solved by adding a known optical frequency shift f_B (using the Bragg cell in Fig. 27.16) in the reference arm of the interferometer (the heterodyne technique is described in [27.46]) to obtain a virtual frequency offset. Another way is to add polarization components and one more detector (a homodyne technique) to get signals in quadrature.

Modern vibrometers are often equipped with a scanner. These scanning vibrometers scan the surface of
Fig. 27.17 Two vibration modes of a lightweight aluminium structure measured by scanning vibrometry, with vibration amplitude coded in grayscale. The structure was excited by a pseudo-random signal feeding a mechanical exciter. The vibration frequencies are 2825 Hz and 4258 Hz, respectively

a vibrating object pointwise and can present the results as animated video movies. In Fig. 27.17 two modes of vibration of a lightweight aluminium structure are shown. The structure is excited by a pseudo-random signal feeding a mechanical exciter and the different modes of vibration are estimated by Fourier analysis of the complex measuring signal. A reference signal from an accelerometer is necessary to ensure that phase at all measuring points are measured relative to the same reference.

Not only vibration modes but also sound fields are measured using vibrometry. In Fig. 27.18 the vibration behavior of the body of a guitar is pictured together with the emitted sound field from the instrument [27.72].
Fig. 27.18a–d Measured vibration patterns of a guitar top plate (*left*) and the projected radiated sound fields from the guitar (*right*): (**a**) and (**b**) at 600 Hz; (**c**) and (**d**) at 1200 Hz. Scanning vibrometry was used for both recordings. Observe that in (**b**) and (**d**) it is the projected sound field across the guitar body that is measured (after [27.72], courtesy of S. Hirzel Verlag)

Fig. 27.19 The sound field at 1303 Hz inside a saxophone cavity model measured with scanning vibrometry. The model is a conical transparent model about 54 cm long with a rectangular cross section, excited at the mouthpiece end by a normal saxophone mouthpiece and it has an artificial mouth

Vibration patterns of a guitar front plate at harmonic excitation are shown in the left part of the figure. A guitar string was continuously excited by a shaker at 600 Hz and 1200 Hz, respectively. To measure and visualize the acoustic waves emitted from the guitar by this vibration, the guitar is rotated 90°, so that the probing laser light rays is passing in front of and in parallel to the top plate. The probing laser then hits to a heavy, rigid reflector and is reflected back again into the measuring unit of the vibrometer instrument. The reflector must be absolutely rigid, as in TV holography and pulsed TV holography, to record sound fields, compare Fig. 27.8.

The temporal and spatial pressure fluctuations $\Delta p(x, y, z, t)$, which are connected with acoustic or fluidic phenomena, cause changes of the optical refractive index $\Delta n(x, y, z, t) = n(x, y, z, t) - n_0$ and, consequently, the rate of change of the measured optical phase. In the simplest case a linear acoustic wave travels in the x-direction in the measuring volume; compare Fig. 27.8. Then the optical phase varies from point to point but at each point it also varies sinusoidally with time. This signal therefore behaves as a *virtual* displacement of the rigid reflector. In real measurements the

acoustic wave is not ideally shaped in the measuring volume (i.e. it is usually not two-dimensional) and a vibrometer senses, by phase demodulation, a projected virtual reflector displacement,

$$s(x, z, t) = \int_L \Delta n(x, y, z, t) \, dy \qquad (27.10)$$

or by frequency demodulation, a virtual reflector velocity

$$v(x, z, t) = \int_L \dot{n}(x, y, z, t) \, dy , \qquad (27.11)$$

i.e. the reflector seems to vibrate although it is immovable. These virtual vibrations represent the acoustic wave in the measuring volume. But, according to (27.10) and (27.11), the integrated sum of all fluctuations of the refractive index $\Delta n(x, y, z, t)$ along the laser beam contributes to the measured result. An ideal measurement situation is therefore a 2-D acoustic field as in Fig. 27.8. If not, several projections may be used or, if possible, enough that a tomographic reconstruction can be obtained.

To study the sound generation in, and the sound propagation from, a saxophone or a clarinet cavity, rectangular model pipes (two-dimensional structures) with one transparent side wall were fabricated. Figure 27.19 shows a standing acoustic wave at 1303 Hz of a model pipe when it is excited by an artificial mouth at the reed in a normal saxophone mouthpiece (to the left in the figure). Different air-column modes inside and at the bell of the pipe can be observed.

A transient pressure pulse in a water-filled cavity, $25 \times 25 \times 25 \, \text{cm}^3$, is shown in Fig. 27.20a. The pressure pulse is recorded through two opposite transparent walls from one side by pulsed TV holography. The impacted left side wall is made of steel and is hit in the middle by a pendulum (not seen in the interferogram) that creates a propagating, almost hemispherical, pressure wave in the water moving to the right at a speed of about 1500 m/s. The recording is taken 25.4 µs after the start of the impact. The pendulum is still in contact with the wall so energy and momentum are still being transferred to the tank. Figure 27.20b shows a line di-

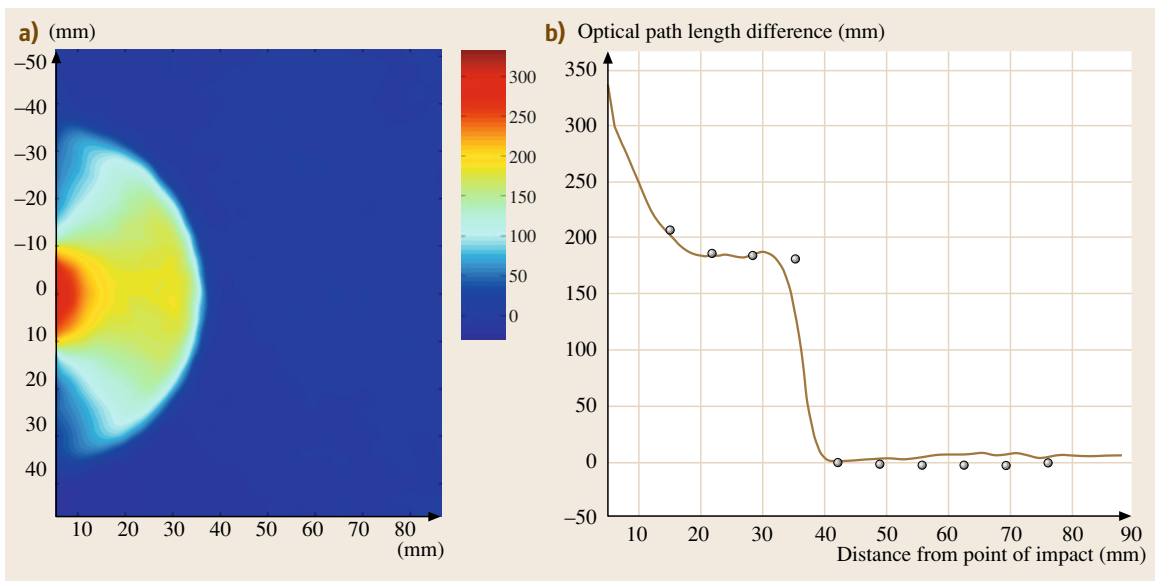
agram of the same wave but now measured along the center horizontal line. The circles in the graph are measured using the vibrometer at different distances from the wall but at the same time instants, as in pulsed TV holography recording. The different points are recorded from different experiments (the scanning facility cannot be used since the event is not repetitive and is far too rapid). As seen in the figure, the optical path differences at coincident time and space values agree quite well between the methods. The pulsed TV holography experiment measures and compares the disturbed field with the undisturbed one at one time instant. To obtain a sequence the experiment has to be repeated or a multiple-pulsed laser has to be used to record several time instants of one event. The vibrometer on the other hand can take measurements of a single transient event one point at a time as a function of time, and at several points as a function of time if the event can be repeated. The vibrometer thus records a time sequence of the optical path (or velocity) difference at each point.


Fig. 27.20 (a) A pulsed TV holography recording of the wave propagation 25.4 µs after impact start in a water-filled transparent channel impacted at the *left wall* by a pendulum. The pendulum is hitting the *left wall* from the outside, not seen in the picture, and is still in contact with the wall when this interferogram was recorded, so energy and momentum are still being transferred to the water from the impact. The *bar* to the *right* shows the coding in optical path difference. (b) The *full line* shows the optical path difference along the *center horizontal line* measured in Fig. 27.20a, using pulsed TV holography. The *circles* in the graph are measured points using a vibrometer. The measurements are performed at different distances from the wall but evaluated at 25.4 µs. The different *points* are, however, obtained from different experiments (the scanning facility cannot be used since the event is far too rapid). The optical path differences at coincident time and space point values agree quite well between the two methods

27.2.6 Digital Speckle Photography (DSP), Correlation Methods and Particle Image Velocimetry (PIV)

The equipment needed in the interferometry-based methods described above is often rather expensive and some of the techniques can unfortunately be quite difficult for an untrained user to apply. Simpler and cheaper methods have therefore been sought. Less expensive, less sensitive methods are the speckle photography (SP) and digital speckle photography (DSP) methods [27.73], which are also called speckle correlation [27.32–34]. Here the motion of the speckles themselves is measured, rather than the change in intensity of the stationary speckles as with interferometric methods. As mentioned before, the speckled random pattern *acts as if glued* to the surface of the laser-illuminated object. This pattern is imaged twice, usually with a CCD camera on individual frames, before and after some external or internal load is applied to the object, which changes the speckle pattern field. The il-

Fig. 27.21 Defocused digital speckle photography (DSP) recording, of a transparent helium jet entering air, recorded using a continuous He-Ne laser

lumination and the camera are left stationary, so it is the motion of the microstructure of the object surface that is responsible for the motion of the speckles. The deformation field of the object may consist of the sum of rigid-body motions (translation and rotation) and some strain-induced deformation field (at crack tips, elastic and plastic deformation fields etc.). So far this is reminiscent of TV holography (or digital speckle pattern interferometry (DSPI)) but no reference wave is added here. The experiments are not as sensitive to disturbances as interferometric measurements and can usually be performed in a workshop without vibration isolation of the quite simple optical setup. It is the position of each speckle in the speckled object wave that is recorded and the motion of small sub-images containing this pattern that is determined.

Two main types of random patterns are in use: (1) laser speckle, which is the random pattern generated by the surface microstructure of a laser-illuminated diffuse object (laser speckles in DSP) together with the specific illumination and recording geometry; and (2) white-light speckle in DSP, where there may already exist a random pattern at the object surface, such as random fibers in a paper or wood sample, which is imaged using an ordinary, broadband incandescent lamp. A random dot pattern may also be painted or sprayed onto the surface and imaged. White-light illumination can be used so that lasers can be avoided in these cases.

Two main imaging techniques are in use, one where the object surface is focused by the recording CCD camera and one where the camera is defocused behind or in front of the object surface. The focused case, which is the simplest and most commonly used, gives a measure of the in-plane motion field of the surface. However, it is important that the object is in focus, otherwise, using laser speckles, strain fields and rotations may disturb the result. It must be understood that laser speckles exist in all space, not only when focused at the object surface. Therefore, if the camera is defocused, other components of the strain tensor that affect the speckle motion will eventually become important. Using this defocused technique it has been possible to measure the strain field directly, i.e. without first measuring the deformation field and then differentiating the result to obtain the strain field [27.74].

A digital correlation technique is then used to determine how far small sub-areas in the first recording have to be moved to correlate as exactly as possible with those in the second recording. Performing this for all sub-areas, an in-plane deformation map (for the focused case) is formed. As well as yielding information
Fig. 27.22 The principle of particle image velocimetry (PIV). Pulsed laser light is sent through a cylinder lens system to form a sheet of light in the measuring volume. A CCD camera captures the seeded flow in this light sheet from above at two time instances

on the in-plane motion, the value of the correlation peak height is measured for each sub-area. This peak value gives a measure of how similar the sub-images are, even if they have not moved. If the correlation is high (almost 1) then the speckles in the two sub-surfaces are identical; if not, the correlation value will drop. Reasons for this drop include different kinds of noise and limitations in the recording system (limited and varying optical resolution and the digitalization of the intensity etc.); but it may also be that the microstructure itself has changed between the two exposures, for instance due to plastic deformation of parts of the object surface. Figure 27.21 shows an example of a defocused laser DSP recording of a transparent helium jet entering air. From similar recordings [27.75, 76] where pulsed lasers were used, it is possible to calculate where the gas jet is situated and how strong the refractive-index field of the gas is.

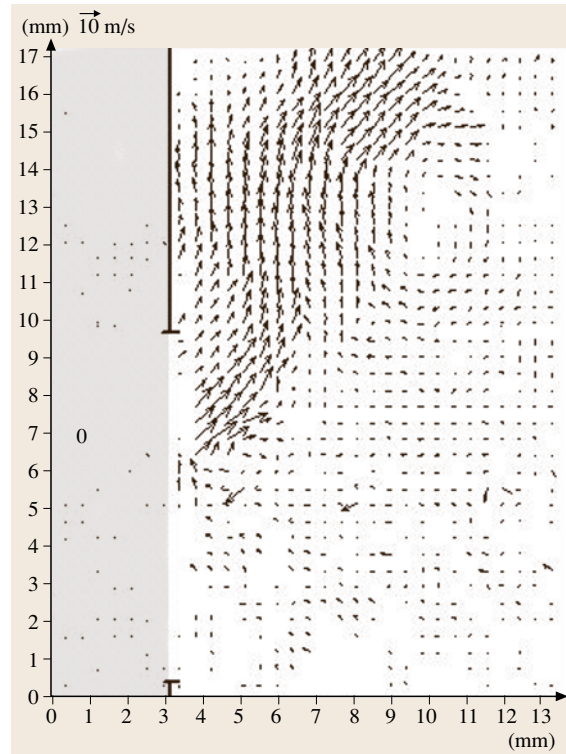
Particle image velocimetry (PIV) [27.77, 78] is highly reminiscent of the focused version of the speckle photography technique. However, the measurements are now made of a flow in a transparent medium, usually water or air. It is a nonintrusive optical measuring method. Tracer particles are illuminated with pulsed laser light in a light sheet, for instance smoke in air that follows the fluid motion. The displacements of the particles between two exposures are determined with a cross-correlation technique, as in digital speckle photography or speckle correlation. Figure 27.22 shows a PIV setup. Since the time between the exposures is known (often the time between repetitive pulses from a pulsed laser) and the motion of the small sub-areas between exposures of the imaged flow can be calculated, the velocity fields in the flow are determined.


Fig. 27.23 Particle image velocimetry (PIV) measurements of the flow field at the labium (the opening to the *left*) of an organ pipe. A pulsed laser was used as an illumination source as the flow is quite fast at the labium; see the *reference arrow* in the *top left*

With two cameras viewing the illuminated plane from two directions and/or illuminating two different and crossing planes, not only the in-plane components but also out-of-plane velocity components can be estimated, so both 2-D and 3-D stereoscopic PIV techniques are available. With fast repetitive pulsed lasers, so called time-resolved PIV (TR-PIV), even fast turbulent flows can be measured. Microflow systems have been developed for flow studies at the microscopic scale [27.79]. By adding fluorescent particles to the flow and illuminating in a plane with a laser at a shorter wavelength and observing it at a longer (fluorescent) wavelength, concentration and temperatures can also be measured. This is called planar laser-induced fluorescent (PLIF). Sophisticated PIV systems, including hardware and software for industrial or research use, are sold by several manufacturers.

Figure 27.23 shows the flow field at the labium of a blown organ pipe, measured using PIV with

a pulsed laser as the illuminating source [27.80]. The number of papers using PIV and LDA presented at acoustical conferences is rapidly increasing [27.81, 82].

27.3 Summary

Several new optical, all-electronic measuring techniques and systems have entered the market in recent decades. The rapid technical development of new lasers, new optical sensors such as the CCD camera, optical fibers and powerful and cheap PCs has made this possible. The demands for optical techniques have increased because validation of large numerical calculations is becoming more important. Optical methods have the advantage over traditional vibration detectors that they are fast and do not disturb what is being measured, and they also often yield an image field – for instance a flow velocity field – rather than just measuring values at one single point.

Equipment can be purchased from many manufacturers and in many cases you do not have to be a specialist in optics to use them. It is also possible to make, for instance, a speckle interferometer or a shearing interferometer in most laboratories [27.83]. Methods exist today that have the sensitivity and spatial resolution needed to visualize and measure sound fields

in musical acoustics. In Table 27.1 some modern optical measuring methods and their temporal application areas are indicated.

Optical metrology on the whole is growing in importance and applicability to scientists and engineers in solid mechanics, fluid mechanics and in acoustics. Techniques such as phase-modulated TV holography, pulsed TV holography and scanning vibrometry are commonly used for modal analysis and increasingly to measure phase shifts in transparent phase objects such as sound fields. Flow fields in air and water can be measured with speckle photography or correlation methods such as digital speckle photography (DSP) and particle image velocimetry (PIV); these methods provide both illustrative images as well as quantitative measures. Reciprocity methods can also be of great help in such experiments. Optical measuring methods have the advantage of being contact-less, non-disturbing and whole-field methods. The future for optical metrology in acoustics looks bright.

Table 27.1 Some modern optical measuring methods and their temporal application areas

Optical measuring methods and their temporal application areas	Static or (slow) quasistatic events	Harmonic motions, single frequency	Repetitive motions, multi-frequencies	Transients, fast, dynamic events
Real-time holographic int. with continuous lasers	×	×		
Double-exposure holographic int. with continuous lasers	×			
Time-average holographic int. with continuous lasers		×		
TV holography, DSPI, ESPI with continuous lasers	×	×		
Pulsed TV holography and pulsed DSPI and ESPI with pulsed lasers	(×)	(×)	×	×
Scanning laser vibrometry		×	×	× (one point, no scanning)
Speckle correlation/photography (DSP)	×			× (with pulsed lasers)
Particle image velocimetry, PIV	×	(×)	(×)	× (with pulsed lasers)
int.: interferometry

28. Modal Analysis

Thomas D. Rossing

Modal analysis is widely used to describe the dynamic properties of a structure in terms of the modal parameters: natural frequency, damping factor, modal mass and mode shape. The analysis may be done either experimentally or mathematically. In mathematical modal analysis, one attempts to uncouple the structural equations of motion so that each uncoupled equation can be solved separately. When exact solutions are not possible, numerical approximations such as finite-element and boundary-element methods are used.

In experimental modal testing, a measured force at one or more points excites the structure and the response is measured at one or more points to construct frequency response functions. The modal parameters can be determined from these functions by curve fitting with a computer. Various curve-fitting methods are used. Several convenient ways have developed for representing these modes graphically, either statically or dynamically. By substituting microphones or intensity probes for the accelerometers, modal analysis methods can

be used to explore sound fields. In this chapter we mention some theoretical methods but we emphasize experimental modal testing applied to structural vibrations and also to acoustic fields.

Part H | 28

28.1 Modes of Vibration

The complex vibrations of a complex structure can be described in terms of normal modes of vibration.

A normal mode of vibration represents the motion of a linear system at a normal frequency (eigenfrequency). Each mode is characterized by a natural frequency, a damping factor, and a mode shape. *Normal* implies that each shape is independent of, and orthogonal to, all other mode shapes of vibration for the system. Any deformation pattern the structure can exhibit can thus be expressed as a linear combination of the mode shapes.

In a stricter mathematical sense, *normal* modes provide a solution for an undamped system. Each mode

shape is a list of displacements at various places and in various directions. These normal-mode vectors contain one real number for each motional degree of freedom (DOF) studied. Since real structures are invariably damped, normal modes represent an approximation that may prove imprecise when the damping level is significant. In instances where the energy absorbing damping mechanisms are distributed in a manner proportional to the structural stiffness, normal modes provide an exact solution. In this case, the damping factor of each mode is proportional to its associated natural frequency. The normal modes also provide an exact solution when the damping is proportional to the mass distribution, but in

this case each damping factor is inversely proportional to its associated natural frequency.

A structure is said to be proportionally damped when the matrix describing its damping can be written as a linear combination of the corresponding mass and stiffness matrices. Normal-mode shapes provide the exact solution to such equations, and the damping factors may be expressed as a linear combination of the natural frequencies and their reciprocals. When these restrictive proportionality conditions do not exist, the structure may be better modeled by complex mode shapes.

Complex modes result when the instantaneous velocity at each DOF is treated as being independent of the displacement. This doubles the number of system differential equations, but simplifies them from second order to first order. The solution vectors are most commonly written in terms of complex displacements, one for each DOF. Expressing the modal displacements in this manner eliminates any constraints between the damping factors and the natural frequencies. All but the simplest experimental curve-fitting algorithms can identify complex modes. Most finite-element codes are restricted to the undamped analysis of structures and can therefore only identify the approximating real or normal modes.

Each modal vector represents a displacement pattern. A zero in the vector denotes a node, a point and direction on the structure that does not move in that mode. The element in a modal vector that is largest in displacement value is termed an anti-node. A given mode shape can be readily excited by a sinusoidal force at or near its natural frequency applied to an anti-node. The same force applied at a node will impart no motion in that shape.

It should be noted that the real or complex displacement values in each modal vector are relative numbers. The mode shape is inferred by the ratio between the vector elements, not their specific values. The elements within each modal vector may be scaled by any of various methods, the simplest of which is division by the anti-node value. This is useful for display or plotting so that all modes have a common maximum value. However, the inner product or length of each vector is related to the modal mass of the mode. For many analytical purposes, including structural dynamic modification, it is necessary to choose the length of each vector so that the corresponding modal mass is equal to 1. When the shape vectors are scaled in this manner, they are said to be orthonormal or unit modal mass (UMM) modal vectors.

It is normally possible to excite a mode of vibration from any point on a structure that is not a node and to observe motion at all points that are not nodes. A mode shape is a characteristic only of the structure itself, independent of the way it is excited or observed. In practical terms, however, instrumentation associated with both excitation and observation may modify the structure slightly by adding mass or stiffness (or both). This results in small shifts in frequency and mode shape, which in most cases are negligible. Acoustic excitation and optical monitoring are the least intrusive, but mechanical means of driving and observing are frequently more convenient and less costly.

Mode shapes are unique for a structure, whereas the deflection of a structure at a particular frequency, called an operating deflection shape (ODS), may result from the excitation of more than one normal mode. When exciting a structure at a resonance frequency, the ODS will be determined mainly by one mode, although if several modes have nearly the same frequency, special techniques may be required to determine their contributions to the observed ODS. Modes of a structure are functions of the entire structure. A mode shape describes how every point on the structure moves when it is excited at any point.

28.2 Experimental Modal Testing

Modal testing is a systematic method for identification of the modal parameters of a structure. Generally these include natural frequencies, modal damping, and UMM mode shapes. In experimental modal testing the structure is excited with a measured force at one or more points and the response is determined at one or more points. From these sets of data, the modal parameters are determined, often by the use of multidimensional curve-fitting routines on a digital computer.

Modal testing may use sinusoidal, random, pseudorandom, or impulsive excitation. The response may be measured mechanically, optically, or indirectly (by observing the radiated sound field, for example). The first step in experimental modal testing is generally to obtain a set of frequency response functions.

There is a vast amount of good literature describing experimental modal testing. *Ewins* [28.1] provides a good overall introduction. The proceedings of the an-

nual International Modal Analysis Conference (IMAC), held every year since 1982, is a gold mine of papers on the subject [28.2]. The Structural Dynamics Research Laboratory at the University of Cincinnati has published many scientific papers and reports on the subject, and has included several tutorials on their website [28.3].

28.2.1 Frequency Response Function

The frequency response function (FRF) is a fundamental measurement that isolates the inherent dynamic properties of a mechanical structure. The FRF describes the motion-per-force input–output relationship between two points on a structure as a function of frequency. Since both force and motion are vector quantities, they have directions associated with them. An FRF is actually defined between a single-input DOF (point and direction) and a single-output DOF.

In practice, the force and response are usually measured as functions of time, and transformed into the frequency domain using a fast Fourier transform (FFT) analyzer. Due to this transformation, the functions end up as complex numbers; the functions contain real and imaginary components (or magnitude and phase components). Depending on whether the response motion is measured as displacement, velocity, or acceleration, the FRF can be expressed as *compliance* (displacement/force), *mobility* (velocity/force), accelerance or *inertance* (acceleration/force), *dynamic stiffness* (1/compliance), *impedance* (1/mobility), or *dynamic mass* (1/accelerance). Force can be measured with a piezoelectric force transducer or load cell; acceleration can be measured with an accelerometer; velocity can be measured with a laser velocimeter or obtained by integrating acceleration; displacement can be determined by holographic interferometry or by integrating velocity.

Because it is a complex quantity, the FRF cannot be fully displayed on a single two-dimensional plot. One way to present an FRF is to plot the magnitude and the phase as in Fig. 28.1a. At resonance, the magnitude is a maximum and is limited only by the damping in the system. The phase ranges from 0 to 180° and the response lags the input by 90° at resonance. The 3 dB width of each resonance peak (bounding locations of 0.707 resonance amplitude) is determined by the damping. At these half-power points the phase angle is ±45°.

Another way of presenting the FRF is to plot the real and imaginary parts as in Fig. 28.1b. The imaginary part has a peak at resonance, while the real part goes through zero at resonance. The real component exhibits

peaks of opposite sign at the extremes of the half-power bandwidth.

A third method of presenting the FRF is to plot the real part versus the imaginary part as shown in Fig. 28.1c. This is called a Nyquist or vector response
Fig. 28.1a–c Three methods for presenting the frequency response function (FRF) of a vibrating system graphically. **(a)** Magnitude and phase versus frequency; **(b)** real and imaginary parts versus frequency; **(c)** real part versus imaginary part (a Nyquist plot)

plot. Each mode produces a circular pattern. The diameter of the circle is proportional to the product of the UMM vector elements for the force and response DOFs. Maximum change in arc length with frequency occurs at the natural frequency.

If measurements are made at n points, the FRFs can be arranged in an $n \times n$ matrix with elements designated h_{ij}. The diagonal elements denote that the excitation and observation occurred at the same point. Such measurements are termed driving-point FRFs and they are of particular importance as at least one driving-point measurement is required to scale the mode shapes to UMM form. In a linear system the FRF matrix is symmetric: $h_{ij} = h_{ji}$. We do not have to measure all the terms of the FRF matrix. In practice, it is (generally) possible to obtain mode shapes from only one row or column of the FRF matrix.

Theoretically, it does not matter whether the measured frequency response comes from a shaker test or an impact test. If the structure is impacted at n points while the response is measured at one point, one row of the FRF is obtained. If a shaker is used to excite it at one point while an accelerometer (or other sensor) is moved from one point to another, one column of the FRF is obtained. In practice, there may be differences between the results of the *roving hammer* and the *roving accelerometer* methods, but these are the result of experimental compromises, not structural properties. Roving impact and roving response techniques provide essentially the same answers because a linear structure exhibits reciprocity. The motion produced at DOF a by a force applied at DOF b is identical to the motion at b due to a force at a.

The analog signals obtained from the measuring devices are generally digitized in an FFT analyzer. Sampling and quantization errors can occur in the process, but the most worrisome of signal-processing errors is probably leakage, which will be discussed later.

Serious consideration must be given to the way the structure is mounted and supported. Boundary conditions can be specified exactly in a completely free or completely constrained situation. In practice it is generally not possible to fully achieve these conditions. In order to approximate a free system, the structure can be suspended from very soft elastic cords or placed on a very soft cushion. The structure will be constrained to a degree and the rigid-body modes will not have zero frequency. However, they will generally be much lower than the frequencies of the flexible modes and will therefore have negligible effect. Some support fixtures affect damping as well.

28.2.2 Impact Testing

A roving hammer test is the most common type of impact test. An accelerometer is fixed at a single DOF, and the structure is impacted at as many DOFs as desired to define the mode shapes of the structure. Using a two-channel FFT analyzer, FRFs are computed, one at a time, between each impact DOF and the fixed response DOF. A suitable grid is usually marked on the structure to define the impact points.

Piezoelectric transducers are generally used to sense both force and acceleration. They generate an electrical charge when mechanically strained. Because of their high impedance, charge amplifiers are generally used to amplify the signals. More-modern sensors incorporate an amplifier within the transducer and power it from a constant-current source using the same two-conductor cable that transmits the signal (at low impedance). The resonant frequencies of the transducers must be well above the highest frequency that will be measured. The mass of the accelerometer should be small enough that the effect of mass loading is small. One way to determine if mass loading is significant is to measure an FRF with the accelerometer and compare it to a second measurement with an additional accelerometer (or equivalent mass) attached to it. An obvious advantage of this testing setup is that the response transducer is never moved; the structure is subjected to a consistent mass loading.

In some circumstances, the symmetry of the test object may produce repeated roots. These are modes with different mode shapes that have the same natural frequency. When such modes are encountered, they may be separated by using two or more fixed reference accelerometers and multi-reference curve-fitting techniques. Of course, an analyzer with three or more channels is required if the data is to be acquired in a single measurement set.

It is generally impossible to impact a structure in all three directions at all points, so three-dimensional (3-D) motion cannot be measured at all points. When 3-D motion at all points is desired, a roving triaxial accelerometer may be used and the structure is impacted at a fixed DOF with the hammer. Triaxial accelerometers are usually more massive, however. Since the triaxial accelerometer must be simultaneously sampled together with the force data, a four-channel FFT analyzer is required [28.4]. Note, however, that the roving accelerometer presents a different mass-load to the structure at each response site. This can lead to inconsistencies in the data that make an accurate curve fit more difficult.

Because the impulse signal exists for such a short period, it is important to capture all of it in the sampling window of the FFT analyzer. To insure that the entire signal is captured, the analyzer must be able to capture the impulse and response signals prior to the occurrence of the impulse. The analyzer must begin sampling data before the trigger point occurs. This is called a pre-trigger delay.

Modern FFT analyzers provide very high-resolution (24 bit) analog-to-digital converters (ADCs) and large capture block sizes (64 kpoint typical). These characteristics nullify the need to use weighting functions or *windows* when performing an impact test. The preferred analysis is conducted without weighting, also termed using a *rectangular* window.

Two common time-domain windows that are used in impact testing with older equipment are the force and exponential windows. These windows are applied to the signals after they are sampled but before the FFT is applied to them in the analyzer. The *force* window is used to remove noise from the force signal. Any nonzero data following the impulse signal in the sampling window is assumed to be measurement noise. The force window preserves the samples in the vicinity of the impulse but removes the noise from all other samples in the force signal.

The *exponential* window is used to reduce leakage in the spectrum of the response. The FFT analyzer assumes that the signal is periodic in the transform window. This is true of signals that are completely contained within the transform window or cyclic signals that complete an integer number of cycles within the transform window. If a time signal is not periodic in the transform window a smearing of its spectrum will occur when it is transformed to the frequency domain. This is called *leakage*. Leakage distorts the spectrum and makes it inaccurate. If the response does not decay to zero before the end of the sampling window, an exponential window can add artificial damping to all modes of the structure. This artificial damping must be removed by the subsequent curve-fitting algorithm to obtain proper damping factors.

It is important that the impact hammer provides a pulse that is well matched to the frequency span of the analysis. This is accomplished by fitting a striking tip of appropriate stiffness to the hammer's force gauge. A soft tip produces a broad pulse time-history with a narrow spectrum. A hard tip increases the force spectrum bandwidth by applying a narrow pulse. The spectrum of the force pulse has a *lobed* structure and all tests are done using the spectral content of the first lobe. Trial measurements are made to select a tip that provides a force spectrum that falls off no more than 25 dB from the direct-current (DC) point to the selected analysis bandwidth.

It is often difficult to strike at exactly the same place and angle multiple times. For this reason, averaging is less useful in an impact test than in other types of experimental modal analysis. Many experienced practitioners favor conducting tests with a single strike at each target DOF. This precludes calculating a coherence function, but that very useful causality measurement often tells you more about your ability to hit the same place twice than it does about structural nonlinearities or noise in measurement. For this reason, it is imperative to inspect every measurement set in the time domain before accepting it. Most analyzers automate this type of acquisition, giving you an accept/reject control.

28.2.3 Shaker Testing

Not all structures can be impact tested. Sometimes the surface is too delicate. Sometimes the impact force has too low an energy density over the entire frequency range of interest. In this case, FRF measurements must be made by attaching one or more shakers to the structure.

Since the FRF is a single input function, the shaker should transmit only one component of force in line with the main axis of the load cell. Often a structure tends to rotate slightly when it is displaced along an axis. To minimize the problem of forces being applied in other directions, the shaker is generally connected to the load cell through a slender rod called a stinger to allow the structure to move freely in the other directions. The stinger should have a strong axial stiffness but weak bending and shear stiffnesses.

A variety of broadband excitation signals have been developed for making shaker measurements with FFT analyzers: transient, random, pseudo-random, burst random, sine sweep (chirp). A true random signal is synthesized with a random number generator. Since it is nonperiodic in the sampling window, a Hanning window must always be used to minimize leakage.

A pseudo-random signal is specially synthesized by an FFT analyzer to coincide with the window parameters. It is synthesized over the desired frequency range and then passed through an inverse FFT algorithm to obtain a random time-domain signal, converted to an analog signal and used as the shaker excitation signal. Since the excitation signal is periodic in the sampling window, the acquired signals are leakage-free.

However pseudo-random excitation does not excite nonlinearities differently between spectrum averages and will not, therefore, remove nonlinearities from FRF measurements.

Burst random excitation combines some advantages of both random and pseudo random testing. Its signals are leakage free and when used with spectrum averaging, will remove nonlinearities from the FRFs. In burst random testing, either a true random or time-varying pseudo-random signal can be used, but it is turned off prior to the end of the sampling window time period so that the response decays within the sampling window. Hence, they are periodic in the window and leakage-free [28.1].

In large structures more than one shaker may be needed to obtain sufficient excitation. These are driven simultaneously so that the structure is subjected to multiple inputs. The FRFs between each of the inputs and each of the multiple outputs are calculated by using a matrix inversion process. This type of measurement is called multiple-input multiple-output (MIMO) testing. It provides FRFs from multiple columns of the FRF matrix and two special types of coherence functions. One multiple coherence function is generated for each shaker used. This function may be thought of as a generalization of ordinary coherence; it asserts what fraction of all the response output power spectra may be attributed to the single measured force power spectrum and the FRFs in one column of the FRF matrix. One partial coherence function is generated for each FRF; it asserts what fraction of a single response power spectrum can be attributed to one force power spectrum and a single FRF. MIMO data is analyzed using a multi-reference curve fitter.

28.2.4 Obtaining Modal Parameters

Most experimental modal analysis relies on a modal parameter estimation (curve-fitting) technique to obtain modal parameters from the FRFs. Curve fitting is a process of matching a mathematical expression to a set of experimental points by minimizing the squared error between the analytical function and the measured data. Curve-fitting methods used for modal analysis fall into one of the following categories: local single degree of freedom, local multiple degree of freedom, global, or multi-reference.

Single-degree-of-freedom (SDOF) methods estimate modal parameters one mode at a time. Multiple-degree-of-freedom (MDOF), global, and multi-reference methods can estimate modal parameters for two or more modes at a time. Local methods are applied to one FRF at a time. Global and multi-reference methods are applied to an entire set of FRFs at once.

SDOF methods can be applied to most FRF data sets with low modal density, but MDOF methods must be used in cases of high modal density. Global methods work better than MDOF methods for cases with local modes. Multi-reference methods can find repeated roots (very closely coupled modes) where the other methods cannot [28.4].

Perhaps the simplest of the SDOF methods is the quadrature or peak-picking method. Modal coefficients are estimated from the real and imaginary parts of the frequency response, so the method is really not a curve fit in the strict sense of the term. First the resonance peaks are detected on the imaginary plot and the frequencies of maximum response taken as the natural frequencies of these modes. Then the line width between the half-power points is determined from the real plot, from which damping can be estimated. The magnitude of the modal coefficient is taken as the value of the imaginary part at resonance. This method is adequate for structures whose modes are well separated and have modest damping [28.5].

Another SDOF method is the circle-fit method. This is based on the fact that a Nyquist plot of frequency response of a SDOF system near a resonance is a circle. Thus the circle that best fits the data points is determined. Half-power points are those frequencies for which $\theta = \pm 90$. The modal coefficient is determined from the diameter of the circle.

Two of the most popular MDOF methods are the complex exponential and rational fraction polynomial methods. The complex exponential method (or Prony algorithm) fits the impulse response function (IRF), which is the inverse Fourier transform of the FRF rather than the FRF itself. A potentially serious error, called wrap-around error or time-domain leakage, can occur but can be mitigated by using an exponential window on the IRF This error is caused by the limited frequency range of the FRF measurement, and distorts the impulse response. The complex exponential algorithm works very well for FRFs with high modal density. In most applications, the algorithm is allowed to fit far more modes than the FRF form suggests are present. The resulting extraneous *computational modes* are then discarded, normally by using a stability diagram.

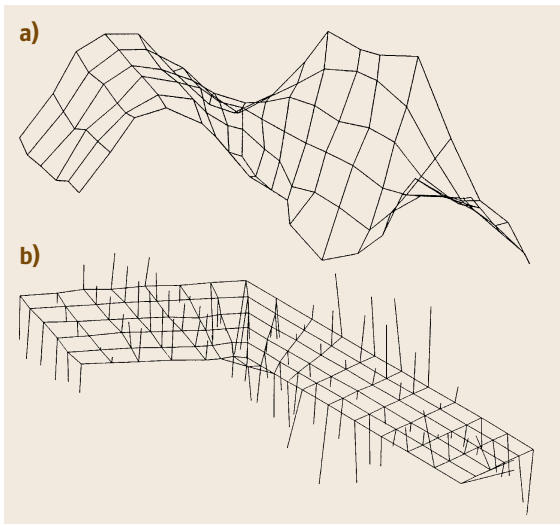
The rational fraction polynomial method fits a rational fraction of polynomials expression directly to an FRF measurement. Its advantage is that it can be applied over a user-selected frequency range of data, focusing


Fig. 28.2a,b Two ways of representing a vibrational mode in a Korean *pyeongyeong*: **(a)** The shape at maximum bending; **(b)** the neutral shape with vectors

Fig. 28.3 Gray-scale representation of a vibration mode in a violin (courtesy of George Bissinger)

its findings upon that frequency interval. It does not generate *computational modes* and therefore does not require the use of a stability diagram or other methods to filter its outputs.

Global curve fitting divides the curve-fitting process into two steps: estimating the frequency and damping parameters, and using these to obtain mode shape estimates by a second estimation process. The advantage of global curve fitting is that more-accurate frequency and damping estimates can potentially be obtained by processing all of the measurements rather than relying on a single measurement. Another advantage is that, because damping is already known and fixed as a result of the first step, the modal coefficients are more accurately estimated during the second step. Both the complex exponential and rational fraction polynomial methods can be formulated to obtain global estimates from a set of measurements [28.6].

28.2.5 Real and Complex Modes

The assumption of proportional viscous damping implies the existence of real, or normal modes. Mathematically, this implies that the damping matrix can be defined as a linear combination of the physical mass and

stiffness matrices. Physically, all the points in a structure reach their maximum excursion, in one or the other direction, at the same time. The imaginary part of the FRF reaches a maximum at resonance, and the Nyquist circle lies along the imaginary axis.

Some structures exhibit a more complicated form of damping, and the mode shapes are complex, meaning the phase angles can have values other than 0 or 180°. Different points on the structure reach their maxima at various times as in a traveling wave pattern. The imaginary part of the FRF no longer reaches a maximum at resonance nor is the real part zero. The Nyquist circle is rotated at an angle in the complex plane. When damping is light, the proportional damping assumption is generally an accurate approximation, [28.5] although it can be argued that a complex-mode formulation is essential to preserve accuracy in damping evaluation [28.7].

28.2.6 Graphical Representation

One of the nice features of experimental modal testing is the way that the modes can be represented graphically. Animations of the vibration can be viewed from any angle to comprehend complex mode shapes. Static representations include the shape at maximum bending, and the neutral shape with vectors, as shown in Fig. 28.2. Another representation is shown in Fig. 28.3.

28.3 Mathematical Modal Analysis

In mathematical modal analysis, one attempts to uncouple the structural equation of motion by means of some suitable transformation, so that the uncoupled equations can be solved. The frequency response of the structure can then be found by summing the respective modal responses in accordance with their degree of participation in the structural motion.

Sometimes it is not possible to obtain exact solutions to the equation of motion. Computers have popularized the use of numerical approximations such as finite-element and boundary-element methods.

28.3.1 Finite–Element Analysis

The finite-element method of analysis (FEA or FEM) started in the late 1940s as a structural analysis tool useful in helping aerospace engineers design better aircraft structures. Aided by the rapid increase in computer power since then, it has become a very sophisticated tool for a wide array of engineering tasks. It can be used to predict how a system will react to environmental factors such as forces, heat, and vibration.

The technique is based on the premise that an approximate solution to any complex engineering problem can be reached by subdividing the problem into smaller more manageable (finite) elements. Using finite elements, solving complex equations that describe the behavior of a structure can often be reduced to a set of linear equations that can be solved using the standard techniques of matrix algebra.

The finite-element method works by breaking a real object down into a large number of elements, which are regular in shape and whose behavior can be predicted by a set of mathematical equations. The summation of the behavior of each individual element produces the expected behavior of the actual object. Finite-element analysis (FEA) uses a complex system of points called *nodes*, which make a grid called a *mesh*. The mesh is programmed to include the material and structural properties that define how the structure will react to certain loading conditions.

General-purpose finite-element codes, such as NASTRAN and ANSYS, are programmed to solve the matrix equation of motion for the structure of the form

$$[M]\{\ddot{u}\} + [C]\{\dot{u}\} + [K]\{u\} = \{F\cos(\omega t + \phi)\}\,,$$

$$(28.1)$$

where $[M]$ is the mass matrix, $[C]$ is the damping matrix, $[K]$ is the stiffness matrix, $\{u\}$ is displacement, and $\{F\}$ is force.

The model details are entered in a standard format, and the computer assembles the matrix equation of the structure. The first step is to solve the matrix equation $[M]\{\ddot{u}\} + [K]\{u\} = \{0\}$ for free vibrations of the structure. The solution to this equation gives the natural frequencies (eigenvalues) and the undamped mode shapes (eigenvectors). These parameters are the basic dynamical properties of the structure, and they are used in subsequent analysis for dynamic displacements and stresses. For harmonic motions, $\{\ddot{u}\} = -\omega^2\{u\}$, so that $[K]^{-1}[M]\{u\} = [I]\{u\}$, where $[I]$ is the unity matrix. Typically the matrix equations of motion for the structure contain off-diagonal terms, but they may be decoupled by introducing a suitable transformation. The damping matrix may also be uncoupled on the condition that the damping terms are proportional to either the corresponding stiffness matrix terms or the corresponding mass matrix terms [28.8].

Finite-element analysis in conjunction with high-speed digital computers permits the efficient solution of large, complex structural dynamics problems. Structural dynamics problems that are linear can generally be solved in the frequency domain. There are other applications of finite-element analysis in acoustics. The sound field produced in an enclosure or by a radiating surface vibrating at a single frequency can be described by the Helmholtz equation

$$\nabla^2 p + k^2 p = 0\,,$$

$$(28.2)$$

where p is the acoustic pressure, k is the wave number ($k = \omega/c$) and ∇ is the Hamiltonian nabla operator.

The most common boundary conditions are fixed pressure and fixed velocity on the surface of the enclosed or radiating body. Other types of boundary conditions are normal and transfer impedances [28.9].

Exact analytical solutions of the Helmholtz equation exist for a very limited number of idealized geometries corresponding to situations where the geometry of the radiating surface can be described by orthogonal coordinate systems that are separable. In order to solve the Helmholtz equation for more general applications, numerical schemes are necessary.

28.3.2 Boundary-Element Methods

The boundary-element method (BEM) is also a powerful computational technique, providing numerical solutions to a wide range of scientific and engineering problems. Since only a mesh of the boundary of the domain is required, the method is generally easier to apply than the finite-element method. The boundary-element method has found application in stress analysis, structural vibrations, acoustic fields, heat transfer, and potential flow. The advantage in the boundary-element method is that only the boundaries of the domain of the partial differential equation require subdivision, compared to FEA in which the whole domain of the equation requires discretization.

The boundary-element method is especially effective for calculating the sound radiated by a vibrating body or for predicting the sound field inside a cavity. A typical BEM input file consists of a surface mesh, a normal velocity profile on the surface, the fluid density, speed of sound, and frequency. The output of the BEM includes the sound pressure distribution on the surface of the body and at other points in the field, the sound intensity, and the sound power. BEM may be formulated in either the time domain or the frequency domain [28.10].

In cases where the domain is exterior to the boundary, as in acoustic radiation, the extent of the domain may be infinite and hence the advantages of BEM are even more striking [28.11]. The boundary-element mesh, which consists of a series of points called *nodes* connected together to form triangular or quadrilateral elements, covers the entire surface of the radiating body. The magnitude and phase of the vibration velocity must be known at every point. BEM calculates the sound pressure distribution on the surface of the body from which the sound pressure and sound intensity at field points in the acoustic domain can be calculated. BEM will even calculate the sound pressure in the *shadow zone* behind a body due to radiation from the other side [28.10].

Another class of problems to which the BEM may be applied is the so-called interior problem, such as the prediction of the sound field inside an enclosure. The procedure is similar to the solution of exterior problems.

There are two different formulations for BEM: *direct* and *indirect* methods. The primary variables in the direct BEM are the acoustic pressure and acoustic velocity, while the indirect method uses the difference in acoustic pressure and the difference in the normal gradient of acoustic pressure across the boundary [28.12]. There is no distinction between an interior and an exterior problem when using indirect BEM, since it considers both sides of the boundary simultaneously.

Yet another class of problems is that in which an interior acoustic space is connected to an exterior space through one or more openings. The radiation of sound from a source within a partial enclosure is one example of such a problem. In one approach, the integral equations for the interior and exterior domains are coupled using continuity conditions at the interface surface between the two domains. The integral equations are then reduced to numerical form using second-order boundary elements [28.13].

To apply BEM to the Helmholtz equation, it must essentially be reduced to a two-dimensional integral equation by use of Green's theorem. This means that only a description of the radiating surface is necessary rather than a complete discretization of the surrounding medium. The technique is suited to both interior- and exterior-domain problems.

Some methods couple a finite element of the structure with a boundary-element model of the surrounding fluid. The surface fluid pressures and normal velocities are first calculated by coupling the finite-element model of the structure with a discretized form of the Helmholtz surface integral equation for the exterior fluid [28.13].

Both BEM and FEM can be computationally intensive if the model has a large number of nodes. The solution time is roughly proportional to the number of nodes squared for an FEM analysis and to the number of nodes cubed for a BEM analysis. The accuracy of both methods depends on having a sufficient number of nodes in the model, so engineers try to straddle the line between having a mesh that is accurate yet can be solved in a reasonable time. The general rule of thumb is that six linear or three parabolic elements are needed per wavelength [28.10].

28.3.3 Finite-Element Correlation

It is often desirable to validate the results of a finite-element analysis with measured data from a modal test. This correlation is generally an iterative process incorporating two major steps. First the modal frequencies and mode shapes are compared and the differences quantified. Then, adjustments and modifications are made to the finite-element model to achieve more-comparable results.

It is useful to graphically compare the sets of frequencies by plotting predicted versus measured frequencies. This shows the global trends and suggests possible causes of these differences. If the random scatter is too great, then the finite-element model may not be an accurate representation of the structure. If the points lie on a straight line, but with a slope other than 1, then the problem may be a mass loading problem in the modal test or an incorrect material property such as elastic modulus or material density in the finite-element model.

Numerical techniques have been developed to perform statistical comparisons between mode shapes. The modal assurance criterion (MAC) is a correlation coefficient between the measured and calculated mode shapes. Another technique, called direct system parameter identification, is the derivation of a physical model of a structure from measured force and response data [28.5]. Various forms of cross-orthogonality tests have also been employed. In general these methods see how well the experimental shapes can uncouple the mathematical model. As with many comparison methods, difficulty is often encountered in reducing the FEA degrees of freedom to a set of DOFs consistent with the experiment.

28.4 Sound-Field Analysis

Although modal analysis developed primarily as a way of analyzing mechanical vibrations, by substituting microphones or acoustic intensity probes for accelerometers, experimental modal testing techniques can be used to explore sound fields. Modal testing has been used to explore standing acoustic waves inside air columns and to explore radiated sound fields from a vibrating structure. It could also be used to explore acoustical modes in rooms.

Figure 28.4 shows an arrangement for measuring the sound field inside a flute. The exciter is a loudspeaker coupled to the flute by a capillary tube. A pressure microphone probes the sound field at successive points, and the input and output signals are fed to a 2-channel FFT analyzer in the usual manner. The sound pressure amplitudes and phases for four modes in the flute (D5 fingering) are shown in Fig. 28.5 [28.14].

The sound field radiated by a piano soundboard has been similarly explored by driving the soundboard with a shaker and probing the radiated field at 200 points with a pressure microphone. Figure 28.6 shows the sound pressure in the radiated sound field at two frequencies. The sound field shows a 180° phase difference above and below the plane of the soundboard as expected [28.14].

28.5 Holographic Modal Analysis

Holographic interferometry offers the best spatial resolution of operating deflections shapes. In cases where the damping is small and the modes are well separatd in frequency, the operating deflection shapes correspond closely to the normal mode shapes. Modal damping can be estimated with a fair degree of accuracy from half-power points determined by counting fringes [28.15]. Phase modulation allows analysis to be done at exceedingly small amplitudes and also offers a means to separate modes that overlap in frequency [28.16]. TV holography allows the observation of vibrational motion in real time, and it is a fast, convenient way to record deflection shapes. Holographic interferograms of several vibra-

tional modes of a Chinese opera gong appear in Fig. 28.7.

Holographic interferometry was once done on photographic film, but now electronic TV holography [28.17] and electronic speckle pattern interferometry (ESPI) [28.18] allow interferograms to be observed in real time and to be recorded rapidly. Holographic interferograms of several modes of a Chinese opera gong are shown in Fig. 28.7. A relatively inexpensive setup for ESPI (also known as digital speckle interferometry or DSI), developed by *Moore* [28.18], has been the basis for a number of interferometers now used for modal analysis of musical instruments. Holographic techniques are discussed in Chap. 27.

28.6 Experimental Modal Analysis for Microsystems

Microsystems also known as microelectromechanical systems or MEMS, have become increasingly common in recent years. For example, silicon-based microsystems have been manufactured by surface and bulk micro-machining. Metal, ceramic, plastic, and polymer based systems have been produced using lithography, electro-plating, and molding techniques. Synchrotron radiation has been used to make molds, which are then filled by means of electrodeposition. Traditional modal testing techniques are often not suitable for microsystems. In this section we will briefly discuss techniques that can be used for modal testing of microsystems [28.20].

Direct excitation methods, such as impact hammers or shakers directly attached to the structure, are generally not satisfactory for testing microstructures. Indirect, noncontact excitation methods are often required. In additon, the natural frequencies encountered in microsystems are typically higher than in traditional structures, and the exciter must be capa-

ble of exciting the structure in the high-frequency range.

Induced electrostatic forces can be used for excitation of microstructures. Although relatively easy to apply, the electrostatic forces may be nonlinear functions of structural motions, and they cannot be easily measured. Excitation can also be provided by embedded piezoelectric elements, but these may load the structure. Magnetic and thermal excitation techniques can also be used.

Another technique is base excitation using external elements [28.21]. In this case, a transducer (such as a piezoelectric disk or an electromagnetic shaker) is used to shake the entire structure.

Meaurement of the motion of the microstructure also presents a considerable challenge, partly due to the high frequencies involved. Holographic modal analysis is discussed in Sect. 28.6 and other optical methods are discussed in Chap. 27. Video imaging techniques can also be applied for measuring structural motion [28.22].

29. Microphone Array

Rolf Bader

This chapter deals with microphone arrays. It is arranged according to the different methods available to proceed through the different problems and through the different mathematical methods. After discussing general properties of different array types, such as plane arrays, spherical arrays, or scanning arrays, it proceeds to the signal processing tools that are most used in speech processing. In the third section, backpropagating methods based on the Helmholtz–Kirchhoff integral are discussed, which result in spatial radiation patterns of vibrating bodies or air.

29.1 Overview

Concert spaces, classrooms and auditoriums, industrial cites, or the interior of cars, trains, or planes, and even outdoor spaces like streets or plazas, all are complex sound environments, where when the position of the listener changes, the sound perception also often changes tremendously. Additionally, our acoustical perception is a binaural one which is able to perceive spaciousness or envelopment of rooms and spaces. We estimate the distance to a source, locate this source at a certain angle of our perceptual field, separate different speakers, and are able to concentrate on one of them; this is well known as the cocktail party effect. We are able to separate musical instruments in a musical piece according to their position in a musical space. We can estimate the size, depth, or height of a space using reverberation information. Also, we are able to neglect much reverberation when we want to concentrate on a speaker in a space and extract the speech, neglecting the reverberation.

In many acoustical applications and problems this spaciousness occurs and needs to be handled, both with respect to the recording and analysis, as well as from the sound-field reconstruction side. Here, microphone arrays help us to get closer to spatial analysis. The basic idea is simple, many microphones hear more than only one or two. With more information collected on the space, the reconstruction and analysis is easier. Also some problems can only be solved using multiple microphones.

The range of applications where microphone arrays are used today is very wide. Still it may be split into two main fields which differ both in terms of their problems and their mathematical treatment. The first set of methods is based on signal processing and is referred to as the family of beamforming methods. A second set is backpropagating a recorded sound field onto a radiating body and is mostly based on the Helmholtz–Kirchhoff integral.

A standard beamforming problem would be a simple localization of a source which is enhanced by using many microphones recording this source at different positions. This is especially the case in reverberant environments where the source is reflected many times, and the position of the source is therefore much harder to find compared to a free space. This problem becomes even more difficult if there are multiple sources, e.g., several speakers in a room.

To go a step further one might want not to only localize the source but to use the microphone array to get rid of noise in the recorded signal. This is a common application for conference rooms or in a car, where reverberation or noise is strong. One might also wish to dereverberate a signal, so get rid of the reverberation and only reconstruct the speech signal alone. Although this, as well as denoising, is a basic task of speech signal processing using only one channel, many recordings often help to fulfill the task much better. Installations of such arrays are found in conference rooms, where the array is fixed and the reverberation can easily be measured. There this approach it is very helpful to increase speech intelligibility [29.1].

Microphone arrays may also be used to record signals, which are then played back later in another space. Thus, e.g., when recording a musical piece with several musicians, this piece may be reproduced in another concert hall with similar spaciousness to the original recording. Here many microphones help to understand the complex spatial pattern of the sound field and to reconstruct this pattern in another space.

A different task is to reconstruct the vibration of a complex radiating source. Musical instruments are a good example of complex radiating sources. The radiating patterns of the instrument body is caused by the vibrational behavior of its geometry. Knowing this complex pattern helps to understand the instrument and may lead to construction rules for instrument builders to alter the instrument's sound. It it also interesting to know the complex radiation pattern of machines, as often multiple source points of a noise signal are present on the geometry and their interaction may lead to helpful conclusions about the internal vibrational relations of this machine. For solving such problems a very different family of mathematical methods have been developed, which allow us to backpropagate a recorded signal to a radiating body. When this radiation pattern is known, it is trivial to propagate this radiation to any point in the surrounding space, which therefore results in a directivity pattern of the radiating body. The boundary-element method may be the best known of these methods, where the geometry of the radiating body needs to be known in advance to be able to reconstruct the radiation from it. Still many other methods have been proposed and all use the Helmholtz–Kirchhoff integral as their basis, which connects the sound pressure at a point in space to a radiating surface. Another method, which also backpropagates the recording of a microphone array to a source but not using this integral formulation, is the method of acoustic holography. It is not treated here as it is discussed in much detail in Chap. 26.

29.2 Array Geometries

29.2.1 Scanning Arrays

When measuring a complex radiation field or when backpropagating a complex radiation pattern, as a simple rule of thumb, the more microphones that are used, the better the representation. Of course, more microphones mean more recording channels and this may become quite expensive.

A simple alternative is the scanning array. Here a small set of microphones, maybe only four or eight, are placed at all desired positions, recording the field in parts. For practical reasons, the total configuration of the array depends on the basic mounting of the microphones. If they are mounted in a linear array, they are suitable to be used in a regular grid spacing. If they are mounted to a half-circle, this circle may be moved around a center point over 360° in equally spaced angles to obtain a full sphere covered with microphone recordings.

This approach can only be used for static signals, and one needs to rely on the signal to be the same no matter at which position the small array is recording. Often an automatic recording setup is built with a motor moving the array around and, therefore, it is possible to

partly record the sound field at the different positions, one after another.

29.2.2 Plane Microphone Arrays

Historically, plane arrays appeared first [29.4]. Here a regular grid of microphones is used; this grid may also have different configurations. A simplification is the line array, which is often used with small numbers of microphones, like four to eight. Plane arrays are often used with the reconstruction of complex radiating surfaces, as then the array has a similar geometry. Figure 29.1 shows an example of a near-field recording of a guitar with a plane array consisting of 121 microphones.

29.2.3 Spherical Microphone Arrays

Spherical microphone array configurations seem attractive at first when decomposing radiation into spherical

harmonics. This configuration is known as an open-sphere array. Still, for the lowest of the harmonics, the simple monopole radiation, the pressures are all the same at all microphones. Therefore, the condition of the transfer matrix, the matrix associating the radiation points with the microphones, is very bad, with nearly linearly dependent rows. So for this type of radiation, a spherical array may not be the best choice [29.5–13].

A dual-sphere array, where two spheres with different radii are used is better in this case. However, the problem of determining the best radius is often not easily solved before the recording. Additionally, twice as many positions need to be scanned. Still, the dual-sphere array clearly is an improvement over the simple spherical array.

Spherical arrays are also a natural choice when it comes to a simple sound field recording around a source; Fig. 29.2 shows measuring of the radiation directivity of musical instruments. Then, as the sphere covers the sound source in a regular angle, the radiation strength of the radiating body is directly measured, and no complex signal processing or backpropagation methods need to be applied.

Many alternative spherical array configuration and signal processing tools have been proposed [29.14–22]. Spherical arrays may also come as compact arrays using a small sphere in space rather than a large sphere

Fig. 29.1 Example of a plane array for recording sound fields. The array consists of 121 microphones arranged in a regular grid of 11×11 microphones with a grid constant of 4.75 cm recording a guitar in its near field [29.2]
Fig. 29.2 Example of a spherical array as used at the RWTH in Aachen, Germany, arranged around a radiating source, here a musical instrument, to record sound radiation and, therefore, the directivity pattern of the instruments [29.3]
Fig. 29.3 Example of a compact array as used at the Center for New Music and Audio Technologies (CNMAT) in Berkeley, where microphones are arranged on the surface of a small sphere to record the surrounding sound field [29.3]

surrounding the radiator. Compact arrays may also be seen as more elaborated microphone recording configurations improving the traditional XY or AB recording, where two directional microphones with different orientation are used to record, e.g., musical instruments. One example is shown in Fig. 29.3. With more microphones within a small sphere, a more complex ambient sound can be recorded and afterwards spatially reconstructed when playing this recording back in a concert space. Here wave field synthesis methods are often used today with many speakers to reconstruct an original sound field in a 3-D space.

29.2.4 Alternative Array Geometries

To take this reasoning a step further, the more irregular the microphone spacing, the better the transfer matrix condition [29.8, 23]. Again as a rule of thumb, this is because regularities in an array means regularities in a matrix, which is the cause of linear dependencies between rows and, therefore, a bad matrix condition. Still, when using a scanning array procedure, this is very difficult to realize in practice, as all microphones need to be placed randomly.

Other array arrangements have also been proposed. A spindle torus array may serve as a good compromise for a configuration that is not too regular; this is still possible to perform using an automatic motor driven experimental setup [29.5, 8, 9, 13].

29.3 Beamforming

The beamforming microphone array technique belongs to signal processing. It has a wide variety of applications, from source detection and separation to denoising or dereverberation. Mathematically, all these have common ground in delay and filter techniques, which are discussed in this section. The methods aim at an improvement of a signal using a multichannel recording. Therefore, most often these signal reconstructions become better the more recordings are made, to converge to good results often only using four to eight microphones. Many filter techniques known from signal processing, especially from speech processing, like the Kalman [29.24–26] or Wiener filters [29.27–32] are used. These are not discussed in this section in detail and the reader is referred to the literature for filter techniques in general.

The interfering parameters in all these methods are measurement noise, additional signals next to the one of interest, and reverberations. The measurement noise is assumed to be uncorrelated between the microphones, and is, therefore, considered as random Gaussian noise.

The additional sources are correlated between the microphones; they are not correlated to the source of interest. Last the reverberation is correlated between the microphones and also with the source in focus. So these three disturbing signals need to be treated separately, which each method does differently.

Moreover, the kind of signal expected plays a crucial role when choosing an algorithm suitable for a certain situation. The signal may be steady, like with industrial noise, or it may be transient, like with speech. Basically, stationary signals are more simple to deal with, and transient sources need additional assumptions. Also the source may be a broad or narrowband signal. Most often broadband sources are split into single bands, where each band is treated separately. Then the same basic algorithm may be used with both kinds of signals.

29.3.1 Sound Source Localization

Here the task is to localize a single sound source in a distance. The proposed method may also be used for

near-field sources if these sources are not too close. In contrast to the equivalent source methods which result in a complex radiation pattern of a surface or radiator, the localization estimation results in a single value of an angle relative to the normal direction of the microphone array, at which the single source is most likely to be placed.

The most important property to detect such a signal $s(t)$ is its phase. This needs to be different at each of N microphones, recording a time series $m_i(t)$ with $i = 1, 2, 3, \ldots N$, where

$$m_i(t) = A_i s(t + \Delta t_i) + \xi_i(t) , \tag{29.1}$$

where $\xi_i(t)$ is the noise uncorrelated between the microphones and Δt_i are the different time delays between the source point and the i microphones. In Fig. 29.4 the free-field case of a single radiating source is shown schematically. When a wave arrives at the array traveling from the far field, the difference of arrival times of this wave at the microphones is

$$\Delta t_{ij} = \Delta t_i - \Delta t_j = \frac{r_i - r_j}{c} , \tag{29.2}$$

where r_i and r_j are the distances between the source and the respective microphones and c is the speed of sound.
Fig. 29.4 Free-field case of a singe radiating source recorded using a microphone array consisting of eight microphones. The different distances r between the source and the microphones result in eight different time delays Δt_i that a wave arrives at the microphones. From this time delay information the sound source can be localized

A source is to be localized at a direction of arrival (DOA), the angle φ_i between the source and the microphone array plane at microphone i. Then using three microphones with distance (or microphone array grid constant) d

$$r_2^2 = r_1^2 + d^2 + 2r_1 d \cos(\varphi_1) , \tag{29.3}$$
$$r_3^2 = r_1^2 + 4d^2 + 4r_1 d \cos(\varphi_1) . \tag{29.4}$$

Substituting the respective variables for the three microphones in (29.2), the time delay between a sensor i and its n-th neighbor is

$$\Delta t_i = \frac{(n-1)d}{c} \cos(\varphi) . \tag{29.5}$$

From the phase difference between the two sensors for a single frequency the time delay Δt_i can be estimated. Then DOA φ can be calculated. Additionally, when the angle is known using (29.4), the distances r_i between the sensors and the source can also be estimated.

29.3.2 Time Difference of Arrival Estimation

As was shown above with localization, the difference of arrival time of a wavefront at different microphones is often needed as a parameter for further calculations. Several other methods have been proposed to estimate this parameter.

A well-established method is the generalized cross-correlation (GCC) algorithm, which uses only $N = 2$ microphones [29.33, 34] with several derivatives [29.35–37]. The basic idea is to use the maximum of a two-cannel cross-correlation function to estimate the time difference of arrival as

$$\Delta t = \arg \max_t f_{m1,m2}(s) . \tag{29.6}$$

Here, the $f_{m1,m2}$ is the cross-correlation between the two microphones, which is defined as the inverse Fourier transform of the weighted cross-spectrum $C[M_1(f), M_2(f)]$ between the Fourier transformed time series M_1 and M_2 of the two signals m_1 and m_2 as

$$f_{m1,m2}(s) = \int_{-\infty}^{+\infty} C[M_1(f)M_2(f)]w(f)e^{i2\pi fs} \, df . \tag{29.7}$$

Here $w(f)$ is a weight function of the Fourier kernel to improve the effect of sidebands and so to smooth the cross-correlation function.

29.3.3 Denoising Using the Delay–and–Sum Technique

A simple way of reducing the noise ξ in (29.1) using microphone arrays is to use the assumption of the uncorrelated noise of the different recordings. This method can be applied if the DOA φ and, therefore, the time delays Δt_i are known. Then, as the source signal is correlated between recordings $m_i(t)$ and the noise signal is not, averaging the time-shifted signals enhances the source signal and reduces the noise. This is often referred to as the delay-and-sum technique [29.34,38–44], where the reconstructed signal $s'(t)$ is

$$
\begin{aligned}
s'(t) &= \frac{1}{N} \sum_{i=1}^{N} m_i(t + \Delta t_i) , \\
&= \frac{1}{N} \sum_{i=1}^{N} [A_i s(t + \Delta t_i) + \xi_i(t)] , \\
&= \frac{1}{N} \sum_{i=1}^{N} A_i s(t + \Delta t_i) + \frac{1}{N} \sum_{i=1}^{N} \xi_i(t) .
\end{aligned} \tag{29.8}
$$

As the $\xi_i(t)$ have zero means,

$$
\lim_{N \to \infty} \frac{1}{N} \sum_{i=1}^{N} \xi_i(t) = 0 . \tag{29.9}
$$

Furthermore, as the $\xi_i(t)$ are uncorrelated and the signals are not,

$$
\lim_{N \to \infty} \sum_{i=1}^{N} \frac{1}{N} A_i s(t + \Delta t_i) = s(t) . \tag{29.10}
$$

If the noise at the different microphones is correlated to a certain extent the noise reduction is decreased. This so-called beamforming delay-and-sum algorithm performs better when more microphones are used, but the improvement is logarithmic and, therefore, four to eight microphones reduces the noise considerably. Indeed, the time delays, and therefore the DOA need to be known in advance.

29.3.4 Directivity Pattern

Microphone arrays can also be used to determine the DOA of a sound source by estimating the directivity pattern. Using a line array, the directivity of the arrival pattern according to an angle $0 < \varphi < \pi$ in front of the microphones can be estimated. Therefore, the time difference of arrivals Δt_i of $i = 1, 2, 3, \ldots N$ microphones is

$$
\Delta t_i = \frac{(n-1)d}{c} \cos(\varphi) , \tag{29.11}
$$

where d is the grid constant of the array, the distance between the microphones, and c is the speed of sound again. The directivity pattern can then be determined by use of a spatial Fourier transform. This transform needs the angle $0 < \Phi < \pi$ as a filter. Then the spectrum is

$$
\begin{aligned}
S(\varphi, \Psi) &= \frac{1}{N} \sum_{i=1}^{N} e^{i2\pi(n-1)fd/c \cos \Phi} e^{-i2\pi(n-1)fd/c \cos \Psi} \\
&= \frac{1}{N} \sum_{i=1}^{N} e^{-i2\pi(n-1)fd/c(\cos \Psi - \cos \varphi)} .
\end{aligned} \tag{29.12}
$$

Here f is the frequency of the wave, since this technique works for single frequencies only. Therefore, for each fixed possible arrival angle φ, the directivity pattern over the angle Ψ is

$$
\begin{aligned}
D(\varphi, \Psi) &= |S(\varphi, \Psi)| \\
&= \left| \frac{\sin \left[N\pi f \frac{d}{c} (\cos \varphi - \cos \Psi) \right]}{N \sin \left[\pi f \frac{d}{c} (\cos \varphi - \cos \Psi) \right]} \right| .
\end{aligned} \tag{29.13}
$$

This directivity pattern has the disadvantage that it depends on the grid constant d. Thus, if the pattern is to be optimized, the only parameter we can change is the distance between the microphones, which would mean rearrangement of the array. This is often not very practical, and thus other methods are used when an optimization of the directivity pattern is to be applied, like the least-square method of a fixed beamformer [29.45–48]. The directivity pattern can also be improved by adaptive beamforming to reduce the signal to noise ratio (SNR) [29.49] using the minimum variance distortionless response (MVDR) beamformer [29.39,50–52]. Since the basic idea is equivalent to the linear constraint minimum variance (LCMV) filter technique for sound source separation, this method is discussed in Sect. 29.3.6.

29.3.5 Dereverberation

Signals recorded in spaces, like speakers in a classroom or a conference hall, are normally reverberated, which reduces speech intelligibility. Figure 29.5 shows the situation of a single source recorded by eight microphones, where the closed space reflects sound and, therefore, many more pathways from the source to the receivers are present, resulting in a reverberated sound.
Fig. 29.5 Closed space case of a single sound source recorded by eight microphones. More than eight paths between the source and the receiver exist and the sound is, therefore, reverberated

Thus, it may be desirable to get rid of the reverberation and reconstruct the original signal. The beamforming time-delay approach uses the impulse responses $H_{s,m}(t)$ of all sources s to all microphones m in the space for dereverberation. Then

$$\boldsymbol{m}(t) = \mathbf{H}\boldsymbol{s}(t) + \boldsymbol{\xi}(t) , \qquad (29.14)$$

where $\boldsymbol{m}(t)$ is the vector of microphone recordings, $\mathbf{H}$ is the matrix of all impulse responses, and $\boldsymbol{\xi}(t)$ is the noise vector. Equation (29.14) has several drawbacks. First, all impulse responses would need to be known. Then, estimating $\boldsymbol{s}(t)$ would be an ill-posed problem, which is discussed in Sect. 29.4. Thus, dereverberation may be better treated in with the more general approach of source separation discussed in Sect. 29.3.6.

29.3.6 Source Separation Using Linear Constraint Minimum Variance (LCMV) Filters

Separating one source out of M sources can be done with the use of filter techniques. In Fig. 29.6, an application of multiple sources in a free field, recorded by multiple microphones, is shown. The same setting, now in a reverberant space, is shown in Fig. 29.7. Many applications are in closed spaces like concert halls or classrooms, and therefore, next to additional sources,
Fig. 29.6 Setup of multiple (in this example three) sources radiating sound which is recorded by multiple microphones in a free field

the reverberation of the room needs to be taken into account. Also, most often the recordings have a finite noise background.

The Frost algorithm [29.53] with modifications [29.25, 54–56] uses a constraint on a matrix of
Fig. 29.7 Setup of multiple (in this example three) sources radiating sound recorded by multiple microphones in a closed space with reverberation

impulse responses to separate the source from the signals recorded by the microphone array $m_i(t)$ of $i = 1, 2, 3 \ldots, N$ microphones. If M sources $s(t)$ are present, like, e.g., speakers in a room, there are R_{nm} impulse responses from each speaker to each microphone.

To reconstruct the signals of one desired source S from N microphone recordings, a filter $\boldsymbol{h}$ can be used (assuming constant time delays Δt), like

$$s_S(t + \Delta t) = \sum_{i=1}^{N} \boldsymbol{h}_{Si}^{T} \boldsymbol{m}_i(t) . \tag{29.15}$$

The task is to estimate this filter. When the recordings are combined to a single vector like

$$\boldsymbol{m}(t) = \{\boldsymbol{m}_1(t) \boldsymbol{m}_2(t) \boldsymbol{m}_3(t) \ldots \boldsymbol{m}_N(t)\}^{T} , \tag{29.16}$$

and likewise the sources are combined to one source vector

$$\boldsymbol{s}(t) = \{\boldsymbol{s}_1(t) \boldsymbol{s}_2(t) \boldsymbol{s}_3(t) \ldots \boldsymbol{s}_N(t)\}^{T} . \tag{29.17}$$

Then the recordings and the sources can be related via the matrix $\mathbf{R}$ of the impulse responses as

$$\boldsymbol{m}(t) = \mathbf{R}\boldsymbol{s}(t) . \tag{29.18}$$

One of the tasks is noise reduction, where the basic idea is similar to the delay-and-sum algorithm mentioned above, again assuming that the noise is not correlated to the signal and has a zero mean. Thus, when averaging over the recordings, the noise will be reduced. This idea is incorporated in the method by the covariance matrix

$$\boldsymbol{C} = \boldsymbol{m}(t)\boldsymbol{m}^{T}(t) . \tag{29.19}$$

Then the noise reduction part means to minimize

$$\boldsymbol{h}_S^{T}\boldsymbol{C}\boldsymbol{h}_S = \min_{\boldsymbol{h}_S} . \tag{29.20}$$

To point to the desired source to reconstruct, the constraint

$$\mathbf{R}^{T}\boldsymbol{h}_S = \boldsymbol{f}_S , \tag{29.21}$$

needs to be applied to this minimization. The constraint vector $\boldsymbol{f}_S$ for the case of a single source extraction has a single unit entry at the source point and is zero elsewhere. As the $\mathbf{R}^{T}$ matrix contains all the impulse responses, the filter $\boldsymbol{h}_S$ is, therefore, constrained by $\boldsymbol{f}_S$ in such a way that all impulse responses of the other sources will be orthonormal to the filter vector and only the one for the subject to extract becomes $R_{\text{subject}} = 1$ when applied to the impulse response matrix.

From this constraint, and because $\mathbf{R}$ is full range and positive definite and therefore invertible, calculating the filter could simply be done as follows

$$\boldsymbol{h}_S = \mathbf{R}^{-1}\boldsymbol{f}_S . \tag{29.22}$$

The the noise reduction should be included, which can be done by using a pseudo-inverse of the covariance matrix, using the impulse response matrix, as follows

$$\boldsymbol{h}_S = \mathbf{R}^{-1}\boldsymbol{C}\left[\boldsymbol{C}^{T}\mathbf{R}^{-1}\boldsymbol{C}\right]^{-1}\boldsymbol{f}_S . \tag{29.23}$$

This is also known as the LCMV method. The method includes all three problems of source estimation, noise reduction, dereverberation, and source separation. Noise reduction is performed by the covariance method. If $\boldsymbol{h}_S(1 = N)\boldsymbol{I}$, with unit vector $\boldsymbol{1}$, the delay-and-sum algorithm is present. Dereverberation is performed by the impulse responses incorporated in a single matrix. The source separation is done via the constraint vector $\boldsymbol{f}$, which forces the filter $\boldsymbol{h}$ to filter the impulse responses such that only the desired source remains and all others are set to zero. All impulse responses need to be known in advance.

Many alternatives of this method have been proposed. In a nonreverberant environment the impulse responses may be replaced by simple attenuation factors between M sources and N microphones. Then noise reduction and source separation are still carried out. Another simplification is to assume only one source in a reverberant environment, which simplifies the impulse response matrix. Then it is a noise reduction and a dereverberation algorithm. The most simple form of the Frost algorithm is to assume one source and a simple attenuation from the source to the microphones without the impulse response. Then it is a simple noise reduction and reduces to the delay-and-sum algorithm.

The length of the impulse response or filter vector can also be changed with this method. Estimations for different cases of the number of sources and the number of receivers have been discussed. In some cases not all impulse responses need to be known. Also side lobes can be present, which may be reduced in amplitude.

The problem of blind source separation where several sources are present in a space and both the sources and the transfer matrix are unknown, may be solved by introducing spherical harmonics. The use of spherical harmonics is discussed in detail in Sect. 29.4.10. However, it is also used in the world of beamforming [29.6, 9–12, 57, 58], and is often called modal beamforming. When describing the sources as a set

29.4 Equivalent Source Methods

The equivalent source methods represent the radiating surface using multiple sources [29.59–65]. The real radiation is then approximated by a linear superposition of such sources with respective amplitudes [29.66]. These sources are often assumed to be behind the radiating surface, they may also be on it. Many different versions of these methods have been proposed and they differ mostly in the choice of sources and the procedure of regularization necessary to converge the solution.

The basic equation behind all these methods consists of the sum over N virtual radiation positions with M poles Ψ_{nm} each and their respective amplitudes A_{nm}, as follows

$$p(x, y, z) = \sum_{n=1}^{N} \sum_{m=1}^{M} A_{nm} \Psi_{nm}(x, y, z) . \qquad (29.24)$$

This is the formula of the *forward-propagation* of the problem. When all poles are chosen to be at respective positions and all amplitudes are known, the pressure at any arbitrary position in front of the radiating geometry $p(x, y, z)$ can be calculated as the sum over all virtual sources. Equation (29.24) holds for only one frequency.

However, with these methods the problem is vice versa at first. Normally with the microphone array, many pressures at several room positions have been measured and one wants to know the pressures at a radiating surface. Then in (29.24) the left-hand side is known, the sources Ψ_{nm} are chosen, and the amplitudes A_{nm} are the unknowns. Calculating these amplitudes is known as *backpropagation*, propagating the measured pressure values back to the radiating surface.

So although the forward problem is trivial, the backpropagation is not. The solution often depends crucially on the choice of the virtual radiation points, as well as on their position. The methods proposed mainly use the following:

- Multiple monopoles at different positions
- Multiple mono and dipoles at different positions, or
- Only one virtual radiation point with many higher-order poles.

A second problem is the ill-posedness of (29.24). Although mathematically perfectly sound, solving for the amplitudes A a matrix equation is built of the kind

$$\mathbf{\Psi} A = p , \qquad (29.25)$$

where p is the vector of all measured pressures, $\mathbf{\Psi}$ is a matrix of all poles assumed at their virtual positions

with respect to the recording positions of the pressures, and A is the amplitude vector. Solving this equation is only possible in the absence of any error, otherwise the solution for A does not converge; a linear equation *easily blows up* the solution. This ill-posedness is discussed below in detail. Many sources for errors are present in the sound; the most prominent ones are the following:

- Measurement noise
- Nonperfect microphone placing
- The difference between the real radiation field and the one reconstructed by the finite amount of virtual source points.

All these small errors have a fatal effect on the direct solution of the matrix equation and, therefore, regularizations are necessary to solve the problem. Therefore, all algorithms proposed to solve the problem are different kinds of these regulatizations. Before going deeper into these methods, the poles used will briefly be introduced.

29.4.1 Definition of Sources

The wave equation for a three-dimensional space in its eigenvalue formulation is

$$c^2 \left(\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial x^2} \right) = \omega^2 p . \qquad (29.26)$$

The solution $\tilde{p}(x, y, z, t)$ is decomposed into its spatial part $p(x, y, z)$ and time-dependent part $q(t)$ as follows

$$\tilde{p}(x, y, z, t) = p(x, y, z)q(t) , \qquad (29.27)$$

assuming $q(t) = e^{i\omega t}$. When transformed into spherical coordinates with radius r, angles φ and θ, and pressure $p(r, \theta, \varphi)$, the Helmholtz equation reads

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial p}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial p}{\partial \theta} \right)$$
$$+ \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 p}{\partial \varphi^2} = \frac{1}{c^2} \omega^2 p , \quad (29.28)$$

with the solution

$$p(r, \theta, \varphi) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \Psi_{nm}(k, r, \theta, \varphi) , \qquad (29.29)$$

with

$$\Psi_{nm}(k, r, \theta, \varphi) = \left[A_{nm} h^{(1)}(kr) + B_{nm} h^{(2)}(kr) \right]$$
$$\times Y_n^m(\theta, \varphi) , \qquad (29.30)$$

with wave vector k, amplitudes A_{nm} and B_{nm}, the Hankel function of first and second-order $h^{(1)}$ and $h^{(2)}$, which are complex Bessel functions, and the spherical harmonic

$$Y_n^m(\theta, \varphi) = \sqrt{\frac{(2n+1)}{4\pi} \frac{(n-m)!}{(n+m)!}} P_n^m(\cos\theta) e^{im\varphi} .$$

(29.31)

Here, P_n^m are the associated Legendre polynomials. These spherical harmonic functions are displayed in Fig. 29.8. The index $n = 0, 1, 2, 3 \ldots$ determines the harmonic order, where $n = 0$ is a monopole, $n = 1$ is the dipole, $n = 2$ is the quadrupole, etc. The second index runs from $m = -n, \ldots, 0, \ldots, +n$, determining the different parts of the radiating poles to be able to describe all possible pole orientations in space. Note that most spherical harmonics have a real part and an imaginary part representing phase relations.

29.4.2 Kirchhoff–Helmholtz Integral

The fundamental equation governing many methods used with microphone arrays is the Kirchhoff–Helmholtz integral, also called Green's theorem or known as the Fresnel integral [29.60, 62, 67–70]. Suppose a sound pressure $p(y)$ travels in free space and radiates over a volume Ω with surface S, surface coordinate y, and outward surface normal vector $n(y)$. Then the Gauss theorem, also known as divergence or Ostogradsky's theorem, states that the integration of divergence of the gradient of that pressure over Ω is like

the integration of the normal gradient $n(y)$ of the pressure over S like

$$\int \nabla^2 p \, d\Omega = \int \frac{\partial p}{\partial n} \, dS .$$

(29.32)

The pressure p is governed by the Helmholtz equation

$$\nabla^2 p + k^2 p = 0 .$$

(29.33)

The integral is not easily solved. To arrive at a solution that can be used in applications like scattering or radiation problems, a test function is used that scans the domain. This function is known as Green's function. To avoid mathematical conflict at the boundary S of Ω, concerning Green's function, several constraints must be met, namely:

1. It must fulfill the Helmholtz equation $\nabla^2 G + k^2 G = 0$ on Ω.
2. It must become the pressure when approaching the source point like $\lim_{r\to 0} G = p$,
3. Be $G = 0$ on S, and
4. It must fulfill the Sommerfeld radiation condition discussed below.

As we formulate the problem for single frequencies, constraint b means that Green's function needs to act like a monopole around the source point.

From here on, omitting the arguments x and y, we can formulate a new function, where Green's function *tests* the pressure field p

$$U = G\nabla p - p\nabla G .$$

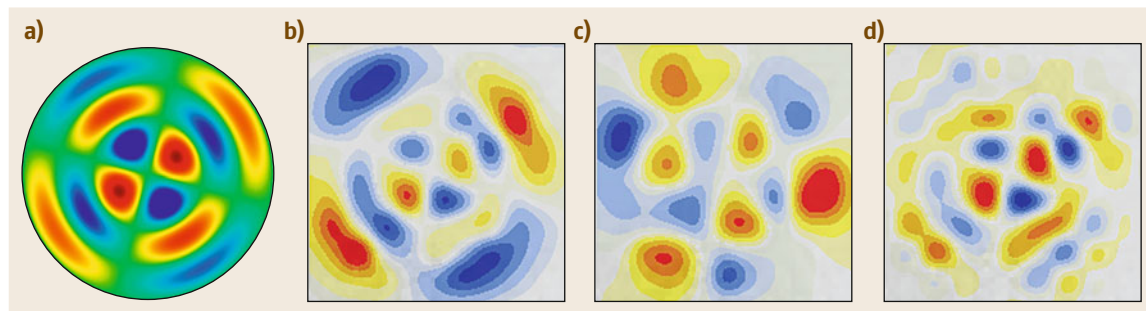
(29.34)


Fig. 29.8a–d Eigenmode (2,3) of a membrane. **(a)** Finite-element solution of 681 Hz of a perfectly isotropic membrane with perfectly fixed boundary condition, others of a goat skin frame drum with complex distribution of tension and membrane thickness and with a wooden shell as the boundary, as measured with a microphone array at 741 Hz; **(b)** backpropagated using the minimum energy method, taking the ill-posedness into consideration, the solution comes close to the finite-element solution; **(c)** raw data as measured at the microphone positions; **(d)** backpropagated without any regularization and, therefore, not taking the ill-posedness into consideration, showing considerable artifacts. All plots are interpolations of discrete positions (nodes with FEM, microphone positions with array)

Because of the Gauss theorem it can also be written as

$$U = G\frac{\partial p}{\partial n} - p\frac{\partial G}{\partial n}. \tag{29.35}$$

If the divergence of U is taken, to arrive at the second-order differentials needed for the Helmholtz equation, we have

$$\nabla(G\nabla p) = \nabla G\nabla p + G\nabla^2 p, \tag{29.36}$$

and

$$\nabla(p\nabla G) = \nabla p\nabla G + p\nabla^2 G. \tag{29.37}$$

Thus

$$\nabla U = G\nabla^2 p - p\nabla^2 G, \tag{29.38}$$

and, therefore, we arrive at

$$\int\left(G\nabla^2 p - p\nabla^2 G\,\mathrm{d}\Omega\right) = \int\left(G\frac{\partial p}{\partial n} - p\frac{\partial G}{\partial n}\right)\mathrm{d}S, \tag{29.39}$$

again by applying the Gauss theorem of (29.32).

To solve this equation we first find that in the free field the pressure and Green's function both need to satisfy the Helmholtz equation without a source term

$$\nabla^2 p + k^2 p = 0, \tag{29.40}$$

or

$$\nabla^2 G + k^2 G = 0, \tag{29.41}$$

respectively, and therefore the volume integral on the left-hand side of (29.39) is zero.

Thus only the surface integral remains, which can be summed over all surfaces present in Ω. To arrive at a solution, three of these surfaces are assumed. One is the real radiating (or scattering) surface S of the body. The other two surfaces are needed to obtain a solution. One is a sphere S_C around the source point. It is necessary since Green's function has a singularity and becomes infinite at $r = 0$. So integration needs to be done over a tiny sphere around this source point. The other sphere, S_S, is concentric and close to S_C so for S_S the Sommerfeld radiation boundary (29.42) cannot be used as we still find considerable sound pressure at S_S [29.68, 69]

$$\lim_{|\mathbf{r}-\mathbf{r_0}|\to\infty} |\mathbf{r} - \mathbf{r_0}|\left[\frac{\partial G(\mathbf{r}, \mathbf{r_0})}{\partial|\mathbf{r} - \mathbf{r_0}|} + \mathrm{i}kG(\mathbf{r}, \mathbf{r_0})\right] = 0. \tag{29.42}$$

Finally, the surface integral has the three parts

$$\int_{S+S_C+S_S}\left(G\frac{\partial p}{\partial n} - p\frac{\partial G}{\partial n}\right)\mathrm{d}S = 0. \tag{29.43}$$

When the source point is outside Ω, calculating the integral for S_C with the radius $r_C \to 0$, this integral becomes p [29.67], because first the derivative of p includes r_C, which vanishes, and second, because Green's function has r_C in its exponent and therefore becomes 1. The integral over S_S with $r_S \to \infty$ becomes zero because of the Sommerfeld radiation condition. Then the only integral left is the one of interest, the integration over the boundary of the body, which is then

$$\int_S\left(G\frac{\partial p}{\partial n} - p\frac{\partial G}{\partial n}\right)\mathrm{d}S = p. \tag{29.44}$$

When the source point is at the boundary of Ω, the integral over S_C is different. If the radiation point is outside Ω, the integration needs to be done over the whole sphere S_C of 2π. If it is at the boundary of Ω, this integration is often performed only over π. Therefore, the result of this integration is no longer p but $\frac{1}{2}p$. However, in some cases the geometry of the boundary may be complicated, especially at corners, where the integration may only be about a quarter or three fourths of this sphere. Some textbooks, therefore, give a parameter α with pressure p instead of $\frac{1}{2}p$.

When the source point is within Ω the integration over S_C becomes zero, as then also the integration over S becomes zero. This is a necessary consequence of the constraint c for Green's function on S discussed above.

We can also understand this by going back to the solution for Green's theorem in an alternative formulation, using (29.36), again together with (29.32), which gives

$$\int\nabla G\nabla p\,\mathrm{d}\Omega + \int G\nabla^2 p\,\mathrm{d}\Omega = \int G\frac{\partial p}{\partial n}\,\mathrm{d}S. \tag{29.45}$$

If we only discuss one frequency at a time, which is the case for nearly all microphone-array techniques, we can set $G = p$ and find

$$\int(\nabla p)^2\,\mathrm{d}\Omega + \int p\nabla^2 p = \int p\frac{\partial p}{\partial n}\,\mathrm{d}S. \tag{29.46}$$

This is an important finding when using the theory of potentials, where $\nabla^2 p = 0$, because then

$$\int(\nabla p)^2\,\mathrm{d}\Omega = 0. \tag{29.47}$$

As ∇p^2 cannot be negative anywhere in Ω, it needs to be zero all over Ω. A potential vanishing over a closed

surface and continuous within the domain vanishes within the domain completely [29.69].

Thus when using the Gauss theorem, Green's function, the Helmholtz equation, the Sommerfeld radiation condition, the theory of potentials, and surface boundary integration reduction, we arrive at the Kirchhoff–Helmholtz integral solutions

$$\int p(y) \frac{\partial G(x, y)}{\partial n(y)} - \frac{\partial p(y)}{\partial n(y)} G(x, y) \, \mathrm{d}S$$
$$= \begin{cases} -p(x), & x \text{ in } \Gamma \\ -0.5\,p(x), & x \text{ on } S \\ 0, & x \text{ in } \Omega \end{cases} . \tag{29.48}$$

The three possible solutions of the integral have led to three different methods. The integral at the surface, which would be the boundary of a radiating structure, is used in the boundary element method (BEM). The integration within the structure, which is zero all over, is the basis for the null-field method, and the solution for the outside pressure field is used in the full-field method. All of these methods have advantages and trade-offs, where again the most critical point is the stability of the solution, the ill-posed behavior of the integral.

29.4.3 The Ill–Posed Problem

Most backpropagating methods of microphone-arrays use linear equation solvers to find the pressure or velocities on or behind the radiating surface or of the coefficients of spherical harmonics composing the complex radiation as measured by the microphone array. Although today many sophisticated linear equation solvers are available (e.g., UMFPAK or PARDISO), the main problem of ill-posed formulations, measurement noise, or matrices which are badly conditioned, make alternative methods of solution necessary [29.71–74]. First we discuss the basic problems mathematically and then turn to alternative solutions of regularizations such as single-value decomposition and pseudo-inverse techniques. Additional conditioning methods, like the often used so-called l-shaped method are discussed later in the respective sections.

Hadamard [29.75] formulates three conditions for a physical problem to be well-formed or well-posed. A solution needs to exist, this solution needs to be unique, and this solution needs to continuously depend on small data variations. The last point concerns us here, as when the data only have small deviations from perfectly measured data, the solution is not only a lit-

tle distorted bit but may *blow up* completely and show totally unreasonable, mostly very large values.

As mentioned before and will be shown later in Sect. 29.4.5, the backpropagation problem most often leads to a linear equation system of the kind

$$\mathbf{R}p_S = p_M , \tag{29.49}$$

where p_M is the pressure (it also may be velocities) measured with the microphone array at different microphone positions in space, p_S is the pressure at the radiating surface we want to calculate, and $\mathbf{R}$ is a transition matrix connecting both pressures. This is the mathematical formulation of the ill-posed problem, as the calculation of p_S needs a very precise matrix $\mathbf{R}$ and very accurately measured pressure p_M, otherwise the linear equation system does not hold. This is not a problem for forward-propagation where we have p_S and are looking for p_M somewhere in space. There, small deviations in $\mathbf{R}$ or p_S may lead to small errors in p_M, but do not challenge the equation system. In the backpropagating case p_S are calculated by balancing the measured pressures p_M via the propagation matrix $\mathbf{R}$ in such a way that the correct surface pressures are calculated. Such balancing is highly sensitive to distortions or noise and, therefore, the problem is ill posed. This explains the multiple methods and approaches to this backpropagation problem; most of them have been proposed to make advances in dealing with this ill-posed equation.

Figure 29.8 shows an example of this problem. The (2,3) eigenmode of a membrane was estimated using a finite-element method as an idealized membrane and by a microphone array recording the membrane radiation in the near-field of a nonidealized, goat skin drum. The finite-element calculation assumes a perfectly isotropic distribution of the membrane tension and its thickness, as well as a perfectly fixed boundary condition, resulting in an eigenmode solution as known from analytical solutions for a circular membrane of Bessel functions. The membrane measured is a frame drum made of goat skin, which has a complex distribution of pressure and membrane thickness and has a wooden frame that is not perfectly fixed. The recorded sound pressures in front of the membrane are then backpropagated to the surface of the membrane (shown in the middle left plot of the figure), resulting in a complex mode pattern for this frequency of 741 Hz on the membrane surface, which clearly appears to be very similar to the *perfect* (2,3) mode expected from an idealized membrane. The middle plot of the figure shows the raw data for this membrane as measured at the microphones.

Although different phases are present, the mode shape does not appear. Figure 29.8d again shows a backpropagated case but this time without taking the ill-posed nature of the equation into consideration. The resulting mode shape does not come close to the real mode shape but shows many sharp peaks. In this case, the minimum energy method was used for the backpropagation. Similar results would be obtained with any other equivalent source method.

The basic problems causing such distortions are discussed below, followed by the most common solution procedures.

Evanescent Waves

A main problem with backpropagation is a physical problem that appears mostly with radiations from structures where the speed of the sound of a wave traveling over the structure is faster than the speed of sound in air [29.4, 76–80].

As all backpropagating methods of microphone arrays use single frequencies, the wave vector

$$k = \pm\sqrt{k_x^2 + k_y^2 + k_z^2} \,, \tag{29.50}$$

of the wave in air can be decomposed in its three spatial directions. If a wave travels along the $x-y$ plane, where the z-direction is the radiation normal to the plane, the free-field Green's function is

$$G = \frac{1}{r}e^{ik\mathbf{x}} \,, \tag{29.51}$$

where $\mathbf{x} = \sqrt{x^2 + y^2 + z^2}$. If the speed c_S of this wave on the surface compared to its speed in air c_A is subsonic, where $c_S < c_A$, the wave vector component k_z in the radiation direction is

$$k_z^2 = k^2 - k_x^2 - k_y^2 > 0 \,. \tag{29.52}$$

Moreover, if $c_S > c_A$, $k_x^2 + k_y^2 > k^2$, the square root becomes negative and, therefore, k_z becomes imaginary like

$$k_z = i\sqrt{|k^2 - k_x^2 - k_y^2|} \,. \tag{29.53}$$

Thus, for frequencies with supersonic wave speed Green's function for the propagation in the radiating z-direction

$$G = \frac{1}{r}e^{-k_z z} \tag{29.54}$$

is no longer of a wave-type but a decaying exponential. Therefore, these waves are only present in the near-field of the structure and vanish in the far-field. These waves are called evanescent waves.

Now, if a backpropagation linear equation system tries to propagate such an evanescent wave it will have great difficulties to do so, as the assumption is that of a wave-type radiation of this wave, while in reality it is an exponentially decaying one. So there are two problems with this wave type. First, it is only recordable in the near-field and gone in the far-field. Second, the backpropagation equation assumes it to be exponentially increasing towards the surface of the structure, an assumption easily leading to an overestimation of its amplitude on the surface. This is the reason why many backpropagating methods use near-field recordings, where the microphone array is only a few centimeters from the radiating surface to be able to also record the evanescent waves, because from a certain distance on the radiated sound the pressure is below the measurement noise.

This phenomenon may also appear with complex radiation patterns, also of forced oscillations, where complex phase relations between the radiating areas may appear and the radiation, therefore, cancels itself out in such a way that the wave amplitudes have decayed below measurement noise only at about 20 cm in front of the surface.

Measurement Noise and Microphone Placement

Another source of distortion of the backpropagation results leading to great problems when solving the linear equation system are nonsystematic errors like measurement noise, microphone placements, finite calibration accuracy, or additional sound sources.

As most measurements assume a steady state of the radiation and not transient behavior, measurements average over a certain time span. As most methods use single frequencies for backpropagation, the signals measured signals are Fourier transformed, which results in a complex pressure value. When averaging over a time span, the measurement noise of the microphone will result in an overestimation of the absolute pressure, where the pressure measured is the actual physical one plus the measurement noise. However, it most likely preserves the correct phase when the noise is completely random, as deviations from the phase will cancel out in the Fourier integral. Thus, often the phase is more reliable than the absolute pressure. Nevertheless, if the amplitudes are not correct, the linear equation solver easily blows up the solution. This is because the solver tries to understand the measurements as superpositions

of radiators. Wrong amplitudes easily lead to unphysical radiation contributions of the single sources, which the solver can only deal with by assuming very large source amplitudes, balancing the wrong amplitudes of the measurement.

The reliability of the phase is good news also in terms of calibration errors. Most class-A microphones show a very stable frequency-dependent amplitude curve, yet none of these is perfect. As normally calibration is performed with a 1 kHz sinusoidal, for other frequencies the calibration may be different. One should bear in mind that only small deviations in the measurements lead to a failure of the linear equation system solution. However, the phase, which is very important for backpropagation, can be assumed to be stable and, indeed, is most often not a problem when backpropagating the measured pressures to the radiating surface.

Another issue is the placement of the microphones. Especially within the near-field of the sound source a small deviation of the real position of the microphone to the position used in the backpropagating linear equation system may blow-up the linear equation solver. This is a problem that again cannot be solved perfectly, also because the microphone membranes are a finite area and, therefore, integrate over the pressures at this area.

Common with nearly all backpropagation methods discussed below is that they assume that all radiating surfaces are described in the linear equation system. If additional sound sources are present next to the radiating sphere, or if any reflections in the room are present, of course backpropagation must fail. This is especially a problem in real environments like classrooms or manufactories, and therefore microphone array measurements are often done in unechoic chambers or in the free field. However, often reflections or additional sources cannot be avoided completely and, therefore, the methods need to take this into consideration.

The Matrix Condition

When placing the microphones at certain positions in space and when choosing positions on (or in) the radiating surface, the propagation matrix $\mathbf{R}$ of the linear equation system

$$\mathbf{R}p_S = p_M \tag{29.55}$$

is determined [29.81]. This matrix, of course, differs for each method used, as will be discussed later; however, in general some problems may occur. One is the matrix condition. The ill-posed problem also means that not all rows of $\mathbf{R}$ are completely linearly indepen-

dent from each other. Of course, if only two rows are perfectly linearly dependent, a linear equation solver cannot be used successfully. Most often, depending on the method, the spacing of microphones and the choice of radiation points change this linear dependence of the matrix rows. The solution will improve considerably when the rows are as linearly independent from one another as possible.

This feature is most often described by the condition $C(\mathbf{R})$ of the matrix $\mathbf{R}$. It can be calculated using its determinant, but a better way is to define it as the fraction between the highest and the lowest eigenvalue λ of the matrix as follows

$$C(\mathbf{R}) = \frac{\lambda_{\max}(\mathbf{R})}{\lambda_{\min}(\mathbf{R})} \ . \tag{29.56}$$

The closer these maximum and minimum eigenvalues are to each other, the better the matrix condition.

In many cases this can be understood quite easily from a geometrical point of view. Suppose we have a microphone array with a small grid constant, i.e., the microphones are placed near each other. Additionally, suppose that this array is far apart from the geometry. Then we would expect all microphones to more or less record the same signal, as a radiation field that small and that far away will not vary very much. No matter which method one uses, with such a placement the rows of the propagation matrix need to be very similar, although of course not perfectly the same. As there is not much difference in the relation between the microphones and the surface in this example, the propagation matrix rows will not have very different information from microphone to microphone. Therefore, the condition of the matrix will be bad, as will be the solution. On the other hand, if the microphones are placed in the near-field with considerable differences, the rows will also be considerably different, and the condition of the matrix is much better. Therefore, the solution is much improved. Thus, the spacing of the microphones around the surface is, indeed, a crucial point for improving backpropagation.

Another important issue that often appears with backpropagation and the construction of the propagation matrix is the size of the diagonal elements of $\mathbf{R}$. As each row of the linear equation system represents the sum of all radiating points onto one microphone, the diagonal element of $\mathbf{R}$ is the impact of one of these radiation points onto the recorded pressure. Normally, there is a systematic relation between these diagonal element radiators and the respective recording microphone. In-

deed, with some applications these diagonal elements are very low.

For a linear equation system solver this is a considerable problem, as the diagonal elements are the coefficients of the solution pressure p_S itself. If this impact is low, the matrix solver often fails. Thus, e.g., a simple Gauss elimination procedure for solving a linear equation system will fail if only one diagonal element is zero, as it uses this element as denominator in its calculation algorithm. Hence, an improvement of this matrix is often performed, which strengthens the value of the diagonal elements.

29.4.4 Regularization Techniques

To overcome the ill-posed nature of the Fresnel integral, regularization techniques are applied [29.82]. As discussed above, these techniques are all necessary to reduce the behavior of a solver to be crucially dependent on small deviations in the measurement data. Many regularization methods have been proposed and the most used are presented below.

Singular–Value Decomposition
The single-value decomposition achieves to overcome the *blow up* appearing with the ill-posed nature of the Fresnel integral. It represents a radiation matrix, obtained from one of the methods discussed below by orthonormal functions, its eigenvalues and eigenfunctions. Then, only the lowest of these eigenfunctions are used to reconstruct a radiation from a sound pressure field as measured by a microphone array [29.65, 83–85].

A radiation matrix $\mathbf{R}$ can be decomposed as follows

$$\mathbf{R} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^* , \tag{29.57}$$

where the columns of $\boldsymbol{U}$ and $\boldsymbol{V}^*$, which is a conjugate transpose of $\boldsymbol{V}$, are the eigenvectors. They are connected by the eigenvalues Σ_i, so that $\boldsymbol{\Sigma}$ is a diagonal matrix. Then a radiation can be formulated, where the sound power W in the field can be expended by the columns of $\boldsymbol{V}$ weighted by the velocity vector at the radiating surface $\boldsymbol{v}$ as

$$W = \sum_{i=1}^{N} \Sigma_i^2 |\boldsymbol{V}_i \boldsymbol{v}| . \tag{29.58}$$

This is a complete set and, therefore, within the range of precision of discretization, the reproduction of a sound field from the radiating surface is perfect. This is a forward-propagation, which is not problematic as it is not ill posed. Moreover, this formulation can also be used with backpropagation as then the velocity vector $\boldsymbol{v}$ can be computed when the eigenvectors of the radiation matrix as contained in $\boldsymbol{V}_i$ and the eigenvalues Σ_i of these vectors are known. However, this again results in solving a linear equation system and is, therefore, again an ill-posed formulation.

Thus up to here we have only reformulated the old problem into a new one. The advantage of this new formulation is that the solution is decomposed into a set of orthonormal solutions. Therefore, we know that we approach the real solution a bit more each time we add one of the single solutions. Thus the solution can be stabilized by only using a few of these eigenvectors and truncating the rest. As the eigenvalues Σ_i often decay exponentially, usually only a few eigenvalues are needed to reconstruct the radiation and the backpropagation with only a small error. Therefore, the ill-posed nature of the integral is smoothed by discarding complex but very small radiation partitions, which on the other hand, would blow up the solution altogether.

Tikhonov Regularization
The condition of the radiation matrix is a crucial point. A well-conditioned matrix, as measured by the fraction of the highest and lowest matrix eigenvalue, is expected to lead to much better results.

A common way of error reduction is to formulate an error function

$$\epsilon = (\mathbf{R}\boldsymbol{v} - \boldsymbol{p})^2 , \tag{29.59}$$

which is to be minimized. The Tikhonov method adds a regularization parameter λ to the error function as

$$\epsilon = (\mathbf{R}\boldsymbol{v} - \boldsymbol{p})^2 + \lambda^2 |\boldsymbol{v}| . \tag{29.60}$$

Then the condition of $\mathbf{R}$ can be improved by strengthening its diagonal elements via λ by replacing $\mathbf{R}$ by

$$\mathbf{R}_\lambda = \mathbf{R}^*\mathbf{R} + \lambda^2 \mathbf{I} , \tag{29.61}$$

where $\mathbf{I}$ is a diagonal unity matrix and $\mathbf{R}^*$ again is a conjugate transpose of $\mathbf{R}$. As the term $\mathbf{R}^*\mathbf{R}$ is positive definite and λ^2 is positive, the lowest eigenvalue of $\mathbf{R}_\lambda$ is increased and, therefore, its condition is improved.

Tikhonov regularization is much faster than singular-value decomposition as no eigenvalue calculation needs to be performed.

Pseudo–Inverse Matrix Solution
Another way to solve the linear equation system not using a linear equation solver is to use the pseudo-inverse of a matrix [29.81, 86]. In principle, the equation system

$$\mathbf{R}p_S = p_M \tag{29.62}$$

could be solved by bringing $\mathbf{R}$ to the right-hand side like

$$p_S = \mathbf{R}^{-1}p_M .\tag{29.63}$$

However, then the inverse of $\mathbf{R}$ would need to be computed, which often fails. Therefore, a pseudo-inverse $\mathbf{R}'$ can be computed from the transposed matrix $\mathbf{R}^T$ as follows

$$\mathbf{R}' = \frac{\mathbf{R}^T}{\mathbf{R}^T\mathbf{R}} .\tag{29.64}$$

It is much easier to calculate the transposed matrix and the calculation is most often stable. The terms $\mathbf{R}^T\mathbf{R}$ are easy to invert, and so we have

$$p_S = \mathbf{R}'p_M .\tag{29.65}$$

This is most convenient to solve as each row can be calculated on its own. As a consequence, the matrix $\mathbf{R}$ need not be $n \times m$ with $n = m$ but may have a different number of rows and columns. Sometimes, the radiation field is to be computed using many more shape functions or internal sources than microphones present, or vice versa, which is not a problem when using a pseudo-inverse matrix solution.

29.4.5 Wave Superposition Method

The The Kirchhoff–Helmholtz integral can also be understood as a mathematical formulation of the Huygens principle of wave superpositions [29.63, 64, 67, 74]. If the radiation of a surface is substituted by a number of radiating monopoles placed on this surface, all possible radiation patterns can be composed by using different radiation strengths of the single monopoles. This approach is clearly close to the numerical splitting of a continuous surface into a finite number of lines as the boundary-element method does. Then the Kirchhoff–Helmholtz integral becomes

$$p(x) = \int p(y)\frac{\partial G(x, y)}{\partial n}\,dS .\tag{29.66}$$

This can be rewritten in terms of velocity using the Euler equation

$$i\omega\varrho v = \nabla p ,\tag{29.67}$$

relating pressure and velocity, and using the source's strength $q(x)$, like

$$v(x) = \int q(y)\frac{\partial G(x, y)}{\partial n}\,dS .\tag{29.68}$$

Therefore, the second part of the integrant vanishes, which means that the free-field Green's function is zero.

This can easily be achieved by choosing a radiating sphere inside an arbitrarily shaped radiating body and choosing $G(x, y)$ such that it is zero at the surface S of this body with radius r_S. So all radiation is assumed to have one point r_0 in the volume Ω to start from, and so $G(x, y)$ becomes $G(r)$ with radius r starting from r_0 inside Ω. In other words, the Kirchhoff–Helmholtz integral becomes the Huygens principle of superposition when a boundary condition of Green's function is chosen to be zero at the radiating surface S. As this second part of the Kirchhoff–Helmholtz integrant is associated with the scattering effect at a surface, with the wave superposition method this scattering is reasonably assumed not to be part of this radiation problem. Then the Huygens principle holds alone.

Still another advantage of this formulation is that the radiating sphere is assumed to be within the medium. Then Green's function is never zero, which would lead to a singularity because of the $1/r$ part of Green's function. As the radiation starts at $r_S \neq 0$, this singularity problem, which appears with the boundary element method, is avoided. It is also assumed that the radiation continues over the real surface of the complex radiating geometry without scattering or refraction. This can be assumed as the radiating sphere inside the body is only a virtual one that is convenient for calculation.

Equation (29.68) can then easily be formulated in a discrete way like

$$p(r) \approx \sum_{i=1}^{N} q_i \frac{\partial G(r - r_S)}{\partial n} .\tag{29.69}$$

This leads to a matrix equation

$$\mathbf{R}Q = U ,\tag{29.70}$$

with velocity vector U measured outside the body, radiation strength vector Q on the sphere inside the body, and a so-called dipole matrix $\mathbf{R}$ with coefficients

$$D_{ij} = -\frac{1}{4\pi}\frac{ik|r_j - r_i| - 1}{|r_j - r_i|^2}e^{ik|r_j - r_i|}\cos\Theta_{ij} .\tag{29.71}$$

The angle Θ_{ij} is replaced with directivity of the normal vector derivative. Thus points on the body j orthonormal to points outside the body i do not contribute to the velocity measured at i, while points j on the body right opposite points i outside the body contribute fully with respect to the radiation strength reduction caused by the distance $|r_j - r_i|$.

The procedure of back and forward-propagation is again the same:

- *Backpropagation*: first the velocities at points outside the body are measured and stored in the vector U. Then the linear equation system (29.70) is solved for Q after the dipole matrix $\mathbf{R}$ is built by simply inserting the spatial points of measurements on the virtual sphere.
- *Forward-propagation*: the velocities calculated on the body can then be transformed into pressure values, again using the Euler equation, and at any point in space the pressure can then be calculated using the simplified Kirchhoff–Helmholtz (or Huygens) equation. This also includes the pressures and velocity on the surface of the body, which are also in the radiating field of these virtual source points in the radiating body.

As all of the methods used with microphone array and backpropagation in the wave superposition method have the problem of ill posedness. Truncated single-value decomposition is often used to overcome this problem. As with most methods, solving the above linear equation system is not trivial as the problem is ill posed.

29.4.6 Boundary Element Method (BEM)

BEM uses the Kirchhoff–Helmholtz integral in the form of (29.48) with integration at the boundary of $\frac{1}{2}p$ [29.87, 88]. Therefore, the boundary of the domain Ω is split into discrete elements, where the shape is represented by interpolated isoparametric shape functions. Such shape functions or boundary elements, are defined in a local coordinate system and are then transferred to the global coordinate system using a transformation and rotation matrix. This means that the Lagrange shape functions of a quadratic isoparametric element are

$$N_1 = \frac{1}{4}(1-\xi)(1-\eta) , \tag{29.72}$$

$$N_2 = \frac{1}{4}(1+\xi)(1-\eta) , \tag{29.73}$$

$$N_3 = \frac{1}{4}(1+\xi)(1+\eta) , \tag{29.74}$$

$$N_4 = \frac{1}{4}(1-\xi)(1+\eta) . \tag{29.75}$$

Then the interpolation function of this element is

$$u(\boldsymbol{\xi}) = \sum_{i=1}^{N} N_i(\boldsymbol{\xi}) x^{\mathrm{e}} , \tag{29.76}$$

where $\boldsymbol{\Xi} = \{\xi, \eta\}$, with $n = 4$, since there are four shape functions, and x^{e} are points in the local coordinate sys-

tem. Here, ξ and η are local coordinates for the x and y-directions, and the element is defined for

$$-1 \leq \xi, \eta \leq 1 . \tag{29.77}$$

This element has the advantage that it can be precisely integrated analytically once for all elements, which later need to be performed when introducing the integration over the domain. Each element must then be transferred from the local to the global coordinate system using a Jacobian matrix

$$\mathbf{J} = \sum_{i=1}^{n} X_i \frac{\partial N_i}{\partial \boldsymbol{\Xi}} , \tag{29.78}$$

where $X_i = \{x, y, z\}$ are the coordinates in the global coordinate system on the domain Ω boundary Γ, which is also called the reference frame, resulting in N global shape functions Γ_i, $i = 1, 2, 3, \ldots N$. Then,

$$\frac{\partial}{\partial \boldsymbol{X}} = \mathbf{J}^{-1} \frac{\partial}{\partial \boldsymbol{\Xi}} , \tag{29.79}$$

and, therefore, differentiations with respect to the global coordinate system can be referred to differentiations in the local coordinate system. Then the integral over the element can be calculated directly using the determinant of the Jacobian $\det(\mathbf{J}) = |\mathbf{J}|$ as

$$\mathrm{d}F = |\mathbf{J}| \, \mathrm{d}\xi \, \mathrm{d}\eta , \tag{29.80}$$

which is used in the integration over the domain.

Note that the boundary elements are surfaces and, therefore, differ from the elements used with the finite element method for 3-D problems. Moreover, the surface may be placed anywhere in space and, therefore, the reference frame coordinate system is again three dimensional.

Then the pressure and the velocity at the boundary can be written as interpolations like

$$p(\boldsymbol{X}) = \sum_{i=1}^{N} p(\boldsymbol{X}_i) \Gamma_i \tag{29.81}$$

$$v(\boldsymbol{X}) = \sum_{i=1}^{N} v(\boldsymbol{X}_i) \Gamma_i . \tag{29.82}$$

When using the Kirchhoff–Helmholtz integral, also Green's functions need to be written in an analog way. Moreover, four cases need to be computed. As the boundary element method is used to back and then forward-propagate the pressure field, first Green's functions G_{ij}^{B} are needed for propagating the recorded

pressure from microphone positions X_m to the boundary S of Ω, and second, functions G_{ij}^F are needed to again propagate the resulting pressure field at the boundary S into a surrounding space point X_F. Additionally, both are needed once for the plain Green's function

$$\mathbf{G}_{ij}^P = \int_{\Gamma_i} G(X|X_M)\Gamma_j\, dX \tag{29.83}$$

$$\mathbf{G}_{ij}^F = \int_{\Gamma_i} G(X|X_F)\Gamma_j\, dX, \tag{29.84}$$

and for their first derivatives

$$\mathbf{G}_{ij}^{\prime P} = \int_{\Gamma_i} \frac{\partial G(X|X_M)}{\partial n_i}\Gamma_j\, dX \tag{29.85}$$

$$\mathbf{G}_{ij}^{\prime F} = \int_{\Gamma_i} \frac{\partial G(X|X_F)}{\partial n}\Gamma_j\, dX. \tag{29.86}$$

The Kirchhoff–Helmholtz integral is then formulated for the boundary case additionally, by using the Euler equation, transforming the pressure derivative into velocity like

$$\sum_{i=1}^{N} \mathrm{i}\omega\varrho\mathbf{G}_{ij}^P \boldsymbol{v}_i - \mathbf{G}_{ij}^{\prime P}\boldsymbol{p}_i = \frac{1}{2}p(X). \tag{29.87}$$

This equation can be written in matrix form as

$$\mathbf{P}\boldsymbol{p} = \mathbf{V}\boldsymbol{v}, \tag{29.88}$$

where V is the matrix for the velocity terms $\mathrm{i}\omega\varrho\mathbf{G}_{ij}^P$, and

$$\mathbf{P} = \mathbf{P}' + \frac{1}{2}\mathbf{I}, \tag{29.89}$$

summing the pressures on both sides. Equation (29.88) can be solved for the pressure to obtain the pressure distribution on the node points on the surface of the domain Ω.

To forward-propagate this pressure, the Kirchhoff–Helmholtz integral for the free field

$$\sum_{i=1}^{N} \mathrm{i}\omega\varrho\mathbf{G}_{ij}^F \boldsymbol{v}_i - \mathbf{G}_{ij}^{\prime F}\boldsymbol{p}_i = p(X) \tag{29.90}$$

with the free-field Green's functions is used. Then the pressures $\boldsymbol{p}^F$ can be written as

$$\boldsymbol{p}^F = \mathbf{V}^F\boldsymbol{v} - \mathbf{P}^F\boldsymbol{p}. \tag{29.91}$$

Inserting (29.88) into (29.91) gives

$$\boldsymbol{p}^F = (\mathbf{V}^F - \mathbf{P}^F\mathbf{P}^{-1}\mathbf{V})\boldsymbol{v}, \tag{29.92}$$

which can be written as the linear equation system

$$\boldsymbol{p}^F = \mathbf{R}\boldsymbol{v} \tag{29.93}$$

with

$$\mathbf{R} = (\mathbf{V}^F - \mathbf{P}^F\mathbf{P}^{-1}\mathbf{V}). \tag{29.94}$$

The matrix $\mathbf{R}$ contains all information to relate the velocities at the radiating surface S to radiation points outside this surface.

29.4.7 Full-Field Method

To avoid the problem of vanishing diagonal elements in the radiation matrix, which is a main source for the ill-posed problem, as an alternative to using the Kirchhoff–Helmholtz integral for the interior Ω of the radiating body, the integral for the exterior of such a body is used [29.60]. As the interior integration becomes zero, the diagonal elements of the radiation matrix are very small. In contrast, exterior integration with the pressure as the result of the integration leads to a strengthening of these diagonal elements. Therefore, the solution is much more stable and one avoids regularization techniques.

The full-field method uses orthonormal spherical harmonics Φ_i to represent any kind of complex radiation by summing over N of these harmonics with respective amplitudes c_i to arrive at a pressure p in the exterior of Ω like

$$p = \sum_{i=1}^{N} c_i\Psi_i. \tag{29.95}$$

This is the main equation for microphone-array forward and backpropagation methods. Although spherical harmonics run over two indices, as discussed above, for the sake of convenience, a single running index is used here.

To be able to substitute this into the Kirchhoff–Helmholtz integral, Green's function needs to be formulated using spherical harmonics. Therefore, next to Ψ_i,

$$\Xi_i = \mathrm{Re}\{\Psi_i\} \tag{29.96}$$

as the real part of Ψ is needed to represent a standing wave in the exterior of the body domain Ω. Then Green's function can be written as

$$G(x, y) = \mathrm{i}k\sum_{i=1}^{N} \Psi_i(x)\Xi_i(y), \tag{29.97}$$

with x as a point outside Ω and y a point on the surface S of Ω.

To now be able to substitute this into the Kirchhoff–Helmholtz integral, two additional steps are helpful. First it is reasonable to integrate the pressure, and, therefore, also the Kirchhoff integral over a much larger exterior body F, including Ω and x. This integral can later be solved analytically. Secondly, to enhance stability of the method further, the Galerkin method or method of weighted residuals is used. Therefore, both sides are weighted, or multiplied, by a function to again change the condition of the radiation matrix obtained in the end. Mathematically, this function is arbitrary, as both sides of the equation are multiplied by it. Moreover, it is most convenient to use a function which is already available and, therefore, again the spherical harmonic function Ψ_j^* is used in its complex conjugate form, where j can be chosen arbitrarily. Then we end up with the equation

$$\int p\Psi_j^* \, dF = ik \sum_{i=1}^{N} \int \Psi_i \Psi_j^* \, dF$$
$$\times \int \left(p\frac{\partial \Xi_i}{\partial n} - \Xi_i \frac{\partial p}{\partial n} \right) dS \, . \quad (29.98)$$

The integral over F can be performed using the orthonormal relation of the spherical harmonics. Then, integrating this into (29.95), we have

$$\frac{2i}{k} c_j + \sum_{i=1}^{N} c_i \int \Psi_i \frac{\partial \Psi_j^*}{\partial n} \, dS = i\Omega\varrho \int v\Psi_j^* \, dS \, .$$
$$(29.99)$$

Because of the integration over F and the orthonormal relation of the spherical harmonics, the Ψ_j functions become Ξ_j. On the right-hand side of (29.99) the Euler equation

$$\frac{\partial p}{\partial n} = i\omega\varrho v \qquad (29.100)$$

was used to substitute the velocity for the pressure.

To solve (29.99) numerically, the left-hand side is transformed into a matrix. Clearly the strength of the diagonal elements of this matrix is increased because of the i/kc_j term. This leads to stability of the method and is an alternative to the Tikhonov regularization technique, which also adds another term to the diagonal using a regularization parameter (Sect. 29.4.4).

29.4.8 Null–Field Method

Historically, the null-field was introduced much earlier than the full-field equations [29.89–93]. However, as the full-field equations discussed above in some detail are very similar to the null-field method and additionally have the problem of small diagonal element strength, they need further regularization techniques, such as single-value decomposition [29.59, 94, 95].

When solving the Kirchhoff–Helmholtz integral for a point in the domain Ω, this integral becomes zero. When again assuming the basic equation for forward and backpropagation for microphone arrays (29.95) and incorporating the spherical harmonics with their orthonormal properties and the Kirchhoff–Helmholtz integral, the resulting null-field equation,

$$\sum_{i=1}^{N} c_i \int \Psi_i \frac{\partial \Psi_j^*}{\partial n} \, dS = i\Omega\varrho \int v\Psi_j^* \, dS \, , \quad (29.101)$$

again over $j = 1, 2, 3 \ldots$, is very similar to that of the full-field (29.99) with only the first term on the left-hand side missing. Precisely this term allows for stronger diagonal elements of the matrix, which is therefore better conditioned. Also the complex conjugates Ψ^* of the spherical harmonics Ψ are again used, summed over with amplitudes c_i, as a Galerkin or weighted-residual approach. It can be shown that the equivalent source methods differ basically only in using different weighting functions [29.96].

29.4.9 Internal Source Density Methods

Different approaches have been proposed to use multiple source points in the radiating body instead of only one [29.2, 63–65, 82, 97–102] or using higher-order poles [29.86, 103–106]; this is discussed in detail in Sect. 29.4.10.

One example is the generalized internal source density method (GISD) [29.107–110]. This method needs a microphone array placed in a surface of revolution to meet the virtual source distribution in the radiating body, which is an axial distribution of the ring sources. It also results in a Fredholm integral and is, therefore, ill posed. A single-value decomposition method is used to make the solution stable.

A multiple distribution of sources within a body has been proposed [29.61, 99] to improve the representation of the radiation at the boundaries of the body. Often higher-order spherical harmonics are used with a single source point within the body, which, when representing complex radiation patterns, converge only slowly, needing many higher-order shape functions. This leads to higher computational cost. When using multiple radiation points at different locations, especially near the

radiating surface, a much better differentiation of the radiating source can be obtained more easily.

An approach to represent the radiating surface using many monopole radiators with continuously sharpening radiation directivity [29.2, 100–102] has been proposed as the minimum energy method. This is discussed in Sect. 29.4.11 below. Because of the multiple source points it easily represents complex radiation patterns. Additionally, it overcomes the ill-posed nature of the problem by slightly releasing the radiation directivity, which results in a continuous sharpening of the results with wider directivity of the single sources. It also results in a frequency-dependent directivity value of the radiation patterns.

29.4.10 Helmholtz Equation Least Squares (HELS)

The Helmholtz equation least squares (HELS) method assumes only one single radiation point behind the radiating surface [29.86, 103–106, 111]. Then, to achieve a high amount of precision, many higher-order poles are assumed. The poles used with the HELS method are, again, the spherical harmonics. Figure 29.9 shows examples of a monopole, a dipole, and a quadrupole radiating behind the surface to be investigated and recorded by microphones in the surrounding space. These spherical harmonics are a set of orthonormal functions. Thus, when summing over them with respective amplitudes, as suggested in the solution above, all possible radiation patterns can be achieved. On the other hand, when analyzing a radiation sound field, this sound field can be decomposed into these poles. Moreover, when using a microphone array with arbitrary spacing of the microphones and only covering a finite space with the array, the harmonic functions at the array points will no longer be orthonormal to each other. Thus, from spherical harmonics another set of orthonormal functions Ψ^* need to be calculated. When summing over a discrete set of N points with amplitudes C the resulting pressures at the microphone positions are

$$p^* = \varrho c \sum_{i=1}^{N} C_i \Psi_i^* \qquad (29.102)$$

with density of air ρ and speed of sound c. The orthonormalization proposed is the Gram–Schmidt method,

$$\Xi_1 = \Psi_1 \, ,$$

$$\Psi_1^* = \frac{\Xi_1}{||\Xi_1||} \, ,$$

$$\Xi_2 = \Psi_2 - (\Psi_2, \Psi_1^*)\Psi_1^* \, ,$$

$$\Psi_2^* = \frac{\Xi_2}{||\Xi_2||} \, ,$$

$$\cdots \, ,$$

$$\Xi_{n+1} = \Psi_{n+1} - \sum_{i=1}^{n} n(\Psi_{n+1}, \Psi_i^*)\Psi_i^* \, ,$$

$$\Psi_{n+1}^* = \Xi_{n+1} = \frac{\Xi_{n+1}}{||\Xi_{n+1}||} \, . \qquad (29.103)$$

Here, out of the spherical harmonics for the spatial section where the microphone array is placed, a new set of functions is built, which is again an orthonormal set by this iterative method. The orthonormality is re-achieved by starting with the first function and from each higher one subtracting the part that these functions have in common.

Equation (29.102) can also be written in matrix form as follows

$$\begin{pmatrix} \Psi_{11}^* & \Psi_{12}^* & \cdots & \Psi_{1N}^* \\ \Psi_{21}^* & \Psi_{22}^* & \cdots & \Psi_{2N}^* \\ \cdots & \cdots & \cdots & \cdots \\ \Psi_{N1}^* & \Psi_{N2}^* & \cdots & \Psi_{NN}^* \\ \cdots & \cdots & \cdots & \cdots \\ \Psi_{M1}^* & \Psi_{M2}^* & \cdots & \Psi_{MN}^* \end{pmatrix} \begin{pmatrix} C_1 \\ C_2 \\ \cdots \\ \cdots \\ C_N \end{pmatrix} = \begin{pmatrix} p_1 \\ p_2 \\ \cdots \\ p_N \\ \cdots \\ p_M \end{pmatrix} \, . \qquad (29.104)$$

Here, as is often the case with microphone arrays, solving this equation system diverges due to measurement noise and spatial errors. Furthermore, the number of microphones may not fit the amount of orthonormal functions used and, therefore, there may be more variables than equations. To overcome the first problem of noise a least-squares method is used, where the error may be expressed by

$$\epsilon = \sum_{m=1}^{M} \left(\varrho c \sum_{n=1}^{N} C_n \Psi_{nm}^* - p_m \right)^2 \, . \qquad (29.105)$$

Minimizing this error with respect to the amplitudes reads as

$$\frac{\partial \epsilon}{\partial C_i} = \frac{\partial}{\partial C_i} \left[\sum_{m=1}^{M} \left(\varrho c \sum_{n=1}^{N} NC_n \Psi_{nm}^* - p_m \right)^2 \right]$$

$$= 2 \left(\varrho c \sum_{m=1}^{N} \Psi_{mi}^* \sum_{n=1}^{N} C_n \Psi_{nm}^* - \sum_{m=1}^{M} p_m \Psi_{mi}^* \right)$$

$$= 0 \, . \qquad (29.106)$$

Thus both sides have been multiplied by a weighting function, which can be any reasonable function, most simply the function itself. Equation (29.106) can then be written in matrix form as

$$\boldsymbol{\Psi}'\boldsymbol{C} = \boldsymbol{p}' , \qquad (29.107)$$

where the matrix elements are

$$\Psi'_{mi} = \varrho c \sum_{n=1}^{N} \Psi_{nm}^* \Psi_{ni}^* , \qquad (29.108)$$

and

$$p'_m = \sum_{n=1}^{N} p_n \Psi_{nm}^* . \qquad (29.109)$$

The second problem, that the number of microphones may not fit the number of harmonic functions, is overcome by calculating the coefficients directly. Therefore, the inverse of the matrix $\boldsymbol{\Psi}'$ is calculated. As this may cause problems as discussed above, the pseudo-inverse

$$\boldsymbol{\Psi}'^{+} = \frac{\boldsymbol{\Psi}'^{\mathrm{T}}}{\boldsymbol{\Psi}'^{\mathrm{T}}\boldsymbol{\Psi}'} \qquad (29.110)$$

of the matrix $\boldsymbol{\Psi}'$ is used to finally calculate the coefficients as follows

$$\boldsymbol{C} = \frac{1}{\varrho c} \boldsymbol{\Psi}'^{+} \boldsymbol{p}' . \qquad (29.111)$$

Once the coefficients are known, the pressure can be calculated by using (29.102) for all points in space.

The parameters in the HELS method that need to be treated carefully are the number of spherical harmonics used and the selection of the virtual source point behind the radiating surface. Both parameters may change the results considerably.

In terms of the number of spherical harmonics used, when reconstructing a complex sound field with those functions, a large number of them are actually needed because sharp edges or steep raises in the radiation function need a large number of harmonics to be constructed. This is equivalent to Fourier analysis or synthesis; there a very steep raise needs a large number of Fourier coefficients to be represented. So for complex spatial representations, the convergence of the solution may be slow, needing a large number of harmonic functions.

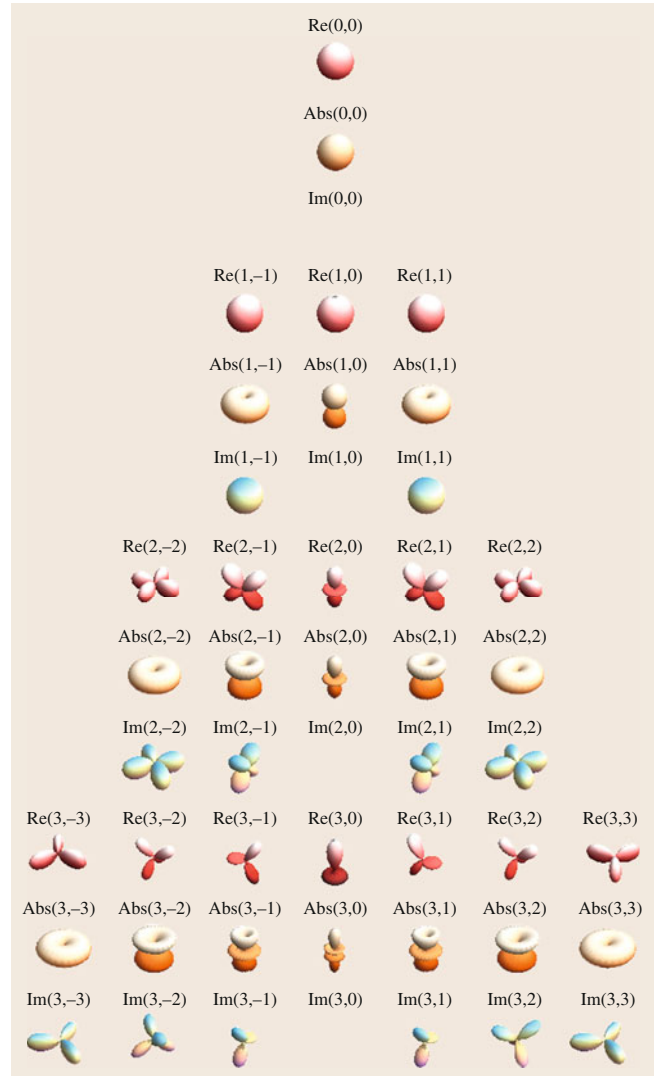
The selection of a virtual source point behind the radiating structure may also change the solution, especially, again, when only a few harmonics are used. The closer this source point is set to the surface, the sharper the solution, because the harmonics are more distinct


Fig. 29.9 Spherical harmonics as solution to the three-dimensional Helmholtz wave equation in spherical coordinates for a single source point as needed in the HELS method. Each solution $Y_{n,m}(r, k, \theta, \varphi)$ with $n = 0, 1, 2\ldots$ runs through $m = -n, \ldots, 0, \ldots, +n$. So, e.g., $n = 0$ is the monopole, $n = 1$ for $m = -1, 0, 1$ are the dipole functions, etc. Each radiation can be completely described by a linear superposition of these functions with the respective amplitudes

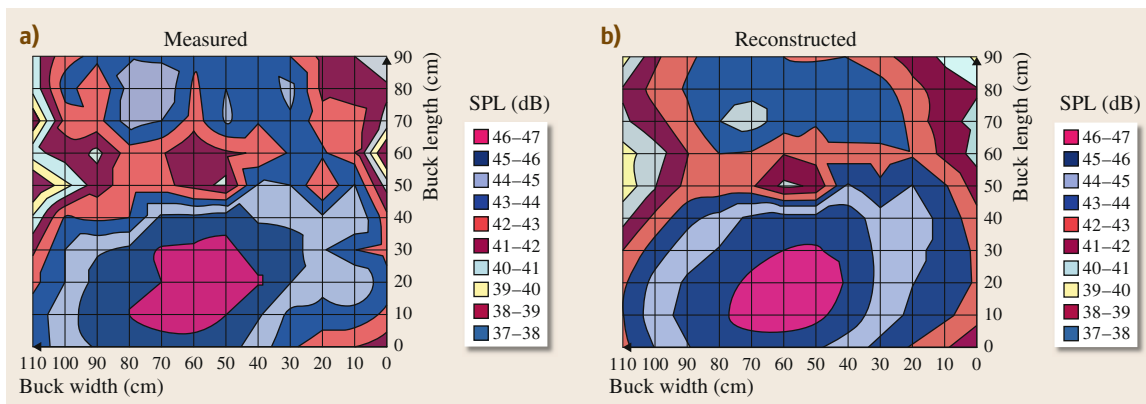
near the source and become wider with increasing distance. This distinctiveness of the shape functions varies with the position of the virtual source point behind the surface and enhances the reconstruction precision in those regions where the source point is set and decreases this precision at more distant regions.


Fig. 29.10 (a) Measurement and **(b)** reconstruction of the radiation of the front top of a car at a frequency of 323 Hz using the HELS method (after [29.112])

An example of the reconstruction of a radiating sound field of the front top of a car at a frequency of 323 Hz is shown in Fig. 29.10 [29.112]. The reconstruction is compared to a measurement right at the surface of the structure.

HELS has also been formulated for transient vibrations [29.105], where the sound field is decomposed into Fourier components; for each frequency backpropagation is performed and the single reconstructed sound

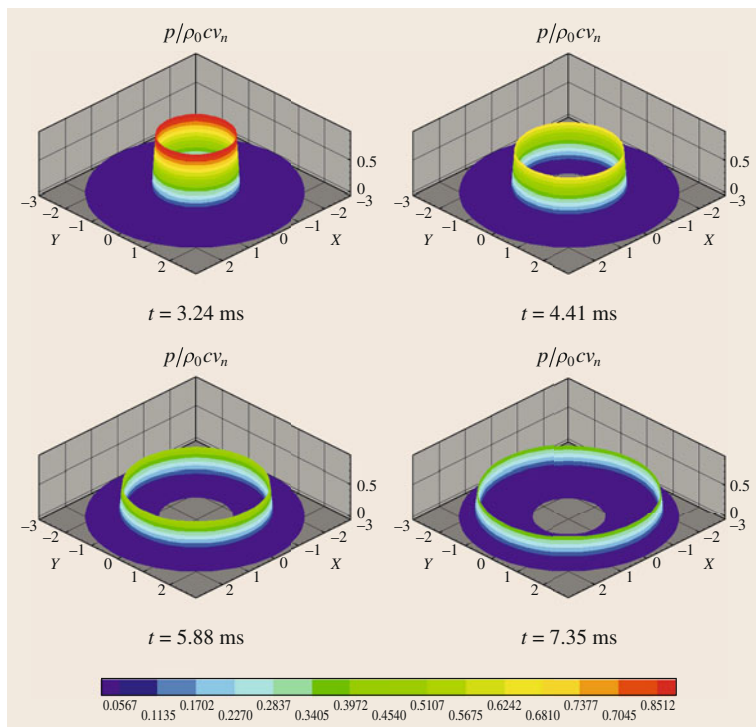
fields are then summed to result in a transient solution (Fig. 29.11). Note that this is different from solving backpropagation for integration times of maybe 1 s to also obtain a changing solution. The transient behavior in this case occurs within a few milliseconds. In Fig. 29.12 a wave traveling over a sphere is shown at four different time steps. The wave is initiated at the center point of the circles and expands over the surface of the sphere.


Fig. 29.11 A transient solution of the HELS method showing four time steps of a sound wave traveling over a sphere (after [29.105])

29.4.11 Minimum Energy Method

Another approach that uses many virtual source points right behind the radiating surface is the minimum energy method [29.2, 100–102]. Again the basic equation for multipole radiation is used as follows

$$p^j = \sum_{i=1}^{N} R_{ij} p^i \,. \tag{29.112}$$

Here the pressure p^j in the free field is assumed to be the sum over radiating points p^i on the radiating surface with a radiation matrix R_{ij} relating both pressures. With this method the source points are assumed to be right on the surface, which avoids the problem of source point placing in the radiating body. Then although mathematically the amplitudes are infinite on the surface $r = 0$, because of the $\frac{1}{r}$ amplitude drop of monopoles, the solution is still stable because the calculated sources are amplitudes and are taken as the radiation strength on the surface.

This is again an ill-posed formulation. To overcome the solution overflow, the source points are not assumed to be perfect monopoles, although they might be, but may show a directivity, narrowing the radiation in the normal direction of the radiating surface according to a directivity value α. Then the radiation matrix is the free-field Green's function

$$R^{ij} = \frac{1}{\Gamma^{ij}} e^{ikr^{ij}} \,, \tag{29.113}$$

with wave vector k and distances r_{ij} between source and receiver point, where the amplitude attenuation

$$\Gamma^{ij}(\alpha) = r^{ij}[1 + \alpha(1 - \beta^{ij})] \,, \tag{29.114}$$

depends on direction via the directivity parameter α, with

$$\beta^{ij} = \left| \frac{r^{ij}}{|r^{ij}|} \cdot n^i \right| \,, \tag{29.115}$$

determining the direction as the inner product between the normal vector n^i with the normalized distance vector matrix r^{ij} between microphone j and radiating point i with

$$r^{ij} = x_g^i - x_m^j \quad i, j = 1, 2, 3 \ldots N \,. \tag{29.116}$$

Figure 29.13 shows the radiation directivity for different values of α in a polar plot. For $\alpha = 0$ the radiation is a monopole and the regular Green's function holds. For larger values of α, a directivity in the direction of the normal vector of the radiation plane is enhanced.
Fig. 29.12a–c HELS assumes a virtual source behind the actual radiating surface. The radiation from this source is a superposition of the orthonormal set of spherical harmonics (monopole, dipole, quadrupole, etc.) as displayed. The *black dots* on the *right* represent the microphones, which are placed in a regular grid here, although it could have any shape. The virtual source point on the *left* is radiating in (**a**) a monopole, (**b**) a dipole, and (**c**) a quadrupole spherical harmonic. This series is continued with higher-order poles with all their real and imaginary parts. When decomposing the recorded sound field at the microphones into these spherical harmonics, the amplitudes of each of these harmonics is determined. Then, again assuming the same virtual source point, for each point in space the sound field can be reconstructed

Thus, Γ has the following properties:

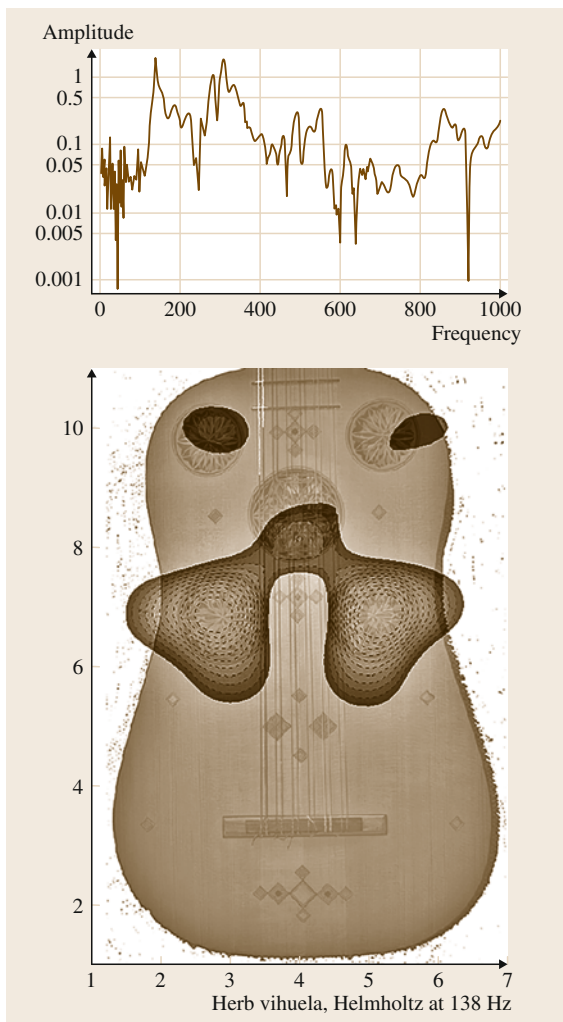
- If $\alpha = 0$, then the radiation is that of a *perfect sphere* with an amplitude decay of $1/r$ independent from the radiation angle.
- If $\alpha > 0$ and $\beta^{ij} = 1$, the radiation in the normal direction is investigated, and then the *maximum radiation* for a fixed α and r^{ij} is achieved.
Fig. 29.13 Polar plot of radiation directivity for different values of α as used with the minimum energy method for each virtual radiation point on the surface of the radiating structure. For $\alpha = 0$ the radiation is a monopole, for higher values its directivity is enhanced in the normal direction of the radiation plane


Fig. 29.14 Reconstruction of the radiation of a vihuela, a Renaissance guitar with five sound holes, using the minimum energy method. The radiation strength of the sound holes depends on their position with respect to its distance from the boundaries of the top plate (after [29.2])

- If $\alpha > 0$ and $\beta^{ij} = 0$, radiation in a direction orthonormal to the normal direction is investigated and then the *minimum radiation* for a fixed α and r^{ij} is achieved.

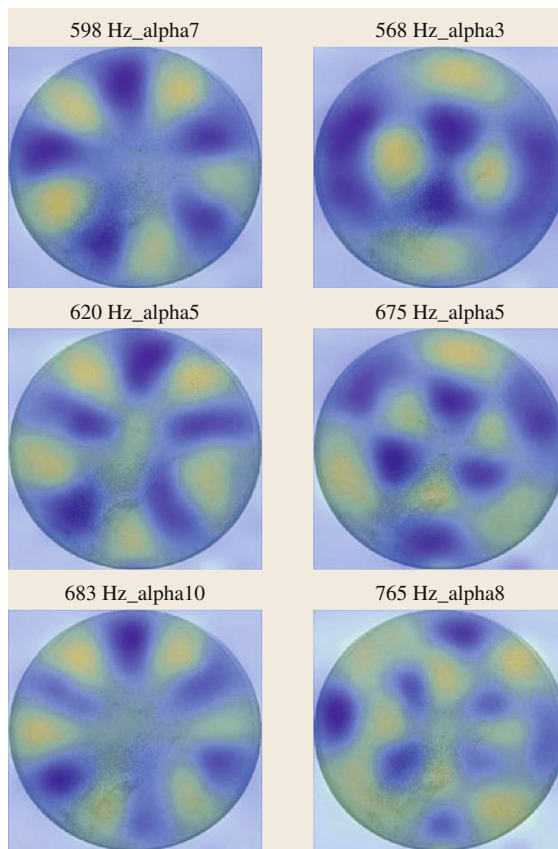
This directivity of α is needed to overcome the instability of the ill-posed nature of the problem. On the other hand, it is physically associated with the directivity of the radiating plane.


Fig. 29.15 Example of the modes of a frame drum between 598–765 Hz backpropagated using the minimum energy method. The different radiation directivities appear through the values of α, where higher values mean a narrower overall radiation directivity

The task is to find an optimum value for α to minimize the reconstruction energy so that α is fixed for all radiation positions. Only β changes with radiation angle from the radiation positions to the microphones, where all of them have the same phase but different radiation strength, depending on this angle. The maximum radiation is always in the normal direction, the minimum radiation is always in the directions orthonormal to the normal direction.

Thus, the radiation matrix is

$$R^{ij}(\alpha) = e^{ikr} \frac{1}{r^{ij}[1 + \alpha(1 - \beta^{ij})]} \ . \tag{29.117}$$

When writing the pressures as vectors as $\boldsymbol{p}_g$ and $\boldsymbol{p}_m$ and the radiation matrix as $\mathbf{R}$, we have the linear equation

a)

16. Partial: 1771 Hz, neck direction

17. Partial: 1882 Hz, neck direction

18. Partial: 1993 Hz, neck direction

19. Partial: 2104 Hz, neck direction

20. Partial: 2215 Hz, neck direction

b)

16. Partial: 1771 Hz, orthogonal to neck

17. Partial: 1882 Hz, orthogonal to neck

18. Partial: 1993 Hz, orthogonal to neck

19. Partial: 2104 Hz, orthogonal to neck

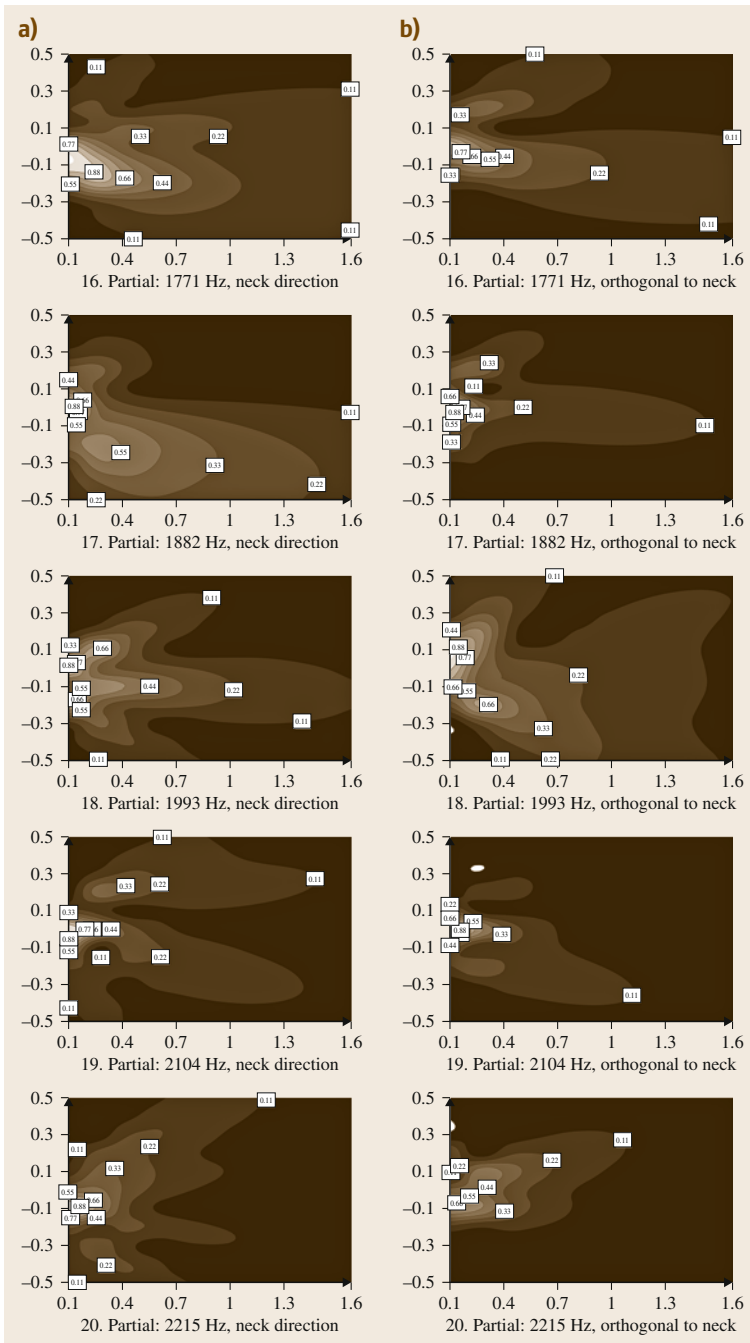
20. Partial: 2215 Hz, orthogonal to neck


Fig. 29.16a,b A forward propagation of the sound field in front of a classical guitar for frequencies between 1771–2215 Hz. Two surfaces are shown, (**a**) left/right cut, (**b**) top/bottom cut. As the frequencies are in the mid-range, the radiation patterns are quite complex (after [29.100])

system

$$\mathbf{R}(\alpha)\boldsymbol{p}_\mathrm{g} = \boldsymbol{p}_\mathrm{m} \ , \tag{29.118}$$

which can be solved by initially guessing α. Thus the correct value of α needs to be evaluated first, which leads to the basic idea of this method.

The use of α is at the core of backpropagation. If α is very large, the reconstruction of the radiation on the surface only considers the recording microphones in the normal direction of each point alone. So the reconstruction will look like the recording of the microphone array. By reducing α, more and more microphones in the near area of the microphone in the normal direction of the radiation plane are taken into consideration to reconstruct the pressure field on the radiating surface. Thus the solution will improve. This will continue, and when looking at several reconstructions with lower α, the blurred and mostly quite smooth pressure field recorded becomes sharper and sharper, reconstructing the real radiating surface better and better. Figure 29.9 shows two solutions for one mode on a frame drum that is a circular membrane for different values of α. When α is chosen correctly, the solution shows the mode of vibration. When α is too small, the ill-posedness of the problem leads to an overflow of the solution, which results in an unreasonable radiation pattern.

However, when α becomes too low, the influence of radiation points on neighboring microphone points becomes too much. In this case, the ill-posed nature of the problem causes the linear equation solver to *blow up* the solution, resulting in unreasonably large reconstructed pressure values.

With this behavior in mind, the correct value of α, which needs to be guessed first, can be found by minimizing the reconstruction energy

$$E \approx \sum_i |\, \boldsymbol{p}_\mathrm{g}^i \,|^2 = \mathrm{Min} \ . \tag{29.119}$$

When α is too low, the ill-posedness of the equation system will make the linear equation solver end in unreasonably large values, so the reconstruction energy is unreasonably high. On the other hand, if α is too high, each radiation point is assumed to deliver all the energy recorded at a microphone in its normal direction, which is unphysical and, again, leads to a reconstruction energy that is too high. Thus, the correct value of α is the one that minimizes the reconstruction energy.

It can be shown that this method deals with measurement noise or misplaced microphones in such a way so as to balance this by slightly increasing α [29.102]. Then even strong measurement noise leads to a reasonable reconstruction. As the method is very stable in this respect and the reconstruction improvement can easily be observed by trying different reconstructions with different values of α, it is an intuitive way of backpropagation.

An example of a sound field reconstruction of the sound hole radiation of a vihuela, a Spanish Renaissance guitar, is shown in Fig. 29.14 [29.2]. It has the special feature of five sound holes. The method determines the radiation pressure strength, which is differently distributed over the five holes.

Another example of backpropagation of the modes of a frame drum is shown in Fig. 29.15 for higher modes between 598–765 Hz with more complex modes shapes. The different directivities appear through different reconstruction values of α.

An example of forward-propagation is shown in Fig. 29.16 [29.100]. A tone was plucked on a classical guitar and backpropagated to the guitar top plate, which resulted in a radiation pattern of pressure values on this top plate. Then this radiation pattern was used to forward-propagate the sound into the space in front of the guitar, which resulted in a sound field both in the left/right and top/bottom surfaces. In this example, tone partials with frequencies between 1771–2215 Hz are shown, which show a quite complex sound field in front of the instrument.

30. Acoustic Emission

Kanji Ono

Acoustic emission (AE) originates from mechanical deformation and fracture, as well as from phase transformation, corrosion, friction, and magnetic processes. It refers to the generation of transient elastic waves due to the rapid release of energy from a localized source or sources within a material or structure. It is an indispensable and effective nondestructive inspection method and a valuable tool of materials research, detecting dynamic microscopic processes of materials. Sensors attached to the structure detect AE signals, from which the locations and activity levels of the sources are evaluated, and structural integrity is assessed.

Acoustic emission (AE) is transient elastic waves produced by the rapid release of strain energy from a localized source or sources within a material or structure [30.1–7]. This term (or microseismic activity in the geotechnical field) is also used to describe the class of phenomena that generate such waves per ASTM (American Society for Testing and Materials) E610-98A. Under loading, AE typically originates at cracks in structures of all kind, defective welds and

yielding regions in alloys and at delamination, and fiber and matrix cracks in fiber-reinforced composites. Other active sources of AE include fretting at extant flaws, especially in concrete structures, leaks of pressurized fluids, and hydrogen gas evolution in aqueous corrosion. All these AE phenomena provide the foundation of sensitive, nondestructive evaluation methods and an effective tool in structural health monitoring [30.8].

30.1 Background

A dynamic mechanical event typically produces AE. When a crack advances under stress, it proceeds in discrete steps that give rise to AE from the stress relaxation at the crack tip [30.9, 10]. AE can originate from a number of mechanisms in any engineering ma-

terials and structures. AE is also reported in bones and teeth [30.11] and its use for biomedical studies has expanded to knee and hip joints [30.12, 13] and to soft tissues and ligaments [30.14–16]. Mechanical deformation and fracture are the primary sources of AE, while

Part H | 30

phase transformation, corrosion, friction, and magnetic processes, among others, also produce AE [30.17, 18]. The elastic waves then travel through the structure to a sensor. Wave propagation and attenuation greatly affect the nature of AE signals at the sensor. For example, when a section size is comparable to the wavelength, the wave travels as a guided wave. In thick-walled structures, the surface wave is often the dominant mode of propagation, while fluids in tanks and pipes carry waves efficiently over long distances [30.1]. Wave attenuation poses serious problems to AE detection in polymeric materials and biological tissues [30.19]. Weak electrical signals produced by the sensor are amplified and characterized, relying on the waveform shape, intensity, frequency spectrum, and other features. For a large structure, like a bridge, hundreds of sensors are used to cover all the critical sections under scrutiny [30.1, 20].

The detected AE signals are used to determine the locations and activity levels of the sources in real time. Results are utilized for the evaluation of the structure or component. Since AE signals can usually travel over a long distance, the entire structure can be examined in a single test sequence, e.g., during preservice

or periodic inspection. AE can continuously monitor the integrity of a structure in service. AE is a passive test method, in that no direct excitation is applied, unlike the ultrasonic test method. However, AE testing does require the application of a certain stimulus to a test piece. With bridges, live traffic and loaded trucks are sufficient. In pressure vessels and piping, hydrostatic pressurization slightly above the operating level is usually employed to activate AE sources. Acoustic emission has become the inspection method of choice for fiber-reinforced composite vessels and for metallic tanks, especially in the aerospace, petrochemical, and transport industries [30.1, 3–6, 20].

Materials research is another area where AE is valuable because of its sensitivity to dynamic microscopic processes [30.17, 18]. It is difficult, however, to establish a mechanical phenomenon at the source of a detected AE signal. This stems from the high sensitivity of AE techniques (since no other means exist to independently observe most dynamic source phenomena). Increasingly detailed modeling offers new insights in gaining the understanding of AE mechanisms and AE signal propagation [30.21–24].

30.2 Acoustic Emission Signals

We classify AE signals into two types, burst-type (pulse-like) and continuous-type (random noise-like) signals. Burst-type emissions arise from distinct events of elastic energy release, such as crack advances,
Fig. 30.1 A representative burst acoustic emission signal waveform of the transverse matrix crack from a cross-ply carbon fiber composite test. Defined in the figure are rise time (23 μs), signal duration (205 μs), peak amplitude (2.9 mV), along with the threshold value used (0.3 mV), and PAC WD wideband sensor (after [30.25])

fiber fracture and delamination. A representative example from a cross-ply composite test is shown in Fig. 30.1, in which commonly used signal features are indicated [30.25]. It has a sharp rise, followed by an exponential decay. This ringing pattern arises from various resonances in a structure and the resonance of the sensor. Continuous-type emissions are produced by many overlapping events and observed from the plastic deformation of metals and from liquid or gas leaks. For typical structural monitoring, ultrasonic frequencies of 30 kHz to 2 MHz are detected. Air-borne noise interferes with AE measurements at lower frequencies, while signal attenuation makes the higher frequency range difficult to use. In industrial composite testing, the upper frequency limit is 300 kHz [30.26, 27]. For applications involving concrete and rocks, a range of several kHz to 100 kHz is used. For geotechnical monitoring and soft tissue diagnosis, useful signal frequencies lie below several kHz [30.2, 19].

30.2.1 AE Signals and Source Functions

An AE signal contains the information on its source, the propagation medium (sample or structure), AE

sensor, and electrical instrument used. These can be expressed by the characteristic or transfer functions of the source, propagation medium, sensor, and electronics (H_s, H_m, H_t, and H_e), respectively [30.17,18]. In the time domain, the source function of a crack is force or displacement versus time history, describing the normal displacement of the crack of area A. This is combined using a convolution integral with the impulse response of the mechanical system (or Green's function) to represent a source. In the frequency domain, the transfer function of the AE signal, H_{AE}, is given by the product of the four transfer functions above,

$$H_{AE} = H_s H_m H_t H_e . \tag{30.1}$$

Figure 30.2 shows an example from a model signal in a fiber composite [30.23]. While the AE source is given as a smoothly decreasing function with frequency, the medium has the major effect on the final signal detected. In this example system, even a large change in H_s is hardly detectable. For a simple geometry, source functions can be recovered by deconvolution when wideband sensors are employed and the first motions of signals are clearly recorded [30.28–30]. However,

this approach is limited and impractical for most applications. AE signals detected with a wideband sensor can still be classified according to the generating source types by means of pattern recognition analysis. This scheme depends on the differences in the excitation of various modes of resonance and wave propagation and on their time history.

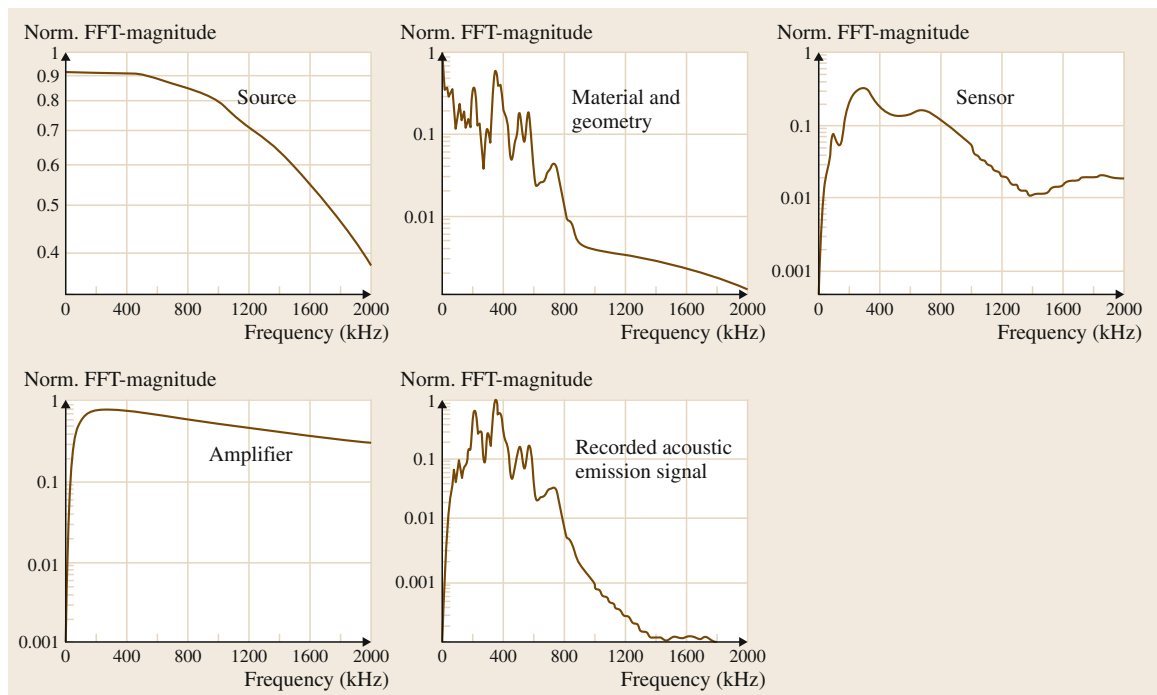
AE waveforms can be simulated using elastodynamic formulation or finite element analysis for certain geometries [30.9, 10, 21, 22]. By varying source parameters (rise time and source strength or the product of displacement amplitude and source area), a simulated waveform can be matched to the observed one for specific test geometry. Elastodynamic displacement solutions assuming smooth-rising source functions of varying rise time are given in terms of dislocation motion, or by using a moment tensor, which is commonly used in geophysics [30.3–5, 9, 10, 31]. Such modeling is most useful for obtaining details of a source by seeking the best fit of calculated and observed waveforms. This forward-processing scheme avoids the deconvolution procedure, which is prone to instability in the presence of noise. This method has been used successfully in analyzing various AE signal types in


Fig. 30.2 Normalized magnitude of fast Fourier transform (FFT) of various transfer functions in the frequency domain in log-linear plots (0–2 MHz) (after [30.23])
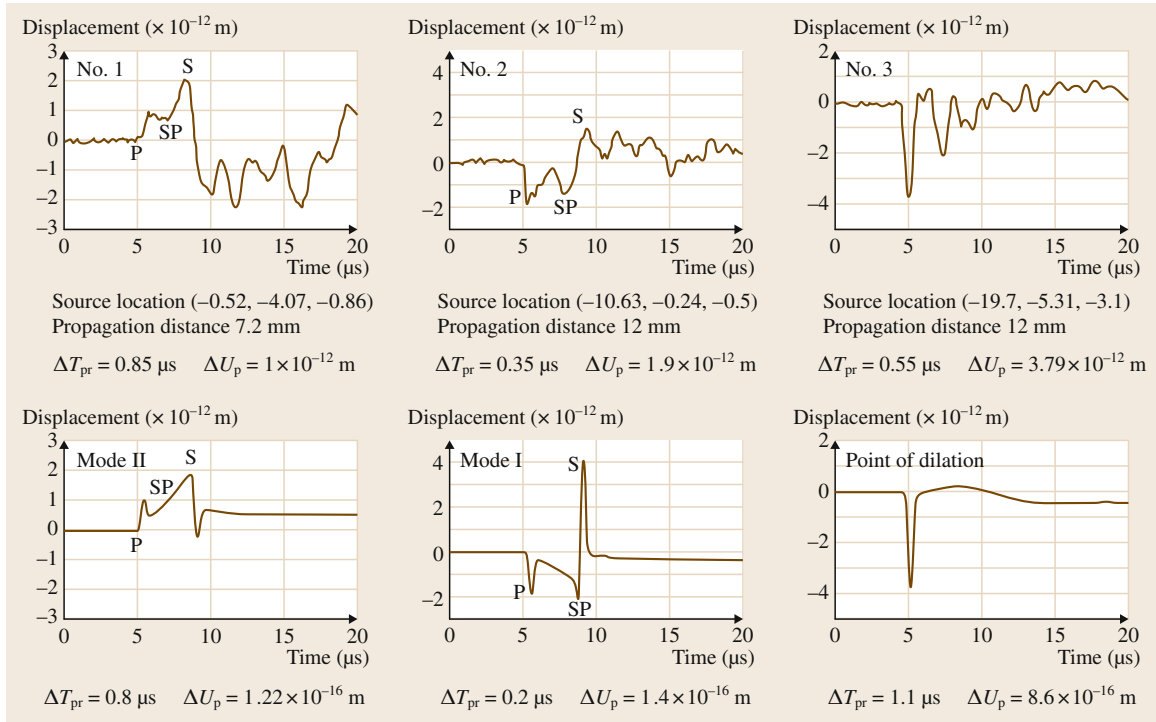

Fig. 30.3 Observed and matched calculated waveforms with source parameters. Unidirectional glass fiber composite test (after [30.32])

composite materials under loading [30.32]. For example, Fig. 30.3 shows three types of failure, displacement signals observed, and matched simulated waveforms for a unidirectional glass-fiber composite. This led to signal classification as a function of loading. From the source function, crack velocity estimates were also obtained (Fig. 30.4) [30.32].

The use of the moment-tensor representation of a source function leads to *moment tensor analysis* or moment tensor inversion [30.3–5]. This method is an extension of a similar method used in geophysics, but in AE applications it is important to find tensile cracks in addition to shear cracks, which are the focus in seismology. It relies on the first arriving P-waves at multiple sensor locations and obtains the tensile and shear components of the source motion. This approach is most suited for large civil engineering structures. In concrete and rock testing, the source types of AE during crack propagation have been identified (Fig. 30.5) [30.33]. In most other materials testing, however, sample sizes are too small to use this method.

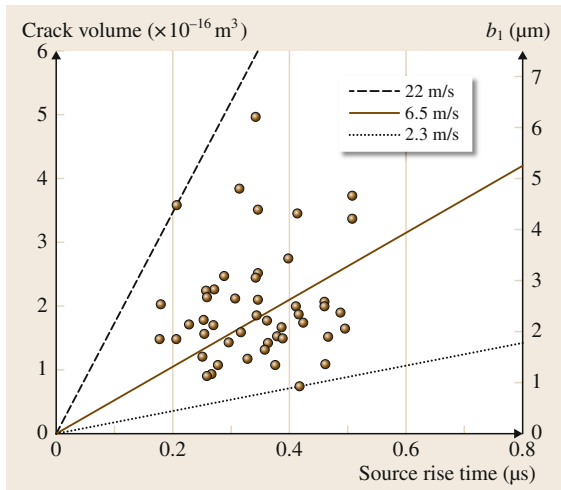
The use of 3-D finite element analysis (FEA) is effective in characterizing AE signals and their propaga-


Fig. 30.4 Crack volume versus source rise time, giving the average crack velocity of $6.5 \, \mathrm{m\,s^{-1}}$. Data points are within the zone between crack velocities of 2.3 and $22 \, \mathrm{m\,s^{-1}}$ (after [30.32]) ◄
Fig. 30.5 Results of moment tensor analysis of acoustic-emission signals from simulated corrosion cracks in a large concrete block. *Arrows* indicate stress direction and *disks* mark the plane of crack. *Pink*: tensile; *blue*: mixed mode; *yellow*: shear crack (after [30.33])

Fig. 30.6a,b Simulated Lamb wave from a finite crack at the mid-plane in a carbon-fiber composite plate, propagated 50 mm. (**a**) Choi–Williams distribution diagram, showing dominant S0 mode (zeroth order symmetric Lamb mode). (**b**) waveform of displacement, normal to the plate [30.24]

tion. A wide range of AE signals generated and propagated on a plate, both isotropic metals and anisotropic composites, are analyzed [30.21–24]. The completed modeling includes Lamb waves generated by an artificial source in thin and thick plates, the effects of the source rise time, monopole versus dipole sources, plate thickness, and plate width. The FEA method is especially valuable for modeling interior AE sources as these cannot be simulated experimentally. Figure 30.6 shows a result of Lamb wave propagation of 50 mm from a finite crack source at the mid-plane in a carbon-fiber composite plate. This signal essentially comprises the symmetric Lamb wave mode as the crack opening displacement is in the direction of the propagation [30.24].

30.2.2 Sensors

Acoustic emission sensors typically employ a disk of piezoelectric ceramic or crystal and respond to velocity or acceleration normal to the face of a sensor. One type has a broadened frequency response using a backing material behind a transducer element. This construction is common to that of the ultrasonic transducers. Another type enhances the sensitivity by using the thickness and/or radial resonance of a transducer element without using a backing material. These are resonant or narrowband sensors and are employed most often in AE testing because of their high sensitivity. Typical resonant AE sensors have peak velocity sensitivities

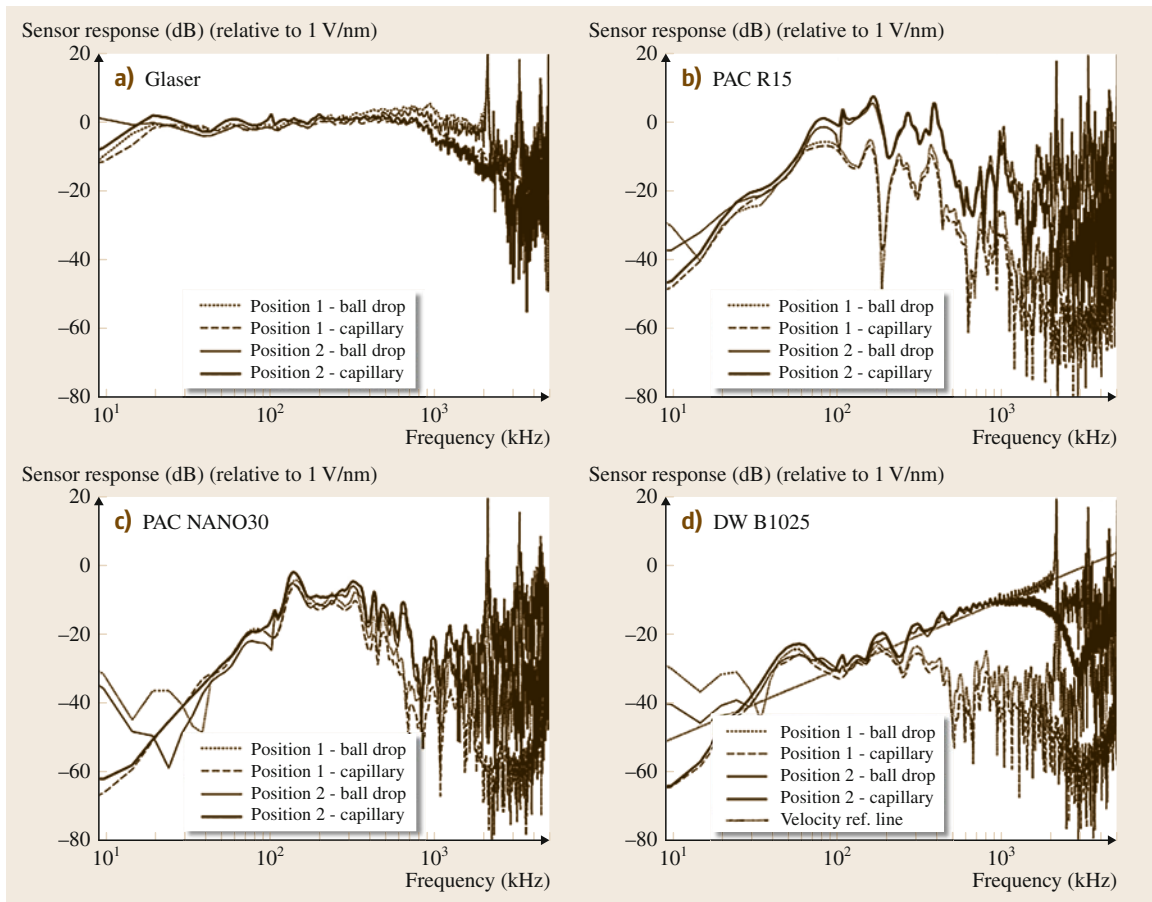
of a few tens of $kV\,s/m^{-1}$, these are 20–40 dB more sensitive than those used for conventional ultrasonic testing. Given a resonant AE sensor with 10.5 kV s/m peak sensitivity at 200 kHz (-70 dB in reference to $1\,V\,\mu bar^{-1}$), a 1 µV signal corresponds to a 0.1 fm surface displacement over 1 µs. Since a preamplifier has the input noise of $0.6\,\mu V_{rms}$, this signal is at the detection limit. Another method to enhance the sensitivity is to place a high impedance amplifier within the sensor housing. This eliminates the effects of cable capacitance, allowing the use of long sensor cables. The frequency responses of AE sensors are usually characterized (face-to-face) against a secondary standard using compressional waves at normal incidence. For many applications, however, surface or plate waves are dominant and their movements normal to the surface are detected, and the size of a sensor affects its responses through the aperture effect. Proper sensor selection for frequency ranges or wave modes improves the sensitivity of AE detection. For concrete, rocks, and geotechnical applications, low frequency sensors, such as geo-phones, hydrophones, and accelerometers are also used. These can have flat frequency responses and some have good directionality, allowing the construction of tri-axial sensors [30.2–6].


Fig. 30.7 (a) Frequency response of a conical sensor of Glaser design showing flatness over 10 kHz to 1 MHz. **(b,c)** Narrowband AE sensor responses for PAC-R15 and PAC nano30. **(d)** A broadband velocity response of DW B1025 (after [30.37])

Surface displacements are also measured using a capacitive sensor or a laser interferometer. Both serve an important role in sensor calibration, although these are still impractical for field use due to difficulty of handling and surface preparation (capacitive sensor) and to their large size, high cost, and low sensitivity (interferometer). A primary sensor calibration system has been constructed using a capacitive sensor in combination with a large steel block and a mechanism to break a fine glass capillary (≈ 0.2 mm outer diameter) [30.34, 35]. The breaking of the glass capillary produces a sudden release of force (≈ 20 N within a few tenths of μs) and provides a reproducible source of body waves and surface waves that match well with theoretical predictions. Peak surface displacements of ≈ 0.15 nm are generated at 0.1 m from the capillary break. Here, a sensor

under test is placed at a symmetric position to the capacitive sensor standard (or a laser interferometer). For a working calibration of the AE measuring system, the breaking of pencil lead ($0.3 \approx 0.5$ mm outer diameter) has been used effectively. This is known as the Hsu–Nielsen source and generates ≈ 1 N force drop over a 1 μs period [30.36].

High-fidelity capture of signal waveforms is needed for specialized studies of AE sources. A special sensor design based on a truncated conical element achieves an exceptional fidelity in the surface displacement detection. *Proctor* at NBS (now NIST) used a small element with matched backing and obtained a flat (± 3 dB) response to 2 MHz [30.38]. This design has been refined, reduced in size to that of a conventional sensor and ruggedized, thus joining the rank of practical AE sen-

sors [30.29, 37]. The frequency response of the most recent design by *Glaser* exhibits exceptional flatness in over 10 kHz to 1 MHz, as shown in Fig. 30.7a [30.37], which also shows two other narrowband AE sensor responses with resonances (Fig. 30.7b,c) and a broadband velocity response (Fig. 30.7d).

30.2.3 Signal Characterization

Characteristics of the acoustic-emission signals in common use are:

1. AE event count (and AE event rates): the number (and rates) of burst-type emissions (in multisensor AE detection systems, the term *hit* is used in place of *event* since a single AE event can reach more than one sensor and is counted each time).
2. The averaged signal intensity of continuous-type emissions (e.g., root mean square (rms) voltages of amplified signals).
3. The peak amplitude.
4. Rise time.
5. Duration of burst emissions (defined with the threshold).
6. The signal strength of burst emission (area of the signal envelope, Fig. 30.1 for the definition of 3.–5.).

In addition, the distributions of peak amplitude, rise time, and duration are also obtained, as well as arrival time differences of burst emissions at different sensors [30.1–7]. Frequency-based parameters are also useful. These include peak frequency, median frequency, spectral centroid (or mean frequency), and partial powers for various frequency bands. These signal parameters can be acquired in real time with dedicated hardware. The duration of typical burst emissions is 0.1–1 ms, however, at most several thousand signals per second can be distinguished from a sensor. For higher rates of emissions, average intensity measurements are utilized. By recording acoustic-emission signals digitally, the power density spectrum or more commonly frequency spectrum and shape parameters of the signal waveforms can be utilized. Peak intensity and position in the frequency domain, shifts in dominant frequency over time and rates of rise and decay of the waveform are the features of importance. Their values diminish when narrowband sensors are used. These features are also used in constructing intelligent classifiers of pattern recognition analysis [30.23, 25, 39]. Combinations of these and other test parameters, such as applied force or pressure, time under load, and ground tilt and displacement are used to evaluate the nature of AE sources.

30.3 Source Location

A major goal of acoustic-emission testing is to determine the location of active flaws in a structure. AE testing uses the structure itself to discover discontinuities through the generation and propagation of AE signals, which can be continuous (e.g., fluid/gas leaks and fretting) or burst emissions (e.g., metal fracture and delamination of composites). Two sensors are used to locate the source in a linear structure such as a pipe and a tube (linear location). More sensors are needed when the linear structure becomes longer or when two or three-dimensional structures are examined. Figure 30.8 shows typical sensor placements on a storage tank when complete coverage is desired in AE testing [30.40, 41]. In most applications, the structures can be regarded as a two-dimensional shell structure, and the surfaces can be laid out on a plane. For example, a spherical tank can be represented by an icosahedron and by 20 triangles on a planar display. This method can also be applied locally on large structures, when expected damage locations can be anticipated. It is common to cover an area of a few square meters with several sensors and as many sets as required are utilized to monitor the critical zones of a large bridge, for example [30.42].

Source location utilizes two general approaches, i. e., zone location and discrete source location. In the zone location method, a source is presumed to exist within the zone that belongs to the sensor receiving the first hit signal or receiving the strongest AE signal (typically in peak amplitude). This method is suited for locating leaks (continuous emissions) and for sources in a highly attenuating medium (fiber composites and metals coated with viscous insulation). This method can be refined by determining which sensor receives the second-hit signal or the second strongest signal. In zone location, the zone around each sensor is subdivided, and the number of the subdivision is equal to that of surrounding sensors. When the amplitudes of the signals received are measured, further improvements in source location accuracy are possible through
Fig. 30.8 Typical acoustic-emission sensor placements on a storage tank (after [30.40, 41])

Fig. 30.9a,b Distribution of energetic acoustic-emission events in a 24 h period before the final fracture. Kevlar composite overwrapped pressure vessel (COPV) (after [30.43])

an interpolation technique by taking the attenuation into account [30.40, 41].

In a discrete source location, the full spatial coordinates of an AE source are defined by measuring the differences in arrival times of AE signals at multiple sensors. The AE signals must be burst-type and strong enough to reach three or more sensors. In attenuating media, the sensor spacing must be sufficiently small. Generally, the wave velocity is assumed constant and triangulation techniques are used. A pair of sensors defines an arrival time difference and a hyperbola passing through a source. The location of the source can be obtained as the intersection of two such hyperbolae. Hundreds of sources per second can be located by typical AE instruments. For this method to be practical, the attenuation through the structure cannot be high to avoid the use of excessive sensors and signal processing channels. Emission rates must be moderate so that the arrival time differences of a single event can be detected without interference of the next event. Several source location algorithms are available in modern AE systems for optimizing the results [30.44, 45]. A number of more sophisticated algorithms from seismology are also adopted, especially in the geotechnical

field. The accurate determination of signal arrival times, or signal onset, is also important in assuring good source location. Several automatic onset pickers have been incorporated, but one based on the Akaike information criterion is best suited for AE signals [30.6]. Another important source location approach uses orientation and propagation-mode dependence of wave velocity [30.45–47], in particular, those of plate waves that are dominant in thin composite structures [30.48].

In order to evaluate the severity of an AE source, the intensity and activity of the source and its proximity to neighboring sources are determined. This requires the collection of additional data on the AE sources and typically involves post-test analysis. Such data include the presence of high amplitude emissions, AE activities during load hold, those during stress increases, and Felicity ratios (FR) during load cycling [30.49]. Statistical analysis, e.g., amplitude distribution, of AE signals received at individual sensors is also useful. An example of a located source display is given in Fig. 30.9. This spherical vessel is a carbon-fiber composite, subjected to stress rupture testing. Clusters of energetic events were detected in the final day of a 250-day test prior to failure [30.43].

30.4 Sources of Emissions and Materials Behavior

Plastic deformation of most structural alloys generates acoustic emission that reaches a maximum at or near the yield stress and diminishes with work hard-

ening (4340 steel; Fig. 30.10) [30.50–52]. AE from plastic deformation is due to dislocation motion, and AE signals are of the continuous type. Purely elastic
Fig. 30.10 Acoustic-emission behavior of 4340 steel, oil quenched and annealed at 600 °C. Acoustic-emission intensity is measured using rms voltages. See *insert* for strain values (after [30.52])

Fig. 30.11 (a) Acoustic-emission behavior of A533B steel, quenched and tempered at 550 °C. Loaded in short transverse orientation, showing inclusion-induced acoustic emission in the elastic region. **(b)** Immediate reloading after the first loading in **(a)**. Kaiser effect is observed (after [30.53])

deformation produces no AE. Once the work hardening begins, the AE activities subside and the rms voltage is only slightly above the background with occasional spikes due to burst emissions (Fig. 30.10). These burst emissions originate from microcracks or from the fracture and decohesion of nonmetallic inclusions. The latter is active in short transverse loading, even from the preyield elastic region (Fig. 30.11a) [30.53]. In some alloys, twinning produces burst-type AE. At high temperatures where work hardening is low, the AE signal intensity remains strong even at high strains.

30.4.1 Plastic Deformation of Metals

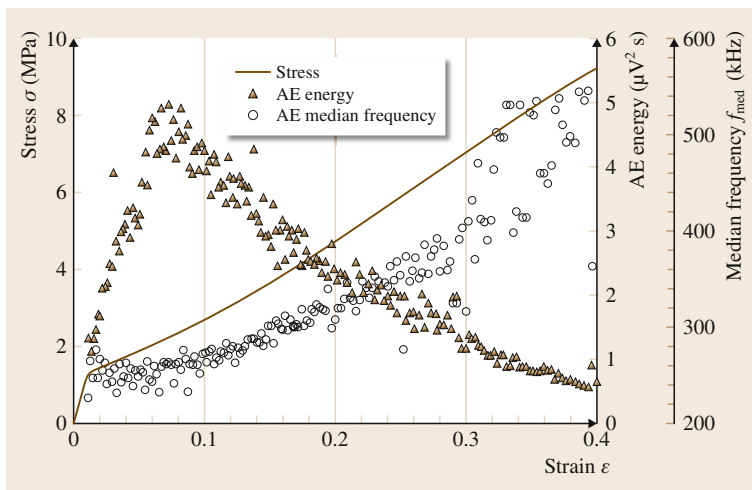
Figure 30.12 shows AE behavior of a copper single crystal, deformed at 300 K [30.54]. The stress–strain plot shows typical three-stage behavior, while AE energy peaked at the start of Stage II. Median frequency was ≈ 250 kHz in Stage I; it increased with decreas-


Fig. 30.12 Acoustic-emission behavior of a copper single crystal deformed at 300 K (after [30.54])

ing AE energy in Stage II and jumped at Stage III. This trend developed from the reduced glide distance of dislocations with work hardening and the resultant increase in the number of glide loops. Solid solution alloying shows a reduction in the intensity of AE, which is attributed to the raised frictional stress due to solution hardening, which in turn increases median frequency as more dislocations are needed to account for the reduced dislocation velocity [30.54, 55].

Acoustic emission phenomena are irreversible. When a sample is deformed, unloaded, and reloaded, it emits no AE until the previously applied load is exceeded. This is known as the Kaiser effect. This behavior is illustrated in Fig. 30.11a,b where a sample was loaded, unloaded, and reloaded immediately [30.53]. The Kaiser effect is useful for the determination of a prior loading level, but it is not permanent. Extended holding and/or annealing before the second loading may reduce the load at which AE starts to be emitted again.

Microstructural variation affects the AE behavior. When a metal or alloy is cold worked, the AE activity is suppressed; often it is eliminated completely as these have high dislocation densities, which limits glide distances. When the grain size is reduced, AE intensity often increases along with the strength. Other factors may, however, override the grain size effect. In most precipitation-hardened alloys, AE intensity decreases with aging. In Al alloys, peak AE intensity at yield decreases by more than a factor of 3 from the solution-treated condition to the fully aged condition. When alloys are strengthened by the addition of dislocations or hard precipitates, the mean free path of mobile dislocations is reduced. When an individual glide motion of the mobile dislocations is restricted, the AE intensity diminishes even though the number of such mobile dislocations increases, raising the median frequency [30.17, 18, 50, 51].

The test temperature affects the AE behavior of materials undergoing plastic deformation. In pure metals and dilute alloys, the peak AE level at yield initially increased by 50 to 100% with the test temperature, but decreased above T/T_m of 0.3–0.4, where T_m is the absolute melting temperature. In normalized steels, the AE level at yield increased fivefold over -150–$150\,°\mathrm{C}$, while the yield strength decreased by 30%. AE from austenitic stainless steels increased 10–20 times from room temperature to 1000 K, where the AE level reached a maximum. The large changes in stainless steels appear to reflect an increase in the stacking fault energy, thus altering the slip mode from planar to nonplanar with increasing test temperature [30.17, 18].

Dynamic strain aging or the Portevin–Le Chatelier effect produces repeated load drops from the locking and unlocking of gliding dislocations. This effect is prominent at room temperature in Al alloys, while in steels, it causes so-called blue-brittleness at $\approx 300\,°\mathrm{C}$. These load drops or serrations result in AE intensity fluctuations [30.50, 51]. Similarly, Lüders deformation in steel also exhibits high AE activity, as shown in Fig. 30.10. Lüders deformation, however, occurs only once at the start of yielding.

Inclusions and second phase particles are another important origin of AE during deformation. Inclusions are significant AE sources during tensile loading of steels in the short-transverse direction and of most high strength Al alloys. In steels, decohesion of MnS inclusions is the most important (Fig. 30.11a). These are burst-type emissions and their number is proportional to the inclusion content. Inclusion-induced AE exhibits anisotropic behavior, i. e., the strongest AE activities are found in the short-transverse direction and the lowest in the longitudinal direction. In many Al alloys, the fracture of Al-Si-Fe and other nonmetallic inclusions causes most AE observed, often masking the AE activity at yielding. Here, inclusion-induced acoustic emission is of continuous-type, since many small particles contribute to the overall activity [30.17, 18, 50, 51].

30.4.2 Fracture and Crack Growth

Most materials and structures produce large, audible sounds during final fracture. In high strength materials, strong elastic waves are generated during cracking. AE can be detected long before final fracture and can be utilized in preventing catastrophic failures of engineering structures. This application has been and remains the major driving force of AE technology development [30.1, 20].

Brittle solids under tension or in bending, including ultra-high strength steels and ceramics, often generate only a small number (< 100) of AE signals just before final fracture [30.17, 18]. Subcritical crack growth is minimal, which limits the AE activities. This behavior is unfortunate because these materials are most likely to fail suddenly and the need for preventing such failures is the greatest. However, all the microfracture mechanisms that are operative in these materials, i. e., cleavage, quasi-cleavage, and intergranular fracture, can be detected easily since a large fraction of the AE events have peak amplitudes above 1 mV or 60 dB, in reference to 1 µV at the sensor. (This is often denoted as $60\,\mathrm{dB_{AE}}$.) In some brittle materials, subcritical crack
Fig. 30.13 Acoustic-emission event counts increase with stress intensity factor

Fig. 30.14 Amplitude distribution of burst AE of A533B steel for brittle (quenched) and ductile (tempered) conditions (after [30.56])

growth (or the fracture process zone ahead of the crack tip) is found. During subcritical crack growth, AE event counts increase in proportion to the m-th power of stress intensity factor K_I, which is equal to $Y\sigma\sqrt{a}$, where Y is a geometrical factor, σ stress, and a the crack length;

$$N_c = A(K_I)^m , \tag{30.2}$$

where N_c is the cumulative number of AE events and A is a constant. The cumulative amplitude distribution of such AE signals can be approximated by a power-law distribution of the form,

$$N_c = B(V_p)^{-b} , \tag{30.3}$$

where V_p is the peak amplitude, and B and b are constants. In low toughness materials (e.g., alumina) showing cleavage and intergranular fracture, $m = 4$. In steels, m varies from 2.5 to 10 (Fig. 30.13). The values of b in brittle materials (alumina, quenched steels) are $0.5-1$, while ductile steels showed b of $1-2$ (Fig. 30.14) [30.17, 18, 56]. When plastic flow occurs at the crack tip or when inclusion failure occurs, different distribution laws (Weibull types) were found [30.56].

When the J-integral (J_I) values increase from 2 to 200 kN/m, as in high strength Al and Ti alloys and in high strength steels, AE signals are produced as the plastic zone ahead of the crack tip expands. AE activity becomes significant with many high amplitude emissions (> 60 dB) when the crack starts to grow. In this stage, various mechanisms of microfracture are in-

volved. That is, in addition to those mentioned above, low energy tear, alternating shear, and microvoid coalescence are observed. Again, AE event counts increase with the stress intensity factor according to (30.2) with higher m values of $3-20$ (Fig. 30.13) and a power law amplitude distribution of (30.3) with $b = 0.7-1.5$. The exponent m often increases as K_I approaches the fracture criticality. Transition in microfracture mechanisms can be reflected more clearly by plotting cumulative AE energy against J_I (Fig. 30.15). Here, AE energy is defined as the square of the peak amplitude, and J_I is given by $(1-\nu)K_I^2/E$, where E and ν are Young's modulus and Poisson's ratio. The transition is sharp
Fig. 30.15 Cumulative AE energy against J_I for steels and 2024 Al (data from [30.17] and others)

when cleavage microcracks initiate as in SNCM8 and as-quenched 4340 steels (4340-Q), but is also visible when fibrous microfracture begins as in 2024Al, 0.5Mo, A533B, and quenched and tempered (at 600 °C) 4340 (4340-6) steels [30.17, 18].

Higher fracture toughness materials typically fail under plane stress conditions by microvoid coalescence and shear mechanisms with some tearing. In these ductile solids, the expansion of plastic zones ahead of the crack tip initially generates AE, with AE activity reaching a maximum at general yield just like the AE behavior of plastic deformation. This is the weakest among fracture-related AE with a peak amplitude of $< 40 \, dB_{AE}$. Beyond the general yield, stable crack growth processes begin. It is often difficult to detect this by AE, as the AE amplitude is still low ($< 60 \, dB_{AE}$), which reflects the high microscopic ductility of the materials.

In moderate to high fracture toughness materials, nonmetallic inclusions exert a substantial influence on the AE behavior. The decohesion of MnS inclusions emits moderately strong AE (a peak amplitude of $< 55 \, dB_{AE}$) from the early part of elastic loading and is the primary source of strong emissions in ductile steels. This is shown as AE in the nominally elastic loading range in Fig. 30.11a [30.53]. Plastic flow and fracture

of inclusions (especially in Al alloys) also produce AE events. Still, even the maximum AE intensity due to inclusions is less than that from brittle fracture in low toughness materials. This inclusion effect is strongest in samples stressed in the short-transverse direction. The total counts at the maximum load for the short-transverse samples are 20–50 times that of longitudinal samples of the same steel.

Fatigue leads to eventual fracture in a number of engineering structures under repeated loading. AE accompanies fatigue crack initiation and subsequent growth, showing rapid rise just before final fracture. As shown in Fig. 30.16, AE activity is low in Region II (the Paris law) fatigue crack growth. As Region III fatigue begins, AE counts rise [30.57]. Here, SUJ2 high-strength steel was examined and da/dN matches the established Paris law. The absence of AE in Region I is natural, as even fatigue striations are not found at these low K_{max} levels. In [30.57], the crack was transgranular until K_{max} exceeded 8 MPa $\sqrt{m}$ (near Region III). Above this level, the crack became intergranular and AE activity increased. Often, the detection of AE precedes an optical observation of a fatigue crack, but initial stages of fatigue are hard to detect because of attendant noise under typical cyclic loading conditions. In cyclically loaded structures, similar trends have been found. For welded steel cruciform under cyclic loading, da/dN and dU/dN (= integrated AE en-
Fig. 30.16 Fatigue crack growth rate (da/dN) and AE (event) counts against K_{max} for SUJ2 steel $f = 20$ Hz, $R = 0.1$. ○: ΔK increasing test; ◑: ΔK decreasing test; *solid line*: $da/dN = 1.35 \times 10^{-10} \Delta K^{2.25}$ (after [30.57])

ergy per cycle) follow similar power laws against ΔK (Fig. 30.17) [30.58].

Once a crack develops, different types of AE are emitted as a function of loading cycle phase:

1. Near a peak tensile load, AE due to crack growth and inclusion fracture is observed.
2. As the load is reduced to zero, crack closure noise is detected as AE, i.e., AE from crack face fretting and crushing of oxide particles.
3. As the load increases again, crack faces that had stuck together separate, producing AE.

All three types of fatigue AE can be used in detecting the presence of a fatigue crack. Peak load AE contributes less than 10% of the total AE activity in some cases, but more when high stress ranges are used. Initially, AE events are detected over a wide range of loading, but tend to concentrate at the maximum load toward the end of fatigue loading. For the detection of fatigue cracking, frictional AE due to fretting and crack face separation are important. In addition, particles of oxides and various corrosion products often form between the crack faces. Their subsequent fracture also contributes to AE due to fatigue [30.1].

30.4.3 Fiber Fracture and Delamination of Composite Materials

Most composite materials in current use are reinforced by glass and carbon fibers, which take various forms, such as short random fibers, mats, woven rovings, and continuous fibers. Aerospace composites use higher modulus carbon and aramid fibers. Matrix materials include thermosetting plastics (polyester and epoxy) and thermoplastics (polypropylene and polysulfone). These resin-matrix composites are difficult to inspect with conventional nondestructive test methods and AE has been used widely. Main sources of emissions are fiber fracture, delamination (matrix cracks between reinforcement layers), splitting (matrix cracks parallel to fibers), and transverse matrix cracks [30.59].

When unidirectionally reinforced composites are stressed, fiber fracture and matrix cracks contribute to AE. Glass fibers generate high amplitude emissions ($> 70\,\mathrm{dB_{AE}}$) just prior to composite fracture ($> 90\%$ of the fracture load). Carbon fibers start to fracture locally above 50% of the fracture load of the composites and produce low amplitude ($30-60\,\mathrm{dB_{AE}}$) emissions, which reflects their smaller diameters and lower fracture strain. The rate of emissions increases rapidly as the final fracture load is approached, similarly to the

behavior of brittle solids. Near the final fracture, high amplitude, long duration signals from splitting are also observed. Delamination occurs when reinforcement layers (called plies) have different fiber orientations or notches. AE signals from delamination are the strongest ($50-130\,\mathrm{dB_{AE}}$ peak amplitude) and have the longest duration ($0.1-10\,\mathrm{ms}$) [30.59].

Most composite structures are fabricated with multiple plies with various combinations of reinforcement orientations. When they are stressed, complex stress patterns develop between reinforcing fibers and plies, and copious emissions are generated, mainly from the transverse matrix cracks and delamination. Discrimination of individual AE signals relies on peak amplitude, rise time, and duration. Damage indications in glass fiber composites include high amplitude emissions ($> 70\,\mathrm{dB_{AE}}$), long duration signals, and emissions during load hold periods. However, signal discrimination is often difficult because of high rates of emissions and strong signal attenuation. The use of pattern recognition analysis is essential to differentiate various sources [30.25, 39].

When a composite sustains damages, the Kaiser effect is no longer observed. FR is defined as a ratio of the load, at which AE is observed upon reloading, to the maximum prior load. FR is 1.0 or higher when the composite is sound and decreases after severe loading. As shown in Fig. 30.18, FR drops to 0.75 by stressing to 80% of the fracture load in glass and carbon
Fig. 30.18 FR versus applied stress normalized by the fracture load in glass and carbon fiber reinforced composite vessels. Results for unidirectional carbon fiber composite retains high FR (data from [30.59] and others)
Fig. 30.19 Burst pressure–felicity ratio correlation for Kevlar COPV with different levels of impact damage (after [30.60])

Fig. 30.20a,b Loading curve in deviatoric stress and sound velocity versus time for Westerly granite (**a**). Microcracks develop in A and B with 30% drop in sound velocity. Fracture nucleus begins at C and D. Final fracture at F. (**b**) Observed AE locations for B, D, and F given in the bottom row (after [30.61])

fiber reinforced composites. Such damage depends on the ply sequence and is less in simpler ply structures; a unidirectional carbon fiber composite retains high felicity ratios (> 0.9) up to 95% of the fracture load. The Felicity effect is a valuable tool in assessing composite damages. An example is shown in Fig. 30.19, where burst pressure-Felicity ratio correlation is given [30.60]. This applies to Kevlar-overwrapped pressure vessels, which shows that this ratio can predict burst pressure from AE testing at lower stress levels. While several other AE parameters have been used for this purpose since the earliest days of AE technology, the Felicity effect appears most promising. Yet a number of factors influence FR ratio at burst, and more work is needed, as is reviewed in [30.59].

30.4.4 Rock and Concrete Fracture

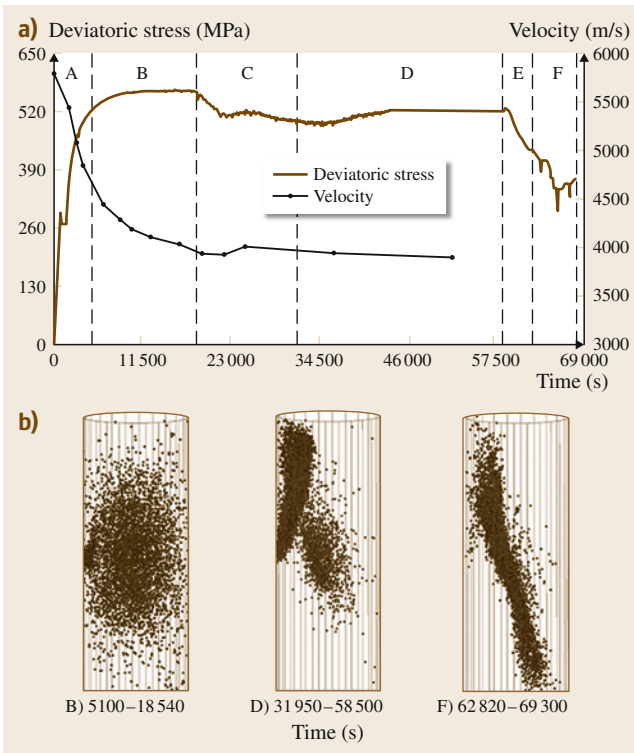
AE monitoring for mine safety is the oldest application and started in the 1930s at the US Bureau of Mines [30.2–6]. Rock fracture initiates throughout the stressed region from uniformly distributed microcrack nucleation. This stage corresponds to AE source locations spread over the entire sample. At close to peak stress, faults nucleate and propagate by the interaction of tensile microcracks, when a clustering of AE occurs and leads to an expanding fracture nucleus with concentrated AE activity. This becomes the fracture process zone of intense tensile cracking, followed by a region of shear cracking [30.61]. These stages are shown in Fig. 30.20, where microcracks develop in A and B (accompanied by 30% drop in sound velocity), the fracture nucleus begins at C, and final fracture at F. Observed AE locations for B, D, and F are indicated in the bottom row. AE signal characteristics varied with crack devel-


Fig. 30.21 AE signal characteristics, b values, decreased with crack development (after [30.61])

Fig. 30.22 AE behavior of concrete under repeat-loading (after [30.3])

opment, which is revealed clearly in the decrease of b values, as shown in Fig. 30.21 [30.61]. The b values are above 1.5 until shear cracking develops and drop suddenly when fracture is imminent. A similar trend in b values was found in steel fracture, as noted in Sect. 30.4.2.

Concrete fracture is similar to that of rock above. Here, tensile microcracks initiate at large aggregates that are mixed with a mortar matrix. At a later stage of fracture, shear cracks become dominant from the shearing of crack surfaces. This shearing/fretting also contributes to AE during unloading in cyclically stressed concrete. The AE behavior of concrete under repeat loading is shown in Fig. 30.22 [30.3]. AE events increase with load and even during unloading beyond the fourth loading. The Felicity effect is found immediately from the second loading and the load ratio (this term is used in the concrete field in place of FR)

decreases to 0.3 at the seventh loading. This AE during unloading is useful in concrete damage evaluation. A calm ratio for a load cycle is defined as (unloading AE activity)/(total AE activity of the particular load cycle) [30.33]. In this case, it started to rise at the fourth cycle (≈ 0.1) and reached a high value of 0.27 at the seventh cycle. A low load ratio and a high calm ratio are indicative of severe damage, while a high load ratio and a low calm ratio correlate to minor damage, as shown in Fig. 30.23 [30.33]. The frictional origin of AE during unloading is manifested as low average frequency and long duration of AE signals.

30.4.5 Other Emission Sources

Acoustic emission is observed under corrosion from hydrogen evolution, pitting, and exfoliation, but anodic metal dissolution produces no AE. When materials are subjected to stress corrosion or hydrogen environments, they produce AE by a number of different mechanisms, including film breakage, hydrogen-induced cracking, inclusion and particle fracture at the crack tip, and plastic deformation. The detection of hydrogen embrittlement is one of the early applications of AE techniques. During crack propagation due to hydrogen embrittlement, high amplitude emissions are observed and can be distinguished easily from the active path corrosion process. The latter generates only a small number of low amplitude emissions. The crack growth rate for stress corrosion cracking shows a three-stage behavior with respect to the K_I applied; that is, an initial increase above a threshold K_I, followed by a region with a nearly constant rate and the final rise near the critical K_I. AE activities follow a similar trend [30.18, 62].
Fig. 30.23 Concrete damage classification using the load and calm ratios of AE activity (after [30.33])

An exceptional stress corrosion AE involving polythionic acid and stainless steels should be noted. This industrially important corrosion occurs via active path dissolution, yet very strong AE bursts are emitted from the ejection of individual grains (also called grain drop-off) [30.62, 63]. Simultaneous monitoring of AE and corrosion potential fluctuation helps clarify operative corrosion mechanisms [30.63, 64].

AE monitoring of welding processes can locate weld cracks and slag inclusions and find the depth of weld penetration and mistracking. Expulsion and lack of welds in spot-welding can also be detected. These in-process monitoring methods may avoid electrical welding noise by using guard sensors and gating circuits synchronized to the welding steps. Evaluation of welds has been the primary goal of AE monitoring of welded structures, such as pressure vessels, tanks, and highway bridges. Defective welds can be located by AE in real time or in post-tests and further evaluated by other nondestructive test methods [30.1].

Monitoring of various machining or metal removal processes detects tool wear, tool fracture, and cutting conditions. These are based on AE due to friction between tool and chips or a workpiece, abnormal signals from chipped tools, plastic deformation, and fracture of chips. This application is important with automated manufacturing processes. Other important AE sources in metals include: martensitic transformation, solidification (hot cracking), oxidation (oxide cracking and spalling). Other sources are gas and fluid leakage, magnetization (AE equivalent of the Barkhausen effect), corona discharges in power transformers, and friction and rubbing noise from rotating machinery. AE also is used in detecting crack initiation during scratch testing of thin films [30.1, 18].

30.5 Structural Integrity Monitoring

Modern AE technology grew from the need to inspect glass-fiber reinforced rocket motorcases in the 1960s [30.65]. It developed rapidly and was used extensively in the US space and defense industries. The use of AE in the chemical industry followed. AE testing procedures of fiber reinforced plastic vessels and piping have been standardized [30.40, 41, 49, 59, 66].

30.5.1 Fiber–Reinforced Composite Pressure Vessels, Tanks, and Piping

Test vessels and piping are typically pressurized to 110% of the maximum allowable working pressure to locate substantial flaws. Using the zone location method, AE activities of flaws within each zone are detected and the zone represents the approximate position of these flaws. Sensors are positioned to detect structural flaws at critical sections of the test vessel, i. e., high stress areas, geometrical discontinuities, nozzles, and manways. Pressurization in AE testing of a vessel proceeds in steps with pressure hold periods with depressure increments. A test is terminated whenever a rapid increase in AE activities indicates an impending failure. Detected flaws are graded using several criteria, including emissions during pressure hold periods, FR, historic index (average signal strength of recent events divided by that of all events), severity (average signal strength of ten largest events), and high ampli-

tude events. Emissions during hold indicate continuing permanent damage and a lack of structural integrity. For in-service vessels, an FR criterion (when it is less than 0.95) is an important measure of previous damage. The historic index is a sensitive measure to detect a sudden increase in signal strength. Large severity values result from delamination, adhesive bond failure, and crack growth. High amplitude events indicate structural (glass-fiber) damages, especially in new vessels. AE testing of these tanks and vessels has been highly successful over the last three decades.

A recent technical challenge to AE testing is the inspection of small, but extremely high-pressure (100 MPa hydrogen) cylinders. The AE-based ASME Code Case has now been developed to provide the accept-or-reject criteria using the curvatures of cumulative events and energy curves [30.67–69]. Another problem for composite tanks is the inspection of liquefied natural gas (LNG)/compressed natural gas (CNG) tanks as well as self contained breathing apparatus (SCBA) air tanks. Technically, AE can be used for certain. However, testing these tanks at low cost to assure extended use life is yet to be resolved. One other challenge is the long-term uses of composite tanks and how to assure/estimate their remaining life. Figure 30.24 shows the stress rupture life of three types of composite strands [30.70–73]. The poor stress rupture property of glass fibers is understandable, but even aramid (Kevlar) fiber loses 1/4
Fig. 30.24 Stress rupture data for three types of fiber composite strands (data from [30.70])

Fig. 30.25 Tank bottom thickness data (*in color*) and active AE clusters (a–e). Two AE clusters at a and b matched well with thinned spots in the third quadrant. No AE was detected from a spot between Ch. 1 and 8 at 340 °C (after [30.74])

its strength in a few hundred hours. Recent stress rupture data for Kevlar-overwrapped pressure vessels show comparable behavior to that of Kevlar strands [30.70–72]. While AS-4 carbon fiber strands are comparable to the first generation T-50S, current generation (T-1000) carbon fiber exhibits vast improvements with the apparent absence of stress rupture behavior to almost 100 000 h [30.73]. The Felicity effect is the probable basis for the AE method for remaining life estimation. Research continues [30.59], but more work is needed.

30.5.2 Metal Pressure Vessels, Tanks, and Piping

Acoustic emission testing of metallic tanks and pressure vessels is conducted during pressurization. The tanks and vessels are pressurized following applicable code specifications. The maximum pressure is typically up to 110% of the operating pressure. Sources of emissions are usually crack growth, yielding, corrosion effects (cracking or spalling of corrosion product, local yielding of thinned section), stress corrosion cracking and embrittlement. The most likely locations of flaws are at various weldments. When metals are ductile, AE activities are low and AE test results should be evaluated carefully. Once the metals are embrittled by the environment or at low temperatures, even early stages of stressing activate AE sources. In fact, AE is the best method for detecting hydrogen-induced cracking and stress corrosion cracking [30.1].

Highway gas-trailer tubes and chemical and petrochemical vessels are monitored with AE periodically without the vessels being emptied, thus minimizing the cost of testing. According to current industrial prac-

tice, the located flaws are usually confirmed by other nondestructive test methods. Increasingly, however, AE testing alone is used to evaluate tanks and pressure vessels. For certain classes of metallic vessels, the use of AE examination alone can be used to satisfy code-mandated inspection requirements in lieu of ultrasonic testing or radiography. After AE testing indicates the locations of active AE sources, these are graded according to criteria similar to those for composite vessels. These provide real-time indications of defective areas of the pressure vessel being tested and prevent catastrophic failure of the vessel. The identified defective areas are then inspected using other test methods. Acoustic emission testing is applied on various types of vessels, including ammonia spheres and tanks, hydroformer reactors, and catalytic cracking units [30.1, 75].

In condition monitoring of the bottom plates of aged petroleum tanks, experience with standard AE test methods was reviewed [30.76]. These often encounter difficult conditions and have poor location accuracy. Lamb wave-based methods can bring the needed improvements, accurately positioning corroded sections. Correlations of active AE areas with thinned sections are shown in Fig. 30.25 [30.74].

30.5.3 Aerospace

The first application of AE testing was to verify the structural integrity of filament-wound Polaris rocket motorcases in 1961 [30.65]. Hydrostatic testing of rocket motorcases was instrumented using accelerom-

eters, audio recording, and sound analysis equipment. Crack initiation and propagation were detected prior to catastrophic failure. Later, burst pressure was successfully predicted based on AE data during proof testing. The composite rocket motorcases are still successfully inspected with the use of three (or four) pressurization cycles. The first cycle is to find leaks at a low pressure. The second goes to 100% (or 80%) of the mean expected operating pressure, followed by the third to the 80% level. The AE behavior during the third cycle is used to examine the Felicity effect and is the determining factor in the evaluation of the rocket motorcase integrity.

AE testing is as yet unable to monitor the integrity of aircraft structures in flight because of the substantial noise generated from structures that are joined by numerous fasteners and from engines. For specific components, however, AE can detect the presence of cracks and incipient fracture. For surveillance of structural and fatigue damage of aircraft components during limit load and fatigue testing, AE has demonstrated its utility. All significant cracks were located during full-scale fatigue testing, including those emanating from bolt holes amid a wide range of spurious AE sources. AE in curved fuselage panes of honeycomb sandwich composites was monitored, showing the evolution of notches and a good correlation with accumulated AE. Strong AE from fiber damage was less than 5% of the total AE events recorded [30.77]. AE indications of damage severity vary depending on the particular component, but include load hold emissions, FR, AE event rates, and high amplitude emissions. In structural tests, wave propagation characteristics and the nature of crack-related (crack growth and crack face fretting) sources are also essential in evaluating AE observations. Other developments include fiber sensors capable of being integrated into composite structures and active surveillance schemes using AE sensing for damage detection [30.78–80].

30.5.4 Geological Structures

AE monitoring has been studied to promote mine safety by detecting incipient rock bursts and gas outbursts and by estimating the areas of stress concentration ahead of mining regions [30.2–6]. For this purpose many AE sensors are placed in and around mine tunnels and monitor low frequency (below several kHz) AE signals. A mining operation itself can be a stimulus, as underground rocks have numerous preexisting flaws and are under geological pressure. Drilling exploratory holes ahead

of a mining region can also activate the areas of high local stresses. Multichannel AE sensing has also been applied to the evaluation of hydrofracturing in geothermal wells [30.81]. The stability of underground storage caverns is another area of AE applications [30.5].

By using the Kaiser effect, underground stresses may be estimated. Compressive stresses are applied on a sample bored out from underground. When the previously existing stress is exceeded, AE activities increase and the preexisting stress can be estimated. Since a high compressive pressure always exists, the directionality of stresses must be taken into account. However, loading methods and relaxation after coring may have effects on the results [30.82].

AE techniques have been applied to monitoring the stability of highway slopes, tunnels, and landslide-prone areas [30.2]. AE measurements utilize waveguides that are driven into the ground. By mapping high AE activity areas, potential instability regions can be predicted. Concrete with steel reinforcement is another material used widely in civil engineering structures. Because of the large size of concrete structures and high attenuation rates of AE signals in concrete, suitable AE techniques for structural integrity monitoring are yet to be perfected [30.3–6].

30.5.5 Bridges

AE monitoring of thousands of steel bridges has been conducted, providing operators ample warning of potential disasters [30.83, 84]. Most test sites had no fatigue indications, but a dozen or so had high AE activity in a 10-year period. AE monitoring is applied to selected locations, not globally to large structures. These include: hanger connections, link pin connection, copes and stringers, and stiffener to weld connection. Loading is supplied by regular rail traffic. Other monitoring efforts are summarized in [30.85].

A recent example of large bridge monitoring used 600+ AE channels to monitor about 400 critical sites on the San Francisco-Oakland Bay Bridge [30.86]. Remote monitoring was implemented and success was achieved. The system will be transferred to the replacement bridge opened in 2013 and AE monitoring will be continued.

Many other new and old AE applications to structural integrity evaluation exist, including off-shore oil rigs, on-board rocket and spacecraft, continuous monitoring of rocket motorcases, cable-stayed bridges, wind turbine blades, power plants, refinery, factory installations, and gas tanks. Details are usually inaccessible, but some references are listed in [30.87–90].

About the Authors

Iskander Akhatov

North Dakota State University
Center for Nanoscale Science and
Engineering, Department of Mechanical
Engineering
Fargo, ND, USA
iskander.akhatov@ndsu.edu

Chapter B.8

Iskander Akhatov earned his BS and MS in Physics and PhD in Mechanical Engineering from Lomonosov University of Moscow. He has extensive experience in multiphase fluid dynamics, nonlinear dynamics and acoustics of bubbles and bubbly liquids. Prior to joining faculty at NDSU, Professor Akhatov worked at the Russian Academy of Sciences, State University of Ufa (Russia), Göttingen University (Germany), Boston University and RPI (USA). His current research interests include fluid dynamics in micro and nano scales, nanotechnology.

Yoichi Ando

Kita, Kobe, Japan
andoy@cameo.plala.or.jp

Chapter C.10

Professor Yoichi Ando received his PhD from Waseda University in 1975. He was an Alexander-von-Humboldt Fellow from 1975–1977 at the Drittes Physikalisches Institut of the Universität Göttingen. In 2001 he established the Journal of Temporal Design organizing every two years the International Symposium Temporal Design in Architecture and the Environment. In 2002 he received the Dottore AD Honorem from the University of Ferrara, Italy. Since 2003 he is Professor Emeritus of Kobe University, Japan. He is the Author of the books Concert Hall Acoustics (1985) and Architectural Acoustics (1998) both published by Springer. His research work was on auditory and visual sensations and brain activities.

Keith Attenborough

The Open University
Department of Engineering and
Innovation
Milton Keynes, UK
keith.attenborough@open.ac.uk

Chapter A.4

Keith Attenborough is Research Professor in Acoustics at the Open University and a Chartered Engineer. In 1996 he received the Institute of Acoustics Rayleigh Medal for distinguished contributions to acoustics and in 2012 he was awarded the Silver Medal (Noise) by the Acoustical Society of America. His research has included pioneering studies of acoustic-to-seismic coupling, sonic crystal noise barriers and noise reduction using granular materials and rough surfaces. Current research involves meta-materials and -surfaces in acoustics.

Whitlow W.L. Au

Hawaii Institute of Marine Biology
Kailua, HI, USA
wau@hawaii.edu

Chapter F.20

Dr. Au is the Chief Scientist of the Marine Mammal Research Program, Hawaii Institute of Marine Biology. He received his PhD degree in Electrical Engineering from Washington State University in 1970. His research has focused on the sonar system of dolphins and on marine bioacoustics. He is a fellow of the Acoustical Society of America and a recipient of the society's Silver Medal in Animal Bioacoustics.

Rolf Bader

University of Hamburg
Institute of Musicology
Hamburg, Germany
r_bader@t-online.de

Chapter H.29

Rolf Bader is Professor for Systematic Musicology at the University of Hamburg. He also studied Physics, Ethnology, and Historical Musicology. After teaching at Stanford University as a Visiting Scholar he became Lecturer for Systematic Musicology in Hamburg in 2007. His main research interests are physical modeling of musical instruments, timbre and rhythm perception, musical signal processing, and room acoustics. He also worked on self-organization and synergetics of musical instruments and music perception. He developed several software tools, e.g. for solving the inverse problem of determining the construction of a classical guitar starting from a desired sound. His interest in music theory lead to a syllogistic music theory founding tonal systems on logic, as well as music semantics and musical ethics. He is also a musician and composer in the fields of free improvised and electronic music, as well as Fusion and Rock, and published several CDs.

Kirk W. Beach

University of Washington
Applied Physics Laboratory
Seattle, WA, USA
kwbeach@u.washington.edu

Chapter F.21

Kirk Beach received his BS in Electrical Engineering from the University of Washington, his PhD in Chemical Engineering from the University of California at Berkeley and his MD from the University of Washington. He develops noninvasive devices to explore arterial, venous and microvascular diseases using ultrasonic, optical and electronic methods and uses those devices to characterize disease.

Mack A. Breazeale

The University of Mississippi
Department of Physics and Astronomy
University, MS, USA

Chapter B.6

Mack A. Breazeale earned his PhD in Physics at Michigan State University and is co-editor of a book. He has more than 150 publications on Physical Acoustics. He is Fellow of the Acoustical Society, the Institute of Acoustics, and Life Fellow of IEEE. He has been President's Lecturer and Distinguished Lecturer of IEEE and was awarded the Silver Medal in Physical Acoustics by the Acoustical Society of America.

James V. Candy

Lawrence Livermore National Laboratory
Livermore, CA, USA

Chapter D.14

James V. Candy is the Chief Scientist for Engineering, a Distinguished Member of the Technical Staff and founder/former Director of the Center for Advanced Signal & Image Sciences (CASIS) at the Lawrence Livermore National Laboratory. Educationally, he received his BSEE degree from the University of Cincinnati and his MSE and PhD degrees in Electrical Engineering from the University of Florida. Dr. Candy is a Fellow of the IEEE *for contributions to model-based ocean acoustic signal processing* and a Fellow of the Acoustical Society of America (ASA) *for contributions to model-based acoustic signal processing.* Dr. Candy received the IEEE Distinguished Technical Achievement Award for the *development of model-based signal processing in ocean acoustics,* and is an IEEE Distinguished Lecturer for oceanic signal processing. He has most recently received the R&D100 award for his innovative invention in radiation threat detection. His research interests include Bayesian learning, estimation, identification, spatial estimation, signal and image processing, array signal processing, nonlinear signal processing, tomography, sonar/radar processing, radiation detection and biomedical applications.

Antoine Chaigne   Chapter G.22

Unité de Mécanique (UME)
Ecole Nationale Supérieure de Techniques
Avancées (ENSTA ParisTech)
Palaiseau Cedex, France
antchaigne@gmail.com

Antoine Chaigne received his PhD in Acoustics from the University of Strasbourg. He is currently the Head of the Mechanical Engineering Department at The Ecole Nationale Supérieure de Tecnique Avancées (ENSTA ParisTech), one of the top ten Institutes of higher education for Engineering in France, which belongs to the Paris Institute of Technology (ParisTech). Professor Chaigne's main areas of research are musical acoustics, transportation acoustics and modeling of sound sources. He is a Fellow member of the Acoustical Society of America and a member of the French Acoustical Society (SFA)

Perry R. Cook   Chapter E.17

Princeton University
Department of Computer Science
Princeton, NJ, USA
prc@cs.princeton.edu

Professor Cook received bachelor's degrees in music and EE at the University of Missouri-Kansas City, worked as a sound engineer, and received an EE PhD from Stanford. He was Technical Director of Stanford's CCRMA, and is now a Princeton Computer Science Professor (jointly in Music). He is a 2003 Guggenheim Fellowship recipient for a new book on Technology and the Voice, and co-founder of the Princeton Laptop Orchestra.

James Cowan   Chapter C.11

URS Corporation
INCE Bd.Cert, Principal Engineer,
Acoustics and Noise Control
Salem, NH, USA
jim.cowan@urs.com

James Cowan has consulted on hundreds of projects over the past 30 years in the areas of building acoustics and noise control. He has taught university courses in building acoustics for the past 25 years both in live classes and on the internet. He has authored 2 books and several interactive CD sets and book chapters on architectural and environmental acoustics.

Mark F. Davis   Chapter E.18

Dolby Laboratories
San Francisco, CA, USA
mfd@dolby.com

Dr. Davis obtained his PhD in Electrical Engineering from MIT in 1980. He is a Principal Member of the Technical Staff at Dolby Laboratories, where he has worked since 1985. He has been involved with the development of the AC-3 multichannel coder, MTS analog noise reduction system, Atmos surround system, DSP implementations of Pro Logic upmixer, virtual loudspeaker, and SR noise reduction. His current work is principally involved with investigation of advanced surround sound systems and binaural reproduction.

Barbrina Dunmire   Chapter F.21

University of Washington
Applied Physics Laboratory
Seattle, WA, USA

Barbrina Dunmire is an engineer within the Center for Industrial and Medical Ultrasound (CIMU) division of the Applied Physics Laboratoryat the University of Washington. She holds an MS in Aero/Astronautical Engineering and Bio Engineering. Her current areas of research include ultrasonic tissue strain imaging and its application to functional brain imaging and breast cancer, and high intensity focused ultrasound (HIFU).

Neville H. Fletcher   Chapter F.19

Australian National University
Research School of Physics and
Engineering
Canberra, Australia
neville.fletcher@anu.edu.au

Professor Neville Fletcher has a PhD from Harvard and a DSc from Sydney University and is a Fellow of the Australian Academy of Science. After 20 years as a university physics professor, he became an Institute Director in CSIRO, Australia's National Research Organization. Since retirement he has been a Visiting Fellow at the Australian National University. His research interests include solid-state physics, cloud physics, and both musical and biological acoustics. He has published five books and more than 200 papers on these subjects

Anders C. Gade

Technical University of Denmark
Acoustic Technology, Oersted.DTU
Lyngby, Denmark
acg@oersted.dtu.dk

Chapter C.9

Anders Gade is an expert in architectural acoustics and shares his time between the Technical University of Denmark and private consultancy. His research areas are acoustic conditions for musicians on orchestra stages, the relationships between concert hall geometry and their acoustic properties and electro acoustic enhancement systems for auditoria. Anders Gade is a fellow of the Acoustical Society of America.

Colin Gough

University of Birmingham
School of Physics and Astronomy
Birmingham, UK
profgough@googlemail.com

Chapter E.15

Colin Gough is an Emeritus Professor of Physics at the University of Birmingham, where he supervised research projects and taught courses in musical acoustics, in addition to leading a large interdisciplinary research group in superconductivity. He also led the University string quartet and many other local chamber and orchestral ensembles, providing a strong musical focus to his academic research.

William M. Hartmann

Michigan State University
Physics and Astronomy
East Lansing, MI, USA
hartmann@pa.msu.edu

Chapter D.14

William Hartmann studied electrical engineering (BS, Iowa State) and theoretical physics (D. Phil., Oxford, England). He is currently a Professor of Physics at Michigan State University, where he does research on psychoacoustics and signal processing. His early psychoacoustical work was on human pitch perception and auditory organization. He currently studies binaural hearing and sound localization in complicated environments. His book Signals, Sound, and Sensation (Springer, 1998) is a mathematically-based, intermediate level psychoacoustics text. His book Principles of Musical Acoustics (Springer, 2013) is an elementary book intended for non-science students. He was president of the Acoustical Society of America (2001–2002) and received the Society's Helmholtz–Rayleigh Award.

Finn Jacobsen

Technical University of Denmark
Acoustic Technology, Oersted.DTU
Lyngby, Denmark
fja@oersted.dtu.dk

Chapter H.25

Finn Jacobsen received a PhD in acoustics from the Technical University of Denmark in 1981. His research interests include general linear acoustics, numerical acoustics, statistical methods in acoustics, and acoustic measurement techniques. He has recently turned his research interests towards methods based on transducer arrays, e.g. acoustic holography.

Yang–Hann Kim

Korea Advanced Institute of Science and
Technology (KAIST)
Department of Mechanical Engineering
Center for Noise and Vibration Control
(NOVIC)
Acoustics and Vibration Laboratory
Yusong–gu Daejeon, Korea
yanghannkim@kaist.ac.kr

Chapter H.26

Dr. Yang-Hann Kim is a Professor of Mechanical Engineering Department at the Korea Advanced Institute of Science and Technology (KAIST) and a Director of the Center for Noise and Vibration Control (NOVIC). He received his PhD degree in the field of acoustics and vibration from MIT in 1985. He has been working in the field of acoustics and noise/vibration control, especially sound field visualization (acoustic holography) and sound source identification. He has been extending his research area to acoustic holography analysis, sound manipulation (3-D sound coloring), and MEMS-sensors/actuators. He is a member of Sigma Xi, KSME, ASME, ASA, INCE, the Acoustical Society of Korea, and the Korea Society for Noise and Vibration (KSNVE) and has been on the editorial board of Mechanical Systems and Signal Processing (MSSP) and the Journal of Sound and Vibration (JSV).

William A. Kuperman   Chapter A.5

University of California at San Diego
Scripps Institution of Oceanography
La Jolla, CA, USA
wkuperman@ucsd.edu

William Kuperman is an ocean acoustician who has spent a total of about three years at sea. He is a co-author of the textbook Computational Ocean Acoustics. His most recent ocean research interests have been in time reversal acoustics and in ambient noise imaging. Presently he is a Professor at the Scripps Institution of Oceanography and Director of its Marine Physical Laboratory.

Thomas Kurz   Chapter B.8

Drittes Physikalisches Institut
Universität Göttingen
Göttingen, Germany
t.kurz@dpi.physik.uni-goettingen.de

Thomas Kurz obtained his PhD in physics from Göttingen university in 1988. He is now a staff scientist at the Third Physics Institute of this university working on problems in nonlinear physics and ultrashort phenomena. His current research is focused on cavitation collapse, sonoluminescence and the propagation of ultrashort optical pulses.

Werner Lauterborn   Chapter B.8

Drittes Physikalisches Institut
Universität Göttingen
Göttingen, Germany
*w.lauterborn@dpi.physik.
uni-goettingen.de*

Dr. Lauterborn is Professor of Physics at the University of Göttingen and Head of the Drittes Physikalisches Institut directing the research on vibration and waves in acoustics and optics. He is co-author of a book on Coherent Optics and Editor of Proceedings on Cavitation and Nonlinear Acoustics. His main research interest is on nonlinear physics with special interest in acoustic and optic cavitation, acoustic chaos, bubble dynamics and sonoluminescence, nonlinear time series analysis and investigation of chaotic systems.

Björn Lindblom   Chapter E.16

Stockholm University
Department of Linguistics
Stockholm, Sweden
lindblom@ling.su.se

After obtaining his PhD in 1968, Lindblom set up a laboratory to do research on phonetics at Stockholm University. His academic experience includes teaching and research at various laboratories in Sweden and the US. In 1970 he became Fellow of the Acoustical Society of America. He is also Fellow of the AAAS (2006) and Honorary Member of the Linguistic Society of America (2013). Currently, he is Professor Emeritus and continues his research on phonetics at Stockholm University and the University of Texas at Austin.

George C. Maling Jr.   Chapter G.23

Institute of Noise Control Engineering
of the USA
Harpswell, ME, USA
maling@alum.mit.edu

George Maling received a PhD degree in physics from the Massachusetts Institute of Technology. He is the author of more than 76 papers and 8 handbook articles related to acoustics and noise control. He has edited or co-edited more than 10 conference proceedings. He is the recipient of the Rayleigh Medal from the Institute of Acoustics in the UK, and is a member of the National Academy of Engineering (NAE). He was chair of the study committee which produced the *Technology for a Quieter America* report for the NAE in 2010.

Nils-Erik Molin   Chapter H.27

Luleå University of Technology
Experimental Mechanics
Luleå, Sweden
nem@ltu.se

Nils-Erik Molin received his PhD in 1970 at the Royal Institute of Technology, Stockholm, Sweden, with "On fringe formation in hologram interferometry and vibration analysis of stringed musical instruments". Thereafter he has worked as lecturer and professor in experimental mechanics at Luleå University of Technology, Sweden. His main research field is optical metrology to measure mechanical and acoustical quantities.

Brian C.J. Moore

University of Cambridge
Department of Experimental Psychology
Cambridge, UK
bcjm@cam.ac.uk

Chapter D.13

Brian Moore's research field is psychoacoustics. He is a Fellow of the Royal Society of London, the Academy of Medical Sciences, and the Acoustical Society of America. He has written or edited 19 books and over 600 scientific papers and book chapters. He has received the Acoustical Society of America Silver Medal in physiological and psychological acoustics, the International Award in Hearing from the American Academy of Audiology, the Award of Merit from the Association for Research in Otolaryngology, the Hugh Knowles Prize from Northwestern University, and the Littler Prize from the British Society of Audiology (twice).

Kanji Ono

University of California, Los Angeles
Department of Materials Science and
Engineering
Los Angeles, CA, USA
ono@ucla.edu

Chapter H.30

Kanji Ono received a BE from Tokyo Institute of Technology, and PhD in Materials Science from Northwestern University. After a year of postdoctoral research at Northwestern, he joined the faculty of University of California, Los Angeles, where he became Professor of Engineering in 1976 and Professor Emeritus in 2005. He was awarded H.M. Howe medal by ASM International, Achievement Award by ASNT, Gold medal award by AEWG and Kishinoue Award by JSNDI. He is the author of more than 250 publications in materials science, acoustic emission and nondestructive testing and has been the editor of Journal of Acoustic Emission. His areas of research have included strength and fracture of materials, composite materials, nondestructive testing and physical acoustics.

Alan D. Pierce

Boston University
College of Engineering
Boston, MA, USA
adp@bu.edu

Chapter A.3

Allan D. Pierce received his doctorate from the Massachusetts Institute of Technology (MIT) and has held research positions at the Rand Corporation, the Avco Corporation, the Max Planck Institute for Fluids Research in Göttingen, Germany, resulting from a Humboldt award, and the US Department of Transportation. He has held professorial positions at MIT, Georgia Institute of Technology (Regents Professor), and the Pennsylvania State University (Leonhard Chair in Engineering). He is Professor Emeritus of Mechanical Engineering at Boston University and also serves as the Editor-in-Chief for the Acoustical Society of America (ASA). His research and teaching in acoustics have been recognized with his being awarded the ASA's Silver Medal in Physical Acoustics, the ASA's Gold Medal, and the Per Bruel Gold Medal in Acoustics and Noise Control from the American Society of Mechanical Engineers. He was the first recipient of the ASA's Rossing Prize in Acoustics Education, and was a founding Co-Editor-in-Chief of the Journal of Computational Acoustics.

Thomas D. Rossing   Chapters 1, A.2, H.28

Stanford University
Center for Computer Research in Music
and Acoustics (CCRMA)
Department of Music
Stanford, CA, USA
rossing@ccrma.stanford.edu

Thomas Rossing received a BA from Luther College, and MS and PhD degrees in physics from Iowa State University. After three years as a research physicist with the UNIVAC Division of Sperry Rand, he joined the faculty of St. Olaf College (Minnesota), where he was professor of physics for 14 years and chaired the department for 6 years. Since 1971 he has been a professor of physics at Northern Illinois University. He was named distinguished Research Professor in 1987, and Professor Emeritus in 2002. He is presently a Visiting Professor of Music at Stanford University. He is a Fellow of the American Physical Society, the Acoustical Society of America, IEEE, and AAAS. He was awarded the Silver Medal in Musical Acoustics by ASA and the Robert A. Millikan Medal by the American Association of Physics Teachers. He was a Sigma Xi National Lecturer 1984–87 and a Visiting Exchange Scholar in China in 1988. He is the author of more than 400 publications (including 17 books, 9 US and 11 foreign patents), mainly in acoustics, magnetism, environmental noise control, and physics education. His areas of research have included musical acoustics, psychoacoustics, speech and singing, vibration analysis, magnetic levitation, surface effects in fusion reactors, spin waves in metals, and physics education.

Philippe Roux   Chapter A.5

Université Joseph Fourier
Institut des Sciences de la Terre (ISTerre)
Grenoble, France
philippe.roux@.ujf-grenoble.fr

Philippe Roux is a physicist with a strong background in ultrasonic and underwater acoustics. He obtained his PhD in 1997 from the University of Paris on the application of time-reversal to ultrasounds. After a few years spent as a Research Associate at the Scripps Institution of Oceanography (San Diego), he is now a full-time CNRS Director of Research in Grenoble where he develops laboratory experiments in geophysics and underwater acoustics. He is a Fellow of the Acoustical Society of America since 2004. He was awarded the Medwin Prize of Acoustical Oceanography in 2013.

Johan Sundberg   Chapter E.16

KTH–Royal Institute of Technology
Department of Speech, Music, and
Hearing
Stockholm, Sweden
pjohan@speech.kth.se
Johan Sundberg (PhD musicology, doctor honoris causae 1996 University of York, UK) had a personal chair in Music Acoustics at the department of Speech Music Hearing, KTH and founded and was head of its music acoustics research group untilhis retirement in 2001. His research concerns particularly the singing voice and music performance. Written The Science of the Singing Voice (1987) and The Science of Musical Sounds (1991), he edited or co-edited many proceedings of music acoustic meetings. He has practical experience of performing music (choir and solo singing). He is Member of the Royal Swedish Academy of Music (President of its Music Acoustics Committee 1974–1982), the Swedish Acoustical Society (President 1976–1981) and fellow of the Acoustical Society of America, receiving its Silver Medal in Musical Acoustics 2003.

Gregory W. Swift   Chapter B.7

Condensed Matter and Thermal Physics
Group
Los Alamos National Laboratory
Los Alamos, NM, USA
swift@lanl.gov

Greg Swift invents, studies, and develops novel energy-conversion technologies in the Condensed Matter and Thermal Physics Group at Los Alamos National Laboratory. He is a Fellow of the American Physical Society, of the Acoustical Society of America, and of Los Alamos. He is a co-author of thermoacoustics software used worldwide, and the author of a graduate-level textbook on thermoacoustics.

George S.K. Wong

National Research Council Canada (NRC)
Institute for National Measurement
Standards (INMS)
Ottawa, Canada
george.wong@nrc−cnrc.gc.ca

Chapter H.24

Dr. George Wong is an expert in acoustical metrology and works in the development of measuring techniques for the calibration of microphones, sound calibrators, sound level meters and National and international acoustical standards including ultrasound and vibration. His research area includes velocity of sound in gases and water, shock and vibration, microphone calibration and acoustical measuring techniques. He is a Distinguished International member of the Institute of Noise Control Engineering.

Eric D. Young

Johns Hopkins University
Baltimore, MD, USA
eyoung@jhu.edu

Chapter D.12

Eric Young is a Professor of Biomedical Engineering at the Johns Hopkins University. His research concerns the representation of complex stimuli in the auditory parts of the brain. This includes normal function and impaired function following acoustic trauma.
